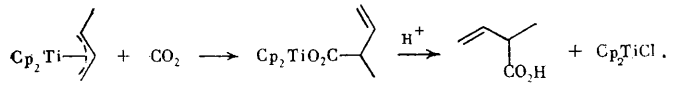
Since the insertion of CO_2 at an M–C bond has been fairly fully reviewed,[1,3,5,7] only the principal results obtained in the last ten years will be presented here.



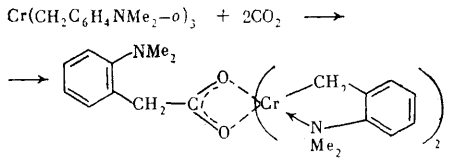
Elements of group I (copper, silver). The insertion of CO_2 at an M–C bond in the copper complex $(Ph_3P)_2CuMe$ and the organometallic derivatives of silver RAg, where R = n-tolyl, etc., gives in the first case the compound $(Ph_3P)_2CuO_2CMe.CO_2$, and in the second case the silver complexes $RAgCO_2Ag$, which can be regarded as the silver salts of silver-carboxylic acids.[1] The reversible insertion of CO_2 at a Cu–C bond has been studied in detail (see the review of Kolomnikov and Grigoryan[1] and section III.2 of the present review).

The reaction of carbon dioxide with the compounds RM, where R = fluorenyl or phenylacetylenyl, and M = Cu or Ag, in the presence of different ligands (BuNC, R_3P, Py, etc.) in a number of cases gives the corresponding acids, identified as the esters.[84] Carbon dioxide can be inserted at the M–C bond in the compound $(CF_3)_2CFAg$, to give the corresponding carboxylate.[92] It has been reported that CO_2 is not inserted at the M–C bond in the complex Ph_3PAuMe, even under severe conditions.[1]

Elements of group II (zinc). The insertion of carbon dioxide at the zinc–carbon bond in the compounds ZnR_2, where R = Alk, has been reported in connection with the use of organometallic compounds of zinc as catalysts of the co-condensation of oxiranes with CO_2.[1,85]

Elements of group IV (titanium, zirconium). The titanium and zirconium compounds R_4M, where R = CH_2Ph, react readily with carbon dioxide to form unstable carboxylates.[1] The reaction of CO_2 with diphenyltitanocene to give the cyclic carboxylate $Cp_2TiO_2CC_6H_4$ has been studied in detail.[1] The mechanism of the thermal decomposition of the compounds Cp_2TiR_2, where R = *m*- or *p*-tolyl, in a carbon dioxide atmosphere has been studied.[86] The detection, among the products of this reaction, of the cyclic titanium carboxylates $Cp_2TiO_2C[m(p)\text{-}C_6H_4Me]$, similar to that noted above, made it possible to determine the nature of the reaction taking place and to establish fairly reliably the appearance of a dehydrobenzene intermediate of titanium in this reaction.

The reaction of carbon dioxide with the organometallic compounds of titanium(III) Cp_2TiR, where R = allyl or methallyl, has been studied.[87–90] The insertion of CO_2 at the M–C bond gives the corresponding carboxylates Cp_2TiO_2CR. In the case of the alkylallyl ligand, asymmetric insertion takes place:[90]



The zirconium compounds $Cp_2Zr(R)Cl$, where R = Me or C_6H_{11}, do not react with carbon dioxide.[83] The reaction of Ph_2ZrEt_2O with CO_2, however, readily gives a zirconium carboxylate.

Elements of group V (vanadium). The reaction of the vanadium(III) compounds R_3V, where R = C_6H_5 or CH_2SiMe_3, with CO_2 gives vanadium(II) carboxylates:[91]

$$2R_3V.THF + CO_2 \rightarrow V(O_2CR)_2 + R_4V.THF.$$

Elements of group VI (chromium, molybdenum, tungsten). Carbon dioxide is not inserted at an M–C bond of the complex $(PhCH_2)_3Cr.H_2O$,[1] but this reaction can take place with the complex $Cr(CH_2C_6H_4NMe_2\text{-}o)_3$:[92]

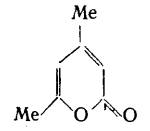
The reaction of CO_2 with $MeCr(CO)_5^-$ anions has been reported.[7,93] The rate of formation of the carboxylates $MeCO_2Cr(CO)_5^-$ increases considerably when alkali metal salts are added. A similar reaction takes place with $MeW(CO)_5^-$.[94]

Carboxylates are also formed in the reaction of carbon dioxide with bis(ethylene)-complexes of molybdenum and tungsten:[95]

$$trans\text{-}[M(C_2H_4)_2(PMe_3)_4] \xrightarrow{CO_2} \tfrac{1}{2}[M(H_2CCHCO_2H)(C_2H_4)(PMe_3)_2]_2.$$

The reaction of $CpW(CO)_3Me$ with carbon dioxide gives the corresponding carboxylate.[96] The rate of this reaction is increased when Lewis acids are added.

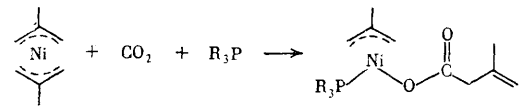
The addition of transition metal salts to the $C_6H_6-AlX_3-CO_2$ system increases the yield of benzoic acid.[97] The highest yield was observed when $MoCl_5$ was added, and this may be due to the formation of an intermediate containing an Mo–C bond.



Elements of group VII (manganese). Carbon dioxide reacts readily with $(PhCH_2)_2Mn$ to give an unstable carboxylate.[98]

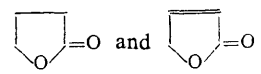
Elements of group VIII. The reversible insertion of CO_2 at the Fe–C bond formed by the rupture of the P–C bond in the complex $(Me_3P)_4Fe$ has been noted.[62] The intermediate formed in the reaction of a phosphine complex of iron with acetonitrile reacts with CO_2 to give cyanoacetic acid:[99]

$$(dmpe)_2Fe(H)(CH_2CN) \xrightarrow{CO_2;\ H^+} NCCH_2CO_2H.$$

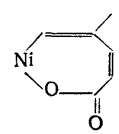


For organometallic derivatives of cobalt it has been shown that, in addition to the usual insertion of carbon dioxide at a Co–C bond to give a carboxylate, "anomalous" insertion to give the ester of a cobalt-carboxylic acid is possible.[1,7] Carbon dioxide can be inserted at the Co–Me bond of a complex of cobalt with salicylidene-ethylenediamine.[1] This reaction is promoted by the addition of dithiols, and does not take place in their absence.

The reaction of carbon dioxide with the rhodium complexes $(Ph_3P)_3RhR$, where R = Me or Ph, gives the carboxylates $(Ph_3P)_3RhO_2CR$.[1] In the oligomerisation of methylacetylene in the presence of *cis*-$(dppe)Rh(CO)_2^+$, 4,6-dimethyl-2-pyrone is formed as the product of the oligomerisation of the alkene and the insertion of CO_2 at a rhodium–carbon bond:[100]

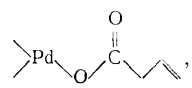


The CO_2 molecule undergoes reversible insertion at an Ir–C bond with the rupture of a P–C bond formed by the phosphine ligand in the complex $(dmpe)_2IrCl$.[37] The insertion of CO_2 at Ir–C and Rh–C bonds has been discussed.[82]

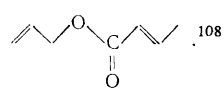


Carbon dioxide is readily inserted at an Ni–C bond in its reaction with bis(methylallyl)nickel in the presence of phosphines:[101]

The author cited also described the formation of cyclic derivatives of nickel as the products of the cyclodimerisation of butadiene on a nickel complex and the insertion of CO_2 at an Ni–C bond. The reaction of CO_2 with bis(allyl)nickel in dimethylformamide gives lactones:[102]

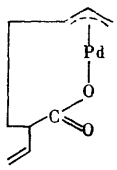


The reactions of carbon dioxide with intermediates formed in the oligomerisation of hex-1-yne and but-2-yne in the presence of phosphine complexes of zerovalent nickel have been studied.[103,104] The final products are substituted pyrones,[103] and a complex of the following type[104]



is formed in the reaction. The insertion of a CO_2 molecule at an Ni–C bond has also been described by Yamamoto and Yamamoto.[105]

A wide range of reactions involving the insertion of CO_2 at a Pd–C bond are now known. The telomerisation of butadiene in a CO_2 atmosphere readily gives lactones and octadienyl esters.[106,107] An interesting feature is that the rate of the dimerisation of butadiene and isoprene is increased in the presence of carbon dioxide. The action of carbon dioxide on bis(η^1,η^3-allyl)Pd.R_3P gives the fragment



which subsequently reacts with carbon monoxide to give

[108]

The similar insertion of CO_2 at a Pd–C(η-allyl) bond has been reported.[109] In the carboxylation of bis(η^3-butenyl)palladium, but-1-ene-3-carboxylic acid is formed selectively after acidification.[110]

This reaction takes place with the formation of the intermediate

In a CO_2 atmosphere in the presence of the catalytic system bis(allyl)Pd$-PR_3$, allene undergoes copolymerisation to give a mixture of esters and lactones.[111] The corresponding lactone is formed smoothly from methylcyclopropane and CO_2 in the presence of $(dppe)_2Pd$.[112] The reversible insertion of carbon dioxide at a Pd$-$C bond to give cyclic adducts has been observed.[113]

Finally, carbon dioxide can also be inserted at an M$-$C bond in reactions involving lanthanides and actinides.[114,115]

3. The insertion of carbon dioxide at M$-$O and M$-$N bonds

The insertion of CO_2 at an M$-$OH bond can give a stable hydrogen carbonate complex or an unstable adduct with carbon dioxide:[1,2]

$$[M]{-}OH + CO_2 \rightleftarrows [M](CO_2)OH \rightarrow [M]O_2COH.$$

In the absence of X-ray diffraction data, the determination of the nature of the complexes formed is extremely difficult.[25] The ease of formation of hydroxo-complexes of transition metals in catalytic systems in the presence of traces of water makes it possible to regard this reaction in the case of reversible addition as a stage in the activation of the CO_2 molecule.

Copper(I) alkoxides readily undergo the following reversible reaction:[25]

$$CuOR + CO_2 \rightleftarrows CuO_2COR.$$

Zinc-containing complexes and enzymes such as carbanhydrase, containing a Zn$-$OH bond, can catalyse the reaction of CO_2 and H_2O to give carbonic acid.[1] The ready formation of hydrogen carbonates and alkyl carbonates has also been observed in reactions involving hydroxo-complexes and alkoxides of ruthenium, rhodium, iridium, palladium, etc.[25]

The insertion of CO_2 at an M$-$N bond is similar to its insertion at an M$-$O bond. The addition of carbon dioxide again may be reversible, or may give stable carbamates. The structure of various carbamates obtained in this way has been established by X-ray diffraction.[2] The insertion of a CO_2 molecule at an M$-$N bond has been studied in detail (see for example the papers of Chisholm and co-workers,[116,117] and references therein). The formation of carbamates by the insertion of CO_2 at an M$-$N bond has been observed for compounds of titanium,[118] tungsten,[2,119] and uranium.[120]

The insertion of CO_2 at a Cu$-$N bond is reversible.[121] EPR has shown unambiguously that the reaction of copper(II) ephedrinate with carbon dioxide gives an unstable carbamate,[122,123] and not a complex of copper with CO_2, as suggested in early studies.

Finally, it may be noted that the insertion of CO_2 at M$-$O and M$-$N bonds, like its insertion at an M$-$C bond, provides a new method for obtaining the hydrogen carbonates, carbamates, and carboxylates of transition metals, lanthanides, and actinides. It is well known that the addition of amines to catalytic systems facilitates the insertion of carbon dioxide at an M$-$C bond, that is the activation of the latter.[1] It is also possible that carbon dioxide is activated in these systems as a result of simultaneous reaction with the atoms of the transition metal and nitrogen (bifunctional catalysis). This indicates the importance of the study of the mechanism of the insertion of carbon dioxide at an M$-$N bond for the solution of the problem of involving this molecule in catalytic processes to give organic products.

V. Reduction of carbon dioxide

1. Chemical reduction of carbon dioxide

The reduction of carbon dioxide by alkali metal amalgams gives oxalate ion in the absence of moisture, and formic acid in the presence of moisture.[2] In addition to oxalic acid, the products of the reaction of CO_2 with alkali metal amalgams in aprotic media, after hydrolysis, contain acetic, malonic, glycollic, tartaric, and other acids.[2]

The coordination of CO_2 to the alkali metals, and the reaction products, have been studied.[22,23] An interesting feature is that the adduct $LiCO_2CO_2$ was detected among the products of the reaction of CO_2 with lithium vapour in a matrix. The published[22] reaction scheme explains, on the one hand, the formation of the oxalate ion, and on the other hand the formation of the carbonate ion and carbon monoxide.

An example of bifunctional catalysis is provided by the reduction of carbon dioxide in the presence of the Cp_2TiCl + Al system in tetrahydrofuran.[124] $Cp_2Ti(CO)_2$ is formed in this system as the main product, in 80% yield. The influence of the Lewis acids VCl_4, $HgCl_2$, and $GaCl_3$ on the yield of dicarbonyltitanocene has been studied. The carbonate $(Cp_2Ti)_2CO_3$ was detected in addition to the titanium carbonyl.

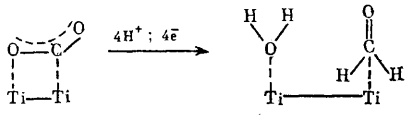
The reduction of carbon dioxide by molecular hydrogen to methanol and methane in the presence of bifunctional catalysts has been examined.[125]

The reduction of CO_2 in aqueous media, when the water molecules act as hydrogen donors, are of particular interest. An extremely important feature of these systems is the ability of the transition metal to activate a water molecule with the formation of a hydride complex. Thus the splitting of water by cobalt complexes takes place under mild conditions according to the scheme[126]

$$2[Co] + H_2O \rightarrow [Co]H + [Co]OH,$$

and its splitting by phosphine complexes of platinum takes place according to the scheme[127]

$$[Pt] + H_2O \rightarrow H[Pt]OH.$$



The hydrogenating power of the cobalt complex increases when reducing agents (Zn/Hg etc.) are introduced into the system.[126]

In the reduction of salts and oxides of vanadium by amalgamated zinc in aqueous solutions in a CO_2 atmosphere, the chief reaction product is HCO_2H, whereas malic acid is formed preferentially under the same conditions in the presence of molybdenum derivatives, and malic and tartaric acids in the presence of $TiCl_4$.[128] In aqueous solutions in the presence of the $Ti(SO_4)_2-Al/Hg$ system, formaldehyde and formic acid are produced (10% of the yield of H_2CO).[129] HCO_2H, H_2CO, MeOH, and CH_4 have been detected in the reduction of carbon dioxide in acidic solutions in the presence of sodium amalgam and compounds of manganese, tungsten, and molybdenum. The main product is methanol in the absence of oxygen, and H_2CO and MeOH in the presence of oxygen.

In the presence of the $Ti^{2+}-Al/Hg$ system at pH 1.7 and a CO_2 pressure of 5 atm, the main product of the reduction of CO_2 is H_2CO, whereas in the $Cr^{3+}-Al/Hg$ system, HCO_2H is formed preferentially. The selective reduction of carbon dioxide to formaldehyde in aqueous solution was observed in the presence of the $TiCl_3-Al/Hg$ system.[130] The competing reaction of molecular hydrogen liberation takes place in parallel. The highest yield of H_2CO is achieved at pH 3.5. An interesting feature is that at pH 3.8 in aqueous solutions, the following equilibrium is established[2]

$$CO_2^{\cdot-} + H^+ \rightleftarrows \dot{C}O_2H.$$

It has been shown using $^{14}CO_2$ that the reduction of CO_2 in the presence of the $Ti^{3+}-Al/Hg$ system is a four-electron process taking place according to the scheme

2. The electrochemical and electrocatalytic reduction of CO_2

a. Electrochemical reduction

Considerable attention has been paid to the electrolytic reduction of carbon dioxide in aprotic and proton-containing electrolytes.[2,131-136] The interest in this problem is due largely to the utilisation of CO_2 in isolated systems,[135] and also in relation to the production of organic compounds of interest as future sources of energy (HCO_2H), MeOH, CH_4, etc.) or as foodstuffs.[136-138]

The principal reactions in the electrolytic reduction of carbon dioxide are the formation of oxalate or carbonate ions and carbon monoxide in aprotic media, and the formation of formic acid in aqueous media and in general in the presence of proton donors.[2,131-134] In all cases, the radical-anion $CO_2^{\cdot-}$ is formed in the first stage as the product of electron transfer from the electrode surface to an adsorbed CO_2 molecule:

$$CO_2 + e^- \rightarrow CO_2^{\cdot-} \begin{cases} \xrightarrow{+(CO_2)} CO_3^{2-} + CO \\ \xrightarrow{+(CO_2^{\cdot-})} C_2O_4^{2-} \\ \xrightarrow{+H^+(+e^-)} HCO_2^- \end{cases}$$

The formation of the radical-anion $CO_2^{\cdot-}$ requires a fairly high potential. Thus according to Eggins and McNeill,[139] the direct reduction of carbon dioxide takes place with great difficulty at a potential of -2.0 V (normal hydrogen electrode). In aqueous solutions, this high potential lowers the yield of organic products as a consequence of the competing process of molecular hydrogen liberation.

In a study of the mechanism of oxalate formation, two radical species were detected in the reaction mixture:[134,140]

$$CO_2 + e^- \rightarrow CO_2^{\cdot-},$$
$$CO_2^{\cdot-} + CO_2 \rightarrow CO_2CO_2^{\cdot-},$$
$$(CO_2)_2^{\cdot-} + e^- \rightarrow C_2O_4^{2-}.$$

According to Kafafi and co-workers,[141] the oxalate ion is formed by the dimerisation of two $CO_2^{\cdot-}$ radical-ions. An interesting feature is that the formation of dimers $M(CO_2CO_2)^-$ was suggested as one of the stages in the reaction of alkali metal vapour with CO_2 [141,142] or in the insertion of this molecule at an Fe–Na bond[64] (see also section III). When the adsorption of the dimer $CO_2CO_2^{\cdot-}$ on the electrode is weak, the oxalate ion is formed, and when its adsorption is strong, the carbonate ion and CO are formed.[143] On Pt, Au, and Ag electrodes in DMSO and other aprotic solvents, carbon monoxide is formed,[144-146] whereas on Hg and Pb electrodes in DMF and DMSO, $C_2O_4^{2-}$ is liberated in addition to CO.[131] The lead electrode is preferred for the preparation of oxalate, and the mercury electrode for the preparation of CO. On In, Sn, and Zn electrodes in DMSO at an increased CO_2 pressure, the main product is carbon monoxide.[147] A systematic study of the influence of the electrode material, the carbon dioxide pressure, and other parameters on the yield of oxalic acid in aprotic solvents has been carried out.[139,148] The cathode materials studied were Pb, Pb/Hg, stainless steel, Cr, Cd, Al, Cu, Zn,[139] glass carbon, Hg, Pt, Pb, and Au.[148]

In aprotic media, other organic products are formed in addition to oxalate and carbonate ions and carbon monoxide. Thus at a lead cathode in DMSO, in addition to oxalate, another ten products were detected, including propionic, maleic, tartaric, and other acids.[147] The formation of various organic products in the synthesis of oxalic acid in aprotic solvents has been reported.[131,150] In the presence of moisture in an aprotic solvent, hydroxyacids are formed in addition to oxalate and HCO_2H.[2,147,149] Thus in the presence of water, glycollic acid is liberated at a Pb electrode,[131,151] and malic acid at an Hg electrode.[152]

As noted above, in aqueous solutions the main product of the reduction of carbon dioxide is formic acid. HCO_2H is formed via the radical-anion $CO_2^{\cdot-}$. The electrolytic reduction can take place by a one-electron or by a two-electron mechanism:[2,133]

$$CO_2 + e^- \rightarrow CO_2^{\cdot-},$$
$$CO_2^{\cdot-}(ads) + H_2O \rightarrow CO_2^{\cdot-}(H_2O),$$
$$2\,CO_2^{\cdot-}(H_2O) \rightarrow CO_2 + HCO_2^- + OH^-,$$

or

$$CO_2 + e^- \rightarrow CO_2^{\cdot-}(ads),$$
$$CO_2^{\cdot-}(ads) + e^- \xrightarrow{H_2O} HCO_2^- + OH^-.$$

A mechanism for the electrolytic reduction of carbon dioxide with the simultaneous transfer of two electrons in the CO_2 molecule has been proposed:[153]

$$CO_2 + 2e^- \rightarrow CO_2^{2-},$$
$$CO_2^{2-} + H_2O \rightarrow HCO_2^- + OH^-.$$

The formation of CO_2^{2-} in the reaction of carbon dioxide with alkali metals has been reported.[154] The CO_2 pressure has a significant influence on the order of the reaction.[155]

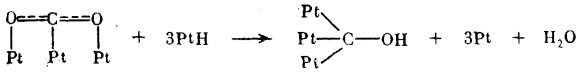
The $CO_2^{\cdot-}$ radical-anion is extremely unstable, making it difficult to study the mechanism of the electrolytic reduction of carbon dioxide by the methods of electrochemical kinetics.[131] From known thermodynamic quantities, the electron affinity of CO_2 in aqueous solution has been estimated as ~ 0.5 eV.[155,156] The highest current efficiency under optimum conditions was observed at -1.9 V (silver chloride reference electrode) at Zn, Pb, and In cathodes, and at -1.7 V at an Sn electrode.[157] The study of cathode materials with medium and high hydrogen overvoltages showed that in the electrolytic reduction of carbon dioxide, the overvoltage increases in the order Sn < Cu < Zn < Cd < Pb < Au [158] (see also the paper by Vasil'ev and co-workers[133]). The highest efficiency in this process is shown by metals with a medium overvoltage. The high overvoltage at the Sn electrode also ensures high rates of the

electrolytic reduction of CO_2.[159] In the electrolytic reduction of carbon dioxide in aqueous solutions, the formation of propionic[160] and butyric[161] acids in addition to HCO_2H has been noted.

The more extensive reduction of carbon dioxide to formaldehyde, methanol, and methane is accompanied by the transfer of four, six, and eight electrons respectively, that is it requires a much greater expenditure of energy:[162]

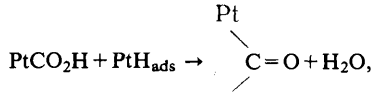
$$CO_2(gas) + 2H_2O(liquid) = HCO_2H(solv.) + \tfrac{1}{2}O_2 \quad (E^0 = 1.428 \text{ eV});$$

$$CO_2(gas) + H_2O(liquid) = H_2CO(solv.) + O_2(gas) \quad (E^0 = 1.350 \text{ eV});$$

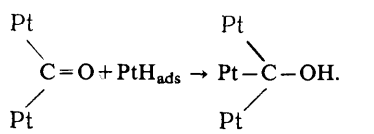


$$CO_2(gas) + 2H_2O(liquid) = MeOH(solv.) + \tfrac{1}{2}O_2 \quad (E^0 = 1.119 \text{ eV});$$

$$CO_2(gas) + 2H_2O(liquid) = CH_4(gas) + 2O_2(gas) \quad (E^0 = 1.037 \text{ eV}).$$



Cyclic voltammetry, preparative electrolysis, and other methods have been used to make a detailed study of the mechanism of the electrolytic reduction of CO_2 to H_2CO and HCO_2H at Hg, Pb, and Sn electrodes in the pH range 6.8–13.0.[137]



At a platinum electrode in a saturated carbonate solution in a cell with non-separated anode and cathode compartments, formaldehyde is formed in addition to HCO_2^-.[163,164] Fairly high methanol current efficiencies are achieved in the electrolytic reduction of carbon dioxide at an In cathode in lithium carbonate solution.[136] HCO_2H is reduced in acidic media at Pb and Sn to methanol.[137] At a dropping mercury electrode, the reduction of H_2CO to MeOH takes place by two different mechanisms, depending on the pH of the medium. The more extensive reduction of HCO_2H on Sn at comparatively low current densities, in the opinion of the authors cited,[137] is due to the formation of organotin compounds on the electrode surface. The formation of hydrocarbons in the electrochemical reduction of carbon dioxide at an Ag electrode has been reported.[165] In the opinion of the authors cited, the electrolytic reduction of CO_2 passes through a stage involving the formation of unstable silver formate on the electrode surface.

The mechanism of the chemisorption of carbon dioxide in its electrolytic reduction at smooth electrodes is of fundamental importance.[134,166,167] This problem is closely related to the chemisorption of carbon dioxide on the surface of heterogeneous catalysts,[2] and also to the coordination of CO_2 to metals in matrices or in various metallic centres. Of particular interest in this connection is the coordination of carbon dioxide to the surface of a platinum electrode through the carbon atom with the subsequent formation of organometallic adducts during the reduction:[166]

$$Pt_3(CO_2)_{ads} + PtH_{ads} \rightarrow Pt{-}CO_2H,$$

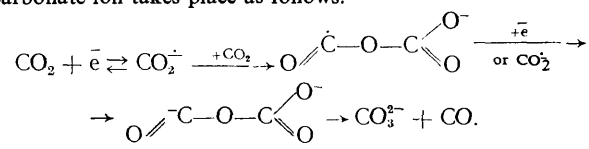
As already noted in section III, X-ray diffraction data show that the bent CO_2 molecule forms a complex with three metal atoms (rhenium and osmium). It is quite possible that a CO_2 molecule coordinated on the surface of a platinum electrode forms a π-allyl adduct. In this connection it should be noted that in the chemistry of coordination compounds there are known cases of the transfer of an allyl ligand from one metallic centre to another.[168,169] Transfer of this kind is particularly important in the electrocatalytic reduction of carbon dioxide.

Hydrogen chemisorbed on a Pt electrode can reduce carbon dioxide to formic acid.[170] The reaction of CO_2 with H_{ads} at the surface of a platinum electrode in 0.5 M sulphuric acid gives the fragment $[Pt]CO_2H$.[171] As noted in section III, the action of water on a cationic complex of platinum gives a stable platinum-carboxylic acid $(Et_3P)_2Pt(Cl)CO_2H$.[36] The formation of esters of a platinum-carboxylic acid of the type $[Pt]-CO_2R$ was detected in the electrocatalytic carboxylation of unsaturated compounds in the presence of platinum clusters.[172] To this it should be added that carbon dioxide can react with the hydride complexes of transition metals in two ways:[1,2,173]

$$[M]{-}H + CO_2 \rightarrow [M]O_2CH,$$
$$[M]{-}H + CO_2 \rightarrow [M]CO_2H,$$

that is with the formation of either formates or metal-carboxylic acids.

Fundamental difficulties in the electrolytic reduction of CO_2 at smooth electrodes are associated with increasing the current density. The low current density is a consequence of the low solubility of carbon dioxide in many solvents. This problem can be solved, in particular, by using porous electrodes, increasing the CO_2 pressure, introducing catalytic additives, etc.



b. Electrocatalytic reduction

In the last ten years, a fairly large number of published papers have described the electrolytic reduction of carbon dioxide in the presence of transition metal compounds acting as catalysts. The introduction of transition metal compounds into the electrocatalytic circuit makes it possible to solve a number of fundamental problems, in particular to lower considerably the potential of the electrolytic reduction of CO_2, to create conditions for many-electron transfer, etc. The nature of the transition metals whose compounds are used as catalysts determines the specific features of the electrocatalytic stage and hence the organic reaction products formed. The way in which the metal compound is introduced into the catalytic circuit is extremely important: the coordination compound is either deposited on the electrode surface or dissolved in the electrolyte.

c. The reduction of CO_2 to CO_3^{2-} and CO

Carbon monoxide is a valuable raw material for the synthesis of organic compounds. For example, methanol can be obtained from carbon monoxide in good yield by electrocatalytic reduction under mild conditions.[174] Organic acids can be obtained by electrocatalytic reduction from unsaturated compounds, CO, and water in the presence of platinum complexes.[172] Finally, the electrocatalytic reduction of carbon monoxide in aqueous solution is of considerable importance for the production of "synthetic gas".[175]

The electrolytic reduction of carbon dioxide to carbon monoxide and carbonate ion takes place as follows:[150]

In the electrolytic reduction of carbon dioxide at a mercury electrode in acetonitrile containing KNO_3 or $LiClO_4$ as background, carbon monoxide is not formed in the absence of a catalyst at -1.6 V. When tetra-aza-macrocyclic derivatives of divalent cobalt and nickel complexes are added to the electrolyte, the reduction of CO_2 to CO takes place at -1.3 V with a current efficiency of up to 90%.[145] In the presence of a catalyst but in the absence of water, carbon monoxide is not formed. The electrocatalytic behaviour of the complex $Ni^{2+}L_2$, where L_2 = 1,4,8,11-tetra-azacyclotetradecane, has been studied.[176] At an Hg electrode in an electrolyte consisting of an MeCN + H_2O mixture, or in an aqueous medium in the presence of this complex, carbon monoxide is formed from CO_2. The authors cited[176] relate the formation of CO in aqueous solution to the geometry of the macrocyclic ligand, which creates round the metallic centre a hydrophobic space or "aprotic niche", which does not prevent the approach of CO_2 to the metal but which hinders the approach of moisture. Of the large number of divalent nickel complexes studied, only dicyclic compounds of nickel were found to be active, and complexes of nickel with unsaturated macrocyclic ligands or with open chains are inactive in this process. In the opinion of Pearce and Pletcher,[132] the fact that no formic or oxalic acid is formed in electrocatalytic processes involving nickel and cobalt chelates is due to the fact that this process takes place by the following mechanism:

$$[LM^{I}]^{n+} + \bar{e} \rightleftarrows [LM^{I}]^{(n-1)+},$$

$$[LM^{I}]^{(n-1)+} + CO_2 + Na^+ \rightleftarrows [LM^{III}CO_2^-Na^+]^{n+},$$

$$[LM^{III}CO_2^-Na^+]^{n+} + H_2O \xrightarrow{\text{rapidly}} [LM^{III}CO_2H]^{n+} + NaOH,$$

$$[LM^{III}CO_2H]^{n+} + \bar{e} \rightarrow [LM^{II}CO_2H]^{(n-1)+},$$

$$[LM^{II}CO_2H]^{(n-1)+} \xrightarrow{\text{slowly}} [LM^{II}]^{n+} + CO + OH^-,$$

$$2\,NaOH + 2\,CO_2 \rightarrow 2\,NaHCO_3,$$

where M = Co or Ni, and L represents the macrocyclic ligand.

According to the data of Tinnemans and co-workers,[177] the complexes of cobalt and nickel with tetra-aza-macrocyclic ligands are effective electron acceptors (first stage). The next stage, according to the above scheme, involves the formation of an adduct with carbon dioxide, in which an alkali metal atom also takes part (bifunctional catalysis). The products of the insertion of CO_2 at a transition metal–alkali metal etc. bond were examined in sections III and IV. The metal-carboxylic acid formed at the stage of protonation of the coordinated CO_2 molecule may be stable even in aqueous media.[36] Nickel-carboxylic and cobalt-carboxylic acids are unstable.[36]

The formation of a complex of carbon dioxide with a Co^{2+} complex obtained by the electrolytic reduction of a Co^{3+} chelate has been described.[178]

The reduction of carbon dioxide to the monoxide in aqueous media can be carried out at a graphite electrode modified by the deposition of cobalt phthalocyanine.[175] The electrocatalytic reduction of CO_2 on this electrode in a citrate buffer at pH 5 takes place at -1.0 V (standard calomel electrode). The efficiency of the electrolytic reduction of CO_2 is sufficiently high only when cobalt phthalocyanine is deposited on the electrode surface; when it is added to the electrolyte, the system has a low catalytic activity, and the results are not reproducible. The potential for the reduction of carbon dioxide is lowered considerably in the presence of complexes of metals with sulphonated phthalocyanines at an amalgamated platinum electrode.[179] In this case the reduction of CO_2 involves two stages; in the first, a complex of the metal with carbon dioxide is formed on the electrode surface, and in the second, an electron is transferred to the CO_2 molecule from the electrode via the transition metal complex.

The electrocatalytic reduction of carbon dioxide to CO also takes place in the presence of bipyridyl complexes of rhenium[180] and ruthenium.[181,182] Thus selective formation of carbon monoxide takes place in the electrolytic reduction of CO_2 in the presence of (bipy)$Re(CO)_3Cl$ in DMF–water (9:1) solution at a glass electrode at -1.25 V (normal hydrogen electrode).[180] The absence of other carbon-containing reduction products was confirmed by ^{13}C NMR. Carbon dioxide is reduced in the presence of the cationic complex of ruthenium $(bipy)_2Ru(CO)_2^{2+}$ in DMF–H_2O solution at -1.5 V (saturated calomel electrode) at an Hg electrode.[181] When the concentration of water in the electrolyte is high, formic acid is also produced. The processes taking place in the electrocatalytic reduction include the formation of an unstable adduct of ruthenium with carbon dioxide:[181]

$$(bipy)_2Ru(CO)_2^{2+} \underset{-OH^-}{\overset{+OH^-}{\rightleftharpoons}} [(bipy)_2Ru(CO)(CO_2H)]^+ \underset{-OH^-}{\overset{+OH^-}{\rightleftarrows}}$$

$$\rightleftarrows [(bipy)_2Ru(CO)(CO_2^-)]^+ + H_2O.$$

Carbon monoxide is liberated with a high current efficiency, together with methanol and methane, at a ruthenium electrode deposited on a carbon electrode at $-(0.35-0.65)$ V (normal hydrogen electrode).[183] CO is also formed in the electrolytic reduction of CO_2 in the presence of sulphur-containing iron clusters.[184] Carbon monoxide and carbonate ion are formed by the photoelectrocatalytic reduction of CO_2 in aqueous solutions at an electrode of the semiconducting *p*-GaAs at -1.2 ± 0.1 V (normal hydrogen electrode)[185] (see next section).

The preparation of CO by the reduction of the hydrogen carbonate ion by a bipyridyl complex of cobalt(I) in aqueous solution at pH 8.5–10.0 has been studied.[186] The carbon monoxide formed reacts with the bipyridyl complex of cobalt to give the stable complex (bipy)$Co(CO)_2$, which has been isolated. Small quantities of formate ion were also produced. The results indicate that the reaction of H_2O and HCO_3^- with $(bipy)_3Co^+$ involves the intermediate formation of the hydride complex of cobalt $(bipy)_2Co(H_2O)H^{2+}$.

Thus the electrocatalytic reduction of CO_2 to CO and CO_3^{2-} differs significantly from the electrolytic reduction of this molecule at smooth electrodes. The study of the electrocatalytic reduction of carbon dioxide in aqueous media involves considerable difficulties, due primarily to the fact that the stages involving the protonation of the coordinated CO_2 molecule, the formation of complexes with carbon dioxide from the metal-carboxylic acids, and the reaction of the hydroxo-complexes with CO_2 have been insufficiently studied, and also to the lack of detailed information on the behaviour of the hydrogen carbonate ligand at the metallic centre, etc.

d. The reduction of CO_2 to formic acid

Formic acid is a product of the reaction of the radical-anion $CO_2^{\cdot-}$, formed by the electrolytic reduction of carbon dioxide, with water or other proton sources in the electrolyte.[2] Among the methods for obtaining HCO_2H, a unique place is occupied by the electrocatalytic reduction of CO_2.

Formic acid is produced by the electrocatalytic reduction of carbon dioxide at a graphite electrode on which the phthalocyanines of cobalt, iron, or copper have been deposited.[187] The highest yields of HCO_2H are obtained when cobalt phthalocyanine is used. This result does not agree with earlier data, according to which oxalic and

glycollic acids, but not formic acid, are produced in the presence of metal phthalocyanines deposited on a graphite electrode.[188] A later study of the behaviour of metal phthalocyanines on an electrode surface showed that formic acid is produced at pH 3.7.[189] In less acidic solutions, the catalytic system in inactive. It was also found that the cathode current increases linearly with increase in the carbon dioxide concentration. The activity of the metals in this process decreases in the order Co^{2+}, $Ni^{2+} \gg Fe^{2+} \simeq Cu^{2+} > Cr^{3+}$.[189] In the electrocatalytic reduction of CO_2 in the presence of cobalt phthalocyanine, small quantities of methanol were detected.

The formate ion is produced in acetonitrile at a graphite electrode on which the complexes of rhodium or ruthenium with 2,6-bis-(2-pyridyl)pyridine have been deposited.[190] When the rhodium complex is used, the electrolytic reduction of CO_2 takes place at -1.55 V (saturated calomel electrode) and gives HCO_2^- (current efficiency 64%) and H_2 (current efficiency 12%), and in the case of ruthenium, formate ion and CO are produced at -1.4 V. It was suggested that an important role in the catalytic act is played by the polypyridyl ligand, acting as an "electron reservoir'. In the electrolytic reduction of CO_2 for a short time interval at a mercury electrode in acetonitrile containing the dissolved complex $(dppe)_2RhCl$, formate is produced with a current efficiency of 42%; with increase in the reduction time, the yield of formate decreases.[191] It is suggested that a complex of rhodium with carbon dioxide is formed during the reaction; this complex in turn reacts with the proton donor to form a hydride, which takes part in the transfer of hydrogen to the coordinated CO_2 molecule.

The electrocatalytic reduction of carbon dioxide has been carried out at a mercury electrode in DMF containing dissolved sulphur-containing iron clusters $[Fe_4S_4(SR)_4]^{2-}$, with R = $PhCH_2$ and Ph.[192] In the presence of these clusters, with a corresponding lowering of the potential, only formic acid is produced, whereas in the absence of the catalyst the main product is oxalate, formed with a current efficiency of 73% (formate ion and carbon monoxide are also obtained, with current efficiencies of 12% and 13% respectively). The authors cited[192] suggest that the source of hydrogen in the synthesis of HCO_2H is the organic radical Bu_4N^+, used as background.

Electrocatalytic reduction always occurs with the formation of a hydride complex, which takes part in the transfer of hydrogen to the CO_2 molecule coordinated to the metal.[191] In principle, the hydride complexes can be formed in two ways:

$$[M] + H_2O \rightleftarrows M(H)OH,$$
$$2[M] + H_2O \rightleftarrows [M]OH + [M]H.$$

Finally, it may be noted that the electrocatalytic reduction of carbon dioxide may involve a fairly complex chain of processes. Thus the preparation of sugars and aminoacids in aqueous solutions has been carried out by creating a catalytic chain in which the photosynthetic stage is replaced by the electrochemical reduction of $NADP^+$ (nicotinamide phosphate) in the presence of ferredoxin or methylviologen to bring about the electron transfer from the electrode to $NADP^+$.[138] The closure of the catalytic ring is achieved by the regeneration of NADPH by electrolytic reduction.

3. The photoelectrocatalytic reduction of carbon dioxide

a. Photoreduction at electrodes of semiconducting materials

The ability of various semiconductors (TiO_2, *p*-GaAs, etc.) to transform light energy into a photo-current has been used, in particular, to reduce carbon dioxide in aqueous solutions.[136] The photoreduction of CO_2 in these media is closely related to the photocatalytic decomposition of water.[193] The solution of the problems of transforming solar energy into electrochemical energy depends to a large extent on the development of studies in this field.[194–196] The efficiency of the transformation of solar into electrical energy on single crystals of *n*-GaAs and *p*-InP reaches 12%.[197]

The photo-process taking place when a quantum of light acts on a semiconductor reduces to the transfer of an excited electron from the valence band of the semiconductor to the substrate. Thus on the irradiation of electrodes to *p*-GaP [198] and *p*-GaTe [199] in the presence of CO_2, the radical-ions $CO_2^{\cdot-}$ are formed on the surface of the photo-cathodes. Carbon monoxide has been obtained from CO_2 at an *n*-CdTe photo-cathode in DMF or MeCN containing small quantities of water.[200] The replacement of Bu_4NClO_4 as electrolyte by NH_4ClO_4 has a marked influence on the magnitude of the photo-current.[201] In the mechanism proposed for the reaction, the ammonium ion transfers the electron to CO_2. CO is formed with a current efficiency of 80% from CO_2 at electrodes of CdTe, GaAs, GaP, and InP in DMSO, DMF, or propylene carbonate.[202] In contrast to the electrolytic reduction of CO on In, Pb, and Hg (see previous section), the reduction of CO_2 on photo-cathodes takes place at potentials between -0.7 V and $+1.0$ V.

In the photo-reduction of CO_2 in aqueous solutions at GaP and GaAs electrodes, the main product is HCO_2H with a small quantity of H_2CO and MeOH. The highest current efficiency of 80% is achieved at a CO_2 pressure of 8.5 atm and a potential of -1.0 V (silver reference electrode). The potential of the cathodic photo-current changes linearly with increase in the pressure. The formation of HCO_2H with a current efficiency of 1% has been observed in the photo-reduction of CO_2 at GaAs in an electrolyte containing the redox system V^{2+}/V^{3+} to prevent photo-corrosion.[204]

Carbon dioxide is reduced to H_2CO, MeOH, and HCO_2H when a *p*-GaP photo-cathode is irradiated with an Hg lamp at pH 6.8.[205] The accumulation of HCO_2H and MeOH at room temperature was observed for 18–90 h. The maximum efficiency of the formation of H_2CO and MeOH when monochromatic light (365 nm) is used has the values 5.6% and 3.6% respectively. For illumination with sunlight, the efficiency decreases to 0.97% and 0.61% respectively. Methanol, CO, and H_2 were detected on the irradiation of a solution of hydrogen carbonate at a GaP photo-cathode using Hg, Xe, and W halide lamps.[206] The addition of crown ethers to lithium carbonate solution in the photo-reduction of CO_2 on GaP increases both the photo-current and the current efficiency of H_2CO, HCO_2H, and MeOH. It has been suggested that the metallic lithium liberated in the presence of the crown ethers reacts with CO_2 to give $CO_2^{\cdot-}$.

Methanol is also formed in the photo-reduction of CO_2 on *p*-GaAs and *p*-InP in an electrolyte containing sodium sulphate.[198] The density of the photo-current and the current efficiency of MeOH depend significantly on the type of electrolyte. The irradiation of CO_2 with monochromatic light in 0.5 M H_2SO_4 on *p*-GaP at -1.5 V gives formaldehyde and methanol.[207] With a disc electrode in the form of a single crystal of *p*-GaAs (As 111) at pH 4.2, the current efficiency of MeOH in the reduction of CO_2 reaches 10% at a current density of 1.4×10^{-4} A cm^{-2}.[185] Increase in the current density leads to a decrease in the yield of MeOH. A study of the influence of the deposition on the *p*-GaP photo-cathode of films of metals with a high hydrogen liberation overvoltage (Pb, Zn, Au) showed that when a Pb film is used, the chief product of the reduction of CO_2 is HCO_2H with a current efficiency of 42%, and the yield of this product is ten times lower at a cathode without a

coating.[208] When the cathode is coated with a Zn film, the main product is CO with a current efficiency of 18%. In both cases, H_2CO and MeOH were not detected in the reaction products. Irradiation with an Xe lamp at a *p*-type silicon photo-cathode alloyed with boron gives HCO_2H (current efficiency 28%) and H_2CO (19%),[207] and the photo-irradiation of CO_2 on photo-electrodes of TiO_2 and titanates containing 0.05–0.5 wt.% added Mn, Fe, Co, and Nb gives H_2CO and MeOH.[208] An apparatus for the photo-initiation of the reaction of CO_2 with water, adsorbed on the [111] face of strontium titanate, on irradiation with an Hg lamp has been described.[209] The products of this reaction include not only methane but also other hydrocarbons, HCO_2H, H_2, and O_2. In the monochromatic (752 nm) irradiation of a *p*-GaP electrode in $MeCN-H_2O$ solution containing tetra-aza-macrocyclic metal complexes, the potential for the reduction of CO_2 is 0.6 V lower than that on metallic electrodes in the presence of the corresponding catalysts.[210]

A laboratory photocatalytic cell for the preparation of HCO_2H from CO_2 using solar energy has been proposed.[211] The efficiency of the cell depends markedly on its design, particularly if the anode and cathode compartments are separated.

Finally, it should be emphasised that an extremely important characteristic of semiconducting photo-electrodes is their ability to reduce CO_2 under "dark" conditions by the creation of a reserve of electrons on preliminary illumination of the photo-cathode.[205,212]

b. Photo-reduction in suspensions of semiconducting materials

The photoelectrocatalytic reduction of carbon dioxide can also be carried out using semiconducting materials in the form of suspensions and colloids. In these systems, the particles of the semiconductor can be regarded as microphoto-electrodes, since the action of light on the surface of the particles produces regions capable of acting as cathodes and anodes. A systematic study of the reduction of CO_2 in aqueous solutions in the presence of suspensions of S, C, CdS, GaP, ZnO, TiO_2, and WO_3 has been carried out.[213] H_2CO and MeOH are formed in the reduction. The yield of MeOH correlates with the potential of the conductivity band of the semiconducting material; catalysts for which the potential is more negative are more effective. Formaldehyde is produced in the presence of suspensions of TiO_2 and calcium and strontium titanates.[214,215] The addition of ruthenium dioxide to TiO_2 leads to the more complete transformation of solar into electrochemical energy, compared with the use of niobium and uranium oxides.[216] The reaction products are H_2CO, MeOH, and HCO_2H. Formaldehyde is produced on the irradiation with an Hg lamp of TiO_2 suspensions covered with films of Pt, Au, Ag, Hg, Co, or Pb.[217] The highest yield is achieved when Hg films are used. Although mercury is oxidised during the photo-reduction, the reverse reduction of mercury oxide to the metal takes place at $\lambda = 600$ nm. H_2CO, HCO_2H, MeOH, MeCHO, and EtOH were obtained from CO_2 and water by the irradiation with an Hg lamp of strontium titanate containing the added oxides of Rh, Ir, Pt, and Ru.[218] The addition of 0.5% $LaCrO_3$ to this system increased the yield of MeOH three-fold. HCO_2H is formed from CO_2 on the irradiation of a suspension of $BaTiO_3$ containing added lanthanide oxides.[219]

An assembly has been proposed[220] for obtaining organic products by irradiation of a CO_2-H_2O-photo-activator (titanates) system. When Li_2CO_3 is added to this system, the degree of transformation of solar energy reaches 0.011–0.016%. The reaction $CO + H_2O \rightleftarrows CO_2 + H_2$ taking place when a TiO_2 suspension is irradiated with an Hg lamp has been studied.[221,222] In particular, it was found that the rate of this reaction is proportional to the light intensity. The preliminary reduction of TiO_2 with molecular hydrogen leads to a marked increase in the photocatalytic activity of the oxide.[223]

4. The photochemical and photocatalytic fixation of carbon dioxide

The problem of obtaining organic products from CO_2 and water under the influence of different forms of radiation is directly related to the study of chemical evolution on the Earth.[2,224] The progress made in recent years in the activation of CO_2 and H_2O by systems based on transition metals has also made a significant contribution to the development of these studies. Early studies examined mainly the effect of ultraviolet irradiation on the CO_2-H_2O system,[2,225–234] to which compounds of transition metals or uranium were added in some cases. Systematic studies[230–234] showed that the ultraviolet irradiation of the CO_2-H_2O system gives CO, HCO_2, H_2CO, and MeCHO. The yield of the photolytic reaction products increases slightly in the presence of Fe^{2+} ions. When aqueous solutions containing CO_2 in the presence of Fe^{2+} were irradiated using a lamp with a power of 375 W (365.5 nm), the formation of oxalic, acetic, and malonic acids was observed. Fe^{2+} ions are usually added to the photolytic system to stabilise $^{\cdot}OH$ radicals.[2] It is possible that they also stabilise $CO_2^{\cdot-}$ radical-anions, which according to the data obtained[230–234] are formed in the photolytic system being considered. In the photolysis of CO_2 using light with arbitrary wavelength, the principal products are CO, O, and small quantities of ozone.[224] The photolysis of carbon dioxide in the presence of metallic mercury gives CO_3,[2] probably via the intermediate $Hg.CO_2$.

Since water and CO_2 do not absorb visible light, a photocatalytic process in this case is possible only when a photosensitiser capable of transferring its absorbed energy to CO_2 and H_2O is added to the system. If the lifetime of the photosensitiser in the excited state is insufficient for the transfer of a quantum of light, the photocatalytic act may be brought about by the introduction of a special agent to transfer an electron from the photosensitiser to the CO_2 molecule. Photocatalytic systems of this type containing a photosensitiser and electron-transfer agents have recently been detected and studied. Thus in the presence of bipyridyl complexes of ruthenium and cobalt, the photocatalytic decomposition of water by visible light can be brought about, with further transformation involving CO_2, by two different paths.[186] The first path can be represented as follows:

$$Ru^{2+} \xrightarrow{h\nu} {}^{*}Ru^{2+},$$

$$^{*}Ru^{2+} + AH^- \rightarrow Ru^+ \ (AH^- \text{ represents the ascorbate ion}),$$

$$Ru^+ + Co^{2+} \rightarrow Ru^{2+} + Co^+,$$

$$Co^+ + H_2O \rightarrow Co^{2+} + {}^1/_2H_2 + OH^-.$$

The Co^+ ion by itself undergoes practically no reaction with CO_2, but in the presence of bipyridyl it becomes a strong reducing agent:[186,235]

$$2(bipy)_3Co^+ + HCO_3^- + H_2O \rightarrow 2(bipy)_3Co^{2+} + CO + 3OH^-,$$

$$(bipy)_3Co^+ + CO \rightarrow {}^1/_4[(bipy)Co(CO)_2]_2 + {}^1/_2(bipy)_3Co^{2+} + bipy.$$

It can be seen from this scheme that the bipyridyl complex of ruthenium acts as the photosensitiser, and the bipyridyl complex of Co acts as the electron-transfer agent. The chief product is CO, but in the pH range 5–10, H_2 and small quantities of HCO_2H are formed.

The second path is represented by the scheme:

$$Ru^{2+} \xrightarrow{h\nu} {}^{*}Ru^{2+},$$
$${}^{*}Ru^{2+} + Co^{2+} \rightarrow Ru^{3+} + Co^{+},$$
$$Ru^{3+} + NTE \rightarrow Ru^{2+} + NTE^{\cdot+} + NTE \rightarrow NTE^{\cdot} + NTEH^{+},$$
$$NTE^{\cdot} + Co^{2+} \rightarrow \text{products} + Co^{+},$$
$$Co^{+} + H_2O \rightarrow Co^{2+} + {}^{1}/_{2}H_2 + OH^{-},$$

where NTE = 2,2′,2″-nitrilotri(ethanol).

The variety of functions which can be carried out by cobalt ions in catalytic systems was noted above; they bring about the decomposition of water,[76] form an adduct with CO_2 in electrolytic reduction,[36] are involved in the formation of cobalt-carboxylic acids,[1,36] etc.

HCO_2H is formed in the photocatalytic reduction of CO_2 in water on irradiation with an Hg lamp with a light filter (λ = 320 nm) in the presence of the system $(bipy)_3Ru^{2+}$ – methylviologen (MV) – triethanolamine (or ethylenediaminetetra-acetic acid).[236] The process involves the MV^{+} radical-cation, which in turn is the product of electron transfer from the photo-excited ruthenium complex. The formation of HCO_2H was confirmed using labelled $^{13}CO_2$.[237] It was also shown that the photolysis involves the formation of ruthenium(I), which reacts with water to give a hydride involved in the formation of the complex with CO_2.

The influence of bipyridyl and 1,10-phenanthroline on the photocatalytic behaviour of M^{2+} ions (Ru, Fe, Co, Cr) on the ultraviolet irradiation (254 nm) of the CO_2-H_2O system has been studied.[238] MeOH and H_2CO are formed in the presence of Fe, Co, and Cr ions. The formaldehyde obtained can be further reduced to MeOH and CH_4.

CO_2 has been reduced to CO in visible light in the presence of $(bipy)Re(CO)_3Cl$ in NTE–DMF solution.[239] Depending on the amine, the photocatalytic system is capable of up to 50 cycles. An attempt has been made to use the photochemical reaction

$$Na_2Ru_3(CO)_{11} \xrightarrow{h\nu} Ru(CO)_5$$

to close the catalytic chain in the production of CO and CO_3^{2-} from CO_2:

$$Ru(CO)_5 \xrightarrow{h\nu} Ru_3(CO)_{12} \xrightarrow{2Na^{+}} Na_2Ru_3(CO)_{11} + CO_2$$
$$\uparrow \qquad\qquad (CO;\ CO_3^{2-}) \qquad\qquad \uparrow$$

The $Ru_3(CO)_{12}$ obtained photochemically was found to be inactive, however.[240]

The ultraviolet irradiation of the CO_2-H_2O system in the presence of luminophors gives H_2CO, oxalic acid, and traces of HCO_2H.[241] H_2CO has been obtained from CO_2 in water in the presence of WO_3, Fe_2O_3, and Hg.[214,215] Formaldehyde has also been detected when CO_2 in water was irradiated with visible and ultraviolet light in the presence of molybdenum compounds.[242] H_2CO, oxalate ion, etc. are formed at room temperature and atmospheric pressure in the presence of the catalyst $TiCl_3$ deposited on a zeolite.[243] The addition of Cr^{2+}, V^{2+}, and Mo^{5+} ions and reducing agents in the form of Mg, Zn, and Al powders have a significant influence on the yield of the photo-reaction.

5. The radiation-catalytic reduction of CO_2 in water

Questions related to the radiolysis of small molecules have been reviewed.[244] According to the data of Getoff,[245] the main products in γ-radiolysis are radicals. In the γ-irradiation of CO_2 in the presence of Al_2O_3 and ZnO, carbon monoxide is formed,[246,247] and in the presence of titanium dioxide, the products are H_2CO, $H_2C_2O_4$, and HCO_2H.[248–250] Increase in pressure from 10 atm to 50 atm has no significant influence on the yield of H_2CO, but the yield increases in the presence of added molybdophosphates. The preliminary γ-irradiation of titanium and zirconium oxides has a significant influence on the nature of the radiation-catalytic process.[248] The radiation-chemical yield (RCY) of the reaction products also depends on the irradiation dose. Formic and oxalic acids and H_2CO have been obtained by the γ-irradiation of homogeneous aqueous solutions of molybdophosphates in a CO_2 atmosphere.[251] Their RCY is influenced by the pH of the medium, the addition of Mg and Al powders, the catalyst concentration, and the irradiation dose. The γ-irradiation of a suspension of $MgCO_3$ in water gives formic, oxalic, and glycollic acids, H_2CO, and other unidentified organic products.[252] The addition of TiO_2 to this system increases the yield of oxalic acid relative to the other products. The nature of the products formed on the γ-irradiation of various carbonates depends on the nature of the cation. Thus the yield of H_2CO in the irradiation of malachite in water is ten times than on the irradiation of Tl_2CO_3. When $MgCO_3$ in water was irradiated with X-rays, H_2CO, HCO_2H, and glycollic acid were not detected, whereas the yield of oxalate was much greater than on the irradiation of other carbonates.[252] The formation of organic products from carbonates in aqueous solutions on different forms of irradiation is of considerable importance for an understanding of questions related to the carbon cycle in nature. The reactions taking place on the γ-irradiation of carbonates provide models of the processes taking place in nature (biogeological catalysis). The minerals taking part in these processes may provide a source of carbon for organic synthesis, and may also provide catalysts for the synthesis of organic substances from inorganic compounds, in particular CO_2 and H_2O.

VI. Summary

The preparation of stable complexes of transition metals with CO_2, which represent a new class of coordination compound, has led to the development of catalytic systems in which carbon dioxide is used as a source of carbon for organic synthesis. This in turn has led to the appearance and development of electrocatalytic, photocatalytic, and radiation-cataiytic methods for the fixation of carbon dioxide. The interest in the problem of CO_2 fixation is due to the role played by carbon dioxide as an inexhaustible source of carbon for the production of fuel and foodstuffs. The results of the studies examined in the present review indicate an increasing interest in this problem from specialists in coordination chemistry, catalysis, electrocatalysis, photocatalysis, bioinorganic chemistry, etc. The solution of the problems of the fixation of carbon dioxide and its use to obtain organic compounds undoubtedly depends to a large extent on the development of combined physicochemical methods for the activation of the CO_2 molecule.

Control of the efficiency, selectivity, and capacity in single-column capillary gas chromatography

M Kh Lunskii
All Union Geological Exploration and Petroleum Scientific Research Institute, Moscow

ABSTRACT. The present review examines published data on a key problem related to the control over wide limits of the efficiency of separation of the components of complex mixtures in single-column capillary gas chromatography and the selectivity and capacity of the capillary columns. Methods of varying these important parameters of the gas-chromatographic experiment, based on the selection of capillary columns of different types and changes in the conditions of the experiment, have been examined in relation to one another and to their influence on the operational characteristics of the capillary columns and the analysis time. The advantages, disadvantages, and ranges of application of different methods for varying the parameters of efficiency, selectivity, and capacity have been noted, and methods for their further improvement in capillary gas chromatography have been indicated.

The bibliography contains 291 references.

I. Introduction

Capillary gas chromatography (CGC) has found extensive application primarily as a method for analysing multicomponent mixtures. In recent years this method has been used to study complex mixtures containing hundreds or thousands of components belonging to different classes of chemical compound, whose boiling points sometimes differ by hundreds of degrees.[1–21] The analysis of these mixtures is often complicated by the fact that the concentration of the components to be determined varies over extremely wide limits from micro-quantities to several tens percent.[1–6,9–13,16]

In relation to these characteristics of the specimens being analysed, it is possible to distinguish three main groups of problem encountered at the present stage of development of CGC.

The first group of problems is related to the resolving power of the columns, the reliability of the results of the analysis, and the sensitivity of the method, and solutions are sought by improving the efficiency, selectivity, and capacity, and also by using highly sensitive detectors and by improving the methods used to introduce the specimens into the chromatograph.[1–8,12,14,16,20–46] The problems of the second group are associated with the identification of a wide range of components, many of which are present in extremely low concentrations.[7,8,12,15,16,35,45,47–49] The solution of the problems of these two groups is inseparable from problems associated with the improvement and the development of new methods for the treatment of chromatographic information, making it possible to increase both the reliability of the identification of the components and their quantitative determination and also the amount of detail in the data on composition obtained.[17–19,50–54] The third group of problems is related to the development and application of multi-column gas-chromatographic systems which make it possible to decrease the total time taken for determinations without decreasing the reliability and amount of detail in the information obtained.[7–13,16,18,55–66] In a number of cases the use of these systems makes it possible to increase considerably the sensitivity of the determination of micro-quantities by using large specimen volumes.[11–13,62]

The present review examines the problems of increasing the efficiency of separation in single-column CGC and the selectivity and capacity of the capillary columns (CC). In fact, the problem reduces not to the optimisation of each of these characteristics but to the optimisation of the separation factor R_s. In many cases, the requirements relating to the individual parameters may contradict one another, that is the improvement of one characteristic may lead to a simultaneous deterioration in another. To simplify the systematisation, however, it is appropriate to examine the optimisation of each of these characteristics separately.

II. The efficiency of separation in single-column capillary gas chromatography and methods for increasing it

Capillary gas chromatography originated with Golay's discovery in 1956–1957 of open CC whose internal surface was covered with a layer of a stationary liquid phase (SLP).[1,3,6,35,67–69] This discovery marked a qualitatively new giant step towards a sharp increase in the efficiency of gas-chromatographic separations in general. The very first studies, carried out using mainly metal, plastic, and glass CC with an internal diameter d_c = 0.2–0.5 mm, demonstrated the extensive possibilities provided by CGC as a result of the high permeability of the CC and their high specific efficiency.[1,3,6,35,67–71] The use of even very long CC (100 m or more) removes the need to use extremely high inlet pressures, and in practice this makes it possible to achieve a very high efficiency of separation, reaching 1 million theoretical plates (t.p.) or more.[1,3,6,35,67–71] The unique possibilities provided by CGC as a powerful method for the fine separation of complex mixtures are demonstrated particularly clearly by the chromatogram obtained for petrol, with 378 separate peaks,

obtained on a CC (300 m × 0.5 mm) containing squalane.[14,15] Only 17 of these peaks belong to unidentified components. This chromatogram is the most complete chromatogram for petrol known at present.

1. Methods for increasing the efficiency of separation based on the use of capillary columns of different types

a. Treatment of the internal surface of glass CC

In the initial stages of the development of CGC, the specific efficiency of CC was 1000–2000 t.p. m^{-1}.[1,3,6,67–71] The development of various methods for the preliminary treatment of the internal surface of glass CC (deactivation, treatment with surface-active substances, chemical modification, the production of a rough surface, the creation of an intermediate layer of polymeric materials, carbon, salts, etc.)[1–3,6,21,35,68,72–89] made it possible to increase the specific efficiency of glass CC to 3000–4000 t.p. m^{-1}. This was related to the production, by both static and dynamic deposition, of a stable and uniform film of SLP and to the decrease in the adsorption and catalytic activity of the internal surface of the CC with respect to extremely polar compounds.[1,3,6,21,35,68,69,72–86,88,90] CGC on glass CC became an extremely effective method for separating the components of tobacco smoke,[1,3,91] mixtures of various aminoacids and their enantiomers,[1,4,75,92] aliphatic acids,[1,88,91] alcohols,[75,91] esters,[6,88] amines,[75] steroids,[1,3,4,77,88] the components responsible for the odour and taste of various food products and wines,[1,3,4,49,85,88,93] mixtures of pesticides,[1,3,35,85,88] various derivatives of saccharides,[1,88] and other complex mixtures.[1,3,4,6,35,49,68,69,74–80, 85,88,90–94] The increased possibilities provided by CGC are clearly confirmed by the chromatogram for a middle fraction of cigarette smoke, containing more than 3000 components of different chemical character (hydrocarbons, acids, bases, polyalcohols, ketones, etc.), recorded as 1000 peaks; this chromatogram was obtained on a glass CC (145 m × 0.32 mm) containing Emulphor ON 870 with linear temperature programming (1 °C min^{-1} in the range 25–190 °C).[91] The reliable identification of the components of such a complex mixture obviously requires a complex approach using several columns and detectors with different selectivities.[7,8,12,13,16,35,91]

The extensive application of glass CC was facilitated by such factors as the possibility of preparing glass capillaries with a clean internal surface under laboratory conditions and by the ease of visual control of the deposition of SLP films. Other important factors in the application of glass CC at high temperatures include the possibility of observing the stability of the SLP film and the ease of determining the section in which the macromolecular compounds present in the specimens being analysed are deposited irreversibly. Nevertheless, the range of application of glass CC is restricted, because of the residual adsorption activity of the surface with respect to a whole series of chemical compounds, determined to a large extent by the type of glass and the method of treatment; moreover, the mechanical strength of glass CC is too low.[1,3,6,74,75]

b. The use of quartz CC

A new and promising direction in the development of CGC is associated with the use of flexible CC of fused quartz, having d_c = 0.05–0.32 mm and a wall thickness of 40–70 μm.[20,27,28,34,35,39,40, 68,86,95–109] These CC have a high mechanical bending strength, which together with the low adsorption and catalytic activity of their internal surface has led in recent years to the extensive replacement of glass by quartz CC.[20,27,28,34,35,86,95–110] The specific efficiency of columns of this kind with an internal diameter d_c = 0.2 mm approaches 5500 t.p. m^{-1},[109,110] and they can be used to analyse mixtures containing strongly polar and readily adsorbed compounds: polyaromatic hydrocarbons (PAH),[4,100,107–110] alcohols,[27,28,103,109] phenols,[97,109] acids,[97,98,103,109] esters,[27,28,97,98,103,109] anilines, amines, and nitro-compounds,[97,109] pyridines and quinolines,[100,103] peptides and other substances present in biological specimens,[4,111] the components of medicinal products,[28,107] the components responsible for the taste and odour of foodstuffs† and cosmetic materials,[27,28] and many other compounds.[4,105,106,111] Because of their low catalytic activity, quartz CC are used successfully to separate various labile compounds.[97,105,111]

c. The efficiency of separation on CC with a small diameter

In CGC, increasing use is being made of CC with a small internal diameter (d_c = 0.035–0.1 mm).[6,96,104,112,113] It has been shown[104] that the height equivalent to a theoretical plate (HETP), measured for n-pentadecane on a 10-metre quartz CC (d_c = 0.1 mm) containing phenylmethylsiloxane at a medium linear carrier-gas velocity corresponding to the minimum of the Van Deemter curve, is 0.105 mm, which is only 1.08 times the height 0.097 mm calculated from the equation

$$H_{\min} = \frac{d_c}{2}\sqrt{\frac{1 + 6k' + 11(k')^2}{3(1 + k')^2}} \qquad (1)$$

for the theoretical minimum value of the HETP[32,114] [the capacity (extraction) coefficient k' for an SLP film thickness d_f = 0.17 μm and a CC temperature t_{CC} = 143 °C is 6.5]. For a 70-metre CC with d_c = 0.05 mm, the HETP was 0.066 mm.[96]

Short CC of small diameter with a high specific efficiency are characterised by a displacement of the minimum of the Van Deemter curve to high linear carrier-gas velocities (50–70 cm s^{-1}), which, together with the small quantity of SLP in these columns creates a realistic basis for increasing considerably the speed of analysis and the sensitivity of determinations.[6,96,104,112,115] For rapid separation it is appropriate to use hydrogen as the carrier gas.[116] In high-speed CGC using open tubular CC, the record time is 2 s, achieved in the separation of 15 components on a CC (1.2 m × 0.035 mm) with an efficiency of 7000 t.p.[115] It has been suggested that it should be possible to develop a high-speed analyser using a CC with a length of several centimetres and a diameter of 1 μm.[117] In addition to the high speed of analysis, specific efficiency, and sensitivity of the determinations, an undoubted advantage of CC with a small diameter is the low loss of SLP, ensuring stability of operation over a long time.[96,113] The low noise level makes it possible to use CC of small diameter for high-temperature analyses and the determination of traces of substances.[113] Nevertheless, the use of CC of small diameter involves difficulties associated with their low sorptive capacity, so that the size of the specimen calculated for one component is only 0.02–1 ng for a CC with d_c = 0.05 mm,[112] and ~8 ng for CC with d_c = 0.1 mm,[104] and also with the severe requirements to be satisfied by the inertia of the recording apparatus. The limitations associated with the need for a high inlet pressure can be overcome by creating a vacuum at the outlet from the CC, and this in turn favours the use of a mass spectrometer as detector.[104]

† T Aishima, Y Ozawa *Chromatographia*, 1989, **28** 405

The extensive application of CC of small diameter is also prevented at present by difficulties associated with the deposition of viscous high-temperature SLP. This also applies to some extent to CC with a diameter d_c = 0.1–0.25 mm. Static methods for preparing CC using traditional solvents with the boiling points of n-pentane (b.p. = 36.07 °C) and above do not always give CC with high specific efficiency and reproducible values of other gas-chromatographic parameters. This is largely due to the need to use relatively high pressures to fill the CC with the solution of the SLP in the appropriate solvent and special methods for subsequently making the ends of the CC air-tight, which do not always eliminate completely the formation of bubbles of gas and solvent vapour.[1,3,88] Of particular interest is a recently described‡ new method for the static deposition of non-polar and weakly polar SLP on the walls of CC whose internal diameter, according to the authors cited, may be smaller than 0.1 mm. Characteristic features of this method are the use of n-butane (b.p. = –0.5 °C) as solvent for the SLP, and the method used to make one of the ends of the CC air-tight by freezing the solution of the SLP in n-butane with liquid nitrogen in a closed vessel, into which gas nitrogen can be passed at a pressure of 2 atm. This method eliminates completely the formation of gas bubbles at the boundary between the liquid and solid solutions. The solvent (n-butane) is removed from the CC at room temperature and atmospheric pressure. The method developed makes it possible in practically 100% of cases to obtain CC with specified properties with a simultaneous decrease in the time taken for their preparation compared with traditional static methods. In particular, the time taken to prepare a quartz CC (25 m × 0.25 mm) at 30 °C is not more than 5 h, and this is reduced considerably (to tens of minutes) on going to CC with a smaller diameter. Other advantages of the new method for preparing CC can be seen from Table 1, which gives the gas-chromatographic parameters of quartz CC with different geometric characteristics (length L and internal diameter d_c) and different SLP. Table 1 shows, in particular, that the specific efficiency of quartz CC of small diameter (d_c = 0.10 mm), measured from the peak of n-tridecane, is close to 10000 t.p. m^{-1}. The new static method for preparing CC of any diameter should lead to their wider application in gas chromatography.

Table 1. Characteristics of various quartz capillary columns prepared by a new static method.

L, m	d_c, mm	SLP	t, °C	k' (measured from n-C_{13})	n, t.p. m^{-1} (measured from n-C_{13})	Efficiency of deposition, %

d. The influence of the SLP film thickness on the efficiency of separation

Decrease in the thickness d_f of the SLP film in CC makes it possible not only to decrease the analysis time and lower the analysis temperature but also to increase the efficiency of separation by decreasing the contribution of the intra-diffusion resistance and the resistance to mass exchange at the interphase boundaries. This follows directly from the Kahn equation for the HETP in open CC, which, unlike the familiar Golay equation, takes account of the resistance to mass transfer at the interphase boundaries:[3,6,118,119]

$$H = \frac{2D_g}{\bar{u}} + \frac{1 + 6k' + 11(k')^2}{24(1 + k')^2}\frac{\bar{u}d_c^2}{4D_g} + \frac{2k'}{3(1 + k')^2}\frac{d_f^2\bar{u}}{D_l} + \frac{2k'd_f}{(1 + k')^2 k_d} \quad (2)$$

Here, $\bar{u}$ is the average linear velocity of the carrier gas, D_g and D_l the coefficients of molecular diffusion of the sorbate molecules in the gas and liquid phases respectively; and k_d the rate constant of the desorption of the substance from the surface. The first term of this equation describes the contribution to the flattening of the chromatographic band made by the longitudinal diffusion of the sorbate molecules in the gas phase, the second term characterises the contribution of dynamic diffusion, and the third and fourth terms, which contain the quantity d_f, give respectively the resistance to mass transfer in the SLP film and the resistance to mass exchange at the interphase boundaries, which is equivalent to a slight deviation from the equilibrium state.

The existence of the third and fourth terms in Eqn. (2) indicates the strong dependence of the efficiency of separation on the thickness of the SLP film. The role of the film thickness increases for values of $\bar{u}$ greater than the optimum velocity u_{opt}, which corresponds to the minimum of the Van Deemter curve. Overall, however, the influence of d_f on the quality of separation of the components is much more complex, and depends on the capacity coefficient k'.[1,3,6,118,120] It should also be noted that a decrease in d_f carries the danger of overloading the CC.[104,112]

e. The efficiency of micropacked CC

Considerable advantages over open tubular CC in relation to the specific efficiency of separation, capacity, and speed of determination are shown by micropacked quartz capillary columns (MPQCC) having d_c = 0.15–0.5 mm and sorbent particle diameters of 5–100 μm.[121–127] The use of quartz CC with smooth walls simplifies considerably the filling of the column with the sorbent,[121–124,126] making it possible to achieve uniform packing of the latter. Together with the small particle size of the packing, the small internal diameter of the MPQCC, and the inertness of their internal surface, this feature ensures a high specific efficiency for the MPQCC, which for a sorbent particle diameter of 7.5 μm may reach 30000 t.p.[121–125] The high specific efficiency of MPQCC makes it possible to use short columns with typical lengths of tens of centimetres, and hence to reduce the expenditure on scarce and expensive sorbents. An important positive feature of MPQCC is the extremely weak dependence of the HETP on $\bar{u}$ at $\bar{u} > u_{opt}$,[121–123,125] particularly for a sorbent particle size less than 1 mm. This makes it possible to increase considerably the speed of the determination. The use of MPQCC, which makes it possible to miniaturise the equipment, retains all the advantages of open tubular

‡H F Yin, A J Huang, Y L Sun *Chromatographia*, 1989, **28**(5/6) 313

quartz CC, namely their flexibility, mechanical strength, and adsorption and chemical inertness.[121–126]

f. The influence of the length of the CC on the overall efficiency of separation

A radical method for increasing the overall efficiency of CC is by increasing their length. Short CC always have smaller HETP than long columns with identical properties.[116,128] This is related to the large change in the carrier-gas velocity along the length of the CC. Thus the increase in the number of theoretical plates is not directly proportional to the increase in the length of the CC. In practice, the CC used most frequently have lengths not exceeding 50 – 100 mm.[1,6,15,17–21,27–46,52–89,92–109,111–120,128,129] Further increase in the length of the CC is not appropriate, because of the increase in the total analysis time and the decrease in the sensitivity of the determinations as a result of the diffusion flattening of the chromatographic bands. Increase in the length of CC is particularly unjustified when carrying out analyses using CC with a small internal diameter (0.035 – 0.1 mm) or MPQCC, since it leads to a multiplication of the inlet pressure, makes more severe demands on the apparatus used, and also leads to a large pressure drop along the length of the CC, which in the final analysis lowers the overall specific efficiency of separation.[96,104,112,115,116,121–124,128] Moreover, the long analysis time on long CC and the need to increase the column temperature create difficulties in the study of mixtures of substances with a wide range of boiling points, non-volatile substances, and mixtures containing thermally labile and reactive compounds.[1,3,6,116,118]

g. The efficiency of CC with non-circular cross-section

In recent years there has been an increase in interest in open tubular CC with rectangular cross-section,[3,88,90,130–138] whose walls are covered with a thin film of SLP. Under certain conditions, the use of these columns leads to a marked increase in the efficiency of separation compared with CC having circular and elliptical cross-sections. This is related primarily to the significant decrease in the contribution to the HETP made by the dynamic dispersion due to the non-uniform distribution of the carrier-gas velocities over the cross-section of an open CC in a laminary stream. These theoretical postulates[132–138] were confirmed experimentally by comparing the efficiencies of CC having cross-sections with different shapes but identical areas.[133,135,137] In particular, it was shown[136,137] that the efficiency of CC having cross-sections with different shapes depends on the capacity coefficient k' and on the ratio of the sides a and b of the rectangular cross-section. Thus the efficiency of a rectangular CC increases rapidly with increase in a/b and becomes greater than the efficiency of a cylindrical CC at $a/b > 3.5$ (if $k' = 0$) and $a/b > 2$ (if $k' = 2$). The study of the influence on the efficiency of separation of a change in the cross-sectional area of a CC along its length is also of considerable and theoretical and practical interest.[132]

2. Methods for increasing the efficiency of separation based on a change in the parameters of the gas-chromatographic experiment

The main disadvantage of all the above methods for increasing the efficiency in single-column gas-chromatographic systems is the need to replace the CC, which is inconvenient.

a. The influence of the nature of the carrier gas, its average linear velocity, and the average pressure on the efficiency of separation

Among the methods for increasing the efficiency of separation without replacing the CC, mention must be made of readily accessible methods involving a change in the nature of carrier gas, its average linear velocity, and the average pressure.[1,3,6,115,118,119] The first two methods make it possible to change the efficiency of separation only over a narrow range, particularly at $\bar{u} > u_{opt}$.[118,119] An increase in the average pressure of the carrier gas from 1 atom to 10 atm, however, decreases H_{min} by 55% with a simultaneous displacement of the minimum of the Van Deemter curve to low linear velocities,[115] leading to an increase in the analysis time. The use of high pressure also creates experimental difficulties, and all these features make this method inefficient.

b. The use of gaseous mobile phases

An interesting method for increasing the efficiency of separation involves the use in the CC of gaseous mobile phases containing volatile polar substances.[3,6,16,122,139–144] A high efficiency of separation by this method was first achieved using water vapour.[3,140] Water vapour as a modifying additive was subsequently used successfully in a number of other studies.[141,144] Suppression of the adsorption activity of the walls of the CC, leading to the production of symmetrical peaks and an increase in the efficiency of separation of the components, can also be achieved by the constant supply of the vapours of other polar substances such as ammonia,[139] formamide,[143] formic acid,[143] and other compounds which, like water, give practically no signal when the most widely encountered flame-ionisation detector (FID) is used. The addition of these compounds to the carrier gas, which leads to a decrease in the part played by both the reversible and the irreversible adsorption of the compounds, also makes it possible to increase considerably the reliability of the quantitative analysis of the mixtures studied and the reproducibility of the retention parameters of their components.[122]

c. The influence of the method of introducing the specimen, and extra-column effects, on the efficiency of separation

The efficiency of separation in CGC depends to a marked extent on the method of introducing the specimen into the chromatograph.[1–3,6,22–24,27–32,35,36,38,88,93,144,146] To achieve the maximum efficiency of the CC it is necessary to eliminate or reduce to a minimum the unfavourable consequences of various extra-column effects leading to additional spreading of the specimen in the volatiliser of the chromatograph and its connections in front of the CC.[1,3,6,22,29,36,38,88,145,146] It is also important to eliminate overloading of the CC with the components of the specimen, which unavoidably leads to a decrease in the efficiency of separation.[1,3,6,22,23,29,88,104,112,118,119] These requirements are satisfied to a significant extent by the following methods of introducing the specimen: 1, a method based on splitting the stream of carrier gas at a volatiliser temperature equal to or greater than the boiling point of the least volatile component of the specimen;[1,3,6,23,88,104,112] 2, a method based on the so-called "solvent effect";[1,93,145,146] and 3, various modifications of a method involving the cryogenic focussing of the components in the initial section of the CC.[3,25,26,28,35–38,147–152] A high efficiency of separation is also obtained using various versions of the method of cold introduction of the specimen into the CC.[31,32,153] Promising possibilities are

provided by the recently employed method of introducing a liquid specimen with temperature programming of the injector,[29–33] which combines the advantages of the methods involving splitting of the stream of carrier gas and cold introduction.

The use of low-inertia ionisation detectors and mass spectrometers,[3,12,17,21,68,69,118,119,153] and the improvements of methods for combining them with CC[3,21,36] eliminate practically completely the loss of efficiency of separation at the outlet from the CC.[3,12,36,68,118,119,153]

Methods for introducing the specimen also have to satisfy high requirements in relation to the reliability of quantitative analysis,[1,3,23,29,31–34,37,38,113,129,149,150,153,154] the high sensitivity of determinations,[1,3,6,23,28,30,33,35,37,129,145–148,151,152,155] and the high stability of operation of the CC over a long period.[23,32]

III. The influence of various factors on the selectivity and capacity of capillary columns

High efficiency is a necessary but not a sufficient condition for the qualitative separation of components with similar physicochemical properties. This can be seen from the fundamental equation of Purnell.[1,120,122]

$$R_s = \frac{\sqrt{n}}{4}\,\frac{\alpha-1}{\alpha}\,\frac{k'}{k'+1}, \qquad (3)$$

which establishes the relationship between the separation criterion§ R_s,[1,6,119,122] characterising the completeness of the separation of two components, and not only the kinetic parameter (the number of t.p. n, measured from the second component) but also the equilibrium parameters of the chromatographic process—the selectivity coefficient α[1,16,122,] and the capacity coefficient k',[1,88,122] calculated from the second component.

The selectivity coefficient $\alpha \geqslant 1$, which is the ratio of the reduced¶ retention times (volumes) of two components being separated,[1,3,16,88,122] is determined by the partial pressures p_1^0 and p_2^0 of the vapours of these components and their activity coefficients γ_1 and γ_2 in solution in the SLP used:[16,35,156]

$$\alpha = \frac{p_1^0}{p_2^0}\,\frac{\gamma_1}{\gamma_2}, \qquad (4)$$

The quantity α is also called the "separation coefficient"[3,88] or the "separation factor".[1]

The capacity coefficient k' depends on the distribution constant K_L of the component between the liquid and gas phases and the ratio of their volumes $\beta = V_G/V_L$:[1,3,6,118]

$$k' = K_L/\beta. \qquad (5)$$

The quantity k' is sometimes called the "extraction coefficient"[1,3,88,118,122] or the "distribution ratio".[3] This is related to the fact that the capacity coefficient k' is a measure of the time for which the molecule of a given component is in the stationary phase relative to the time t_0 for which it is in the gas phase [$k' = (t_R - t_0)/t_0 = t'_R/t_0$]. In other words, k' is the ratio of the capacities of the stationary and mobile phases.

Analysis of the simple relationships (4) and (5) indicates several possible ways of controlling the selectivity and capacity in gas-chromatographic systems with one CC in the analysis of complex mixtures containing pairs and groups of components which are difficult to separate.

All known methods for controlling the selectivity and capacity in these systems can be divided into two main groups. The first is not associated with replacement of the CC,[1,3,16,35,118,119,122] while the second provides for replacement of the CC.[1,3,7,8,16] The factors influencing the selectivity of the separation of the components also influence the capacity coefficient k'. The converse does not always apply, since with change in the geometric parameters of the CC (L, d_c, d_f), the separation factor α may remain unchanged if the part played by adsorption effects at the phase interfaces in the system is negligible.[122]

1. Methods for controlling the selectivity and capacity parameters without replacing the capillary column

a. Changing the temperature conditions of the analyses

The simplest and most readily available method of varying the selectivity and capacity over wide limits is by changing the temperature conditions of the gas-chromatographic process.[1,3,15–19,21–35,87,118,119] In the analysis of complex mixtures consisting of chemical compounds of different classes, characterised by different temperature dependences of the retention parameters, however, this method is not always effective, since an improvement in the degree of separation of some pairs of compounds may be accompanied by a deterioration in the degree of separation of other pairs.[1,17–19,158] In a number of cases, a change in the temperature of the CC also changes the order of elution of compounds differing in the type and number of functional groups and the molecular framework.[1,17–19,158]

Changing the working temperature of the CC not only influences the selectivity and capacity but also opens up additional possibilities for the group identification of the components of complex mixtures, since the temperature coefficient of the retention index dI/dt depends on the structure of the molecule and the class of compound to which the component being identified belongs.[1,15,16,17–19,47,48,157–169]

Decrease in the temperature of the CC ensures a definite gain in selectivity in the separation of compounds with similar values of dI/dt. With decrease in temperature, in accordance with Eqn. (5), there is a simultaneous increase in the extraction coefficient k' according to a law close to exponential, and this unavoidably leads to a sharp increase in the analysis time.[1,118,119] For this reason, the analysis of mixtures of compounds belonging to the same homologous series and having appreciably different boiling points is carried out with temperature programming of the CC, which makes it possible not only to decrease sharply the separation time but also to increase considerably the sensitivity of the determinations.[1,3–6,15,21,44,53,87,98,108,118,119,157,168,170,171] Temperature programming also has some unfavourable consequences, associated primarily with the unsatisfactory reproducibility of the retention parameters used to identify the components,[6,15,47,48,116,172] possible decomposition of the substances being analysed, deterioration in the stability of the operation of the CC under the influence of the brief

§The quantity R_s is sometimes called the "resolution"[88] or the "degree of separation".[3,35,157]

¶As in the works cited,[6,16,157] the reduced quantities are the equilibrium characteristics of the gas-chromatographic process, calculated using the quantities obtained by subtracting from the gas-chromatographic retention time t_R the retention time t_0 of a non-sorbed component.

application of high temperatures,[1,6,8,118] and the incomplete utilisation of the potential efficiency of the CC.[1]

b. The influence of the composition and pressure of the carrier gas

In some cases the selectivity and capacity of CC can be controlled effectively by varying the composition of the carrier gas by adding to it various volatile readily adsorbed polar substances.[3,16,122,141] These substances dissolve selectively in the SLP and are adsorbed on various active centres of the CC, changing its capacity and selectivity with respect to both polar and non-polar compounds.[3,16,122,141]

The range of change in the selectivity and capacity of CC with change in the composition of the mobile phase can be increased considerably by altering the pressure of the mobile phase. Increase in pressure leads to an increased influence of the non-ideality of the gas phase on the solubility of the components in the SLP and on the retention characteristics.[16,142,173,174] Thus this method makes it possible to vary the selectivity and capacity of CC over wide limits, by controlling the pressure in the CC and the composition of both the mobile and the stationary phase. This is achieved by using vapour–gas mixtures under conditions in which the stationary phase is capable of sorbing the vapour strongly.

The use of gaseous mobile phases with modifying polar additives increases not only the selectivity and capacity of the CC but also, as noted above, the efficiency of separation and the reliability of the qualitative and quantitative analysis of complex mixtures.[3,6,16,35,122,139–144] An important factor is the increase in the sensitivity of the determination with a simultaneous decrease in the analysis time as a result of a decrease in the contribution of adsorption retention centres to the total retention of the sorbates[122] and an increase in the carrier-gas velocity.

An increase in the selectivity with change in the pressure of the carrier gas in CC is achieved even without adding polar additives to the carrier gas. This is particularly characteristic of argon and carbon dioxide, which are appreciably non-ideal at increased pressures.[16,141,142,173,175] This method of varying the selectivity of CC is also of interest for the group identification of components, since the value of $dI/d\bar{p}$, characterising the dependence of the retention index I on the average pressure $\bar{p}$ in the CC, is specific for definite groups of compound and is related to the value of the second virial coefficient in the equation of state of the vapour.[1,173,175] A study of the retention of various aromatic sorbates from benzene to 1,2,3,4-tetramethylbenzene (a total of 31 compounds) on CC with an efficiency of 150–200 thousand t.p. with polyethylene glycol 400 at 80 °C showed that in this series the value of $dI/d\bar{p}$, changes in the range 1.0–1.5 index units per atom[173] (the range of change in the pressure of Ar and CO_2 was 1.2–30 atm).

c. A method for continuously changing the selectivity and capacity

An interesting method for gradually changing the selectivity and capacity is based on the continuous removal from the CC of a volatile component of a binary SLP under isothermal conditions.[7,174] The possibilities provided by the method have been examined for the case of an analysis of petrol on a CC filled with a mixture of FS-16 fluorinated silicone and octadec-1-ene, which is gradually removed at 60 °C.[174] When both components of the binary SLP used are non-volatile at the working temperature, the CC is heated between analyses to remove a definite quantity of one of the phases. This method makes it possible, by examining the set of chromatograms, to establish the regularities of the change in the order of elution of the components of a complex mixture on going from one phase to another and on this basis to compile a binary (two-dimensional) spectrum of the signals relating to each component of the mixture. The method is restricted to a relatively narrow range of control of the selectivity and capacity of the CC, determined by the characteristics of the binary SLP used and its less volatile component, and also by the inadequate reproducibility of the retention parameters.

d. The use of an electric field

An extremely promising method of controlling the selectivity of liquid-crystalline SLP is by applying an electric field.[176] The method makes it possible, by changing the modulus and direction of the electric field intensity vector, to vary over a wide range not only the selectivity of the CC but also its capacity, and even to achieve the complete retention of some components. After the removal of the electric field, the compounds retained in the CC are rapidly eluted with a stream of carrier gas. In this way it is possible to achieve the complete separation of substances showing only extremely small differences in their molecular structures.[35,176] The method is restricted by the need to use liquid-crystalline SLP.

2. Methods for improving the selectivity and capacity by selecting capillary columns with different properties

General advantages of all the above methods for controlling the selectivity and capacity of CC are their simplicity and the possibility of achieving fairly smooth control of these important parameters.[16] Nevertheless, the impossibility in a number of cases of achieving the selectivity and capacity parameters required for the separation of all the components of complex mixtures of organic compounds, and the insufficient reproducibility of the retention characteristics, make it necessary in single-column gas-chromatographic systems to use a succession of several CC with different sorbents and SLP.[6–8,16,18,19,21,47,48,157,177] The possibilities provided by this approach have increased significantly in recent years as a result of the introduction into gas-chromatographic practice of different types of CC,[1,3,6,35,42,68,74,75,86,88,95–108,113,121–125,178–194] and also such SLP as nematic liquid crystals, showing a high selectivity with respect to many pairs of components difficult to separate,[7,35,39–41,66,89,195,196] and chemically grafted,[42,80,88,113,191,192,194,198] immobilised (transverse cross-linked),[35,42,68,102,105,107–109,171,194,197–205] mixed,[86,206,207] and colloidal[122,208,209] SLP.

The successive use of CC with different sorbents and SLP makes it possible to carry out separations using different types of intermolecular interaction, and on this basis to obtain a many-element chromatographic spectrum characterising the retention of the individual components of the complex mixture being analysed on the CC used.[7,8,16,18,19,48,177] To increase the reliability of the identification of the components and decrease the volume of excess information, it is desirable that the elements of the spectrum be as far as possible mutually independent.[7,8,16,18,19,48,177] It is therefore appropriate to reduce to a minimum the number of CC used, in which there is a predominance of definite types of interaction giving a selective separation and the required operational characteristics of the CC, the most important of which are the upper temperature limit (UTL) at which the SLP can be used, the efficiency and capacity of the CC, the stability of its operation over a long period, and the possibility of combining the CC with selective detectors.[1,3,6–8,12,35,46,68,107,113]

The change in the order of separation of components belonging to different classes of organic compound with change in the temperature of the CC and the polarity of the SLP has been successfully used[17–19,177] to identify the components and increase the amount of detail in the information obtained on the composition of complex natural mixtures of hydrocarbons. A method has been proposed[17–19,177] for the treatment of chromatographic data based on the combination of the results of the quantitative analysis of the compounds, determined at different temperatures on one CC, and also on different CC with different selectivities with respect to the same pairs of compound. The applicability of the method, which makes it possible to obtain information on the separate concentrations of components which do not give independent peaks, has been examined for the case of the analysis of specimens with markedly different quantitative compositions, namely broad petrol fractions from low-boiling to 150 °C and unfractionated petroleums and condensates, on relative short 50-metre CC containing squalane[17,18,56] and dinonyl phthalate.[18,19,177] The use of a method for the treatment of chromatograms to give detailed information on the composition of complex specimens identified approximately 200 C_1-C_9 hydrocarbons, and 17 [177] groups of hydrocarbons remained unseparated, whereas on CC with squalane and dinonyl phthalate the number of these groups was 46 and 40 respectively. From the increase in the amount of detail in the information on the composition, the combination of the results of quantitative analysis obtained under different gas-chromatographic conditions is equivalent to the use of long CC at low temperatures. This unavoidably leads, however, to a multiple increase in the analysis time and to a considerable decrease in the sensitivity of the determinations. In the works cited,[17–19,177] the results of the quantitative analysis of complex organic mixtures were used for the first time in gas chromatography to identify their components.

a. The production of a highly developed internal surface in CC

Various methods have been described for preparing CC with a high sorptive capacity. The nineteen-sixties saw the beginning of the intensive development of methods for the treatment of the internal surface of glass CC by etching it and giving it different types of roughness,[1,3,6,35,68,73,77,80,81,84,88,186,210] and also by forming on it thin layers of crystals of different substances[1,3,6,68,73,80,83,211] and whiskers.[1,6,68,73,76,81,84] The surface obtained in this way is readily wetted by a thick layer of both polar and non-polar SLP. Despite the high stability of the CC obtained,[1,83] they have a low efficiency, since the porous layer formed by etching has an extremely strong adsorbing power,[1,6,77,88] leading to the production of unsymmetrical chromatographic zones. Salt crystals formed on the internal surface of CC are also unstable to water vapour.[6,212] These features restrict considerably the application of glass CC with a highly developed surface in gas–liquid chromatography, and in a number of cases it is necessary to carry out subsequent operations to deactivate the surface.[1,3,6,88] These CC are fully applicable, however, in gas-adsorption chromatography.[6,77,88]

b. Columns with a porous layer of sorbent

The disadvantage of CC with a highly developed surface, noted above, led to the development of open capillary columns (OCC) containing a porous layer of sorbent on the internal surface. Theoretically, these columns should be free from one of the main disadvantages of OCC (WCOT) with a thin layer of SLP deposited directly on a smooth internal surface, namely the large ratio β of the volumes of the mobile and stationary phases.[3,68,213] This idea was first successfully realised by the application of a static method for depositing porous layers of carriers and active adsorbents from a suspension of these materials in various solvents.[1,3,6,35,68,88,214,215] After the deposition of the porous layer, the internal surface of a metallic capillary (d_c = 0.5 mm) was increased by a factor of 130.[214,215] This led to a decrease in the value of β from 208 to 35.5 with preservation of the HETP characteristic of the original capillary covered with a uniform SLP film with a thickness $d_f \simeq 0.6$ μm. A similar method of preparing CC has been used in other studies.[1,3,88,179] In addition to the static method, use is also made of a dynamic method, which is more suitable for glass CC.[1,3,6,88,216]

Two main types of OCC can be distinguished, depending on the nature of the porous material used: with a porous layer (OCC-PL, or SCOT) and with a solid carrier or adsorbent (OCC-SC, or PLOT).[1,6,68,73,88,113,216–222] The OCC-PL columns used in gas–liquid chromatography are prepared in two ways: a, by depositing a solid carrier previously impregnated with SLP; and b, by the preliminary deposition of a carrier and its subsequent impregnation with the SLP. The thickness of the porous layer in CC of this type is 1–5 μm.[88] In contrast to OCC-PL columns, OCC-SC columns with internal walls carrying a porous layer with a thickness of 10 μm or more, deposited or obtained by chemical methods, are most frequently used in gas-adsorption chromatography.[1,3,6,88,113,215,222] If a porous layer obtained by chemical methods is wetted with an SLP, $d_f > 1$ μm. It is often difficult to draw a line between OCC-PL columns containing an SLP and OCC columns of the WCOT type, obtained by depositing an SLP on an internal surface modified by various methods.[1,3,6,68,88]

OCC-PL columns are prepared using finely divided diatomite carriers,[1,3,6,88,179,214,216] or a mixture of celite with LiCl [223] or with glass.[224] The porous layers may occupy up to 42% of the transverse cross-section of the CC, leading to an increase in the quantity of SLP in the column and hence in the capacity coefficient k' by a factor of more than 100.[3,179] This makes it possible to increase considerably the volume of the specimen introduced, without the danger of overloading the CC.

The properties of OCC-PL columns are intermediate between those of ordinary packed columns and CC with an SLP deposited on the internal walls.[178] Thus in the separation of the methyl stearate–methyl oleate pair (α = 1.12) the values of R_s for a packed column (2.4 m × 2.2 mm), a column with an SLP on the internal wall (WCOT) (46 m × 0.25 mm), and an OCC-PL column (15.2 m × 0.5 mm) were 1.54, 7.06, and 4.09 respectively for analysis times of 35.6, 51.7, and 23.0 min. Increase in the carrier-gas velocity in the capillary columns to values at which R_s = 1.54, as in the case of the packed column, decreased the analysis time to 3.25 min on the OCC-PL column, and to 2.46 min on the WCOT capillary column. Short OCC-PL columns have been used extremely successfully for the rapid analysis of complex organic mixtures, where the times taken for the determination are measured in seconds and tens of seconds.[70,225,226]

OCC-PL columns, while retaining all the main advantages of ordinary packed columns (high capacity, relative short analysis time, stability of operation for a long time) and WCOT capillary columns (high efficiency of separation, possibility of achieving rapid analysis using short CC), show a high stability, durability and reproducibility of the results of qualitative and quantitative analysis.[1,3,6,88] Despite the major achievements of CGC associated with the extensive use of glass and more particularly quartz CC with the most varied

diameters, and also the use of SLP of new types, the importance of OCC-PL columns has not decreased in recent years.[5,68] This is indicated by the fact that one of the leading firms, namely Perkin–Elmer (USA), is continuing up to the present (since 1964) to produce columns of this type.[88]

OCC-SC (PLOT) columns, used in gas-adsorption CGC, have a fairly high capacity and selectivity even in the analysis of low-boiling substances with extremely similar physicochemical properties.[3,5,35,113,180–190,222,227–229] They are therefore widely used to separate isotopes and spin isomers of hydrogen.[227,228] The extensive possibilities provided by capillary gas-adsorption chromatography are indicated, in particular, by the separation at 190 °C of six isotopically substituted methanes on a glass CC (47 m × 0.2 mm) treated with sodium hydroxide.[190] A mixture of gases (He, Ne, Ar, O_2, N_2, and CH_4) was completely separated in 10 min using a 25-metre CC containing as porous layer a thin film of molecular sieves (5 Å).[229] OCC-SC columns have also been used for the successful separation of multicomponent mixtures of hydrocarbons (including C_9), present in natural gases,[3,5,35,113,180,229] and also higher-boiling compounds.[35,181–186,222] In particular, an OCC-SC column (50 m × 0.32 mm) containing as sorbent a mixture of Al_2O_3 and KCl has been used for the successful separation of hydrocarbons up to n-C_{10} and some of their halogen derivatives.[222]

The undoubted advantages of high-capacity OCC-SC columns, namely their high stability, practically unlimited thermal stability, the absence of complications associated with the volatilisation and degradation of SLP, and the fairly high separating power, guarantee a promising future for columns of this type. New methods for preparing OCC-SC columns have much in common with the methods used to prepare OCC-PL columns.[88] CC with high-capacity porous layers with a thickness of 100 μm or more are most frequently prepared by drawing capillaries from tubes containing the adsorbent or carrier.[1,3,88]

c. CC containing colloidal SLP

CC containing colloidal SLP can also be regarded as a form of OCC-SC.[6,84,122,208,209,230–235] Columns of this type are obtained by depositing under static and dynamic conditions a previously stabilised suspension of micro-particles of an active adsorbent with dimensions of $10^{-5}-10^{-7}$ cm in a solution of an SLP which acts as the dispersion medium.[6] Various inorganic substances are used as dispersion phases, including silanised silicas (Silanox),[6,84,230–232,235] highly dispersed silica adsorbents (Aerosil),[208,209] carbon blacks, and zeolites.[3,6,88,122,236,237] The advantages of CC containing colloidal SLP include the possibility of varying their selectivity over a wide range (from the selectivity of the pure SLP forming the dispersion medium to the selectivity of the active adsorbent used as the dispersion phase), the much higher thermal stability of colloidal SLP compared with ordinary SLP, and the universal nature of these columns.[209] Moreover, the use of colloids ensures a higher reproducibility of the adsorption properties of the sorbent compared with SLP modified by small quantities of additives, since in the colloidal deposition, the particles of the dispersion phase are covered with a macro-layer of the SLP.[122] This achieves reproducibility of the retention parameters of the sorbates. While having the same efficiency, CC with colloidal SLP, as a result of their high sorptive capacity, show better separating power than columns on which the stationary phase is deposited from the individual liquid.[208,237]

d. CC with a thick layer of SLP

There is a simple relationship between the extraction coefficient k' and the thickness d_f of the SLP film in WCOT capillary columns; from Eqn. (5) it follows that

$$k' = 4K_L d_f/d_c. \qquad (6)$$

Eqn. (6) indicates one of the most radical methods of increasing the sorptive capacity of these CC, namely by increasing the thickness of the SLP film uniformly deposited on their internal surface. This method became possible as a result of: 1, the introduction into CGC of flexible quartz CC with an internal diameter d_c = 0.32 mm and 0.53 mm, and also glass CC with d_c = 0.75 mm[42,107,113,194,238] and d_c = 0.85 mm;[239] 2, the development of effective methods for treating the internal surface of glass and quartz CC to improve its wettability, making it possible to achieve d_f = 1–8 μm;[42,192,194,197,203,205,240] and 3, the development of varied methods for preparing CC with chemically grafted and transverse cross-linked (immobilised) SLP.[35,42,68,80,88,102,105,109,191,192,194,197,203–205,240–250]

Until early 1983, the thickness of the SLP film in quartz CC with an internal diameter of 0.25 mm and 0.32 mm did not usually exceed 1 μm (as a rule d_f amounted to 0.1–0.5 μm). This made it possible to introduce into CC about 400 ng of any component of a mixture being analysed, without the danger of appreciable overloading.[194] The use of CC with thick SLP films (d_f = 1–8 μm) made it possible to increase several fold the volume of the specimens introduced and to determine the concentration of traces without lowering the efficiency of separation of the components of complex mixtures. Thus when quartz CC (50 m × 0.32 mm) with a methylsilicone immobilised SLP (d_f = 5 μm) was used, increase in the volume of a petrol specimen from 6.5 μg to 130 μg had practically no influence on the separation of the components (the splitting ratio of the stream of carrier gas was 1:10, and the specimen was introduced directly into the CC[107]). In the same work, in an analysis of the middle fraction of hydrocarbons extracted from coal, it was possible to increase the size of the specimen introduced into the CC to 758 μg. Analysis of Eqn. (3) shows that it is appropriate to use CC of large diameter (d_c = 0.53 mm), characterised by high values of k', when the specimen contains pairs of light components difficult to separate.[194] Thus to achieve a degree of separation R_s = 1.5 for a pair of components with α = 1.05 on a CC having a film thickness d_f = 1 μm (k' = 1.9), it is necessary that the number of theoretical plates (n_{req}) be 37120, whereas for a five-fold increase in d_f (k' = 9.6), n_{req} = 19356 t.p. At the same time the ratio of the phase volumes changes from 132 to 26. According to Grob and Grob,[42] an increase in d_f for elastomeric silicone SLP in quartz CC (d_c = 0.32 mm) at the optimum carrier-gas (nitrogen) velocity leads to practically no decrease in the efficiency of separation.

e. The use of immobilised SLP

CC of large diameter (d_c = 0.32, 0.53, and 0.75 mm) with immobilised SLP, operating under isothermal conditions or with temperature programming, are used for the analysis of natural,[113,194,229] petroleum, and fuel gases,[42,107] petrols,[42,194,198,238] mixtures of heavier hydrocarbons,[194,198,239] mixtures of aliphatic acids,[194] pesticides,[194] alcohols,[194] phenols,[194] amines,[201] and various medicinal products.[107,194]

Of particular interest is the use of high-capacity CC with ordinary and chemically cross-linked SLP for the analysis of mixtures of low-boiling compounds having low values of the distribution constant K_L.[42,113,192–194,198,229,238,251] This follows from an analysis of the factor $f(k') = k'/(k' + 1)$ in Eqn. (3). Thus for large values of k', when $k' \simeq k' + 1$, the function $f(k')$ approaches 1 asymptotically with increase in k', and can be regarded as a constant. At low values of k', increase in k' leads to an increase in the function $f(k')$, and hence to an increase in the separation criterion R_s.

The use of a quartz CC (50 m × 0.32 mm) with an immobilised OV-1 methylsilicone SLP (d_f = 1.5 μm) made it possible, with temperature programming, to achieve the practically complete separation of complex mixtures containing saturated, alkene, diene, and acetylene hydrocarbons, formed by the thermal and catalytic transformation of hydrocarbon raw materials.[238]

In addition to the main advantages of CC of large diameter (d_c = 0.53 mm and 0.75 mm) with thick films of immobilised SLP, namely the achievement of high values of the capacity coefficient k',[239,252–254] these columns have a number of other advantages, leading to their extensive application. These advantages are the following: 1, the possibility of introducing the specimen directly into the CC[107,113,194,254] and using other techniques for introducing the specimen without splitting the stream of carrier gas;[239,252,254] 2, the possibility of using CC with an immobilised SLP not only with a flame-ionisation detector but also with other detectors, including a katharometer, a mass spectrometer, and a detector based on Fourier transform infrared spectroscopy;[107,113,194,254] 3, the absence of any need for an additional supply of carrier gas to the detector;[239,254] 4, the possibility of setting up these CC in the thermostat of a chromatograph designed for ordinary packed columns;[107,113,254] 5, the high efficiency of separation (like that of CC of small diameter 0.2–0.25 mm);[107,113,254] 6, a high upper temperature limit for the use of SLP (300–325 °C) with minimum drift of the zero line;[193,239] 7, rapid determination (as when packed columns are used);[252–254] 8, good reproducibility of the specified properties and operational characteristics of the CC during their preparation;[194] 9, the possibility of removing from the CC by means of various solvents the non-volatile components and SLP particles which have not undergone chemical cross-linking, while preserving a high efficiency of separation;[113,194,240] 10, the resistance of the film of immobilised SLP to extraction and elution under the influence of solvents and large specimens of mixtures being analysed;[113,194,240] 11, high stability, which is preserved practically without limit;[113,194,240] 12, a significant decrease in the relative contribution of adsorption effects to the total retention of the sorbates;[254] 13, low catalytic activity, which makes it possible to analyse mixtures containing labile compounds;[239,254] 14, the higher (compared with packed columns) efficiency of CC with a thick SLP film under programmed-temperature conditions, due to the appreciably smaller transverse temperature gradient in the CC and hence the less extensive spreading of the chromatographic zones during the separation;[254] and 15, the low inertia of the heating (compared with packed columns) of CC of large diameter in temperature programming in the thermostat of the columns.[254]

Advantages 8–13 increase considerably the reliability of the identification of the components from the retention parameters. Moreover, the stability of the operation of quartz and glass CC with a thick layer of immobilised SLP under high-temperature conditions makes them particularly convenient for the determination of traces of components in complex mixtures of organic compounds, since a low background level is preserved, and, in particular, it is possible to introduce large specimens directly into a column of large diameter (d_c > 0.32 mm) with a small stream splitting ratio or without splitting of the stream of carrier gas.

A significant disadvantage of CC with thick immobilised SLP films is that their efficiency of separation is lower than that of classical open tubular WCOT capillary columns, because of the increased contribution of intra-diffusion spreading and dynamic diffusion to the spreading of the chromatographic bands.[253]

f. CC with a thin film of immobilised SLP

Chemical immobilisation of the SLP is used not only to increase the extraction coefficient k' of the components but also to increase the selectivity of separation of high-boiling polar and adsorption-active compounds, and also non-polar high-boiling isomers with extremely similar physicochemical properties.[105,108–110,200,203–205,242–250] For this purpose, use is generally made of CC with a diameter of 0.20–0.32 mm with a thin SLP film ($d \leqslant 0.5$ μm), which simultaneously leads to an increase in the efficiency of separation.[105,108–110,200,201,203–205,242–250] Columns of small diameter with a thin film of immobilised SLP retain many of the above-mentioned advantages (5–11, 14, and 15) characteristic of analogous CC of large diameter. On a CC of length 25 m (d_c = 0.20–0.22 mm) with immobilised silicone (SE-30 and OV-101) SLP under programmed-temperature conditions it was possible to achieve the complete separation of fifteen PAH from naphthalene to benz[*g*,*h*,*i*]perylene; C_8, C_{14}, C_{16}, C_{18}, C_{20}, C_{22}, and C_{24} n-alkanes and squalane were added to the mixture.[108,109,204] The analysis on glass CC with grafted SLP (OV-1701 methylphenylsiloxane and methylsilicone rubber) of a methylene chloride extract of the particles present in car exhaust gases detected sixteen PAH from phenanthrene to coronene.[250] The high selectivity of immobilised SLP is indicated by the fact that it has been possible, on a CC with a length of not more than 25 m, under programmed-temperature conditions, to achieve the separation of compounds difficult to separate, such as alkyl- and arylcycloalkylphenols (SLP OV-101 and SKTFT-50) and the diastereoisomers of the isoprene alkanes pristane and phytane (SE-30 SLP) in diesel fuel.[109] Capillary columns with immobilised SLP have been used successfully to separate mixtures of varied polar compounds such as amines,[201] phenols, and alkylanilines,[109,205,249] esters, pyridines, alcohols, and free aliphatic acids,[203,205,249] mixtures of high-boiling petroleum distillation products,[105] perfumery products,[249] and mixtures of chemically unstable compounds used in biology and medicine.[105,250]

Relatively short (14–15 m) glass and quartz CC with a thin film of immobilised SLP (d_f = 0.07–0.1 μm) have been used under programmed-temperature conditions[255] to obtain the distillation curve of heavy fractions of petroleum products containing hydrocarbons up to C_{60}–C_{120} (sometimes up to C_{140}) with boiling points of 615–800 °C. Depending on the SLP, the maximum working temperature of the CC was 350–450 °C, and the analysis time did not exceed 2–2.5 h.

g. The preparation of CC with an immobilised SLP

The variety of methods for the immobilisation of the most varied non-polar and polar SLP is leading to their extensive application in CGC.[88,110,194,200,201,238,240,241,256] Grafted SLP are obtained by the reaction of the functional groups of the liquid phase with the surface

hydroxyl groups of the glass.[240,241] The most widely encountered method of immobilisation is by the transverse cross-linking of polymeric liquid phases, carried out directly in the CC.[42,88,105,108–110,194,201–205,240,242–250,256] The phases immobilised include polyethylene glycols,[113,201,203,205,240] methylsilicone phases (SE-30, SE-52, OV-1, OV-101),[102,108–110,194,200,204,238,255] polysiloxane phases SE-54, SE-31, OV-1701, and OV-225 with a small concentration of vinyl and phenyl groups,[42,197,240] phenyl-containing silicone SLP of the OV-17 type,[194,257] phenyl-substituted silicones,[102] etc. Quartz CC with immobilised SLP of the SKTFT-50 silicone type, with operational characteristics equivalent to those of non-Soviet quartz CC, have been obtained in the Soviet Union.[109] The materials used to initiate the transverse cross-linking include various organic peroxides,[42,108–110,197,200,204,238,240,249,256,257] for example benzoyl, dibenzoyl, dicumyl, and t-butyl peroxides, and also cumene and ethylene oxides,[201] and ozone.[240,258] Increased temperature in the presence of a catalyst,[102,203,205] radioactive irradiation,[240,256] and other methods are also used. SLP based on Carbowax 20M have been prepared by carrying out the chemical reaction between the terminal hydroxyl groups of polyethylene glycol and the NCO groups of 1,6-di-isocyanate in glass CC [(11–14) m × 0.25 mm] in the presence of a catalyst at 110–145 °C for 1–5 h.[203] Films of immobilised SLP based on Carbowax 20M-TPA, FFAP, or OV-351 can be obtained by the thermal treatment of these phases in CC at 145 °C for 5 h in the presence of the catalysts Desmodur L-75 (0.002 M) and DABCO R-8020.[204] The immobilisation of silicones leads not only to a marked increase in the UTL at which the SLP can be used (up to 370 °C), but also to an increase in the selectivity, achieved by the preliminary introduction of phenol groups into the framework of the molecule instead of definite oxygen atoms.[102] The polymer obtained in this way, subsequently subjected to dimethyl-substitution and thermal treatment, is immobilised to the extent of 60%, whereas the cross-linking of dimethylsiloxane polymers takes place to the extent of 10%. The extensive application of CC with SLP differing in their selectivity and other important operational characteristics to solve the most varied analytical problems is to a large extent due to studies carried out in the last six years by the firm of Supelco (USA), which has begun the production of columns of this kind with different diameters (0.25, 0.32, 0.53, and 0.75 mm).[113,259,260]

The use of immobilised and other high-temperature SLP extends considerably the range of analytical problems that can be solved by CGC, and enables the latter to compete successfully with highly efficient liquid and fluid chromatography for the determination of high-boiling compounds. Of considerable interest in this connection, in particular, are the carborane–siloxane SLP, many of which (Dexyl-300GC, Dexyl-400GC, Dexyl-410GC, KBS-2, KBS-3, KBS-2F, and KBS-3F) have an UTL of 450–500 °C.[217] Thus an efficient glass CC containing Dexyl-300 (UTL 350 °C) has been used to achieve the complete separation of isomer pairs, difficult to determine, in a 36-component mixture containing a number of PAH from biphenyl to coronene and dibenz(*a*,*h*)pyrenene.[261] These pairs include phenanthrene and anthracene, benz(*a*)anthracene and chrysene, and benz(*e*)pyrene and benz(*a*)pyrene.

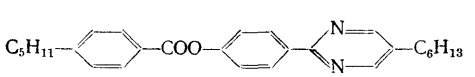
Open tubular glass CC with a solid carrier on the internal walls, impregnated with Dexyl-300, can be used under conditions of linear increase in temperature up to 400 °C.[217–221] These CC have been used to separate mixtures of PAH up to coronene,[218] and also microcrystalline waxes.[221]

h. The use of packing as an effective method of increasing the sorptive capacity and selectivity of CC

The most radical method of increasing the sorptive capacity of CC is by filling them with a packing consisting of either an active adsorbent[1,121–123,262–264] or a solid carrier impregnated with the SLP.[1,122,123,126,262,264] To ensure simultaneously a high efficiency of separation, capillary packed columns (CPC) with internal diameter not exceeding 1 mm are generally used.[1,121–125,262–264] Filling CC with a sorbent leads to a sharp decrease in the value of β compared with open tubular CC, with a corresponding marked increase in the capacity coefficient k'. A 23-component mixture containing air, CO_2, and saturated and unsaturated hydrocarbons up to C_6 (specimen volume 50 μl) has been separated on a steel CPC (3 m × 1 mm) filled with aluminium oxide modified with oleic acid (sorbent particle diameter 0.14–0.25 mm) in 16 min at 40 °C.[263] The range of application of these CPC with d_c = 0.6–1 mm is much wider, however.[262–264] The use of long columns, including glass columns, makes it possible to carry out the rapid gas-chromatographic analysis of complex mixtures of alcohols, steroids, barbiturates, and various impurities in air.[1,262]

As noted above in the examination of the efficiency of separation in CGC, in recent years there has been intensive development in a new direction involving the use of micropacked quartz capillary columns (MPQCC) of small diameter (d_c = 0.15–0.37 mm), filled with fine sorbent granules (5–100 μm).[121–127] Short MPQCC with lengths measured in tens of centimetres combine the advantages of open tubular CC and packed columns in relation to their efficiency, capacity, selectivity, and reproducibility of the results of qualitative and quantitative analysis. This makes it possible to use them for the rapid analysis of not only complex mixtures of hydrocarbons[121,123] but also mixtures of strongly polar compounds such as ketones[122,126] and aliphatic and aromatic alcohols.[123]

CPC in general, and MPQCC in particular, have a number of advantages over open tubular CC of the WCOT type.[1,124,126,127,262,263] These advantages, which are a consequence of the high capacity of these CC, are: 1, the possibility of adding the specimen directly to the CC and avoiding splitting of the carrier-gas stream, which decreases the uncertainty in quantitative determinations and lowers the requirements to be satisfied by the sensitivity of the detector (micro-katharometer, mass spectrometer, etc.); 2, the possibility of determining traces; 3, the possibility of separating substances which are weakly sorbed; and 4, the possibility of the micro-preparative separation of extremely narrow fractions of a complex mixture for their subsequent more detailed study by gas-chromatographic and other physicochemical methods. Other advantages of CPC are their practically unlimited thermal stability and their stability of operation when filled with adsorbents, and the much less severe requirements to be satisfied by the solid carrier and the SLP, compared with OCC-PL and columns in which a phase is deposited directly on the internal surface.

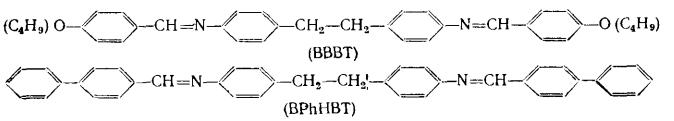


Nevertheless, the extensive use of these columns is limited by the complexity and time-consuming nature of the procedure for filling CPC (and more particularly MPQCC) and by the high pressure drops established during use, which in a number of cases reach several MPa.[122]

i. The use of liquid-crystalline SLP

The use of nematic liquid-crystalline SLP in CGC is directed mainly to increasing the selectivity of separation of isomeric

compounds with extremely similar boiling points and other physicochemical properties.[7,35,39–41,66,89,122,176,195,196,237,265–269] The high selectivity of liquid crystals in the nematic state is due to the long-range orientational order of the arrangement of the long axes of their molecules. The use of these SLP combined with highly effective CC makes it possible to solve the most complex analytical problems, including the separation of stereoisomers. The possibility of separating C_8 arenes and isopropylbenzene on a 50-metre CC containing *p,p'*-azoxyphenol (AOP) and *p,p'*-methoxyethoxyazoxybenzene (MEAB) has been studied.[268] A more detailed study of the *meta–para* selectivity of liquid-crystalline SLP and their mixtures in the temperature range 90–160 °C in copper CC (40 m × 0.35 mm) showed that the maximum selectivity is achieved with the maximum steric effect in the liquid-crystalline melt.[195] An interesting feature is that in the temperature range of existence of the nematic liquid-crystalline state, the more linear isomer *p*-xylene is retained more strongly than *m*-xylene, distinguishing these SLP from most other SLP which are not liquid crystals.[195,237,268] The influence of temperature on the efficiency of separation, the separation factor α, and the capacity coefficient k' in CC with liquid-crystalline phases is much more complex than in the case of SLP in which there is only short-range translational order. This is related both to the change in the state of aggregation of the SLP on passing through the melting point and to the change in the phase state of the liquid phase with increase in temperature (the change from the smectic to the nematic and then to the isotropic state).[89,195,237] In general, the temperature of maximum selectivity does not necessarily coincide with the temperature of the maximum capacity.[195] The optimum separation temperature may not coincide with the temperature of maximum retention in the range of the meso-phase.[195]



The use of sodium glass capillary columns (d_c = 0.23 mm) of different length containing the new liquid-crystalline SLP 2-[4-(4-pentylbenzoyloxy)phenyl]-5-hexylpyrimidine (PBHP)

(PBHP)

in the temperature range 80–130 °C has been used to separate a complex 32-component mixture consisting of C_8–C_{13} n-alkanes and C_8–C_{13} alkylbenzenes.[66] The specific efficiency of the CC used was 3500 t.p. m^{-1}, the capacity coefficient k' = 3.5 (at 90 °C), and d_f = 0.115 μm. A remarkable feature is that despite the fact that the SLP used by the authors cited[66] had a higher selectivity with respect to *p*- and *m*-xylenes than all known liquid-crystalline SLP ($\alpha^{100\ °C}$ = 1.09, $\alpha^{50\ °C}$ = 1.13, $\alpha^{25\ °C}$ = 1.20), it was not possible to separate all the components of the mixture studied on a single column of length 50 m. An extremely satisfactory separation in a relatively short time (~20 min) at 25 °C was achieved only using a combined CC, the first section of which, of length 35 m, contained OV-101 methylsiloxane rubber as SLP, while the second, of length 15 m, contained PBHP. The temperature range corresponding to the nematic liquid-crystalline state of PBHP is 38–159 °C.

Interesting studies have been carried out on the separation of PAH.[89,196] In particular, a CC with the liquid-crystalline SLP N,N'-bis-4-butoxybenzylidene-*a,a'*-bi-*p*-toluidine [N,N'-bis-(BaBT)] has been used for the complete separation of benz(*a*)anthracene and chrysene.[196] The complete separation of a number of tricyclic, tetracyclic, and pentacyclic PAH and two benzofluoranthenes has been carried out using glass CC containing the liquid-crystalline SLP

(BBBT)

(BPhHBT)

whose nematic phase is thermodynamically stable at relatively high temperatures (188–300 °C for BBBT).[89] To increase the UTL and the stability of operation of the CC at high temperatures, the BPhHBT and BBBT were deposited on a previously treated surface carrying $BaCO_3$ crystals. The further development of this promising field is restricted at present by the non-availability of liquid crystals having sufficient thermal stability and undergoing phase transitions in the range 300–350 °C, so that it is not possible to cover all the PAH present in the specimens in the analysis of petroleum products and environmental specimens. Difficulties arise as a result of the instability of the separating power of liquid crystals, which leads to a sharp deterioration in the efficiency of the CC during use, particularly under temperature-programming conditions at high temperatures. When combined with highly efficient liquid chromatography, however, the use of CC containing liquid-crystalline SLP provides unique analytical possibilities for determining PAH in various technical and natural materials. As noted above, the separating power of CC containing liquid-crystalline SLP can be increased considerably by the action of an electric field.[176]

Interesting results have been obtained[39] using a quartz CC with a liquid-crystalline SLP to separate isomeric polycyclic aromatic compounds whose molecules contain different heteroatoms. Quartz CC (15 m × 0.20 mm) containing a nematic polysiloxane SLP have been used to separate PAH with relative molecular masses of 276–302 at 280 °C, and quartz CC (25 m × 0.20 mm) with a smectic polysiloxane SLP have been used to separate the methyl esters of aliphatic acids at 140 °C.[40] The unique selectivity of liquid-crystalline SLP is indicated by the results of studies[41] in which a glass CC was used to separate a number of geometric isomers of various polar and non-polar compounds.

Additional possibilities for the rapid determination of various hydrocarbons, aliphatic acids, esters, and nitriles are provided by the use of short CC (up to 10 m) containing colloidal liquid-crystalline SLP.[237]

j. The influence of adsorption effects

An important factor controlling the selectivity and capacity in CGC is the adsorption of the sorbates at the inter-phase surfaces in CC in which their internal surface plays the part of the solid carrier.[75,122,269,270] It has been shown convincingly[122,270–273] that the additive theory of retention is equally applicable to capillary and packed columns. The important part played by adsorption phenomena in CGC is indicated primarily by the dependence of the retention indices of a number of compounds, including even low-boiling C_6–C_7 hydrocarbons, on the nature of the surface of the walls of the capillary and the thickness of the SLP film.[122,169,269–274] The factors indicated have a significant influence on the retention of compounds in chromatography using both polar and non-polar SLP. A change in selectivity has been observed with increase in the effective thickness of the film of a liquid-crystalline SLP.[269] The influence of the thickness of the layer of SLP on retention has been observed for CC of practically all types.[122,169,270] An extremely important practical feature is that in some cases a change in the

concentration of the SLP in the CC even changes the order of elution of the compounds being determined. For example, in a glass CC containing Carbowax 20 M (k' = 2.1 for *cis*-pentadec-5-ene), *trans*-pentadec-6-ene is eluted first, followed by *cis*-pentadec-5-ene, whereas in a CC with a thin layer of the same SLP (k' = 1.3), the opposite order of elution is observed.[270,271]

k. The use of mixed SLP

Despite the high specific efficiency of CC, in particular quartz CC, the use of mixed SLP to carry out complex separations in single-column CGC is still of considerable interest, since it makes it possible to control the capacity and selectivity factors over wide limits and to some extent to avoid the successive use of several individual SLP.[86,174,206,207,275] The smooth control of the polarity of the stationary phase by the simultaneous deposition of two readily available individual SLP in definite proportions is appropriate for separating extremely complex organic mixtures consisting of substances of different classes which differ in the polarity of the molecules to be separated.[206] Here, the polarity of molecules is understood to mean not the empirical value of their dipole moment but a quantity determined by the concentration of polar functional groups or by the ratio of the polar and non-polar atomic groups in the sorbate molecule.

Glass (d_c = 0.45 mm) and quartz (d_c = 0.22 mm and 0.33 mm) CC with binary SLP containing Superox 20M† (polar component) and OV-1 (non-polar component) in different proportions (1:3, 1:1, and 3:1) have been used to separate synthetic mixtures containing alcohols, aliphatic acids, diols, phenols, anilines, primary and secondary amines, and the components of vegetable oil from hops with the addition of various aromatic substances.[68] It has been shown that by varying the composition of this mixed SLP over a wide range it is possible to cover a wide range of McReynolds constants, characteristic of five individual SLP of the Yukon type. An important result of the work cited[86] is that it proved that it is possible to deposit, on the untreated internal surface of a CC, films of mixed SLP capable of stable functioning up to 250 °C, in spite of the fact that one of its components (Superox 20M) tends to form droplets, and the UTL of each of the individual SLP does not exceed 170–180 °C. The formation of stable films of mixed SLP on a smooth fused quartz surface which has not been treated to give it roughness has made it possible to make full use of the advantages of quartz CC, which have low adsorption and catalytic activity, and at the same time to achieve a high efficiency of separation.

A number of mixtures of PAH have been analysed in CC with liquid-crystalline SLP of the N,N'-bis-(BaBT) type, mixed with OV-101 polysiloxane, and the optimum ratio of the polysiloxane and the liquid-crystalline components of the SLP has been determined.[207]

The use of CC with mixed SLP previously made possible the detailed determination of the light hydrocarbons present in petrol fractions.[158,170,276–278] In particular, a CC with a mixed SLP was used under programmed-temperature conditions to obtain detailed information on the composition of a broad C_4–C_{12} petrol fraction.[170] CC with a mixed SLP have been used to separate aromatic C_6–C_{10} hydrocarbons.[277,278]

The use of mixed SLP often makes it possible to pass smoothly through the entire range of polarity. The optimum composition of the binary SLP and the length of the CC are usually calculated from the required degree of separation of the components of the mixture being analysed and the minimum analysis time. The most convenient for this purpose is the method of "window" diagrams,[279] subsequently extended to the selection of the optimum experimental conditions for the use of combined columns (connected in series).[66,275,280–282] In this method, the linear dependence of the coefficient k' on the composition of the mixed SLP is constructed for each component of the mixture being analysed. From these relationships, for any specified composition of the SLP, it is possible to calculate the selectivity coefficient α for pairs of components most difficult to separate. The plot of α against the SLP composition, called the "windows" diagram, makes it possible to select the optimum composition of the binary SLP corresponding to the maximum value of α. The length of the CC required for the separation is selected from the number of theoretical plates (n_{req}) required for the complete separation of the components.

Despite their obvious advantages, the extensive use of mixed SLP in CGC is associated with a number of difficulties, including the following: 1, the limited mutual solubility of the polar and non-polar components of the SLP, which in a number of cases leads to the adsorption of the sorbates on a new inter-phase boundary which is difficult to take into acocunt, and the possibility of varying the capacity and selectivity factors only in a relatively narrow range;[275] 2, the deterioration in the efficiency of separation and the poor reproducibility of the properties of the CC as a consequence of the insufficient wettability of their internal surface by the mixed SLP;[275] and 3, the need in a number of cases for the successive application of CC containing mixed SLP with different compositions to obtain the required volume of information.

IV. Summary

The examination of a large number of methods for controlling efficiency, selectivity, and capacity in single-column CGC indicates the significant achievements and the promising possibilities of this most widely encountered and flexible method for the analysis of multicomponent mixtures of organic and inorganic compounds. At the same time there are obvious limitations and difficulties associated with use of CGC to solve various complex analytical problems, which cannot always be overcome using gas-chromatographic systems with one CC. This applies primarily to the analysis of natural and other mixtures boiling over a wide temperature range and consisting of representatives of varied classes of chemical compound. The separation of these mixtures often becomes possible only after the preliminary isolation of the fractions to be analysed, which unavoidably leads to distortion of the initial composition of the specimens being studied and is also time-consuming. In a number of cases, to obtain detailed data on the concentration of the individual components in specimens characterised by a wide variation in composition, it is necessary to carry out parallel or successive analyses using several instruments, sometimes under different temperature conditions and using CC with SLP having different polarity. The frequent replacement and alternation of CC having different efficiencies, selectivities, and capacities, and analyses using different chromatographs, are also time-consuming and inconvenient, and lead to an increase in the number of sources of error in the determination of the composition of complex mixtures.

Difficulties frequently arise, associated with the need to carry out analyses at a low temperature or, on the other hand, a temperature

† Superox 20 M is a linear polyethylene glycol with a relative molecular mass of 20000–40000, readily soluble in dichloromethane.

which is too high, with large pressure drops, when using long CC and CC of other types characterised by a high specific resistance to the flow of carrier gas (CC with a diameter reaching 0.1 mm, MPQCC, etc.). Change in the temperature of the CC and the use of temperature programming in the analyses are not always effective in the study of complex mixtures, since improvement in the separation of some pairs of compound may be accompanied by a deterioration in the separation of other pairs. Moreover, the use of high temperatures, even for a short time interval, leads to the danger of decomposition of the substances being analysed, to a decrease in the lifetime of the CC, and to the incomplete realisation of their potential efficiency.

Although glass and more particularly quartz CC with ordinary and immobilised SLP have good operational characteristics, their use in large-scale analyses requires highly qualified workers. Many types of CC and SLP are difficult to obtain, in short supply, and expensive. Certain difficulties are associated with the procedures preceding the deposition of SLP on the internal surfaces of CC and carried out to eliminate or decrease its adsorption and catalytic activity and to improve the wettability of this surface by the liquid phase.

Despite the fact that the chromatographic characteristics of OCC-PL, OCC-SC, and micropacked glass and quartz CC are highly stable for a long time, and their UTL fairly high, they have not yet been widely applied, because of the difficulty of their preparation.

The extensive use of liquid-crystalline, mixed, and colloidal SLP in CGC is prevented by the changeability of their separating power, particularly at relatively high temperatures, and by the difficulty of achieving reproducibility of the efficiency and selectivity of columns containing these phases.

Extensive possibilities for varying the efficiency of separation over a wide range are provided by two-stage systems with capillary columns functioning under circulation gas-chromatographic conditions.[283–286] Programming the length of the layer of sorbent in the gas-chromatographic process makes it possible, at low carrier-gas inlet pressures, and by the repeated use of each of two CC with the same SLP, to achieve values of the efficiency of separation measured in tens of millions of t.p., which makes it possible to achieve values of the separation factor α extremely close to 1 (1.002 – 1.01) in the separation of isotopically substituted organic compounds with extremely similar properties (cyclohexane, benzene, naphthalene, acetone) and their partly or completely deuteriated analogues.[283–286]

Promising possibilities for the extension of the use of CGC for the analysis of complex mixtures and the reliable determination of micro-quantities are provided by the use of gas-chromatographic systems with several columns, of which at least one is a capillary column.[9–13,16,18,55–64,66,177,275,280–282,287–291] These systems make it possible to obtain extremely detailed information on the composition of the mixture being analysed, since it is possible to vary the capacity and selectivity parameters over an extremely wide range and to carry out the analyses at relatively low temperatures. The last feature guarantees the high stability of the CC for a long time, and extends the range of compounds that can be determined, by including thermally labile and reactive substances. This makes it possible, even with an extremely limited number of CC and SLP and small quantities of the substance being analysed, to decrease the total time taken for the determination and to increase the reliability of the analysis by eliminating undesirable operations of specimen preparation, using relatively short CC, and decreasing the total number of experiments. The use of high-capacity packed columns combined with highly efficient CC provides extensive possibilities for increasing the sensitivity of determinations. By carrying out analyses in multi-stage gas-chromatographic systems containing two or more CC with different SLP and detectors, it is also possible in a number of cases to increase the reliability of the identification of the components of complex mixtures of organic compounds.

The synthesis and properties of thioaldehydes

V A Usov, L V Timokhina, M G Voronkov
Irkutsk Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences

ABSTRACT. Data on the synthesis of thioaldehydes, a little investigated class of organic sulphur compounds, are described systematically and surveyed. Various types of relatively unstable thioaldehydes and thioaldehydes stabilised by electronic and steric factors are examined. Their physical, spectroscopic, and chemical properties are discussed. The important role of thioformyl compounds as intermediates and synthons is demonstrated.

The bibliography includes 92 references.

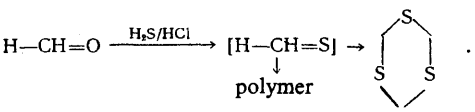
I. Introduction



The chemistry of aldehydes has been developing successfully since the beginning of the past century. They are used widely in the synthesis of acetals, oximes, hydrazones, carboxylic acids, amines, alcohols, diols, etc., and in the manufacture of polymers, medicinal preparations and perfumes, dyes, pesticides, explosives, etc.[1] However, their sulphur analogues, thioaldehydes (TA), were ignored for a long time. This was because for historical reasons the view was established that TA are extremely unstable and that their synthesis and study are therefore difficult.

The first communications on stable TA appeared as late as 1960.[2,3] They probably in fact initiated the development of the chemistry of this class of compound. The role of TA as important intermediates and synthons in organic chemistry and also as practically useful substances became increasingly clear from the individual publications which appeared in the second half of the present century. For example, 5-thioformyldipyrrolylmethane has been used as a key compound in the total synthesis of chlorophyll.[3] Penicillins have been converted into biosynthetically important peptides through TA derived from mercaptoazetidinone;[4,5] thioformylmethylene derivatives of heterocyclic bases have begun to be used in the synthesis of photosensitive materials.[3] At the present time, there has been an appreciable growth of interest in TA. Communications about the generation and reactions of thioformaldehyde, thioacetaldehyde (Section II), thioacrolein, and thiobenzaldehyde (Section IV), which previously did not attract attention because of their extreme instability, are being published with increasing frequency. Modern physicochemical methods have made it possible to establish the lifetimes of these compounds, to obtain their spectroscopic characteristics, and to discover their involvement as intermediates in many chemical reactions. A trend has arisen towards the specific synthesis of fairly stable TA stabilised by electronic (Section IV) or steric (Section V) factors associated with substituents. Increasing attention is being devoted to the study of the properties of TA.

The chemistry of TA has been developing mainly abroad and chapters in several reviews in the German language have already been devoted to them,[6–12] but unfortunately they have by no means covered all the available data. The present review is being published because of a wish to draw the attention of Soviet investigators to compounds of this class.

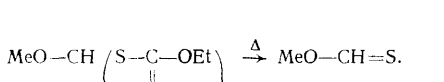
II. Thioformaldehyde and thioacetaldehyde

The simplest representative of TA, thioformaldehyde, is extremely unstable. Its half life is ~6 min at a pressure of 0.01–0.05 Pa.[11] One of the initial (1868) synthetic approaches to thioformaldehyde was based on what has now become the classical reaction of formaldehyde with hydrogen sulphide in the presence of acid catalysts:[6]

The thioformaldehyde reaction products, which are, depending on the reaction conditions, 1,3,5-trithiane (trithioformaldehyde) or polymethylene sulphides, have served as indirect evidence for the primary formation of thioformaldehyde. Subsequently, the successful development of the methods of synthesis of thioformaldehyde in combination with modern physicochemical research methods made it possible to establish unambiguously the possibility of the existence of monomeric thioformaldehyde.[7,8,10] The use of the pulse thermolysis technique, whose undoubted advantages are a very short reaction time (at a reduced pressure) and the possibility of analysing the pyrolysis product in the gas phase, should be regarded as one of the most productive achievements in this field. Monomeric thioformaldehyde has been obtained by the thermolysis of various sulphur compounds, for example thietan, dimethyl disulphide, 1,2,4-trithiolan, and methanesulphenyl chloride.[10,13]

It is very remarkable that thioformaldehyde has been detected in cosmic space.[10] The prolonged existence of such highly reactive molecules in the interstellar vacuum and cold is possible because of the large intermolecular distances. Such conditions in fact ensure the

stability of individual thioformaldehyde molecules, which usually exhibit a high tendency towards oligomerisation and polymerisation.



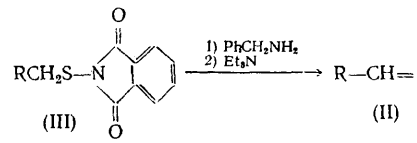
The closest homologue of thioformaldehyde, namely thioacetaldehyde, is also very unstable. In contrast to thioformaldehyde, it can exist in the tautomeric enethiol form (ethenethiol):

$$CH_3{-}CH{=}S \rightleftarrows CH_2{=}CH{-}SH.$$

Thioacetaldehyde is generated in different ways: photochemically by adding hydrogen sulphide to acetylene,[10] by the thermolysis of ethane-1,2-dithiol[10] and dimethyl sulphide,[14] and by the reaction of vinyl chloride with an excess of hydrogen sulphide.[14] On thermal decomposition of 2-vinylthiotetrahydropyran, the isomeric α- and β-trithioacetaldehydes were isolated.[15]

III. Alkoxy-, acyl-, and alkoxycarbonyl-thioformaldehydes

O-Substituted thioformates (RO−CH = S), which can be regarded as alkoxythioformaldehydes, are interesting not only as unusual representatives of thiocarbonyl compounds but also as reagents for the introduction of the thioaldehyde group.[16,17] *O*-Ethyl thioformate was first obtained in 33% yield by the hydrothiolysis of ethyl orthoformate.[18] Later a new, simple, and more effective procedure, starting with the readily available 1,1-dichloromethyl methyl ether, was proposed for the synthesis of *O*-alkyl thioformates using the *O*-methyl derivative as an example.[19] Heating potassium *gem*-bis(*O*-ethyl dithiocarbonate) (I), obtained by the reaction of dichloromethyl methyl ether with *O*-ethyl dithiocarbonate, to 200−220 °C leads to *O*-methyl thioformate. This compound is sensitive to oxygen but can be stored in a nitrogen atmosphere at 0 °C for several months:

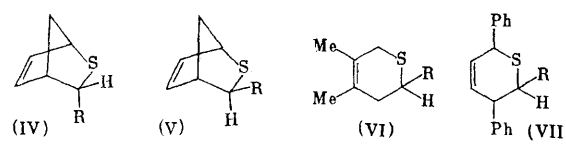


(I)

The attempt to synthesise *O*-phenyl thioformate by a similar procedure led to polymerisation products only.[19]

Acyl- and alkoxycarbonyl-thioformaldehydes (R−CO−CH = S, RO−CO−CH = S) represent a special variety of thiocarbonyl derivatives in which the electron-accepting carbonyl functional group is linked to the CH = S group. Such compounds have not been isolated in the monomeric state. However, their intermediate formation has been used for the synthesis of cyclic adducts.[20–22]

Bunte salts RCH_2SSO_3Na are used for the synthesis of R−CO−CH = S with R = Ph or PhNH[20] (see above), while the corresponding α-sulphonyl disulphide $4\text{-}BrC_6H_4COCH_2SSCH.(SO_2Tol)COC_6H_4Br\text{-}4$ has been used to obtain the thial with R = $4\text{-}BrC_6H_4$[21] (see below). Ph−CO−CH = S can also be obtained by the photolysis of diphenacyl sulphide.[22]



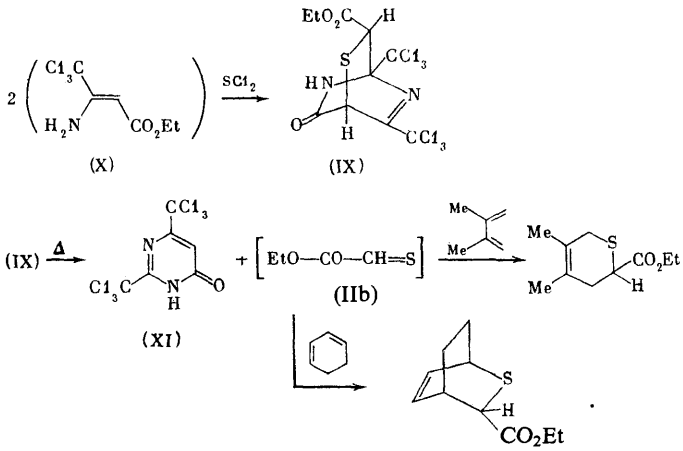
The first information about methoxycarbonylthioformaldehyde (IIa) can be found in the communication by Harpp and Back.[23] In a study of the reaction of *N*-(methoxycarbonylmethylthio)-phthalimide (IIIa) with benzylamine at room temperature, the thioxoamide $PhCH_2NHCOCSNHCH_2Ph$ was isolated. It was then assumed that methoxycarbonylthioformaldehyde (IIa) is an intermediate in this reaction:

(III) (II)

R = MeO−CO (a), EtO−CO (b).

The reactions of compounds (IIIa, b) with triethylamine in the presence of conjugated dienes lead to the corresponding alkoxycarbonylthioformaldehydes (IIa, b) *in situ*.[24] The *endo*-adducts (IV) and the *exo*-adducts (V) of cyclopentadiene and ethoxycarbonylthioformaldehyde (IIb) dissociate at 111 °C, which makes it possible to achieve the transfer of the TA (IIb) to other conjugated dienes. Thus, when a "kinetic mixture" of compounds (IV) and (V) with 2,3-dimethylbuta-1,3-diene was heated in toluene under nitrogen in a sealed tube at 120 °C for 21 h, the individual adduct (VI) was obtained in 82% yield. In the case of *trans,trans*-1,4-diphenylbuta-1,3-diene, which reacts with maleic anhydride 114 times more slowly than 2,3-dimethylbuta-1,3-diene,[25] refluxing of a mixture of the isomers (IV) and (V) in xylene readily affords the adduct (VII) (mixture of stereoisomers). Thus the thermal dissociation of the adducts (IV) and (V) can be used preparatively as the source of ethoxycarbonylthioformaldehyde (IIb):

(IV) (V) (VI) (VII)



R = EtO—CO.

Bunte salts[20] and α-sulphonyl disulphides[21] are excellent substrates for the synthesis of alkoxycarbonylthioformaldehydes (II) and the acyl derivatives.

The 1,2-elimination of HCl; from ethoxycarbonylmethanesulphenyl chloride (EtO−CO−CH_2SCl) (VIII) when it is treated with triethylamine leads to ethoxycarbonylthioformaldehyde (IIb).[26] It too is trapped by various conjugated dienes. The yield of the products of [2 + 4]cycloaddition is then satisfactory. However, the interaction of the TA (IIb) with cyclohexa-1,3-diene is accompanied by the formation of other reaction products, probably as a result of the competing attack by the sulphenyl chloride (VIII) on the diene.[26]

A derivative of diazathiabicyclooctene (IX) has been recommended as a new precursor of alkoxycarbonylthioformaldehydes (II).[27] Compound (IX) was obtained in 34% yield by the reaction of ethyl 3-amino-4,4,4-trichlorocrotonate (X) with SCl_2. Heating of a solution of compound (IX) in chlorobenzene at 80 °C induces a retro-Diels-Alder reaction and the formation, together with the product (XI), of ethoxycarbonlthioformaldehyde (IIb), which has been successfully trapped with cyclohexa-1,3-diene or 2,3-dimethyl-

buta-1,3-diene (the yields of the adducts were 85% and 48% respectively):

This method of generating and trapping ethoxycarbonylthioformaldehyde (IIb) supplements effectively the recently developed elegant methods of synthesis of thioformyl compounds.[20–22]

The synthesis of n-butoxycarbonylthioformaldehyde from n-butylglyoxal and P_4S_{10} as well as its reactions with dienes have been briefly reported.[26]

IV. αβ-Unstaturated and aromatic thioaldehydes

The methods of synthesis of αβ-unsaturated and aromatic TA are extremely varied. At the present time they can be subdivided into 12 general methods.

1. Thionation of aldehydes

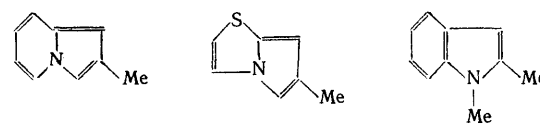
The methods for the direct conversion of the carbonyl group ($>C=O$) into the thiocarbonyl group ($>C=S$)[11] in order to synthesise TA are rarely used. In the synthesis of 3-thioformylindolizines (XII) by the appropriate treatment of the corresponding formyl derivatives, the use of tetraphosphorus decasulphide is by no means as convenient as the employment of other thionating agents[28] (Table 1, Nos. 1–3). P_4S_{10} has been used to synthesise dimethylaminothioacroleine (XIII),[29] but no experimental data have been published.

The interaction of 2-pyrrolidinobenzaldehyde with Lawson's Reagent† in boiling toluene leads initially to the corresponding TA (XIV).[30]

The reactions of boron sulphide with benzaldehyde and its 3-methyl and 3-nitro-derivatives have also been investigated.[31] The 3-nitro-derivatives do not react with P_2S_3, while in the two remaining cases cyclic trimers of the corresponding TA—substituted 1,3,5-trithianes—were isolated. Such trimerisation is apparently promoted by thionation catalysts (HCl, I_2).

† 4-MeOC$_6$H$_4$—P(S)(S)P(S)—C$_6$H$_4$OMe-4

2. Thionation of oximes and hydrazones



Refluxing of the oxime (XV) or the hydrazone (XVI) of 6-formylpurine in thioacetic acid or its anhydride leads to *N*-acetyl-6-thioformylpurine (XVII)[32] (Table 1, No. 4).

3. Hydrothiolysis of iminium salts

Iminium salts have been used successfully for the synthesis of thioformyl compounds (Table 1, Nos. 5–15).

The first stable thioaldehyde—3-ethyl-4′-methoxycarbonyl-5′-(2-methoxycarbonylpropionyl)-3′, 4-dimethyl-5-thioformyldipyrrolylmethane (XVIII)—was obtained by Woodward et al.[2] by the reaction of *N*-ethylformiminium bromide (XIX) with hydrogen sulphide in the presence of sodium methoxide in a benzene–methanol mixture. Slightly later, the enaminothial (XXI) was synthesised in a satisfactory yield by the reaction of a 1-ethyl-2-(2-*N*-methyl-*N*-phenylaminoethenyl)benzothiazolium salt (XX) with sodium hydrogen sulphide in methanol.[3]

A brief communication appeared in 1966[33] in which the problem of the synthesis of stable TA from 2-methylindolizine (XXII), 6-methylpryolo[2,1-*b*]thiazole (XXIII), and 1,2-dimethylindole (XXIV) was posed for the first time. It was correctly suggested that coupling of the thioformyl group to a nitrogen atom in a heterocycle can lead to the mesomeric stabilisation of the corresponding TA, for the synthesis of which a new version of the Vilsmeier–Haack reaction was used:[33]

(XXII) (XXIII) (XXIV)

Treatment of the initial compounds (XXII)–(XXIV) in dimethylformamide (DMF) with phosphoryl chloride leads to the Vilsmeier salts (XXV)–(XXVII) respectively, whose solvolysis *in situ* by aqueous sodium hydrogen sulphide affords the orange or red TA (XIIb), (XXVIIIa), and (XXIX).

Later the thioformylindolizines (XII) and (XXX)[28] and thioformylpyrrolo-[2,1-*b*]thiazoles (XXVIII) and (XXXI)[34] were synthesised by the same procedure and investigated in detail. The electrophilic substitution reactions in indolizines occur preferentially at the 3-position or, if the latter is occupied, to the 1-position. 3-Thioformyl-substituted compounds (XIIa, b, d–g) have been obtained in excellent yields from indolizine, 2-methylindolizine, and 1,2-, 2,6-, 2,7-, and 2,8-dimethylindolizines. 2-t-Butylindolizine gives rise to 5% of 1-thioformylindolizine (XXXa) together with the 3-formyl-substituted derivative (XIIc). The attempts to obtain the 1,3-dithioformyl derivative (XIIh)[28] led only to a polymer. Under these conditions, the two thioformyl groups were probably mutually destabilised as a result of cross-coupling.

A modified Vilsmeier reaction made it possible to synthesise a large series of thioformyl-substituted 5- and 7-pyrrolo[2,1-*b*]thiazoles (XXVIII) and (XXXI).[34] A 4:1 mixture of the 5-thioformyl derivative (XXVIIIe) and the 7-thioformyl derivative (XXXIe) has been obtained from 3,6-dimethylpyrrolo[2,1-*b*]thiazole. 6-t-Butyl-3-methylpyrrolo[2,1-*b*]thiazole also affords a mixture from which the 5-thioformyl derivative (XXVIIId) and the 7-thioformyl derivative (XXXId) were isolated by preparative thin-layer chromatography (TLC). The structure of the 5-thioformyl derivative (XXVIIId) was reliably confirmed by X-ray diffraction.[34]

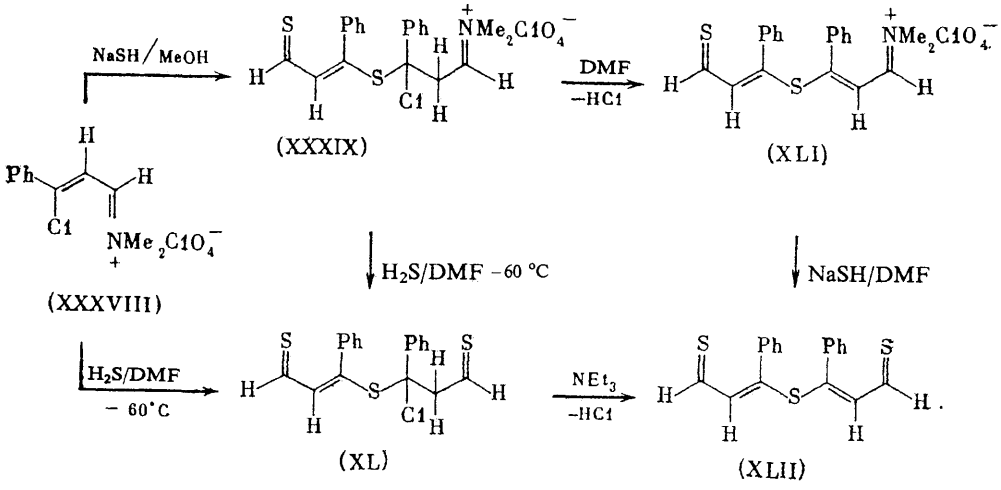
The deuteriated TA (XXXIIa, b) were synthesised from the corresponding pyrrolo[2,1-*b*]thiazoles using [$^2H_7$]dimethylformamide and phosphoryl chloride in 1,2-dichloroethane for studies by NMR and IR spectroscopy.[34]

The synthesis of stable thioformyl derivatives of 10*H*-indeno-[2,1-*d*]-pyrido-[2,1-*b*]thiazole (XXXIIIa, b) has also been reported.[35] Instead of DMF, dimethylthioformamide was used, which made it possible to increase the yield of the salts (XXXIVa) and (XXXIVb) from 63 and 40% to 93 and 87% respectively. This can be explained by the different formylating capacities of the ion-pair reaction intermediate $Me_2\overset{+}{N}CH-XPOCl_2Cl^-$, where X = S or O.[35]

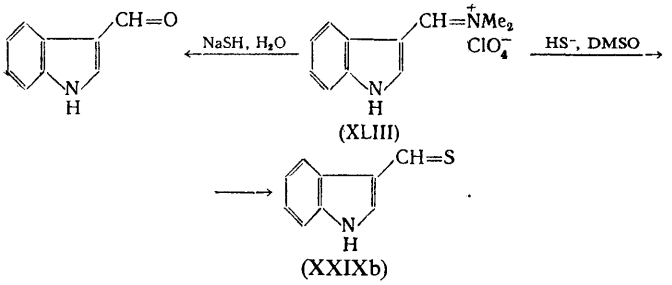
The neutral structure (A) of the thioaldehyde (XXXIIIa), formally containing a tetracovalent endocyclic sulphur atom, is undoubtedly stabilised by the formation of the resonance zwitter-ion (B).[35]

(A), (XXXIIIa)



(B), (XXXIIIa)

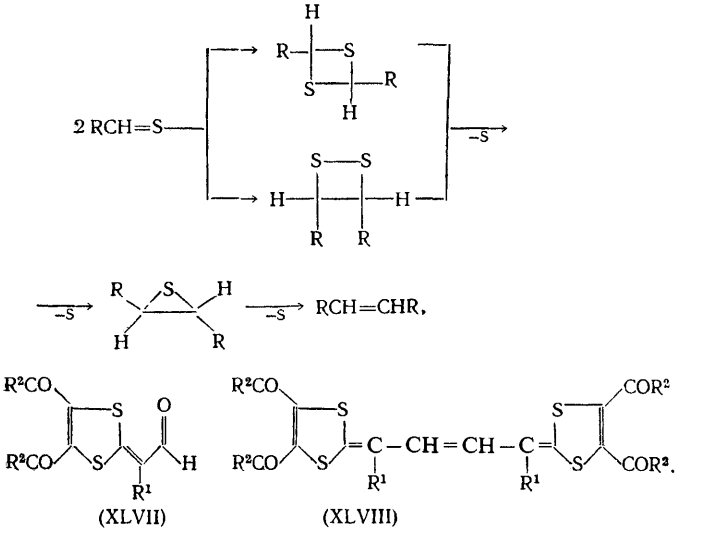
A method of synthesis of thioformylindolizines (XII) from ethoxymethyleneindolizinium salts (XXXV) has been proposed.[28,33] It is based on the condensation of 3*H*-indolizinium perchlorates with triethyl orthoformate and subsequent treatment of the resulting salts (XXXV) with sodium hydrogen sulphide.



A single-stage method of synthesis of aliphatic and alicyclic enaminothioaldehydes (XXXVI), involving the successive treatment of the enamines (XXXVII) with DMF, $POCl_3$, and NaSH, has been described recently.[36] The thials (XXXVI) are orange or red crystalline substances which are stable for several months even at room temperature.

New synthetic possibilities for the hydrothiolysis of salts of the type (XXXVIII) have been demonstrated.[37] Depending on the character of the ion-pair states of the reactant and temperature, the hydrothiolysis of 3-chloro-*NN*-dimethyl-3-phenylprop-2-en-1-yliminium perchlorates (XXXVIII) leads to the asymmetric sulphides (XXXIX) or (XL). Their dehydrohalogenation products

are 1,7-bishetero-substituted dipropenyl sulphides (XLI) and (XLII) respectively:

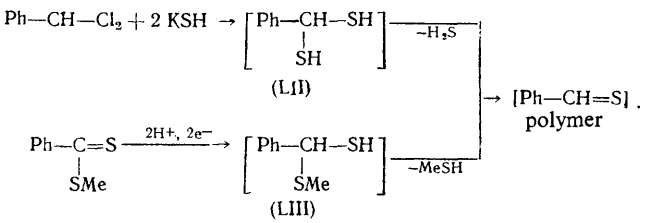


Under the conditions of the synthesis of 3-thioformyl derivatives of indole and indolizine by treating the corresponding methyleneiminium salts with an aqueous solution of sodium hydrogen sulphide,[33] *N*-[(3-indolyl)methyl]-*NN*-dimethyliminium perchlorate (XLIII) hydrolyses to 3-formylindole.[38] The hydrothiolysis of the salt (XLIII) can be readily achieved by treatment with anhydrous NaSH or hydrogen sulphide in dimethyl sulphoxide at 20 °C and leads to the formation of 3-thioformylindole (XXIXb) in solution:

4. Alkynylation of 1,2-dithiole-3-thiones

[2 + 3]Cycloaddition of acetylenedicarboxylic acid esters (XLIV, $R^1 = R^2$ = COOMe or COOEt) or dibenzoylacetylene (XLIV, $R^1 = R^2$ = COPh) as well as other activated acetylenes to 5-unsubstituted 1,2-dithiole-3-thiones (XLV) leads to 2-thioformylmethylene-1,3-dithioles (XLVI)[39–42] (Table 1, No. 16). These substances almost always contain an admixture of the isostructural aldehyde (XLVII). A long reaction time (24 h) as well as refluxing of the TA (XLVI) in benzene lead mainly to the alkenes (XLVIII)—the products of the bimolecular elimination of thial sulphur in accordance with the scheme[40]

5. Aminolysis of 1,2-dithiolium salts

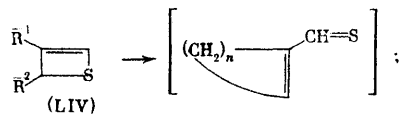


Treatment of 1,2-dithiolium salts (XLIX) at 25 °C with an equivalent amount of ethylenediamine in ethanol or of trimethylenediamine in benzene leads to the stable TA (La, b)[43] (Table 1, No. 17). This reaction opened a convenient synthetic route to 14-, 15-, and 16-membered tetraazamacrocycles.[43]

6. Hydrothiolysis of 1-chloro-2-benzoylstyrene

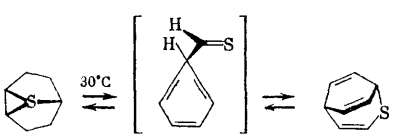
The hydrothiolysis of alkenyl chlorides is a widely used approach to the synthesis of thiocarbonyl compounds.[11] 2-Oxo-1,2-diphenyl-1-thioformylethane (LI), which exists in the stable alkenethiol tautomeric form[44] (Table 1, No. 18), has been obtained in this way.

7. The cleavage of *gem*-dithiols and their derivatives



gem-Dithiols and their S-derivatives can be cleaved at one of the C–S bonds with formation of the thiocarbonyl group.[45] Thus the *gem*-dithiol (LII), obtained from benzylidene dichloride and potassium hydrogen sulphide, is readily converted into thiobenzaldehyde.[45] The primary product (LIII) of the reduction of methyl dithiobenzoate splits off methanethiol and is also converted into thiobenzaldehyde, which immediately polymerises.[45]

Certain 1,3,5-trithianes are readily cleaved on heating to the initial TA.[6,9,11,46] This can be used for the "storage" of the corresponding TA as trimers in order to investigate them subsequently.



8. Rearrangement of cyclic sulphides

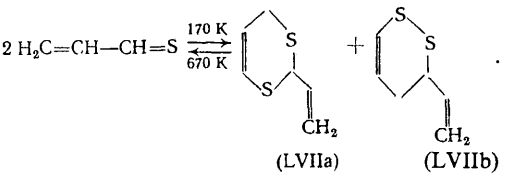
The spontaneous decomposition of certain 3,4-disubstituted thiets (LIV) begins with ring opening and the formation of αβ-unsaturated TA (LV), which rapidly polymerise.[47,48] When compounds (LV, n = 4, 5) were allowed to interact with 2,4-dinitrophenylhydrazine, the hydrazones of 2-thioformylcyclohexene and 2-thioformylcycloheptene were isolated.[47]

$R^1 = R^2 = (CH_2)_4$.
$R^1 = R^2 = (CH_2)_5$

1-Thioformylcycloheptatriene (LVI) is an active intermediate in thermal isomerisation via the mechanism[49]

9. Thermolysis of Unsaturated Sulphides

The synthesis of two extremely reactive compounds—thioacrolein and thiobenzaldehyde—has been achieved by the flash thermolysis of diallyl sulphide and allyl benzyl sulphide respectively.[50–53] According to IR spectroscopic data, thioacrolein begins to change slowly already at 77 K, while thiobenzaldehyde persists up to 110 K.[50]

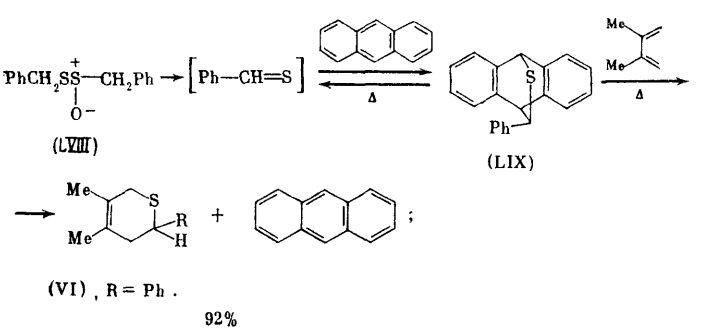


$$H_2C{=}CHCH_2{-}S{-}CH_2CH{=}CH_2 \xrightarrow{\Delta} [CH_2{=}CH{-}CH{=}S],$$

$$PhCH_2{-}S{-}CH_2CH{=}CH_2 \xrightarrow{\Delta} [Ph{-}CH{=}S].$$

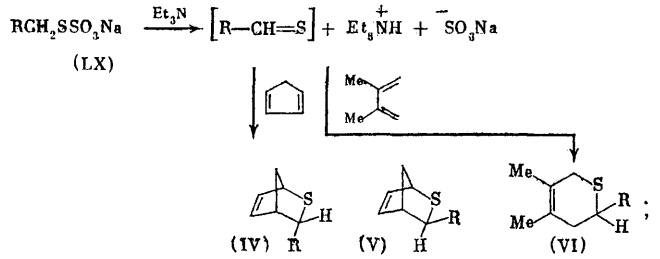
Thioacrolein was identified in the thermolysis products of diallyl sulphide (550 °C, 10–50 mmHg) by microwave spectroscopy.[51] Under normal conditions, this thial persists for 1–2 min.

The use of photoelectron spectroscopy (interpretation of "molecular fingerprints") during thermolysis made it possible to determine the optimum temperature at which thioacrolein is formed from diallyl sulphide (660 K).[52,53]



The photoelectron spectrum of monomeric thioacrolein was obtained in a study of the thermolysis products of the Diels–Alder dimers (LVIIa, b). This thermal reaction made thioacrolein available for preparative purposes and further spectroscopic studies.[52,53]

10. The cleavage of disulphides and their derivatives

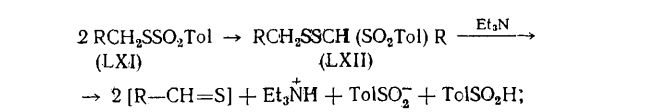


New precursors of TA have been discovered in recent years.[20,21,54] In particular, these proved to be alkyl thiosulphinates, whose thermolysis has become a general and convenient method of synthesis of TA.[54,55] Thus, when *S*-benzyl phenylmethanethiosulphinate (LVIII) is heated in toluene at 100 °C, thiobenzaldehyde is formed. The blue colour which its presence imparts to the reaction mixture [UV spectrum: λ_{max} = 580–590 and 610 nm (shoulder), which corresponds to the spectrum at 77 K of thiobenzaldehyde obtained by the vacuum flash pyrolysis of allyl benzyl sulphide[50]] vanishes after 15 min at 20 °C.[54]

The thermolysis of the thiosulphinates (LVIII) is usually carried out in the presence of dienes of anthracene, which are TA "trapping agents".[54,55] The adduct with anthracene (LIX) (97% yield) can itself serve as a source of thiobenzaldehyde. When it is heated in the presence of 2,3-dimethylbutadiene in a sealed tube, the 2*H*-dihydrothiane (VI) and anthracene are formed.

The readily available Bunte salts (LX) are very convenient for the synthesis of TA with electron-accepting substituents.[20] They readily undergo 1,2-elimination on treatment with triethylamine and calcium chloride. The corresponding cyclic adducts (IV)–(VI) were obtained from them in the presence of conjugated dienes. Under these conditions, sodium *S*-4-nitrobenzyl thiosulphate (LXe) gives rise to the adduct (IV)–(VI) in high yields. On the other hand, the unsubstituted benzyl derivative (LXd) does not afford such adducts at all. This example demonstrates the significant role of the CH acidity of the methylene group in compound (LX) and shows that the conjugation of the thioformyl functional group with the benzene

ring cannot by itself ensure the 1,2-elimination process.[20]

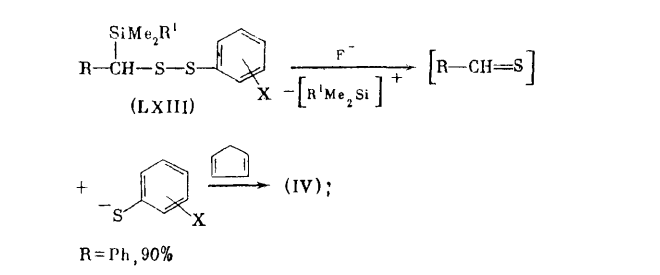


R = Et–CO (a), (Sect.III), Ph–CO (b), (Sect.III), PhNH–CO (c) (Sect.III), Ph (d), 4-$NO_2C_6H_4$ (e).

In methanol at 20 °C, thials react with cyclopentadiene to form the adducts (IV) and (V) in high yields (66–86%), while the reaction with 2,3-dimethylbuta-1,3-diene produces adducts in a lower yield. In a less polar system (benzene–ethanol), the yield of the adducts (VI) rises to 55–65%. The competitive attack by nucleophiles (for example, SO_3^{2-}) on the TA is probably lessened under these conditions.

The ability of the adducts (IV)–(VI) to dissociate on heating makes them valuable sources of reactive TA.[20]

Toluene-*p*-thiosulphonates (LXI) are readily converted into α-sulphonyl disulphides (LXII) which are cleaved with formation of TA on treatment with triethylamine similarly to the Bunte salts:[21]

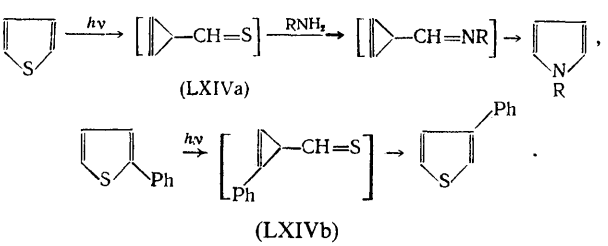


R = EtO–CO (a) (Sect.III), 4-BrC_6H_4–CO (b) (Sect.III), Ph (c), 4-$NO_2C_6H_4$ (d); Tol = 4-MeC_6H_4.

The disulphides (LXIIa, b, d) react with triethylamine at 20 °C and with a solution of cyclopentadiene in benzene to form the corresponding adducts (IV) and (V), the *endo*-isomer (IV) predominating. Among the starting compounds, the benzyl derivative (LXIIc) is least reactive. Nevertheless, it forms the adducts (IVc) and (Vc) in acetonitrile.

This new TA generating reaction has been called a fragmentation–elimination process via a concerted mechanism.[21]

An elegant and general method of synthesis of thioformyl compounds from aryl[α-(dimethylorganylsilyl)organylmethyl] disulphides (LXIII) has been proposed recently.[56] On treatment with the F^- anion, the disulphides are readily cleaved to the corresponding TA and the arenethiolate anion.

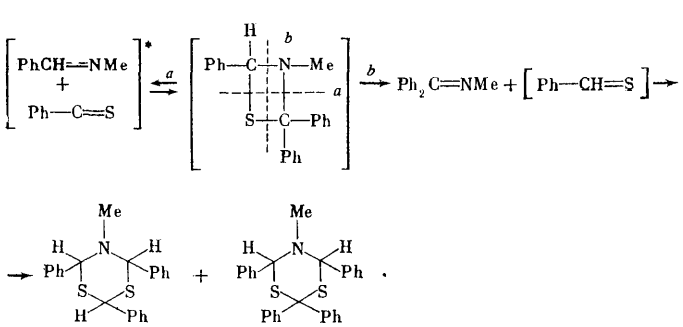


The effectiveness of the cleavage is determined by the stability of the arenethiolate leaving group. 2,4,6-Trichlorophenyl disulphides (LXIII, X = 2,4,6-trichloro-group) are extremely unstable. The 2-nitro-4-chloro-derivatives (LXIII, X = 2-NO_2 or 4-Cl) are extremely reactive, while the unsubstituted disulphides (LXIII, X absent) are cleaved only on heating.

The rate of fragmentation-elimination is also influenced by the reactivity of the source of the fluoride ion. In the presence of 18-crown-6, CsF or KF generate TA slowly at 20 °C, while tetrabutylammonium fluoride ($NBu_4^+F^-$) in tetrahydrofuran acts rapidly in the temperature range from 0 °C to –78 °C.

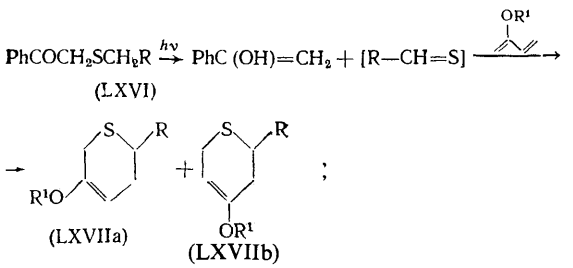
Thiobenzaldehyde adds to cyclopentadiene, forming a mixture of the cyclic *exo*- and *endo*-adducts (V) and (IV) in proportions of 1 : 7. The predominance of the *endo*-isomer can be due to the kinetic factor, but Dreiding models show that the *endo*-isomers are sterically less hindered and should therefore be more stable.[56]

11. Photochemical methods



Certain types of conjugated TA are generated in photochemical reactions and play an important role in them.[8,57,58] Thus 3-thioformylcyclopropene (LXIVa) is an intermediate in the photolytic conversion of thiophen into *N*-alkylpyrroles in the presence of amines.[57] The formation of 1-thioformyl-2-phenylcyclopropene (LXIVb) has been explained by the rearrangement of 2-phenylthiophen to 3-phenylthiophen under the influence of UV irradiation.[58]

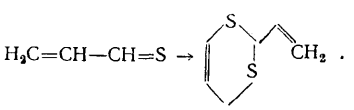
(LXIVa)



(LXIVb)

The formation of a polymer in the photolysis of ω-benzylthioacetophenones is apparently due to the intermediate generation of the monomeric thiobenzaldehyde.[8] The same TA is probably an intermediate in the formation of substituted 1,3,5-dithiazines (LXVa, b) and benzophenone methylimine from photoexcited thiobenzophenone and benzaldehyde *N*-methylimine.[8]

(LXVa) (LXVb)

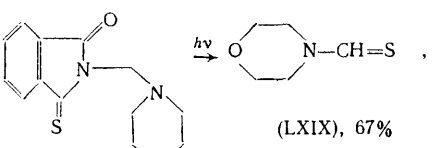


A simple method of synthesis of dienophilic TA by irradiating a mixture of organyl phenacyl sulphide (LXVI) with a diene at 0 °C has been developed recently.[59,60]

(LXVI) (LXVIIa) (LXVIIb)

R=H, Ph, Me—CO, Ph—CO, CN, AlkO—CO, Ph_2PO, $PhSO_2$, EtO—CO—CH=CH; $R^1 = SiMe_2$—t-Bu.

The use of the most reactive dienes (for example, Danishevskii's diene)‡ makes it possible to "trap" the "exotic" thioformylsulphone ($PhSO_2$—CH=S) and thioformylphosphine oxide (Ph_2PO—CH=S), whose oxygen analogues are unknown.[60] In the case of the αβ-unsaturated TA (EtO—CO—CH=CH—CH=S), the yield of the adduct (LXVIIa) is low (10%), although the products of the self-condensation of this thial have not been detected. Under analogous conditions, thioacrolein cannot be trapped by the usual dienes, since it is stabilised as the dimer—2-vinyl-1,3-dithiene:[59]

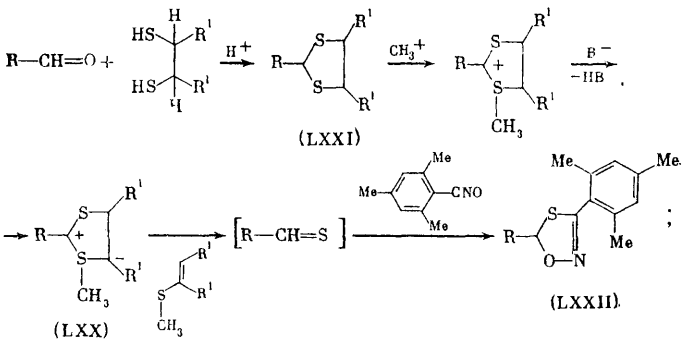


An excess of the diene and carefully purified reagents are necessary for the synthesis of the adducts (LXVII) in order to reduce to a minimum the catalytic thial self-condensation.[60] The yields of the adducts of TA with electron-donating substituents depend significantly on the structure of the diene, the nature of the substituent R in the TA, and the reaction conditions.

The regiospecificities of the cyloaddition of the compounds R—CH=S containing electron-accepting or electron-donating substituents R are not the same. In the presence of electron-accepting substituents, TA react like carbon dienophiles. Otherwise they behave similarly to carbonyl dienophiles. This difference agrees with quantum-chemical calculations.[60]

By virtue of the different regioselectivities of the reactions of dienes with TA having electron-donating or electron-accepting substituents, a large series of dihydrothiopyrans have become available.[61]

The photolytic cleavage of *N*-(*N*-morpholinomethyl)thiophthalimide (LXVIII) to the *N*-thioformylamine (LXIX),[62] which belongs to the class of the simplest thioformamides, proceeds in an unusual manner. The initial stage of this process is apparently the elimination of a proton from the methylene bridge.



(LXVIII) (LXIX), 67%

‡CH_2=CH(OSiMe$_3$)—CH=CH—OMe.

12. Fragmentation of S-ylides

A novel method of synthesis of TA, based on the fragmentation of S-ylides of type (LXX), generated from an aldehyde (the oxygen analogue of the target TA) via the 1,3-dithiolan (LXXI), was proposed in 1985.[63] It proceeds in accordance with the scheme

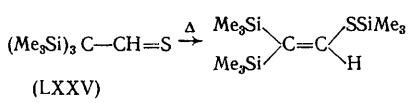
(LXXI) (LXX) (LXXII)

R = Ph, H_2C=CH.....

The TA obtained react with mesitonitrile *N*-oxide to form stable 1,4,2-oxathiazoles (LXXII). In the absence of a "trapping agent", polymers or trimers are formed. In order to obtain thioacrolein, it is sufficient to treat its precursor—1,3-dithiolan (LXXI, R=CH=CH_2, R^1 = COOMe)—with lithium diisopropylamide. Thus 1,3-dithiolans are convenient reagents for the single-stage synthesis of highly reactive TA.[63,64]

This method harmoniously supplements the photochemical[59,60] or thermochemical[50–53] approaches to the synthesis of TA. It provides greater synthetic possibilities than does the 1,2-elimination induced by a base[20,21] or the cleavage of aryl [α-(dimethylorganylsilyl)-organylmethyl] disulphides.[56]

V. Sterically stabilised thioaldehydes



For more than 100 years, the attempts to obtain monomeric aliphatic TA were unsuccessful.[6,11] It was not until 1983 that it was possible to synthesise the first long-lived aliphatic TA—2,2-dimethylpropanethial (LXXIII).[65] The starting material for its synthesis was neopentyl phenacyl sulphide (LXXIV), whose photolysis in benzene in the presence of 5% of 2,3-dimethylbutadiene leads to the polymer [t-BuCH—S—]$_n$ in 60% yield. When this polymer is heated *in vacuo* (≥ 250 °C), 2,2-dimethylpropanethial (LXXIII) is formed (Table 1, No. 19).

The lifetime of this TA in chloroform, benzene, methylene chloride, or ether at 20 °C reaches 16 h. The relative stability of the TA (LXXIII) is probably determined not only by the bulky t-butyl group but also by the purity of the starting materials, which rules out the catalytic self-reactions of the thial. Indeed, its lifetime in a chloroform—ethanol mixture (15 min) falls to 5 min after the addition of trieythylamine and to several seconds in the presence of traces of HCl. The monomeric trimethylpropanethial (LXXIII) and its solution are extremely stable in air.

The first stable aliphatic Si-functional TA—tris(trimethylsilyl)-ethanethial (LXXV)—has been described recently.[17] Its synthesis is based on the reaction of tris(trimethylsilyl)methyllithium (LXXVI) with *O*-ethyl thioformate in tetrahydrofuran at –78 °C (10 min) and further at 20 °C (1.5 h) (Table 1, No. 20).

The thial (LXXV) is a pink-red crystalline compound which can be stored for a long time in the refrigator without changes and is

stable in air at 20 °C for about a week. This compound can be purified by column chromatography on silica gel or by freezing out from pentane at −78 °C. At ~80 °C, the TA (LXXV) rearranges quantitatively to 1,1-bis(trimethylsilyl)-2-trimethylsilylthioethene:

(LXXV)

The first stable *exo*-substituted thiobenzaldehyde—2,4,6-tris-t-butylthiobenzaldehyde (LXXVII)—was obtained by the reaction of 2,4,6-tri(t-butyl)phenyllithium (LXXVIII) with *O*-ethyl thioformate in tetrahydrofuran followed by chromatographic purification.[16] Another route to the synthesis of the TA (LXXVII) is based on the reaction of the hydrazone (LXXIX) with sulphur dichloride in the presence of triethylamine[16] (Table 1, No. 21).

The thial (LXXVII) is a strikingly stable purple crystalline compound which can be preserved for about a year at 20 °C or for two weeks on refluxing in benzene without access by air. The unsubstituted thiobenzaldehyde polymerises already at −160 °C.[50]

VI. Physical properties of compounds with the thioaldehyde group

According to microwave specroscopic data, the C=S bond length in the monomeric thioformaldehyde is 1.6108 Å.[66] This is longer than the C=O bond length in formaldehyde (1.2083 Å)[66] and is consistent with the predicted interatomic distance in the unperturbed thiocarbonyl group (1.607 Å).[11] The calculated dipole moment of thioformaldehyde is 1.6474(14) D.[67] Since μ for gaseous $CH_2=O$ is 2.27 D,[68] this shows that the polarity of the C=S bond is smaller than that of the C=O bond.

It has been established by microwave spectroscopy that the thioacrolein molecule is planar and has a dipole moment of 2.61 D.[51]

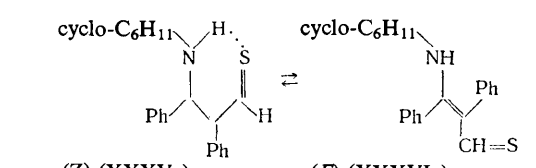
The photoelectron spectra of thioacrolein and acrolein are almost the same with ionisation peaks at 8.87 and 10.2 eV respectively.[52]

It is remarkable that the mass spectra of heterocyclic TA, namely 1,2-dimethyl-3-thioformylindole (XXIXa), 2-methyl-3-thioformylindolizine (XIIb), and 6-methyl-5-thioformylpyrrolo[2,1-*b*]thiazole (XXVIIIa), are characterised by an intense $(M-45)^+$ peak corresponding to the loss of the thioformyl group.[33]

The position of the absorption band of the thiocarbonyl group in the IR spectra (1100−1270 cm^{-1}) has now been reliably established as a result of the successful development of the chemistry of thioketones.[11]. The C=S bond stretching vibrations in the spectra of TA are in the same region. Thus the band at 1063 cm^{-1} corresponds to the absorption of the thiocarbonyl group in the IR spectrum of thioformaldehyde in an inert gas matrix at 14 K.[69] The absorption bands of the C=S group in the spectra of sterically stabilised TA, i.e. $Me_3C-CH=S$ (LXXIII) and $(Me_3Si)_3C-CH=S$ (LXXV), are at 1085 and 1120 cm^{-1} respectively.[17,65] The IR spectra of the stable heterocyclic TA (XXIXa), (XII), and (XXVIII) contain an intense band in the range 950−985 cm^{-1}.[33] The study of the solvent effect led to its assignment to the C=S bond vibration. In the spectrum of the TA (XXIXa), this band shifts from 978 cm^{-1} in cyclohexane to 956 cm^{-1} in 1,1,2,2-tetrabromoethane.[33] In the spectrum of the enaminothioaldehyde (XIII), the band at 1260 cm^{-1} corresponds to the ν(C=S) vibration.[29]

The electronic spectra of TA are characterised as a rule by three absorption regions due to the $n \rightarrow \pi^*$ transition in the visible part of the spectrum and the $\pi \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ transitions in the UV region. The electronic spectra of stable heterocyclic TA—thioformylindolizines (XII)[28] and thioformylpyrrolo[2,1-*b*]thiazoles (XXVIII) and (XXXI)[34]—have been studied in detail. Thus the spectra of 3-thioformylindolizines (XII) contain four groups of intense maxima in the ranges 420−460, 300−325, 250−275, and 205−230 nm ($lg\varepsilon > 3.7$). Three intense absorption regions can be observed in the spectra of 1-thioformylindolizines (XXX): 420−460, 260−280, and 210−240 nm. The difference between the overall forms of the spectra makes it possible to recognise readily 1- and 3-thioformylindolizines.[28] The spectra of 3-thioformylindolizines (XII) are characterised by two broad low-intensity bands (~520 and ~550 nm) ($lg\varepsilon$ = 1.9−2.2), which do not have a distinct minimum. These bands undergo a hypsochromic shift with increase in solvent polarity and belong to the $n \rightarrow \pi^*$ transition in the thiocarbonyl group. The cause of the multiplicity of the spectrum still remains obscure. The spectrum of 2-t-butyl-1-thioformylindolizine (XXXa) in cyclohexane has a very broad $n \rightarrow \pi^*$ band with λ_{max} = 534 nm ($lg\varepsilon$ = 1.84) and a shoulder at ~570 nm, while in the spectrum of 2,3-dimethyl- 1-thioformylindolizine (XXXb) there is a similar band in the range from ~510 to 560 nm ($lg\varepsilon \simeq 1.9$).[28]

The electronic spectra of thioformylpyrrolo[2,1-*b*]thiazoles (XXVIII) and (XXXI)[34] and of 3-thioformylindole (XXIXb)[38] have a similar line form and the nature of the bands is likewise similar.



The electronic spectra of the sterically stabilised TA are characterised by the following parameters [the compound, λ_{max} (nm) (ε) the solvent, and the literature reference are quoted in succession]: $(CH_3)_3C-CH=S$, 508(16) (MeCN);[65] $(Me_3Si)_3C-CH=S$, 518(15), 272(9940), 212(4320) (C_6H_{12}); 503(14), 277(8720), 211(5330) (MeCN);[17] 2,4,6-t-$Bu_3C_6H_{12}-CH=S$, 564(19), 338(1850) (C_6H_{12}); 552(19), 340(1690) (EtOH).[16]

The spectra of the labile thioacrolein and thiobenzaldehyde have been recorded at 77 K under specially selected conditions.[50] The calculated values of λ_{max} agree very well with the experimental data.

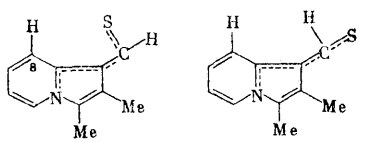
	λ_{max} (found)			λ_{max} (calc.)		
	$n\rightarrow\pi^*$	$\pi\rightarrow\pi^*$	$n\rightarrow\sigma^*$	$n\rightarrow\pi^*$	$\pi\rightarrow\pi^*$	$n\rightarrow\sigma^*$
$CH_2=CH-CH=S$	580	276	—	570	265	—
$C_6H_5-CH=S$	575	320	228	567	302, 296	231, 226

In the ^1H NMR spectra of thioaldehydes, the signal of the thioformyl proton is in a low field within a fairly wide range [δ(p.p.m.) ranges from 9 to 13].[17,28,29,33,34,36,38–40,42,65] It is believed that 2,4,6-tri(t-butyl)thiobenzaldehyde (LXXVII) contains the "purest" thioformyl group whose proton signal is at δ = 13.02 p.p.m.[16]

According to ^1H NMR spectroscopic data, the enaminothial (XIII) exists to the extent of 95% as the rotational *S-trans*-isomer with a barrier to the unhindered rotation about the C−N bond of 17.1 kcal mol^{-1} at the coalescence temperature of 330 K.[29]

(Z)-(XXXVe) (*E*)-(XXXVIe)

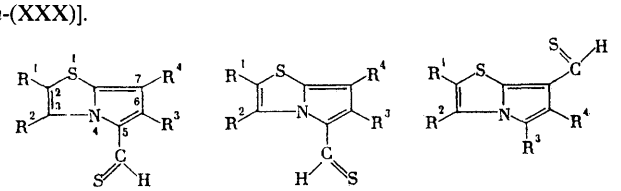
δ, p.p.m. 15.24 (NH) 5.41 (NH)



9.82 (CH=S) 9.95 (CH=S)

The thioaldehydes (XXXVIa–d) and (*Z*)-isomers and their structure corresponds to that of the initial enamines. The cyclohexylamino-substituted TA (XXXVIe) contains ~10% of the (*E*)-isomer.[36]

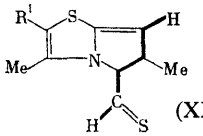
The ^{1}H NMR spectra of the thioformylindolizines (XII) and (XXX) have been investigated in detail.[28] The 1- and 3-thioformyl groups exert a strong diamagnetic anisotropic deshielding effect on the H(8) and H(5) atoms respectively located on the opposite side. The H(5) chemical shifts in the spectra of 3-thioformylindolizines (XII) are in the range δ = 11.1–11.6 p.p.m. In 2,3-dimethyl-1-thioformylindolizine (XXXb), the rotation about the ring–CH=S bond is hindered. This can be explained by the appreciable contribution of the dipolar mesomeric form (B):[28]



$$\underset{(A)}{R{-}CH{=}S} \leftrightarrow \underset{(B)}{\overset{+}{R}{=}CH{-}S^-}$$

Pronounced deshielding of H(8) and the singlet signal of the thioformyl proton show that below the coalescence temperature, the TA (XXXb) exists exclusively in the *syn*-configuration, which is more stable than the *anti*-form. This is determined by the intramolecular electrostatic attraction between the charges on the sulphur atom and the pyridine ring, which corresponds to a minimum in the potential energy of the molecule.[28]

syn-(XXXb) *anti*-(XXXb)



The temperature dependence of the ^{1}H NMR spectra shows that the rotation about the heterocyclic-CH=S bond is hindered in thioformylpyrrolo[2,1-*b*]thiazoles (XXVIII) and (XXXI).[34] These data agree with the existence of the 5-thioformyl derivatives (XXVIII) ether in the *syn*-configuration [compounds (XXVIIIa–d)] or in the *anti*-configuration [compounds (XXVIIIe, f)], while the 7-thioformyl derivatives exist only in the *syn*-configuration [*syn*-(XXX)].

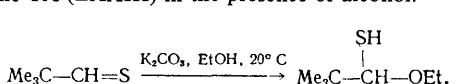
syn-(XXVIII) *anti*-(XXVIII) *syn*-(XXX)

	syn-(XXVIII)				*anti*-(XXVIII)				
	R^1	R^2	R^3	R^4		R^1	R^2	R^3	R^4
a	H	H	Me	H	e	H	Me	Me	H
b	Me	H	Me	H	f	Me	Me	Me	H
c	H	H	Me	Me					
d	H	Me	t-Bu	H					

The higher stability of the 5- and 7-*syn*-thioformyl derivatives relative to their *anti*-isomers is a consequence of the intramolecular electrostatic attraction of the partial charges on the sulphur atom of the thioformyl group and on the thiazole ring. Compounds (XXVIIIe, f) exist preferentially in the *anti*-form owing to the steric effect of the 3-methyl substituent, which repels the thioformyl sulphur atom from the plane of the ring. In compounds (XXVIIId), the effect of the t-butyl group is superimposed on that of the 3-methyl group, which forces the thioformyl group into the *syn*-configuration. The presence of the long-range spin–spin H(7)–CH=S interaction [the spin–spin coupling constant (SSCC) is 0.8 Hz] in the thioaldehydes (XXVIIIe, f) constitutes additional demonstration of their existence in the *anti*-form. In these TA, the H(7)–CH=S protons are disposed in the *W*-configuration (*W*), which is most favourable for the effective interaction through the conjugated system.[34]

(XXVIII), R^1 = H (e) or Me (f)

(*W*)

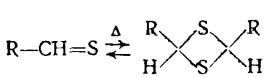


The ^{13}C NMR spectroscopic data for thioaldehydes are extremely limited. However, the existing information shows that the carbon nucleus of the ^{13}C=S moiety of the thioformyl group resonates in the region characteristic of thioketones.[11,16,17,70]

VII. Chemical properties of thioformyl compounds

The high reactivity of thioaldehydes can be inferred even from their extremely high tendency to undergo trimerisation, oligomerisation, and polymerisation. Not only the structure but also the conditions of the synthesis of TA determine the yield of particular products. Thus the synthesis of thioformaldehyde from formaldehyde and hydrogen sulphide in the presence of HCl leads mainly to the formation of the cyclic trimer (1,3,5-trithiane), while in an alkaline medium readily fusible polymers have been obtained.[71] The synthesis of thiobenzaldehyde from benzaldehyde and H_2S in a highly acid medium leads mainly to the more stable β-isomer; a weakly acid medium and a low reaction temperature afford not only greater amounts of the α-isomer but also a greater amount of the polymer with a molecular weight of ~1000.[71]

It has been convincingly demonstrated[72] that the self-transformations of the monomeric TA are catalytic processes. The addition of protic or Lewis acids induces the instantaneous trimerisation and polymerisation of 2,2-dimethylpropanethial (LXXIII) in all solvents. The authors explain by this observation the failure of many investigators to detect monomeric TA in the acid-catalysed thionation of aldehydes.



The decomposition of TA is also promoted by basic catalysts (triethylamine, K_2CO_3). Small amounts of the thioacetal (LXXX) and the isomeric 1,3,5-trithianes are formed under these conditions from the TA (LXXIII) in the presence of alcohol.[72]

(LXXIII) (LXXX)

In pure ether and chloroform, the TA (LXXIII) exists for a long time in the monomeric state but hydroxylated solvents induce its rapid trimerisation.[72]

Like non-enolisable thioketones, TA undergo reversible "head to tail" thermal dimerisation.[73]

R=Alk, Ar.

Thioacrolein is stabilised as the dimer (1,3-dithietan)[59] (see Section IV); dithianes can lose their thial sulphur and can be converted into symmetrically substituted ethylenes.[40] However, evidence for the formation of a dimeric product from 2,2-dimethylpropanethial (LXXIII) has not been obtained.[72]

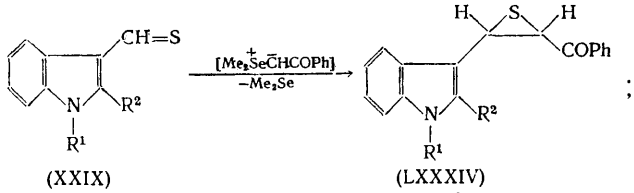
TA are reactive in various reactions with nucleophiles. The aminolysis of the intermediate thioformaldehyde is an important step in the reactions of methanesulphenyl halides with secondary amines.[7]

$$[H{-}CH{=}S] \xrightarrow{R_2NH} (R_2N)_2CH_2 + H_2S.$$

Benzoylthioformaldehyde and morpholine, formed on decomposition of the sulphenamide (LXXXI), immediately react to form the *gem*-aminothiol (LXXXII).[74]

$$Ph{-}CO{-}CH_2{-}S{-}N(CH_2)_4 \rightarrow Ph{-}CO{-}CH{=}S + HN(CH_2)_4 \rightarrow Ph{-}CO{-}CH(SH){-}N(CH_2)_4$$

(LXXXI) (LXXXII)

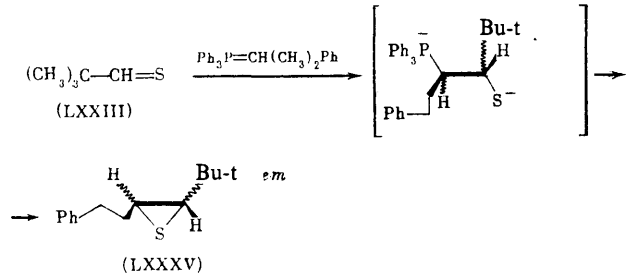


The *gem*-aminothiols (LXXXIII) are readily formed from thioformylimines and ammonia.[74]

$$R{-}C(=NH){-}CH{=}S \xrightarrow{NH_3} R{-}C(=NH){-}CH(SH){-}NH_2$$

(LXXXIII)

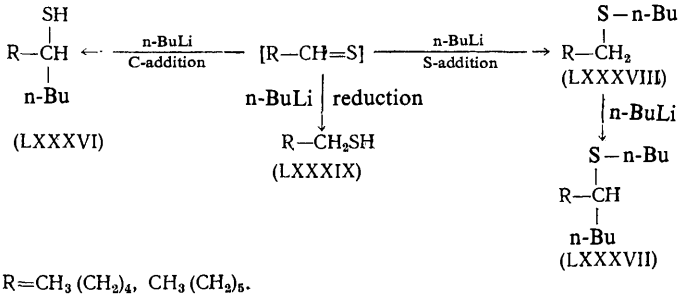
Like thioketones, thioaldehydes give rise to hydrazones and semicarbazones.[32,38]



Ylides behave as nucleophiles in reactions with thiocarbonyl compounds.[11] The interaction of 3-thioformylindoles (XXIX) with dimethylselenonium benzoylmethylide takes place readily in solution in DMF at 0 °C and leads to 3-benzoyl-2-indolythiirans (LXXXIV).[75]

(XXIX) (LXXXIV)

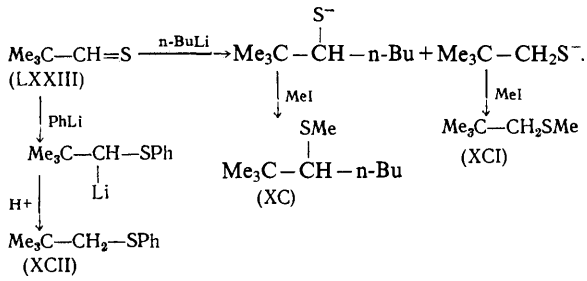
$R^1 = R^2 = Me$ (a); $R^1 = R^2 = H$ (b); $R^1 = H$, $R^2 = Me$ (c).



2,2-Dimethylpropanethial (LXXIII) reacts with (3-phenylpropylidene)triphenylphosphorane to form the thiiran (LXXXV).[72]

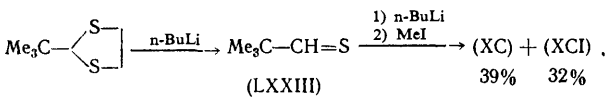
(LXXIII) (LXXXV)

The reactions of thioketones with organometallic compounds proceed via two competing pathways—the usual nucleophilic and/or thiophilic addition.[11]



In their study of the interaction of TA with n-butyllithium, Wilson and co-workers observed four types of reactions: C-addition, S-addition, double addition, and reduction.[76] The ratios of the products depend on the structure of the substrate, the solvent, and temperature. For example, $CH_3(CH_2)_4{-}CH{=}S$ reacts with a fourfold excess of n-BuLi in ether at 25 °C to form 73% of the thiol (LXXXVI), 19% of the sulphide (LXXXVII), and insignificant amounts (3 and 4%) of compounds (LXXXVIII) and (LXXXIX). At 0 °C, the yield of compound (LXXXVI) falls to 17%, while in tetrahydrofuran it falls to 2%.

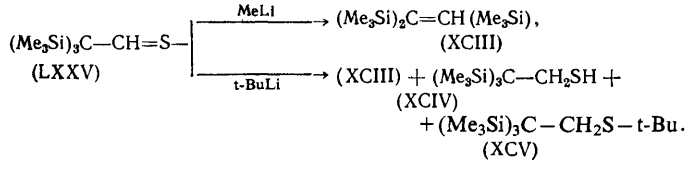
(LXXXVI) (LXXXIX) (LXXXVIII) (LXXXVII)



$R = CH_3(CH_2)_4$, $CH_3(CH_2)_5$.

2,2-Dimethylpropanethial (LXXIII) reacts in ether with n-BuLi to form an adduct via the carbon atom and a reduction product.[72] The formation of compounds (XC) (70%) and (XCI) (17%) after the addition of methyl iodide to the reaction mixture is convincing proof of the operation of the reaction pathways illustrated in the scheme.

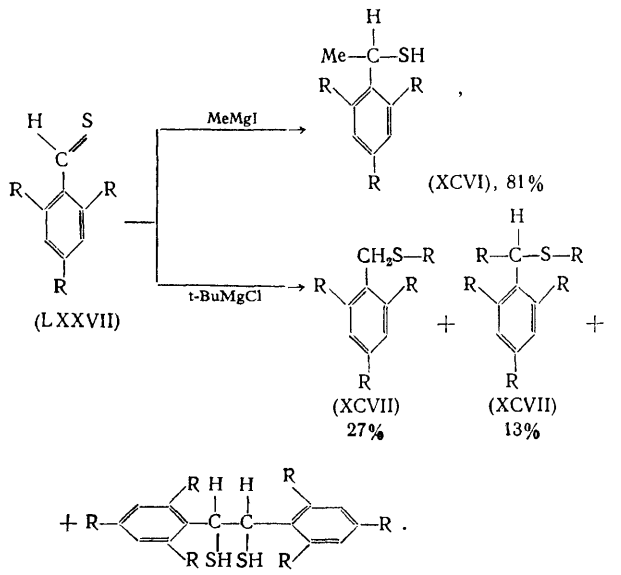
(LXXIII) (XC) (XCI) (XCII)



The reaction of 2-t-butyl-1,3-dithiolan with n-BuLi has been achieved[72] by Wilson's method.[76] The formation of the products (XC) and (XCI) in both cases indicates the involvement of the same TA (LXXIII) in the reactions.

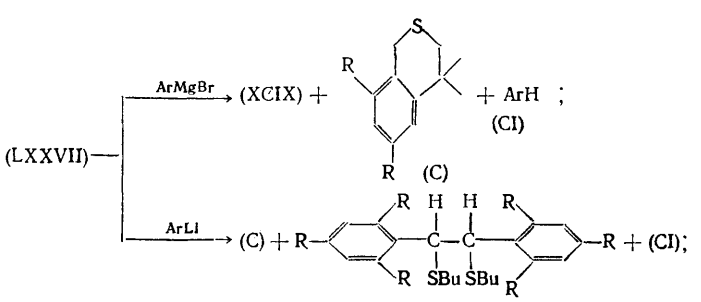
(LXXIII) (XC) 39% (XCI) 32%

The TA (LXXIII) reacts with phenyllithium via a thiophilic mechanism with formation of neopentyl phenyl sulphide (XCII) (30%).[65]



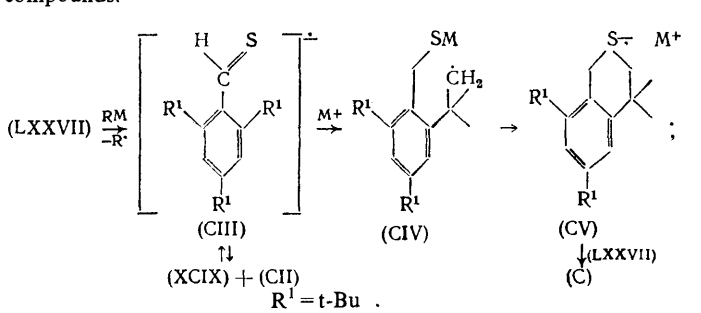
Treatment of tris(trimethylsilyl)ethanethial (LXXV) with methyl- or t-butyl-lithium leads to the alkene (XCIII) in 79 and 34% yields respectively.[17] The thiol (XCIV) (35%) and the sulphide (XCV) (10%) are also formed in the latter case.

(LXXV) (XCIII) (XCIV) (XCV)



The TA (LXXV) react with a Grignard reagent similarly but at a much lower rate.[17]

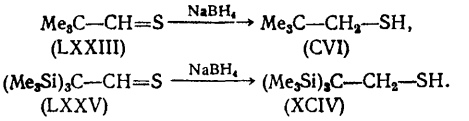
Interesting results have been obtained in the study of the reactions of the stable (2,4,6-tri-t-butyl)thiobenzaldehyde (LXXVII) with Grignard and organolithium reagents.[77] The interaction of the thial (LXXVII) with methylmagnesium iodide affords the thiol (XCVI), while the reaction with t-butylmagnesium chloride gives rise to three products: the sulphides (XCVII) and (XCVIII) and the α-dithiol (XCIX).



R = t-Bu (XCIX), 31%

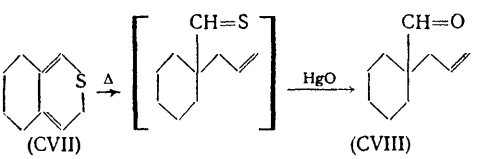
In the reactions with the very bulky 2,4,6-tri-t-butyl-substituted phenylmagnesium bromide or phenyllithium, the adducts formed via the carbon or sulphur atom were not detected.[77]

Ar = 2,4,6-(t-Bu)$_3$C$_6$H$_2$; R = t-Bu.



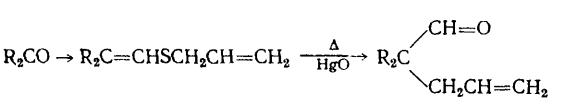
In order to account for the course of the reactions investigated, the authors resorted to the one-electron transfer mechanism[77] used at one time for the reactions of thioketones with organometallic compounds.[11]

R^1 = t-Bu.

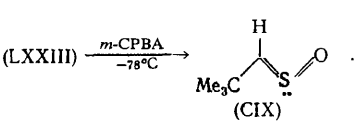


The key intermediate in the proposed scheme is the radical-anion (CIII). Its transformation via the pathway (CIII) → (CIV) → (CV) leads to compound (C), while its dimerisation affords the products (XCIX) and (CII). One should note especially that this is the first example of the dimerisation of thioketyl radicals and the first observation of the generation of a radical-anion from a TA.[77]

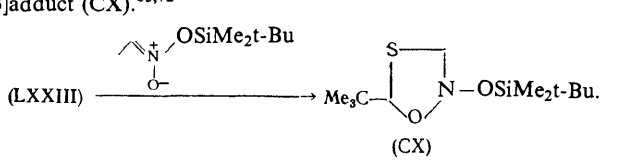
Like thioketones, thioaldehydes are readily reduced by the usual reductants to the corresponding thiols. Thus, treatment of 2,2-dimethylpropanethial (LXXIII) with sodium tetrahydroborate gives rise to the neopentanethiol (CVI);[65,72] tris(trimethylsilyl)-ethanethial (LXXV) is transformed quantitatively into the thiol (XCIV).[17] The reactions of TA with alkyl(aryl)lithium reagents or Grignard reagents are accompanied by reduction.[17,65,72,77]



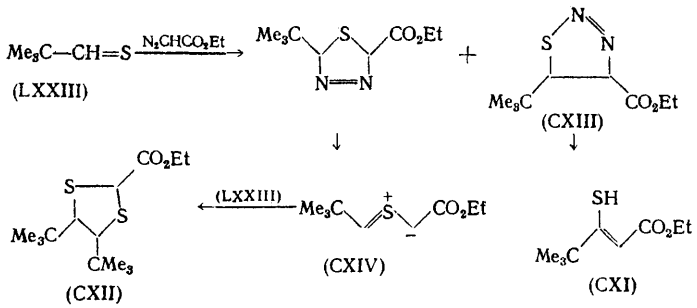
The tendency of TA to oxidise in the presence of atmospheric oxygen has been noted.[39–42] Even the extremely stable t-butyl-substituted thiobenzaldehyde (LXXVII) is converted into the corresponding aldehyde on treatment with oxygen.[16]



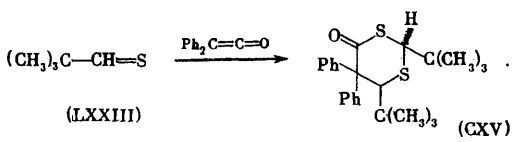
The oxidation of TA *in situ* is of interest for the determination of the reaction mechanism and for preparative purposes. Thus, whereas simple heating of the sulphide (CVII) at 160–180 °C leads to polymeric products, in the presence of red mercury oxide the aldehyde (CVIII) has been obtained in 82% yield.[78]



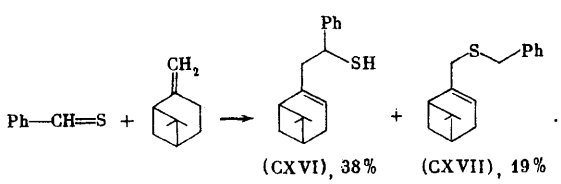
This procedure expands significantly the applicability of the thio-Claisen rearrangement and permits its employment for the synthesis of unsaturated aldehydes from carbonyl compounds.[78]



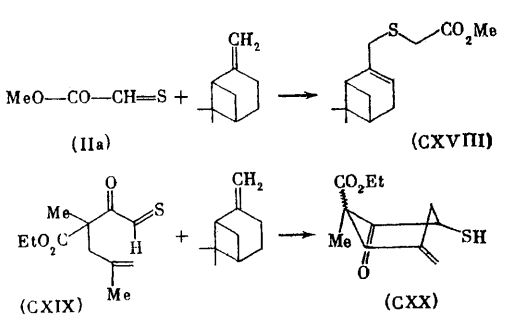
The oxidation of the TA (LXXIII) with *m*-chloroperbenzoic acid (*m*-CPBA) at a low temperature leads to the sulphine (CIX).[65,72]



A distinctive feature of thiocarbonyl compounds is their ability to enter into 1,3-dipolar cycloaddition reactions with formation of valuable heterocyclic compounds.[11] In TA, this property is particularly marked and it has been used successfully to trap TA *in situ*.[22,72] Thus, 2,2-dimethylpropanethial (LXXIII) reacts instantaneously with the nitronate ester and affords the cyclic [2 + 3]adduct (CX).[65,72]

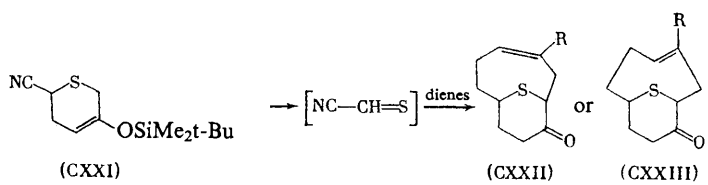


Thiocarbonyl compounds react with diazoalkanes to form the regioisomeric cyclic [2+3]adducts.[11] After the interaction of 2,2-dimethylpropanethial (LXXIII) with ethyl diazoacetate, the thiol (CXI) and an inseparable mixture of the diastereoisomers of compound (CXII) were obtained in equal amounts. The formation of compound (CXI) has been explained by the S–N heterolysis of the thiadiazoline (CXIII) formed initially and subsequent hydride transfer. The dithiolan (CXII) is formed via the thiocarbonyl ylide (CXIV).[65]

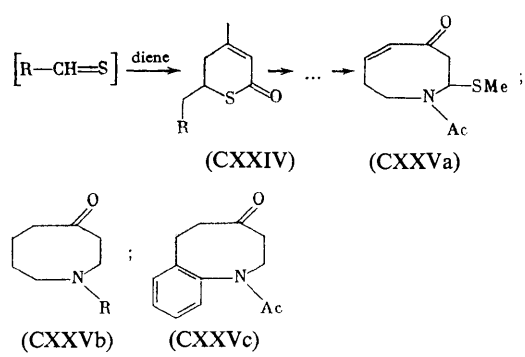


The reaction of the TA (LXXIII) with diphenylketen affords a mixture of 2:1 cyclic adducts (CXV) in a moderate yield. The reaction with dimethylketen or 1,1-diphenylallene do not occur.[72]

Thiobenzaldehyde is capable of participating as a 2π-component in the reaction involving addition to the double bond of β-pinene.[55] The formation of two adducts (CXVI) and (CXVII) is due to the different modes of addition.



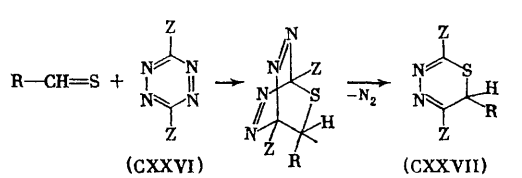
The photochemically generated TA (IIa) reacts with β-pinene at 20 °C to form the sulphide (CXVIII), while the TA (CXIX) affords the substituted cyclohexanone (CXX).[79]



The reactions involving the "ene-inclusion" of TA are evidently promising for the synthesis of cyclic structures under mild conditions. The reactions of TA having electron donor or electron acceptor substituents, generated in different ways, with a wide variety of dienes were examined in detail in Sections III–V. Here it is useful to note studies specially devoted to the cycloaddition reactions of TA.

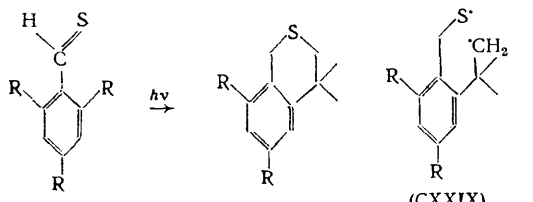
The characteristic features of the behaviour of thiobenzaldehyde, thioacetaldehyde, and certain other TA in reactions with 2,3-dimethylbutadiene (2,3-DMBD), anthracene, and 9,10-dimethylanthracene have been investigated in detail.[55] It has been found that benzene and toluene are the most suitable solvents, while DMF reduce the yield of the adduct. Appreciable attention has been devoted to the regiochemistry of the cycloaddition reactions and to its relation with the nature of the substituent in TA.[22,61] The dihydrothiopyrans obtained from TA in accordance with Diels–Alder principle can play an important role in the synthesis of natural products, especially of the juvenile hormone, erythronolides, analogues of zygosporin, etc.[61]

The adduct of cyanothioformaldehyde with 2-(t-butyldimethylsiloxy)buta-1,3-diene (CXXI) served as the starting compound for the recently developed synthesis of sulphur-containing bridged cyclodecenones (CXXII) and (CXXIII), which are otherwise difficult to obtain.[80]



Several methods of synthesis of azocine derivatives (CXXV) have been developed from nitrogen-containing cyclic adducts (CXXIV).[81]

R = $NHCO_2t$-Bu, CH_2NHCO_2t-Bu, $CH_2N(Me)CO_2t$-Bu.

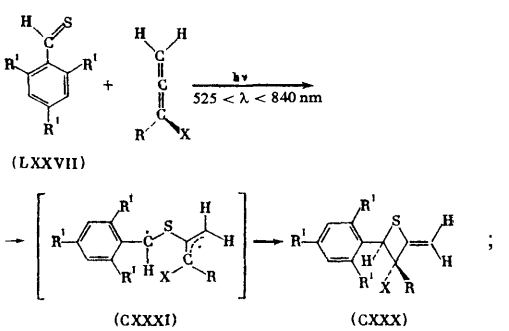


TA with electron-dontaing substituents—thioformates, thioformamides, and thiobenzaldehyde—behave as heterodienophiles in the reaction with tetrazine (CXXVI).[82] The thiadiazones (CXXVII), obtained as a result of the [4+2]cycloaddition, can lose the sulphur atom and can be converted into pharmacologically interesting pyrazoles.

R = OEt, OPr, $N(CH_3)_2$, $N(CH_2)_4O$, $N(CH_2)_5$, Ph.

The unusual properties of the excited thiocarbonyl functional group have been responsible for the development of the photochemistry of thiocarbonyl compounds.[11] The irradiation of a

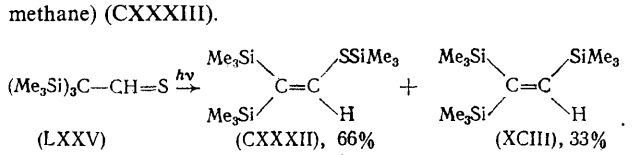
benzene solution of (2,4,6-tri-t-butyl)thiobenzaldehyde (LXXVII) solution by light from a mercury or sodium lamp ($\pi \rightarrow \pi^*$ or $n \rightarrow \pi^*$ excitation respectively) leads to the benzothiolan derivative (CX) in 91 or 96% yield respectively.[83] The photochemical formation of the heterocycle (CX) is in this instance unexpected, since the known photochemical reactions of aromatic thioketone containing δ-hydrogen atoms afford cyclopentanethiol derivatives.[11] The occurrence of δ-cyclisation via $n \rightarrow \pi^*$ excitation is also of special interest; in aromatic thioketones, this process takes place via the $S_2(\pi \rightarrow \pi^*)$ state.[11]



(LXXVII) (C) (CXXIX)

R = t-Bu.

A choice between the possible mechanisms of this reaction—the concerted [2+2]reaction or radical cyclisation via the biradical (CXXIX)—has not so far been made.[83]

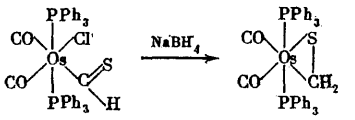


The photochemical reaction of the TA (LXXVII) with unsaturated cumulated systems has been investigated.[84] Irradiation of the TA (LXXVII) jointly with alkoxy-, alkylthio-, or phenylallenes led to a single stereoisomer, namely the thietan (CXXX), via the intermediate biradical (CXXXI).[84]

(LXXVII) (CXXXI) (CXXX)

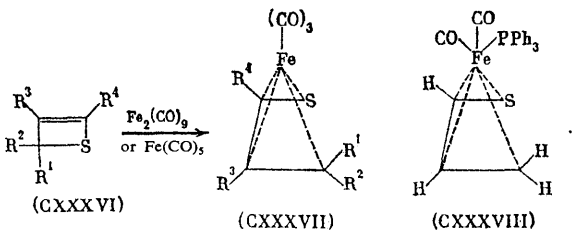
R = t-Bu.

The photolysis of tris(trimethylsilyl)ethanethial (LXXV) affords two compounds—the substituted sulphide (CXXXII) and the substituted ethene (XCIII).[17] Irradiation of the corresponding aldehyde under analogous conditions led to tris(trimethylsilylmethane) (CXXXIII).



(LXXV) (CXXXII), 66% (XCIII), 33%

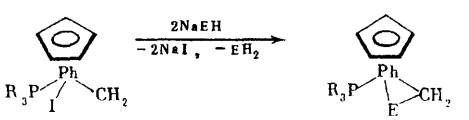
$(Me_3Si)_3C-CH=O \xrightarrow{h\nu} (Me_3Si)_3CH.$ (CXXXIII)



The formation of compound (CXXXII) from the TA (LXXV) via the 1,2-shift of the $SiMe_3$ group from the α-position to the thiocarbonyl carbon atom with the accompanying desulphurisation constitutes a new type of photochemical reaction of thiocarbonyl compounds.[17]

The ability of thioformyl compounds to form complexes with transition metals has been used successfully to detect short-lived TA. The first stable crystalline complex (CXXXIV) of thioformaldehyde has been obtained by the reaction of the unstable thioformyl derivative (CXXXV) with sodium tetrahydroborate.[85]

(CXXXV) (CXXXVI)



Complexes of the unstable thioacrolein (CXXXVII) have been obtained as red or orange crystals or oils by heating the thiets (CXXXVI) with iron nonacarbonyl or by treating them with iron pentacarbonyl and irradiating.[86] The structure of the complexes (CXXXVII) was established by the X-ray diffraction of the triphenylphosphine derivative (CXXXVIII) formed from compound (CXXXVII) by substituting one of the carbonyl groups by the PPh_3 ligand. The ^1H NMR spectra of the complexes (CXXXVII) have been compared with the spectrum of the molybdenum complex of acrolein.[86]

(CXXXVI) (CXXXVII) (CXXXVIII)

Rhodium complexes of thioformaldehyde and its chalcogen analogues have been obtained recently.[87] The first data are already available on selenoformaldehyde,[88] while telluroformaldehyde is so far unknown.

Compound (CXXXIX) reacts at room temperature in tetrahydrofuran with sodium hydrogen sulphide to form the thioformaldehyde complex (CXLa) in 50% yield. Treatment with NaSeH or NaTeH afforded similarly the complexes of selenoformaldehyde (CXLb) and telluroformaldehyde (CXLc).[87]

(CXXXIX) (CXL)

E = S (a), Se (b), Te (c).

- - - o0o - - -

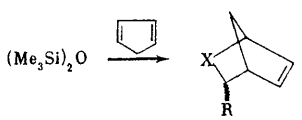
The fluorine-containing aliphatic TA (CXLI) are formed in the reactions of trialkyl phosphorothionates with ω-hydroperfluoroaldehydes (CXLII) on heating the reactants at 80 °C for 3 h.[89] The ^1H NMR spectrum of the reaction mixture shows a signal at δ = 10.35 p.p.m., which refers to the proton of the monomeric form of the TA (CXLIa), whose content is about 10%. The TA (CXLI) persist in solution at 20 °C for a long time. They react with 2,3-DMBD and isoprene to form the corresponding cyclic adducts.

$$\underset{\text{(CXLII)}}{H(CF_2)_nCH=O} + (RO)_3P=S \rightarrow \underset{\text{(CXLI)}}{[H(CF_2)_nCH=S]} + (RO)_3P=O,$$

n = 4 (a), 6 (b).

A selective route to the synthesis of the unstable thiopropynal (CXLIII) involving the vacuum pyrolysis of dipropargyl sulphide has been found.[90]

$$CH{\equiv}CCH_2SCH_2C{\equiv}CH \xrightarrow[-CH_2{=}C{=}CH_2]{750-950\,^{\circ}C,\ 10^{-3}\ torr} CH{\equiv}C{-}CH{=}S.$$



(CXLIII)

The ionisation potential of the TA (CXLIII) is 8.92 ± 0.05 eV and agrees well with the ionisation potentials of other thiocarbonyl compounds.[90] The C=S bond stretching vibration frequency in the IR spectrum of the TA (CXLIII) recorded in an argon matrix at 12 K is about 1100 cm^{-1}.[91]

A new simple method for the direct conversion of aldehydes into thio- and seleno-aldehydes with the aid of bis(trimethylsilyl)sulphide or selenide (CXLIV) in the presence of a catalytic amount n-butyllithium has been proposed.[92]

$$R{-}CH{=}O + (Me_3Si)_2X \xrightarrow[THF]{n\text{-}BuLi} \left[R{-}CH{=}S\right] +$$

(CXLIV)

X = S, Se
R = Ph, 2-thienyl, n-Pr, t-Bu.

Advances in the chemistry of sulphenic acid amides

I V Koval'
F E Dzerzhinskii Dnepropetrovsk Chemico-Technological Institute

ABSTRACT. Results of recent investigations in the area of sulphenic acid amides have been systematised and correlated in the review. Reactions of sulphenamides occurring with the generation of anions, radicals and nitrenes have been considered, as well as reactions accompanied by fussion of the S–N bond and oxidation of the sulphur atom.

The bibliography contains 95 references.

Contents

III. Reactions occurring with fission of the S–N bond 398
IV. Reactions occurring with oxidation of the sulphur atom 400

I. Introduction

The chemistry of sulphenic acid amides began in 1911 with the discovery by Zincke of sulphenic acid chlorides and the study of their reactions with nitrogen-containing compounds.[1] The rapid development of this area of hetero-organic chemistry is explained primarily by the useful properties of representative compounds of this class, which are widely used as pesticides,[2] vulcanising agents,[3] electrolytic additives[4,5] and other valuable reagents used in industry and agriculture. The high lability of the S–N bond in sulphenamides, and also the presence of two centres for reaction (sulphur and nitrogen) make sulphenic acid amides extremely valuable as reagents for the synthesis of sulphides,[6,7] disulphides,[8–11] trisulphides,[12] new types of suphenamides,[13] sulphenic acid esters,[14] sulphinamides[15] and sulphonamides.[16]

The interest displayed in sulphenic acid amides by any investigators caused at one time the appearance of a series of reviews[17–22] which reflected in some degree the progress in the chemistry of sulphenamides in a particular period. In the present review results of recent investigations in the chemistry of sulphenic acid amides are systematised and correlated. In particular, reactions are considered which occur with fission of the N–H bond and generation of anions, radicals and nitrenes and reactions accompanied by fission of the S–N bond and oxidation of the sulphur atom.

II. Reactions occurring with fission of the N–H bond

1. Generation of N-anions

Dissociation of N-substituted sulphenamides containing electron-acceptor groups at the sulphur and nitrogen atoms in polar organic solvents leads to the formation of N-anions of the sulphenamides in the stabilisation of which the sulphur atom and the electron acceptor groups participate:[23–25]

$$RSNHR^1 \rightleftharpoons RS\overset{\ominus}{N}R^1 + H^{\oplus},$$
$$RS\overset{\ominus}{N}R^1 \leftrightarrow R\overset{\ominus}{S}{=}NR^1.$$

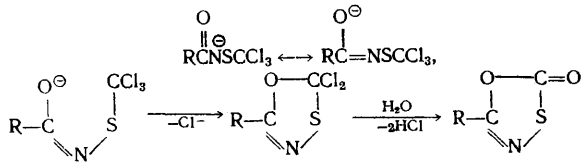

Table 1. pK_a values of N-substituted sulphenamides[25] $RSNHR^1$.

R	R^1	pK_a	Method of determination
C_6H_5	$C_6H_5SO_2$	11.87	a
4-$CH_3C_6H_4$	$C_6H_5SO_2$	12.66	a
4-ClC_6H_4	$C_6H_5SO_2$	10.80	a
4-$NO_2C_6H_4$	$C_6H_5SO_2$	8.20	a
2-$NO_2C_6H_4$	$C_6H_5SO_2$	8.45	a
2,4-$(NO_2)_2C_6H_3$	$C_6H_5SO_2$	5.76	a
2,4-$(NO_2)_2C_6H_3$	4-$CH_3OC_6H_4SO_2$	6.08	a
2,4-$(NO_2)_2C_6H_3$	4-$CH_3C_6H_4SO_2$	5.98	a
2,4-$(NO_2)_2C_6H_3$	4-$ClC_6H_4SO_2$	5.33	a
2,4-$(NO_2)_2C_6H_3$	4-$BrC_6H_4SO_2$	5.31	a
2,4-$(NO_2)_2C_6H_3$	3-$NO_2C_6H_4SO_2$	4.62	a
2,4,6-$(NO_2)_3C_6H_2$	$C_6H_5SO_2$	2.69	a
2,4,6-$(NO_2)_3C_6H_2$	4-$CH_3C_6H_4SO_2$	2.90	a
2,4,6-$(NO_2)_3C_6H_2$	4-$ClC_6H_4SO_2$	2.44	a
3,4,5-$(NO_2)_3C_6H_2$	4-$ClC_6H_4SO_2$	2.88	a
C_6H_5	C_6H_5CO	12.30	a

2-$NO_2C_6H_4$	C_6H_5CO	10.40	a
4-$NO_2C_6H_4$	CH_3CO	10.78	a
2-$NO_2C_6H_4$	CH_3CO	11.38	a
2,4-$(NO_2)_2C_6H_3$	CH_3CO	9.67	a
CCl_3	C_6H_5CO	7.64	b
CCl_3	4-$CH_3C_6H_4CO$	7.67	b
CCl_3	4-$CH_3OC_6H_4CO$	7.69	b

Note. a, potentiometric titration in 50% acetone; b, indicator buffer-free method in acetone.

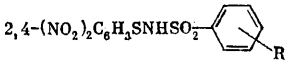
The stability of the N-anions formed in the dissociation process was determined by the pK_a of sulphenamides (Table 1) the magnitude of which varied over a wide range depending on sulphenamide structure.

Anions of N-acyltrichloromethanesulphenamides are converted in the presence of base into 5-aryl-1,3,4-oxathiazol-2-ones,[24] which limits the choice of method for determining the pK_a of these compounds.

From a comparison of the pK_a values of N-acyltrichloromethanesulphenamides and the pK_a of dichloroacetic acid (2.70) determined by the same method,[24] it may be concluded that the anions of N-acyltrichloromethanesulphenamides possess high stability.

The character of the substituent on the arenesulphenyl group of N-arenesulphonylarenesulphenamides exerts a greater influence on the stability of the N-anion than does the character of a substituent on the arenesulphonyl group. This is linked with the greater ability of divalent sulphur in comparison with hexavalent sulphur to transmit the inductive influence of the substituent. This situation is also confirmed by correlation analysis, specifically by a comparison of the reaction constants ρ_1 and ρ_2 obtained from the correlation relationships between the pK_a values of two series of N-arenesulphonylarenesulphenamides and the Hammett σ constants (Tables 2, 3).

Table 2. Correlation parameters of a reaction series of N-benzenesulphonylarenesulphenamides.[25]



R	pK_a	σ	ρ_1	r
4-NO_2	8.20	0.232	4.717	0.999
4-Cl	10.80	0.227		
H	11.87	0.000		
4-CH_3	12.86	−0.170		

The maximum in the 380–420 nm region in the electronic spectra of solutions of N-arenesulphonylarenesulphenamides corresponds to the absorption of N-anions and is absent from the spectra of N-arenesulphonylalkylarenesulphenamides. An increase in absorption maximum was observed with increase in the acidic properties of N-arenesulphonylarenesulphenamides and also with increase in solvent polarity.[25]

The generation of anions from N-acyl- and N-arenesulphonylarenesulphenamides may be affected by the action on them of alkali or alcoholates.[25] The stability of the resulting sodium salts is caused by the acidic properties of sulphenamides. The sodium salts of N-arenesulphonylnitrobenzenesulphenamides are converted during a few minutes in air to a dark wine-red resin dissolving readily in water with the formation of dark red solutions. The sodium salts of N-arenesulphonyldinitrobenzenesulphenamides are more stable towards the action of moisture and remain unchanged for an extended time.

Table 3. Correlation parameters of a reaction series of N-arenesulphonyl-2,4-dinitrobenzenesulphenamides.[25]

R	pK_a	σ	ρ_2	r
3-NO_2	4.62	0.710	1.537	0.997
4-Br	5.31	0.232		
4-Cl	5.33	0.227		
H	5.76	0.000		
4-CH_3	5.98	−0.170		
4-CH_3O	6.08	−0.268		

In alcoholic solution the sodium salts of N-arenesulphonylarenesulphenamides are methylated at the nitrogen atom by methyl iodide with the formaiton of N-arenesulphonylmethylarenesulphenamides.

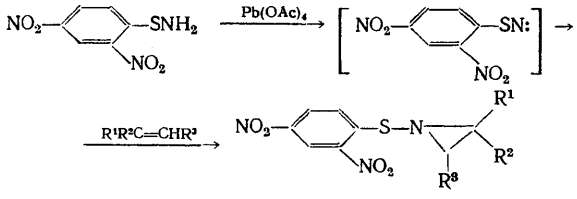
2. Generation of N-radicals

Homolysis of the N–H bond in sulphenamides by the action of oxidising agents was noticed for the first time by Lecher and co-workers.[26] They established that under the action of PbO_2 on bis-(benzenesulphenyl)imide in an inert organic solvent the bis-(benzenesulphenyl)imine radical is formed in the stabilisation of which the sulphur atom participates:

$$\cdot\,\mathrm{PhS\!-\!N\!-\!SPh} \leftrightarrow \mathrm{PhS{=}N\!-\!SPh} \leftrightarrow \mathrm{PhS\!-\!N{=}SPh}$$

The action of PbO_2 or (tert.-BuO)$_2$ on N-arenesulphenamides in an inert organic solvent leads to the generation of N-arenesulphenylarylaminyl radicals Ar–SN–Ar^1 (Ar is Ph, 2-$NO_2C_6H_4$, 4-ClC_6H_3; Ar^1 is $MeOC_6H_4$, 4-$(Me)_2(NC_6H_4)$, having as a rule a red colour.[18,26–28]

It was established by EPR[29] that radicals RSNS(Ar) = NSR, coloured blue, green or brown depending on the structure of R and Ar, are formed on oxidation of sulphenamides RSNHC(Ar) = NSR with lead dioxide or silver oxide in diethyl ether in the presence of potassium carbonate.



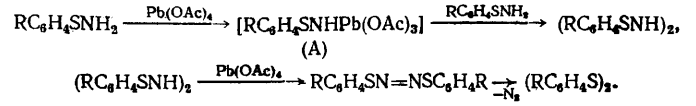
The formation of N-arenesulphenylacylaminyl radicals has been observed[30–33] on heating N-arylsulphenyl-N,N′-bis-(acyl)-arenesulphinamidines in inert organic solvents (benzene, toluene, etc.).

$$\mathrm{ArS(=NAc)N(SAr)Ac} \overset{70\text{–}80^\circ\mathrm{C}}{\rightleftharpoons} 2\mathrm{ArS\dot{N}Ac},$$
$$\mathrm{Ac} = \mathrm{ArSO_2},\ \mathrm{ArCO}.$$

At 120–140 °C the homolysis became irreversible.

3. Generation of nitrenes

The oxidation of 2,4-dinitrobenzenesulphenamide with lead tetraacetate in aprotic organic solvents leads to 2,4-dinitrobenzenesulphenylnitrene which forms the corresponding aziridines with olefins:[34–36]



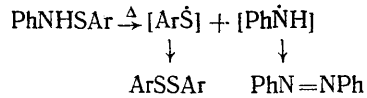
The capture of 2,4-dinitrobenzenesulphenylnitrene by olefins and not by the sulfenamide as in the case of sulphides[37] is explained by the fact that the 2,4-dinitrophenyl group reduces the electron density at the sulphur atom as a result of which the sulphur atom is not capable of undergoing electrophilic attack by 2,4-dinitrobenzenesulphenylnitrene.

In the absence of olefins the oxidation of 2,4-dinitrobenzenesulphenamide by lead tetraacetate leads to N-(2,4-dinitrophenyl)-2,4,dinitrobenzenesulphenamide, which in the opinion of the authors[35] is formed by attack of the nitrene at the nitrogen or sulphur atoms of 2,4-dinitrobenzenesulphenamide. The formation of N,N′-di-[2,4,6-tri-(tert.-butyl)benzene]diiminosulphur in the reaction of 2,4,6-tri-(tert.-butyl)benzenesulphenamide with lead tetraacetate,[38] is also explained by attack of the nitrene at the sulphur atom of the sulphenylamide.

Oxidation of 2,4-dinitrobenzenesulphenamide with lead tetraacetate in the presence of (*Z*)-phenylpropene[34,36] leads to a mixture of trans- and cis-1-(2,4-dinitrobenzenesulphenyl)-2-methyl-3-phenylaziridines, the ratio of which depends on the type of solvent used, the ratio of reactants, and also the order of mixing the reagents. In benzene the ratio of trans- and cis-isomers is 1 : 1, but in chloroform and in methylene chloride it is 3 : 1. In more polar solvents (CH_3CN, CH_3OH) the overall yield of both isomers is reduced. On introducing lead tetraacetate into a mixture of 2,4-dinitrobenzenesulphenamide and (*Z*)-phenylpropene, together with aziridine the formation is observed of N-(2,4-dinitrophenyl)-2,4-dinitrobenzenesulphenamide and partial isomerisation of (*Z*)-phenylpropene into (*E*)-phenylpropene, while addition of a mixture of 2,4-dinitrobenzenesulphenamide and lead tetraacetate in chloroform to (*Z*)-phenylpropene leads to the formation in high yield of only aziridine.

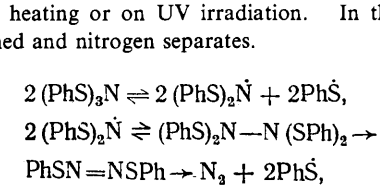
It has been assumed[34] that triplet nitrene is formed initially in the oxidation. This is in equilibrium with singlet nitrene and they both react with (*Z*)-phenylpropane. Since sulphides are effective traps for singlet nitrenes[39] then introduction of sulphide $4\text{-}ClC_6H_4.SCH_2CH=CH_2$ into the reaction mixture changes both the overall yield of aziridines and the ratio of isomers. At the same time in the presence of effective trapping agents for triplet nitrenes $PhC(R)=CH_2$ (R = Ph, Me) the ratio of cis- and trans-isomers is unchanged although the overall yield of aziridines is reduced.

When sulphenamides $RC_6H_4SNH_2$ (R = 2-NO_2, 4-NO_2, 4-Cl) are oxidised with lead tetraacetate in the presence of olefins the corresponding disulphides are isolated. These are formed as a result of the following conversions:[40]



The formation of the nitrenoid intermediate (A) was confirmed by the fact that on oxidation of 4-nitrobenzenesulphenamide with lead tetraacetate in DMSO, N-4-nitrobenzenesulphenyldimethylsulphoximide was obtained.[40]

III. Reactions proceeding with fission of the S–N bond



In contrast to the sulphur–nitrogen bond in sulphonamides, which is very stable, the S–N bond in sulphenamides is labile and is readily split by nucleophilic and electrophilic reagents. This was even mentioned by Zincke and co-workers[41] when studying the reaction of naphthalenesulphenyl chlorides with naphthylamines. The stability of S–N bonds in sulphenamides towards nucleophilic and electrophilic reagents is in direct relationship to their bond energies on which there are no data in the literature. This gap is compensated to some extent by data on the order of the S–N bond and force constants. From a study of the vibrational spectra of sulphenamides it was established that the bond order of S–N in N-methyl- and N,N-dimethylsulphenamides is greater than unity,[3] but the force constants of the stretching vibrations of this bond in bis-(arenesulphenyl)imides, N-acyl- and N-arenesulphonylarenesulphenamides are $1894.7-2024.9 \times 10^{-17}$ J.mol.m^2.[42]

1. Homolytic fission of the S–N bond

Homolytic fission of the S–N bond of sulphenamides is as a rule observed on heating or on UV irradiation. For example heating N-phenylarenesulphenamides to 195 °C[43] leads to the formation of the corresponding disulphides and azobenzene which is explained by homolysis of the S–N bond and subsequent dimerisation of the resulting radicals:

The thermal stability of sulphenamides is reduced with increase in their basicity, which occurs in the presence of electron donating substituents bound to the sulphur and nitrogen atoms.[44] Thus homolysis of the S–N bond in tribenzenesulphenamide[45] occurs on mild heating or on UV irradiation. In this case the disulphide is formed and nitrogen separates.

The ease of homolysis of the S–N bond in the given case is explained by the increased stability of the dibenzenesulphenylaminyl radical in the stabilisation of which the sulphur atom participates. In support of this case tristrifluoromethanesulphenylamide is also inclined to photolyse.[46]

$$(CF_3S)_3N + (CF_3S)_2NMe \xrightarrow{h\nu} (CF_3S)_2NH + CF_3SSCF_3 + \\ + (CF_3S)_2NCH_2NHSCF_3.$$

Stable free radicals RSNC(Ar) = NSR are formed on photolysis of sulphenamides $(RS_2)NC(Ar) = NSR$ in aprotic organic solvents.[29] It is not excluded that thermal rearrangement of sulphenamides $4\text{-}RC_6H_4N(R^1)SC = CR^2$ with the formation of derivatives of indole[47] is also effected after homolysis of the S–N bond.

2. Heterolytic fission of the S–N bond

Heterolysis of the S–N bond in sulphenamides occurs under the action of both electrophilic and nucleophilic reagents which are frequently used for synthetic purposes. The reactions of sulphenamides with hydrogen halides, carboxylic and sulphonic acid chlorides and with isocyanates have been well studied and proceed according to the general scheme.[3]

$$RSNHR^1 + X^{\delta+} - Y^{\delta-} \rightarrow \left[\begin{array}{c} \overset{\oplus}{R}SNHR^1 - Y^{\ominus} \\ | \\ X \end{array} \right] \rightarrow RSY + R^1NHX,$$

$XY = HCl,\ TsCl,\ AcCl,\ PhNCO.$

Nucleophilic substitution at the sulphur atom of the amide group is also widely used in various syntheses. Thus reactions of sulphenamides with dialkyl phosphites,[48] thiols,[49] thiocarboxylic acids,[50] and compounds containing active methylene groups[51] are used for obtaining O,O′-dialkyl 5-alkyl phosphonothionates, disulphides, bis-(acyl)disulphides and sulphides:

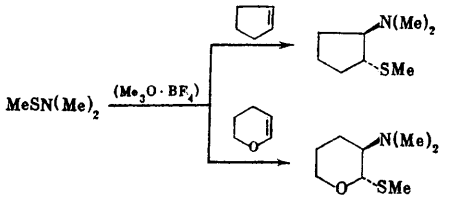
$$R^1SN(R^2)R^3 + NuH \rightarrow R^1SNu + R^2(R^3)NH,$$
$$NuH = (RO)_2POH,\ RSH,\ RCOSH,\ (NC)_2CH_2,\ (RCO)_2CH_2.$$

When sulphenamides interact with thiol esters of sulphonic acids[52,53] a trans-sulphenylation of the sulphenamide occurs:

$$R^1SN(R^2)R^3 + R^4SO_2SR^5 \rightarrow R^5SN(R^2)R^3 + R^4SO_2SR^1.$$

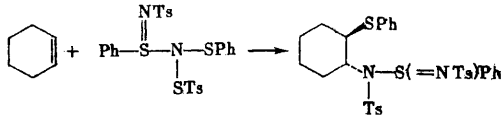
The reaction is irreversible and takes place only on the interaction of highly nucleophilic sulphenamides (R^2 and R^3 are electron-donating groups) with highly reactive thiol esters of sulphonic acids (R^4 is an electron-accepting group).

Heterolysis of the two S–N bonds in trisulphenamides on interaction with trivalent phosphorus and arsenic compounds leads to the formation of the corresponding imides and disulphides:[54,55]



$$Ph_3E + \underset{\underset{R}{|}}{S-N(SR)_2} \rightarrow \underset{\underset{R}{|}}{\overset{\oplus}{Ph_3E}-\overset{\ominus}{S}N(SR)_2} \rightleftharpoons Ph_3E\begin{array}{l} \diagup SR \\ \diagdown N(SR)_2 \end{array} \rightarrow$$

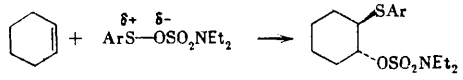
$$\rightarrow Ph_3E{=}NSR + RSSR,$$



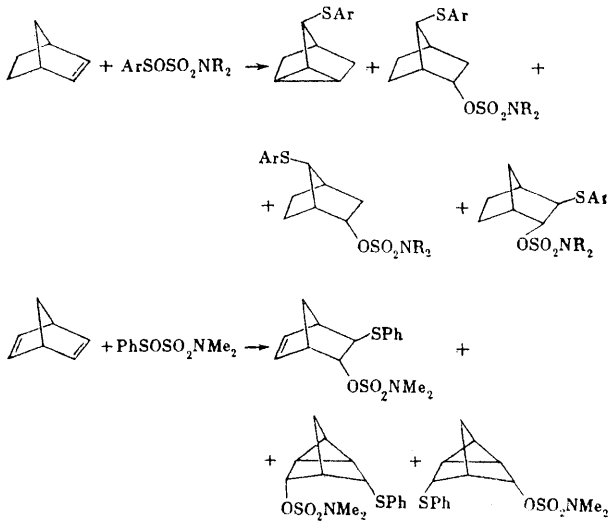
$R = Ph,\ CF_3;\ E = P,\ As.$

At the same time the interaction of *p*-nitrobenzenesulphenamide with triphenylphosphine under the conditions of the Appel reaction proceeds anomalously with splitting of the S–N bond and the formation of the ylide $(p\text{-}NO_2C_6H_4S)_2C{=}P(Ph)_3$.[56]

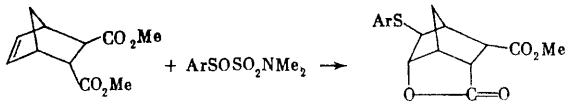
Heterolytic fission of the S–N bond in the presence of olefins is accompanied by addition of the resulting fragments to the C=C bond of the olefin. For example, heterolytic fission of the S–N bond of N-(dimethyl)methanesulphenamide in nitromethane in the presence of cyclopentene or 3,4-dihydro-2H-pyran leads to the formation of trans-1-dimethylamino-2-methylthiocyclopentane or trans-2-dimethyl-amino-3-methylthiotetrahydropyran.[57,58]



The addition of sulphenamides $PhSNR^1R^2$ [$R^1 + R^2 = (CH)_4$, $R^1 + R^2 = (CH_2)_2O(CH_2)_2$, $R^1 = H$, R^2 = t.-Bu] to the C=C bond of cyclohexene, octene and indene[59,60] also occurs predominantly at the trans-position. Strong proton acids or Lewis acids are catalysts of the aminosulphenylation of olefins. Under conditions of acid catalysis N-benzenesulphenyl-N,N′-bis-(p-toluenesulphonyl)benzenesulphinamidine adds to the C=C bond of cyclohexene with the formation of a benzosulphinamidine trisubstituted at the nitrogen atom.[61]



The reactivity of sulphenamides towards olefins in the heterolytic addition reaction increases with an increase in the electrophilicity of the sulphur atom which may be achieved by inserting SO_3 in the S–N bond of sulphenamides.[62] Using this procedure Zefirov and co-workers[63] carried out for the first time the sulphamatosulphenylation of olefins which comprises the interaction of sulphenamides with SO_3 in an inert solvent at a reduced temperature of −85 °C, with subsequent addition of the insertion products to the C=C bond of olefins. The sulphamatosulphenylation of cyclohexene is stereospecific and leads to the trans-1,2-adduct:



$$ArSNEt_2 + SO_3 \xrightarrow[-\,80^\circ C]{CH_2Cl_2} ArSOSO_2NEt_2$$

The sulphamatosulphenylation of norbornene and norbornadiene[63] is accompanied by rearrangement of the carbon skeleton which finally leads to a mixture of several products:

On sulfamatosulphenylation of bicyclo[2.2.1]hept-2-en-endo-cis-5,6-dicarboxylic acid dimethyl ester cyclisation of the adducts occurs with the formation of arylthiolactones:[63]

The use of pyridine/sulphur trioxide as SO_3 donor[64] makes it possible to carry out this reaction at room temperature. It was shown[65] that the sulphamate group is relatively easily replaced both by weak (CF_3COO^-, $HCOO^-$) and by strong (Br^-) nucleophiles.

IV. Reactions occurring with oxidation of the sulphur atom

Oxidation reactions of the divalent sulphur in sulphenamide to the quadri- and hexavalent state forming sulphin- and sulphonamides have been known and studied for a long time. However a series of reactions has been carried out during which the sulphur in sulphenamides increases its valency by two units and adds an atom of halogen or an imino, alkoxy or amido group. These reactions have become known relatively recently and have still not been studied fully.

1. Oxidative imination of sulphenamides

Conversions accompanied by oxidation of an element and by addition of an imino group are taken to be called oxidative imination reactions.[66]

It has been established[67] that sulphenamides $ArSNRR^1$ (R = H, Alk; R^1 = Alk) react with the sodiochloroamides of arenesulphonic acids according to the general reaction scheme of oxidative imination with the formation of N,N′-substituted amides of iminosulphinic acids:

$$ArSNRR^1 + TsNNaCl \xrightarrow{-NaCl} ArS(=NTs)NRR^1.$$

Sulphenamides ArSNHX [X = C(=NH)NH_2, C(=NH)Alk, C(=NH)SAlk, C(=NH)OAlk] are iminated by sodiochloroamides of sulphonic acids,[67] N-chlorobenzamide,[68] and N-bromobenzamidine.[69] N-Acylsulphenamides p-$NO_2C_6H_4SNHAc$ are iminated in the presence of base by N-chloroacet- and N-chlorobenzamide[70] and also by N-bromobenzamidine.[68] However attempts[67] to effect the imination of N-acyl- and N-arenesulphonylarenesulphenamides with the sodiochloroamides of sulphonic acids in acetone were completed without a result which is explained by the reduced electron density at the sulphur atom of these sulphenamides.

The mechanism of oxidative imination of sulphenamides by N-halogen compounds has not been investigated in detail, however by analogy with the oxidative imination of sulphides[71,72] it has been proposed[73] that the chlorine atom of the N-halogen compound attacks electrophilically the sulphur atom of the sulphenamide with the formation of a chlorosulphonium intermediate which forms an ion pair with the amidate anion:

$$ArSNRR^1 + ClNHR^2 \rightleftharpoons \left[Ar\overset{\oplus}{S}(Cl)NRR^1\overset{\ominus}{N}HR^2 \right] \xrightarrow{-HCl} ArS(=NR^2)NRR^1.$$

The possibility of forming the chlorosulphonium intermediate by electron transfer from the sulphur atom to the positively charged chlorine atom is not excluded.[74] It is evident that the electron density on the sulphur atom must be sufficient for electrophilic attack by chlorine cations. In this connection it seemed of interest to activate the sulphur atom in the oxidative imination reaction by creating an α-N-anionic centre[75] which makes possible the imination of N-substituted sulphenamides containing electron accepting groups on the sulphur and nitrogen atoms. Thus the selection of conditions for imination in the case of N-monosubstituted sulphenamides is determined by their acidic properties.[25] Unionised sulphenamides with $pK_a > 11$[74–76] are iminated in acetone by sodiochloroamides of sulphonic acids:

$$RSNHR^1 + ArSO_2NNaCl \xrightarrow{-NaCl} RS(=NSO_2Ar)NHR^1,$$

R=Ph, 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$, R^1=H;
R=CH_2Cl, R^1=AlkCO, ArCO; R=Ph, R^1=AlkCO, ArCO; R=Ph, 4-MeC_6H_4, R^1=$ArSO_2$.

Sulphenamides with pK_a 8–11[77,78] are not iminated in acetone but are iminated in strongly basic solvents of high dielectric constant (aqueous alkaline solution, pyridine, etc.) capable of dissociating sulphenamides with the formation of an α-N-anionic centre:

$$RSNHR^1 \rightleftharpoons RS\overset{\ominus}{N}R^1 + H^{\oplus},$$
$$RS\overset{\ominus}{N}R^1 \leftrightarrow R\overset{\ominus}{S}=NR^1.$$

The sodium salts of such sulphenamides are readily iminated by sodiochloramides of sulphonic acids in acetone.

$$\left[RS{=}NR^1 \right]^{\ominus}Na^{\oplus} + ArSO_2NNaCl \xrightarrow{-NaCl} \left[ArSO_2N{=}\underset{R}{S}{=}NR^1 \right]^{\ominus}Na^{\oplus}$$

R=4-$NO_2C_6H_4$, R^1=AlkCO, ArCO
R=4-ClC_6H_4, 2-NOC_6H_4, 4-$NO_2C_6H_4$, R^1=$ArSO_2$.

Sulphenamides with pK_a < 8 [79–82] are iminated in acetone and also in aqueous alkaline medium and in pyridine since the concentration of N-anion is still sufficiently high, however they are not iminated in benzene, toluene, hexane or in solvents of low dielectric constant suppressing the dissociation of the sulphenamide.

$$\left[RS{=}NR^1\right]^{\ominus}H^{\oplus} + ArSO_2NNaCl \xrightarrow[-NaCl]{} \left[ArSO_2N{=}\underset{\underset{R}{|}}{S}{=}NR^1\right]^{\ominus}Na^{\oplus}$$

R=EtOCOCCl$_2$, R^1=ArCO, R=CCl$_3$, R^1=AlkCO, ArCO, ArSO$_2$; R=CFCl$_2$, R^1=AlkCO, ArCO; R=CF$_2$Cl, R^1=AlkCO, ArCO.

Since the formation of sodium salts of sulphenamides occurs first on interacting sulphenamides having pK_a < 6 with sodiochloroamides of sulphonic acids (N-chlorobenzenesulphonamide has pK_a 9.5 [83]), their imination was conducted at a reactant ratio of 1 : 2.[25,80]

$$RSNHSO_2R^1 + ArSO_2NNaCl \xrightarrow[-\left[ArSO_2NHCl\right]]{} \left[RS{=}NSO_2R^1\right]^{\ominus}Na^{\oplus} \xrightarrow{ArSO_2NNaCl} \rightarrow \left[ArSO_2N{=}\underset{\underset{R}{|}}{S}{=}NSO_2R^1\right]^{\ominus}Na^{\oplus}$$

R = 2,4-(NO$_2$)$_2$C$_6$H$_3$, CCl$_3$

The direction of the reaction of N-acyl-p-nitrobenzenesulphenylamides with the sodiochloroamide of sulphonic acids depends on the conditions. Imination of these sulphenamides is effected in aqueous alkaline medium but in pyridine the interaction of these compounds is accompanied by fission of the S–N bond and the formation of symmetrical N,N′-bis-(arenesulphonyl)-p-nitrobenzenesulphinamidines.[78] A similar symmetrisation was also observed[24] in the interaction of N-acylmethanesulphenamides with sodiochloroamides of sulphonic acids in acetone.

$$MeSNHCOR + ArSO_2NNaCl \cdot xH_2O \rightarrow \begin{cases} \rightarrow MeS(=NSO_2Ar)NHCOR \\ \rightarrow MeS(=NSO_2Ar)NHSO_2Ar \end{cases}$$

This process has been studied in more detail in the example of the reaction of sodiochloroamides of sulphonic acids with bis-(arenesulphenyl)imides, the products of which were a mixture of N,N′-bis-(arenesulphonyl)arenesulphinamidines and N-arenesulphonylarenesulphinamidines.[84]

$$ArSNHSAr + 3PhSO_2NNaCl \cdot xH_2O \rightarrow \begin{cases} \rightarrow ArS(=NSO_2Ph)NH_2 \\ \rightarrow Ar(=NSO_2Ph)NHSO_2Ph \end{cases}$$

Ar = 2-NO$_2$C$_6$H$_4$, 4-NO$_2$C$_6$H$_4$.

The formation of a mixture of two products is explained by two factors. The first is the low rate of imination of sulphenamides which is determined by the low electron density on the sulphur atom and the impossibility of compensating for it by the formation of an α-N-anionic centre since bis-(arenesulphenyl)imides are relatively weak NH-acids with pK_a 10.8.[84] The second is the lability of the sulphur–nitrogen bond, and its fission in the presence of water of crystallisation with the formation of diaryldisulphides and arenesulphenamides, the further imination of which leads to the formation of the reaction products.

$$ArSNHSAr \rightarrow \begin{cases} \rightarrow ArSNH_2 \\ \rightarrow [ArSOH] \rightarrow 0.4ArSSAr + 0.2ArSO_3H + 0.4H_2O \end{cases}$$

$$ArSNH_2 + PhSO_2NNaCl \rightarrow ArS(=NSO_2Ph)NH_2,$$

$$0.4ArSSAr + PhSO_2NNaCl \rightarrow 0.8ArS(=NSO_2Ph)NHSO_2Ph.$$

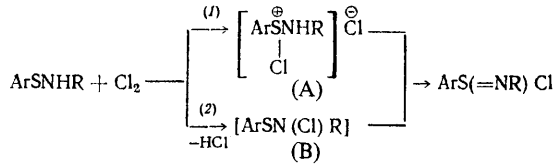
Such ideas were confirmed on studying the reaction of bis-(2,4-dinitrobenzenesulphenyl)imide with the sodiochloroamide of benzenesulphonic acid in acetone where the formation of N-benzenesulphonyl-2,4-dinitrobenzenesulphinamidine and of 2,4,2′,4′-tetranitrodiphenyldisulphide was observed. These, as is known[85], are not imidated by the sodiochloroamides of sulphonic acids:

$$[2,4\text{-}(NO_2)_2C_6H_3S]_2NH \xrightarrow{PhSO_2NNaCl \cdot xH_2O} \begin{cases} \rightarrow 2,4\text{-}(NO_2)_2C_6H_3S(=NSO_2Ph)NH_2 \\ \rightarrow [2,4\text{-}(NO_2)_2C_6H_3S-]_2 \end{cases}$$

The imination of N-acyl- and N-arenesulphonylsulphenamides by N-chloroamides of carboxylic acids[68,86] is carried out in the presence of organic bases which play the role not only of acceptors of hydrogen chloride but also are capable of dissociating the initial sulphenamides:

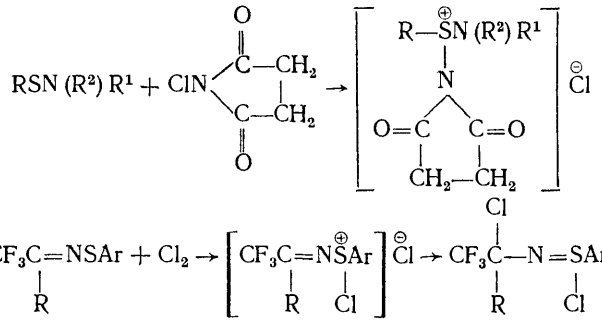
$$\left[RS{=}NAc\right]^{\ominus}H^{\oplus} + R^1CONHCl \xrightarrow[-HCl]{} \left[R^1CON{=}\underset{\underset{R}{|}}{S}{=}NAc\right]^{\ominus}H^{\oplus}$$

2. Oxidative halogenation of sulphenamides



The chlorination of N-substituted sulphenamides by chlorine in non-aqueous aprotic organic solvents leads to the formation of the acid chlorides of N-substituted iminosulphinic acids.[87]

$$ArSNHR + Cl_2 \xrightarrow[-HCl]{} ArS(=NR)Cl,$$



R=ArSO$_2$, ArCO, tert-Bu.

Dichloroamides of sulphonic acids, N-chloroimides, and tert.-butyl hypochlorite are also used as chlorinating agents. The chlorination of weakly nucleophilic sulphenamides is carried out in the presence of organic bases. The susceptibility of sulphenamides to oxidative chlorination is explained by the electron density on the sulphur atom. The presence of electron accepting groups on the sulphur and nitrogen atoms hinders oxidative chlorination or makes it impossible.[87]

The mechanism of the oxidative chlorination of sulphenamides has not been studied in detail. However allowing for the possibility of attack of chlorine cations at both the sulphur atom and the nitrogen atom it has been proposed[87] that the formation of the acid chlorides of iminosulphinic acids may occur by two concurrent schemes (1) and (2).

The most probable of these seems to be Scheme (1) since the intermediate N-chlorosulphenamides (B) [Scheme (2)] do not always succeed in rearranging to acid chlorides of iminosulphinic acids.[87] At the same time the appearance of chlorosulphonium salts of type (A) is recorded in reactions of N,N-dialkylsulphenamides with N-chlorosuccinimide,[88] and also of N-arylsulphenylketimines with chlorine:[89,90]

The hypothesis of a high probability of chlorinating sulphenamides at the sulphur atom is also in agreement with the principle of hard and soft acids and bases.[91] Evidently chlorination at the nitrogen atom is possible only in the event of low electron density at the sulphur atom, i.e. in the presence of strongly electron-accepting groups on the sulphur and nitrogen atoms. Replacement of a hydrogen atom on the nitrogen of N-arenesulphonylarene-sulphenamides by a metal atom increases the reactivity of the latter in oxidative chlorination reactions, which is seemingly explained by the increase in electron density at the sulphur atom as a result of the effects of the α-N-anionic centre:[92]

$$ArSN(Na)SO_2Ph + Cl_2 \rightarrow ArS(=NSO_2Ph)Cl + NaCl.$$

The oxidative chlorination of N,N-di(trifluoromethylsilyl)-trifluoro-methanesulphenamides is accompanied by splitting of the N–Si bond:[93]

$$CF_3SN(SiMe_3)_2 \xrightarrow[-ClSiMe_3]{Cl_2} [CF_3S(=NSiMe_3)Cl] \xrightarrow[-ClSiMe_3]{Cl_2} CF_3S(=NCl)Cl.$$

Only one sulphur atom participates in the oxidative chlorination of bis-(trifluoromethanesulphenyl)imide:[93]

$$(CF_3S)_2NH + Cl_2 \rightarrow CF_3S(=NSCF_3)Cl + HCl.$$

3. Oxidative alkoxylation and amidation of sulphenamides

The increased susceptibility of the sulphur atom of N-substituted sulphenamides to attack by chlorine cations under conditions of generating an α-N-anionic centre makes this method of activating sulphur promising in reactions accompanied by oxidation of the sulphur atom. For example, it has been shown[94] that the sodium salts of N-arenesulphonylarenesulphenamides are very readily chlorinated by tert.-butyl hypochlorite in alcohols (the reaction is exothermic) with the formation of alkyl esters of N-arene-sulphonylareneiminosulphinic acids (oxidative alkoxylation reaction).

$$ArSNHSO_2Ph + \text{tert-BuOCl} \xrightarrow{RONa} ArS(=NSO_2Ph)OR + \text{tert-BuOH} + NaCl,$$
$$R = Me, Et;\ Ar = 2\text{-}NO_2C_6H_4.$$

The chlorination of these salts by chlorine in acetone in the presence of dialkylamines[95] leads to the formation of N,N-dialkyl-N′-arenesulphonylarenesulphinamidines (oxidative amidation reaction).

$$ArSN(Na)SO_2Ph + Cl_2 + 2R_2NH \rightarrow ArS(=NSO_2Ph)NR_2 + NaCl + R_2NH\cdot HCl.$$

New advances in the chemistry of thiirans

A V Fokin, M A Allakhverdiev, A F Kolomiets
Nesmeyanov Institute of Organoelement Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. Data concerning the methods of synthesis of thiirans, their reactions with nucleophiles and electrophiles, as well as their desulphurisation and homolytic reactions and their behaviour in cycloaddition reactions are surveyed.

The bibliography includes 285 references.

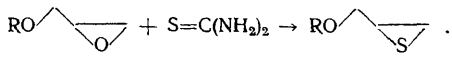
I. Introduction

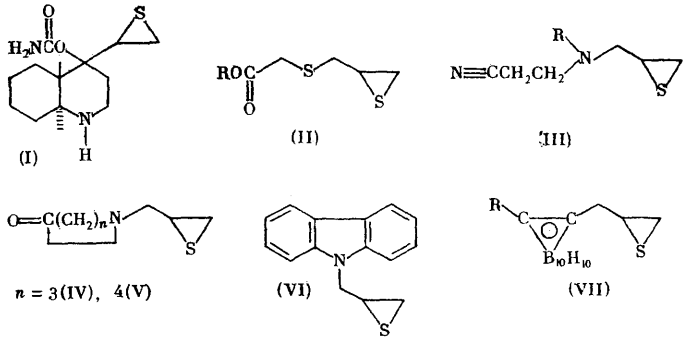
Data on thiirans and their derivatives published after 1976 inclusive have been examined in a monograph.[1] Certain new ways of synthesising thiirans have been discussed in a review.[2] L'Abbé's communication[3] is devoted to a new type of thiirans—thiiran imines. Some of the studies published after 1976 have been included in annual publications on three-membered heterocycles[4–8] and in review articles.[9–12] These data reflect fairly completely the state of the chemistry of thiirans by the end of the 1970's but they do not enable one to obtain an idea about the pathways and trends followed in its development during the current decade.

The present review deals with the principal advances in the synthesis and in the study of the properties of thiirans and their derivatives published in the last ten years. The restricted size of the review precluded the inclusion in it of information about the theoretical and physicochemical studies of these substances and about their applications.



A characteristic feature of the latest studies in the field of thiirans is their increasing applied bias with expansion of the range of their applications. Thus the possibility of synthesising from these compounds of a wide variety of biologically active substances, for example adrenoblocking agents,[13] immunomodulators,[14] antiseptics,[15] antihypertension agents,[16] hypoglycaemic agents,[17] etc., has been demonstrated in recent years. New technical applications of thiirans have been developed: for the preparation of liquid crystals,[18] photoresistors,[19] components of paint and varnish coatings,[20,21] antioxidants,[22,23] thermostable insulating materials,[24] heat-resistant polymers,[25] semiconductors,[26] elastomers,[27] etc.

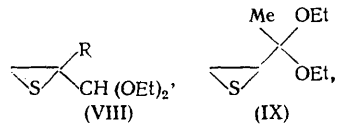
II. Methods of synthesis



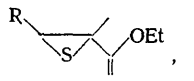
The classical methods of synthesis of thiirans[1] have been the basis of the majority of new synthetic studies in the field. During the past period, there has been an expansion of ideas concerning the effect of conditions on the formation and yield of thiirans in classical reactions, on the limits of their applications, and on the range of precursors of epithio-compounds. Ideas about the mechanisms of the formation of thiiran rings developed earlier have exerted a major influence on the new syntheses of thiirans.[1] By testing them with new models, it has been possible to discover new effective thiolating agents and to develop in a number of instances new non-traditional approaches to the synthesis of thiirans.

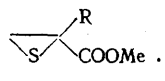
1. Conversions of oxirans into thiirans

The reactions of oxirans with thiourea have been used to obtain a large number of new epithio-compounds, including some which had been previously unavailable. With the aid of thiourea, substituted epithioglycidyl ethers containing polychloroalkyl,[28,29] 2-alkoxyethyl,[30] furfuryl,[31] organosilylalkyl, alkenyl, and alkynyl,[32,33] and t-butyl[34] end groups have been obtained.[28–34]



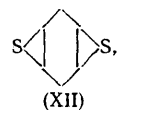
Acid catalysis has been used successfully in a number of instances.[31,34] The selection of the solvent, catalyst, and reaction conditions made it possible to devise simple methods of synthesis of a wide variety of epithioglycidyl ethers.[21,28–34] Many compounds containing the thiiran ring have been obtained by the reaction of thiourea with oxirans: the amide (I),[35] thioglycolic esters (II),[36] cyanoethylated amines (III),[37] the pyrrolidinone (IV) and the piperidinone (V),[38] the carbazole (VI),[39] and the *o*-carbaboranes (VII).[40]



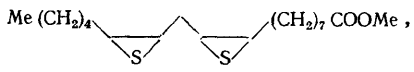


The presence of electron-accepting substituents in the ring of oxirans hinders their reactions with thiourea. The diethylacetals (VIII) have been obtained from the corresponding oxirans only on heating in methanol.[41,42] Acetylthiiran diethylketal (IX) was obtained similarly.[43] The ketals of 2-R-2-acetylthiirans polymerise under these conditions, while 2-R-2-(1-ethoxyvinyl)thiirans (X) are formed in preparative yields.[43] The reactions of sterically hindered

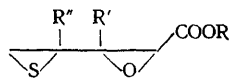
glycidates with thiourea in methanol are catalysed by H_2SO_4, which made it possible to obtain in high yields the thioglycidates (XI), which were previously difficult to synthesise.



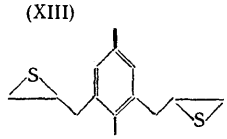
(VIII)



(IX)

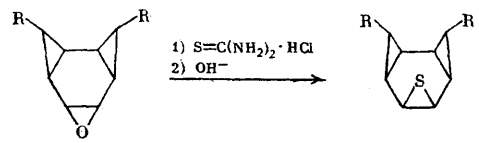


(X)



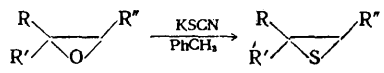
(XI)

Diepithio-compounds have been obtained by the reaction of thiourea with diepoxides. In the presence of H_2SO_4, *cis*- and *trans*-1,4-diepoxycyclohexanes were converted into the corresponding diepithio-compounds (XII).[44] The stereoisomers of the methyl esters of 9,10,12,13-diepithiooctadecanoic acid (XIII) have been synthesised in dioxan (XIII).[45] The sterically hindered esters of 3-substitutes and 3,4-disubstituted 2,3,4,5-diepoxyvaleric acids have been selectively converted in methanol (40 °C, 5–6 h) into the 3,4-epithio-derivative (XIV).[46] 2,5-Di(2,3-epithiopropyl)-1,4-dimethylbenzene (XV) has been obtained under mild conditions.[47]



(XII)

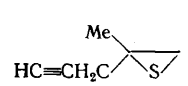
(XIII)

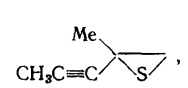


(XIV)

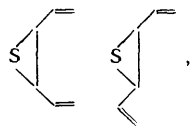
(XV)

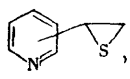
Thiourea salts are sometimes used for the thiolation of oxirans. Thus 3,4-epithiothiolan 1,1-dioxide has been obtained by the reaction of 3,4-epoxythiolan 1,1-dioxide with a thiourea salt.[48] *cis*-Thiatris-σ-homobenzenes have been obtained similarly.[49]



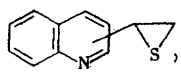


New aspects of the thiolation of oxirans by metal thiocyanates have been less thoroughly investigated. The use of potassium thiocyanate in toluene in the presence of silica gel made it possible to obtain substituted thiirans in 70–90% yield.[50]





When an attempt was made to increase the rate of thiolation of oxirans by thiocyanates with the aid of a phase transfer catalyst, the yield of thiirans fell appreciably.[51]



Under the conditions usual for the reactions of oxirans with KSCN, certain new epithio-compounds have been obtained. The thiirans with alkynyl substituents (XVI) and (XVII),[52] and *cis*- and *trans*-divinylthiirans (XVIII)[53] are formed in aqueous alcohol in yields up to 70%, while pyridyl-, quinolinyl-, and isoquinolinyl-thiirans (XIX)–(XXIII) are formed in a yield up to 50%.[54] The epithio-derivatives of limonene (XXIV) and terpinolene (XXV) have been obtained in anhydrous alcohol,[55] while a mixture of *cis*- and *trans*-dideuterio-thiirans have been synthesised in water.[56] Furyl- and thienyl-thiirans (XXVI) have been synthesised in the presence of small amounts of water.[57]

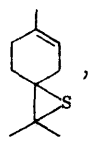
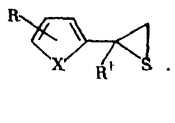
(XIX)

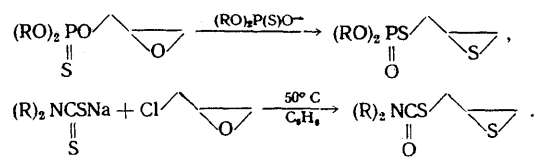


(XX)



(XXI)

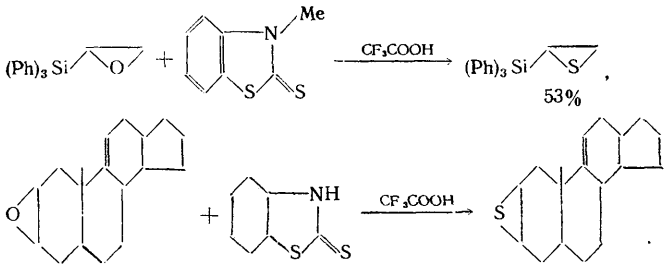
(XXII)



(XXIII)

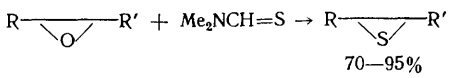
(XXIV)

(XXV)



(XXVI)

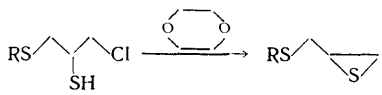
Thiono-compounds have been used as thiolating agents for the conversion of oxirans into thiirans. Triphenylphosphine sulphide with an equimolar amount of CF_3COOH has been used to synthesise 3,4-epithiothiolan 1,1-dioxide.[58] 10β-Epithiosteroids have been obtained from epoxysteroids and triphenylphosphine sulphide in the presence of picric acid.[59] Ethylene and propylene sulphides are formed on reaction of the corresponding oxirans with the monoesters of alkylphosphonothioic acids.[60] A similar reaction occurs on heating glycidyl phosphorothioates with salts of dialkyl phosphorothioic acids.[61] The salts of dithiocarbamic acid also have similar properties.[62]



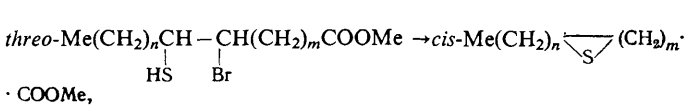
The interaction of triphenylsilyloxiran with an equimolar amount of 3-methylbenzothiazole-2-thione and CF_3COOH afforded the first representative of silylthiirans.[63] Epoxy-compounds are converted

into thiirans under the same conditions on treatment with perhydrobenzothiazole-2-thione.[64]

The thiono-derivatives of triazoline, imidazoline, benzimidazoline, and oxadiazoline thiolate oxirans also in the absence of CF_3COOH, which is indicated by the formation of 1-heteroaryl-2,3-epithiopropanes on interaction of azolethiones with epichlorohydrin.[65,66] Many side processes are ruled out in the presence of CF_3COOH.



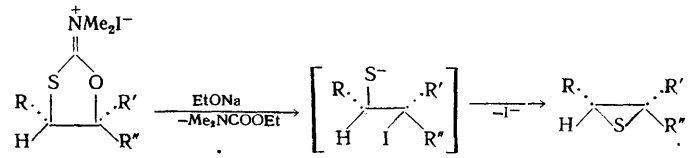
Among thiono-compounds investigated, dimethylthioformamide in the presence of catalytic amounts of CF_3COOH proved to be the most effective.[67]



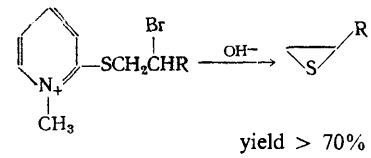
2-Mercaptobenzothiazole[68] and 5-mercapto-1-phenyltetrazole[69] were also found to be highly effective thiolating agents.

2. Cyclisation of 2-substituted thioles and their derivatives

2-Chloroalkanethiol fragments in a polymer matrix are converted into epithioalkyl groups even on solvation with 1,4-dioxan.[70]

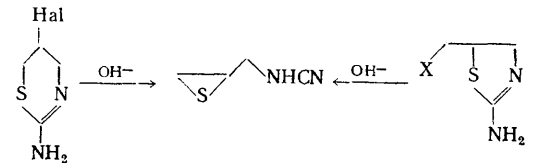


Analogous reactions are characteristic also of monomeric 2-halogenoalkanethiols. Thus the carbaboranylthiirans (VII) are formed rapidly from 3-chloro-2-mercaptopropyl-*o*-carbaboranes on heating in methanol.[71,72] 3-Halogeno-4-mercaptothiolan 1,1-dioxides are spontaneously converted into 3,4-epithiothiolan 1,1-dioxides.[73] In both cases, the formation of a ring is energetically so favourable that its opening by anhydrous HCl either does not occur or takes place to only a slight extent. 2-Chloro-1-trifluoromethylethanethiol is somewhat more stable, but on treatment with *N*-methylpyrrolidinone it is converted into trifluoromethylthiiran already at 20 °C.[74,75] The stereospecificity of the reactions considered, taking place with inversion of configuration has been demonstrated on new examples.[76]



$n = m = 7$; $n = 10$, $m = 4$.

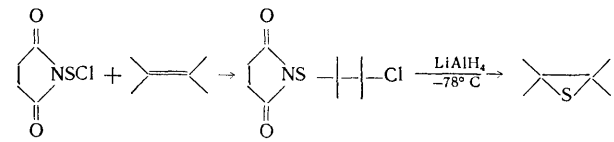
2-Halogenoalkanethiolate ions are precursors of thiirans in many reactions. The interaction of 3,4-dibromo-3-methylbutan-2-one oxime with Na_2S in acetone leads to the oxime of 2-acetyl-2-methylthiiran.[77] The methiodides of 2-methylimino-1,3-oxathiolans are converted into epithio-compounds,[78] apparently in accordance with the mechanism



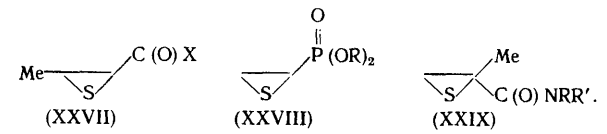
The vicinal alicyclic substituted iodine thiocyanates, including steroids are converted quantitatively into thiirans on treatment with $EtBH_3Li$.[79]

Ethylene sulphide or its polymer are formed from 2-bromoethylisothiuronium bromide[80] and 2R-thiirans are produced from 2-(2-bromoalkylthio)pyridinium salts.[81]

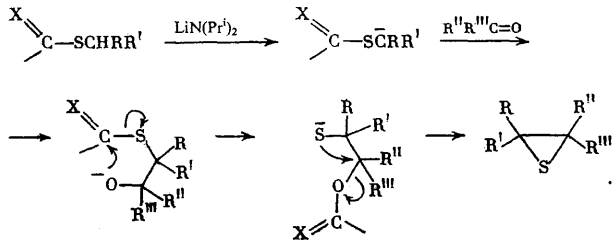
yield > 70%



The skeletal rearrangement of cyclic 2-halogenoalkylisothioureas into 2,3-epithiopropylcyanamide can apparently be explained by the formation of 2-halogenoalkanethiolate anions.[82]

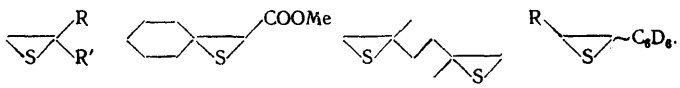


Dibenzoylthiiran is formed from α-thiocyanatoacetophenone on treatment with bases under phase transfer conditions.[83]

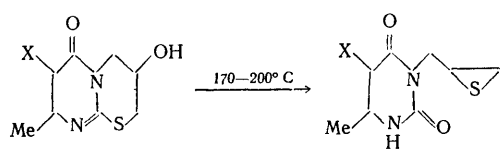


The adducts of *N*-chlorosulphenylated succinimides and phthalimides with alkenes also proved to be precursors of thiirans.[84,85] Their reduction with $LiAlH_4$ makes it possible to obtain thiirans in yields up to 90% and more.

The thiirans (XXVII)–(XXIX), which readily lose the sulphur atom, have been obtained under mild conditions from β-acylthio-α-chloro-derivatives of carboxylic[86] or phosphonic[87] acids and from derivatives of 3-chlorothietan-2-one.[88]



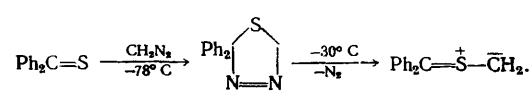
A new aspect of the synthesis of thiirans is based on the reactions of carbonyl compounds with sulphur-containing carbanions in which the sulphur atom is linked to a coordinatively unsaturated carbon atom.[89–94] The intermediate oxy-anions of these compounds rearrange to precursors of thiirans—2-substituted thiolate anions.



Thio- and dithio-carbonates and 2-alkylthio-1,3-oxazolines have been widely investigated in reactions with carbonyl compounds (aliphatic and aromatic aldehydes and acyclic and alicyclic ketones). The method makes it possible to obtain different thiirans, including optically active thiirans (XXX), substituted thioglycidates (XXXI), bisthiirans (XXXII), etc.

Instead of aldehydes and ketones, it is possible to use alkyl thiolocarboxylates; they acylate sulphur-containing carbanions to α-thiolated ketones, which after reduction afford thiirans, for example, compound (XXXIII), in high yields.[95]

(XXX) (XXXI) (XXXII) (XXXIII)

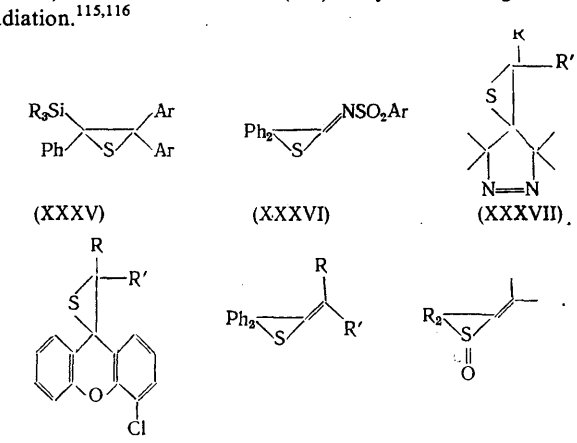


The thermal reactions of 2-hydroxyalkanethiol derivatives, in which the sulphur atom is linked to a coordinatively unsaturated atom, belong to this type. Thus, 2-R-thiirans and (especially readily) 2-R-2-R′-thiirans are formed on thermolysis of 2-hydroxyalkanethiol esters of phosphorus acids.[96] Epithiopropylpyrimidines are formed similarly from 3-hydroxypyrimidothiazines:[97]

trans-2-Bromocyclohexanol is converted into epithiocyclohexane in a similar way on interaction with an excess of KSCN in aqueous alcohol.[98]

3. Homolytic Methods of Synthesis

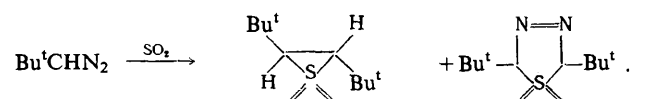
The biradical mechanism of the formation of thiirans by the reaction of diazoalkanes with thiones has been questioned. It is believed[99] that the interaction of thiobenzophenone with diazomethane leads initially to 1,3,4-thiadiazoline, which is converted into the thiocarbonylide (XXXIV) at –30 °C.



(XXXIV)

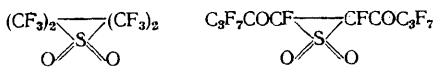
The following selective reactions of compound (XXXIV) are believed to constitute confirmation of its formation: isomerisation to 1,1-diphenylthiiran, dimerisation to 2,2,3,3-tetraphenyl-1,4-dithiane, and 1,3-dipolar addition to active dipolarophiles.

The data obtained in the above study[99] apparently reflect the anomalous behaviour of diazomethane in these reactions. Thus the same workers obtained only 3,3-diphenylthioglycidate in the reaction of thiobenzophenone with diazoacetic ester,[100] while the reactions with diazoethane and phenyldiazomethane afforded 3-methyl-2,2-diphenyl- and 2,2,3-triphenyl-thiirans.[101] The formation of thiocarbonylides was not demonstrated in such cases.



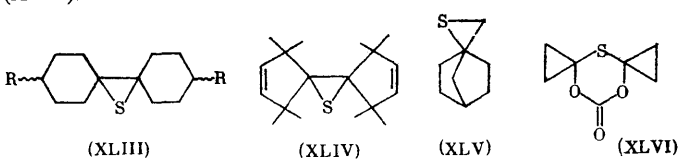
Two examples of this reaction have been investigated.[102–117] Thiirans are formed on interaction of Ph_2CN_2 with tetraphenyl-4-thiopyrone,[102] mono- and di-thio-*N*-arylphthalimides,[103] and *N*-substituted 3-aminoindene-1-thiones.[104] Silylated thiirans (XXXV) have been obtained by the reaction of diaryldiazomethanes with thioacylsilanes,[105,106] while the reactions with sulphonyl isothiocyanates afforded the thiiran imines (XXXVI).[107,108] Diazomethane, diazoethane, diazoacetic ester, and phenyl- and diphenyldiazomethanes interact under mild conditions with tetramethylpyrazoline-4-thione to form the spirothiirans (XXXVII).[109] Diphenyldiazomethane, 4-chloro-9-diazoxanthene, and 9-diazofluorene react with 4-chloroxanthene-9-thione, affording the spirothiirans (XXXVIII).[110] Thiirans have also been obtained in the reactions of 4,4-dimethoxythiobenzophenone with 1-diazo-2,3-dihydroindene,[111] of monothioanthraquinone with 10-diazoanthrone,[112] and of norbornanethiones and thiobenzophenone with diazopropellanes.[113] Diazoketones having the structure $ArCOCHN_2$ react with thiones in a complex manner:[114] aroylthiirans have been obtained only by reaction with fluorene-5-thione. Thioketens and thioketen *S*-oxides react with diazoalkanes to form the corresponding thiadiazolines, which are converted into the thiirans (XXXIX) and thiiran oxides (XL) only on heating or on UV irradiation.[115,116]

(XXXV) (XXXVI) (XXXVII)



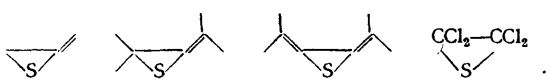
(XXXVIII) (XXXIX) (XL)

The effect of conditions on the mode of reaction of diazoalkanes with sulphur dioxide has been investigated.[117] In the case of t-butyldiazomethane, *trans*-2,3-di(t-butyl)thiiran 1,1-dioxide is formed together with a mixture of *cis*- and *trans*-thiadiazoline 1,1-dioxides whose decomposition affords a mixture of *cis*- and *trans*-thiiran dioxides:



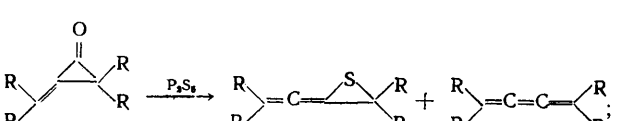
Mixtures of *cis*- and *trans*-thiiran dioxides have been obtained under similar conditions by the reactions of phenyl- and phenylmethyldiazomethanes.

Tetrakis(trifluoromethyl)thiiran 1,1-dioxide (XLI) is one of the products of the reaction of the highly electrophilic hexafluorodimethylsulphonene.[118] The dehydrofluorination of α-fluoro-α-fluoro-sulphonylmethyl perfluoropropyl ketone by the complex $NEt_3.BF_3$ led to 2,3-bis(perfluorobutyryl)-2,3-difluorothiiran 1,1-dioxide (XLII) as a mixture of the *cis*- and *trans*-isomers.[119] Thiiran 1,1-dioxide is believed[120] to be formed as an intermediate in the catalytic high-temperature oxidation of ethylene by sulphur dioxide.



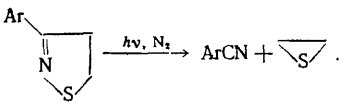
(XLI) (XLII)

Much attention has been devoted to the pyrolytic and photolytic methods of synthesis of thiirans. The thiirans (XLIII)[121,122] and (XLIV)[123] have been obtained by the thermolysis of spirocyclic 1,3,4-thiadiazolines. The relatively unstable methylenethiiran (XLVII) has been synthesised by the vacuum flash pyrolysis of the cyclopropanethione trimer, the episulphide (XLV), or the carbonate (XLVI).[124,125]



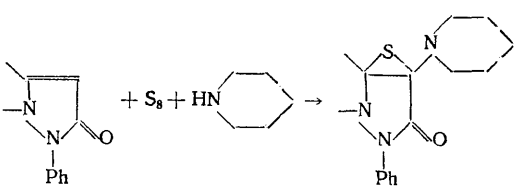
(XLIII) (XLIV) (XLV) (XLVI)

(XLVII) (XLVIII) (XLIX) (L)



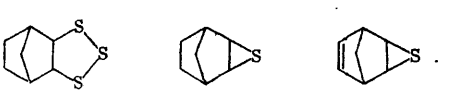
The episulphide derivative of the tetramethylallene (XLVIII) is formed on pyrolysis of the sodium salt of the tosylhydrazone of 2,2,4,4-tetramethylthietanone[126] and on photolysis of tetramethylcyclopropanethione.[127] The vacuum pyrolysis of 2,4-diisopropylidenethietanthione[128] or of the lithium salt of the tosylhydrazone of 4-isopropylidene-2,2-dimethylthietanone[129] has been used to synthesise diisopropylidenethiiran (XLIX). 2,4-Diisopropylidene-1,3-dithietan 1,1-dioxide[130] and tetrachloro-1,3-dithietan 1,1-dioxide[131] are converted on flash pyrolysis into the thiiran (XLIX) and tetrachlorothiiran (L) respectively. The vacuum flash pyrolysis of 2,5-disubstituted 1,3-oxathiolan-5-ones leads to various 1,3-disubstituted thiirans.[132]

The episulphide derivative of buta-1,2,3-trienes were obtained by the thiolation of alkylidenecyclopropanones with phosphorus pentasulphide in pyridine at 80 °C. The episulphide derivatives are partly converted into buta-1,2,3-trienes.[133,134]



R = Bu^t.

3-Aryl-1,2-thiazolines are converted into thiiran and aryl cyanides on UV irradiation.[135]



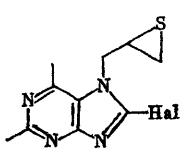
The behaviour of substituted 2*H*-1,3-oxathioles has been investigated under mass spectrometric electron impact conditions.[136] Their cyclodecomposition leads to the thiocarbonylides $RR'C{=}S{-}CBzR''$. Depending on the nature of R and R', the latter cyclise either into thiirans or into the initial oxathioles. The radical-ion reactions of dibenzoyldibromomethane with potassium xanthate[137] and of dibenzoylmethane with sulphur *NN*-bis-(arenesulphonyl)diimide[138] under mild conditions led to tetrabenzoylthiiran, which isomerises to 2,2,4-tribenzoyl-5-phenyl-1,3-oxathiole already during the formation process according to the results of two investigations.[136,139]

Publications have appeared on the syntheses of thiirans from alkenes and elemental sulphur. Irradiation of a mixture of norbornene and S_8 and CS_2 leads to trithiatricyclodecane (LI) and epithionorbornane (LII).[140] Norbornadiene gives rise to the episulphide (LIII) on heating with S_8 in dimethylformamide (DMF) and activation with NH_3.[141] The reaction of antipyrine with sulphur in the presence of cyclic amines leads to an aminothiiran.[142]

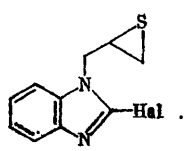
The synthesis of natural sesquiterpene episulphide derivatives of caryophyllene, isolated from the essential oil of hops, has been achieved. These compounds are formed on UV irradiation with mixtures of sesquiterpenes with S_8 in cyclohexane or on radiolysis of sesquiterpenes in the presence of phenyl isothiocyanate.[143]

(LI) (LII) (LIII)

New data have also been obtained on the photochemical reaction of COS with ethylene.[144]

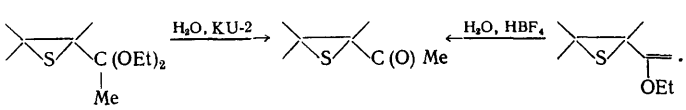


It has been shown that the formation of ethylenethiol is associated with the participation of excited $S(^1D_2)$ atoms. Recommendations concerning the control of the process have been developed.



Calculations have been carried out for the $\dot{C}H_2CH_2\dot{S}$ species.[145] Their characteristic feature is the occurrence of the effective spin–orbital interactions of the unpaired electrons, which induces ready $T{-}S$ transitions and ensures the stereospecificity of the formation of the thiiran ring under mild conditions.

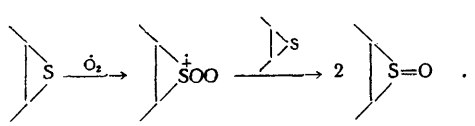
4. Reactions of thiirans without ring opening



In the presence of alkalies, thioepichlorohydrin reacts in ether with mono-, di-, and tri-halogenoallyl alcohols, dichloropropanol,[28] alkylcellosolves,[29,30] and 3-(triorganosilyl)-substituted allyl[32] and propargyl[33,146] alcohols. Carboxylic acid salts react similarly with thioepichlorohydrin.[147] On treatment with 3-(trimethylsilyl)-propargyl alcohol, the Si—C≡C bond is cleaved and 2,3-epithio-1-propargyloxypropane is formed.[32]

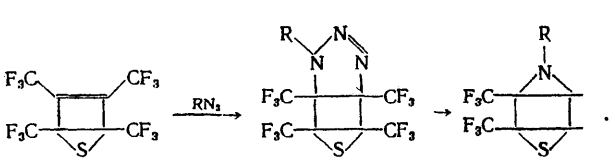
The thiirans (III) have been obtained in the presence of bases under mild conditions from thioepichlorohydrin and alkyl-2-cyanoethylamines.[37] Lithio-*o*-carbaboranes form compounds (VII) in these reactions.[148] Thioepichlorohydrin reacts with sodium, potassium, and ammonium thiocyanates in alcohol to form 2,3-epithio-1-thiocyanatopropane with a small admixture of isothiocyanate, while the reaction with potassium diethyl phosphorothioate affords *OO*-diethyl thioglycidyl phosphorothioate.[149] The epithiopropanes (LIV) and (LV) have been obtained in aprotic media [DMF, dimethyl sulphoxide (DMSO)] by the reaction of thioepichlorohydrin with 8-halogenoxanthines and 2-halogenobenzimidazoles.[150]

(LIV)



(LV)

The conditions governing the formation of acetylthiiran from acetylthiiran acetal and 2R-2-(α-ethoxyvinyl)thiiran have been investigated.[43]

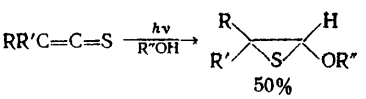


Formylthiiran is formed just as smoothly from its diethylacetal.[42]

The photochemical oxidation of alkylthiirans with oxygen in acetone, CH_3CN, $CHCl_3$, and CH_2Cl_2 leads to thiiran oxides in accordance with the scheme,[151]

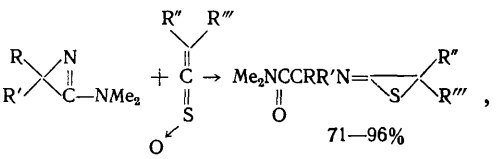
In alcohol, the thiiran ring is opened and the sulphur atom is oxidised. Diallyl-thiirans are indifferent to oxygen on UV irradiation.

The conversion of the stable "Dewar thiophen" into a valence isomer of 1,4-thiazine may serve as an example of the modification of thiirans at the multiple bond of a ring substituent.[152]



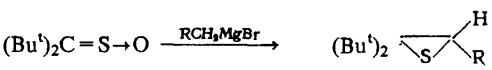
5. Other methods

A novel method of synthesis of thiirans was discovered in a study of the reaction of dimethylaniline oxide with CS_2 in the presence of alkenes.[153]

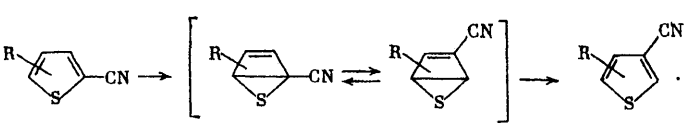


The yield increases with increase in the excess of CS_2 and the alkene. The thiolating agent is believed to be the oxathiiranthione formed from CS_2 and the *N*-oxide.

Alkoxythiirans are formed on UV irradiation of thioketens in benzene in the presence of alcohols.[154] The carbene RR'C—CS is believed to be a precursor of alkoxythiirans.

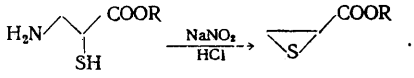


New methods of synthesis of thiiran imines are based on the reaction of dimethylaminoazirines with thioketen *S*-oxides.[155] It is believed that the reaction

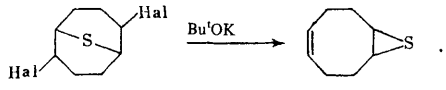


proceeds via a 1,3-dipolar addition mechanism. the formation of an epithio-compound in the reaction of pivaloylthioaldehyde with Wittig reagents has been explained by the formation and reactions of cyclic [2 + 2]adducts.[156]

Thiirans are the main products of the reactions of primary organomagnesium or organolithium compounds with the *S*-oxide of di(t-butyl) thioketone.[157]

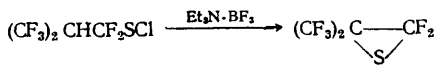


Bicyclic thiirans of the type of "Dewar thiophen" are apparently formed as intermediates in the photolysis of 2-cyanothiophens, which is the cause of their isomerisation to 3-cyanothiophens.[158,159]

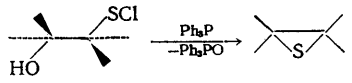


Thiirancarboxylic acids are formed stereoselectively on deamination of aminothiols.[160] The enantiomers of cysteine or its esters afford in this reaction epithioglycidates with the inverted

configuration. The enantiomers of 6-aminopencillanic acid are converted into 3,3-dimethylthioglycidic acid.



Dihalogeno-derivatives of thiabicyclooctanes and thiabicyclononanes are converted almost quantitatively into monoepithio-derivatives of cyclodienes on dehydrohalogenation by potassium t-butoxide.[161]



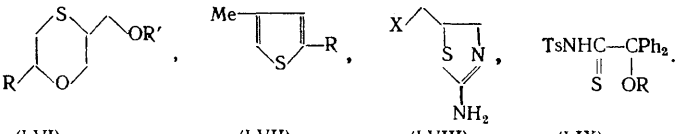
Epithiodiadamantylidene was obtained by the reaction of diadamantylidene with S_2Cl_2 in CH_2Cl_2 at 20 °C.[162–164] In the presence of SCl_2, the epithio-compound is chlorinated to 4-chloro-, 4,4'-dichloro-, and 4,4',8-trichloroepithiodiadamantylidenes.

Epthio-compounds have been obtained[165,166] from sulphenyl chlorides. 2-Hydrooctafluoroisobutanesulphenyl chloride is dehydrochlorinated by the complex $NEt_3.BF_3$ to epithioperfluoroisobutane.[165]

2-Hydroxyalkanesulphenyl chlorides are converted stereospecifically into epithio-compounds on treatment with triphenylphosphine.[167]

The reaction of the monothio-derivative of ethylene glycol with diethoxytriphenylphosphorane in toluene leads to a mixture of thiiran and ethyl 2-hydroxyethyl sulphide.[168]

63% 37%



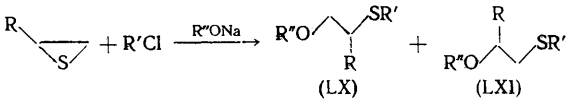
III. Reactivity

Extensive data on the reactivities of a wide variety of thiirans in reactions with hydroxy- and amino-compounds, thiols, CH acids, and various electrophiles as well as data on the behaviour of thiirans in desulphurisation and cyclisation reactions have accumulated during the last decade. There has been considerable expansion of available information about the intramolecular reactions of thiirans with functional group substituents. New quantitative characteristics of the principal types of reactions of thiirans have appeared.

1. Reactions with hydroxy-compounds

The polymerisation of thiirans in the presence of hydroxy-compounds and basic catalysts prevents the preparative use of this reaction.[1] It had been used earlier only for the synthesis of thietan-3-ol and its derivatives by the opening of the ring of thioepichlorohydrin by certain oxy-anions. This reaction (the thiiran–thietan rearrangement) is being investigated, as before, both for preparative purposes[4–12] and theoretically.[169] At the same time, new examples of the synthetic employment of the nucleophilic opening of the thiiran ring by hydroxy-compounds have appeared.

Thus the interaction of 1-(2-halogenoalkoxy)-2,3-epithiopropanes with alcohols in the presence of bases leads to 1,4-oxathianes (LVI).[29] Propargyl- or propyn-1-yl-thiirans isomerise to thiophens (LVII) on treatment with potassium t-butoxide.[52] Under the conditions of nucleophilic ring opening, *N*-2,3-epithiopropylcyanamide is quantitatively converted into 2-amino-1,3-thiazoline (LVIII).[82] Thiiran imines (XXXVI) react with alcohols under mild conditions to form the amides of α-alkoxy-substituted thiocarboxylic acids (LIX).[107,108] When ethylene sulphide is heated with phenyl acetate in the presence of tri-n-butylamine, 2-phenoxyethyl thioacetate is formed in a high yield.[170]



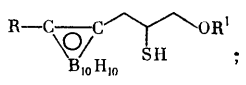
(LVI) (LVII) (LVIII) (LIX)

Another aspect is based on the competing reactions in thiiran–RONa–benzyl chloride systems.[171]

The study of such reactions has shown[172–182] that, in the presence of benzyl and allyl chlorides, monomeric products are formed in 50–80% yield from ethylene sulphide and sodium alkoxides derived from primary aliphatic alcohols, benzyl alcohol, and trifluoroethanol, and also sodium phenoxides. 2-R-Thiirans, including methylthiiran, butylthiiran, phenylthiiran, alkoxy- and aryloxymethylthiirans, and vinylthiiran react similarly in these systems.

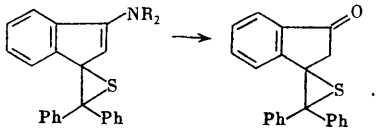
It has been established that only alkoxy- and aryloxymethylthiirans interact regioselectively with alkoxy- and aryloxy-anions, mainly in accordance with Krasuskii's rule, i.e. with formation of products having the "normal" structure (LX). The reactions with other 2-R-thiirans afford mixtures of products containing also substances having the "anomalous" structure (LXI).[179–182]

(LX) (LXI)



The mixture composition depends significantly on the nature of the oxy-anion and the ring substituent.

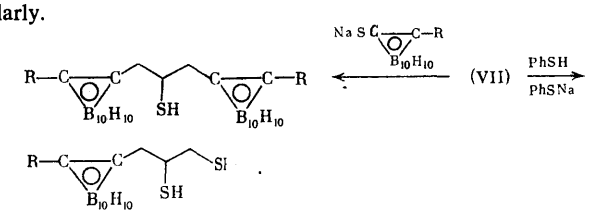
The kinetic characteristics and thermodynamic parameters of the reaction permit the conclusion that the reactions proceed via the "push-pull" (Ad_1) mechanism.[173,175–182] The rate-limiting stage in these reactions is the formation of the thiiran–hydroxy-compound ion pair which is facilitated by solvation by proton-donating solvents. The reactivity of this pair is higher than in the analogous reactions of oxirans, which is the reason for the increased tendency of thiirans to be polymerised by hydroxy-compounds. In all the cases investigated, large (in absolute magnitude) negative entropies for the activation of the "normal" opening of the thiiran ring compared with the "anomalous" opening are observed, which is also characteristic of the analogous reactions of oxirans.



The polymerisation in the reactions of thiirans with hydroxy-compounds can also be suppressed under the conditions of acid catalysis. Thus, in the presence of sulphuric acid, 1,2-epithiodecane interacts with primary aliphatic alcohols to form mixtures of primary and secondary alkoxydecanethiols;[183,184] the isomer ratio depends on the nature of the alcohol and the amount of catalyst. With decrease in the solvating capacity of the solvent, the yield of the monomeric product falls. Tertiary alcohols are ineffective in these reactions in view of their low stability in the presence of acids.

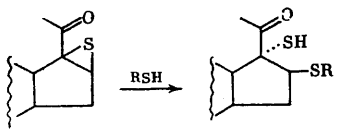
In contrast to epithiodecane, carbaboranylthiirans (VII) react unambiguously with water and alcohols under the conditions of acid catalysis, forming the "normal" structure products (LXII).[71] Under the conditions of nucleophilic catalysis, these reactions lead to oligomers only.[185]

It is noteworthy that the acid-catalysed reactions of thiirans with hydroxy-compounds take place under comparatively severe conditions. Without affecting the thiiran ring, this made it possible to replace the enamine group of compound (LXIII) by the keto-group[104] and to obtain 16,17α-epithiopregnenolene from its acetate.[186] Some of the bicycloalkylidenethiirans are fairly resistant also to bases. This property has been used to remove with the aid of methanol the acetyl protecting group in the diacetates of epithiosecosteroids in the presence of Na_2CO_3.[121]



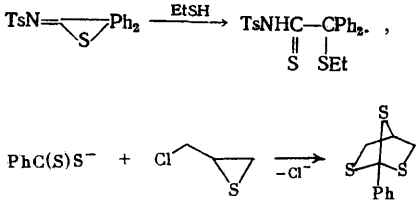
(LXII)

(LXIII)



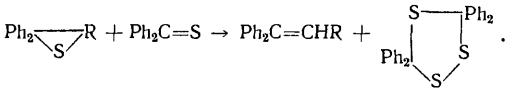
2. Reactions with thiols and thiones

There are few new data on the reactions of thiirans with thiols. The study of the properties of carbaboranylthiirans (VII) established that their interaction with thiophenol in the presence of sodium thiophenoxide in ethanol takes place unambiguously in accordance with Krasuskii's rule.[185] Sodium *o*-carbaboranyl-thiolates react similarly.



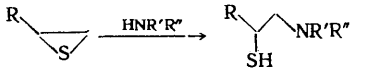
Under the same conditions, carbaboranylthiirans are converted into bismercaptans on reaction with sodium hydrogen sulphide[186] and into trithiocarbabonates on reaction with potassium methyl-xanthate.[72]

Interesting results have been obtained in the study of the reactions of the 16,17α-episulphide ring of 20-ketopregnanes and their hydrazones.[187,188] The reactions of the 3-acetate of 16,17α-epithio-pregnolone with phenylmethanethiol (under the conditions of electrophilic catalysis) or with thioloacetic acid take place stereospecifically in accordance with Krasuskii's rule.



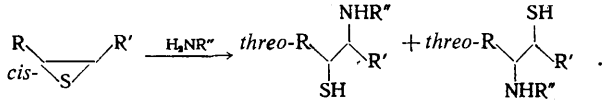
However, ethanethiol splits off sulphur from the epithio-compound under these conditions. The hydrazone of epithiopregnolone undergoes desulphurisation even by thioloacetic acid.

The results of the reactions of thiiran imines with ethanethiol[108] and of thioepichlorohydrin with aluminium dithiobenzoate[189] are of interest.



Data have been published on the reactions of thiirans with thiocarbonyl compounds. Di- and tri-substituted thiirans are desulphurised by thiobenzophenones under mild conditions with formation of alkenes and 1,2,4-trithiolans.[190]

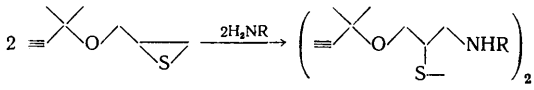
Mono- and di-substituted thiolans react with carbon disulphide in solutions in tertiary amines at a high pressure and are converted into trithiocarbonates.[191] 1-(*N*-Carbazolyl)-2,3-epithiopropane readily forms a cyclic adduct with CS_2.[39] In the presence of zinc, cadmium, merury, and ammonium hydrogen sulphides, thiirans react with carbon disulphide and are converted into oligomeric polythio-carbonates.[192]



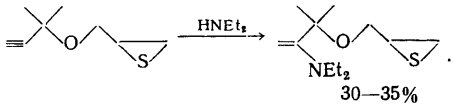
3. Reactions with amines

Reactions with amines constitute the most widely investigated branch of the chemistry of thiirans.[1] In addition to the known quantitative characteristics of the processes involving the opening of the ring in thiirans by amines[1] (Ref. 1, p. 219), a comparative study has been made of the kinetics of the reactions of epoxypropane and epithiopropane with dibutylamine.[193] The results of this study confirmed the qualitative idea that in aprotic media the thiiran ring is opened by dibutylamine more readily than the oxiran ring. The high regioselectivity of the opening of the epithiopropane ring by dibutylamine in conformity with Krasuskii's rule was established. This is a general feature of the reactions of 2-R-thiirans with amines.

The first data on the stereochemistry of this reaction have appeared. It has been shown that *cis*- and *trans*-2,3-dimethyl-thiirans are converted exclusively into *threo*- and *erythro*-aminothiols respectively on heating (90–100 °C) with primary amines (in 200% excess).[194] Mixtures of esters of the regioisomers of anilino-mercaptooctadecanoic acid having the *threo*-configuration have been obtained in the reactions of the methyl esters of *cis*-6,7- and *cis*-9,10-epithiooctadecanoic acids with aniline in the presence of Ag^+ as

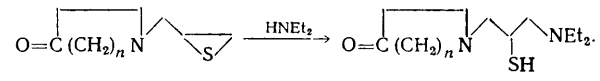


the catalyst; the *trans*-isomers give rise to the analogous products having the *erythro*-structure.[76] Thus the thiiran ring is opened by amines stereospecifically with inversion of the configuration:



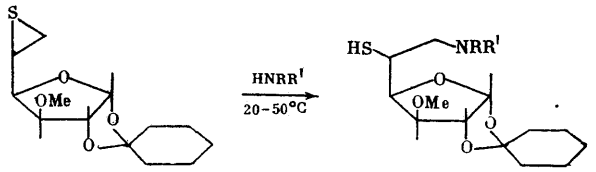
The influence of temperature, solvents, reactant ratio, and the presence of hydroxylated agents on the results of the reaction of 1,2-epithiodecane with secondary amines of different basicity has been investigated in detail.[195] The excess of the amine has a decisive influence on the yield of monomeric products, which indicates the participation of two molecules of the amine in the opening of the ring.

The regioselective formation of aminothiols with the "normal" structure has been established in the reactions of secondary amines with esters based on epithioglycidol. They include 1-triorganylsilylalkoxy(alkenyloxy)-2,3-dimethylthiirans,[32,33] polyhalogenoalkoxymethylthiirans, furfuryloxy- and t-butoxymethyl-thiirans,[31,34] and derivatives of *O*-(2,3-epithiopropyl)hydroxylamine.[196,197]

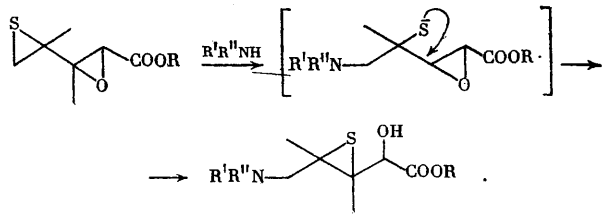


Alkynyloxymethylthiirans react with aliphatic primary amines even in the presence of their excess (100%) only under severe conditions (100–105 °C) with formation of disulphides.[198] Tryptamine, thyramine, and histamine react similarly.[199]

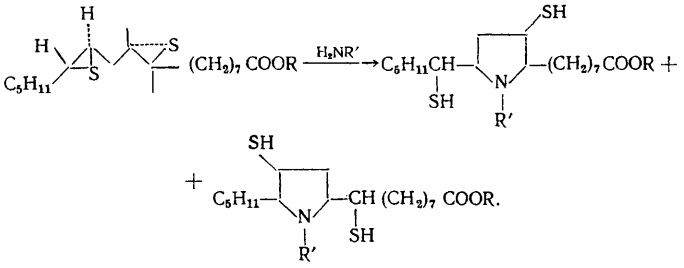
Under more severe conditions (130 °C), the disulphides formed combine with alkylamines via the triple bond. Dialkylamines do not enter into this reaction even in the presence of a large excess of the amine, while in the reaction catalysed by $Et_2O.BF_3$ they add to the triple bond.[200]



The reactions of *N*-(2,3-epithiopropyl)-substituted 2-pyrrolidinone and 2-piperidinone with diethylamine under severe conditions lead to products with the "normal" structure, which are partly oxidised to disulphides:[38]

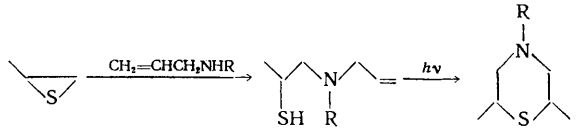


Ring opening via the Krasuskii mechanism has been established in reactions of amines with thiirans having electron-accepting ring substituents—trifluoromethylthiiran[75] and *o*-carbaboranylthiirans.[148,185,187]

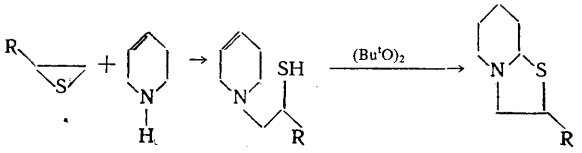


The amination of epithiocarbohydrates by primary and secondary amines and aminoacid esters takes place under unusually mild conditions, which made it possible to obtain aminomercaptoderivatives of glucofuranose,[201] isofuranose,[202] and sorbitol.[203]

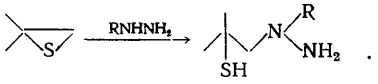
The interaction of esters of 2,3-epoxy-4,5-epithiovaleric acids with secondary amines is accompanied by the 2,5-addition of the nucleophile and the 5,3-migration of the thiiran ring, which is a consequence of its "normal" opening and subsequent reaction of the aminothiolate formed.[46]



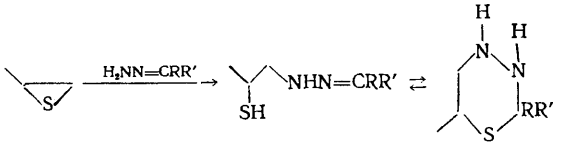
The reactions of primary amines with bisthiirans are accompanied by cyclisation. Thus the only products of the reaction of methyl-, isopropyl-, and benzyl-amines with the *threo*-isomer of *cis*-9,10-*cis*-12,13-diepithiooctadecanoic acid and its esters in aqueous alcohol in the presence of Ag^+ as the catalyst proved to be substituted mercaptopyrrolidines.[204–206]



Aniline enters into this reaction with greater difficulty, affording substituted mercaptopyrrolidines with an admixture of aminomercaptothiirans.



Allyl-, ethylallyl-, and benzylallyl-amines react with thiirans to form mainly the "normal" ring opening products, which cyclise to perhydro-1,4-thiazines on UV irradiation.[207]



When 2-R-thiirans are heated in benzene with a twofold excess of tetrahydropyridine, secondary aminothiols are obtained in a high yield. They are converted into 7-thia-1-azobicyclo[4.3.0]nonanes under the conditions of a free-radical reaction.[208]

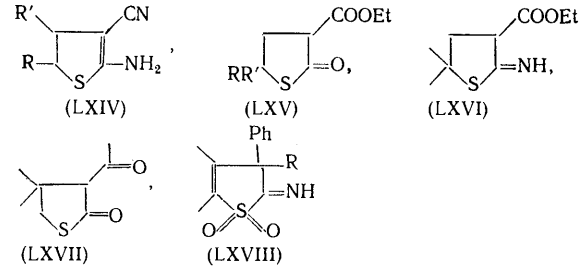
2-Mercaptoalkylation of alkylhydrazines by thiiran, methylthiiran, and epithioisobutane takes place at the substituted nitrogen atom, the ring being opened mainly in accordance with Krasuskii's rule.[209–211]

In benzene at 60 °C, thiiran, methylthiiran, and 2-epithiobutane interact with hydrazones[212,213] to form mainly the "normal" ring opening products, which cyclise reversibly to perhydro-1,3,4-thiadiazines.

The products of the "anomalous" ring opening and the products of the bis-2-mercaptoalkylation of the hydrazones are formed at the same time.

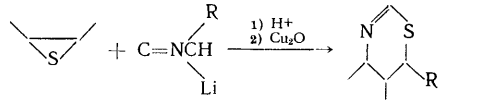
In the search for physiologically active substances, the mono-2-mercaptoethylation of σω-alkylenediamines[13] and the bis-2-mercaptoalkylation of *NN'*-dimethyl-σω-alkylenediamines[214] has been achieved; the products of the reaction of thiirans with *p*-aminophenylacetate esters have been obtained.[14] In the last case, the reaction takes place regioselectively in accordance with Krasuskii's rule.

Under the usual conditions for the 2-mercaptoalkylation of amines, thiiran interacts with macroporous styrene–divinylbenzene copolymers modified by amino-compounds.[215]



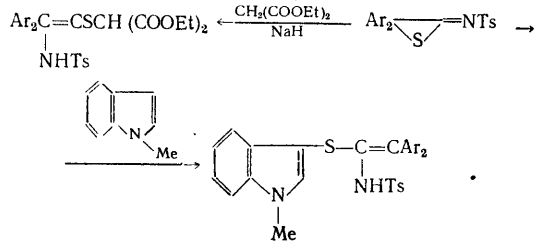
4. Reactions with CH acids

CH acids usually initiate the polymerisation of thiirans under the conditions of nucleophilic catalysis and 3-ethoxycarbonyl-2-imino-tetrahydrothiophens have been obtained earlier only in the reaction with ethyl cyanoacetate (Ref. 1, p. 201). The conditions for the formation of the products of the cyclocondensation of epithio-compounds with other CH acids and their salts have been found recently and the regioselectivity of these reactions has been investigated.



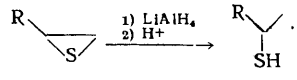
In the presence of NaH in DMSO, malonodinitrile interacts with thiiran, 2-methylthiiran, and 2-phenylthiiran, forming enaminonitriles of the dihydrothiophen series (LXIV) in 50–62% yield. The 2-methylthiiran ring is then opened in accordance with Krasuskii's rule, while that of 2-phenylthiiran is opened contrary to this rule.[216] An enaminonitrile was obtained from thiiran in diglyme in 23% yield,[217] while the product of the cyclocondensation of the enaminonitrile obtained from 2,2-dimethylthiiran in ethanol in the presence of EtONa of the catalyst was obtained in 62% yield.[218]

The reactions of thiirans with malonic ester in alcohol in the presence of EtONa lead to 3-ethoxycarbonyltetrahydrothiophen-2-ones (LXV) in 35–65% yield.[218] 2-Phenylthiiran is converted in the analogous reaction into a mixture of regioisomers (the "anomalous" ring opening product is the main component). 2,2-Dimethylthiiran reacts with cyanoacetic and acetoacetic esters, affording the "normal" ring opening products (LXVI) and (LXVII).[218]

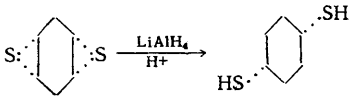


Substituted sodiophenylacetonitriles form the cyclocondensation products (LXVIII) with 2,3-dimethylthiirene 1,1-dioxide in tetrahydrofuran.[219]

The lithio-derivatives of isocyanides add to methylthiiran, epithiocyclohexane, and epithiocyclopentane, affording γ-mercaptoalkyl isocyanides, which cyclise to 4*H*-5,6-dihydro-1,3-thiazines.[220]



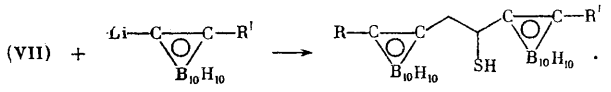
In the presence of NaH, tosyliminothiirans interact with malonic ester,[108] affording enaminosulphides. *N*-Methylindole interacts analogously.



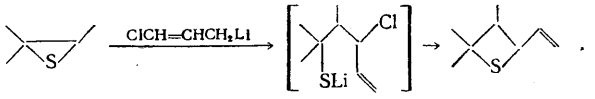
The attempt to involve diisopropylidenethiiran in the reaction with malonic ester in the presence of palladium diacetate as the catalyst was unsuccessful.[128] The product of this reaction was 1,1,4,4-tetramethylbutatriene.

5. Reactions with metal hydrides and organometallic compounds

The latest studies have confirmed the high regioselectivity of the reduction of thiirans by lithium tetrahydroaluminate to secondary thiols. Triorganylsilylalkoxy(alkenyloxy)methylthiirans,[32,33] trifluoromethylthiiran,[75] and also methyl- and phenyl-*o*-carbaboranylepithiopropanes[72] interact with $LiAlH_4$ exclusively in accordance with Krasuskii's rule.

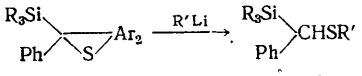


Together with a secondary thiol, an admixture of "anomalous" ring opening product is formed in the reaction of isopropyl-*o*-carbaboranylepithiopropane.[72] The reduction of *cis*-1,2,4,5-diepithiocyclohexane to *cis*-1,4-dimercaptocyclohexane is highly selective.[44]

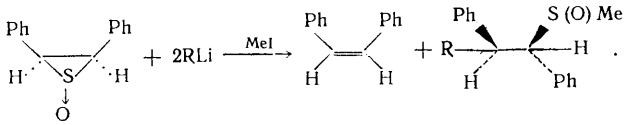


The elimination of sulphur from thiirans has been noted only in isolated instances. For example, the reduction of 4-chlorodiadamantylidenethiiran with $LiAlH_4$ yielded diadamantylidene and not a thiol.[221]

The characteristic features of the reactions of thiirans with organolithium compounds and Grignard reagents have not yet been established. The formation of monomeric products of the reactions of thiirans with organolithium compounds was first demonstrated by Kazantsev et al.[185] and by Ondona et al.[222] Thus carbaboranylthiirans (VII) react with lithio-*o*-carbaboranes to form secondary thiols.[185]

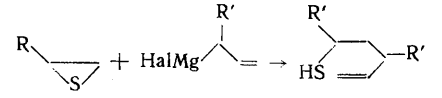


Butyllithium and ethylmagnesium bromide split off a sulphur atom from carbaboranylthiirans.[72,185] At temperatures in the range from −90 °C to −60 °C, substituted thiirans interact with 3-chloroallyllithium to form 2-vinylthietans.[222]

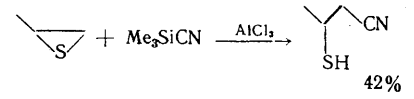


Thioepichlorohydrin is converted in this reaction into the 3-chloro-5,6-epithiohex-1-ene.

The opening of the ring in triorganosilylated triarylthiirans by methyl- and butyl-lithium is accompanied by the cleavage of the C−C bond.[106]

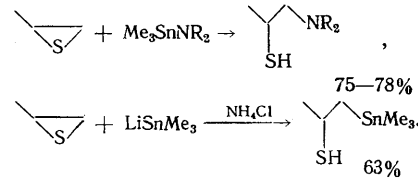


The reactions of butyl- and phenyl-lithium with *cis*- and *trans*-2,3-diphenylthiirans and their *S*-oxides[223] afford the desulphurisation and ring-opening products, which have been isolated as methylated derivatives. *trans*-2,3-Diphenylthiiran and its *S*-oxide are then converted quantitatively into *trans*-stilbene, while the ring opening products with the *threo*-configuration were obtained from the *cis*-isomers together with *cis*-stilbene.



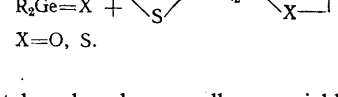
The stereospecificity of the desulphurisation has been explained by the formation and concerted decomposition of intermediate episulphuranes.

New examples of the regioselective interaction of thiirans with Grignard reagents have been described.[224–226] Alkenylmagnesium halides of the allyl type interact with various thiirans to form unsaturated thiols.[224–226]

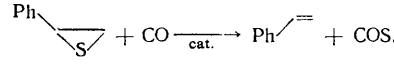


Diisopropylidenethiiran does not react with ethylmagnesium bromide.[129]

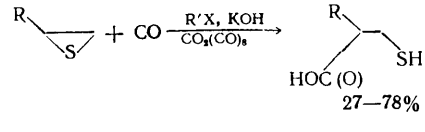
The reactions of thiirans with organic derivatives of Group IV elements have been investigated. Trimethylsilyl cyanide interacts with methylthiiran regioselectively in boiling dichloromethane in the presence of $AlCl_3$ as catalyst, affording silylated β-mercaptobutyronitrile together with propene.[227]



Dialkyl(trimethylstannyl)amides react with methylthiiran and epithiocyclohexane in the absence of the catalyst. In contrast to dialkyl(stannyl)amides, trimethylstannyllithium gives rise to the "normal" ring opening product.[228]

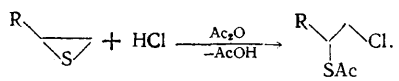


Epthiocyclohexane is partly converted into cyclohexene in this reaction.

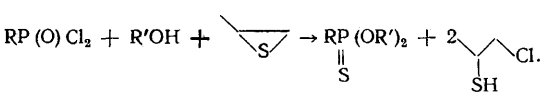


The complex of diethylgermylene and triethylamine interacts with thiiran at 130−150 °C, affording 1,2,5-germadithiolan and ethylene.[229,230] Diethylgermanethione, which undergoes [2 + 3]cycloaddition to thiiran, is believed to be an intermediate in this reaction. This has been confirmed by direct reactions of thiiran with dialkylgermanones and germanethiones.[231]

Metal carbonyls as well as variable valence metal complexes abstract sulphur from thiirans.[232] In the presence of carbon monoxide, rhodium and palladium complexes catalyse the desulphurisation reaction in accordance with the mechanism[233]

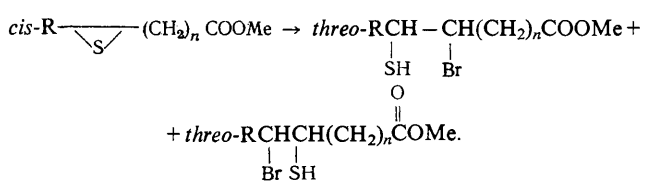


However, the reaction catalysed by $Co_2(CO)_8$ in benzene in the presence of methyl iodide or benzyl bromide and aqueous KOH under phase transfer conditions results in the formation of β-mercaptoalkanecarboxylic acids.[234]

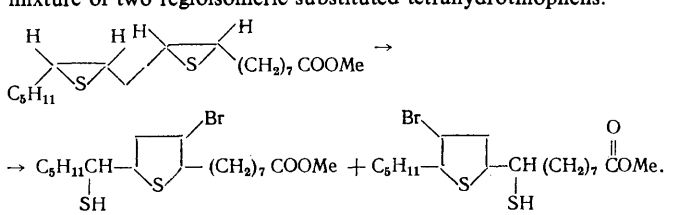


6. Reactions with electrophiles

It has been shown for a large number of examples that the reactions of thiirans with electrophiles are distinguished by a greater variety than had been believed previously. The interaction of carbaboranylthiirans (VII) with concentrated HCl at 0–10 °C resulted in the slow formation (over a period of 10 h) of the "normal" ring opening product. HBr and HI react similarly; in the latter case, the intermediate thiol is oxidised to the disulphide.[71,72,235] In contrast to HCl, HBr interacts with carbaboranylthiirans also in anhydrous media, which can be explained by the specific solvation of the sulphur atom by bromides. HCl in acetic anhydride interacts just as readily with these compounds as with methylthiiran.[70]

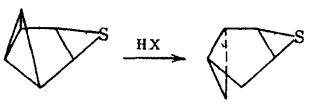


Similar features are characteristic of the reactions of hydrogen halides also with other electron-deficient thiirans, for example, with 3,4-epithiothiolan 1,1-dioxide;[73] in this case too, HCl reacts readily and unambiguously only in acetic anhydride. Under severe conditions, HCl interacts also with trifluoromethylthiiran, affording exclusively the product with the normal structure—a secondary halogenothiol.[75]

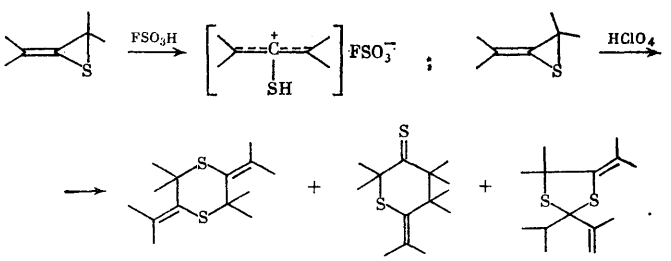


In the absence of electron-accepting substituents in the molecule, thiirans readily combine with HCl in non-polar media. Thus triorganosilylalkoxymethylthiirans[33] and 1-(*N*-phthalimido)-2,3-epithiopropane[236] are converted into secondary halogenothiols in $CHCl_3$ and CCl_4. Aliphatic 2-R-thiirans bind HCl so vigorously that they can be used successfully as hydrogen halide acceptors.[237]

The opening of the ring in thiirans by hydrogen halides is accompanied by the inversion of the configuration. A mixture of *threo*-isomers has been obtained from the esters of higher aliphatic *cis*-epithio-acids on interaction with HBr,[76] while the esters of the *trans*-epithioacids afforded a mixture of *erythro*-isomers.

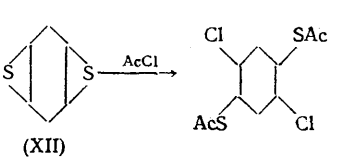


In a number of instances, the interaction of thiirans with hydrogen halides leads to unusual results. The esters of *cis*-9,10-*cis*-12,13-diepithiooctadecanoic acids react with HBr to form a 1:1 mixture of two regioisomeric substituted tetrahydrothiophens.[238]



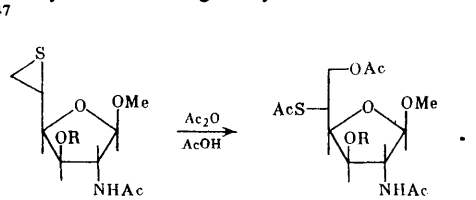
CCl_3COOH reacts similarly.

On treatment with HCl, epithioadamantylidene gives rise to diamantylidene.[221] The reaction of benzvalene sulphide with HCl and acetic acid is accompanied by a skeletal rearrangment.[85]



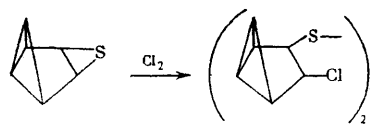
Carbaboranylthiirans (VII) are hydrolysed by 10% H_2SO_4 to mercaptoalkanols in accordance with Krasuskii's rule.[71] The usual thiirans do not polymerise under these conditions.

Tetramethylallene sulphide is protonated by FSO_3H to a stable carbonium ion.[239] However, 70% $HClO_4$ and BF_3 etherate induce its dimerisation.[126,239]

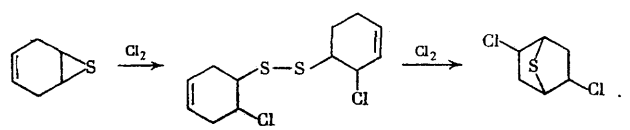


Carbazolylthiiran (VI) is polymerised by dilute inorganic or organic dicarboxylic acids,[240] but acetic acid affords the "normal" ring opening product in 65% yield. Addition in conformity with Krasuskii's rule has been noted also in the reaction of acetic acid with 16,17α-epithiopregnenolones and their hydrazones,[186,188] while the reaction with 1,2-epithiooctane is unambiguous.[241,242]

An uncertain type of ring opening has been observed in the reactions of acetyl chloride with higher 1,2-epithioalkanes[243] and alkylthiomethylthiirans.[244] Carbaboranylthiirans combine with acetyl and benzoyl chlorides in accordance with Krasuskii's rule.[72] Acetyl chloride reacts similarly at 100 °C with trifluoromethylthiiran.[75] The reaction of acetyl chloride with bisepithiocyclohexane (XII) leads to a symmetrical product.[41]

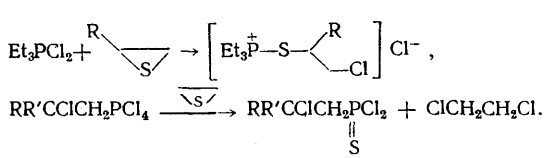


(XII)

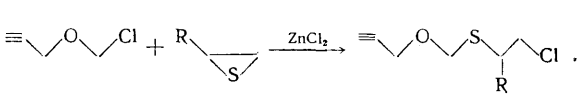


The interaction of higher 1,2-epithioalkanes with carboxylic acid anhydrides in the presence of tertiary amines takes place only under severe conditions and leads to mixtures of 1-acycloxy-2-acylthio-, 2-acyloxy-1-acylthio-, and 1,2-diacylthio-alkanes.[245,246] On the other hand, in acetic acid in the presence of sodium acetate as the catalyst, derivatives of 5,6-epithio-D-glucofuranose interact with acetic anhydride unambiguously in accordance with Krasuskii's rule.[247]

The ambiguity of the ring opening in methylthiiran by chlorine and 2-chloro- or 2-bromo-ethanesulphenyl chlorides (Ref. 1, p. 253) has been confirmed.[248] At the same time, *o*-carbaboranylthiirans (VII) interact unambiguously under mild conditions with chlorine, bromine, iodine,[40,72] and sulphuryl chloride[148] to form the disulphides. The reactions of phthalimidomethylthiiran with bromine[236] and of trifluoromethylthiiran with chlorine[75] are similar. Benzvalene sulphide interacts with chlorine like other thiirans.[86]



However, the monoepithio-derivatives of cycloalkadienes tend to rearrange under the influence of the halogens and sulphuryl chloride.[249]

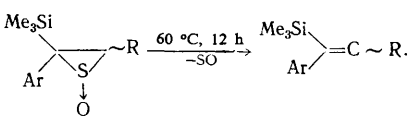


3,3-Ethylenedioxy-4,5-epithiocyclohept-1-ene reacts with halogens to form products corresponding to two possible routes to the opening of the ring.

The reaction of epithiodiamantylidene with SCl_2 leads to the chlorination of the adamantyl groups in the 4-position and then the 4'-position.[162] Methyl iodide abstracts sulphur from these compounds.[211] Refluxing of 4-chloroepithiodiamantylidene with formic acid leads to the substitution of the chlorine atom by the formate group, while the HCl evolved induces the desulphurisation of the epithio-compound formed.[221]

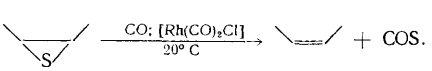
The reactions of 2-R-thiirans with dichlorotriethylphosphorane afforded the relatively stable triethyl-2-chloroalkylthiophosphonium chlorides.[250] Similar products of the reactions of 2-chloroalkyltetrachlorophosphoranes with thiiran decompose readily with evolution of dichloroethane.[251]

The reaction of chloromethyl propargyl ether with 2-R-thiirans in the presence of Friedel–Crafts catalysts results in the preferential formation of products with the "anomalous" structure.[252]



7. Desulphurisation of thiirans

New data refer mainly to the spontaneous or thermal desulphurisation and also to desulphurisation in the presence of metals, organometallic compounds, and trivalent phosphorus compounds.

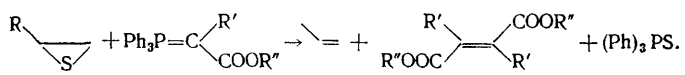


Allene sulphide is converted into allene already at –70 °C,[124,125] while 2,2,3-triphenylthiiran[101] and 2,2-diphenylthiiran[99] split off sulphur after 1 and 15 h respectively at 20 °C. 3-Dialkylaminoindenylidenethiirans (80 °C, 3 h),[104] *cis,trans*-divinylthiirans (90–100 °C),[53] the esters and amides of substituted thioglycidic acids (20–100 °C),[92,93,100,253] the esters of 1,2-epithioethylphosphonic acid,[77] spirothiirans (200–250 °C),[254] and *cis*- and *trans*-dideuteriothiirans (350 °C)[56] are converted into alkenes on heating. Spontaneous or thermal desulphurisation takes place stereospecifically,[53,56,93,253] but in the case of *cis*-2-R-3-R-thiirans it is accompanied by the partial formation of alkenes with the *trans*-configuration.[54]

Several examples of the thermal desulphurisation of thiiran *S*-oxides and *SS*-dioxides have been investigated. For example, the formation of substituted trimethylsilylalkenes from the corresponding *S*-oxides under mild conditions has been demonstrated.[255]

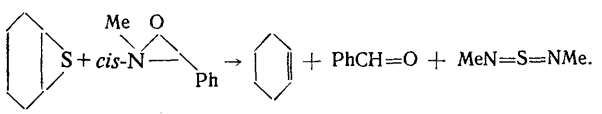
The classical desulphurisation of thiirans by copper bronze at 150–180 °C has been investigated for spirothiirans obtained by the reaction of diazo-compounds with thiopyrans,[102] dithionophthalimide,[103] and xanthones.[110,256] Alkoxythiirans[154] and higher thermal and internal epithioalkanes[257] react under mild conditions (40–90 °C); together with alkenes, alkanes are also formed to some extent under these conditions.

Higher alkenes[257] and secosteroids[121] have been obtained by refluxing the corresponding epithio-compounds with zinc in acetic acid. Thiirans are converted into alkenes on interaction with germylenes,[228] iron pentacarbonyl,[232] and tributyltin hydride in the presence of azobisisobutyronitrile.[257] Stereospecific desulphurisation is catalysed by rhodium complexes in the presence of carbon monoxide.[235]



A wide variety of thiirans have been converted stereospecifically into alkenes on refluxing in dimethoxyethane in the presence of lithium.[55] Carbaboranylthiirans[72] and 2-R-3-R-thiirans[156] split off sulphur also on treatment with butyllithium. Butyl- and phenyllithium convert *cis*- and *trans*-2,3-diphenylthiirans or their *S*-oxides into alkenes.[223]

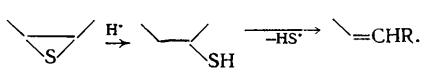
Triphenylphosphine has been used for the desulphurisation of 5-dialkylamino-3,4-epithio-2-hydroxyalkanecarboxylates,[36] a wide variety of 2-R- and 2-R-3-R-thiirans,[90] optically active thiirans,[91] triorganosilylthiirans,[105,106] Dewar's tetrakis(trifluoromethyl)-perhydro-1,4-thiazine,[152] carbaboranylthiirans,[258] and other epithiocompounds. The best desulphurising agents are sometimes PBu_3 and phosphites. Thus, dispirothiirans,[123] tetramethylallene sulphide,[126] and diisopropylidenethiiran[129] are converted into the corresponding alkenes on interaction with PBu_3 and phosphorous tris(dialkylamides). The oxime of 1-acetyl-1-methylthiiran[77] and thiiran imines[155] are readily converted into the oxime of isopropenyl methyl ketone and keten imines respectively on reaction with PBu_3.



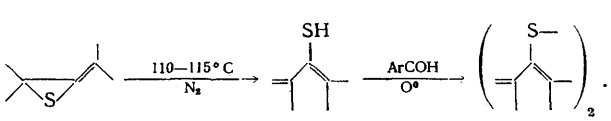
Trialkyl phosphites have been used to synthesise di-, tri-, and tetra-alkylethylenes,[90] *N*-allylpyrimidines,[97] alkylidenepyrazolines,[109] cyclohexylidenecyclohexanes,[122] etc. from thiirans.

New examples of the nucleophilic desulphurisation of thiirans are provided by the conversions into alkenes of triorganosilylated thiirans on reaction with trialkylammonium fluorides[105,106] and by the reactions of carbaboranylthiirans with Grignard reagents.[186] The electrophilic desulphurisation of epithiodiamantylidene has been achieved with methyl iodide.[221] The homolytic elimination of sulphur occurs on the interaction of thiirans with thioketones.[190]

Alkenes are formed from thiiran on reaction of the latter with selenonium ylides (partly)[259] and with phosphonium ylides (quantitatively).[260]

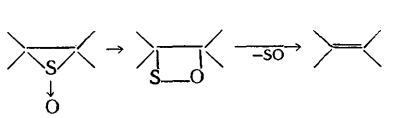


At 20 °C, thiiran, epithiocyclohexane, *cis*- and *trans*-2,3-dimethylthiiran and epithiosteroids are desulphurised quantitatively by oxaziridines.[261]



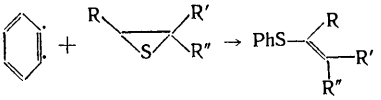
The reaction is stereospecific and is the best method for converting epithio-compounds into alkenes.

cis-2,3-Dimethylthiiran is desulphurised in the gas phase by atomic hydrogen.[262] The quantitative characteristics of such reactions have been obtained for thiiran itself.[263]



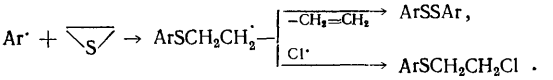
8. Other homolytic reactions

Tetramethylallene sulphide is converted on thermolysis into a 1,3-diene-3-thiol.[264]

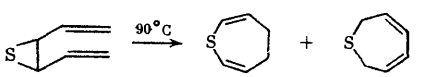


A similar shift of the hydrogen atom takes place also on thermolysis of thiiran with formation of ethylenethiol.[144,265]

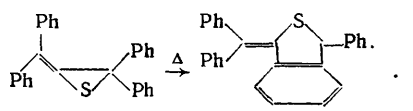
The interaction of epithiodiadamantylidene with singlet oxygen leads to desulphurisation and the formation of an *S*-oxide, dioxetan, and an epoxide.[266] 1,2,3-Oxadithiolan-2-thione undergoes similar reactions under the conditions of vacuum thermolysis.[267] It is suggested that *S*-oxides are formed as intermediates.



The formation of the *S*-oxide of diisopropylidenethiiran from an epithio-compound and *m*-chloroperbenzoic acid is accompanied by desulphurisation.[128] However, only the *S*-oxide has been obtained from dideuteriothiiran.[56]



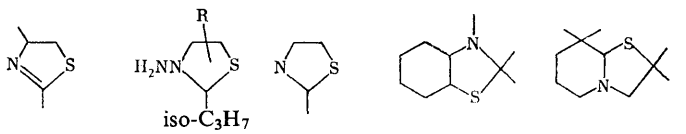
Dehydrobenzene reacts unambiguously with thiirans to form alkenyl phenyl sulphides.[268]



Aryl radicals (produced from ArN_2Cl in the presence of CuCl) react with thiiran to form primary radical species, which are stabilised either by eliminating ethylene or by combining with a chlorine atom.[269]

The homolytic reactions of thiirans are sometimes accompanied by rearrangements. The thermolysis of *cis*-divinylthiiran leads to a mixture of 2,7- and 4,5-dihydrothiepins, while the thermolysis of *trans*-divinylthiiran affords 2,7- and 2,3-dihydrothiepins.[53]

Tetraarylallene sulphides are converted into thiophen derivatives.[115]

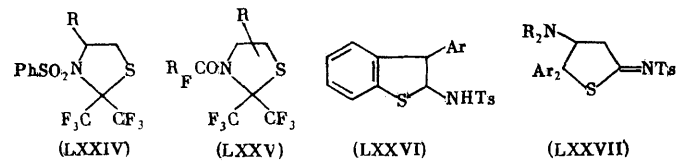


Treatment of α-methylthioglycidamides with amines leads to substituted 1,2,5,6,9,10-hexathiacyclododecanes.[88]

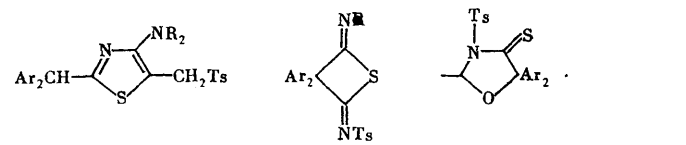
9. Cycloaddition reactions

The earlier ideas concerning the cycloaddition of thiirans to nitriles in the presence of strong acids were tested in 1978 on a large number of examples.[270] The high regioselectivity of these reactions, leading to thiazolines with the "normal" structure (LXIX), was demonstrated. The [2 + 3]cycloaddition of thiirans to the C=N bond in aldehyde hydrazones was described for the first time by Shevchenko and Potekhin.[212] Isobutyraldehyde hydrazone reacts with thiiran, methylthiiran, and 2,2-dimethylthiiran to form 3-amino-thiazolidines;[213] asymmetric thiirans afford a 1:1 mixture of regioisomers of compound (LXX).

The unusually easy (20°, 5 h) cycloaddition of thiiran to the C=N bond in alkaloids belonging to the C_{20} diterpenoid series has been described;[271] in the presence of an excess of the thiiran, cyclic adducts are formed almost quantitatively. The cycloaddition of thiirans to azomethines has been studied systematically,[207,272–274] the *N*-alkyl- and *N*-aryl-imines of aromatic aldehydes and acetone, pyrrolines, tetrahydropyridines, and dihydroquinolines have been made to react with thiiran, methylthiiran, 2,2-dimethylthiiran, and epithiocyclohexane. The ring opening in conformity with Krasuskii's rule results in the formation of a mixture of (*Z*)- and (*E*)-isomers of thiazolidines of the type (LXXI), (LXXII), and



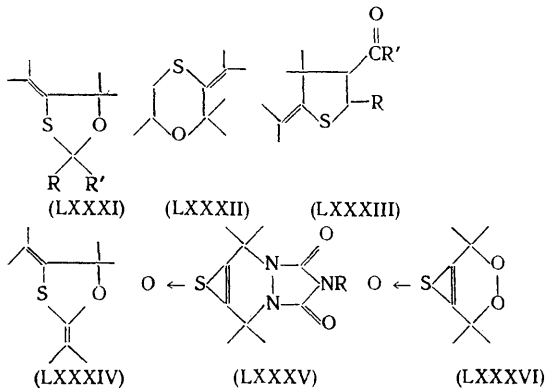
(LXXIII). The diethylacetal of formylthiiran reacts similarly with Schiff bases.[275]



(LXIX) (LXX) (LXXI) (LXXII) (LXXIII)

The highly electrophilic hexafluoroacetone benzenesulphonylimine reacts with thiirans to form the cyclic adducts (LXXIV) only after the preliminary formation of $n\pi$-complexes (–60 °C).[276] The more electrophilic hexafluoroacetone polyfluoroacylimines vigorously open the ring in thiiran and methylthiiran even at –78 °C, which leads to a mixture of the regioisomers of compound (LXXV).[277]

The iminothiirans (XXXVI), obtained from diaryldiazoalkanes and arenesulphonyl isothiocyanates, enter vigorously into the cycloaddition reaction.[107,108,278,279] By virtue of their ready conversion into the acyclic dipolar state, they are converted into 2,3-dihydrobenzothiophens (LXXVI) even in boiling chloroform. At 0 °C, they react with enamines to form 2-iminoperhydrothiophens (LXXVII), with ynamines to form thiazoles (LXXVIII), and with isonitriles to form diiminothietans (LXXIX). They react with aldehydes at 20 °C to form oxazolidinethiones (LXXX). The reactions are highly regiospecific and stereospecific.



(LXXIV) (LXXV) (LXXVI) (LXXVII)

(LXXVIII) (LXXIX) (LXXX)

New types of cycloaddition reactions have been discovered in the study of the reactions of allene sulphides with carbonyl compounds and oxirans.[280,281] Tetramethylallene sulphide interacts with aldehydes and ketones on heating (110–115 °C) or in the presence of an electrophilic catalyst with formation of 1,3-oxathiolans (LXXXI). The analogous reaction with oxirans leads to the cyclic [3 + 3]adduct (LXXXII), while the reaction with αβ-unsaturated ketones affords acylthiophanes (LXXXIII). Diphenylketen gives rise to the oxathiolan (LXXXIV).

The *S*-oxide of diisopropylidenethiiran enters into Diels–Alder reactions with electron-accepting dienophiles at 20 °C. Thus the *S*-oxide reacts with 1,2,4-triazolidinediones to form the cyclic [4 + 2]adduct (LXXXV).[282] Photochemical oxidation with oxygen in the presence of tetraphenylporphyrin also leads to the cyclic [4 + 2]adduct (LXXXVI). The latter proved to be an active dienophile which readily enters into cycloaddition reactions with cyclodienes.[283]

(LXXXI) (LXXXII) (LXXXIII)

(LXXXIV) (LXXXV) (LXXXVI)

Intramolecular cyclisations are characteristic of thermal reactions of a wide variety of tetraallene sulphides[115] and divinylthiirans.[53] The high-temperature reactions of the latter usually lead to mixtures of 4,5-dihydrothiepins, 2-vinylthiophen, and desulphurisation products. 3-Phenyl-2-vinylthiiran is converted under these conditions into a mixture of 2-phenylthiophen and 2-phenyl-2,3-dihydrothiophen.[284]

The formation of cyclic [3 + 2]adducts has been noted in the homolytic opening of the thiiran ring in the presence of aromatic compounds. For example, benzothiophen has been obtained by the thermolysis of thiiran in chlorobenzene.[285]

I. Introduction

In connection with the development of technical means for the recording, storage, and reproduction of information, there has been recently an appreciable growth of demand for new non-silver photographic processes, among which electrophotographic processes occupy a notable place. One of the thermoplastic materials with fairly high chemical, radiation, and thermal stabilities as well as effective electrically insulating properties and most widely used in electrophotography is poly-*N*-vinylcarbazole (PVCA).[1] The electrophotographic materials based on PVCA are light, can be readily charged (positively and negatively), are fairly transparent, and have an effective resolving power. On the other hand, the high softening temperature, low adhesion to different substrates, and poor film-forming properties characteristic of PVCA hinder its wide-scale employment in electrophotography. Since the photoelectric properties of PVCA are determined primarily by the presence and relative disposition of carbazole groups, presumably, on passing from carbochain polymers to polyethers containing analogous substituents with extensive systems of conjugated bonds, the photoelectric properties of the system will not change significantly. As a result of the appearance of ether linkages in the main chain of carbazole-containing polymers, one should then expect a decrease in the softening temperature and an improvement in the adhesion and film-forming properties. One of the cheapest and most promising types of photosemiconducting polyethers used as thermoplastic materials in electrophotography are poly-*N*-epoxypropyl carbazoles (PEPC), obtained by the polymerisation and copolymerisation of *N*-(2,3-epoxypropyl)carbazole (EPC) and its derivatives.

Although little more than 10 years have elapsed since the appearance of the first communications on the synthesis of EPC derivatives and oligomers based on them, fairly extensive information has accumulated in the literature on the synthesis, structures, and the physicochemical and photophysical properties of such materials. These results have been reflected in one way or another in a series of reviews devoted to questions of the synthesis and properties of carbazole-containing polymers.[1–4] In writing the present review, the authors endeavoured as far as possible to arrange systematically and analyse the available information (including patent data) on the synthesis and properties of monomeric and oligomeric EPC published after 1973.

II. Methods of synthesis and properties of *N*-(2,3-epoxypropyl)carbazoles

Epoxypropylcarbazoles are obtained by treating the corresponding *N*-metallated carbazole with epichlorohydrin (ECH) in accordance with the following scheme:

R^1—R^4 = H, Br; R^1 R^4 = H; R^2, R^3=Cl; R^1, R^2, R^4=H, R^3=NO_2.

The reaction is carried out in benzene,[5] ethyl methyl ketone,[6] a mixture of xylene isomers,[8] or dimethylformamide.[9–11] According to Sazonenko et al.[9] and Inaki et al.,[10] the potassiocarbazole formed initially reacts subsequently with epichlorohydrin to form EPC. Since potassiocarbazole is readily hydrolysed in the presence of water, the water evolved in the interaction of carbazole with potassium hydroxide retards the formation of potassiocarbazole and hence EPC.

EPC is also obtained by fusing carbazole together with KOH at 200–250 °C with subsequent treatment of *N*-potassiocarbazole with epichlorohydrin in benzene.[5] The interaction of carbazole and its derivatives with epichlorohydrin in the presence of alkalis has been studied by Rovkina.[7] It has been shown that the interaction of carbazoles with epichlorohydrin can be achieved under mild conditions and in one stage in dipolar aprotic solvents in the presence of solid alkalis. The formation of two types of substances was observed under the conditions investigated—*N*-(2,3-epoxypropyl)carbazoles and dicarbazolylpropanols, the process comprising consecutive stages with respect to epichlorohydrin and parallel stages with respect to carbazole. The selectivity of the conversion of carbazole into the products indicated is mainly influenced by the carbazole: epichlorohydrin ratio.

The low yield of the target product (up to 24%), the long reaction time,[8] the formation of 1,3-di(*N*-carbazolyl)-2-propanol as a side product, and the consumption of large amounts of solvents in the purification of EPC[6] are significant disadvantages of the above methods of synthesis of EPC.

Much better results have been obtained in the reaction of carbazole with sodium ethoxide and epichlorohydrin in purified dimethylformamide (DMF)[11] and also in the presence of substances forming hydrates such as alkali metal carbonates and sulphates.[12] Under these conditions (30–40 °C, 20–30 min), the target product is obtained in 99% yield.

* White crystals. ** Yellow crystals.

Epoxy-derivatives of carbazole have been obtained by the reaction of substituted carbazoles with epichlorohydrin in the presence of KOH: 3-chloro- and 3,6-dichloro-EPC (CEPC and DCEPC), 3-nitro-, 3-bromo-, and 3,6-dibromo-EPC (NEPC, BEPC, and DBEPC), 3,6,8-tribromo-EPC (TBEPC), and 1,3,6,8-tetrabromo-EPC derivatives (data in Table 1). *N*-Glycidyl-7*H*-benzo[*c*]carbazole (GBC), capable of giving rise to polymers and copolymers with a higher diffraction efficiency, was obtained by treating the lithio-derivatives of 7*H*-benzo[*c*]carbazole with epichlorohydrin.[15]

Epoxypropylcarbazole and its derivatives are crystalline substances soluble in tetrahydrofuran, DMF, acetone, dimethyl sulphoxide, aromatic hydrocarbons, and chloroform. All the monomers are insoluble in alkanes and are sparingly soluble in ether and alcohols.

After the isolation of the epoxy-derivatives of carbazole from the reaction mass, they were purified by both recrystallisation[5–15] and by sublimation. The optimum conditions for the sublimation of EPC have been published.[13] Under the selected optimum conditions, an EPC with a high degree of purification and m.p. 113 °C was obtained.

Qualitative[6,11,16] and quantitative[17,18] methods for monitoring the reactions of carbazole and its derivatives with epichlorohydrin by thin-layer chromatography (TLC) have been developed.

The IR absorption bands of EPC derivatives have been assigned.[19] The UV absorption maxima of substituted EPC undergo a bathochromic shift relative to EPC and to a greater extent the more polar the substituent in the carbazole nucleus.[14,20]

Measurements have been made of the photocurrents and dark currents in EPC.[20] The dark currents I_d for EPC, DBEPC, and NEPC are respectively 1.5×10^{-12} A (at 3 V), 1.2×10^{-13} A (at 14 V), and 5.5×10^{-11} A (at 7 V). The ratios of the photocurrent to the dark current (I_{ph}/I_d) at 4 V and for a light energy $W = 6.8 \times 10^{-3}$ W cm^{-2} are respectively ~5, 10, and 20 for EPC, DBEPC, and NEPC.

III. Certain characteristic features of the synthesis of *N*-(2,3-epoxypropyl)carbazole oligomers

The most important properties of epoxypropylcarbazoles are their ability to polymerise on treatment with catalysts with opening of the epoxide ring and the formation of linear oligoethers. Methods are known for the synthesis of oligomers and cooligomers of epoxypropylcarbazoles by their polymerisation in the presence of anionic, cationic, and coordination catalysts and also by the chemical modification of oligomers and by polymer-analogue transformations.

1. Anionic polymerisation

EPC are known to polymerise on treatment with anionic catalysts such as potassium hydroxide,[10,21–23] sodium phenoxide,[24,25] dimethylbenzylamine,[26] triethylamine and water,[7,27] sodium *p*-nitrophenoxide,[28] and the radical-ion salt of sodium and naphthalene (SN),[29,30] zinc acetate and aluminium isopropoxide,[31] and potassium t-butoxide.[32]

The study of the polymerisation of EPC in both homogeneous and heterogeneous media has shown that the polymerisation takes place most effectively in a heterogeneous medium,[21,23,26] especially in bulk on treatment with KOH. The polymerisation of EPC in bulk on treatment with KOH depends to a large extent on the state of the catalyst surface.[21–23] The rate of polymerisation and hence the yield of the polymers are higher when the polymerisation is carried out using finely dispersed KOH.[33]

The kinetic curves for the heterogeneous polymerisation of EPC in bulk on treatment with KOH[21,23,33] indicate the absence of an induction period in contrast to polymerisation on treatment with SN[30] and sodium *p*-nitrophenoxide.[28] The rate of polymerisation which increases with increase in temperature and catalyst concentration is independent of the initial stage and monomer concentration, subsequently diminishes for high degrees of conversion.

The rate of polymerisation of EPC at 120 and 140 °C and for catalyst concentrations ranging from 1 to 8 mol% are 1.38×10^{-4} and 4.84×10^{-3} s^{-1} [21] and 1.0×10^{-3} and 2.0×10^{-3} s^{-1}.[33]

As on initiation by treatment with SN,[30] the introduction of a fresh portion of the monomer after its quantitative conversion in the first stage leads to a non-linear increase in the degree of polymerisation as a function of the degree of conversion of the monomer and to a slight broadening of the molecular weight distribution. Thus, after the formation of the EPC polymer (140 °C, yield 92%) with a number-average molecular weight $\overline{M}_n$ = 1100,[33] the repeated introduction of the monomer results in the formation of a product with $\overline{M}_n$ = 1560 in 90% yield. A similar picture has been observed in studies[21] where $\overline{M}_n$ for the polymer formed in the first and second stages was 1560 and 2300 respectively.

The study of the polymerisation of EPC in a homogeneous medium[24,28–32] and in particular in DMSO in the presence of potassium t-butoxide[32] indicates a high initial rate of the process and its subsequent diminution. According to the authors, the main cause of this is the large difference between the rates of initiation and chain propagation as a consequence of the appreciable nucleophilicity of the t-butoxide ion compared with the nucleophilicity of the active centre. The PEPC obtained on treatment with the above catalysts contains in its structure hydroxy- and propenyl end groups as well as a small number of allyl end groups, formed as a result of the partial isomerisation of the propenyl end groups.[34] It has been shown that hydrolysis of the unsaturated propenyl ether end groups by concentrated hydrochloric acid results in the formation of hydroxy-groups.

On the other hand, the low molecular weights of the EPC polymerisation products obtained in the presence of KOH and other anionic catalysts, the absence of a linear increase in $\overline{M}_n$ with the degree of the conversion of the monomer, the non-proportional increase in the molecular weight after the addition of a fresh portion of the monomer, the presence of unsaturated end groups in PEPC, and also the difference between the calculated and experimental molecular weights indicate chain transfer in the polymerisation process. It has been suggested that chain propagation is stopped by chain transfer to the monomer[21–23,30–33] and, in the case of polymerisation of EPC in dimethyl sulphoxide (DMSO) on treatment with alkali metal alkoxides, also as a result of chain transfer to the solvent.

However, in the polymerisation of EPC on treatment with alkali metal phenoxide in an aprotic solvent (dioxane) in the presence of dibenzo-18-crown-6, it has been possible to reduce the factor associated with chain transfer to the monomer and to obtain PEPC with $\overline{M}_n$ = 4300.[24]

Among the EPC derivatives, poly-3,6-dibromo- and poly-3-nitro-EPC (PDBEPC and PNEPC)[33] and poly-3-chloro-, poly-3-methyl-, and poly-3-acetyl-EPC[34] have been obtained by the anionic mechanism. In the polymerisation of DBEPC in the presence of KOH, the reaction order with respect to the catalyst is 2/3 with a polymerisation process activation energy of 79 kJ mol^{-1}.[33]

2. Cationic polymerisation

N-(2,3-Epoxypropyl)carbazole and its derivatives polymerise[9,35,41] and copolymerise[37,42,43] fairly vigorously in the presence of cationic catalysts. The increased reactivity of EPC derivatives in polymerisation reactions on treatment with boron trifluoride etherate[35,37–40] and tin tetrachloride[36,38] can be accounted for by the electro-donating contribution of the substituent, which promotes an enhancement of the electron density on the epoxy-group.

A characteristic feature of the cationic polymerisation of EPC is the high rate of reaction in the initial stage and the rapid attainment of the limiting degree of conversion of the monomer, which increases with increase in the catalyst concentration. It has been established that, in the polymerisation of EPC in the presence of $BF_3.OEt_2$, the reaction orders with respect to the monomer and the initiator are 1.0 and 0.9 respectively, while the polymerisation rate constant is described by the equation:

$$K = 6.7 \cdot 10^2 \exp\left(-\frac{3.73 \cdot 10^3}{RT}\right). \quad (1)$$

The molecular weight of the oligomers in the cationic polymerisation does not exceed 2000 and depends little on the catalyst concentration. The limitation of the molecular weight in the polymerisation process is caused by the high contribution of the chain transfer reaction and by the deactivation of the active centres.[37] In the polymerisation of EPC in the presence of $SnCl_4$ in dichloroethane, the initial rate of reaction is directly proportional to the monomer and initiator concentrations and the molecular weight of PEPC increases on reducing the temperature and with increase in the initial monomer concentration.[38]

The higher glass point of the EPC oligomers obtained in the presence of $BF_3.OEt_2$ compared with the oligomers synthesised in the presence of KOH can be explained by the presence of macrorings in the PEPC structure.[39]

3. Other methods of synthesis of the oligomers

EPC oligomers and cooligomers have been obtained on treatment with $ZnEt_2$ and $AlBu^n_3$ [35] and also by means of polymer-analogue transformations[44–46] and by the chemical modification of the PEPC structure.[27,47–49] A high-molecular-weight PEPC has been synthesised[44] with a high degree of conversion by the reaction of the potassium or sodium salt of carbazole with polyepichlorohydrin.

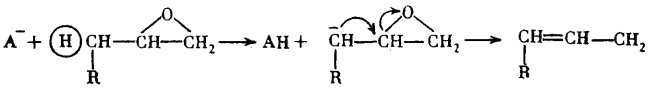
The interaction of the terminal OH groups of PEPC with bi-functional reagents such as dichloromethylphenylsilane and 2,4-tolylene diisocyanate[45] leads to carbazole-containing block copolymers exhibiting a high photosensitivity and diffraction efficiency.[45] Block copolymers of EPC with epichlorohydrin and glycidyl dihydroabietate have been obtained by the reaction involving chain transfer to the polymer with dissociation. In each case, the polymerisation of one of the monomers was carried out in the presence of the other oligomer.[46] However, the analogous statistical cooligomer of glycidylcarbazole (GC) with epichlorohydrin exhibits a higher photosensitivity as a result of the formation of a more effective charge transfer complex (CTC) in this case. The statistical block copolymers of EPC with NEPC (in the presence of KOH as the catalyst) have been described.[13] The chemical modification of PEPC[43,47–49] and of its brominated derivatives[48] constitutes a route to materials with electrophotographic sensitivity over a wide spectral range, which are promising for use in electrophotography. The formyl derivative of PEPC has been condensed[47] with 2,4,5,7-tetranitrofluorene and 6-methyl-2,4-diphenylpyrylium at 30 – 100 °C.

The oligomers obtained were compatible with PVCA and PEPC in any proportions, affording uniform films with a photosensitivity up to 650 nm.

The molecular weights of the cooligomers based on EPC and its di- and tri-bromo-derivatives with butyl glycidyl ether (BGE) are close to those of the EPC homopolymers, while the molecular

weights of the cooligomers of EPC with allyl glycidyl ether are significantly higher. The cooligomer films exhibit two physico-mechanical and optical properties and more effective adhesion to various substrates.[43,48] The integral photosensitivity of the EPC cooligomers increases linearly with increasing fraction of the comonomer.[48] Thus the cooligomer of DBEPC with BGE, sensitised by 9-dicyanomethylene-2,4,7-trinitrofluorene (DCMTNF) has a sensitivity higher by a factor of 4–5 in the range 600–700 nm than that of the unmodified PDBEPC.[43,48] Bromo-substituted PEPC, which have been tested under holographic recording conditions (λ = 633 nm) on layers 1.0–1.5 μm thick with sensitisation by trinitrofluorene, have a diffraction efficiency up to 20%.[48]

4. Some characteristics of the polymerisation of epoxypropylcarbazoles



The study of the anionic polymerisation of EPC and its derivatives has shown that SN is a less effective initiator[30] than other catalysts of polymerisation in a homogeneous medium.[24,28,29,31,32]

The nitro-derivatives of EPC do not polymerise on treatment with SN, which is associated with the ease of electron transfer from SN to the nitro-group of the monomer; this has been confirmed by the results of a polarographic study: the half-wave potentials $E_{1/2}$ for NEPC and naphthalene are respectively −1.28 and −2.53 V. DBEPC partially polymerises in the presence of SN with elimination of sodium bromide. The elimination of bromine is also promoted by electron transfer from the SN molecule to DBEPC with the apparent subsequent formation of the DBEPC carbon ion.[50] The partial elimination of bromine with formation of KBr has also been observed in the polymerisation of DBEPC on treatment with solid potassium hydroxide at high temperatures.[33]

The induction period in the polymerisation of EPC in the presence of SN is apparently associated with the formation of low-molecular-weight polymeric alkoxides and with their insolubility in THF and also with the possibility of electron transfer from SN to the carbazole nucleus. The induction period depends on the initiator concentration and the polymerisation temperature, diminishing as the latter increase.[30]

Since gel-permeation chromatographic data rule out the degradation of the polymer chain, the low molecular weights and the absence of a linear relation between $\overline{M}_n$ and the degree of conversion are evidence for chain transfer to the monomer, which is so significant for substituted epoxides.[51]

According to Akhmedov et al.,[30] unsaturated terminal groups are formed as a result of chain transfer to the monomer via the proton β-elimination mechanism:[52]

R = N-carbazolyl.

The study of the polymerisation of EPC in the presence of SN in solution in THF at catalytic complex concentrations in the range 6.1×10^{-3}–1.2×10^{-1} M suggests that the polymerisation proceeds via a stepwise anionic mechanism. Initiation at high initial initiator concentrations is effected by dianions, while at lower concentrations it is initiated by comparable amounts of the mono- and di-anions. The polymerisation is of the living centres type,[53] i.e. in the presence of material chain termination reactions but with propagation of kinetic chains.

The rate of polymerisation of EPC on treatment with KOH should be described by the following equations in the initial polymerisation stage:[13]

$$W = \frac{d[M]}{dt} = k_1 \cdot [M]_0^0, \quad (2)$$

$$W = k_2 [KOH]^n, \quad (3)$$

where W is the rate of polymerisation in the initial stage, [M] the monomer concentration at time t, $[M]_0$ the initial monomer concentration, t the polymerisation time, k_1 and k_2 are polymerisation rate constants, [KOH] is the catalyst concentration, and n the reaction order.

The experimental data indicate a satisfactory fulfillment of the law $W \propto [KOH]^{2/3}$ in the initial stage, which agrees with the occurrence of the reaction on the interface.[13]

The zero reaction order in the initial stage of the polymerisation with respect to the monomer is evidently associated with the fact that the fraction of the catalyst surface covered by the monomer is close to unity and the rate therefore ceases to depend on the monomer concentration.

The decrease in the rate of polymerisation after the attainment of a definite degree of conversion of the monomer, which is particularly abrupt at low initial catalyst concentrations, is associated with the accumulation in the system of an inactive oligomer, which prevents the access of the monomer to the catalyst surface. This is confirmed by the fact, when the EPC polymerisation is carried out in the presence of an EPC oligomer obtained in an independent experiment, the degree of conversion of the monomer in the initial stage diminishes sharply. When the catalyst is kept beforehand in contact with oligomers obtained in an independent experiment, the polymerisation of the monomer introduced subsequently is inhibited, which indicates the "coating" of the catalyst by the polymerisation products.[33] The above features are somewhat different from those in the polymerisation of EPC in the presence of KOH with vigorous stirring.[21]

The occurrence of the preferential chain transfer to the monomer and not to another reactant with a mobile hydrogen atom (for example, water when aqueous alkali is used as the catalyst, or the polymer) is confirmed by the fact that, in the polymerisation of EPC on treatment with anhydrous EPC, products with a low molecular weight, containing large amounts of propenyl end groups, are also formed. Treatment of the alkaline polymer with an equal amount of polymer obtained in an independent experiment does not increase the degree of unsaturation of the system. However, treatment of the alkaline polymerisation mixture at a ~100% degree of conversion with a fresh portion of the monomer leads to an increase in the degree of unsaturation.[33]

IV. The properties of *N*-(2,3-epoxypropyl)carbazole oligomers

1. Physicochemical properties

The products of the polymerisation of EPC are oligomers with a molecular weight up to 2000, which consist of colourless powders readily soluble in aromatic and chlorinated hydrocarbons, DMF, THF, and acetone and insoluble in alcohols and alkanes.

Depending on the molecular weight, the glass points T_g of the EPC oligomers are in the range 70–105 °C [54,55] and for equal molecular weights are appreciably lower than the T_g for PVCA obtained both by the polymerisation of *N*-vinylcarbazole[56] and by the transvinylation reaction.[57] This can be explained by the increase in the flexibility of the PEPC chain owing to the presence in the macromolecule of ether linkages and the removal of bulky carbazole substituents from the main chain of the oligomer as a result of the introduction of the methylene group.

The dependence of T_g on the weight-average molecular weight M_w for PEPC obtained in the presence of $SnCl_4$ and the $Al(OPr^i)_3-ZnCl_2$ mixture is very pronounced for low values of M_w, becoming less marked for M_w above 2500, and not being manifested at all for still higher values of M_w.[55] When $M_w \simeq 10^4$, one may expect the formation of a thermomechanical segment which depends on the method of synthesis of PEPC.

The products of the cationic polymerisation of EPC (in the presence of $SnCl_4$ or $BF_3.OC_2H_5$) have higher glass points T_g than the polymers with similar M_w obtained in the presence of other catalysts, which has been attributed to intramolecular and intermolecular donor–acceptor interactions between the residues of the catalyst bound covalently to PEPC and the carbazole groups. Another explanation of this finding may be the formation in the first case of cyclic structures, as has been observed for PVCA.[58] Indeed, it has been shown that, in the cationic polymerisation of EPC using $BF_3.OEt_2$, between 31 and 48% of oligomeric cyclic structures are formed.[42] The glass points of the EPC oligomers with molecular weights in the range from 800 to 1800, obtained in the presence of the SN complex, increase from 90 to 100 °C and are almost identical with the T_g of oligomers having the same molecular weights but obtained on treatment with KOH.[54] For similar molecular weights, the T_g of PDBEPC and PNEPC are higher by 10–15 °C than in the case of the unsubstituted PEPC, which is apparently associated with the increase in the polarity of the substituted carbazole groups.

Oligomeric PEPC has been analysed by X-ray diffraction[59] and a study has been made of the relation between its photosemiconducting properties and its phase state. The diffractometer traces of all the oligomers show, regardless of the methods of their synthesis, only an amorphous halo with a maximum at scattering angles $2\theta = 20-21°$ and signs of crystallinity are completely absent. The phase state of the oligomeric PEPC is not affected by the character of the end group (hydroxy-groups, unsaturated groups, and cyclic groups) and also by the heat treatment of the PEPC specimens for 1 h at temperatures up to 150 °C. It has been suggested that PEPC has an atactic molecular structure. It has been shown that the absence of crystallinity of PEPC in anionic polymerisation can be associated with the occurrence, together with the β-dissociation, also of the α-dissociation of the epoxide ring, while in cationic polymerisation it is associated with the formation of cyclic structures, which lead to the breakdown of the structural crystallisation condition.

The physicochemical properties of PEPC have been investigated in order to create thermodynamic foundations for the technology of electrophotographic materials based on it.[60] A study was made of the heat capacity of PEPC ($\overline{M}_n = 1200$) in the temperature range 0–350 K. In the temperature range 320–340 K, the heat capacity increases abruptly under constant pressure by an amount 0.413 J $g^{-1}K^{-1}$, which is associated with the devitrification of the oligomer. The T_g of PEPC determined in this way was 335 K. The heat capacity at room temperature was 1.121 J $g^{-1}K^{-1}$.

The thermal stability of EPC, its oligomer, and PEPC, stabilised by the Santonox-P and Bisalkophen-MCP antioxidants, has been studied by the derivatographic method.[61] It was shown that the ease of the thermo-oxidative degradation in PEPC compared with the monomer indicates the presence in the oligomer of impurities which accelerate this process.

Thin-layer chromatography of the EPC polymerisation products[62] made it possible to discover whether or not the unreacted monomer is present and also to determine the molecular weight distribution in the PEPC. The mechanism of the formation, the molecular weight distribution, and the separation of the oligomeric EPC with $\overline{M}_n$ up to 15000 by gel permeation chromatography have been investigated.[63]

2. Optical and photophysical properties

The study of the electronic spectra of free and sensitised PEPC layers and of the influence of UV radiation on the latter in air, the analysis of the photochemical oxidation products, and also the study of the photochemical reactions in polymers help to elucidate the mechanism of the photophysical phenomena occurring in processes involving the optical recording of information. The electronic absorption and luminescence spectra of PEPC and of its brominated derivatives have been studied[13,20,64–69] both in solution and in thin films. The absorption in PEPC is associated with the presence of carbazole nuclei and is determined by the allowed transitions between the singlet levels of the π electrons. The long-wavelength absorption band in the spectra of EPC oligomers is at 345 nm, while the remaining bands correspond to wavelengths of 295, 262, and 237 nm, the maxima in the absorption spectra of the thin layers undergoing a bathochromic shift by 2–4 nm compared with the maxima in the absorption spectra of the solutions. For the bromo-substituted PEPC oligomers,[69] the long-wavelength absorption band maximum has undergone a bathochromic shift compared with the unsubstituted PEPC, which is associated with the change in the electronic structure of the carbazole chromophore after the introduction of bromine atoms into its nucleus. The influence of structural factors on the formation of CTC in solution by the carbazole fragments of PEPC and its derivatives containing electron-accepting substituents with 2,4,7-trinitro-fluoroenone (TNF), 9-dicyanomethylene-2,4,7-trinitrofluorene (DCMTNF),[70] and triarylpyrylium tetrafluoroborate (TAPS) has been observed.[71,72] It has been found that the broad charge transfer band in the spectra of CTC of PEPC with TNF has $\lambda_{max} = 500$ nm and does not shift after the introduction of substituents into the carbazole nucleus, while the band for the CTC of PEPC with DCMTNF lies in the range 550–625 nm depending on the nature of the substituent. Furthermore, the introduction of electron-accepting substituents into the carbazole nucleus diminishes the equilibrium formation constant of the CTC. Comparison of the stability constants and the enthalpies ΔH of the complexes of PEPC with TAPS, TNF, and 2,4,5,7-tetranitro-fluoroenone (TENF) shows that the TAPS molecules in the CTC exhibit weaker electron-accepting properties.[71]

The luminescence of layers and solutions on irradiation with UV light is characteristic of EPC oligomers. The luminescence spectrum of PEPC depends greatly on the solution concentration. The spectra show maxima at 358 and 386 nm associated with the phosphorescence of the monomeric units and maxima at 408 and 427 nm associated with the emission by excimers,[66,67] the intensity of the glow of which increases with decrease in temperature. The luminescence quantum yield in PEPC at room temperature is $\varphi = 0.25$ and increases with decrease in temperature, which is

apparently associated with the decrease in the probability of non-radiative transitions. As the number of substituents in the carbazole nucleus increases, the emission band maxima in the luminescence spectra undergo a bathochromic shift and for di- and tri-bromo-PEPC consist of a broad band with λ_{max} = 391 and 396 nm respectively, while for tetrabromo-PEPC they are actually located at λ_{max} = 399 nm. The fluorescence spectra of layers of bromo-substituted PEPC with TNF, TENF, and DCMTNF show broad emission bands in the range 500–800 nm associated with the formation of CTC.[67] It is known[73] that in organic semiconductors the carrier generation processes are influenced significantly by the products of photochemical reactions. It has been found that, after exposure to the joint action of oxygen and UV radiation, films of bromo-substituted PEPC undergo photochemical oxidation, which diminishes the fluorescence intensity. Films of poly-tetrabromo-EPC are most sensitive to the action of UV light in air. The decrease in the intensity of the fluorescence emission band in the range 500–800 nm after prolonged UV irradiation (for more than 3 h) has been explained by the decomposition of the CTC and the partial degradation and cross-linking of the oligomer.[67]

On the basis of the study of the products of the photochemical oxidation of various PEPC specimens, attempts have been made to establish the mechanism of this process and its relation with the photosensitivity and the spectroscopic and electrophotographic parameters of layers of EPC oligomers.[74–78] When specimens of PEPC and of its brominated derivatives are UV-irradiated in air, the absorption in the wavelength range 360–600 nm increases, a long-wavelength band appears, and the optical densities of all the absorption bands in the region of the electronic transitions in the carbazole rings diminish, which has been attributed to the formation of carbazole *N*-oxides.[75,76] It has been shown that the intensity of the 1735 cm^{-1} absorption band in the IR spectra of the oligomers obtained in the presence of KOH increases with time and eventually becomes constant when the unsaturated end groups disappear, while the intensity of the 1715 cm^{-1} band increases monotonically.[75,76] Since the absorption bands at 1715 and 1735 cm^{-1} correspond solely to the carbonyl groups, it has been suggested that the photochemical oxidation products may be, together with structures of the ketone type, also quinone imide structures (band at 1715 cm^{-1}), from which units containing several carbonyl groups in the carbonyl nucleus may be formed subsequently. The molecular weight and the degree of polydispersity of the oligomers increase somewhat in highly photochemically oxidised PEPC specimens, which has been explained by the possibility of their cross-linking either via double bonds in the presence of unsaturated end groups or via carbonyl groups in the absence of unsaturation.[76]

Data obtained in studies of the electronic structures and photochemical reactions under the influence of UV irradiation in air of thin PEPC films sensitised by small amounts of added TNF, TENF, DCMTNF, and chloranil (CA) have been published.[77,78] In pure and sensitised PEPC specimens, an increase in absorption (darkening) is observed in the range 350–600 nm, becoming more pronounced as irradiation becomes more prolonged. It has been shown that the highest sensitivity to UV irradiation and hence relatively rapid ageing is exhibited by specimens of pure PEPC whose resistance to irradiation increases by a factor of almost 1.5 after the introduction of 1 mol% of sensitiser. It has also been shown[77,78] that the photochemical oxidation products, formed in the surface layer of the film, have electron-accepting properties and influence significantly the fluorescence intensity of PEPC films. The photochemical oxidation products in the PEPC layers are regarded as effective electron-accepting impurities which play a definite role in the mechanism of the photogeneration of current carriers.[79] The degree of electronic interaction between carbazole groups in photoconductors has been studied by proton and magnetic resonance (^{1}H NMR).[80] An upfield shift of the signal due to the aromatic protons of the carbazole chromophores, characteristic of PVCA, was not observed in the ^{1}H NMR spectra of PEPC solutions. The ^{1}H NMR spectra of PEPC do not differ from those of *N*-ethylcarbazole used as a model compound. A strong electronic interaction between the π-electron systems of the chromophoric nuclei in the ground state has not been observed in solutions of PEPC and of poly(*N*-carbazolylethyl glycidyl ether) by ^{1}H NMR, which has been explained by the greater difference between the carbazole chromophores and by the flexible character of the main chain. It has been suggested that, in solutions of this polyether and of PEPC, the carbazole nuclei can rotate freely about the methylene linkage in contrast to the rigid-chain PVCA.[80]

The manifestation of photosensitivity and the occurrence of a series of photophysical processes in the UV region in PEPC and its derivatives are determined primarily by the presence of the carbazole side group. In the visible region of the spectrum, PEPC does not exhibit photosensitivity.[65] In the early studies, it was already noted[81] that the photosensitivity in carbazole-containing polymers, in particular in PVCA, in the visible region is associated with the formation of donor–acceptor complexes in which the carbazole group functions as the electron donor and the impurity functions as the electron acceptor. It has been found that the photoconductivity of PVCA and of its derivatives is influenced by various electron-donating and electron-accepting additives as well as dyes. It has been shown that a correlation between the photosensitivity and the electron affinity of the sensitiser occurs only in series of electron-accepting compounds with similar π-electron systems. The most effective sensitisers for PVCA and its derivatives are TNF [82] and pyrylium, benzopyrylium, and thiapyrylium salts.[83]

Similar results were obtained in the study of the electrophotographic, optical, and photophysical properties of layers based on PEPC and some of its modified derivatives. In organic PVCA and PEPC semiconductors, there are no bands and hence the ideas of the classical band semiconductors are not applicable to them. In these semiconductors, the carriers apparently move via a jump mechanism, within the framework of which attempts have been made to account for the mechanism of the transport and photogeneration of charge carriers.[84] The photogeneration mechanism is closely related to the mechanism of the sensitisation of these semiconductors, i.e. to the energy transfer from the excited sensitiser molecule in the organic semiconductor and with the generation of a charge transfer state. The mechanism of the charge generation in layers of PEPC photochemically oxidised to different extents under electrophotographic conditions and of the influence on the photosensitivity of such layers by impurities of different kinds (initial carbazole, the monomer, the catalyst residue, and the solvent) has been described.[76] It has been established that the layers obtained from the more oxidised PEPC also have higher photosensitivities. The primary photophysical processes,[85–92] the photogeneration quantum yields,[93–98] and the drift mobilities of the charge carriers[99–104] in pure PEPC layers and PEPC layers sensitised by various additives have been investigated.

The study of the stationary photoconductivity and fluorescence, taking into account the influence on them by an external magnetic field, in PEPC layers with added dyes[87,88,91] has shown that excited charge transfer complexes participate in the current carrier generation

process both in the intrinsing absorption region and in the sensitisation region. The dissociation of the charge transfer complexes is facilitated by the external electric field and by the exciplexes formed by the interaction of the excited state of the dye with the chromophoric group of the oligomer. The dissociation of the complex with formation of current carriers takes place in its vibrationally relaxed state. The study of the characteristic features of the volume photoconductivity in thin PEPC layers sensitised by TNF[88] permitted a conclusion concerning the nature of the appearance of photogenerated current carriers in the region of the CTC absorption. Very interesting results have been obtained by studying and comparing the photophysical properties of PEPC and its brominated derivatives sensitised by different electron acceptors.[90–92] Pure layers of brominated PEPC are less photosensitive than the non-brominated PEPC in the UV region of the spectrum for positive charges and for an electric field strength of 5×10^7 V cm^{-1}. It was found previously[75–78] that, under real operating conditions, the photosensitivity of layers of PEPC and its derivatives is influenced significantly by UV radiation and oxygen (photochemical oxidation process) and that a decrease in the degree of oxidation of oligomers reduces the photosensitivity and the quantum yields of the generation of charge carriers in the UV region of the spectrum.[76]

The oxidation and photochemical oxidation of the carbazole group with formation of electron accepting quinone imide structures, which are ultimately responsible for the decrease in photosensitivity, are hindered in brominated PEPC. Predominately singlet excitons are responsible for the generation of charge carriers in brominated PEPC. The study of the quantum yield β[93–96,98] and of the characteristic features of the photogeneration and recombination of current carriers[97] in pure PEPC and PEPC sensitised by different additives has shown that, when pyrylium salts are used as sensitisers, the yield β in PEPC layers for an electric field strength $E \simeq 10^6$ V cm^{-1} increases to 0.36, whereas for the unsensitised specimen $\beta = 2.7 \times 10^{-2}$. The power dependence of β on E with an exponent of 1.2×3.3, depending on the wavelength and the nature of the sensitiser, has been demonstrated.[95,98] For PEPC layers with a 20% content of a binder and sensitised with 3 mol% of TNF, the power exponent increases from 2.3 to 3.3 when the temperature is reduced from +50 to −60 °C for $E = 10^6$ V cm^{-1} at an exciting light wavelength $\lambda = 295$ nm. In sensitised PEPC layers, the activation energy for the photogeneration of carriers (ΔE) depends only slightly on the exciting light wavelength and increases from 0.039 to 0.13 eV with decrease in the electric field strength from 1.6×10^6 to 4.0×10^5 V cm^{-1}. The increase in β with increase in the TNF concentration is caused by the improvement of electron transfer conditions.[96]

The characteristic features of the drift mobility of charge carriers have been investigated in PEPC[65,99–103] and also in a mixture of PEPC with PVCA.[104] It has been established[100,101] that in PEPC layers electrons remain stationary and the drift mobility of the majority current carriers (holes) depends to a large extent on the temperature and the electric field strength, reaching 7.5×10^{-6} cm^{2}V^{-1}s^{-1} for layers 1.5–4.5 μm thick and $E = 5 \times 10^5$ V cm^{-1}. The distances between the carbazole rings in pure PEPC are 6.8 Å, which is greater by 0.4 Å than in PVCA.[105] Evidently the increase in the drift mobility in PEPC relative to that in PVCA can be explained by the decrease in the distance between the carbazole nuclei in PEPC as a consequence of their displacement from the equilibrium position by 2–3 Å in the direction in which the electric field strength acts with increase in the probability of the transfer of the carrier between them.[100] The drift mobility of holes in PEPC layers diminishes with increase in the acceptor (TNF) concentration. After the introduction of 10 mol% and more of the acceptor, the drift mobility of the electrons can be measured. It becomes approximately equal to the mobility of holes in the presence of 50 mol% of the acceptor. The activation energies for the drift mobility in PEPC layers for electric field strengths of 4.5×10^5 and 1.5×10^5 V cm^{-1} are respectively 0.24 and 0.32 Ev.

The photoconductivity of EPC oligomers increases significantly and is manifested over a wider spectral range in the presence of optical and chemical sensitisers. Optical sensitisation is observed after the introduction of dyes into the oligomer at low concentrations as a result of the absorption of light by the dye molecules in the visible region, while chemical sensitisation is effected after the introduction of electron acceptors, which usually absorb in the UV region of the spectrum. The sensitisation of the photosensitivity of EPC oligomers by added organic dyes,[106–121] electron acceptors,[122–126] and compounds specially synthesised for the sensitisation of PEPC[127–132] has been investigated.

The study of the characteristic features and mechanism of the sensitisation of EPC oligomers by dyes,[109,111,113,114,116] nitrofluorenones,[122,124] and pyrylium salts[113,118,120] has shown that the effectiveness of the sensitisation of PEPC by TNF acyloximes[124] and arylpyrylium salts with perchlorate and tetrafluoroborate anions[114,119] greatly exceeds that of the sensitisation by TNF and TENF both in the intrinsic absorption region and in the long-wavelength region. The strong sensitising effect of pyrylium salts has been explained by the ability of pyrylium cations to bind in PEPC electron-donating impurities which generate centres for the adhesion of holes.[114] The low effectiveness of the sensitisation of PEPC by certain dyes (rhodamine 6G) compared with pyrylium salts has been attributed to the fact that aromatic amino-groups in the dye molecules create deep carrier capture centres in the PEPC layers. However, when up to 1 wt.% of boron trifluoride etherate is introduced into the system, the photosensitivity increases fivefold and reaches the level for pyrylium salts. The increase in the sensitising capacity of the above dyes after the introduction of Lewis acids has been explained by the binding of the amino-groups in the dye molecules and hence by the decrease in the concentration of deep carrier capture centres.

3. Electrical properties

The study of the electrical properties of PEPC and its complexes with various additives helps to obtain additional information for a deeper understanding of photoelectric processes, for the estimation of molecular parameters, and for the elucidation of the mechanism of the polarisation in the dark discharge of electrophotographic layers.

Fairly numerous studies have been devoted to the electrophysical properties of polymers based on *N*-vinylcarbazole and its derivatives.[1,2] However, the available literature data on the electrical properties of oligomers based on EPC are extremely scanty.

The electrical properties of free PEPC films and PEPC films sensitised by low-molecular-weight additives have been investigated.[133–135] The dielectric properties, polarisation effects, and their temperature dependence have been described.[136–138] In the study of the temperature dependence of the parameters of a galvanic cell in the Au–PEPC–Al system, ionic conduction was observed in PEPC. It was shown that the Au–PEPC–Al system forms a galvanic cell, whose e.m.f. is $E_0 = 150$ mV in the initial instant, the Au electrode being charged positively. It has been assumed that the e.m.f. in the

above system is due to oxidation-reduction reactions on the metallic electrodes and indicates the presence of an ionic component of the electrical conductivity, whose nature is associated with low-molecular-weight impurities or with the dissociation of polymer macromolecules in the solvent.[133]

The dependence of the dark current on the potential for PEPC films with added TNF obeys Ohm's law up to an electrical field strength of 10^3 V cm^{-1}. For higher field strengths, there is a break in the voltage–current characteristic and a power dependence of the current I on the applied potential U is observed with an exponent of 2.2. The non-linearity of the voltage–current characteristic is attributed to the injection of charge carriers from the electrode into the PEPC, which establishes a regime in which the current is limited by the space charge.[134] Measurement of the electrical characteristics of the conducting PEPC oligomer and of its complex with tetracyanoquinodimethane (TCQDM) showed that in the region of high potentials the voltage–current characteristics of both the pure oligomer and of its complex are non-linear and exhibit hysteresis. It has been demonstrated by the thermocurrent method that the majority charge carriers in PEPC are electrons, while in the PEPC–TCQDM complex they are holes with concentrations of 8.5×10^{13} and 1.4×10^{14} cm^{-3} respectively.[135] It has been observed that, depending on the conditions in the preparation of the specimen, the real component of the dielectric constant at room temperature is 2.7–3.1 and is associated mainly with electronic polarisation.[138] In layers of the pure EPC oligomer, the tangent of the dielectric losses angle ($\tan\delta$) has a distinct maximum above the glass point; the maximum shifts towards higher temperatures with increase in the molecular weight and with increase in the frequency of the electric field f, the $\tan\delta$ curve becoming broader under these conditions.

The effective activation energy E, obtained from the temperature dependence of the maximum value of $\tan\delta$, amounts to 2.4 eV for the oligomer with $\overline{M}_n$ = 750 and 3.2 eV for PEPC with $\overline{M}_n$ = 1570.[138] The static dielectric constant ε_s of PEPC layers, determined from the Cole–Cole diagram, is 7.84. It has been suggested that ε_s of PEPC layers, like that of PVCA layers,[136] is determined by the polarisation of the carbazole groups.[137]

The dielectric properties and structure of PEPC irradiated with UV light and γ-quanta in the presence of oxygen have been investigated.[139] A significant influence of different types of radiation on the dielectric parameters of PEPC has been observed, which is associated with the structural changes occurring in the polymer.

When PEPC was irradiated with UV light for periods up to 30 min, a sharp decrease in $\tan\delta$ and ε' was observed. With increase in the duration of irradiation, $\tan\delta$ and ε' rise to a maximum and then diminish monotonically until the attainment of a plateau after irradiation for 8 h. The decrease in $\tan\delta$ and ε' in the initial stage of the photochemical process has been explained by a significant contribution of peroxy-radicals, formed during the irradiation process, to the depolarisation of PEPC. The peroxy-radicals, which have a large dipole moment,[140] interact with dipoles and some of the dipoles, whose interaction energy with the charge field is greater than the energy of their interaction with the applied field, are not involved in the relaxation. This diminishes $\tan\delta$ and ε' as a consequence of the decrease in the concentration of the dipoles acting in the relaxation process. The increase in the dielectric parameters has been attributed to the formation of stable carbonyl groups.

The temperature and field dependences of ε' and $\tan\delta$ for layers of pure PEPC and its complex with TNF have been investigated.[141] It has been shown that the character of the temperature dependence of ε' for the PEPC and EPPC–TNF layers is identical but in the complex ε' is somewhat higher than in the pure oligomer, which has been explained by the contribution of the TNF molecule to the polarisation of the system and also by the electronic thermal polarisation due to weakly bound electrons arising in the complex formation process.

The electrical conductivity of films of PEPC and the copolymer of EPC with 5% of BGE (where BGE = butyl glycidyl ether) has been investigated by the method of thermostimulated currents in the Al–PEPC–SnO_2, Al–(EPC + 5% BGE)–SnO_2, and Al–PVB–(EPC + 5% BGE)–SnO_2 sandwich structures (where PVB represents a layer of a dielectric–polyvinylbutyral).[142] It was observed that, in the ranges 213–263 K and $E = 10^7$–10^8 V m^{-1}, a saturation current regime obtains in the PEPC and PEPC + 5% BGE films in which the current varies linearly with the hole generation efficiency within the bulk of the film (having a thermal field character) and with the film thickness, while in the range 273–313 K the electrical conductivity is determined by the generation and drift of ions.

The nature of the dark electrical conductivity of freshly cast and dried PEPC layers has been investigated by the method involving the dark decrease in potential.[143] Measurements were made of the time variation of the capacitance, ε_s, the charging current in long electrisation stages, and the reduction potential of the specimens with the applied potential and on subsequent short-circuiting. The results indicate the operation of several electrical conduction mechanisms in both fresh and stabilised PEPC layers. A two-layer model of the dark electrical conductivity in PEPC, which explains the polarisation phenomena in this material and describes the changes in its properties on stabilisation, has been proposed.

The electrical conductivity of a composition based on PEPC with a filler comprising a triphenylmethylphosphonium–TCQDM radical-ion salt has been investigated.[144] The electrical conductivity of the composition is determined by the contact conductivity at the boundary between the particles of the filler and the binder. The contact conductivity is non-linear and is of the semiconducting type. The activation energy for the electrical conduction in the composition exceeds E_σ for the filler and the binder. It has been suggested that the electrical conduction is effected by the emission of electrons from part of the filler and their activated transport in the layer of the binder.

4. Practical applications of carbazole-containing polymers

The high photoconductivity of carbazole-containing polymers with added organic dyes (OD) and with electron-accepting compounds (EAC) permits their use as photosemiconducting materials for the preparation of electrophotographic layers (EPL) designed for microfilming, the recording of information by the photothermoplastic method, and for the manufacture of multicolour electrophotographic images and slides.[1]

Studies on the possibility of creating EPL and other non-silver layers on the basis of polymeric photoconductors are being widely prosecuted at the present time in the USSR, Japan, the Federal Republic of Germany, the USA, and other countries. Organic compounds belonging to a wide variety of different classes are used as light-sensitive media suitable for electrophotographic processes.[145–148]

Many studies have been devoted to the use in EPL of polymers containing in their structure the carbazole nucleus, for example, polyallylcarbazole, polypropenylcarbazole, poly-*N*-acryloylcarbazole, and their derivatives, as well as 1,4-divinylcarbazole polymers and copolymers.[147] However, PVCA is one of the most thoroughly investigated carbazole-containing polymeric photosemiconductors which is widely used in electrophotography. Oligomeric PVCA is used in the USSR for the manufacture of electrophotographic and photothermoplastic materials.[149–151]

Photothermoplastic layers must be transparent in the visible part of the spectrum and elastic and must have a smooth surface and resistivities in the solid and softened states of $10^{14}-10^{15}$ and $10^{10}-10^{11}$ Ωcm. They must be effectively charged in the dark, must possess thermoplastic properties and a glass point in the range 50–80 °C,[56,152] and must not break on repeated bending and on being immersed in the carrier liquid of the electrophotographic developer and on cooling (to a temperature below –60 °C).[153] In this respect the EPL based on the EPC oligomers[40] are believed to be extremely promising in applications which include the formation of a multicolour electrophotographic image.[154]

Electrophotographic films based on PEPC have been investigated[106] and a detailed study has been made of the photoelectric properties of PEPC and its possible applications have been defined. The sensitisation of PEPC by various electron-accepting compounds and organic dyes has been studied and the most effective sensitisers for this purpose have been discovered. It has been shown that the introduction of electron-accepting compounds and of an organic dye into the PEPC layer alters the conditions in the generation and transport of carriers. PEPC layers sensitised by polynitrofluoroenones are effectively charged, both positively and negatively, and exhibit a weak dark relaxation of the potential and a zero residual potential, while PEPC layers sensitised by organic dyes exhibit a fairly pronounced dark relaxation of the potential.

Organic electrophotographic films (OEPF) of three types have been developed on the basis of PEPC:[153] OEPF-M of type T-1 for the generation of images in accordance with the positive–positive or negative–positive scheme with positive charging, OEPF-M of type T-2 in accordance with the positive–positive scheme with negative charging, and OEPF-M of type T-3 for the preparation of positive images in accordance with the positive–positive (negative charging) or negative–positive (positive charging) scheme. In an OEPF frame, it is possible to form up to eight images and by developing them with different toners it is possible to obtain multicolour images (resolving capacity 300 lines mm^{-1}) which are stable under an illumination of 5×10^4 lx and at a temperature of 55 °C for 24 h.

Panchromatic EPL for colour images have been developed on the basis of PEPC to which 1–15 mol% of TENF has been added.[154] It has been shown that, with increase in the TENF content to 10 mol%, the photosensitivity increases almost linearly. A further increase in the acceptor concentration does not increase the photosensitivity and in the blue region of the spectrum actually reduces it. An increase in the TEMF content leads to a slight diminution of the positive potential in the dark (from 3 to 5%), while the dark decrease in the negative potential is constant and amounts to 6%. The dark decrease in potential rises to 8–10% when the degree of illumination is high (5×10^3 lx in 1 min).

It is known that, when EPL based on PEPC are used under real conditions, the working parameters of the photosemiconductor are influenced by various external factors (UV irradiation, oxygen, temperature, etc.), which lead to photochemical oxidation and other changes. Photochemical oxidation processes can be regarded to some extent as model reactions in relation to the real operating conditions of photothermoplastic materials in electrophotographic and photothermoplastic regimes.

By studying the influence of UV irradiation on the electrophotographic sensitivity (EPS) and diffraction efficiency (DE) of EPL, it is possible to obtain definite information about the characteristics of the degradation of these materials.[78]

The most significant changes in photosensitivity are observed after brief UV irradiation (up to 1 h): there is initially a sharp decrease in the EPS and then a slight increase. The attainment of an EPS plateau as a function of the duration of irradiation is observed for exposures ranging from 1 to 10 h. It has been noted that the character of the variation of EPS during UV irradiation is independent of the type of electron acceptors introduced into the PEPC. Reactions involving carbazole nuclei play the main role in the changes in EPS during photochemical oxidation. Brief UV irradiation does not entail a change in the diffraction efficiency of photothermoplastic carriers (PTC) based on PEPC + 2% TNF. The maximum diffraction efficiency, observed for exposures of 0.1–0.15 mJ cm^{-2} is 20–22% for carriers based on PEPC + 2% TNF and PEPC + 2% CA and 16–18% for PEPC + 5% CA. For carriers with a high TNF concentration (5% and above) and also for DCMTNF (3% and above), holographic recording is hardly feasible.

In the PEPC spectra, the long-wavelength absorption band and the first photosensitivity maximum are determined by the carbazole chromophoric group and are in the UV region of the spectrum at $\lambda = 345$ nm.[119] In order to impart to the organic conductor sensitivity in the visible region of the spectrum, spectral sensitisation by organic dyes or electron-accepting compounds, which form charge-transfer complexes with PEPC, is employed.[106,111,119,122,155]

Table 2. The influence of the nature and concentration of the acceptor on the photosensitivity of PEPC.

Acceptor	Photosensitivity ($E_0 = 75$ V μm^{-1}) at different acceptor concentrations (mol%), 10^3 lx^{-1} s^{-1}					
	0.1	0.5	1.0	2.0	5.0	10.0
9-Fluorenone	0.04	0.045	0.04	0.044	0.04	0.12
DNF	0.08	0.22	0.5	0.5	0.8	2.9
TNF	0.14	0.5	0.8	1.15	2.5	4.2
TENF	0.3	0.6	1.12	3.1	4.0	7.2

The xanthene dye rhodamine 6 G is regarded as a highly effective sensitiser (in relation to electrophotographic sensitivity) of PEPC EPL among organic dyes,[110,111] while among electron-accepting compounds polynitrofluorenones (TNF and TENF) are effective.[106,122]

The dependence of the photosensitivity of PEPC layers on the content of rhodamine 6 G in the layer, shows that the highest photosensitivity is that of PEPC layers containing 0.9 mol% of the dye.[111] At $\lambda = 540$ nm, the photosensitivity of this composition reaches 29 m^2J^{-1}.

Table 2 presents the photosensitivites of positively charged PEPC layers, sensitised by nitrofluorenones, on illumination with white light[122] (DNF = 2,7-dinitrofluorenone).

The decrease in potential in the dark over a period of 1 min at E_0 = 75 V μm^{-1} does not exceed 5%. The absence of the photosensitivity of the unsensitised layers in the presence of a negative charge shows that holes but not electrons are mobile in PEPC. In the PEPC + 1 mol% TNF or TENF compositions, photosensitivity appears also in the presence of a negative charge. At such concentrations of electron-accepting compounds, electrons also become mobile. The introduction of organic dyes and electron-accepting compounds into PEPC results both in an increase in the electrophotographic sensitivity in the intrinsic absorption band of the oligomer and in the expansion of the spectral range of the photosensitivity up to 650 nm.

Measurements have been made of the dependence of the photosensitivity of PEPC layers on the amount of pyrylium salt introduced and the distributions of the spectral sensitivity of the layers in the wavelength range 250–650 nm have been investigated.[119] In order to sensitise PEPC, pyrylium salts with different substituents in the 2-, 4-, and 6-positions in the pyrylium ring, comprising perchlorate and tetrafluoroborate anions, have been studied.

Among the pyrylium salts investigated, the best sensitisers of PEPC layers are 4,6-diphenyl-2-*p*-tolylpyrylium perchlorate (D1), 2,6-dianisyl-4-phenylpyrylium perchlorate (D2), 2,6-dianisylpyrylium perchlorate (D3), 4-anisyl-2,6-dinaphthylpyrylium tetrafluoroborate (E1), 2-anisyl-4,6-diphenylpyrylium tetrafluoroborate (E2), and 2,6-dianisyl-4-phenylpyrylium tetrafluoroborate (E3).

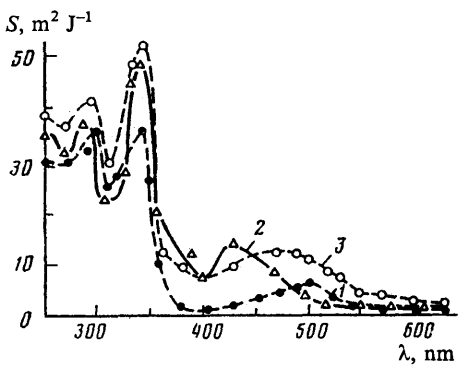


Figure 1. Distribution of the spectral sensitivity (S) of PEPC layers sensitised by the pyrylium salts D3 (curve *1*), D1 (curve *2*), D2 (curve *3*); $E = 5 \times 10^7$ V m^{-1}, c = 1 mol%, positive charge.[119]

The sensitivity of the unsensitised PEPC layers at λ = 295 nm for $E = 5 \times 10^7$ V m^{-1} is about 2 $m^2 J^{-1}$. A small amount of pyrylium salts greatly increases the photosensitivity of PEPC layers. It has been shown that the maximum concentration for the majority of pyrylium salts is 3–5 mol% relative to the PEPC monomeric unit. However, in the presence of 1–3 mol% of the sensitiser, saturation of the photosensitivity is observed and, on further increase in the content of the pyrylium salt, the photosensitivity begins to fall. The decrease in photosensitivity is explained by the formation of a negative space charge which reduces the rate of the photoinduced decrease in the potential.

Figs. 1 and 2 present curves for the distribution of the spectral sensitivity of PEPC layers containing 1 mol% of pyrylium salts. It is seen from the figures that pyrylium salts having a long-wavelength absorption maximum in the visible part of the spectrum have a much higher sensitising effectiveness than polynitrofluorenones and rhodamine 6G.

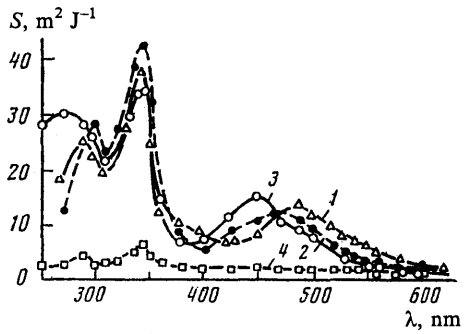

Figure 2. Distribution of the spectral sensitivity (S) of PEPC layers sensitised by pyrylium salts E3 (curve *1*), E2 (curve *2*), and E1 (curve *3*) (c = 1 mol%) and by TNF (curve *4*) (c = 3 mol%); $E = 5 \times 10^7$ V m^{-1}, positive charge.[119]

It is known that low-molecular-weight impurities, polymer end groups, triplet oxygen, polymer oxidation and photochemical oxidation products, and specific local conformations of the macromolecules can serve as deep centres for the capture of mobile holes in carbazole-containing photosemiconductors.[156–158] Low-molecular-weight ionogenic impurities can influence the visualisation of a latent electrophotographic image in the electrophotographic layer, which results in the appearance of different defects and in the diffuseness of information symbols on the developed image. The conditions in the synthesis of PEPC influence significantly the residual potential (U_{res}) of its electrophotographic layer. The main cause of the high value of U_{res} in PEPC layers is traces of the anionic catalyst and of electron-donating substances with a lower ionisation potential than that of the carbazole chromophore.[118,157]

The study of the photosensitivity and U_{res} of PEPC specimens obtained by anionic and cationic polymerisation and sensitised by TNF and 2,4,6-triphenylpyrylium perchlorate, introduced in amounts of 0.5 and 3 mol% respectively and 0.1 and 0.5 mol% respectively into a monomeric unit of the oligomer, showed that PEPC specimens with a low U_{res} are sensitised more effectively in both the UV and visible parts of the spectrum.[157] The residual potassium hydroxide decomposes the pyrylium sensitisers in the PEPC layers.

At the present time, the PEPC used for the preparation of electrophotographic layers is obtained by the anionic polymerisation of EPC in the presence of potassium hydroxide followed by treatment of the product with acetic acid.[157] In order to reduce U_{res}, the PEPC should be carefully freed from technological impurities, including the catalyst, before the preparation of the electrophotographic layer.

Electrophotographic layers based on industrial PEPC, purified by adsorption, chromatographic, and ion-exchange methods, have been investigated.[158] It has been shown that the greatest decrease in the residual potential of the PEPC electrophotographic layer is obtained when solutions of PEPC in polar solvents are treated with activated charcoal and by passing its solutions through layers of Al_2O_3 or silica gel.

The development of electrophotography imposes stringent requirements on the electrophotographic microfilming apparatus for the representation and replication of information. This suggests the use of semiconducting systems with improved electrophotographic properties.[159]

One of the ways of improving electrophotographic properties of layers based on PEPC is its chemical modification.[89]

In order to prepare layers with an improved electrophotographic sensitivity, brominated PEPC, sensitised by TNF and pyrylium salts, can be used as the photosemiconductor. Brominated PEPC layers sensitised by TNF and pyrylium salts are more photosensitive than the analogous PEPC layers.[89,120,121] This is especially appreciable in the case where PEPC is sensitised by pyrylium salts. The pyrylium cation, which has an exceptionally high electron affinity, ensures electron transfer over long distances from bromocarbazolyl to the pyrylium salt, which leads to an appreciable separation of the charges of the ion pair and to effective dissociation of the electron donor–electron acceptor complex in the electric field with formation of a mobile hole.

The characteristic features and the mechanism of the dark charging processes[160–164] and photocharging processes[165–169] involving pure and sensitised PEPC electrophotographic layers have been investigated. The influence of luminescence on the latent electrophotographic image[170,171] and also of prolonged illumination on the optical, photoelectric, and thermomechanical properties of electrophotographic information carriers (EPIC), prepared on the basis of PEPC,[172] have been investigated. As a result of photochemical reactions, on irradiation with UV light the absorption by electrophotographic information carriers increases in the visible region, the photosensitivity falls, and the rate of discharge in the dark increases. Owing to the impairment of thermomechanical properties, cracking on bending is then observed which precludes photothermoplastic recording. The removal from the spectrum of the UV lamp of radiation at wavelengths less than 400 nm makes it possible to eliminate effects associated with the light-induced ageing of electrophotographic information carriers.

PEPC layers with added TNF have been used to prepare photoelectric converters[173,174] and a varistor.[175] On illumination of a "sandwich" cell with a photosensitive PEPC layer to which 0.5–3.0 wt.% of TNF had been added by light from an incandescent lamp, a photo-e.m.f. equal to 0.6 V was generated between the electrodes for an incident light energy of 20 mW cm^{-2}.[174] The short-circuit photocurrent was in the range 0.1–0.5 μA cm^{-2}. The elucidation of the nature of the photo-e.m.f., in particular the character of the transitions at the aluminium–photoconductor and photoconductor–aquadag contact as well as the estimation of the yield of the diffusion photo-e.m.f. (Dember's e.m.f.) requires further studies. The data obtained have shown that the photovoltaic effect is sufficiently large to suggest that PEPC is a promising material for the manufacture of photocells based on it.

The photocells based on PEPC[173,174] and PVCA[176,177] known at the present time have low efficiencies but their appreciable increase may be expected when the optimum metallic electrode–polymer combination has been selected and also after the development of a technology for the preparation of ultrathin uniform films with a high electrical conductivity.

- - - o0o - - -

The study of the polymerisation of epoxypropylcarbazoles in the presence of various catalysts indicates its very effective occurrence under the influence of anionic catalysts. The use of potassium hydroxide as the catalyst is apparently most suitable as regards the technological aspects of the process. In view of the favourable disposition of carbazole side substituents and the presence of ether linkages in the main chain, EPC oligomers have effective physicochemical and photoelectric properties which permit their use in electrophotography and also in the thermoplastic recording of information.

The basic data on the electrical, optical, dielectric, and photovoltaic properties of carbazole-containing polymers and charge-transfer complexes have now been obtained. Electrophotographic layers used for microfilming, photothermoplastic devices, and the recording of information have now been produced on the basis of carbazole-containing polymers and their derivatives with different acceptors. Studies in this field are extremely promising and are being prosecuted in many world laboratories. The first polymeric photocells based on carbazole-containing polymers have already been created, although they still have low efficiencies. However, the simplicity of their preparation and the low cost of the initial materials have stimulated the development of research into the synthesis of new photoconducting polymers in order to manufacture highly efficient photoelectric cells.

The improvement of oxidation catalysts

L Ya Margolis, A A Firsova
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The mechanism of the action of additives introduced into oxide catalysts and silver to increase their activity and selectivity in the oxidation of various organic substances has been examined. Additives can change the kinetic parameters of a process (the rate and activation energy of the reaction) and influence the reaction mechanism by their effect on the structure of the surface compounds and on the energy of the bonds which they form with the surface. The modification of the catalysts gives new compounds (both in the bulk and on the surface), leading to the production of new active centres. The action of additives introduced into multicomponent oxide catalytic systems, and various aspects of their modification by acidic and alkaline additives, have been discussed.

The bibliography contains 62 references.

I. Introduction

The efficiency of catalysts is determined by two parameters—the degree of conversion of the starting materials and the selectivity of their conversion into the required products. One of the principal methods for controlling these parameters is by introducing various additives into the catalyst.

Previously, on the basis of the chemical properties of the materials, two types of additive were distinguished: promoters, which increase the activity of catalysts, and poisons, which decrease the activity.[1]

In the period 1940–1950, the study of the extensive oxidation of hydrocarbons on various oxide catalysts and platinum revealed a new phenomenon: the same additive, introduced into a catalyst, may have a promoting or a poisoning effect on the activity of the catalyst, depending on its concentration in the solid.[2–4] It was suggested that the effect ot additives on the properties of catalysts should be described as their modification. The two-fold action of additives was attributed to the change in the same sense in the activation energy and the pre-exponential factor (Fig. 1). This led to an extremal dependence of the reaction rate on the additive concentration (Fig. 2). The phenomenon of catalyst modification was found to be characteristic of not only extensive but also partial oxidation.[5,6] Thus the introduction of additives into copper oxide CuO, a catalyst for the oxidation of propylene to acrolein, brings about the change in the rate and activation energy of formation of the products characteristic of modification. When lithium ions are added to copper oxide, the energy of formation of acrolein changes from 12 kcal mol^{-1} to 22 kcal mol^{-1}, and that of CO_2 from 26 kcal mol^{-1} to 16 kcal mol^{-1}. The pre-exponential factor increases regularly in the order CuO + Li < CuO + PO_4^{3-} < CuO < CuO + Sb^{3+}, from 10^{17} to 10^{22}.

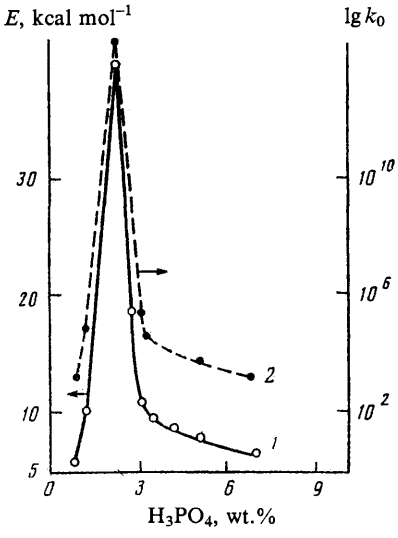

Figure 1. The influence of added H_3PO_4 on the activity of the $MgCr_2O_4$ catalyst in the extensive oxidation of iso-octane: *1*, change in the activation energy; *2*, change in the pre-exponential factor.[3]

Further studies of the control of the conversion and selectivity of oxidation processes showed, however, that these explanations are inadequate. Additives may react with the basic catalyst matrix to form solid solutions and new compounds, and hence increase the number of phases in the catalyst. The effect of these impurities is not limited to changing the phase composition of the catalyst; as a result of the change in the structure, they also influence the probability of electron transitions between the elements in the solid. The rearrangement of the catalyst structure, leading to changes in

the bulk characteristics, also lead to changes in the surface; the additives also take part in the production of the active centres on which the catalytic reaction takes place.

The introduction of additives has produced highly selective catalytic systems used in industry, but the additives have been selected empirically, since the multifunctional character of their action makes it difficult to determine the basic principles of the selection of modifiers for increasing the efficiency of catalysts.

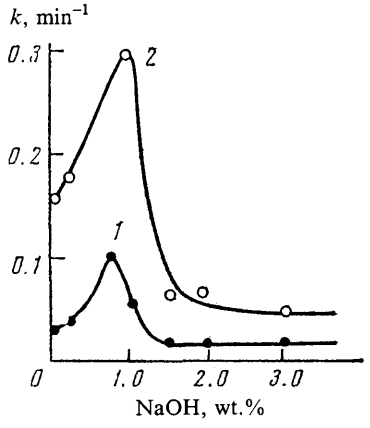

Figure 2. Influence of added NaOH on the rate constant of the oxidation of iso-octane on tungsten oxide at 320 °C (*1*) and 420 °C (*2*).[4]

The accumulated experimental data on modification have not been fully reviewed. A review[8] was published in 1987, dealing with the promotion of various metallic and oxide catalysts for the Fischer–Tropsch synthesis, the hydrogenation of CO, etc., but the nature of the modifying action of the additives introduced into a large number of oxidation catalysts was not examined systematically.

Attempts have been made to explain the mechanism of the modification of catalysts using various theories of catalysis. In the period 1950–1960, Vol'kenshtein,[9] who developed the electronic theory of catalysis, explained the mechanism of the modification of semiconducting oxide catalysts in terms of the band model, attributing it to a change in the position of the Fermi level in the crystals. According to these ideas, additives can change the electronic properties of the crystal in the bulk and on the surface. The catalytic activity of specimens should therefore be compared with the electronic characteristics of the solid, for example the electrical conductivity or the work function. The introduction of donor or acceptor additives changes the position of the Fermi level and decreases the degree of coverage of the catalyst surface by the reagents, which become charged on adsorption (electron acceptors or donors), and this may even lead to a change in the limiting stage of the process and its rate. A large number of papers have been published on the relationship between the electrical conductivity and the work function in the oxidation of various substances on oxide semiconductors.[5] The sign of the charge on a given impurity may be different in the bulk and on the surface of an oxide, however. The electronic characteristics of the impurities in a solid and their influence on a reaction rate may be different, depending on their distribution. It is therefore impossible to establish the mechanism of the varied action of additives by examining only the electronic properties of semiconducting oxides.

In the case of metals, it is considered that the additives and reagents on their surface form charged dipoles, whose electrostatic interaction changes the degree of covering of the surface by the reagents and hence influences the reaction rate.

The study of the modification of silver by additives which are electron donors or acceptors has shown,[5] however, that the mechanism of action of these additives cannot be explained entirely in terms of the interaction of dipoles. The change in the work function when silver is modified cannot be responsible for the change in the activity of the catalyst or the selectivity of the process, and is only an "indicator" of the change in the properties of the surface of the solid. When potassium or halogen ions are introduced into silver, the additive migrates into the bulk, dissolving in its lattice with the formation of microcrystals. The change in the work function is merely a reflection of these processes, and cannot influence the selectivity of catalytic reactions.[10,11]

To determine the mechanism of the action of additives on the properties of catalysts, it is necessary first to study their structure and phase composition, the mobility of oxygen in them, and their acid–base properties.

Of the large number of modified catalysts, various simple and complex oxide systems and one metallic catalyst, namely silver, are examined in the present review.

II. The influence of additives on the structure and phase composition of catalysts

1. Simple metal oxides

Additives are introduced into catalysts in different ways: during the preparation of the basic matrix or by adsorption on the surface of a prepared catalyst. Depending on the method of introduction, the additives may be distributed in different ways in the bulk of the catalyst and on its surface. This may lead to variations in phase composition, which are examined here for the case of a vanadium oxide catalyst.

As a consequence of the characteristics of its structure, vanadium pentoxide reacts readily with foreign metal ions to give vanadium bronzes, that is non-stoichiometric double oxides with the general formula A_xBO_3, showing characteristic semiconducting or metallic conductivity.[12,13] The formation of bronzes can be described as the result of the introduction of foreign atoms or ions into the main lattice. The metal A, entering the lattice, occupies some of the free sites and has no influence on the structure of the main oxide. The introduction of A leads to the production of an impurity level in the band gap of BO_3 below the conductivity band or in the actual band, which is "populated" by electrons of the metal A. Vanadium bronzes are formed particularly readily with the alkali metals and silver. In addition, for the oxidation of aromatic hydrocarbons to aldehydes, use is made of vanadium–molybdenum oxide systems consisting of a solid solution of MoO_3 in V_2O_5 (V : Mo = 1 : 0.27) containing added silver and copper ions. The study of these catalysts by X-ray diffraction, infrared spectroscopy, and EPR has detected the formation of bronzes with vanadium ions in different arrangements. The production of these structures leads to a change in the rate of oxidation of hydrocarbons. According to Volkov and Novak,[13] the diffusion coefficient of oxygen, which is 10^{-8} cm^2 s^{-1} in

V_2O_5, is lower by a factor of 10^2 in the bronzes, due to the presence in the structure of the latter of cavities through which oxygen, the principal component of oxidation processes, moves readily.

To obtain effective oxidation catalysts, vanadium pentoxide is added in different concentrations to MoO_3 and other oxides; the catalytic activity and selectivity depend significantly on the vanadium concentration in the specimen.

According to Andrushkevich and Kuznetsova,[14] the active component of the vanadium–molybdenum oxide catalyst for the oxidation of acrolein to acrylic acid is the compound VMo_3O_{11}, whose maximum concentration in this system is reached at a V_2O_5 concentration of 7–15 mol%; the compounds VMo_2O_{8+x} and $V_6Mo_4O_{25}$ are also formed. Other additives are also frequently introduced into these systems. An effective additive to the vanadium–molybdenum catalyst for the synthesis of acrylic acid is copper oxide.[15] The introduction of the Cu ion gives a V–Mo–Cu oxide compound of variable composition, shown by X-ray diffraction, X-ray photoelectron spectroscopy, and infrared spectroscopy to be based on the structures of VMo_3O_{11} and VMo_2O_{3+x}.

The V_2O_5–MoO_3 system is an active catalyst for the oxidation of benzene to maleic anhydride. It contains the new compound $V_9Mo_8O_{40}$, and also V^{4+} ions, whose maximum concentration, according to EPR data,[16] corresponds to the limiting solubility of MoO_3 in V_2O_5 (about 30 mol%).

A vanadium–titanium oxide catalyst is used for oxidising *o*-xylene to phthalic anhydride.[17] The highest rate of formation of phthalic anhydride and the highest selectivity are observed when 2.5–8 mol% V_2O_5 is introduced into inactive titanium dioxide. Vanadium ions coordinated to titanium ions, and the compound V_6O_{13}, are formed in this system. EXAFS has shown[18] that titanium dioxide brings about disordering of the V_2O_5 structure.

Another example of the action of a modifier on the phase composition of a simple oxide catalyst is provided by the use of MoO_3 as additive. X-Ray diffraction and infrared and ultraviolet spectroscopy[19] have shown that when MoO_3 is introduced into inactive tin dioxide SnO_2 in the ratio Sn : Mo = 9 : 1, a solid solution of MoO_3 in SnO_2, and also Mo and Sn oxides, are detected in the system. This catalyst is used to oxidise propylene to acetone.

The rate of formation of acetone shows an extremal dependence on the concentration of Mo ions in SnO_2; the rate decreases when the Mo concentration is higher than that corresponding to the optimum ratio Sn : Mo = 9 : 1.

Thus the modification of simple oxides by various additives gives new catalytic systems consisting of solid solutions, new compounds, and microheterogeneous formations, with structures and phase compositions differing from those of the simple oxides.

2. Complex metal oxides

Multicomponent mixed oxide systems are highly effective catalysts for the selective oxidation of alkenes.

Bismuth and cobalt molybdates are most frequently used for the oxidation of propylene to acrolein. The vanadium–molybdenum oxide system is used to convert aromatic hydrocarbons into acid anhydrides, and vanadium–phosphorus catalysts are used to oxidise butane to maleic anhydride. The introduction of various additives into these systems increases their efficiency.

The addition of iron to bismuth molybdate gives a complex oxide system containing the triple oxide $Bi_2Fe_2Mo_2O_{12}$ and Bi and Fe molybdates. Table 1 gives data on the influence of the modification of the catalyst by iron on the rate and selectivity of the formation of acrolein from propylene.[20] The individual triple compound $Bi_2Fe_2Mo_2O_{12}$ has a low activity, and its catalytic properties are similar to those of bismuth molybdate. The modification of $CoMoO_4$ by Bi, Fe, and Sb additives leads to a sharp change in its catalytic properties in the oxidation of propylene to acrolein. The X-ray diffraction study of these systems[21] has shown that new compounds are formed (Table 2).

Table 1. Influence of the Fe ion on the activity and selectivity of the Bi–Mo catalyst.

Fe^{3+} concentration, at.%	Phase composition	Rate of formation of acrolein at 340 °C, ml m^{-2} min^{-1}	Selectivity with respect to acrolein, %
0	$Bi_2(MoO_4)_3$	0.44	88
2	$Bi_2(MoO_4)_3$, $Fe_2(MoO_4)_3$, the triple compound $Bi_2Fe_2Mo_2O_{12}$	1.32	98
14.8	$Bi_2(MoO_4)_3$, $Fe_2(MoO_4)_3$, the triple compound $Bi_2Fe_2Mo_2O_{12}$	3.75	91
33.3	the triple compound $Bi_2Fe_2Mo_2O_{12}$	0.58	87

Table 2. Modification of $CoMoO_4$.[21]

Composition of the catalyst	Phase composition
Co + Mo	α-$CoMoO_4$, β-$CoMoO_4$, MoO_3
Co + Mo + Bi	α-$CoMoO_4$, β-$CoMoO_4$, MoO_3, $Bi_2O_3 \cdot 3MoO_3$
Co + Mo + Bi + Fe	α-$CoMoO_4$, β-$CoMoO_4$, MoO_3, $Fe_2(MoO_4)_3$, $Bi_2O_3 \cdot 3MoO_3$
Co + Mo + Bi + Fe + Sb	α-$CoMoO_4$, β-$CoMoO_4$, MoO_3, $Fe_2(MoO_4)_3$, $CoSb_2O_6$, $Bi_2O_3 \cdot 3MoO_3$

The catalytic system Co–Mo–Bi–Fe–Sb–O is used for the partial oxidation of isobutylene to methylacrolein. X-Ray diffraction and Mössbauer spectroscopy[22] have been used to study the structure of this multicomponent oxide system at different concentrations of the additives Bi and Fe. In addition to the basic matrix structure of $CoMoO_4$, the catalyst also contains the molybdates of bismuth $Bi_2(MoO_4)_3$ and iron(III) $Fe_2(MoO_4)_3$, and also the complex compound $M_2FeMo_2O_{12}$, where M = Bi, Sb. Figs. 3 and 4 give the dependence of the conversion of isobutylene and the relative concentration of the phases $Fe_2(MoO_4)_3$ and $M_3FeMo_2O_{12}$ on the concentrations of Bi and Fe in the system $Co_6Mo_{12}Bi_xFe_ySbO_z$. The maximum conversion of isobutylene is achieved for $x = 1$ and $y = 4-6$, when the catalyst contains equal quantities of the two iron-containing phases.

Thus the modification of complex oxide systems, which already contain several phases and elements in different oxidation states, leads to a further increase in their complexity. These complex oxide

systems make it possible to influence different stages of the oxidation and to increase the rate and selectivity of the reaction. The use of new complex catalytic systems has made it possible to achieve almost 90% selectivity, whereas on simple oxides the selectivity does not exceed 40–50%.

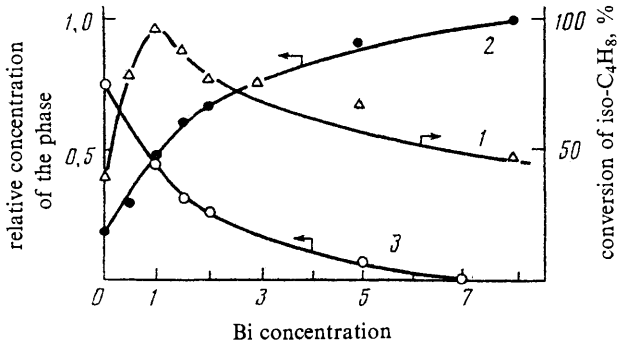

Figure 3. Dependence of the conversion of isobutylene at 370 °C (*1*) and the relative concentration of the phases $Bi_3FeMo_2O_{12}$ (*2*) and $Fe_2(MoO_4)_3$ (*3*) on the concentration of bismuth in the catalyst.[22]

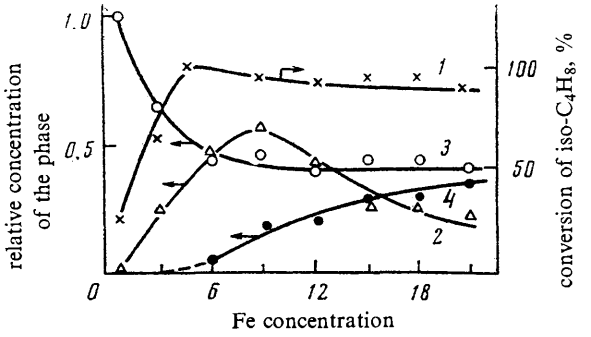

Figure 4. Dependence of the conversion of isobutylene at 370 °C (*1*) and the relative concentration of the phases $Fe_2(MoO_4)_3$ (*2*), $Bi_3FeMo_2O_{12}$ (*3*), and α-Fe_2O_3 (*4*) on the concentration of iron in the catalyst.[22]

III. The influence of additives on the state of oxygen in oxide catalysts

A large number of studies by different methods (using isotopes, reduction–reoxidation, etc.) have shown that the selective oxidation of organic substances on oxide systems involves the oxygen of the catalyst lattice.[5,23,24]

Oxidation involving the oxygen of the lattice is accompanied by the reduction of cations, which, when the process is carried out under stationary conditions, are reoxidised by the oxygen of the gas phase.

The formation of various non-stoichiometric oxides in the reduction of MoO_3 by the substance being oxidised has been examined.[24] The phase transitions do not involve extensive rearrangement of the lattice, but "crystallographic shearing" is observed,[25] that is during reduction, some of the oxygen is removed from the lattice with the production of vacancies, the distance between the Mo ions decreases, and the bonding between the oxygen octahedron around Mo is altered. The process gives blocks having a comparatively unaltered structure, separated by shear planes made up of other small blocks with a different regular structure.

In the reduction of MoO_3, the rapid movement of an electron into the bulk and its capture by Mo^{6+} ions close to a vacancy gives an Mo^{5+} ion

$$Mo_s^{6+}O_s + RH \rightarrow \left[\begin{array}{c} H \\ | \\ Mo_s^{5+}O_s \end{array}\right] R^+ \xrightarrow{Mo_v^{6+}O_v} Mo^{6+}\square\, RO + Mo_v^{5+}O_v + H^+.$$

The vacancy moves from the surface to the defect. The movement of the vacancy corresponds to the diffusion of oxygen to the surface by a mechanism involving a large number of displacements of the micro-blocks; thus the surface layer of the catalyst during the reaction is constantly rearranged, and the oxygen atoms change positions.

Table 3. Characteristics of the catalysts $Bi_{1-x/3}V_{1-x}Mo_xO_4$.[26]

x	Surface concentration of Bi, at.%	Rate of reduction by hydrogen $\times 10^{-6}$, mol min^{-1} m^{-2}	Mobility of the oxygen ions of the lattice,* %

0.21	15.1	7.8	75.1
0.27	14.6	7.6	72.2
0.45	14.0	6.4	100

*The fraction of oxygen ions of the lattice taking part in the oxidation, relative to the total quantity of oxygen ions of the lattice.

The introduction of additives into these systems influences the rate of migration of oxygen, and also the rate of rearrangement of the oxide lattice. The rates of these processes depend on the mobility of the oxygen of the solid lattice. The composition dependence of the mobility of oxygen in the $Bi_{1-x/3}V_{1-x}Mo_xO_4$ system, used to oxidise propylene to acrolein, has been studied using ^{18}O.[26] Table 3 gives the rates of the reduction by hydrogen of catalysts with different compositions, and data characterising the mobility of the lattice oxygen. The rate of reduction by hydrogen changes in the opposite sense to the change in the rate of reduction by propylene, that is the ability of the catalysts to undergo reduction is influenced strongly by the nature of the reducing agent. The dependence of the rate of reduction on the nature of the reducing agent is apparently due to the fact that the reactions of different reagents with the oxygen of the catalyst take place on different active centres. Increase in the concentration of the additive in the catalyst alters the composition of the surface, influencing the rate of its reduction and the activity.

A microcatalytic method combined with Mössbauer spectroscopy has given quantitative data on the reduction by propylene of cobalt molybdate modified by added Fe and Bi.[27] Fig. 5 gives the Mössbauer spectra (MS) of iron in the original Co–Mo–Bi–Fe oxide catalyst and in the catalyst reduced at different temperatures. In the oxidised state, Fe is present in crystalline $Fe_2(MoO_4)_3$, and the chemical shift is $\delta E_I = 0.68 \pm 0.01$ mm s^{-1}. When this catalyst is treated with propylene, partial reduction takes place to give β-$FeMoO_4$. Fig. 5 shows that the extent of the reduction, determined from the ratio of the areas of the spectra as $[Fe^{2+}]/([Fe^{2+}] + [Fe^{3+}])$, increases sharply with temperature; it has the values 0.14 at 270 °C, 0.44 at 350 °C, and 0.76 at 390 °C. These spectroscopic data were used to calculate the quantity of oxygen removed from the lattice in the reduction of $Fe_2(MoO_4)_3$ to $FeMoO_4$. The results of this calculation are compared with the data obtained in the catalytic micro-reactor in Table 4.

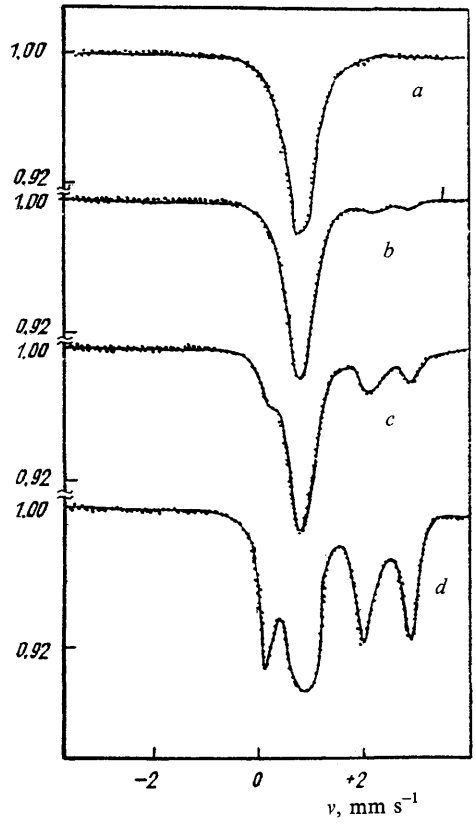

Figure 5. Mössbauer spectra of a Co–Mo–Bi–Fe catalyst before (*a*) and after its reduction by propylene at 270 (*b*), 350 (*c*), and 390 °C (*d*).[27]

Table 4 shows that almost all the oxygen removed belongs to iron molybdate. The Mössbauer spectrum of the reoxidised catalyst is identical to the original spectrum.

The liberation of the oxygen of iron(III)molybdate to give divalent iron molybdate and anion vacancies takes place according to the scheme:

$$Fe_2(MoO_4)_3 \rightarrow \{2FeMoO_4(MoO_3)\}\,\square_x + x[O],$$

where □ represents an anion vacancy.

The ionisation of vacancies leads to the production of an excess negative charge;[28] a redistribution of electron density takes place, affecting the entire iron molybdate crystal and leading to its reduction. Thus the modification of the Co–Mo catalyst leads to the formation of iron molybdate which "supplies" the oxygen for the selective oxidation of hydrocarbons.

Table 4. Quantity of oxygen (*n*) removed from a Co–Mo–Bi–Fe catalyst by the reaction with 40 C_3H_6 pulses.[27]

Reduction temperature, °C	10^{-19} *n*, atom g^{-1}	
	kinetic data	Mössbauer data
270	2.2	2.5
350	7.0	8.0
390	11.0	13.0

The removal of oxygen from the catalyst lattice under the influence of a hydrocarbon is accompanied by a simultaneous change in the oxidation state of the metal ions; if two additives are introduced into the catalyst, charge transfer takes place between them.

Mössbauer spectroscopy has been used to study the reactions of Fe and Te, introduced into $CoMoO_4$, with the components of the reaction mixture during the oxidation of propylene to acrolein.[29] On modification, the activity of the catalyst and the selectivity of the oxidation increase several-fold (Table 5). Spectroscopic data show that the introduction of the additives into the oxide catalyst gives new compounds $Fe_2(MoO_4)_3$ and $CoTeO_4$; reaction with the mixture leads to a partial change in the oxidation states of the Fe and Te ions.

Table 5. Influence of added Fe and Te on the activity of $CoMoO_4$ and the electronic transitions.[29]

Additive	Change in oxidation number	Conversion of C_3H_6, %	Selectivity of C_3H_4O formation, %
None	—	10	10
Fe	$Fe^{3+} \rightarrow Fe^{2+}$	63	36
Te	$Te^{6+} \rightarrow Te^{4+}$	55	30
Fe + Te	$Te^{6+} \rightarrow Te^{4+}$ $Fe^{3+} \rightarrow Fe^{2+}$	72	44

The rate of oxidation of different organic substances on V_2O_5, V_2O_5–MoO_3, and other vanadium-containing catalysts is generally proportional to the concentration of V^{4+}, which is formed during

the process as a result of redox reactions, and also under the influence of the additive. The change in the oxidation state of vanadium is accompanied by the formation of a $V^{4+}=O$ double bond; this form of oxygen is more active in selective oxidation than other forms.

The influence of added P, Mo, W, and Sn on the catalytic properties of V_2O_5 in the oxidation of benzene to maleic anhydride has been studied.[30–32] Mo ions increase the activity of the catalyst and the selectivity of the process, whereas W and P increase the selectivity but decrease the activity. The presence of Sn ions in V_2O_5 leads to the extensive oxidation of benzene. This influence of the additives on the catalytic properties was related to their electronegativities:

$$Sn^{4+} < V^{5+} < W^{6+} < P^{5+} < Mo^{6+}.$$

The introduction of the more electronegative ions (W, P, Mo) leads to a decrease in the electron density of the $V^{4+}=O$ bond, associated with charge transfer between the vanadium ions and the additive, leading to a change in the length of the $V^{4+}=O$ bond. When this bond becomes shorter, the oxygen becomes more reactive, and the catalyst becomes more effective in the oxidation of benzene.

Thus the state and reactivity of oxygen are related to the structure of the catalyst and the electron transitions in the solid. The rearrangement of the structure and the change in the rate of electron transfer under the influence of the additives are factors determining the selectivity of oxidation processes and the activity of catalysts.[28]

IV. The modification of catalysts by acidic and alkaline additives

1. Oxide systems

There is a large amount of data (see for example the published review[33]) on the action of alkaline additives in catalysts on various reactions. The trivial explanation of this phenomenon reduces to the examination of the acid–base properties of the surface of the solids and the reagents. The alkaline and acidic properties of the reaction products and the strength of their bonding with the surface[34] are regarded as factors determining the activity of the catalysts.

It has been shown for the case of the vanadium–molybdenum oxide system that the selectivity of the oxidation of benzene to maleic anhydride can be increased by introducing both alkaline (Na) and acidic (P) additives into the catalyst.[34] This increase in selectivity is probably due not to a change in the acid–base properties of the catalyst but to some other factors. EPR has shown that the presence of Na and P in the catalyst leads to an increase in the concentration of V^{4+} ions and the number of V=O bonds, and XPS has shown a change in the ratio of the ions $Mo^{6+}:V^{4+}$ in the layers next to the surface.

When the ions Na, K, Rb, and Cs were introduced into the vanadium–titanium catalyst for oxidising *o*-xylene to phthalic anhydride (PA),[35] the selectivity of the process increased and reached 87%, as a result of a decrease in the rate of the more extensive oxidation of PA. The selectivity of the formation of PA increases with increase in the electronegativity of the alkali metal ions. All the alkaline elements added to the catalyst keep the vanadium in the vanadium–titanium oxide catalyst in the stable oxidation state, and simultaneously neutralise the acidic centres of the surface.

The introduction of the K ion into the Sn–Mo–Fe catalyst for the oxidation of propylene to acetone increases the selectivity from 23% to 94% by decreasing the rate of more extensive oxidation. The presence of the K ion leads to an increase in the concentration of the reduced form of Mo produced by reaction with propylene.

The influence of alkali metals (Li, Na, K) and alkaline earth metals (Mg, Ca, Ba) on the properties of the unique vanadium–phosphorus catalyst for the oxidation of butane to maleic anhydride has been studied.[36] No relationship between the acidic properties of the surface and the rate of oxidation of butane was detected, but a change in the bond energy of oxygen in the lattice and in the catalytic properties on modification was observed.

The mechanism of the action of alkaline additives has been studied in more detail for the Co–Mo–Bi–Fe catalyst for the partial oxidation of alkenes to unsaturated aldehydes. When the catalyst is modified by Li, Na, K, and Cs, the acid–base properties of its surface remain unchanged.[37] At the same time, modern physical methods (Mössbauer spectroscopy, EPR, ESCA) have shown that the alkali metals influence the structure of the catalyst. The modified Co–Mo–Bi–Fe catalyst contains the phase $Fe_2(MoO_4)_3$ with a garnet-like structure, which includes an unoccupied dodecahedral sub-lattice. On the introduction of the alkali metals, in particular potassium, whose ionic radius is the optimum for this structure, partial filling of the unoccupied sub-lattice takes place; defects are produced in $Fe_2(MoO_4)_3$, which acquires the structure of a non-stoichiometric garnet containing oxygen vacancies:

$$\square_3^0 Fe_2^{3+}(Mo^{6+}O_4^{2-})_3 \xrightarrow{K^+} K_x^+ \square_x^- \square_{3-x}^0 Fe_2^{3+}(Mo^{6+}O_4^{2-})_3,$$

where $\square^0$ represents a vacancy in the dodecahedral sub-lattice, and $\square^-$ represents an oxygen anion vacancy.

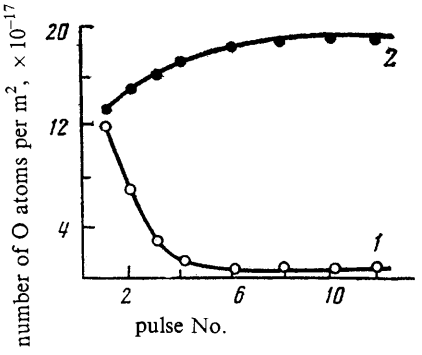

Figure 6. Dependence of the quantity of oxygen of the lattice of the catalysts Co–Mo–Bi–Fe (*1*) and Co–Mo–Bi–Fe–K (*2*) reacting with iso-C_4H_8 in each separate pulse on the number of successive pulses.[38]

These structural changes also have a marked influence on the mobility of the oxygen of the catalyst lattice. Modification of the Co–Mo–Bi–Fe catalyst by potassium leads to an increase in the conversion and the selectivity of the oxidation of isobutylene to methylacrolein. To establish the influence of modification on the

mobility of oxygen of the catalyst, its reduction by isobutylene was studied by the kinetic method and by Mössbauer spectroscopy.[38] Fig. 6 shows the change in the quantity of oxygen reacting in each pulse with isobutylene (size of the pulse 2 ml) in a catalyst with and without the addition of potassium. The concentration of isobutylene on the modified catalyst in each subsequent pulse does not decrease, but increases, and becomes constant after 8–10 pulses. The decrease in the conversion becomes significant only after 25–30 pulses.

The rate of reduction of the catalyst also increases after its modification by potassium. This can be seen particularly clearly after the supply of the fourth or fifth pulse of iso-C_4H_8; at this moment the rate of reduction of the Co–Mo–Bi–Fe catalyst decreases to almost one tenth of the initial rate, and the rate of reduction of Co–Mo–Bi–Fe–K even increases slightly (Table 6). The extent of the reduction of the modified catalyst, that is the quantity of oxygen removed in the reaction with a given number of alkene pulses, is almost ten times greater than that on the catalyst without K.

Table 6. Rate (v_r) and extent (n_0) of the reduction of catalysts by isobutylene.[38]

Catalyst	Conversion of iso-C_4H_8, %	Selectivity of C_4H_6O formation, %	n_0 (atom m^{-2}) after 10 pulses	v_r, μmol m^{-2} s^{-1}	
				initial	after 5 pulses
Co–Mo–Bi–Fe	57	40	$27 \cdot 10^{17}$	0.63	0.05
Co–Mo–Bi–Fe–K	76	83	$18 \cdot 10^{18}$	0.70	0.80

Analysis of the Mössbauer spectra and comparison with the kinetic data obtained in a microcatalytic reactor showed that the reduction of the catalyst involves mainly the oxygen of the $Fe_2(MoO_4)_3$ lattice. When the K ion is introduced into the catalytic system, it is the mobility of the oxygen in this lattice that is increased, as indicated by the spectra of the reduced specimens; in the Co–Mo–Bi–Fe specimen, the extent of the reduction, calculated from the ratio of the normalised areas in the spectrum of Fe^{2+} molybdate to the total area of the spectrum of Fe^{2+} and Fe^{3+} molybdates, is 0.12, whereas that in the Co–Mo–Bi–Fe–K specimen is 0.75.

Modification of the Co–Mo–Bi–Fe catalyst by acidic additives (for example P) leads to a marked deterioration in its catalytic properties.[27] The conversion of C_3H_6 decreases from 87% to 14%, and the selectivity of the oxidation to acrolein decreases from 60% to 32%. The introduction of phosphorus, like that of potassium, produces practically no change in the acid–base properties of the catalyst surface. X-Ray diffraction and Mössbauer spectroscopy have shown that the presence of phosphorus prevents the formation of crystalline iron(III)molybdate in the catalyst. The rate and extent of the reduction of the Co–Mo–Bi–Fe–P catalyst by propylene are ten times lower than those for Co–Mo–Bi–Fe.

Thus the change in the catalytic characteristics of oxide systems under the influence of alkaline and acidic additives is not always due to their influence on the acid–base properties of the catalyst surface.[39] As shown above, these additives influence mainly the structure of the solid and the mobility of the reactive oxygen, leading to a change in the selectivity of the oxidation processes.

2. Silver catalyst

Only the metallic catalyst silver is used for the partial oxidation of ethylene to ethylene oxide. This process has been the subject of a large number of studies[5,6,8] to determine the mechanism of formation of C_2H_4O, the nature of the surface of the catalyst, the state of oxygen, etc. Modification by alkaline and acidic additives (K, Cs, Cl, etc.) is widely used to produce an active and selective silver catalyst.

To determine the mechanism of the action of the additives, it is necessary to examine the forms of oxygen adsorbed on silver, taking part in the oxidation of ethylene.

The following scheme has been given[40] for the reaction of oxygen with silver:

1. $O_2 + Ag \rightarrow O^-_{2\,ads} + Ag^+$,
2. $O_2 + 4Ag(\text{individual atoms}) \rightarrow 2O^{2-}_{ads} + 4Ag^+$,
3. $O_2 + 4Ag(\text{aggregate of atoms}) \rightarrow 2O^-_{ads} + 4Ag(\text{aggregate})$.

Other authors[41,42] consider that isolated silver atoms adsorb oxygen in the molecular form, which then takes part in the oxidation of C_2H_4 to C_2H_4O. Carbon dioxide is formed by the reaction between C_2H_4 and atomic oxygen, which is adsorbed on the aggregate (4Ag). A different view is held by other workers,[43] who consider that the formation of C_2H_4O also involves atomic oxygen. In addition to the production of surface forms, the adsorption of oxygen on polycrystalline silver is accompanied by its solution in the layers of the metal lattice next to the surface.[44]

In the opinion of other workers,[45] dissolved oxygen weakens the bonds between the surface forms of oxygen and the catalyst. The study by modern spectroscopic methods of the action of alkali metal ions adsorbed on different faces of silver showed that these additives increase the rate of the recombination of atomic oxygen to molecular oxygen, and hence increase the degree of covering of the surface by molecular oxygen. Thus on the (111) face of silver on which caesium ions were adsorbed, an oxygen-containing surface structure was detected.[46,47] The addition of caesium decreases the rate of the extensive oxidation of ethylene and alters the activation energy of formation of CO.

Modification of silver by caesium ions changes not only the concentration of oxygen on the surface but also the rate of isomerisation of C_2H_4O.[48]

When the Rb^+ ion is added to silver, the formation of peroxide leads to the production of molecular oxygen by the reaction

$$2\,Rb_2O_4 \rightarrow 2\,Rb_2O + 3\,O_2,$$
$$2\,Rb_2O \rightarrow 4\,Rb + O_2$$

The introduction of the K^+ ion into Ag (110 face) also alters the degree of covering of the surface by oxygen; K_2O_4 is formed, and decomposes by a scheme similar to that for rubidium peroxide.[50]

The addition of alkali ions to silver alters the ratio of the rates of formation of C_2H_4O and CO_2 in the oxidation of ethylene, and also the activation energies of these reactions, so that it influences the selectivity of the process.

The introduction of the Cl ion into a single crystal of Ag (111 face) leads to the displacement of the previously adsorbed oxygen atom.[51] Changes are observed in the rate and order of the

reaction and in the activation energy for the formation of ethylene oxide and CO_2, depending on the degree of covering of the surface by chlorine (Fig. 7). According to other data,[52] chloride ions adsorbed on silver form a surface structure of silver chloride AgCl. The adsorption of Cl ions increases the diffusion of oxygen atoms into the silver lattice.[53]

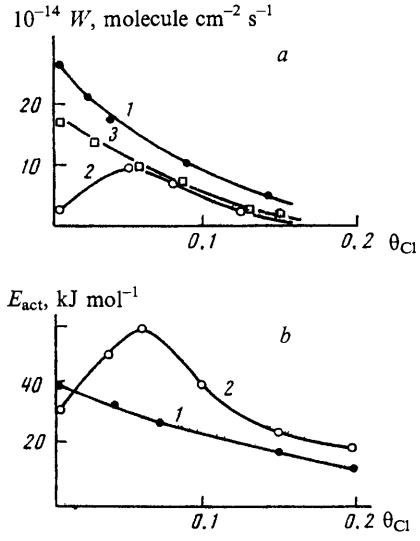

Figure 7. Effect of the degree of covering of the silver surface with chlorine on the rate (*a*) and activation energy (*b*) of formation of ethylene oxide and CO_2:[51] *1*, carbon dioxide; *2*, ethylene oxide; *3*, total rate of transformation of ethylene.

Silver is often modified by chlorine by introducing dichloroethane into the reaction mixture. This method of introducing additives has been called "gas modification",[2] and its mechanism is the same as the usual mechanism of action of additives introduced into a catalyst. On the silver surface, dichloroethane dissociates to form AgCl.[5] Experiments using the ^{36}Cl isotope have shown that the silver chloride formed in the reaction medium is reduced with the generation of a Cl ion, which does not migrate into the metal lattice at 330 °C, but remains on the surface. Similar results were obtained using the ^{131}I isotope.

In the modification of silver, dichloroethane undergoes the following transformations:

$$C_2H_4Cl_2 + Ag \rightarrow Ag(C_2H_4Cl_2)_{ads} \xrightarrow{O_2} \overbrace{Ag\,[AgCl]}^{Ag+(Cl^-)_{ads}} + C_2H_4.$$

Dichloroethane added to the $C_2H_4 + O_2$ reaction mixture inhibits the dissociation of oxygen on silver.[54] The concentration of the modifying additive appears in the kinetic equation for the reaction.

Thus when the potassium ion is introduced into the silver catalyst:

1, the chemisorption of oxygen is increased,

2, peroxides generating molecular oxygen are formed,

3, the rate of recombination of oxygen atoms increases,

4, the rate of isomerisation of ethylene oxide changes,

5, the kinetic parameters of the oxidation of ethylene change.

When the chloride ion is added:

1, the rate of dissociation of molecular oxygen decreases,

2, the strength of the Ag–O bond decreases,

3, the rates of desorption and recombination of oxygen atoms and their diffusion into the Ag lattice increase,

4, chloride ions displace oxygen atoms from the silver surface,

5, the kinetic parameters of the oxidation of ethylene are altered.

Modification of silver influences not only the state of the adsorbed oxygen but also the adsorption of C_2H_4. Ethylene is adsorbed on the silver surface only in the presence of oxygen, reacting with it to form surface complexes whose structure has been studied by infrared spectroscopy.[55] It was previously shown that on adsorption, ethylene is positively charged, but the work function depends on the magnitude of the negative charge on oxygen. The presence of the Ag surface of additives with positive (alkali metals) or negative (halogens) charges alters the heats of adsorption and the bond energies of oxygen and ethylene–oxygen complexes with the surface. This electronic factor should probably also influence the activation energies of the partial and extensive oxidation of ethylene. A study of the combined adsorption of potassium and chlorine on the (100) face of a single crystal of Ag showed that an electrostatic interaction takes place between the Cl^- and K^+ ions.[56] AgCl, stabilised by K^+ ions, is formed on the surface. In addition, KCl, desorbed at 700 K, was also detected.

Thus as in oxide systems, the introduction of acidic and alkaline additives into silver influences chiefly not the acid–base properties of the surface but the forms in which oxygen is adsorbed on the metal, and also the kinetics of the oxidation of ethylene to ethylene oxide.

V. Summary

The term modification is now used to describe not only the introduction of additives into different catalysts but also the change in the quality of the surface, for example the replacement of OH groups in silica gel by various elements, the deposition of various complexes and molecules on the surface, etc.

It is assumed[57] that the modification of simple and complex catalytic systems involves a change in the structure of the solid or a reconstruction of its surface, and also a change in the energy of the bonds between the adsorbed reagents and the surface. It has been noted that modified systems are multi-functional, and that the selectivity can be controlled by controlling their structure.

Attention was drawn above to the fact that practically all selective oxidation catalysts are multi-phase (even in the case of solid solutions, for example $Sb_2O_4-SnO_2$).

Modern spectroscopic methods have detected the migration of the additive from the bulk to the surface with the formation of a separate phase in both oxide and metallic catalysts. When silver is modified by alkali and halide additives, new compounds, peroxides and salts, are produced on the surface.

Since modified catalysts are multi-phase, a separation of functions between different phases has been suggested.[58,59] An example is provided by the oxidation of propylene on a cobalt–molybdenum oxide catalyst modified by Bi and Fe, which consists of Co, Bi, and Fe molybdates. During the oxidation of propylene under stationary conditions, partial reduction of the molybdate $Fe_2(MoO_4)_3$ to $FeMoO_4$ takes place, with the production at the interface between these phases of a super-equilibrium concentration of vacanices, which, by diffusing to the $Fe_2(MoO_4)_3/\beta$-$FeMoO_4$ interface, can act as centres for the dissociative adsorption of oxygen from the gas

phase with the formation of lattice oxygen. The transfer of this oxygen to the active regions of the surface, on which the alkene is adsorbed and oxidised, takes place via the interface between the iron and bismuth molybdate phases. A possible model of a system of this kind is shown in Fig. 8. The phase transitions $Fe_2(MoO_4)_3 \rightleftarrows FeMoO_4$ are facilitated if the catalytic system contains the isostructural phase β-$CoMoO_4$, since the interphase boundaries of β-$FeMoO_4$ and β-$CoMoO_4$ are coherent, and the formation of $FeMoO_4$ in the presence of a sufficient quantity of anion vacancies is associated with practically no energy barrier.

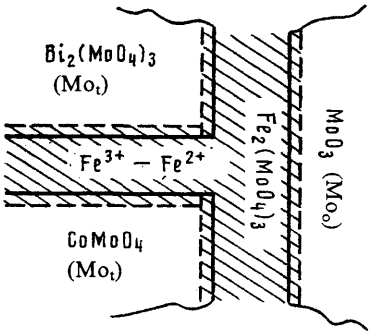

Figure 8. Model of the boundary zone of a Co–Mo–Bi–Fe–O catalyst;[60] Mo_o and Mo_t correspond to octahedral and tetrahedral coordination of the molybdenum ion.

The quantity of anion and cation defects depends on the total extent of the interface between the crystallites of the different phases in the catalyst, and this extent in turn is determined by the size of the actual crystallites, that is by their degree of dispersion. The degree of dispersion of multi-phase and multi-component oxide catalysts based on the molybdates of various divalent metals depends on their composition.[60]

A study of the oxidation of propylene to acrolein on complex oxide catalysts with the general formula $M^{II}_6Mo_{12}Bi_{0.5}Fe_{0.75}O_x$, where M^{II} = Co, Mg, Zn, Mn, established that the highest catalytic activity is shown by the systems with M^{II} = Co and Mg.[60] The Co and Mg molybdates in these systems, like the other phases, are characterised by the maximum degree of dispersion. For M^{II} = Zn and Mn, the individual crystallites are much larger, and the activity of these catalysts is much lower. At the same time, it was shown that the chemical nature of the cation M^{II} in this complex catalyst has practically no influence on the overall activity; in this case the catalytic properties are influenced significantly by the degree of dispersion. The additives introduced into complex oxide catalysts can be divided into two types: those of one type take direct part in the functioning of the active centre and facilitate some stage of the process (for example Fe ions in the Co–Mo–Bi–Fe catalyst), while those of the other type create a definite "macro-structure" (for example Co and Mg ions in the M^{II}–Mo–Bi–Fe system). The action of additives of the first type is called "micro-modification", and that of the second type "macro-modification".[60]

The effect of modification is revealed particularly clearly in the action of the alkali metals on a catalyst. These additives are capable of producing new basic centres on the surface. In addition, the alkali metals can form new compounds (for example salts, bronzes in the case of vanadium catalysts, etc.) and hence increase the multi-phase character of the catalytic system. The alkali metals may also be introduced into the structure, facilitating its rearrangement (for example, when the K^+ ion is introduced into iron molybdate with the garnet structure, it acquires a non-stoichiometric structure with a larger number of defects). All these changes influence the state of oxygen in the catalytic systems. It is believed[61] that the modification by alkali metals of oxide catalysts for the oxidation of hydrocarbons alters the ratio of nucleophilic and electrophilic oxygen on the surface. It is suggested that these forms are involved in the oxidation. To achieve a high selectivity of partial oxidation, it is necessary to suppress extensive oxidation. Both processes involve molecular and atomic oxygen and the oxygen of the oxide lattice. Additives control the concentrations of these forms of oxygen on the oxide surface, and hence alter the ratio of the products of mild and extensive oxidation.

In the present review, most attention has been paid to the promoting action of additives and its mechanism. Increase in the concentration of additives in a catalyst beyond a certain limit, however, decreases the reaction rate and alters the activation energy. The mechanism of this "poisoning" is less clear, and has been little studied. Increase in the concentration of additive probably leads to an increase in the concentration in the system of new compounds which in a number of cases are inactive and decrease the number of active centres. For example, with increase in the concentration of iron ions in the Co–Mo–Bi–Fe system, the products include not only iron molybdate but also iron oxide, on which propylene undergoes extensive oxidation, so that the selectivity of the formation of acrolein from the alkene decreases sharply. This phenomenon is particularly characteristic of solid solutions, in which increase in the quantity of additive exceeds the solubility limit, and an inactive oxide phase separates. In addition, the active centres of the catalyst may be blocked by additive ions, as observed on a silver catalyst with increase in the concentration of Cl^- ions.

The decrease in activity with increase in the concentration of an additive may also be due to a phase transition in one of the compounds in the catalyst. For example, increase in the vanadium concentration in the V_2O_5–TiO_2 system leads to a phase transition in TiO_2 from the rutile to the anatase structure,[62] and the catalyst is deactivated.

The decrease in the catalytic activity of modified catalysts may also be due to reaction between the reaction medium and the solid. The optimum concentration of additives ensuring the maximum activity of a catalyst can be lost by the partial removal of the elements of these additives by the reaction mixture. This takes place, for example, with the phosphorus ion in a V–Ti–P oxide catalyst[62] or with the Cl ion in a silver catalyst.[5] Decrease in the concentration of the additive lowers the activity of the catalyst, and mimics its "poisoning".

In catalytic oxidation, electronic interaction takes place between the ions in the catalyst. At the optimum concentration of the additive, these transitions are facilitated, since a new lattice structure facilitating the transport of electrons is produced. If the concentration of additive exceeds the optimum value, breakdown of the relative arrangement of these ions and the production of electron traps become possible. In this case there is also a decrease in the rate of individual reactions, and "poisoning" of the catalyst takes place.

Thus the modification of various catalytic systems involves the formation of new compounds in the bulk and on the surface of the catalysts, and changes the number and composition of the active

centres, the structure of the solid, its ability to undergo rearrangement, and the electronic interactions between the elements in the catalyst. Additives influence the kinetics (reaction rate, activation energy) and mechanism (structure of surface compounds, energies of their bonds with the surface) of a reaction.

It is difficult to predict the action of different additives, since they influence many functions of catalysts. Modification, however, makes it possible to produce effective catalysts for the oxidation of various organic compounds.

Cement-containing catalysts

V I Yakerson, E Z Golosman
Zelinskii Institute of Organic Chemistry, Moscow

ABSTRACT. The most important achievements in the development and use of cement-containing catalysts for a number of organic and inorganic processes have been reviewed. The possibilities for development in this branch of catalysis have been discussed.

The bibliography contains 365 references.

I. Introduction

Industry is making increasing demands in relation to the activity, selectivity, operational lifetime, mechanical strength, and durability of catalysts. A new direction in the solution of these problems is being opened up by the inclusion of aluminates of calcium (AC) and cements in catalytic compositions. These catalysts are used in the transformation of hydrocarbons, the conversion of methane and naphtha, the purification of gases from oxides of carbon, the dissociation of ammonia, sulphur purification, the conversion of carbon monoxide, the production of glycerol, etc.[1–8] Various aspects of the use of cements for these purposes may be noted.

1. One of the features of cements favouring their use in catalysis is their high mechanical strength. 2. The efficiency of both low-temperature and high-temperature processes depends on the thermal stability of heterogeneous catalysts, and heat resistance is an inherent property of alumina cement.[9] 3. The stability of catalysts used in the treatment of hydrocarbon raw material is determined to a large extent by their stability to coke formation. The cost of combating coke formation sometimes exceeds the cost of the actual catalytic processes.[10] One method of eliminating or preventing coke formation is by introducing basic additives, in particular as cements. 4. The large-scale production of cements, combined with the restricted supply of raw materials for the production of carriers (Al_2O_3, MgO, SiO_2, etc.), has provided a convincing reason for using various cements, in particular high-alumina cements, for this purpose. 5. The important role of the carrier in the production of heterogeneous contact catalysts[11] makes it necessary to study the texture of calcium aluminate sorbents and to develop carriers with a highly developed and controllable surface.[12] 6. Finally, the use of cements in catalysts is encouraged by the efforts to combine a high activity of catalytic systems with ecological cleanliness and waste-free methods of production.

II. The mechanism of formation of cement-containing contact catalysts

In the late sixties and early seventies, the study of the mechanism of formation of nickel-cement (nickel–aluminium–calcium) catalysts obtained by chemical mixing,[7,8,13,14] led to the discovery of the reaction of the cements (calcium aluminates) with the source of the active component (the nickel salts) in the aqueous medium. The reaction takes place at room temperature, and is accompanied by marked changes in texture and phase composition. This made it necessary to re-examine the view that the calcium aluminates and cements were merely hydraulic binding agents.

It was subsequently shown that the mechanism of the reaction of basic metal carbonates with calcium aluminate cements is the same for nickel,[7,8,13–23] zinc,[17,19–26] copper,[17,19–23,27] cobalt,[19–23] copper–zinc,[28] cobalt–manganese,[29] and cobalt–copper[30] contact catalysts. Metal hydroxide carbonates (MHC) react with calcium aluminates in aqueous or aqueous–ammoniacal media to give a multi-phase system. The composition of the reaction products indicates both hydration of the cements and an exchange reaction between the calcium aluminates and the metal hydroxide carbonates. Depending on the conditions, the reaction gives the metal hydroxoaluminates, $CaCO_3$, $Al(OH)_3$, $M(OH)_2$, $Ca_3[Al(OH)_6]_2$, and $Ca(OH)_2$. The metal hydroxoaluminates (MHA) have the following characteristics: a, their structure contains water as OH groups; b, the ratio M/Al in them is close to 1.5, particularly in an aqueous medium, but not in an aqueous–ammoniacal medium, in which some of the metal is lost as ammines; c, they can be synthesised from salts, which act as the source of the metal and aluminium, the latter being present as the $Al(OH)_4^-$ anion; d, on thermal decomposition they give MO and MAl_2O_4, so that in the original MHA the molar ratio $MO/Al_2O_3 > 1$; e, many metal hydroxoaluminates have the formula $M_3Al_2(OH)_{12}$. Since calcium hydroxoaluminates on dissolving in water give Ca^{2+} and $Al(OH)_4^-$, the reaction of MHC with alumina cements can be represented as follows: Ca^{2+} ions react with CO_3^{2-} ions in the labile structure of the MHC to give sparingly soluble $CaCO_3$, whose formation displaces the reaction to the right. To preserve the electrical neutrality of the MHC, the place

of one CO_3^{2-} ion carrying two negative charges must be taken by two $Al(OH)_4^-$ ions, each of which carries only one negative charge:

$$a\,[m\,MCO_3 \cdot n\,M(OH)_2] + 3\,Ca^{2+} + 2\,Al(OH)_4^- + 4\,OH^- = \\ = M_3Al_2(OH)_{12} + (3 - am)\,Ca(OH)_2 + (an + am - 3)\,M(OH)_2 + \\ + am\,CaCO_3, \quad (1)$$

$m \leqslant n$; $m = 1, 2$; $n = 1, 2, 3$

Since $M_3Al_2(OH)_{12}$ has a layer crystal lattice, insertion of $M(OH)_2$ into it is possible, so that the ratio M/Al will increase. In addition to metal hydroxoaluminates, hydroxocarbonatoaluminates may also be formed:

$$a\,[m\,MCO_3 \cdot n\,M(OH)_2] + 3Ca^{2+} + 2\,Al(OH)_4^- + 4\,OH^- = \\ = M_3Al_2(OH)_8(CO_3)_2 + (5 - am)\,Ca(OH)_2 + \\ (an + am - 3)\,M(OH)_2 + (am - 2)\,CaCO_3. \quad (2)$$

The reactions of MHC with calcium mono- and dialuminates are described by the equations

$$3\,CaAl_2O_4 + 12\,H_2O + a\,[m\,MCO_3 \cdot n\,M(OH)_2] = \\ = am\,CaCO_3 + \left(\frac{3 - am}{3}\right) Ca_3[Al(OH)_6]_2 + \\ + \left(\frac{an + am}{3}\right) M_3Al_2(OH)_{12} + \left(\frac{12 - 2an}{3}\right) Al(OH)_3, \quad (3)$$

$$3\,CaAl_4O_7 + 21\,H_2O + a\,[m\,MCO_3 \cdot n\,M(OH)_2] = \\ = \left(\frac{an + am}{3}\right) M_3Al_2(OH)_{12} + am\,CaCO_3 + \\ + \left(\frac{3 - am}{3}\right) Ca_3[Al(OH)_6]_2 + \left(\frac{30 - 2an}{3}\right) Al(OH)_3 \quad (4)$$

In an aqueous–ammoniacal solution, part of the MHC is converted into a carbonatoammine complex. The composition of the reaction products and the extent of the reaction depend on the numerical values of the coefficients *a*, *m*, and *n* (if M = Ni or Co, *m* = 2 and *n* = 3; if M = Zn, *m* = 1 or 2 and *n* = 3; if M = Cu, *m* = *n* = 1). The reactions according to Eqns. (1)–(4) are determined by the ratio of *a* to the values of *m* and *n*. With increase in *a*, the yield of $CaCO_3$ and $M(OH)_2$ increases, and the proportion of $Ca(OH)_2$ decreases. At certain ratios, the reaction will take place according to different stoichiometric equations. Thus when M = Ni, Cu, Zn, or Co, $M(OH)_2$ must take part in the reaction at low values of *a*, and $Ca(OH)_2$ must take part at high values of *a*. The range of possible values of *a* in the case of the formation of hydroxocarbonatoaluminates [Eqn.(2)] is broader than for the formation of MHA. The phase composition of cement-containing catalysts is described extremely accurately by general equations based on the reaction between metal hydroxide carbonates and $CaAl_2O_4$ ($CaAl_4O_7$). The thermal decomposition of the compounds formed by the chemical reaction and containing the active component can be described by the equations

$$M_3Al_2(OH)_{12} \xrightarrow[-H_2O]{} 3MO.Al_2O_3 \text{ (solid solution)} \rightarrow 2MO + MAl_2O_4, \quad (5)$$

$$M_3Al_2(OH)_8(CO_3)_2 \xrightarrow[-H_2O,\ CO_2]{} 3MeO.Al_2O_3 \text{ (solid solution)} \\ \rightarrow 2MO + MAl_2O_4. \quad (6)$$

If two metal hydroxide carbonates take part in the reaction simultaneously (Cu and Zn, Co and Cu, Ni and Cu), the first stage of the reaction gives mixed hydroxide carbonates, from which are formed mixed hydroxoaluminates (possibly hydroxocarbonatoaluminates), which are readily converted into mixed solid solutions

$$m'M'CO_3.n'M'(OH)_2 + m''M''CO_3.n''M''(OH)_2 + CaAl_2O_4(CaAl_4O_7) \\ + H_2O \rightarrow M'M''Al_2(OH)_{12} \\ \rightarrow M'O.M''O.Al_2O_3 \text{ (solid solution)}. \quad (7)$$

Solid solutions of mixed metal hydroxoaluminates and hydroxocarbonatoaluminates are formed from the anion-modified oxides (anionic group OH^- or CO_3^{2-}),[11] that is the oxides of Al, Cu, Co, Ni, Zn; naturally, the solid solutions obtained are also anion-modified.

The reaction of metal hydroxide carbonates with Ca^{2+} and $Al(OH)_4^-$ ions, represented by Eqn. (1) above, can be represented differently:

$$m\,MCO_3 \cdot n\,M(OH)_2 + m\,Ca^{2+} + 2m\,Al(OH)_4^- \rightarrow \\ \rightarrow m\,\{M[Al(OH)_4]_2\} \cdot n\,M(OH)_2 + m\,CaCO_3.$$

Table 1. Composition of the MHC and MHA, the ratio MO/Al_2O_3 in the MHA, and the composition of the thermal decomposition products of the MHA.

MHC $mMCO_3.nM(OH)_2$	MHA $M_{m+n}Al_{2m}(OH)_{8m+2n}$	MO/Al_2O_3	MHA thermal decomposition products $nMO + mMAl_2O_4$, n/m
M = Ni, $m = 1$, $n = 1$	$Ni_3Al_2(OH)_{12}$	3:1	2:1
M = Co, $m = 1$, $n = 2$	$Co_3Al_2(OH)_{12}$	3:1	2:1
M = Cu, $m = 1$, $n = 1$	$Cu_2Al_2(OH)_{10}$	2:1	1:1
M = Zn, $m = 2$, $n = 3$	$Zn_5Al_4(OH)_{22}$	5:2	3:2
M = Zn, $m = 1$, $n = 3$	$Zn_4Al_2(OH)_{14}$	4:1	3:1

The hydroxoaluminates $m\{M[Al(OH)_4]_2\}.nM(OH)_2$ can be represented as $M_{m+n}Al_{2m}(OH)_{8m+2n}$. Thus depending on the composition of the MHC, the products are different MHA with different ratios MO/Al_2O_3, which determine the composition of the thermal decomposition products (see Table 1). Table 1 shows that: a, the composition of the MHA depends markedly on the composition of the MHC; b, the ratio MO/Al_2O_3 in the MHA is always greater than 1; c, the molar ratio $MO/M'Al_2O_4$ in the thermal decomposition products of the MHA, that is the ratio of the free metal oxide to the spinel, is exactly equal to n/m. If the exchange of the ions CO_3^{2-} and AlO_4^- in incomplete, its products will be hydrated metal carbonatoaluminates, and since the number of AlO_4^- ions introduced into the structure is lowered, the ratio MO/Al_2O_3 will be increased.

III. Carriers and adsorbents based on cements

A source of calcium–aluminium carriers and adsorbents is provided by calcium mono- and dialuminates $CaAl_2O_4$ (CA) and $CaAl_4O_7$ (CA_2), which are the principal phases in high-alumina cements. The first stage in the preparation of these carriers is

hydration, which at elevated temperatures gives mainly $Ca_3[Al(OH)_6]_2$ (C_3AH_6):†

$$3CaAl_2O_4\,(CA) + 12H_2O = Ca_3[Al(OH)_6]_2\,(C_3AH_6) + 4Al(OH)_3 \quad (8)$$

$$3CaAl_4O_7\,(CA_2) + 21H_2O = Ca_3[Al(OH)_6]_2\,(C_3AH_6) + 10Al(OH)_3 \quad (9)$$

At lower temperatures, the less stable products C_2AH_8 and CAH_{10} are formed. The compound C_3AH_6 [31] can be obtained either from Ca and Al hydroxides or from the metastable C_2AH_8 and C_4AH_9, which at 25 °C are readily converted into stable C_3AH_6. Amorphous $Al(OH)_3$ is the primary hydration product of calcium aluminates.[31] With the passage of time, that is on ageing, at a suitable pH, amorphous $Al(OH)_3$ crystallises, forming boehmite and hydrargillite (gibbsite).[31,32] Thermodynamic analysis of the hydration of calcium aluminates[9,31–34] confirms that reactions (8) and (9) are possible. The hydroxide $Al(OH)_3$ is formed in the hydration of C_3A, $C_{12}A_7$, CA, and CA_2, and $Ca(OH)_2$ is formed in the reaction of $C_{12}A_7$ with water. Highly basic hydrated Ca aluminates are formed by the reaction of Ca and Al ions in solution and in phase transformations of hydrated calcium aluminates involving OH^-; part of the Al passes into solution as anions. With increase in the basic character of the hydrated Ca aluminates, the probability of their formation increases. Reactions involving $Al(OH)_3$ are thermodynamically more favourable than those with aluminate anions. During hydration and on ageing, the unstable compounds are converted into more stable compounds,[9] in particular into C_3AH_6. The thermal decomposition of hydrated calcium aluminates, the hydration products of anhydrous calcium aluminates, at different temperatures gives $C_{12}A_7$, CaO, Al_2O_3, $Ca(OH)_2$, and other compounds containing Al and/or Ca.[2,7,9,12,15,16,23,32–37] A method has been developed for obtaining the carrier and adsorbent galyumin with a highly developed surface based on calcium monoaluminate (CA).[12,38] X-Ray diffraction has shown that the hydration of CA gives hydrated calcium aluminates, $Al(OH)_3$, and $CaCO_3$; the latter is produced by the reaction of CA with atmospheric CO_2 and with carbonate-containing reagents. To produce an adsorbent with the most highly developed surface, it is necessary to intensify the hydration processes throughout the entire volume of the CA, to break down the layer of $CaCO_3$ and $Al(OH)_3$, and also to extract part of the Ca. The adsorbent and catalyst (galyumin) obtained has not only a highly developed surface (the specific surface increases from 2–4 $m^2\ g^{-1}$ to 400 $m^2\ g^{-1}$, that is by two powers of ten), but also a high mechanical strength.

The aluminium–calcium components of the catalysts have been studied.[39] In one series of experiments, the hydration of CA according to Eqn. (8) was carried out, and the $Al(OH)_3$ formed was combined with the calculated quantity of $Ca(OH)_2$ to give C_3AH_6. In another series of experiments, C_3AH_6 was synthesised by the direct reaction of $Al(OH)_3$ with $Ca(OH)_2$. Thermal decomposition of C_3AH_6 gave the product $12CaO.7Al_2O_3$, that is $Ca_{12}Al_{14}O_{33}$, or $C_{12}A_7$. Some authors[40–42] suggest that water in quantities not less than 1.4% is retained in the $C_{12}A_7$ structure up to high temperatures (1000–1100 °C), and that $C_{12}A_7$ in fact has the composition $12CaO.7Al_2O_3.H_2O$. The properties of $C_{12}A_7$ are such that this water is assumed to be "zeolitic". According to Mamaeva and co-workers,[39] the phase $C_{12}A_7$ is produced at 400 °C; its concentration increases continuously with increase in the heating temperature to 1000 °C. This phase has a highly developed surface, which is preserved even at 800–1000 °C. The higher the degree of dispersion of the phase C_3AH_6 in the unheated specimens, the higher the specific surface (S_{sp}) of the product $C_{12}A_7$ after heating. The data obtained[39,43] have been used to develop a method for obtaining an aluminium–calcium carrier and adsorbent (galyumin-Ts) with a thermally stable texture (withstanding thermal treatment at 600–1000 °C) and a mechanical strength up to 500–700 kg cm^{-2}.

A study of the infrared spectra[44,45] of a number of calcium aluminates (CA, CA_2, $C_{12}A_7$) and catalysts and adsorbents based on them, with different S_{sp} (30–400 $m^2\ g^{-1}$), showed that the bands in the range 400–900 cm^{-1} are due to the vibrations of aluminium–oxygen tetrahedra in the framework zeolite-like structure. The calcium ion apparently acts as compensating cation. Depending on the method of preparation, the value of S_{sp}, and the concentration of CaO, the aluminium–calcium adsorbents and catalysts can be divided into two groups: a, those with a framework structure containing calcium aluminates; and b, those consisting chiefly of γ-Al_2O_3 modified by calcium. The water in the aluminium–calcium adsorbents and catalysts is present in different states; it may be adsorbed, form surface OH groups, and be present as $Ca(OH)_2$, $Al(OH)_3$, and hydrated calcium aluminates. From an analysis of infrared data on the hydration of the calcium aluminates CA, CA_2, C_3A, and $C_{12}A_7$,[9,46] it was suggested that the high strength of cement block is achieved as a result of the formation of Al–O–Al structural bonds between the octahedra of aluminium hydroxide and hydrated calcium aluminates. The highly developed thermally stable porous structure of an adsorbent based on calcium aluminates (novogal), and the possibility of controlling this structure, open up the possibility of using novogal for the gas-chromatographic separation of complex mixtures of C_1–C_4 hydrocarbons.[47,48] From the nature of its reaction with an adsorbate, novogal must be classified as a specific adsorbent of type II.[49]

The genesis of the phase composition and texture of a carrier, adsorbent, and catalyst based on calcium–aluminium cement (talyum), whose mineralogical components are CA and CA_2, have been studied.[50] When talyum is treated with water under the conditions of the preparation of cement-containing catalysts, the original phases (CA, CA_2) dissolve in the first stage (the mixing stage), after which the nuclei of metastable (C_2AH_8, C_4AH_{13}) and stable (C_3AH_6, gibbsite) hydrated new formations separate from the supersaturated solution. The fact that the hydration product of Al_2O_3 is produced in the hydration of aluminium–calcium cements and subsequent thermal decomposition provided the starting point for the production and study of two-component γ-Al_2O_3–CA and γ-Al_2O_3–CA_2 compositions.[51,52] Their mechanical strength reaches 1450 kg cm^{-2} and 1000 kg cm^{-2} for the compositions 40% CA–Al_2O_3 and 20% CA–Al_2O_3 respectively. The highest mechanical strength corresponds to the texture in which a maximum contribution to S_{sp} is made by the narrow pores, and a minimum contribution by the wide pores.

The processes taking place in the production of catalysts based on calcium aluminates have been studied by high-resolution ^{27}Al NMR.[53] The structure of anhydrous calcium aluminates (CA, CA_2, C_3A, $C_{12}A_7$, talyum) contain aluminium–oxygen tetrahedra; the aluminium atoms in the tetrahedra are of different types, and their non-equivalence increases on going from highly basic to weakly

† The following notation is used in the chemistry of cements: C = CaO, A = Al_2O_3, H = H_2O.

basic aluminates. On hydration, which is one of the stages of the production of aluminium–calcium catalysts and carriers, the process $[AlO_4] \rightarrow [AlO_6]$ takes place, and the process $[AlO_6] \rightarrow [AlO_4]$ takes place on thermal decomposition. The non-equivalence of the aluminium atoms in tetrahedral coordination decreases, and the ratio $[AlO_4]/[AlO_6]$ decreases with increase in the degree of hydration. The presence of a framework of aluminium–oxygen $[AlO_4]$ tetrahedra in anhydrous calcium aluminates makes their structure similar to that of zeolites.[44,45] For zeolites, Loewenstein's rule applies; according to this rule, two aluminium atoms in tetrahedral coordination should not have a shared oxygen atom. The structure of calcium aluminates clearly indicates that Loewenstein's rule is not universal.[54] A quantum-chemical analysis of this rule for aluminium-containing catalysts and adsorbents[55] showed that a structure in which two $[AlO_4]$ tetrahedra have a shared oxygen atom is stabilised by a metal ion acting as compensating cation. The reactivity of calcium aluminates with respect to water, which is of considerable importance in the production of aluminium–calcium catalysts, also depends on distortions in the oxygen environment of calcium, and in particular on the Ca–O distances; the shorter this distance, the higher the reactivity of the calcium aluminate with respect to water.[53] Thus the rate of hydration decreases in the order $C_3A < C_{12}A_7 < CA < CA_2$,[56] and the shortest Ca–O distance increases in the same order from 2.26 Å to 2.33 Å.

Thermal desorption, thermal analysis, and X-ray diffraction have been used to study the reaction of water vapour with the aluminium–calcium components of catalysts based on calcium aluminates.[57] The presence of $C_{12}A_7$ is responsible for the increased adsorption of water vapour and the specific form of the thermal-desorption spectrum. The reaction of water vapour with the aluminium–calcium components of the catalysts, unlike the liquid-phase reaction, is not accompanied by a change in the phase composition, and this makes possible the extensive use of these catalysts in gas-phase processes involving water. Millimetre-wave spectroscopy has shown[58] that in the liquid phase, the quantity of immobilised water in $C_{12}A_7$ is more than 100 times the capacity of a monolayer, and this has been attributed to the filling of the cavities in the structure and the superposition of the chemical reaction of $C_{12}A_7$ with water on the adsorption process. The increase in the rate of hydration of aluminate cement[32] with increase in its degree of dispersion is due both to an increase in the surface area and to activation of the reacting particles. The last factor may predominate, as observed in the mechanical activation of calcium aluminates by treatment in mills without change in the degree of dispersion.[59]

Infrared spectroscopy in diffuse scattered light has been used to study the hydroxyl covering and adsorption centres of aluminium–calcium catalysts and carriers with a highly developed surface.[60] The presence of surface OH groups of several types was established. A quantitative infrared spectroscopic study of the basic and acidic (aprotic) centres from the adsorption of deuteriochloroform and CO respectively[61,62] revealed the existence on the surface of two types of aprotic acidic centre, one of which was combined with Ca ions (type I), and the other with Al ions (type II). With increase in the degree of hydration of the calcium aluminates, the concentration of the centres of type I decreases more extensively than that of the centres of type II, corresponding to the greater degree of displacement of calcium ions from the lattice, compared with aluminium ions. Three types of basic centre were detected: the strength of the centres of one type is similar to that of the basic centres in γ-Al_2O_3; other stronger centres correspond to the oxygen in the Al–O–Ca structure; and, finally, the third and strongest centres correspond to the oxygen in the Ca–O structure. According to Sominskii and co-workers,[17,52,63–65] calcium aluminates with a highly developed surface (galyumins) also show Brönsted acidity, detected using butylamine and pyridine; the adsorption of pyridine and acetone also detected Lewis centres, and the adsorption of hexadeuterioacetone detected basic centres. A thermally stable catalyst carrier[66] and an adsorbent[67] are obtained from Al hydroxides and Ca oxide, hydroxide, and carbonate. A carrier based on calcium aluminates has a high S_{sp} and is suitable for use over a wide temperature range, 400–900 °C.[68] Calcium aluminates with a highly developed surface and a high reactivity can be obtained directly from molten Al and Ca nitrates,[69] that is by simple mixing using effluent-free technology.[38,39,43,48,50,51] Thermal-desorption studies of the adsorption of CO_2, H_2O, O_2, and H_2 on calcium aluminates with different CaO/Al_2O_3 ratios and different phase compositions (CaO, C_3A, $C_{12}A_7$, CA, CA_2)[70] indicate that the adsorption bonds are extremely strong. Thus H_2O is desorbed at 930 °C ($C_{12}A_7 . H_2O$), O_2 at 720–825 °C, and CO at 450 °C and 600–760 °C.

Ca, Sr, and Ba aluminates have much in common; they all have high melting points and similar densities, mechanical strength, and tendency to undergo hydration. They are therefore all used in the same way in the production of ceramics, binding agents, and sintering cements.[35] A significant feature is that the crystal structures of the alkaline earth metal monoaluminates are based on $[AlO_4]$ tetrahedra sharing oxygen atoms.[35,71,72] The aluminate $SrO.2Al_2O_3$ is a structural analogue of $CaO.2Al_2O_3$,[35,73] and $3CaO.Al_2O_3$, $3SrO.Al_2O_3$, and $3BaO.Al_2O_3$ are also isostructural.[35] Carriers and adsorbents based on Ca, Sr, and Ba aluminates should therefore show similar behaviour. Thus the addition of Ca, Sr, and Ba oxides to γ-Al_2O_3 decreases sintering and leads to the preservation of a comparatively highly developed surface on formation of the corresponding aluminate.[74–76] The great importance of zeolites in catalysis is drawing attention to cement–zeolite compositions.[77–79] Binders with different compositions based on Portland cement gain strength rapidly, have a high resistance to wear, and can be used to encapsulate sorbents and catalysts.[80] A composition using natural zeolites appears promising.[81–83] Mixed cements containing zeolite have a high strength.[81,82] The use of Portland cement as binding agent makes it possible to obtain granulated NaA zeolites with a high mechanical strength, minimum secondary porosity, and high adsorbing power.[84]

IV. The production of metal-cement catalysts

The formation processes have been studied most intensively for nickel-cement catalysts, which are widely used in the hydrogenation of oxides of carbon, the decomposition of ammonia, the conversion of methane, the hydrogenolysis of glucose, etc.[1,2,3,6,85–87] Thus the synthesis of ammonia in plants with high unit output involves the production of synthesis gas by the conversion of methane and purification on nickel contact catalysts. The production of ammonia and hydrogen alone uses up about 30% of the total world production of catalysts. Cements are used to obtain nickel-cement contact catalysts in three ways: a, calcium aluminates are used as one of the chemical reagents reacting with the source of the active component; b, calcium aluminates are added to the catalyst mass as a binding agent to produce a strong hardened structure by moist-air treatment (MAT) or hydrothermal treatment (HTT); and c, to

combine the processes of contact catalyst formation and hydration hardening of the calcium aluminates, the original components are mixed to give a uniform mixture (alternatively, the mixing is carried out at low liquid : solid ratios), which in the form of tablets are subjected to HTT.[19,20,22,23,88–90] The reactions described by Eqns. (1)–(4) take place in the liquid medium.[7,14,89–91] In the presence of Ni salts, the phases C_2AH_8 and CAH_{10} are not detected. With increase in the ratio Ni salt/cement (CA, CA_2 talyum), the quantity of $CaCO_3$ formed increases, $Ca(OH)_2$ disappears, and $Ni(OH)_2$ appears. In complete accordance with Eqn. (3), with increase in the concentration of nickel hydroxide carbonate, the quantity of $CaCO_3$ (criterion of the exchange reaction) and S_{sp} (criterion of the development of the surface) pass through a maximum.[8] The CO_3^{2-} ion evidently does not enter the structure of the hydrated aluminate, since if a compound of the type $M_3[Al(OH)_4(CO_3)]_2$ were formed, the $CaCO_3$ concentration would have decreased and would differ significantly from that calculated from Eqn. (3). The reactions between calcium aluminates and Ni hydroxide carbonate can take place by a liquid-phase or a solid-phase mechanism, depending on the composition of the medium (water, aqueous ammonia solution) and the liquid : solid ratio. The Ni hydroxoaluminate formed in reactions (3) and (4) decomposes when heated according to Eqn. (5) to give a poorly crystalline disordered $NiO-Al_2O_3$ solid solution, whose structure is perfected at 400–1000 °C, accompanied by the gradual liberation of the excess NiO.[90] Ni hydroxoaluminate is the main form in which the active component exists in the catalysts at the stage preceding thermal decomposition and activation. Since the reaction of the components is limited by the rate of solution of the calcium aluminates (talyum) in aqueous ammonia solution, an effective method of increasing the extent of the reaction is by increasing the degree of dispersion and the ratio CA/CA_2.[92] On thermal treatment, the phase CaO formed by the high-temperature decomposition of $CaCO_3$ reacts with Al_2O_3, preventing the reaction of the superstoichiometric NiO with Al_2O_3 and decreasing the rate of formation of spinel ($NiAl_2O_4$).[92] The specific surface of the nickel catalysts is determined by the value of S_{sp} of the dispersed phase of the $NiO-Al_2O_3$ solid solution. High-temperature X-ray diffraction has shown that nickel–aluminium–calcium catalysts are reduced in two stages, at 400–600 °C and 600–800 °C. The presence of compounds difficult to reduce ensures the preservation of a high degree of dispersion of metallic nickel over a wide temperature range and creates conditions for the effective use of aluminium–calcium-based catalysts in high-temperature processes (conversion of hydrocarbons, decomposition of NH_3). A composition containing CA, CA_2, and Al_2O_3 together with nickel can be used to produce an optimum catalyst for low- and high-temperature processes.[89–91] According to Dzis'ko,[4] mixing does not make it possible to achieve the same extent of reaction between the components as the combined precipitation of $Ni(OH)_2$ and $Al(OH)_3$ and the coprecipitation of $Ni(OH)_2$ on an Al_2O_3 carrier. The nickel–aluminium–calcium system (and, as shown below, all other systems based on calcium aluminates) is an exception to this rule. In this case the product is formed by a new mechanism, in which the original components, on chemical mixing, react with one another practically completely under very mild conditions:

$$\begin{array}{c} Ni_3CO_3(OH)_4\cdot 4H_2O + CaAl_2O_4 + CaAl_4O_7 \rightarrow \\ \rightarrow Ni_3Al_2(OH)_{12} + CaCO_3 + Al(OH)_3 \\ \downarrow 350^\circ C \qquad\qquad \downarrow 740^\circ C \qquad \downarrow 300^\circ C \\ (NiO)_3{-}Al_2O_3 \qquad\quad CaO \qquad Al_2O_3 \\ \downarrow 400\text{–}1000^\circ C \qquad\quad \downarrow 800\text{–}1000^\circ C \\ x\cdot NiO + (NiO)_{3-x}\cdot Al_2O_3 \qquad\quad CaAl_2O_4 \end{array} \qquad (10)$$

X-ray diffraction, texture, thermochromatographic, and spectral studies[90,93–99] confirm that a multiphase system with a highly developed surface is formed. Change in the ratio of Al_2O_3, CA, and CA_2 [89,90] makes it possible to control the degree of dispersion, phase composition, and mechanical strength of Ni catalysts. The plastic deformation of $CaCO_3$ on pressing leads to an increase in the unit contact strength; the mechanical strength increases with increase in the $CaCO_3$ concentration. The sharp increase in strength at high pressing pressures (800–1000 MPa)[100] indicates plastic deformation of the structure-forming particles, in particular calcite. The increased strength of the bond between NiO and the carrier is confirmed by the thermal-vacuum electrical conductivity curves.[101]

V. Catalysts for the methanation of oxides of carbon

In the catalytic purification of technical gases (nitrogen–hydrogen mixture, hydrogen, etc.) from CO and CO_2, the concentration of oxides of carbon at the outlet should not exceed 10–20 $cm^3\ m^{-3}$ (10–20 p.p.m.). The catalytic purification from CO and CO_2 is based mainly on their exothermic hydrogenation to CH_4 (so-called methanation). Methanation can be carried out for different purposes: to remove poisons (CO, CO_2), to obtain a fuel gas, and to transfer the heat of hydrogenation to a distance.[1,102,103] The most suitable catalysts for purifying hydrogen-containing gases from CO and CO_2 are nickel catalysts; they are more active and more selective than iron catalysts, and less expensive than contact catalysts based on the Pt group metals.[85,86,102] Catalysts for purification from CO and CO_2 must satisfy severe requirements in relation to: a, activity; b, thermal stability (the activity should be preserved on superheating, which usually takes place with an increased concentration of CO_2 and CO at the inlet); c, stability, that is resistance to the action of the reaction medium; and d, mechanical strength. Mechanical strength is particularly important when large quantities of catalyst, up to 50 tons, are loaded into the methanation vessels in plants with a high unit output (in particular in NH_3 synthesis plants with an output of up to 1360 tons per day). These requirements are satisfied by Ni contact catalysts based on cement (aluminium–calcium).[7,14,89–91,102,104–115] By selecting the reaction medium, it is possible to control the ratio between the oxide and metallic phases.[93,97] An important part in the production of the contact catalysts is played by the change in the oxygen coordination of aluminium from tetrahedral (Al_t) to octahedral (Al_o) on hydration and from Al_o to Al_t on thermal treatment.[16,98]

The reduction of nickel–aluminium–calcium contact catalysts to give a metallic nickel phase involves several stages. The low-temperature stage (160–400°) involves the reduction of free nickel oxide, and the high-temperature stage involves the reduction of

combined oxide. The second stage may be necessary for the following reasons: a, the difficulty of reducing nickel in CaO–NiO solid solutions; b, the formation of nickel aluminium spinel; and c, the replacement of the metal ion in the zeolite-like structure of the aluminates. The principal form of existence of the precursor of the active form of nickel is nickel hydroxoaluminate, which on thermal decomposition is converted into $NiO-Al_2O_3$ solid solutions.[90] There is restricted mutual solubility of the components, however, in the NiO–Ca(Ba)O system.[116–118] Extensive reaction of nickel oxide with calcium aluminates does not give contact catalysts with a high activity in low-temperature hydrogenation processes. To avoid this limitation, Al_2O_3 is added to the catalyst together with calcium aluminates.[119] The NKM-4 (4A) catalysts obtained in this way can operate at temperatures much lower than the minimum working temperatures (260 °C) for the hydrogenation of CO and CO_2, used in the large-scale production of ammonia.[8,9,108,119] Electron microscopy has shown the decisive part played by the carrier in the distribution of the particles of reduced Ni at temperatures in the range 400–800 °C.[120] Simplex lattices have been used to construct composition–property (total specific surface, surface area of the active component, S_{Ni}, mechanical strength) diagrams to find the optimum ratio of the components NiO, Ca, CA_2, and Al_2O_3.[121] It was found that the NiO–talyum reaction has a greater influence on S_{sp} than the $NiO-Al_2O_3$ reaction; the value of S_{Ni}, on the other hand, depends to a greater extent on the distribution of nickel in Al_2O_3. The change in the strength of the catalyst during hydrothermal treatment is due to the characteristics of the hardening of the binding component (cement); hydration is accompanied by the appearance of micro-strains produced by the crowded growth of the crystals of the new formations.[122] The increase in strength when the contact catalyst is heated to 400° is due to the relaxation of the strains produced on hydrothermal treatment.[123,124] The low-temperature decomposition of $CaCO_3$ has been detected in nickel-cement catalysts in which calcite appears during preparation, at temperatures $\leqslant$400 °C in reducing media.[125,126]

The purification of technical gases from CO and CO_2 on Ni contact catalysts has been studied by Kreindel' and co-workers.[127–129] In the kinetic range, the specific catalytic activity (calculated for 1 m^2 Ni) is constant and independent of the nature of the carrier, the method of preparation, and the temperatures of thermal treatment and reduction of the catalysts. With increase in temperature, the reaction passes into the outer-diffusion range.

The kinetics of the methanation of CO and CO_2 and their mixtures on the industrial nickel–aluminium–calcium catalyst[108] have been studied.[130–138] The principal kinetic characteristics of the methanation of CO are the same at atmospheric pressure and at an increased pressure (up to 3 MPa). In the combined methanation of CO and CO_2, the components have a simple influence on one another, with adsorption competition on the surface. Mass spectrometry, thermal desorption, infrared spectroscopy, and isotope studies[134–136] showed that the mechanism of the methanation does not involve the dissociative adsorption of CO and CO_2; the reaction takes place with the formation of compounds $C_xH_yO_z$ involving atomic adsorbed hydrogen. The data obtained[130–136] made it possible to put forward a new stepwise scheme for the hydrogenation of CO and CO_2, according to which both processes take place without the preliminary dissociation of CO and CO_2. In the methanation of carbon monoxide, the surface is covered by CO, and also HCO, HCOH, CH, and OH; the limiting stage is the reaction of $CH_{(ads)}$ with $H_{(ads)}$. In the methanation of CO_2; the slow stage is the reaction of $CO_{2(ads)}$ and $H_{(ads)}$, and intermediate compounds $C_xH_yO_z$ are present on the surface. These results show good agreement with published conclusions.[103,137,138] The nickel-cement catalysts NKM-4A and GIAP-16 are highly active in the methanation of stoichiometric mixtures of CO and CO_2 with H_2 in the temperature range 300–700 °C;[139] this is of undoubted interest for solving the problem of the transfer of energy over large distances by a combination of exothermic and endothermic reactions (an "Adam and Eve" process).[11]

VI. Catalysts for the conversion of hydrocarbons

One of the indicators of technical progress in developed countries is the level of output in the production of hydrogen. In recent decades, the world production of hydrogen has increased several-fold. This is due to the increase in the production of ammonia, methanol, and the products of petrochemical synthesis, and the vast contribution made to these processes by reactions involving hydrogen. One of the most widely encountered methods for obtaining hydrogen-containing gases is by the catalytic conversion of hydrocarbons.[86,140–142] The steam conversion of methane takes place at high temperatures (800–900 °C), and this naturally makes increased demands on the catalysts and makes it necessary to avoid carriers based on SiO_2, which can be carried away by the steam and deposited on the cold parts of the equipment. As a result, extensive use has been made of nickel catalysts on alumina cements, calcium aluminates, and Al_2O_3 containing alkaline earth metal oxides as promoters.[87,140,141] High-temperature treatment of the carrier or catalyst mass leads to the formation of Ca, Sr, and Ba aluminates in the surface layers or throughout the entire volume of the contact catalyst. To avoid coke formation on catalysts in the conversion of hydrocarbons, attempts were made to introduce a hydraulic cement as early as the nineteen-thirties.[143] The introduction of cements into a mixture of nickel salts and activators gave catalysts with a successful combination of high mechanical strength, stable activity, and resistance to coke formation.[144] A cement-containing nickel catalyst with a high mechanical strength (400 kg cm^{-2}) has been described.[145] The most active catalysts for reforming CH_4 with steam or a mixture of steam and O_2 are contact catalysts including Al_2O_3, CaO, and NiO.[146,147] A catalyst based on alumina with added Ca and Mg oxides has an increased thermal stability and mechanical strength.[147] An Ni/Al_2O_3 catalyst promoted by CaO is used for the steam conversion of petroleum.[148] Nickel-containing contact catalysts produced in the USSR are being used successfully: GIAP-16 (24–26% NiO, 55–59% Al_2O_3, 14–16% CaO, 0.8–1.2% BaO) and KSN-2 (12–15% NiO, 80–83% Al_2O_3, 3% CaO, 1% MgO).[85,149] The use of nickel on a cement carrier makes it possible to carry out the steam reforming of C_2 and higher hydrocarbons with a low steam consumption without coke formation.[150] A mechanically strong catalyst with a long working life and high activity in the steam reforming of hydrocarbons contains a mixture of calcium aluminates and nickel, promoted by a Ba salt.[151] The nickel catalysts based on calcium aluminates C11-2, C11-5, and C11-25 [152] were developed for the steam conversion of petroleum fractions, where there is a danger of extensive coke formation on the contact catalysts and it is necessary to use high steam/hydrocarbon ratios. A stable catalyst for the reforming of hydrocarbons with steam, resistant to coke formation, contains an aluminate cement and a mixture of Ni and Mg oxides.[153] The activity and specific surface of nickel–aluminium–calcium catalysts increase with increased concentrations of Al_2O_3 and

CaO.[154] The effective high-temperature catalyst GIAP-16N for the conversion of CH_4 with steam is obtained by introducing CA, CA_2, and high-alumina cements into a spent nickel–aluminium hydrogenation catalyst.[155] The presence of free CaO in a composition containing NiO and an aluminate cement[156–160] apparently makes it possible, by hydration at 5–35 °C and thermal treatment at 550–1200 °C, to bind free Al_2O_3 and thus to avoid the formation of nickel aluminium spinel, difficult to reduce. The GS-12 catalyst for the conversion of methane[161] is obtained by depositing nickel on Al, Ba, and Ca oxides sintered at 1300 °C, when aluminates are formed. This catalyst can operate at high natural-gas loads and lowered steam/gas and O_2/CH_4 ratios. The residual concentration of CH_4 in the gas is 0.2–0.4%. The cement-containing catalysts for the conversion of methane, GIAP-16 and GIAP-16-2, produced in the Soviet Union, are widely used in large-scale plants for ammonia production; many of the characteristics of GIAP-16-2 match those of the CCI contact catalyst C-11-4.[162–164]

Alumina cements are often used as binding agents.[165,166] X-Ray diffraction has detected the presence of CA_6 in the nickel catalyst KSK-2 on a carrier modified by CaO or MgO.[167,168] A mixed nickel catalyst containing alumina and a fused alumina cement[169] is used to obtain H_2 from hydrocarbons with boiling points below 150 °C. Natural gas is purified from methane homologues by steam conversion at 300–400 °C in the presence of a nickel–chromium catalyst promoted by CaO and Al_2O_3.[170] An extremely productive idea has been put forward for creating a flexible technology for the production of nickel cement-containing contact catalysts for low-temperature (methanation) and high-temperature (methane conversion) processes.[1,114] An equally promising suggestion is that spent methanation catalysts be used as raw material for the preparation of GIAP-16 cement-containing contact catalysts for the conversion of CH_4.[155,171] Catalysts for the conversion of heavy petroleum residues, where the principal components of the catalysts are the calcium aluminates $C_{12}A_7$ and C_3A, have been developed.[172] The development of chemothermal methods for transferring energy over long distances using a cycle involving the steam conversion of methane and the hydrogenation of oxides of carbon required the development of thermally stable contact catalysts containing calcium aluminates.[173–175] Thermally stable and mechanically strong Cu–Ni,[176] V,[177] Rh,[178,179] Fe,[180] and Co–Mn [181,182] catalysts on an aluminium–calcium base for the conversion of hydrocarbons are also known. The base is provided by $C_{12}A_7$, CA_6, CA, CA_2,[177] and C_3A.[181] Ba aluminates, like Ca aluminates, are used successfully to produce Ni conversion catalysts.[183–185] The thermal stability of γ-Al_2O_3 is increased when its surface is modified by CaO, SrO, and BaO,[186] apparently as a result of the formation of surface layers of aluminates. With increase in the concentration of the alkaline earth metal oxides in Al_2O_3, the number of electron-donor centres increases, and this was assumed[187,188] to be related to the increase in the rate of the transformation of CH_4 in the presence of water vapour on promoted Ni catalysts. The presence of a large quantity of basic and reducing centres on the surface of aluminium–calcium carriers or Al_2O_3 modified by CaO leads to the suppression of coke formation on Ni catalysts for the conversion of hydrocarbons.[189] CaO–NiO specimens obtained by the thermal treatment of the $Ca(OH)_2$–$Ni(OH)_2$ system have a micro-structure differing markedly from that of their mechanical mixture; this is attributed to the hindered crystallisation of the oxides in the presence of one another.[189] CaO–NiO, CaO–Al_2O_3, and NiO–Al_2O_3 reactions apparently take place in nickel–aluminium–calcium conversion catalysts. In the NiO–Al_2O_3 system, even after high-temperature treatment (600–900 °C), three oxide phases are preserved: $NiAl_2O_4$ and two nickel oxides, one of which, which has a disordered crystal lattice, contains an appreciable quantity of Al ions;[190] these ions, after reduction of the catalyst, facilitate the formation of Ni crystallites with an extremely high thermal stability. Magnetic studies[191] of Ca^{2+}-promoted nickel–aluminium contact catalysts for the steam reforming of petroleum established that the reaction of metallic Ni with C_3A_5 prevents the migration of Ni over the surface and the formation of large crystallites. The high-temperature forms of adsorbed water (in $C_{12}A_7$) and oxygen may play an important role in hydrocarbon reforming processes.[70] The best carriers are calcium–aluminium cements, treated with the reaction mixture under reforming conditions and containing the phases $C_{12}A_7$ and CA.[192] When evaluating the role of individual components, it is necessary to take into account the fact that the MO–Al_2O_3 compositions (M = Ca, Sr, Ba) catalyse the reaction of hydrocarbons with steam, leading to the formation of CO and CO_2, and at the same time suppress the formation of carbon deposits.[193]

The physicochemical principles of the production and action of nickel–aluminium–calcium catalysts for the conversion of CH_4, examined briefly above, are described more fully elsewhere.[90,91,93–99,122,123] The stability and texture of catalysts are related to their phase composition.[91] It is possible to lower the Ni concentration while preserving the high activity of the contact catalyst as a result of the highly developed surface and the lowered tendency to form spinel.[194] The presence of NiO in the combined state is a condition for obtaining a thermally stable and active catalyst.[114,195] The degree of dispersion and stability of the active phase (Ni phase) depend markedly on the composition and structure of the calcium aluminate cement support.[196] Impregnating a γ-Al_2O_3 carrier with Al and Ca salts to give different calcium aluminates leads to development of the surface, stabilisation of the degree of dispersion, and increase in the stability and resistance of the catalyst to coke formation.[197]

VII. Catalysts for obtaining protective atmospheres

Controlled (protective) atmospheres and reducing media, obtained by the dissociation (cracking) of ammonia and not containing CO and hydrocarbons, are widely used in metallurgy, mechanical engineering, chemistry, and other branches of the national economy.[198–200] Protective inert atmospheres are used to prevent the oxidation and change in the chemical composition of the surface of a metal, in hot zinc plating, electrochemical tin plating, the deposition of coatings, the production of glass, and the treatment of gold and other metal articles. Throughout the world, the dissociation of ammonia is carried out in the presence of iron- and nickel-containing contact catalysts.[198–201] Catalysts for the dissociation of ammonia have to satisfy severe requirements: working temperatures 600–950 °C, concentration of residual $NH_3 \leqslant 0.05$–0.1% at volume velocities of 500–2000 h^{-1}. KDA-5 and KDA-10A nickel catalysts for the dissociation of NH_3 contain cements as components.[108,202] KDA-5 [202] is obtained by mixing nickel hydroxide carbonate (NHC) (20–50% NiO) with calcium aluminates and 25% aqueous ammonia solution. At 800 °C the residual concentration of ammonia decomposing on this catalyst (at a volume velocity of 1000–2000 h^{-1}) does not exceed 0.02–0.025% (equilibrium value 0.013%). In the production of the KDA-10 A catalyst,[108] cements are used together with Al_2O_3, making it possible to combine high activity of the contact catalyst with mechanical

strength and thermal stability. Calcium aluminates have been used as hydraulic binding agents in the production of the nickel contact catalysts KDA-3,[203] KDA-4,[204] and KDA-7.[205] The use of a combination of the properties of calcium aluminates, as components of catalytic compositions and as hydraulic binding agents, forms the basis of the nickel dissociation catalyst NKM-2A.[90,91,114] NHC, calcium aluminates, and aqueous ammonia solution are mixed at the lowest possible liquid : solid ratio (0.2–0.3). At the mixing stage, the reactivity of the cements ensures their reaction with NHC. The use of a low liquid : solid ratio made it possible to preserve most of the catalyst mass in the non-hydrated form, and to make use of the binding properties of the cements at the stage of hydrothermal synthesis and HTT. The high degree of binding of nickel in the NKM-2 catalyst ensures a lowered concentration of NiO, and the nickel phase is stable both to sintering and to binding in nickel aluminium spinel. Experience in the production and use of controlled atmospheres in ferrous metallurgy indicates the promising possibilities provided by iron-containing contact catalysts. A thermally stable catalyst should contain a refractory component, for example cements ($CaAl_2O_4$ melts at 1600 °C, and $CaAl_4O_7$ at 1750 °C). Calcium aluminates can be added either directly or as components which act as sources of Ca and Al. In the production of Fe contact catalysts by fusion, temperatures of 1500–1700 °C are sufficient for the formation of the compounds $Ca_xAl_yO_z$. Fe-containing KDA-1A,[206] KDA-2,[207] and KDA-1M[208] catalysts for the dissociation of NH_3 are obtained in this way. These catalysts contain a solid solution based on magnetite, formed with the participation of $CaAl_2O_4$. This series of catalysts with a high iron concentration (up to 77%) and a high thermal conductivity ensures the decomposition of NH_3 to a residual concentration $\leqslant 0.05-0.1\%$ at 650–950 °C. Experience in the industrial use of KDA catalysts has shown that they are capable of stable operation at temperatures of 700–900 °C and volume velocities of 1000–6000 h^{-1} for not less than 5–7 years, and can withstand brief superheating to 1000–1100 °C.[209] An important and promising development involves the dissociation of NH_3 on metal-cement contact catalysts to give a nitrogen–hydrogen mixture for the reduction of catalysts in the starting-up of assemblies when there are no other sources of hydrogen.[1,209]

VIII. Catalysts for purifying sulphur-containing gases

Sulphur compounds present in technical gases are powerful catalyst poisons, and lead to the corrosion of apparatus and contamination of the atmosphere. Industrial methods for purifying gases from harmful impurities, including sulphur compounds, can be divided into three groups: adsorption, liquid (or absorption), and chemisorption (or chemisorption–catalytic).[85] Zinc oxide absorbers remove H_2S, C_2H_5SH, and COS effectively, and CS_2 less effectively. The absorption of H_2S gives ZnS, which is stable in the reaction medium, so that this reaction is displaced completely to the right. In the production of zinc–aluminium–calcium catalysts, reactions (3) and (4) take place between $CaAl_2O_4$ ($CaAl_4O_7$) and zinc hydroxide carbonate (ZHC) to give zinc hydroxoaluminate (ZHA) and $CaCO_3$.[24,25,52,65] The thermal decomposition of ZHA is described by Eqn. (5). The source of ZnO is ZHA, where the ratio $ZnO/Al_2O_3 > 1$, and also ZHC. The morphology of zinc-cement contact catalysts[28] is characterised by the presence of different structures — block (carrier) and globular (zinc-containing component). The texture of $ZnO-CaAl_2O_4$ and $ZnO-CaAl_4O_7$ catalysts[210] is determined to a large extent by the reaction of the components. The study of the production of zinc oxide absorbers for sulphur-containing gases on $CaAl_2O_4$, $CaAl_4O_7$, and Al_2O_3 carriers[26,52,211] revealed a regular feature: the binding of ZHC in ZHA lowers the activity of the chemisorbing materials to a greater extent, the more extensive the reaction between ZHC and the carrier. The degree of binding of the zinc component in ZHA [26,101,211] decreases in the order $CaAl_2O_4 > CaAl_4O_7 > Al_2O_3 >$ galyumin, whereas the activity increases in this order.[26] Other conditions being equal, the extent of the absorption of H_2S is determined only by the concentration of the free ZnO phase. Zn^{2+} ions in tetrahedral surface centres and bulk zinc aluminium spinel are extremely stable, and this explains the inactivity of the absorbers towards H_2S and the inhibition of sulphidation processes on these contact catalysts.[212] The reaction of C_2H_5SH with absorbers based on ZnO [213] takes place in two stages: ZnS and hydrocarbon are formed initially in the sulphurisation stage, after which degradation hydrogenation, and the synthesis of sulphur-containing compounds take place on ZnS. A thermodynamic analysis[214] has shown that the presence of hydrogen in the reaction mixture prevents the decomposition of the sulphur-containing substances to sulphur, decreases the rate of formation of thiophen and thiophan, and increases the degree of purification to 80–100%. Cement provides an extremely effective means of granulating ZnO.[211,215,216] Calcium aluminates (and also Sr and Ba aluminates) have been used to develop effective zinc-containing contact catalysts for purification from sulphur.[217–219] The catalyst TsKA-1 [217] has a mechanical strength up to 350–500 kg cm^{-2} with a sulphur capacity (400 °C) of 27–33 mass%. The presence of CaO in the cements increases the absorbing power.[220,221] Special-purpose zinc-containing cements are of interest for catalysis.[222–224] One promising method for purifying industrial effluent gases with the simultaneous utilisation of sulphur-containing compounds is provided by the Claus process,[225–227] in which sulphur is obtained using aluminate cements. This process, in particular, uses a wide-pore aluminium-cement catalyst called the Norwegian catalyst.[226] The introduction of the oxides of K, Ba, P, and Ln into catalysts based on high-alumina cements increases the yield of elemental sulphur considerably.[227] A composition containing an alkaline earth metal and aluminium oxide, heated at a high temperature, with S_{sp} = 100–300 $m^2\ g^{-1}$ and a pore volume of 0.30–0.60 $cm^3\ g^{-1}$, has been proposed as an effective sorbent for gases containing SO_x.[228] The extraction of sulphur from SO_2 in flue gases is carried out by reducing the SO_2 with hydrocarbons (CH_4, natural gas) at 450–1300 °C in the presence of calcium aluminates deposited on Al_2O_3.[229]

IX. Catalytic systems for the conversion of CO by water vapour and the synthesis and decomposition of methanol

Copper-containing systems, obtained by deposition, precipitation, or mixing, are extremely effective catalysts for the conversion of CO by water vapour and the synthesis and decomposition of methanol. To maintain the copper-containing component in the active state, it is necessary to use carriers and promoters which are capable of ensuring a uniform distribution of copper in the matrix of stabilising components.

The use of cements has made it possible to obtain catalysts by chemical mixing. The degree of interaction of the components obtained in this way is not less than that obtained by precipitation.

The formation of contact catalysts. The formation of copper-cement contact catalysts has been studied.[52,65,230–233] The catalytic system obtained from copper hydroxide carbonate (CHC) and talyum (CA + CA_2) contains copper hydroxoaluminate, calcium carbonate (as calcite), aluminium hydroxide (as gibbsite), and calcium hydroxide (amorphous to X-rays). The extent of the reaction of CHC with talyum, estimated from the quantities of calcite and gibbsite formed, increases with increase in the fineness of grinding (FG) of talyum, and increases even more strongly with increase in the ratio CA/CA_2.[230,234] The anionic and cationic fractions of CHC have different fates: the carbonate ion is converted into calcite, and the copper ion into copper hydroxoaluminate and $Cu(OH)_2$. At increased temperatures (90 °C), the rate of decomposition of CHC is greater than the rate of its reaction with CA and CA_2; at low temperatures, CA and CA_2 are hydrated slowly, particularly CA_2. On thermal decomposition, copper hydroxoaluminate decomposes to a $CuO-Al_2O_3$ solid solution and CuO. With increase in the heating temperature to 600–800 °C, the spinel $CaAl_2O_4$ is formed from the solid solution. The reactions in the system are described by the general equations (3)–(6). In the three-component CHC–ZHC–talyum system,[230,232] zinc leads to stabilisation of the copper-containing phases and to more uniform distribution of the latter in the catalyst. The two components (ZnO and CuO) are mutually dispersed. Zinc oxide, on the one hand, stabilises copper, and on the other hand competes with it for calcium aluminate, with which they react according to Eqns. (3) and (4). In the two-component CHC–ZHC system, a chemical reaction giving a mixed hydroxide carbonate of Cu and Zn also takes place.[230,232,235] Thermal decomposition gives non-equilibrium solid solutions of Cu^{2+} in ZnO and of Zn^{2+} in CuO; electronic diffuse reflectance spectroscopy (EDRS) detected clusters or associates $(CuO)_x$. In the reduced specimens, an appreciable proportion of the copper is present not as crystallised Cu^0, and the surface of the copper-containing component is increased. Electron microscopy[28] showed that in the $CuO-CaAl_2O_4$ system the disordered copper phase has a globular structure; the introduction of ZnO leads to the formation of a copper phase with a more stable block structure. The thermal decomposition products of copper hydroxoaluminate, namely CuO, the $CuO-Al_2O_3$ solid solution, and then the spinel $CuAl_2O_4$, have a high degree of dispersion, which is preserved up to 600–700 °C.[236,237] A study of the thermal-vacuum electrical conductivity curves.[101,238] established that copper oxide reacts less strongly with the surface of the cements, compared with zinc oxide, and copper has a high surface mobility. A similar study of the CuO–ZnO system[239] detected isolated copper ions and $(CuO)_x$ clusters on the surface, both stabilised by ZnO. In a reducing medium, the copper-cement and nickel-cement systems show an unusual effect of low-temperature decomposition of $CaCO_3$,[125,126] which should lead to changes in the mechanical strength and surface properties of the specimen.

The conversion of CO by water vapour. The conversion of carbon monoxide on highly active copper catalysts at low temperatures makes it possible to decrease sharply the residual concentration of CO and to increase the H_2 concentration. Copper-containing catalysts on a cement base have been used for this purpose.[218,240–244] The NTM catalyst has a high activity at increased pressures.[218] The NTK-10 catalyst subjected to additional treatment[240] has a mechanical strength up to 600–800 kg cm^{-2}, withstands superheating to 300–350 °C, and gives a residual concentration of CO in the converted gas at 200–220 °C close to the equilibrium value. The increase in the strength and degree of compaction of the NTK-10 catalyst at the pressing stage is due to the breakdown of pores with dimensions >300 Å; decrease in the proportion of pores with a radius of 100–200 Å is accompanied by a decrease in the activity.[244] The use of $(NH_4)_2CO_3$ as pore-forming agent in copper-cement contact catalysts alters the porous structure and lowers the activity of the catalyst; this is due to the formation of copper–ammonia–carbonate complexes, which provide a source of copper with an increased ability to undergo recrystallisation.[245] Moist-air and hydrothermal treatment leads to an increase in strength, making it possible to use cement additives to restore the strength of the catalyst and enable it to be used again.[246] The highest activity is shown by catalysts for which the formation of the active phase involves the formation of copper hydroxoaluminate.[65,232,236,237] As finely dispersed CuO separates from the latter (with increase in temperature to 600 °C), the activity increases continuously, after which it decreases sharply as a result of the sintering of copper. For the same reason, the most active contact catalysts are those whose formation involves the reaction of CHC and talyum in the first stage, and the introduction of ZHC in the second:[232] this gives the maximum quantities of copper hydroxoaluminate. In $CuO-Al_2O_3$ and CuO–ZnO solid solutions, copper is converted into an active state ensuring the conversion of CO.[232,235–237]

The mechanism of the low-temperature conversion of CO by water vapour on NTK-10 copper–zinc cement catalysts has been studied.[247–250] The activity of the catalyst is related to its ability to adsorb CO in larger quantities, and H_2O and CO_2 in smaller quantities, on the non-uniform surface.[247] The reaction involves the formation of formate ion by a combined mechanism.[248] The formate complex is produced from CO_{ads} and OH_{ads}; the latter are produced by the dissociative adsorption of H_2O.[249] The temperature of the dissociative adsorption of water provides a criterion of the activity of copper-containing contact catalysts.[250] According to XPES and XAES data,[251] the active species is copper in the Cu^+ state; the zinc maintains copper in this state. A kinetic model of the reaction has been proposed, and the nature of the surface centres responsible for the reaction has been established.[252–254] The limiting stage is the surface reaction of the formate ion with the adsorbed hydroxyl group.

Synthesis of methanol. A large proportion of copper-containing catalysts for the conversion of CO are also active in the synthesis of CH_3OH. This applies to the copper–zinc cement contact catalyst.[218,233] In the synthesis of methanol, as in the conversion of CO, a high activity is shown by contact catalysts containing MHA.[230] A copper–zinc contact catalyst containing hydraulic cement is extremely effective.[255] Cements are also used in other catalysts for the synthesis of CH_3OH at a low pressure.[256]

Decomposition of methanol. Copper–zinc cement catalysts are effective in the decomposition of CH_3OH to CO and H_2.[257] Methyl formate can be obtained by dehydrogenating CH_3OH in the gas phase on a copper-cement catalyst at 150–300 °C.[258,259] The catalyst for the conversion of aqueous CH_3OH by water vapour at 300–600 °C contains group VIII metals, TiO_2, CeO_2, and a Ca aluminate cement.[260]

X. Catalysts for the hydrogenation of oxygen

In various branches of the national economy there is a demand for highly pure gases, in particular gases free from O_2. Gases free from oxygen are required for the hydrogenation of the products of organic synthesis, for example in the production of caprolactam, the hydrogenation of benzene, and the selective and complete hydrogenation of organic compounds. Inert gases free from O_2 are required in chemistry, metallurgy, and other fields. Analysis of data on the purification of technical gases from O_2 [261] showed that the most effective industrial catalysts are Pt, Pd, Cu, and Ni contact catalysts on carriers. The disadvantages of Pt and Pd contact catalysts are their high cost, scarcity, and low mechanical strength. An effective catalyst proposed for the hydrogenation of O_2 contains Ni, Cu, Al_2O_3, $CaCO_3$, and $CaAl_4O_7$;[262-268] this catalyst can operate without breakdown (mechanical strength 300–400 kg cm^{-2}) at temperatures of 100–700 °C and pressures up to 300 atm; the residual concentration of O_2 in Ar is ~0.0007 vol.%. Catalysts for purifying Ar, N_2, and H_2 [263] are obtained by mixing the hydroxide carbonates of Ni (NHC) and Cu (CHC) with talyum in the presence of aqueous NH_4OH solution. The catalyst ensures the removal of oxygen from the gas at oxygen concentrations down to 3.0–3.5% vol. O_2 (this is accompanied by an increase in temperature to 750–800 °C), indicating its high thermal stability and activity. The properties of talyum influence the production of the copper–nickel–aluminium–calcium contact catalyst.[264] Two reduction temperature ranges are observed (300 °C and 540 °C). After high-temperature reduction, the highest activity is shown by the catalyst with the lowest degree of reaction between the components; this may be brought about, for example, by slight preliminary subdivision of the talyum. On the other hand, the catalyst in which the extent of the reaction between the components and the concentrations of Ni and Cu hydroxoaluminates are fairly high shows the highest activity after high-temperature reduction. The possibility of replacing the industrial Pd catalyst AP-1 by the thermally stable and mechanically strong nickel–copper contact catalyst NKO-2 has been examined. Unlike the industrial nickel–chromium catalyst, the NKO-2 catalyst, after being swept with air, is not deactivated and shows no change in its basic characteristics.[265-267] Mixed Ni and Cu hydroxoaluminates provide the starting material for the formation of nickel–copper solid solutions which ensure stability of the active component of the catalysts to the effect of high temperatures and an oxidising medium.[268] The similarity in the reactivities of copper and nickel hydroxoaluminates leads to competition between them in the reaction with talyum. Copper hydroxoaluminate is more reactive.[269] In the NiO–CuO system, a solid solution based on CuO was detected on the surface; the probability of formation of this solid solution increases with increase in the copper concentration and the temperature of treatment.[270]

XI. Catalysts of the Fischer–Tropsch synthesis

Promising methods for the utilisation of coal and natural gas are provided by their conversion into synthesis gas with the subsequent production of hydrocarbons. Aluminium–calcium cements have been used to develop mechanically strong and thermally stable Co and Ni catalysts containing promoting additive (CuO, MgO) for carrying out reactions involving synthesis gas.[271-275] Their selectivity can be altered by varying the composition and conditions of preliminary treatment with hydrogen. Promotion by MgO leads to an increase in the polymerising properties, and modification by copper oxide makes it possible to restrict the growth of the carbon chain to 5–10 carbon atoms. Increase in pressure to 0.82 MPa led to an increase in the yield of liquid hydrocarbons and to the appearance in the products of hydrocarbons with a high melting point (synthetic ceresine).

A distinguishing feature of the mechanism of the production of cobalt–aluminium–calcium contact catalysts, as in the case of other aluminium–calcium catalysts, is the reaction of the components (CA and CA_2) with Co hydroxide carbonate (CoHC), which gives a carrier with a highly developed surface and an active component distributed on the surface. The catalysts show maximum selectivity in the synthesis of liquid hydrocarbons at a degree of reduction of the metal of 65–84%, which requires high-temperature treatment with hydrogen (550 °C).[29] One of the precursors of the catalytically active phase is Co hydroxoaluminate (CoHA),[274,275] which is reduced at 550–650 °C. Modification of the Co catalysts by CuO by the introduction of Cu hydroxide carbonate makes it possible to lower sharply the temperature of the reductive activation of the contact catalysts by 100–150 K and to increase the yield of liquid C_4–C_{10} hydrocarbons.[30,272,276] In the production of the Co–Cu catalysts, a multi-phase system with a highly developed surface (S_{sp} = 170 m^2 g^{-1}) is formed; both components influence the production of the inter-phase boundary.[30] A study of the thermal-vacuum electrical conductivity curves[276] established that CuO forms a solid solution in Co_3O_4, that is Cu cobaltite with variable composition and the spinel structure $Cu_xCo_{3-x}O_4$ ($0 < x < 1$) is produced, and is detected both in the bulk and on the surface. The carrier facilitates the reaction between the oxides and stabilises the surface cobaltite, which is detected even at a CuO concentration of 5% and a temperature of 200 °C. Copper oxide tends to concentrate on the surface of the particles, so that the surface cobaltite is richer in copper than the bulk cobaltite. Cobalt- and nickel-cement contact catalysts containing promoters are regarded as promising catalysts for syntheses based on CO and H_2.[277]

XII. Cement-containing contact catalysts with an acid–base action

The presence of varied acid–base centres in cement-containing catalysts[17,52,61-65,70] strongly suggests that these contact catalysts, in particular the aluminium–calcium catalysts, may be active in the isomerisation of hydrocarbons and the transformation of alcohols even without the introduction of any other elements. The dehydration and dehydrogenation of isopropyl alcohol take place intensively on calcium aluminates with a highly developed surface (galyumins).[52,62,65] The dehydration of the alcohol takes place on a pair of acid–base centres by a two-centre mechanism with the participation of the β-CH-groups of the reagent, and the dehydrogenation takes place on basic centres with the participation of α-CH-groups. The dehydration of α-acetylenic carbinols (prop-2-ynyl alcohol, dimethylethynyl carbinol) [278] also takes place on calcium aluminates by a two-centre mechanism with the participation of acid–base centres. The splitting of α-acetylenic carbinols to give acetylene is an indication of the presence of basic centres. The activity of the catalyst in the splitting reaction increases with increase in the ratio CaO/Al_2O_3. A decrease in the CaO concentration or blocking of the basic centres by the adsorption of an acid intensifies the dehydration of the alcohol. Galyumins

based on aluminium–calcium cements are effective catalysts of the reverse isomerisation of methylacetylene to allene.[279–285] The catalytic isomerisation of methylacetylene provides an accessible method for increasing the supply of allene on an industrial scale. Products based on allene are widely used in various branches of the national economy (dyes, leather, monomers, adhesives, medicines, etc.).[285] The reversible monomolecular isomerisation is described by a first-order equation.[279,282] The maximum value of the specific reaction rate constant is achieved at a definite ratio of the acidic and basic centres in the galyumins; the reaction rate is decreased by both acids (phenol) and bases (pyridine).[279–282] Effective catalytic methods have been developed for obtaining an equilibrium mixture of allene and methylacetylene from pyrolysis gases (methylacetylenic fraction).[283,284]

XIII. Catalytic systems for various organic and inorganic processes

The range of application of high-alumina cements, in particular the alkaline earth aluminates, in catalysis has been increasing continuously in recent years, covering the most varied processes involving the transformation of various nitrogen-, sulphur-, and carbon-containing compounds, from the preparation of the final products to the intensive purification of the effluent gases. The last process is acquiring increasing importance from the ecological viewpoint.

The formation and transformation of nitrogen-containing compounds. A method is known for obtaining oxides of nitrogen by the ionisation of air by a beam of electrons or γ-rays in the presence of calcium aluminates with a highly developed surface (galyumins).[286] The cobalt oxide (Co_3O_4)–calcium aluminate system is an effective and thermally stable catalyst for the oxidation of NH_3;[287–291] the yield of NO at 650 °C is 91.0%.[291] It is suggested[287,289] that $CaAl_2O_4$ actives Co_3O_4. A mechanically strong contact catalyst for the oxidation of NH_3, containing Ca, Al, Fe, and Cr oxides heated at 875–900 °C, has been described.[292] $CaAl_2O_4$ is added to the Fe-containing catalyst for the synthesis of NH_3 to increase its activity.[293] The use of calcium aluminates makes it possible to obtain Fe-containing catalyst blocks for NH_3 synthesis columns with an increased mechanical strength and good operational characteristics.[294] The decomposition of the carbonate component in these contact catalysts[295] takes place as a result of the catalytic action of the highly dispersed metal (Fe). Other metals have a similar effect.[125,126] Intensive enrichment of the surface of the BASF-56-10 industrial catalyst for the synthesis of NH_3 in Al and Ca oxides, which act together as surface promoters, has been described.[296]

Purification of effluent gases from CO. Platinum, rhodium, and ruthenium catalysts on a carrier containing cements and calcium aluminates can bring about the complete oxidation of CO even at room temperature.[297–304] The concentration of calcium aluminates is 35–90%.[299] Calcium aluminates containing 15–35% CaO are used.[300] In addition to Pt and Pd, the addition of compounds of metals of the iron group (Fe, Co, Ni) [305] and also Cu, Ag, Au, Mn, Cr, Sn, and Pb,[306] has been recommended; these contact catalysts are highly stable during use. MnO_2/calcium aluminates are also used to remove CO.[307] The presence of the calcium aluminates makes it possible to carry out the oxidation of CO on these contact catalysts in the presence of SO_2.[308] Fe and Cu oxides are effective promoters of catalysts based on MnO_x and calcium aluminates.[309] Aluminium–copper oxide catalysts with a ratio $Al_2O_3/CuO = 3:1$, modified by Ca, Sr, and Ba aluminates, can be used to oxidise CO at 150–450 °C.[310]

The purification of waste gases. The MnO_2–calcium aluminate catalytic system, which has a fairly high thermal stability, is used to purify spent gases, including exhaust gases, from CO and hydrocarbons.[311–315] Ca silicate and Portland cement can be used as the cement component.[314] Active components of the catalyst, in addition to Mn, are the oxides of Ni, Co, Cu, Fe, and Cr;[316–322] Ba or Sr aluminates are also added in addition to calcium aluminates.[317] The cement component of the catalyst increases its activity and thermal stability.[317] A cement-containing composition has a wide spectrum of action and makes it possible to remove not only hydrocarbons and CO, but also SO_2 and NO.[318,320] Catalysts including metals of the Pt group (Pt, Pd), and also activated carbon and calcium aluminates, have been described.[323–325] A contact catalyst consisting of spinel $M^{2+}M_2^{3+}O_4$ (M^{2+} = Mn, Fe, Co, Ni, Cu, Zn, Ba; M^{3+} = Fe, Al), calcium aluminates, and metal oxides active in oxidation has a high mechanical strength, porosity, and thermal stability;[326] it can be used to oxidise CO, hydrocarbons, SO_2, oxides of nitrogen, aliphatic acids, aldehydes, amines, and other compounds formed in the preparation of foodstuffs. An effective carrier for a catalyst for purifying effluent gases contains Al_2O_3 with added calcium aluminates.[327] An active copper–nickel–aluminium–calcium catalyst, not containing Mn or platinum metals, for purifying exhaust gases has been described.[328]

The catalytic combustion of organic compounds. Catalytic combustion processes are accompanied by strong thermal effects with an increase in temperature, creating severe operational conditions which lead to sintering and the loss of activity by the catalyst. The high melting points of Ca, Sr, and Ba aluminates makes them a suitable base for the production of thermally stable and highly active contact catalysts for catalytic combustion.[74,75,329,330] The sintering of γ-Al_2O_3 is suppressed sharply by adding Ca, Sr, and Ba oxides, capable of forming aluminate structures; a $CoO–BaO–Al_2O_3$ catalyst which has a highly developed surface due to the formation of $BaO.6Al_2O_3$ and which has a high activity in the combustion of CH_4 has been described.[74,75] The dispersion of Mn cations in a Ba aluminate matrix gave a contact catalyst with the composition $BaMnAl_{11}O_x$, whose activity is appreciably greater than that of familiar combustion catalysts such as Pt/Al_2O_3 and $LaCoO_3$.[330]

The partial oxidation of carbon-containing molecules. A highly pure composition containing Al_2O_3 and added barium aluminates, with a low S_{sp} and high mechanical strength, is used in the production of a silver-containing catalyst for the oxidation of ethylene to ethylene oxide.[76] A catalyst consisting of NiO, Al_2O_3, and calcium aluminates is used for the partial oxidation of hydrocarbons.[331] $CaAl_2O_4$ has been proposed as a carrier for a catalyst for the oxidation of C_3H_6 and $(CH_3)_2C=CH_2$ to unsaturated aldehydes and acids.[332] The possible oxidative transformation of CH_3OH to CH_2O over Mo, V, and W oxides deposited on talyum ($CaAl_2O_4$ + $CaAl_4O_7$) has been studied.[333–335] The oxidative dehydrogenation of methanol is accompanied by its oxidation to CO and CO_2, and also by dehydration to $(CH_3)_2O$.

The hydrogenation, dehydrogenation, hydrogenolysis, and alkylation of carbon-containing compounds. The selective dehydrogenation of alkylaromatic hydrocarbons to styrene and its derivatives is carried out on Fe–Cr catalysts containing calcium aluminates, Portland cements, or alumina cement.[336–341] The role of the cements is varied: they increase the selectivity, and act as a binding agent. The introduction of $CaAl_2O_4$ into copper–aluminium and copper–magnesium catalysts for the dehydrogenation of cyclohexanol increases the rigidity of their framework and leads to suppression of the dehydration, increasing the selectivity of the process.[342–344] Aluminium–calcium cement or calcium aluminates with an atomic ratio Ca/Al = 1/(4–10), subjected to thermal treatment at ~1000 °C, after the introduction of Pd are used for the selective hydrogenation of small quantities of more unsaturated compounds (C_2H_2) in the presence of less saturated compounds (C_2H_4).[345,346] The dehydrocyclisation of n-hexane can be carried out on aluminium–chromium–calcium catalysts.[347] The addition of alkaline earth metal oxides, preferably CaO (25%), increases the lifetime, activity, and selectivity of a 0.1–5% Pd/Al_2O_3 catalyst in a single-stage industrial method for obtaining highly pure cyclohexanone by the hydrogenation of phenol at 130–160 °C.[348] The best carrier for the catalyst for the synthesis of stilbene and its derivatives by the oxidative dehydrogenation of toluene and its derivatives in the vapour phase is calcium aluminate or Alcoa-CA-25 aluminate cement.[349–357] During mixing and high-temperature treatment (up to 800 °C), the carrier reacts with the active component; the basic character of the carrier prevents coke formation on the contact catalyst.

The catalytic systems $Ni–Al_2O_3–CaO$, $Ni–Al_2O_3–SrO$, and $Ni–Al_2O_3–BaO$ can be used for the liquid-phase hydrogenolysis of glucose to obtain glycerol and glycols.[358–362] The basic properties of the cement have a positive influence on the process, which takes place preferentially in a medium with a high pH. Since the medium is highly corrosive, it is appropriate to carry out carbonisation of the surface to increase the stability of the contact catalyst. CaO/Al_2O_3, $(CaO + SrO)/Al_2O_3$, and $(CaO + NiO)/Al_2O_3$ compositions have been patented[363] as catalysts for obtaining C_3H_6 from C_4H_{10} at 350–700 °C; the conversion of C_4H_{10} reaches 91%, the yield of C_3H_6 50%, and the ratio C_3H_6/C_2H_4 = 2.7. A catalyst for cracking high-boiling fractions with a large C/H ratio consists of calcium aluminates ($C_{12}A_7$, CA_6, CA, CA_2) and Ba and Sr aluminates, sintered at 1300–1500 °C, with the addition of 0.1–3% of activators (K vanadates).[364] The alkylation of cyclopentadiene and its derivatives by lower alkanols (C_4) is carried out in the presence of basic heterogeneous catalysts, for example a mixture of $Ca(OH)_2$ and Al_2O_3 heated at 1000 °C and treated with water.[365]

The authors have tried to analyse the principal trends and the most important directions of development of heterogeneous catalysis using cement-containing contact catalysts.

There are grounds for hoping that cement-containing catalysts can be used for the most varied low- and high-temperature processes in organic and inorganic technology. A new research field has now been established, associated with the preparation of oxide and metal oxide mixed cement-containing catalysts. Work is beginning to be developed on the production of deposited cement-containing catalysts. The physicochemical principles of the synthesis of cement-containing catalysts, carriers, and adsorbents for use in gas-phase and liquid-phase processes have been developed, and the regular features of the increase in the strength of their structure at the stages of tablet formation and hydration hardening have been studied. For the preparation of these catalysts, in addition to the already fairly familiar Ca, Sr, and Ba aluminates and high-alumina cements of the talyum type (TU-6-03-339-78), successful use is now beginning to be made of aluminothermal cements such as VTs-70, VTs-75 (TU-21-20-60-84), and also the specially developed high-alumina cement which has been called talyumin (TU-113-03-31-50-88). The physicochemical principles of the preparation of new highly pure high alumina cements have been developed.[9,32]

Cement-containing catalysts are used in more than 100 factories only in the Soviet Union. More than 200 patents covering cement-based catalysts have been published. Assemblies are being developed for the production of cement-containing catalysts by a universal and flexible technology. The use of cement-containing catalysts should help to solve problems of saving raw materials and energy, effectively converting carbon-containing raw material into required end products, protecting the environment, and establishing waste-free industries.

Progress in the synthesis of grafted materials using radiation graft polymerisation

L P Krul', A P Polikarpov
Scientific-Research Institute of Physicochemical Problems,
Lenin Belorussian State University, Minsk
Institute of Physical Organic Chemistry,
Academy of Sciences of the Belorussian SSR, Minsk

ABSTRACT. The current state of research into graft polymerisation processes that are initiated by ionising radiation is examined. Particular attention is given to new radiation grafting methods, such as low-temperature graft post-polymerisation, grafting with plasma chemical initiation, grafting in the presence of complexing agents, and grafting of metal-containing monomers. The mechanism of the radiation graft polymerisation process is also discussed.

The bibliography includes 188 references.

I. Introduction

Graft polymerisation is currently one of the most promising methods for obtaining modified polymer materials which combine different, and often contrasting, properties. There is an extensive literature, including a number of monographs and reviews,[1–24] which is devoted to different aspects of graft polymerisation — the procedural method, a study of its basic principles, its kinetics and mechanism, the structure and physicochemical properties of graft polymer materials, and problems in carrying out the processes on a pilot and industrial scale.

Amongst the many methods for obtaining graft copolymers, radiation graft polymerisation plays an important role. The radiation method for initiation of grafting is the most versatile method, and it can be used to carry out the process in virtually any system of matrix–grafted monomer. The radiochemical initiation of graft polymerisation has a number of advantages over a material method.[25]

Radiation graft polymerisation has up to the present time evolved as an independent branch of science with its own methodology and wide range of problems that can be resolved by it relating to the overall task of obtaining materials with a given set of production and operating properties. Considerable progress has been made in the practical realisation of processes based on radiation graft polymerisation. Thus, radiation finishing of textile materials is widely used.[15,16,21,22] Radiation grafting is used to obtain biocompatible polymer materials for medical application and materials for the immobilisation of biologically active compounds and samples,[26–44] adhesive polymers,[45–54] ion-exchange materials,[55–63] and supported catalysts and other materials.[24]

In the present review the most recent advances in the development of methods for obtaining radiation grafted polymer materials and a study of the mechanism of radiation graft polymerisation are examined.

II. Direct grafting

The main methods of radiation graft polymerisation had already been developed by the start of the 1960s and are covered in sufficient detail in review articles.[1–4,6,8,10–12,14–17,19,21,22,24] There are four main methods of radiation grafting: 1) the direct method, i.e., direct irradiation of the system: polymer being modified–monomer being grafted; 2) post-polymerisation, i.e., initial irradiation of the polymer in the absence of air followed by contact of the monomer with the irradiated polymer; 3) the peroxide method, i.e., initial irradiation of the polymer in an atmosphere of air or oxygen followed by treatment of the irradiated polymer with the monomer under conditions where the peroxides and hydroperoxides formed by irradiation decompose; 4) cross-linking of polymer mixtures. The last of these methods has not been developed to any significant extent. In the development of the first three methods, however, there have been a number of new results in recent years that have considerable significance for synthetic radiation chemistry.

The direct method has become the most widely used method for radiation graft polymerisation. Most frequently the polymer is in contact during irradiation with an excess of monomer, which can be used in liquid form (including in solution) or gaseous form. Sometimes use is made of the initial impregnation method, in which the polymer is first impregnated with the monomer and then irradiated. The method is non-stationary since there is no additional supply of monomer when it is consumed. The advantage of the direct method is that it occurs in a single stage, and the main disadvantage is the possibility of homopolymerisation of the monomer used for grafting occurring at the same time as a side-reaction; this is particularly significant in liquid-phase processes.

The methods for suppressing homopolymerisation during direct grafting have been examined in detail.[24]

One of these methods involves the introduction of transition metal ions into the system. This method is used particularly often in liquid-phase grafting. Recently a number of studies have been published on the kinetics of direct radiation liquid-phase grafting in a system of such practical importance as polyethylene (PE)–acrylic acid (AA)–water–Mohr's salt.[64–66] By comparing the effect of the dose rate, concentrations of monomer and ferrous ions on the kinetics of graft polymerisation of AA on to PE and the kinetics of homopolymerisation of AA, it was possible to optimise the conditions for grafting of AA on to PE in an aqueous solution of monomer.[66]

There is a certain interest in introducing organic compounds that are polymerisation inhibitors into the system. By using the difference in the ability of inhibitor and monomer molecules to diffuse to the active sites that initiate polymerisation in the polymer matrix, it is possible not only to suppress the unwanted homopolymerisation process in the external solution but also to control the distribution of graft polymer with respect to the thickness of modified material.[67] The chemical addition of components to the chains of graft polymer is also possible, as a result of which a substantial increase in the stability of the material towards thermal stability and oxidation and also deformation strength properties is achieved.[68–70]

Out of the different variants of the direct method of radiation graft polymerisation, it is gas-phase grafting that has been successfully developed.[15,16,21,22] This method involves the irradiation of different solid supports, including mineral supports,[15,16,22,71] in the presence of monomers that are in the gas phase or in the form of unsaturated vapour. The energy of irradiation in this case is absorbed almost solely by the solid support, as a result of which active sites initiating polymerisation are essentially formed only in it. Consequently, homopolymerisation in the gas phase is almost completely suppressed and, moreover, there is the possibility of grafting in those systems which are characterised by a low radiochemical yield of active sites in the support compared to their yield in the monomer. For graft polymers obtained by gas-phase graft polymerisation, a layered macroheterogeneous structure with a distinct boundary between the grafted and ungrafted layers is typical as is the formation of ordered (crystalline and oriented) structures of the graft polymer when using polymers in an oriented state as supports.[72]

In studying the structure of radiation grafted polymer materials obtained by the direct method, attention has until recently mainly been focussed on the macrodistribution of the graft polymer and the characteristics of ordering of the macromolecules. Experimental methods for analysing non-uniformity in the distribution of a graft polymer on the surface and width of a modified polymer material have been developed further. Thus, for studying the surface of grafted polymer films and fibres, the use of a radioactive indicator method has been proposed[77] along with the traditional methods of optical[73–75] and electron[51,76] microscopy. According to the former method a radioactive label is introduced into grafted chains, after which an image is obtained on a photographic plate, characterising the irregularity of distribution of the graft polymer on the surface of the sample. For this purpose it has been proposed to utilise the different capacity of the chains of polymer matrix and grafted polymer to undergo radiothermoluminescence.[78] In order to study irregularity in the distribution of a grafted polymer along the cross-section of a modified sample, in addition to the known indirect methods that consist of an analysis of the dependence of the content of the grafted polymer on the thickness of the sample and changes in geometric dimensions on the material during grafting and the direct methods related to a study of lateral sections of grafted polymer materials, a method based on comparison of optical densities in IR transition and multiply attenuated internal reflection spectra has been put forward.[79] In addition to inteferrometry,[80] microprobe X-ray spectroscopic analysis[63,81,82] has started to be widely used for the analysis of sections of graft polymer materials. It was possible, in particular, to use this method to establish the broken, step-like nature of the edge of the graft in graft copolymers of PE with AA obtained by direct irradiation in an aqueous solution of AA in the presence of Mohr's salt.[82]

There has also been further development of theoretical methods for analysing the irregularity of distribution of a graft polymer along the cross-section of radiation grafted polymer materials; these are based on the equations of diffusion kinetics.[16,83,84] In one study,[85] in order to determine the characteristic parameter, α, which can be used to determine the concentration distribution profile of a graft polymer along the cross-section of a sample, a transcendental equation has been obtained and solved, which contains only experimentally measured parameters of radiation graft polymerisation—the rate of grafting, the degree of equilibrium sorption of the monomer, the diffusion coefficient of the monomer in the polymer, and also the thickness of the modified material. Calculation of the width of a grafted layer from the value of the parameter α has been improved.[86]

In a study of the radiation grafted films and fibres of PE–polyacrylonitrile and chlorinated polyvinyl chloride–polyacrylonitrile synthesised by direct irradiation in monomer vapour with high dose rates, experimental confirmation has been obtained for the existence of "cut-off" layers on the surface of grafted materials,[87] whose possible occurrence had been considered previously.[15,16] Comparison of the strength and vapour permeability of samples with a "cut-off" layer, obtained at a high dose rate, and samples obtained at a low dose rate and not containing a "cut-off" layer showed that in the first case a considerable change in the properties of the material was achieved even with a small content of grafted polymer whereas in the second case there were only substantial changes in the properties for high degrees of grafting.[87]

In recent times, starting with the studies of Kurilenko et al.,[88–90] for radiation grafted polymer materials there has been considerable development of ideas about the heterogeneous nature of graft polymerisation and the microdistribution of components in graft copolymers, as proposed by Kargin and Platé in the 1950s. In addition to low-angle X-ray dispersion and electron microscopy,[23,75,87–90] low-angle neutron has been successfully used to obtain distribution curves of the dimensions of the particles of the microphase of a graft polymer for an analysis of the microheterogeneous structure of radiation grafted polymer materials.[91,92] Ideas about the microheterogeneous structure of radiation grafted polymer materials and the effect of the particles of the microphase of a grafted polymer on the molecular mobility and interchain interaction in amorphous microregions of a modified polymer have been used to analyse the causes of the change in thermal and deformation strength properties of polymer materials from radiation grafting.[23]

Out of the studies on direct radiation grafting which have undergone considerable development, mention should be made of radiation grafting on to latex particles from emulsions.[24] Radiation emulsion polymerisation is one of the most promising developments

in radiochemical technology.[93] It combines the advantages of emulsion polymerisation and radiation initiation. Several examples of radiation emulsion graft polymerisation are reported in the literature.[94-105] Thus, the radiation emulsion grafting of styrene, vinyl acetate, butyl methacrylate, and methyl methacrylate (MMA) on to lattices of polyvinyl acetate, polybutyl acrylate, and polymethyl methacrylate (PMMA) occurs in high yield (up to 80%).[94] The radiation grafting of styrene, vinyl acetate, ethyl acrylate, and MMA on to polytetrafluoroethylene (PTFE) in a latex has been studied.[95] Grafting did not occur at all with chemical initiation whereas with radiation grafting the quantity of graft polymer reached 6–8% of the weight of PTFE. Grafting by irradiation of lattices in the systems polyvinyl acetate–acrylonitrile (AN) and polyethyl acrylate–MMA was also studied.[95] The content of graft copolymer in the final product reached 40–50%. The radiation graft polymerisation of MMA on to polybutyl acrylate in an emulsion has been established,[96] and the radiation graft polymerisation of styrene in a polybutadiene latex has been studied.[97-99] The results were compared with those obtained by chemical initiation under the same conditions. No significant difference in the degree of grafting was observed for both methods of initiation; this was attributed to the ease of transfer of a growing polystyrene chain to polybutadiene with removal of a hydrogen atom at a α-position relative to the double bond.[24] The resulting polymer radical is one of the main sites of grafting. Therefore, the additional formation of polymer radicals on polybutadiene during irradiation does not make a significant contribution to the overall degree of grafting.

The radiation grafting of styrene and AN on to a polybutyl acrylate latex has been reported.[100] The quantities of graft copolymer amount to double-figure percentages, the yield of graft increasing as the ratio of water to polymer in the initial latex increases, which is related to the preferential participation of the radiolysis products of water in graft polymerisation rather than homopolymerisation. The process of obtaining an atmospherically stable, high-impact plastic which is based on the radiation grafting of a styrene copolymer and AN on to a rubber latex has been reported.[101-105] The plastic obtained has physicomechanical properties which are not inferior to ternary copolymers of AN, butadiene, and styrene (ABS plastic) and are frequently superior to them in terms of atmosphere stability. This extends their range of application.

The combined literature data provide an indication of the high efficiency of radiation graft emulsion polymerisation compared to other forms of radiation grafting due to the more extensive surface of the matrix. In materials obtained by radiation emulsion graft polymerisation there is a sufficiently uniform distribution of macromolecules of a different chemical nature throughout the bulk of the sample.

The advantages of the radiation method for initiation in emulsion graft polymerisation are particularly obvious in grafting on to polymers that do not tend to undergo chain-transfer reactions. We should note that there is virtually no information about the physicochemical properties of polymer materials obtained by radiation emulsion graft polymerisation.

III. Low-temperature post-radiation graft polymerisation

Low-temperature post-radiation grafting with devitrification of the polymer matrix is one of the relatively new methods used to carry out graft polymerisation. This method has been discussed in two reviews.[106,107] and in a study published later.[108] In essence the method involves the introduction of a monomer into the polymer being modified by sorption from a liquid or gas phase, the system is cooled to a temperature below the glass-transition temperature of the polymer, exposed to ionising radiation at this temperature, and then devitrified. Direct grafting of a monomer in solution does not occur in a vitrified polymer. Radiation graft post-polymerisation is only achieved by devitrification of the polymer matrix, and it occurs at a high rate with virtually no formation of homopolymer. Acceleration of grafting at temperatures corresponding to transition of the matrix from a vitreous form to a hyperelastic form had previously been recorded.[109,110] A significant shortcoming of these studies was the use of the traditional gravimetric method for determining the yield of polymer, the yield of graft polymer being determined at room temperature and not at the temperature corresponding to the maximum rate of graft polymerisation. For low-temperature processes the yield of graft polymer was actually determined after decomposition of the vitreous matrix. For quantitative kinetic studies necessary for an understanding of the processes that occur during devitrification of the matrix, methods were needed which would allow a process to be monitored directly as it occurred and not after its completion and decomposition of the surrounding matrix. It was also necessary to analyse in each particular case the two-component system "monomer–vitrifying matrix", to determine the limits of mutual solubility at the glass-transition temperatures of the system, and finally the temperature itself in the region of vitrification. All these methodological problems were successfully resolved by the use of a calorimetric technique.[107]

It was shown that most monomers introduced into a polymer matrix by sorption are preserved in the form of a solution in the pores of the matrix on freezing. A characteristic crystalline phase of monomer is formed when it is in excess, but this occurs in far from every case for all of the monomers. In the devitrification of a polymer mtrix an intense evolution of heat occurred, related to the process of polymerisation, which in a number of cases was confirmed by IR spectra to be grafted in nature.[108,111-115] Studies were also carried out on systems such as polyisobutylene–AN, polyisobutylene–divinylbenzene, polyisobutylene–methyl acrylate, polyisobutylene–MMA,[111] polyisobutylene–tetrafluoroethylene (TFE),[108] PE–TFE,[112] ethylene–propylene rubber (EPR)–TFE,[108,113-115] polydimethylsiloxane–AN, polydimethylsiloxane–MMA, polydimethylsiloxane–methyl acrylate, polydimethylsiloxane–vinyl acetate,[114] polydimethylsiloxane–TFE,[108,114,115] polydimethylsiloxane–styrene, polydimethylsiloxane–butadiene, polydimethylsiloxane–vinyl fluoride,[114] polydimethylvinylsiloxane–TFE, polydimethylphenylmethylvinylsiloxane–TFE, polydimethylmethylphenylsiloxane–TFE, polystyrene–TFE, PMMA–TFE, fluororubber SF-26–TFE, polybutadiene–TFA, butyl rubber–TFE, polyvinyl chloride–TFE.[108] In all systems, with the exception of polydimethylsiloxane–styrene, polydimethylsiloxane–butadiene, polydimethylsiloxane–vinyl fluoride, polymerisation of the introduced monomer occurred at about the temperatures corresponding to devitrification of the polymer matrix. High values of the yield graft of polymer were achieved in the rubber matrices, especially those of silicones. Graft polymerisation occurred

throughout the whole volume of the matrix and yielded materials with a uniform distribution of graft polymer along their cross-section.

The main advantage of low-temperature post-radiation graft polymerisation over other methods of radiation grafting lies in the possibility of obtaining graft copolymers with such readily polymerising and difficult to graft monomers as fluoroolefins, in particular, TFE. There is future potential in the low-temperature post-radiation grafting of TFE to by-products of the processing of PTFE, which would make it possible to obtain monolithic blocks of PTFE from the by-products, similar in properties to the initial polymer,[116,117] as is the low-temperature grafting of vinyl fluoride and vinylidene fluoride to by-products of the production of PTFE, PE, and polyvinyl chloride.[118–122]

The physicochemical properties of the materials obtained by low-temperature post-radiation graft polymerisation have been insufficiently studied. In one review[106] it was pointed out that graft copolymers with TFE have improved thermal and chemical stability and a lower coefficient of friction compared to the initial polymers. The improved heat stability of a graft polymer of PE with vinyl fluoride compared to the initial PE has also been recorded.[119] The properties of graft polymer materials obtained by low-temperature post-radiation grafting and their structures have not been studied in detail.

IV. Plasma-initiated grafting

Initiation of graft polymerisation with a non-equilibrium plasma from a gaseous discharge is regarded at the present time as a novel method of radiation graft polymerisation.[22] Although plasma-initiated graft polymerisation, as was mentioned by Tsetlin et al.,[22] can be achieved using the direct method, most of the published articles relate to plasma-initiated graft post-polymerisation.

The first studies on the effect of a high-frequency gas discharge plasma on solid organic compounds, including monomers in a vitrified state, were carried out at the beginning of the 1960s.[123] At that time the possibility of using radicals formed by discharge on the surface layer of a polymer for the synthesis of graft copolymers was suggested.[124] The preparation of graft copolymers of cellulose with ethyl acrylate by initiating the process with a corona discharge was reported.[125]

In recent years the processes which occur in PE on exposure to a non-equilibrium gas discharge plasma have been studied in detail,[126,127] and methods have been developed from this for plasma-initiated graft polymerisation of MMA, AA, methacrylic acid on to PE powder.[128,129] In essence the methods involve PE powders being evacuated, and then at a small residual pressure of oxygen (10–260 Pa) or in an atmosphere of an inert gas they undergo treatment with a high-frequency gas discharge plasma, after which the PE is again evacuated and brought into contact with monomer vapour, resulting in plasma-initiated post-polymerisation. It has been shown that neither a wide variation in pressure of the inert gas nor in specific power of discharge has an effect on the initial rate of grafting of MMA on to PE, which, however, depends on the time of treatment of PE in the plasma. Thus, for the first 3–5 min of treatment with the plasma, the rate of grafting of MMA on to PE increases substantially and then remains virtually unchanged, which is due to the attainment of a given limiting concentration of active sites or products initiating the reaction.[129] Plasma-initiated grafting of methacrylic acid on to PE occurs at a higher rate than grafting with AA.[128] Grafting of water-soluble monomers on to PE films, polypropylene (PP), and polyethylene terephthalate, treated with a high-frequency discharge plasma, from aqueous solutions of AA, 2-hydroxyethyl methacrylate, 2-dimethylaminoethyl methacrylate, vinylpyridine, acrylamide, and 2-acrylamide-2-methyl-1-propanesulphonic acid has been reported.[130] Comparison of the kinetics of plasma-initiated grafting of AA on to PE powder with γ-initiated graft post-polymerisation (Fig. 1) showed that a similarity of the kinetic curves for formation of graft polyacrylic acid (PAA) is achieved at a dose of 40 kGy.[23,128] Consequently, in certain cases plasma-initiated grafting in terms of both energy and process equipment design may be preferable than that initiated by γ-irradiation or accelerated electrons.

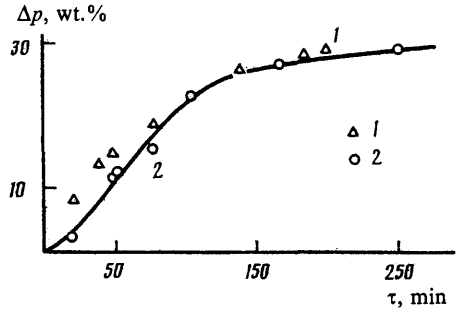

Figure 1. Dependence of the degree of grafting (ΔP) of AA on to PE on the time of the process for plasma-initiated post-polymerisation after initial treatment of PE for 10 min in a helium plasma at a pressure of 9.3×10^2 (*1*) and for γ-initiated post-polymerisation with an irradiation dose of 40 kGy (*2*); temperature of grafting was 323 K.[128]

A characteristic of plasma-initiated graft polymerisation is the occurrence of the process on the surface layer of the modified material with thickness of several μm, where the active sites that initiate grafting are primarily located. The nature of these sites and their relative efficiency in initiating the process of graft polymerisation is not yet completely clear. It has been noted[24] that plasma-initiated grafting may be a convenient method for modifying the surface properties of polymer materials, but these properties have also been sufficiently studied. There is future potential in the use of PE powder grafted by plasma chemical initiation for immobilisation of supported polymerisation catalysts[128] and PE films for adsorption of metal ions.[130] The mechanical properties of films that are grafted by plasma chemical means have hardly been studied at all.

V. Effect of matrix structure on post-radiation grafting

A series of studies by Nikol'skii et al.[75,131–134] is concerned with the dependence of the rate of gas-phase graft post-polymerisation of vinyl monomers (mainly styrene) to polyolefins on the characteristics of their hypermolecular structure. The structure of PE and PP films was modified by changing the rate of cooling the polymer melt and also by annealing. The dependence of the radiochemical yield of the

radicals, stable at 77 K and quasi-stable at room temperature, was studied. The yield of radiation graft copolymer was studied in parallel. It was shown[131] that the radiochemical yield of the free radicals in low-density PE at 77 K did not depend on the rate of cooling the polymer melt when it was changed from 1.5 to 2000 K min^{-1} and constituted 3 sp/100 eV. The magnitude of the radiochemical yield of radicals that were quasi-stable at room temperature increased by 25–30% on reducing the rate of cooling from 2000 to 1.5 K min^{-1}. At the same time the yield of polystyrene and polyacrylonitrile, grafted on to PE by gas-phase graft post-polymerisation on alkyl radicals that were quasi-stable at room temperature and also by liquid-phase grafting on alkoxyl radicals formed by the thermal decomposition of hydroperoxide groups in PE irradiated in air, increased several times on reducing the rate of cooling by a factor of 10–100. Hence, reduction in the rate of cooling a PE film by a factor of 10–100 during its preparation makes it possible to reduce the dose necessary for grafting by a considerable amount.

Studies carried out with low- and high-density PE films obtained with rapid cooling (cooling rate 2000 K min^{-1}) and annealed for 7 h under vacuum at 313–393 K showed that the radiochemical yield of free radicals at 77 K, equal to 3 sp/100 eV for annealed films, increases on annealing by only 10–20% whereas the radiochemical yield of radicals that are quasi-stable at 295 K increases more markedly.[133] The yield of polystyrene grafted on to PE using gas-phase graft polymerisation increases to a greater degree than the yield of radicals that are quasi-stable at room temperature. A study of the structure of annealed films showed that as the temperature of annealing increases the density of polymer and its crystallinity increase. The initial rate of sorption of styrene increases on annealing by 20–30% while the maximum sorption, on the other hand, is slightly reduced. The increase in yield of graft polystyrene correlates with the increase in concentration of free radicals that are quasi-stable at room temperature.

Rapidly cooled low-density PE films were compared[132] with slowly cooled high-density PE films. The rapidly cooled (quenched) low-density PE films did not contain spherulites, but when they were annealed spherulites of diameter 6–9 μm appeared. At the same time the density and (X-ray) crystallinity of the polymer increased and there was a reduction in the adsorption of styrene. The slowly cooled high-density PE films had a spherulite structure with spherulites of average diameter 3–6 μm. On annealing the diameter of the spherulites increased to 15–20 μm. At the same time the density and crystallinity of the polymer increased. The radiochemical yield of free radicals at 77 K in all of the samples was 3 sp/100 eV. The concentration of radicals that were quasi-stable at room temperature in the slowly cooled high-density PE films was 2–3 times higher than in the rapidly cooled low-density PE films. Annealing led to an increase in concentration of these radicals, this being exhibited most distinctly for high-density PE. Gas-phase graft post-polymerisation of styrene on slowly cooled films on the whole occurred at a higher rate than on rapidly cooled films.

Similar characteristics of the effect of the rate of cooling and annealing temperature on the yield of graft polystyrene were determined in the system PP–styrene.[134] A spherulite structure formed in PP on slow cooling of the melt, and on rapid cooling a smectic structure occurred. Annealing led to an increase in crystallinity and a sharp increase in the yield of graft polystyrene, which was due to an increase in concentration of radicals that were quasi-stable at room temperature as well as an improvement in conditions for sorption and diffusion of the monomer.

It was also shown[132–134] that the dependence of the degree of grafting on the thickness of the initial polyolefin film is extremal in nature, the position of the maximum being determined by the conditions of crystallisation and the annealing of the sample and also by parameters of the grafting process such as reaction time and radiation dose. On the basis of the kinetic data, it was suggested[132–134] that the maximum in the dependence of the degree of grafting on the thickness of the sample corresponds to the start of a gradual change from "bulk" grafting, characterised by a comparatively uniform distribution of graft component, to "surface" grafting, where the graft polymer is localised in the layer of material near the surface.

VI. Complexation as a method of controlling graft polymerisation

Complexation which achieves stabilisation of the macroradicals growing during polymerisation is used to control radiation graft post-polymerisation processes.[135–138] Thus, the polymerisation of acrylic and methacrylic monomers in the presence of orthophosphoric acid occurs in apparently homogeneous solutions and after the incorporation of an initiation source.[139] The cause of the suppression of bimolecular termination is the cross-linking of the polymerisation system through the formation of macromolecular and radical associates that are stabilised by hydrogen bonding. By using radicals bound on to cellulose for initiation of polymerisation in the system H_3PO_4–acrylic or methacrylic monomer, it was possible to obtain graft copolymers.[135] We should mention that complexation has also been used in direct radiation grafting, making it possible to obtain graft copolymers with allyl monomers in good yield.[140] The γ-initiated graft post-polymerisation of MMA and methyl α-chloroacrylate on to cellophane film in the presence of H_3PO_4 has been studied in detail.[135] Irradiation of the film was carried out at 77 K with grafting at room temperature. Grafting did not occur in the absence of H_3PO_4. When the complexing agent was added, grafting occurred, and in the initial stages of the process a linear increase in the content of graft polymer and its molecular weight with time was observed when there was a constant number of graft chains. Consequently, in the presence of H_3PO_4 graft post-polymerisation of MMA to γ-irradiated cellulose occurred virtually without termination or chain transfer, so that it was possible to obtain by a "living" mechanism grafted block copolymers of cellulose–(graft)(MMA–block methyl α-chloroacrylate). Graft copolymers of cellulose triacetate with a regularly varying number and length of PMMA chains were synthesised by means of continuous irradiation post-polymerisation of MMA in the presence of H_3PO_4.[136] A characteristic of this system was the increase in the number of grafted chains with grafting, which Akrabov et al.[136] attributed to the progressive involvement in graft polymerisation of macroradicals of cellulose triacetate that accumulated during γ-irradiation. It was observed[135] that the materials obtained using continuous irradiation graft polymerisation are characterised by a uniform distribution of graft polymer along their cross-section. For graft copolymers of cellulose triacetate with PMMA synthesised in the presence of H_3PO_4, the thermodynamic properties of their solutions were studied.[141] The dependence of the physicochemical properties of graft copolymers of PE synthesised using material initiators on the length and frequency of the graft chains has previously been recorded.[142,143] Hence there would be considerable interest in research into the properties of graft copolymers obtained

by means of continuous irradiation polymerisation in the presence of a complexing agent; this could help to determine the dependence of the physicochemical properties of radiation grafted polymer materials on the parameters of their molecular structure.

VII. The peroxide method and grafting of metal-containing monomers

The peroxide method of radiation graft polymerisation has been widely used since the 1950s,[3] but its mechanism cannot yet be regarded as established conclusively. A series of studies relating to both the mechanism of grafting conventional monomers (AA, acrylamide) on to PE and an investigation of the features of graft polymerisation of metal-containing monomers on to PE is of prime importance for the development of research on radiation graft polymerisation using the peroxide method.[144,148,149,151–153]

The nature of the active sites that initate grafting using the peroxide method is still the subject of controversy. The results of experiments on the grafting of AA on to irradiated PE powder and on to the same powder after iodometric titration resulting in decomposition of the hydroperoxides have been compared.[144] In the latter case grafting did not occur at all, from which it was concluded that hydroperoxides had higher activity than dialkylperoxides in graft polymerisation.

Transition metal salts are used to accelerate graft polymerisation by the peroxide method. The addition of small quantities of these leads to a more efficient decomposition of the peroxides.[145–147] It was shown[148] that on increasing the concentration of cobalt palmitate from 0 to 0.8%, the initial rate of radiation grafting of AA on to irradiated PE powder in a solution of monomer in heptane increased by a factor of two. In contrast to the grafting of AA on to PE,[148] there was no detectable accelerating action of cobalt salts on the grafting of acrylamide on to PE. A possible reason for this phenomenon, in the opinion of Savost'yanov et al.,[149] could be the formation of complexes between the cobalt compounds and acrylamide.[150]

In a study of graft polymerisation of Co(II), Ni(II), and Cu(II) acrylates on to PE powder that had previously been irradiated in air, it was shown[152] that this process occurs at lower rates than grafting with AA. In the grafting of acrylamide complexes of Co(II), Ni(II), and Cu(II) [composition of the complex was $MX_2 \cdot 4AA$, where M = Cu(II), Ni(II), Cu(II), X = Cl or NO_3, AA = acrylamide) to PE powder that had previously been irradiated in air, homopolymerisation was completely suppressed and the initial rate of grafting and yield of graft polymer were similar to those values that were observed in grafting of pure acrylamide.[153] The only exception to this was the $CuCl_4 \cdot 4AA$ complex, which underwent virtually no grafting on to irradiated PE.

There is also virtually no grafting of allyl alcohol on to PE previously irradiated in air, whereas complex compounds of allyl alcohol with transition metal salts [particularly with $Co(NO_3)_2 \cdot 6H_2O$, $CoCl_2$, and $CoCl_2 \cdot 6H_2O$] are grafted at a high rate.[151]

Thus, by using metal-containing monomers in the modification of polymer materials by radiation graft polymerisation with the peroxide method, it is possible in certain cases to carry out the grafting of monomers that are usually grafted with difficulty. Metal-containing graft copolymers are of interest in the treatment of polymerisation catalysts.[128] Moreover, they could most probably be used as materials with increased heat stability by analogy with ionomers.[154] However, the physicochemical properties of materials obtained by extrusion of PE with graft metal-containing polymers have hardly been studied at all.

VIII. The mechanism of radiation graft polymerisation

In the 1970s there was considerable progress in studies relating to radiation graft polymerisation.[155–169] For a long time it was thought that radiation graft polymerisation at room temperature and higher temperatures occurred solely by a radical mechanism. Direct evidence for such a graft mechanism was obtained for certain systems. Thus, in a study of radiation gas-phase graft copolymerisation of AA and styrene on to PP fibres there was agreement between the values of the relative activities r_1 and r_2 obtained during radiation copolymerisation from the gas phase and the corresponding values of r_1 and r_2 relating to copolymerisation of the same monomers in bulk form, which was known to occur by a radical mechanism.[170] It was concluded from this that radiation graft polymerisation from the gas phase occurs by a radical mechanism. Most authors accepted this mechanism without further question for all cases of radiation grafting with the exception of grafting in swollen polymer systems at low temperatures.[171–173]

In a series of studies carried out mainly in the 1970s it was shown that radiation graft polymerisation could occur at room temperature even for those monomers which polymerise by an ionic mechanism.[155–169]

The development of these studies resulted from the known fact that certain carefully dried monomers which did not polymerise by a radical mechanism could undergo radiation polymerisation at room temperature by an ionic mechanism.[174,175] These monomers (α-methylstyrene, vinyl n-butyl ether, isobutylene, propylene oxide, acrolein) were also used in the first studies on radiation ionic grafting on to PE, PTFE, and polyvinyl chloride.[155,160,162,165] These monomers, which were dried by the usual methods, including drying over calcium hydride, underwent virtually no grafting on to the above-mentioned polymers during direct liquid-phase grafting at room temperature, whereas after special drying graft polymerisation occurred effectively, the yield of homopolymer at the initial stages of the process being extremely low for radiation liquid-phase graft polymerisation ($\leqslant 1\%$).

In view of its particular importance, the question of the method of drying deserves special consideration. On the basis of a calculation using the value of the radiochemical yields and kinetic polymerisation constants, the upper limit of the water content at which grafting usually occurred was determined. This constituted $\sim 10^{-6}\%$ ($\sim 10^{-8}$ mol litre^{-1}).[158,169] Such a high degree of drying a monomer is a complex technical problem, the more so that such concentrations of traces of moisture in organic liquids cannot even be measured experimentally.[169] It is recommended that all drying operations in grafting from the start to sealing the tubes with modified polymer should be carried out in a completely sealed vacuum system, excluding completely contact with air.[169] The prime importance of careful heating of the glass apparatus at a temperature close to the softening temperature of the glass has been demonstrated.[169] In the choice of suitable drying agents it is necessary to consider not only their ability to absorb water but also the unwanted possibility of initiating on their surface the polymerisation of monomers that are in contact with them. Thus, metallic sodium is a good drying agent, but monomers placed over it

gradually polymerise. Styrene polymerises particularly readily, giving a thin film of polystyrene, which reduces the efficiency of drying, and this occurs not only on the surface of metallic sodium but also on the surface of such efficient drying agents as molecular sieves and barium oxide.[159] For grafting of monomers which only polymerise by an ionic mechanism, drying initially with calcium hydride followed by two or three batches of barium oxide that have been calculated for 6–12 h at 773 K under high vacuum ($\sim 10^{-5}$ mmHg) has proved effective.[155–157, 160] Calcined zeolites of the type CaA and NaA are not very effective. A good drying agent for many monomers, including styrene, is silica gel (KSM-6P grade) with a specific surface area of ~ 500 m^2 g^{-1} and average pore radius of 11.2 Å, which has been activated under vacuum ($\sim 10^{-5}$ mmHg) for 20 h at 773 K.[159,160,162,163,165]

The fact that graft copolymers are obtained at room temperature by radiation graft polymerisation of monomers that do not polymerise by a radical mechanism is evidence for an ionic mechanism.[155–157] In a study of the kinetics of radiation graft polymerisation of vinyl n-butyl ether on to PE, additional evidence for an ionic mechanism was obtained. The initial rate of grafting on a fixed portion proved to be proportional to the dose rate at the first stage and the temperature coefficient of grafting was negative.[157] It was also shown that grafting of vinyl n-butyl ether on to PE by initial irradiation in a "dry", i.e., specially purified, system as opposed to the usual free-radical process on to a "wet" system, i.e., one purified in the normal way, did not occur.[157] It was established using IR spectroscopy in the system PE–acrolein that graft polymerisation in a "dry" system does not occur via a C = C bond as occurs in radical polymerisation but via a C=O bond as in ionic polymerisation.[165]

The nature of the effect of organic solvents on the rate of radiation graft polymerisation in "dry" systems is also confirmation of an ionic mechanism for the process.[162,167] For example, in the system PE–vinyl n-butyl ether grafting is suppressed in electron-donating solvents but is accelerated in electron-withdrawing solvents, which is typical for processes that occur via a cationic mechanism. In this case, for example, in the presence of such a strong electron-withdrawing solvent as 1,2-dichloroethane, grafting of vinyl n-butyl ether, which does not polymerise by a radical mechanism, even takes place in a "wet" system.[162]

The ionic nature of graft polymerisation in "dry" systems has also been confirmed by the direct detection of active sites of an ionic nature in irradiated monomer–polymer systems using low-temperature UV spectroscopy.[164]

Together with monomers that polymerise solely by an ionic mechanism, monomers such as styrene, AN, 4-vinylpyridine, 2-methyl-5-vinylpyridine, phenylacetylene, which can polymerise by both an ionic and a radical mechanism, have also been studied.[159–161,163,166,167,169] When the monomer and the complete system were dried, higher values of the yield of graft polymer were generally obtained compared to "wet" systems. This provided the basis for the proposal of a possible mixed mechanism for grafting, i.e., that it takes place simultaneously by a free-radical and an ionic mechanism.

The fraction of ionic process θ is given by the following equation:[169]

$$\theta = \frac{V_{ion}}{V_{ion} + V_{rad}} = \frac{k_{ig} V_{in}^{ion} k_{rt}^{1/2}}{k_{rg}(V_{in}^{rad})^{1/2}\{(k_{ig}V_{in}^{ion})^{1/2} + k_{ox}[H_2O]\} + k_{rt}^{1/2} k_{it} v_{in}^{ion}}$$

where V_{ion} and V_{rad} are the initial rates for ionic and radical graft polymerisation respectively; k_{rg}, k_{rt}, k_{ig}, k_{it}, and k_{ox} are the growth and termination constants of radical (k_{rg} and k_{rt}) and ionic (k_{ig}, k_{it}, k_{ox}) chains, V_{in}^{rad} and V_{in}^{ion} are the rates of initiation of radical initiation of radical and ionic graft polymerisation.

For monomers with known constants (styrene, for example), figures show the dependence of θ on the dose rate I (Fig. 2) and on the water content (Fig. 3) in the case of grafting on to PE without taking into account chain transfer.[169] It is clear from Fig. 2 that the fraction of the ionic process increases with an increase in dose rate. The complete process can be divided into three bands: a purely radical process, a mixed process, and purely ionic grafting. To achieve ionic grafting over a wide range of dose rates, it is necessary that the water content (or other impurities on which an ionic process can be terminated) should not exceed 10^{-8} mol litre^{-1}. When the concentration of water is $\sim 10^{-4}$ mol litre^{-1}, the transition to a purely ionic grafting only occurs at dose rates exceeding 10^4 Gy s^{-1}.

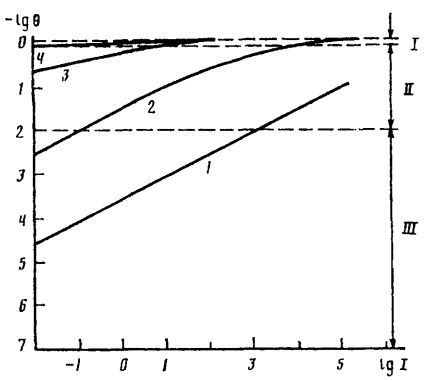

Figure 2. Dependence of the fraction of ionic process on the dose rate (I) with a varying content of water in the system (mol litre^{-1}): *1*, 10^{-2}; *2*, 10^{-4}; *3*, 10^{-6}, *4*, 10^{-8}; $G = 1$; $k_{it} = 10^{11}$; $k_{ig} = 3.5 \times 10^6$; $k_{ox} = 10^{10}$; *I*, purely ionic grafting; *II*, mixed grafting; *III*, radical grafting.[169]

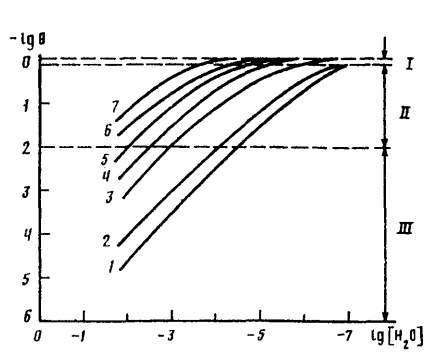

Figure 3. Dependence of the fraction of ionic process on the water content in the system at different dose rates, Gy s^{-1}: *1*, 10^{-2}; *2*, 10^{-1}; *3*, 10; *4*, 10^2; *5*, 10^3; *6*, 10^4; *7*, 10^5; $G = 1$; $k_{it} = 10^{11}$; $k_{ig} = 3.5 \times 10^6$; $k_{ox} = 10^{10}$ (concentration of water, mol litre^{-1}); *I*, purely ionic grafting; *II*, mixed grafting; *III*, radical grafting.[169]

The theoretical dependence of θ on the water content at different dose rates (see Fig. 3) indicates that in order to achieve purely ionic grafting at dose rates of $10^{-2}-10^{0}$ Gy s^{-1}, the water content in the system must be lowered to $10^{-8}-10^{-9}$ mol $litre^{-1}$. With the normal content of water in styrene ($10^{-3}-10^{-1}$ mol $litre^{-1}$) grafting by an ionic mechanism occurs at dose rates of $10-10^{3}$ Gy s^{-1}.

Not only water molecules but also other molecules which accept a positive charge (amines, etc.) act as impurities on which termination of the ionic chains can occur. However, the content of these impurities in the monomers used is negligible.

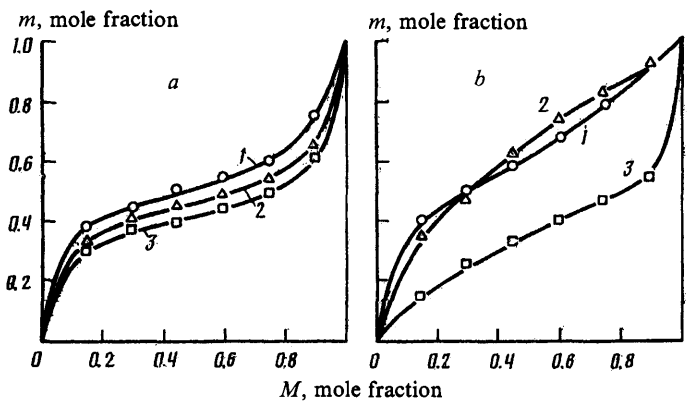

Figure 4. Dependence of the composition of graft copolymer of styrene and acrylonitrile (m) on the composition of the initial mixture of monomers (M); dose rates were 8×10^{-2} Gy s^{-1} (*a*), $(1 \pm 0.2) \times 10^{3}$ Gy s^{-1} (*b*); *1*, without using a solvent; *2*, in methylene dichloride; *3*, in HMPT.[168,169]

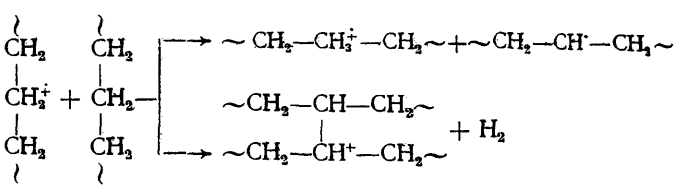
Table 1. Constants for graft copolymerisation of styrene and acrylonitrile.[168,169]

Solvent	Dose rate, Gy s^{-1}	Copolymerisation constant	
		r_1	r_2
No solvent	$8 \cdot 10^{-2}$	0.18±0.03	0.16±0.03
CH_2Cl_2	$8 \cdot 10^{-2}$	0.07±0.02	0.22±0.04
HMPT	$8 \cdot 10^{-2}$	0.06±0.02	0.55±0.06
No solvent	$(1 \pm 0.2) \cdot 10^{3}$	0.94±0.08	0.20±0.04
CH_2Cl_2	$(1 \pm 0.2) \cdot 10^{3}$	1.55±0.13	0.26±0.04
HMPT	$(1 \pm 0.2) \cdot 10^{3}$	0.04±0.01	0.83±0.07

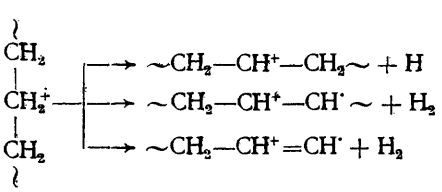
In order to confirm the conclusion that the contribution of the ionic process increases with an increase in dose rate, the radiation graft copolymerisation of styrene with AN on to PE was studied under the same conditions at dose rates of 8×10^{-2} and $(1 \pm 0.2) \times 10^{3}$ Gy s^{-1}. The results of determining the composition of the copolymer (Fig. 4) and the copolymerisation constants r_1 and r_2 (Table 1) show that the effect of the solvents differs considerably at low and high dose rates. When a dose rate of $(1 \pm 0.2) \times 10^{3}$ Gy s^{-1} is used, the copolymer is enriched with the styrene component when grafting is carried out in bulk or in the electron-withdrawing methylene dichloride but is enriched with the nitrile component from grafting in the electron-donating hexamethylphosphorotriamide (HMPT). The copolymerisation constants also differ considerably. These results indicate that the radiation graft copolymerisation of styrene with AN on PE takes place at high dose rates with a significant contribution from the ionic mechanism.

The mechanism of initiation or radiation ionic graft polymerisation (cationic and anionic) has been studied insufficiently. It has been suggested[169] that the active sites of cationic graft polymerisation may be radical cations or carbocations that are formed both directly by radiolysis of PE and by the reaction of a monomer radical ion with a radical of the polymer matrix:



$$R^{\cdot} + M^{\dot{+}} \rightarrow RM^{+}.$$

The first stage in the radiolysis of PE is formation of a radical cation:[169]



$$\sim CH_2-CH_2-CH_2 \sim \xrightarrow{\gamma} \sim CH_2-\dot{C}H_2-CH_2 \sim + e^{-}.$$

The electron undergoes partial thermolysis and can be captured by structural traps in PE. In adding on the monomer, the radical cation forms an active site for cationic graft polymerisation.

The radical cation of PE can react with a neighbouring polymer molecule to form a cross-link or a carbocation:

Moreover, the radical cation can be converted by elimination of an H atom or H_2 molecule

The elimination of an H atom or H_2 molecule depends on the site of formation of the radical cation. The resulting CH^{+} and $=CH^{+}$ carbocations can also act as initiators of cationic graft polymerisation.

Active sites of an anionic nature are mainly formed by capture of an electron by radicals from the matrix

$$R^{\cdot} + e \rightarrow R^{-}.$$

The second route for formation of active anionic sites is reaction of matrix radicals with monomer radical anions:

$$R^{\cdot} + M^{\dot{-}} \rightarrow RM^{-}.$$

All of the schemes shown above for the formation of active sites of ionic graft polymerisation are hypothetical in nature rather than based on experimental confirmation.

There is definite interest in the comparison of the physicochemical properties of radiation grafted copolymers of the same composition which are obtained by different mechanisms, namely free-radical and ionic. Studies of this nature have been carried out in the systems PE–4-vinylpyridine, PE–AN, and PE–styrene.[163] On the thermomechanical curves of PE with 4-vinylpyridine and AN grafted on by a radical mechanism, the flow temperature of the copolymer occurred 17–20 K below that in samples grafted on by an ionic mechanism. Kabanov et al.[163] relate this difference to the higher molecular weight of chains grafted by an ionic mechanism and hence to a stronger interaction between the graft chains. The differential thermal analysis curves of graft copolymers of PE–polystyrene and PE–polyacrylonitrile obtained by different mechanisms do not reveal any significant differences.

In recent years there has been an increase in studies relating a determination of the characteristic of the fundamental stages of radiation polymerisation of monomers adsorbed on the surface of solids, their relationship to the nature of the adsorption of the reactants, and also with the structural features of polymer chains that are formed on the surface of a solid.[71,176–188] A detailed survey of studies on this topic published up to 1984 is given in a review.[71] A considerable number of the studies were conducted on systems with a "weak bond", for which the heat of absorption values were 30–90 kJ mol^{-1}. The adsorption itself is non-localised and reversible in nature and is characterised by a high monomer mobility. Silica (different samples of Aerosil) was used most frequently as the solid matrix and vinyl acetate or MMA were used as monomers. The experiments were carried out at a low concentration of adsorbed monomer, corresponding to one or two monolayers. The initiation rates, the lifetimes of the kinetic curves, and other kinetic parameters of the radical polymerisation of monomers on the surface of silica during radiation initiation were successfully determined in a series of studies.[176–182] The main difficulty was to make a reliable measurement of the initiation rate values and the lifetimes of the kinetic polymerisation chains. Three different methods were used to determine the initiation rates; the results of these are in quite good agreement with each other: 1) determination of the duration of the induction period of polymerisation when an effective non-adsorbing inhibitor such as gaseous oxygen is used: 2) a kinetic method based on the use of expressions from the theory of radical polymerisation which relate the average degree of polymerisation to the kinetic parameters of the process; 3) a method based on the determination of the number of resulting polymer molecules in systems with a low efficiency constant for non-degenerate chain transfer. The lifetimes of the kinetic polymerisation chains were determined from measurements of the length of the initial non-stationary temperature gradient, with the adiabatic temperature gradient method, which essentially involves measurement of the degree of heating of a sample from the heat evolved during polymerisation, being used most frequently.[177–180] Comparison of the kinetic parameters of the radiation polymerisation of vinyl acetate and MMA on the surface of Aerosil and methylated Aerosil containing no hydroxyl groups with the kinetic parameters of radiation liquid-phase polymerisation as reported by Bruk[71] showed that the rate constant for growth decreases approximately by a factor or ten on going from liquid-phase polymerisation to polymerisation on the surface, whereas the rate constant for quadratic termination decreases by a factor of more than 10^3. This results from the diffusion nature of the termination constant and the sharply reduced translational mobility of macroradicals on a surface compared with the gas phase.

On going to systems with a "strong bond", for which localised activated adsorption that is irreversible at room temperature is typical (for example, the adsorption of AA on aminated Aerosil, 4-vinylpyridine on carboxyethylated Aerosil and on Aerosil in the presence of water), as are values of the heat of adsorption of 100–200 kJ mol^{-1} and a low surface mobility of the monomers, a decrease in the rate of growth of chains was recorded because of the strengthening of the adsorptive bond between monomer molecules and the surface of the solid.[183]

A study of the principal mechanisms of radiation adsorptive polymerisation with an increase in thickness of the adsorption layer[184,185] revealed an extremal dependence of the rate of polymerisation on the thickness with a maximum at about four monolayers. It was shown that the rate of initiation decreased with an increase in filling while the rate constant of growth increased rapidly, reaching values typical for mass polymerisation in the region of five to seven monolayers. In a layer of thickness 10–15 monolayers, the rate constant of linear termination was similar to the constant typical for a monolayer, while the rate constant for quadratic termination was approximately 500 times less than that for mass polymerisation.

The conformational features of macromolecules formed by radiation adsorptive polymerisation have been studied.[186–188] It was shown that in systems with a "weak bond" graft macromolecules are formed in conformations that are considerably extended along the surface and can be represented by a model of two-dimensional bundles on the surface. The proportion of units of chains directly synthesised on the surface that are bound to the surface is usually 10–20% higher than in macromolecules adsorbed from solution.

---o0o---

In the summary of this review it may be concluded that definite progress has been achieved during recent years in the development of methods of radiation graft polymerisation, in studying the mechanism of the processes that occur, and also in the practical application of radiation grafting as a method for modifying polymer materials. At the same time the theoretical principles of improved properties of polymer graft materials have not been sufficiently developed. This mainly relates to the question of the dependence of the physicochemical properties of radiation grafted polymer materials on their structure, the most important component of which is the nature of the structural units formed by macromolecules of the graft polymer and the nature of their localisation in the matrix of the main polymer. In our opinion, in studying this question it is to be expected that fundamentally important new results relating to the solution of problems concerning the preparation of polymer materials with required physicochemical properties will be obtained.

Inhibitors of the lipoxygenase conversion of polyenoic acids

D A Zabolotskii, G I Myagkova, R P Evstigneeva
Lomonosov Moscow Institute of Fine Chemical Technology

ABSTRACT. In this reivew lipoxygenase inhibitors are classified and their inhibitory activity, mode of action, specificity, and chemical synthesis are examined. The future prospects for using them to study enzymatic conversions and the development of antiallergic and antiinflammatory drugs from them are discussed.

The bibliography includes 134 references.

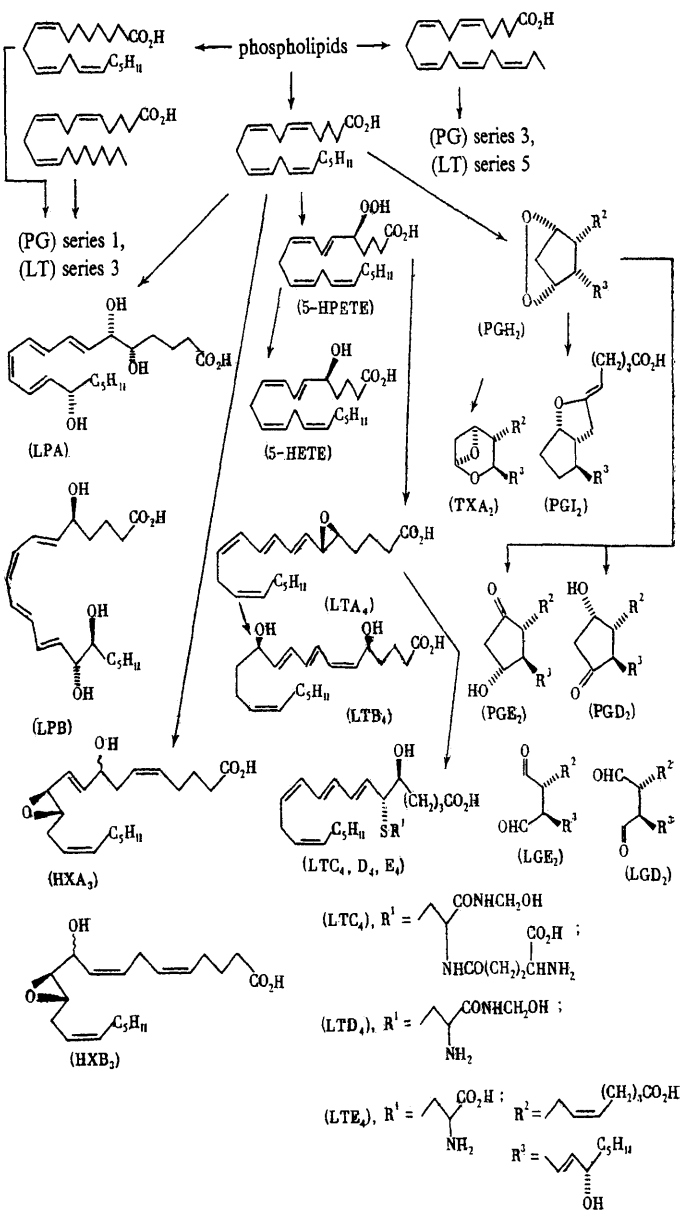
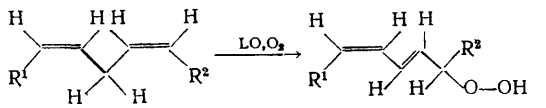
I. Introduction



Enzymatic oxidation of eicosapolyenoic acids—arachidonic (5*Z*,8*Z*,11*Z*,14*Z*-eicosatetraenoic), dihomo-γ-linolenic (8*Z*,11*Z*,14*Z*-eicosatrienoic), and timnodonic (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoic) acids—is of considerable interest for a number of reasons.

It forms the basis for the biosynthesis of a whole series of biologically active metabolites, such as prostaglandins (PG), thromboxanes (TX), leukotrienes (LT), lipoxins (LP), hepoxylins (HX), various hydroxy acids (HETE), etc. Moreover, this key reaction of lipid metabolism is interesting from the point of view of its mechanism, which appears to be unique and having no known analogues.



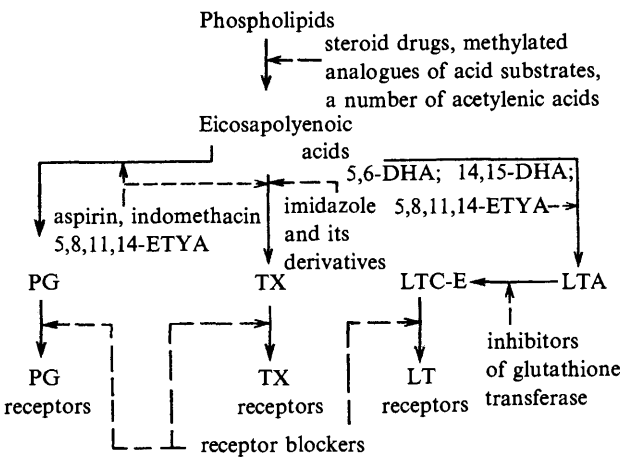
At the present time there are two enzymatic conversion routes of polyunsaturated acids that have been studied to a considerable extent. These are the cyclooxygenase route, in which the biosynthesis of prostaglandins, thromboxanes, prostacyclin (PGI_2), and also levuglandins (LG) takes place through the action of polyenzymatic complexes, and the lipoxygenase route, which results in the formation of acyclic metabolites such as leukotrienes and a number of hydroxy acids, including lipoxins, etc. (Scheme 1).

The mechanism of cyclooxygenase oxidation and cyclooxygenase metabolites have been studied and described in detail in the literature.[1–4] At the same time an active research programme continues on the lipoxygenase metabolism of polyenoic acids, in which the inhibitors of this process play a key role. In the present review the main consideration is given to inhibitors of the biosynthesis of lipoxygenase metabolites and their antagonists in relation to their biological activity and chemical synthesis.

Scheme 1

Lipoxygenases (LO) constitute a group of enzymes containing non-haeme iron that are widely distributed in animals and plants and which catalyse the oxidation of the 1*Z*,4*Z*-pentadiene structure in polyunsaturated fatty acids to a 1-hydroperoxy-2*E*,4*Z*-pentadiene structure:

Lipoxygenase oxidation of polyenoic acids can in principle occur at $2n-2$ carbon positions, where n is the number of *Z*-methylene-separated double bonds. The lipoxygenases known at the present time include 5-LO, which takes part in the biosynthesis of leukotrienes (leucocytes, potato), 8-LO (corals, soybeans), 12-LO (platelets, RBL, PMNL)† and 15-LO (reticulocytes, endothelial cells, soya beans).[5,6]



The interest in lipoxygenase metabolites arises because they play a key role in allergic and inflammatory processes. Thus, peptidoleukotrienes (LTC_4, LTD_4, LTE_4) are powerful stimulators of the contraction of smooth muscle, being 10^2-10^3 times more active than histamine.[7] Leukotriene B_4 is an active chemically toxic agent for polymorphonuclear leucocytes, which also causes an increase in vascular permeability and assists the migration of cells and plasma into extravascular space.[7] An important physiological role is apparently played by lipoxins, which stimulate the elimination of the superoxide anion and regulate the immune activity of lymphocytes[8,9] and by hepoxylins, which are potential natural regulators of insulin release.[10]

Research into lipoxygenase oxidation of polyenoic acids will contribute to a better understanding of the physiological role of acyclic eicosanoids and the pathogenesis of the disorders caused by them. A promising approach to the resolution of this problem is the use of inhibitors of the enzymatic conversion of acid substrates in order to study its mechanism. The search for new inhibitors of enzymes in the arichidonic acid cascade is also related to the development of antiallergic and antiinflammatory drugs from them and is therefore of direct practical interest.

II. Inhibition of enzymatic oxidative conversion of polyenoic acids

The release and enzymatic conversion of the precursor acids to their metabolites and the occurrence of biological activity of the latter constitute a complex, interrelated multistage process, which can be controlled at different points (Scheme 2).

Scheme 2

DHA = dehydroarachidonic acid;
ETYA = eicosatetraynoic acid.

Thus, steroid drugs block the release of eicosapolyenoic acids by inhibiting phospholipase A_2, hence preventing any further stage of their enzymatic conversions.[11,12] Well-known inhibitors of the biosynthesis of cyclic eicosanoids are aspirin and indomethacin.[13,14] Disruption of the balance of acid substrates by these compounds results in an increase in the synthesis of leukotrienes.[15] Imidazole and its derivatives have the ability to suppress selectively the synthesis of TXA_2.[16-18] Inhibitors of the enzymatic conversion of polyunsaturated acids that are of considerable interest are compounds which are close to them in structure, including their acetylene analogues[19-31] and acids modified in various ways on the methylene groups[32-34] and carbon skeleton.[35-39]

The regulation of the biological effects caused by eicosanoids can also be achieved through the use of receptor blocking agents such as analogues of PG, TX, LT, and other metabolites,[40-43] which act as their antagonists.

However, Scheme 2 is far from complete in its representation of the problem of pharmacological regulation of the pathway of arachidonic and other eicosapolyenoic acids. Thus, we have a series of enzymatic reactions in which the analogue of a substrate of one enzyme is at the same time the analogue of the product of another enzyme. Therefore, the same compound can act as an inhibitor of different enzymes in the pathway, exhibiting a variable specificity and activity.

As the enzymatic conversion of acid substrates and their metabolites is, in effect, oxidation with oxygen, many antioxidants that act as its inhibitors have been reported.[44-46]

Compounds which are capable of forming chelate complexes with the iron that forms part of the active site of lipoxygenases constitute an important group.[47-49]

Many nitrogen-containing compounds, such as benzene derivatives with nitrogen-containing substituents, nitrogen monocyclic and condensed heterocycles are also known to be inhibitors of enzymes of the arachidonic acid pathway.[50-52]

Thus, at the present time many inhibitors of the oxidation of eicosapolyunsaturated acids have been obtained with different structures and acting at different points of the enzyme pathway,

† RBL = rat basophile leukaemia cells; PMNL = polymorphonuclear leucocytes.

from the release of acid precursors to metabolic reactions of the eicosanoids themselves.

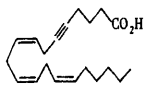
Lipoxygenase inhibitors are valuable agents used to study the functioning of these enzymes, to establish their substrate specificity, the structure of the active site, the nature of the catalytic act, etc. In turn, an understanding of these processes makes it possible to design effectively the structures of compounds which could be used as potential antiallergic and antiinflammatory drugs.

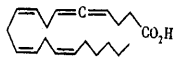
III. Different classes of lipoxygenase inhibitors

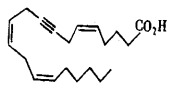
1. Analogues of polyenoic acid substrates

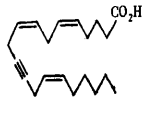
An important class of inhibitors of the enzymatic oxidation of natural eicosapolyenoic acids is made up by compounds that are similar to them in structure. These analogues of acid substrates can bind to the active site of the enzyme, but they either cannot be converted to biologically active metabolites (because of particular structural features), resulting in competitive inhibition, or they deactivate the active site of the enzyme, eliminating its capacity to convert natural substrates. At the present time various eicosapolyunsaturated compounds, acids containing triple or cumulated double bonds,[53,54] with methylene groups replaced by heteroatoms (sulphur),[32,33] or modified in a particular way on the carbon skeleton,[35–39] have been synthesised and studied as lipoxygenase inhibitors.

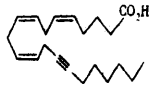
Table 1. Acetylene and allene analogues of acid substrates.

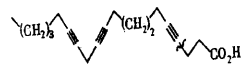


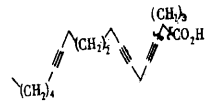












Name	Structural formula	Inhibitory activity	Refs.
5,8,11,14-eicosatetraynoic acid (5,8,11,14-ETYA) (I)		Cyclooxygenase (CO), 5-LO, 12-LO 15-LO	[19—24]
4,7,10,13-eicosatetraynoic acid (4,7,10,13-ETYA) (II)		12-LO	[24, 25]
5,6-dehydroarachidonic acid (5,6-DHA) (III)		5-LO	[53, 54]
4,5-dehydroarachidonic acid (4,5-DHA) (IV)		5-LO	[53, 54]
8,9-dehydroarachidonic acid (8,9-DHA) (V)		weak CO inhibitor (IC_{50} = 50 μM)	[28, 29]
11,12-dehydroarachidonic acid (11,12-DHA) (VI)		CO	[28, 29]
14,15-dehydroarachidonic acid (14,15-DHA) (VII)		15-LO, CO	[28, 29]

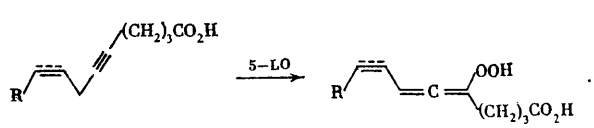


Table 1 (cont'd).

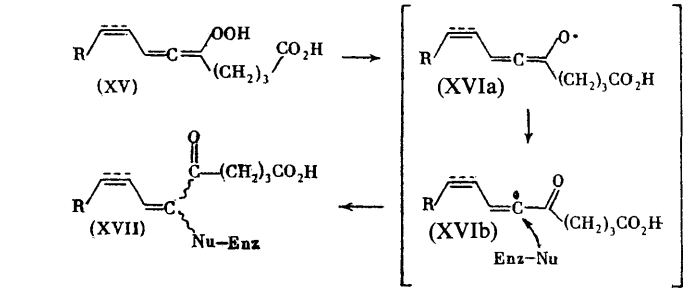
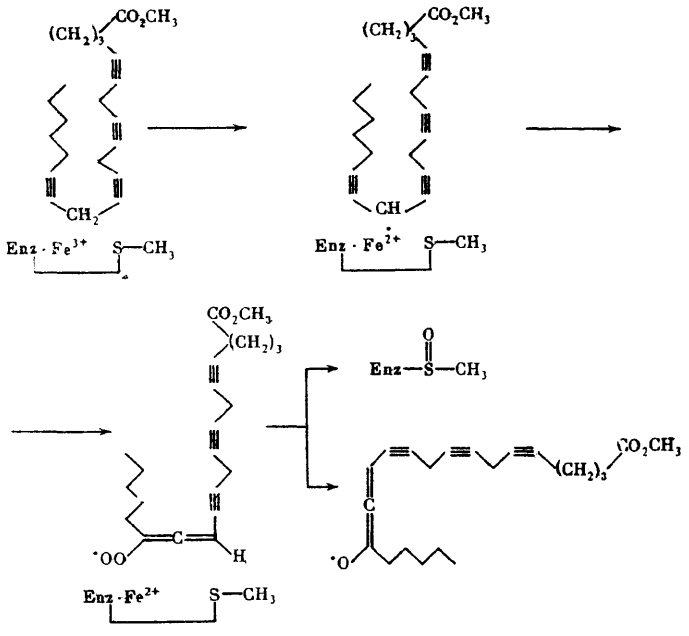
Name	Structural formula	Inhibitory activity	Refs.
5,11,14-eicosatriynoic acid (VIII)		12-LO	[30]
5,8,14-eicosatriynoic acid (IX)		12-LO	[30]
5,8,11,14-heneicosatetraynoic acid ($C_{21:4}$)** (X)		12-LO	[24]
4,7,10,13-heneicosatetraynoic acid ($C_{21:4}$) (XI)		glutathione transferase	[31]
4,7,10,13-nonadecatetraynoic acid ($C_{19:4}$) (XII)		glutathione transferase	[31]
6,9,12,15-docosatetraynoic acid ($C_{22:4}$) (XIII)		12-LO	[25]
7,10,13,16-docosatetraynoic acid ($C_{22:4}$) (XIV)		12-LO	[25]



* IC_{50} is concentration of inhibitor producing a 50% loss of enzymatic activity.



** In $C_{n:m}$ n denotes the number of carbon atoms and m the number of multiple (triple) bonds.

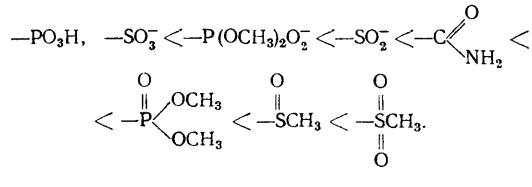
A considerable amount of experimental material on the ability of acetylenic and allenic acids to inhibit enzymes of the arachidonic acid pathway has been collected. The first reports about the inhibitory activity of 5,8,11,14-eicosatetraynoic acid—the acetylene analogue of arachidonic acid—were published in the 1960s.[13] During the following years a considerable amount of work was carried out by different groups of research workers on the synthesis of similar acetylenic fatty acids, some of which as was demonstrated, proved to be selective inhibitors of different lipoxygenases (Table 1).[19–31] Many authors studied the mechanism of inhibition of 5-lipoxygenase by acetylenic acids (5,6-DHA, etc.),[26] which involves the formation of an allenic hydroperoxide as an intermediate:

The unstable allenic hydroperoxide resulting from oxidation of the inhibitor decomposes to form free radicals which irreversibly deactivate the active site of the enzyme. However, different opinions about the exact nature of this step have been advanced. Thus, some authors[7,55,56] maintain that homolysis of the intermediate (XV) results in an active radical product which is attacked by a nucleophile of the active site of 5-lipoxygenase to form a covalent acid–enzyme bond.

Thus, Rapoport et al.[21] regard the deactivation of 15-LO by 5,8,11,14-ETYA as a process that is completely analogous to the deactivation of this enzyme by its reaction product—the hydroperoxy acid—but with the important distinction that deactivation with the acetylenic acid results from each act of substrate conversion.

It should be pointed out that both schemes put forward are based on the formation of the vinyl hydroperoxide (XV), which accords well with the fact that 4,5-dehydroarachidonic acid (4,5-DHA)—the allenic isomer of 5,6-DHA—is a powerful inhibitor of 5-LO.[53,54]

Deactivation of lipoxygenases with acetylenic and allenic acids depends on the time of incubation with the inhibitor and is irreversible, since neither strong dilution of the given system nor subsequent addition of excess substrate (50:1) could regenerate the activity of the enzyme.[21]

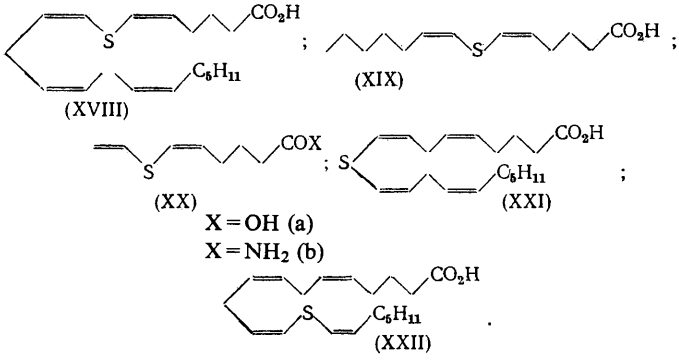


The effect of acetylene analogues of natural fatty acids as inhibitors and their specificity are determined by the number and position of double bonds. In spite of the obvious differences in the steric structure of acid substrates and the polyynoic acids that correspond to them,[50] replacement of particular double bonds leads, as a rule, to inhibition of the enzymatic conversion precisely at those positions. Thus, an obvious disadvantage of 5,8,11,14-ETYA (I) is its lack of specificity since it deactivates both cyclooxygenase and a number of lipoxygenases to approximately the same degree.[30]

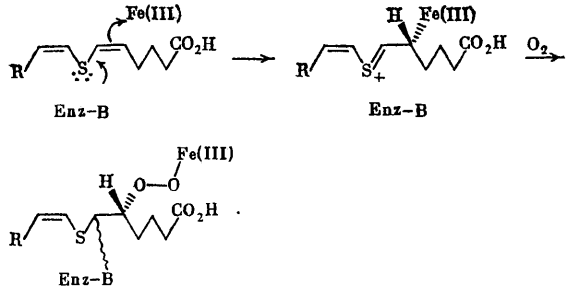
At the present time a number of tetraynoic acids have been synthesised with a different configuration of triple bonds to that in natural acids and a different number of carbon atoms, and they exhibit considerable selectivity.[24,25] Thus 4,7,10,13-eicosatetraynoic acid (II) and 5,8,11,14-heneicosatetraynoic acid (X) inhibit the 12-lipoxygenase oxidation of arachidonic acid to 12-HPETE without any significant effect on the cyclooxygenase oxidation to TXB_2 in human platelets.[24] The IC_{50} values relating to 12-lipoxygenase and cycloxygenase were determined experimentally for 4,7,10,13-ETYA, being 7.8 μM and 100 μM respectively.[25] Evidently acids (II) and (X) can serve as selective modulators of 12-lipoxygenase oxidation in platelets and other tissues.

Other polyynoic acids have also been synthesised, in particular 6,9,12,15-docosatetraynoic acid (XIII) and 7,10,13,16-docosatetraynoic acid (XIV), which fairly selectively inhibit 12-LO (IC_{50} CO/IC_{50} LO is 336.8 for (XIII) and 333.3 for (XIV).[25] It is not excluded, however, that the mechanism of the action of acetylenic acids (II), (X), (XIII), and (XIV) is different to that for 5,8,11,14-ETYA. Thus, according to the results of Corey,[31] 4,7,10,13-heneicosatetraynoic acid (XI) and 4,7,10,13-nonadecatetraynoic acid (XII) block the formation of SRS (slow reacting substance) by inhibiting glutathione transferase, namely, at a later stage of biosynthesis.

Thus, these acetylenic and allenic inhibitors act as irreversible inhibitors of the enzymatic conversion of natural polyenoic acids to their metabolites, since they act as suicide substrates, the oxygenation of which is related to an irreversible loss of enzymatic activity.



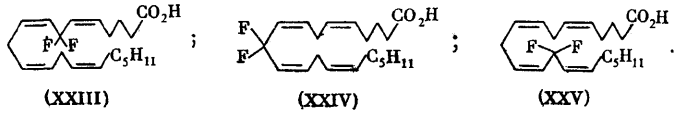
Polyunsaturated acids can be incorporated into the phospholipids of cell membranes, which considerably reduces their activity as inhibitors of lipoxygenase oxidation *in vivo* since phospholipids are not lipoxygenase substrates. A number of analogues of 5,6-DHA (III) containing functional groups other than a carboxyl group have been obtained. The rate of deactivation of 5-LO during aerobic incubation increased in this case according to the following series:



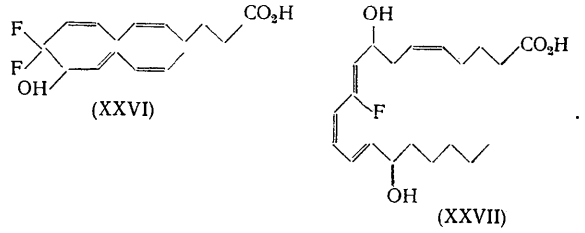
In the opinion of Corey et al.,[26] the inhibition of 5-LO by these 5,6-DHA derivatives indicates that the presence of an anionic group such as carboxyl is not absolutely essential for the binding of acid with enzyme.

Since the mechanism of the catalytic action of lipoxygenases involves the elimination of a hydrogen atom from a bis-allyl methylene group [C(7), C(10), C(13) for arachidonic acid] as the first stage, modification of these positions, making this stage of enzymatic catalysis impossible, opens up extensive possibilities for the development of competitive and non-competitive inhibitors that have the structure of acid substrates with modified methylene groups. This type of modification can be achieved either through the introduction of heteroatoms (sulphur)[32,33] at this position or by replacement of the hydrogen atoms that are prone to elimination with different substituents,[21] and also by converting them into part of ring systems.[38,39,57,58]

In 1985 a series of polyenoic acids containing sulphur atoms at the positions of primary attack by an enzyme of physiological substrates was synthesised by Corey et al.[31–33] and studied as potential inhibitors. It was shown that incubation of 5-LO from RBL-1 with compounds (XVIII)–(XX) leads to the irreversible deactivation of the enzyme, with deactivation showing a dependence on time.

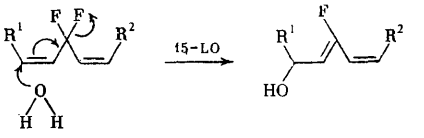


A mechanism for the inhibition of 5-LO by acids (XVIII)–(XX) has been put forward.[32] These compounds do not contain a proton that can be eliminated at the 7-position, but the electron-donating capacity of the thiadivinyl residue, according to Corey et al.,[32] is sufficiently high for direct electron transfer to Fe(III) on the active site of the enzyme to be able to occur, and oxidation can subsequently take place:



The intermediate formed by oxidation is attacked by the proton-acceptor B^- in the active site, resulting in covalent bonding of the inhibitor[32,33] and is the cause of the irreversible deactivation of the enzyme. The effect of thia-acids (XVIII)–(XX) on cyclooxygenase (isolated from rat testes) was also studied, from which acids (XVIII)–(XX) exhibited properties of competitive inhibitors.[32]

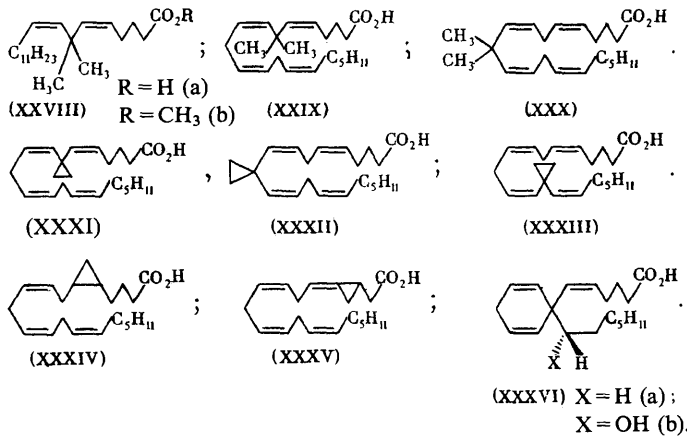
Corey et al.[33] also described the syntheses by 10-thiaarachidonic acid (XXI) and 13-thiaarachidonic acid (XXII). In accordance with the proposed mechanism, it would be reasonable to expect that 13-thia-acid (XXII) would be an irreversible inhibitor of 15-LO. This assumption was confirmed experimentally for 15-LO,[31] which is also fully consistent with the mechanism and substrate specificity of the enzyme.



The difluoro analogues of arachidonic acid (XXIII)–(XXV) were also studied as inhibitors that are modified on the bis-allyl methylene group:[34,59]

It would be logical to expect from the similarity of the van der Waals radii of hydrogen and fluorine that compounds (XXIII)–(XXV) would be either substrates or (because of the inability of the enzyme to cause homolytic cleavage of the C–F bond) specific competitive inhibitors of different LOs. 10,10-Difluoroarachidonic acid (XXIV) was studied as a substrate of cyclooxygenase and 15-lipoxygenase of soybeans.[59] In the first case acid (XXIV) was converted to 10,10-difluoro-11-HETE (XXVI) and 10-fluoro-8*S*,15*S*-di-HETE (XXVII). Cyclisation to a PG did not occur. Incubation of the same acid with soybean 15-LO resulted in the formation of 10-fluoro-8*S*,15*S*-di-HETE (XXVII):

A mechanism of general base-catalysed substitution for the formation of HETE (XXVI) and (XXVII) has been proposed, the driving force of which is formation of a stable fluorodiene system:[59]



No studies on acids (XXIII) and (XXV) as inhibitors of 5-LO and 15-LO were carried out.[59]

This approach to the development of inhibitors also involves the modification of the carbon skeleton of acid substrates, for which a clear dividing line cannot always be drawn between modification of just methylene groups and more general structural changes.

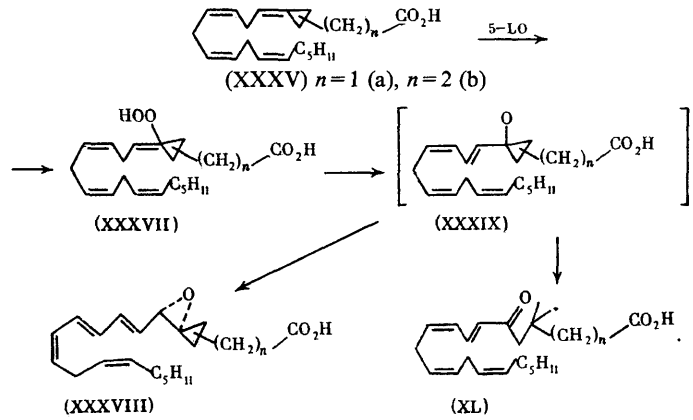
Many analogues of arachidonic acid have been synthesised, in which the methylene positions, which are subject to attack in the natural acids, are either blocked with alkyl substituents or form part

of cyclic cyclopropane structures, and prove to be competitive lipoxygenase inhibitors [compounds (XXVIII)–(XXXIII)].

Acid (XXVIIIa) at a concentration of 50 μM inhibited 5-LO of human RBL-1 and PMNL cells by 43% and 26% respectively. Its methyl ester was somewhat more active, inhibiting the same enzyme by 74% and 50% respectively.[36] The action of this inhibitor was selective, since at this concentration there was no inhibition of either 12-LO or cyclooxygenase.[36]

gem-Dimethyl derivatives of arachidonic acid (XXIX) and (XXX) also proved to be fairly weak inhibitors of 5-LO (Table 2). However, all of the acids (XXVIIIa)–(XXX) were powerful inhibitors of LT biosynthesis.[23]

Table 2. Inhibitory activity of *gem*-dimethyl analogues of arachidonic acid.[37]



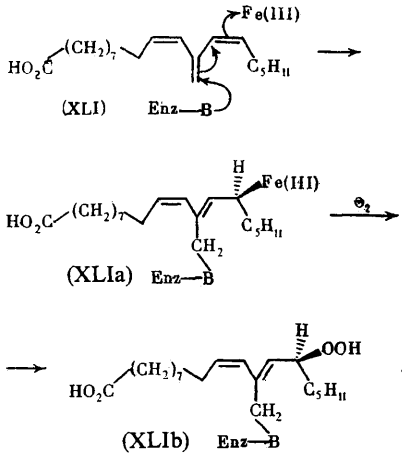
Compound	Inhibition of biosynthesis, % at 10 μM	5-LO inhibition, % at 100 μM	Cyclooxygenase IC_{50}, μM	Phospholipase A_2, %
(XXVIIIa)	100	56	1000	100 (14)
(XXIX)	100 (1–3)	66 (68)	225	100 (14)
(XXX)	98	42	13	100 (14)

Note. IC_{50} values given in brackets.

Thus, it is thought that compounds (XXVIII)–(XXX) block the formation of LT mainly by inhibition of phospholipase A_2 rather than inhibition of 5-LO.[37]

In the opinion of Nicolaou et al.[38,39] by blocking the bis-allyl positions of eicosapolyenoic acids through the introduction of an ethano group in the form of a cyclopropane ring, it is possible not only to achieve the purpose in hand but also to increase the rigidity and stability of the carbon skeleton of arachidonic acid and hence provide a higher biological activity.[38] Studies on the inhibitory activity of ethanoarachidonic acid have been carried out.[39] It was shown that 7-ethanoarachidonic acid (XXXI) is a weak inhibitor of 5-LO (34% inhibition at 100 μM).[60]

A number of methylenecyclopropane analogues of arachidonic acid (XXIV) and (XXXVa) have been synthesised.[57,60] It is assumed that acids (XXXVa) and (XXXVb) can be converted by 5-LO to the HPETE-type hydroperoxide (XXXVII), which can deactivate the enzyme in different ways:[57]



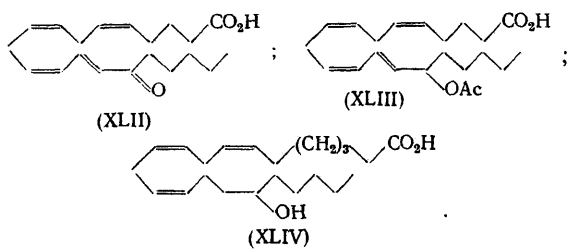
Enzymatic dehydrogenation results in the formation of the reactive oxaspiropentane analogue of LTA_4—(XXXVIII). The additional strain in the carbon skeleton introduced by the cyclopropane ring and the additional cyclopropylcarbinyl stabilisation of the carbonium ion formed by scission of epoxide (XXXVIII) result in the formation of an intermediate at the active site of the enzyme which can bind to nucleophiles contained in it. The alternative conversion of hydroperoxide (XXXVII) to the intermediate (XXXIX) by a homolytic mechanism gives enol (XL) by fragmentation of the cyclopropane ring. Enol (XL) can also irreversibly deactivate the enzyme by binding to a nucleophile.[57] By comparing the ability of compounds (XXXVa) and (XXXVb) to inhibit the synthesis of leukotrienes it would also be possible to determine the preferred conformation of the acid substrate for binding to the enzyme, since these compounds may be regarded as conformers of the C(1)–C(4) carboxyl chain of arachidonic acid that are fixed in a given orientation relative to the 5,6-double bond.[29] Acid (XXXIV) was shown to be inactive as an inhibitor of 5-LO.

By analogy with the *gem*-dimethyl[35,36] and cyclopropane[38,39,57,60] analogues of eicosapolyenoic acids, the 1,1-disubstituted 2,5-cyclohexadienes (XXXVIa) and (XXXVIb) have also been proposed.[58]

Compound (XXXVIa) inhibited 5-LO from RBL-1 (IC_{50} = 120 μM) and inhibited cyclooxygenase to a lesser degree (IC_{50} = 150 μM). By introducing a hydroxyl group on to C(15) it was possible to increase significantly the activity of this structure as an inhibitor of 5-LO (IC_{50} = 6 μM) while its activity towards cyclooxygenase remained unchanged.

In 1986, 12-methylidene-10*Z*,13*Z*-nonadecadienoic acid (XLI), an irreversible inhibitor of soybean 15-lipoxygenase, was synthesised.[31,61] Incubation of acid (XLI) with the enzyme resulted in a time-dependent deactivation. The kinetic characteristics were similar to those in the incubation of 13-thiaarachidonic acid (XXII) and soya bean 15-LO.[61]

The following mechanism of deactivation has been proposed:

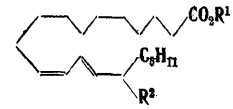


In Corey's opinion[31,61] the activity of this inhibitor is also due to the absence of oxygen that can be eliminated while at the same time there is the ability to be activated on the active site to form intermediates that attack and form covalent bonds with certain functional groups of the active site.

2. Analogues of lipoxygenase metabolites

In addition to the development of various modified acid substrates, a rational approach to the question of obtaining lipoxygenase inhibitors is the use of analogues of lipoxygenase metabolites (leukotrienes, hydroxy acids, etc.).

Thus, in 1980 Vanderhoek et al.[63] reported that 15-hydroxyeicosatetraenoic acid (15-HETE) acts as an inhibitor of 5-LO [62] and 12-LO.[63] These findings served as a basis for the development of a whole class of lipoxygenase inhibitors.

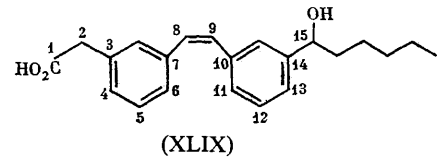


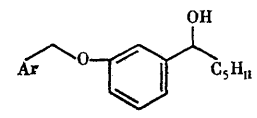
With the aid of three-dimensional computer models, a number of 15-HETE analogues were selected, synthesised, and tested for biological activity:

All modifications directly to the 15-hydroxy group resulted in a reduction of activity. Thus, the 15-keto (XLII) and 15-acetoxy (XLIII) analogues had an IC_{50} (RBL-1, 5-LO) of 26 and 17 μM respectively compared to 7.3 μM for 15-HETE. Extension of the carbon chain by 2 atoms [compound (XLIV)] also reduced the activity.

It was established that 15-HETE analogues that contain a 5*Z*,8*Z*-diene system inhibit 5-LO, by acting as alternative substrates.[64] Research was then initiated on inhibitor compounds that were devoid of this structure. The prototype of this series — 15-hydroxy-11*Z*,13*E*-eicosadienoic acid (15-HEDE) — is a comparatively weak inhibitor (IC_{50} = 26 μM).[64]

Table 3. Inhibitory activity of 15-HEDE derivatives.[64]

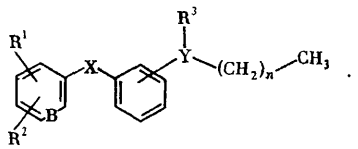




Compound	R^1	R^2	IC_{50}, μM
(XLV)15 *S*	OH	OH	26
(XLVI)15 *S*	OH	OAc	76
(XLVII)	OH	=O	55
(XLVIII)	OH	H	73

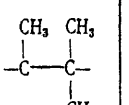
The stereochemistry of the 15-hydroxy group does not appear to be important for inhibition since the natural *S*-isomer and racemic 15-HEDE [64] showed no difference in activity (Table 3). Acetylation and oxidation of the hydroxy group reduced the activity by a factor of 2–3.[64]

Thus, research into 15-HEDE analogues did not yield any active inhibitors of 5-LO, but it confirmed the possibility that the inhibitory activity of compounds lacking the 1*Z*,4*Z*-pentadiene structure that is typical for lipoxygenase substrates would be retained.[60] It was shown that although there are certain structural features in the analogues of 15-HETE and 15-HEDE (the presence of a free carboxyl group, the length of the carboxyl- and ω-chains, the absence in the latter of polar groups, etc.), no single part of the molecule plays a decisive role in determining inhibitory activity.[64] These findings indicate, according to Haviv et al.,[64] that there are many sites for binding of these inhibitors to an enzyme.

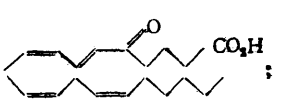


By using three-dimensional computer models of 15-HETE, it was possible to establish the potential application of analogues in which the 11*Z*,13*E*-double bonds were replaced by a benzene ring:[65]

Replacement of the 5- or 8-double bond [compounds (XLIX) and (L) respectively], which involves the formation of a C(3)–C(7) bridge (XLIX) and the introduction of an ether bond at C(8)–C(9) (L) with retention of a good isosteric conformity with 15-HETE is



less apparent.[65] On the basis of the stereochemical arguments presented by Musser et al.,[65] 54 compounds with the general structure (LI) were synthesised:



(LI)

All of the compounds with structure (LI) were tested as inhibitors of 5-LO from rat neutrophiles (Table 4). The most active inhibitors were compounds (LIa) and (LIb) (IC_{50} of 0.12 and 0.13 μM respectively).

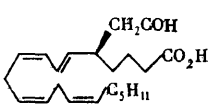


Table 4. Inhibitors (LIa) and (LIb).[65]

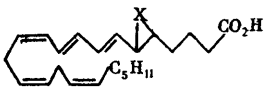
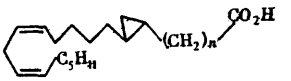
Compound	R^1, R^2	B	X	Y	R^3	*h*
(LIa)		N	CH_2O	$-CH_2CH_2-$	OH	3
(LIb)		N	CH_2O		OH	3

The inhibition of 5-LO by the following 5-HETE analogues has been reported:[66]



(LII)

(LIII)

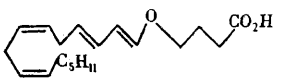


Both compounds are inhibitors of 5-LO from guinea pig PMNL (the second being very weak), with IC_{50} of 20 μM (LII) and 100 μM (LIII).

A number of analogues of LTA_4 which can inhibit 5-LO have been synthesised.[66–69] The carbon analogue of LTA_4—(LIVa)—is an active inhibitor of 5-LO (IC_{50} = 3 μM).[68] Other cyclopropane analogues which differ according to the length of the carbon chain have been reported.[7,66] The position of the cyclopropane ring affects the inhibitory activity of the compounds much less than the presence and position of multiple bonds.[66] The IC_{50} values of compounds (LV) and (LVI) were 20–30 μM, while saturation of the double bonds results in an almost inactive product (LVII) (IC_{50} = 100 μM).

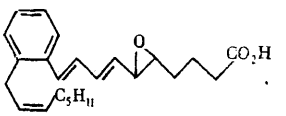
(LIV)
X = CH_2 (a)
X = S (b)
X = NH (c)

;



(LV), *n* = 2;
(LVI), *n* = 4.

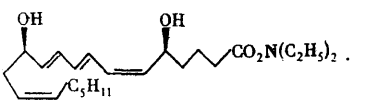
(LVII)



The thio analogue of LTA_4—(LIVb)—is a weak inhibitor of 5-LO (IC_{50} = 65 μM).[66] The synthesis of the aziridine (LIVc) has been reported but its biological activity is not mentioned.[69]

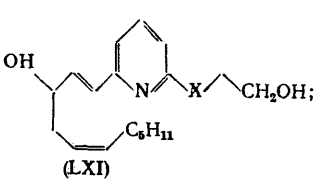
In addition, (LVIII) and (LIX)—two LTA_4 analogues with a modified carbon skeleton—have been synthesised.

(LVIII)



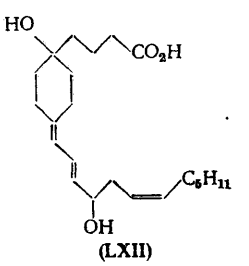
;

(LIX)

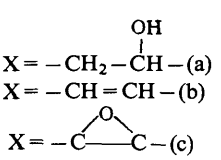


It is thought that their activity is due to the impossibility of opening the epoxide ring because of the modified structure, which excludes their subsequent conversion to LTB_4 and the peptidoleukotrienes LTC_4, LTT_4, and LTE_4.[70]

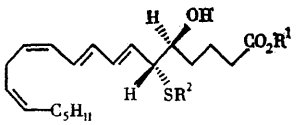
LTB_4 analogues that act as inhibitors of 5-LO have not been prepared up to the present time. Antagonists of LTB_4 have been reported. The LTB_4 diethylamide (LX) inhibits the degranulation of neutrophiles caused by LTB_4 at concentrations of 10^{-6}–10^{-7} M.[7]



(LX)



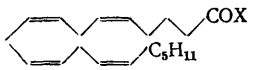
A number of stereoisomers of LTB_4, such as 15*S*,12*S*-di-HETE, proved to be capable of inhibiting 5-LO from PMNL.[71] A number of ring-containing analogues of LTB_4 have been reported; (LXI) [72] and (LXII)[73] act in competition to LTB_4.



(LXI)

(LXII)

Only a few peptidoleukotriene analogues that inhibit 5-LO are known.[74] However, the absence of a common method for determining the activity of 5-LO led Japanese research workers[74] to the conclusion that the activity of compounds with the general structure (LXIII) may in fact be due to their inhibition of glutathione transferase.

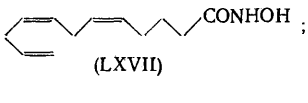


(LXIII) $R^1 = H, CH_3$; $R^2 = CH_2C_6H_5, C_3H_7$, iso-C_4H_9.

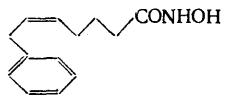
3. Compounds which form chelate complexes with Fe(III)

The enzyme mechanism of the lipoxygenase reaction is associated with the presence of iron [Fe(III)] at the active site of the enzyme.[67,75] These findings formed the theoretical basis for the synthesis of different eicosapolyenoic acid derivatives and compounds of a different structure that can form chelate complexes with Fe(III), hence deactivating the enzyme.

An additional argument to support the key role of iron in the act of catalysis is the theory put forward by Corey[76,77] concerning the formation of an organoiron intermediate with the substrate at the active site of the enzyme.

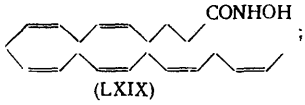


The first compounds to be studied as inhibitors of this type were hydroxamates of arachidonic acid, which are ligands capable of coordinating with Fe(III) ions ($K_{assoc} = 10^{-12}$). The K_m values were consistent with competitive inhibition.[78] However, not one of these compounds (LXIV)–(LXVI) acts as a substrate of 5-LO, although they are some of the most powerful inhibitors of it. Thus, the EC_{50}‡ values for these compounds are 2.2, 0.3 and 0.2 μM respectively:[78]

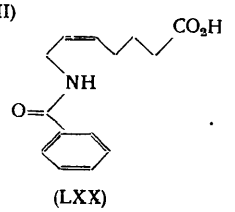


(LXIV), X=NHOH; (LXV), X=N(CH$_3$) OH,
(LXVI), X = N (t-C$_4$H$_9$)OH.

It is the hydroxamate groups which are thought to be responsible for bonding with the ferric ions participating in the catalytic cycle, so that the presence of the complete carbon skeleton of eicosapolyenoic acids is not absolutely essential for inhibitors of this type.[78,79]

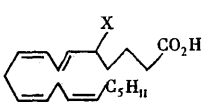


This is supported by the fact that compounds (LXVIII)–(LXX) (obtained by total synthesis) are very powerful inhibitors of 5-LO (EC_{50} = 1.9 μM).[78]

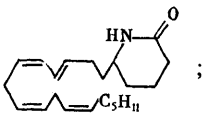


(LXVII)

(LXVIII)



(LXIX)

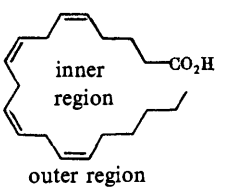


(LXX)

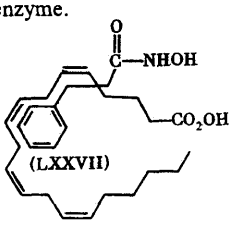
‡ EC_{50} is the effective concentration of inhibitor that produces a 50% loss of enzyme activity.

The 5-hydroxyamates of 6*E*,8*Z*,11*Z*,14*Z*-eicosatetraenoic acid were subsequently synthesised and tested as inhibitors of 5-LO:[80,81]

(LXXI), X = CONHOH;
(LXXII), X = CH_2CONHOH;
(LXXIII), X = NNHCONH$_2$;
(LXXIV), X = NNHCSNH$_2$;
(LXXV), X = SH.



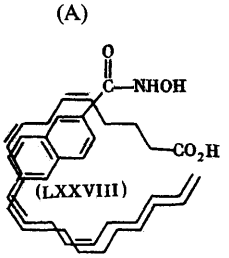
(LXXVI)



Thus, compounds (LXXI) and (LXXII) proved to be powerful inhibitors of 5-LO in a supernatant of homogenised RBL-1 cells (IC_{50} = 1.4 and 0.19 μM respectively).[80] Hydroxamate (LXXII) is over ten times more active than the arachidonic acid hydroxamate (LXIV) (IC_{50} = 0.19 and 2.2 μM respectively).[80,81] Thus, transfer of the hydroxamate functional group to the C(5) position considerably increases the ability to chelate with ferric ions. The effect of replacing the hydroxamate functional group by others was also studied, taking into account the possibility that they could interact with the active site of the enzyme in addition to chelation with Fe(III).[81] The most active of these proved to be the semicarbazide (LXXIII), thiosemicarbazide (LXXIV), the thiol (LXXV) (IC_{50} = 7.0, 7.9, and 7.6 μM respectively). The cyclic lactam (LXXVI) also proved to be an active inhibitor, being three times more active (IC_{50} = 10.0 μM) than its linear analogue.[81]

However, although the compounds reported by Corey et al.[78,80,81] are extremely active inhibitors of 5-LO, it is unlikely that they could be of therapeutic use.[79] As analogues of arachidonic acid they would tend to undergo chemical oxidation and would be rapidly degraded *in vivo*. Therefore, there is considerable interest in more stable hydroxamates with quite a simple structure,[79] which nevertheless retain the high activity which was demonstrated for the arachidonic acid analogues described above.

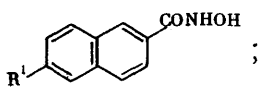
The approach of Summers et al.[79] is based on a selection of compounds that can effectively bind to the active site, which may be regarded as consisting of non-haeme Fe(III), a hydrophobic region, and a section for bonding of the carboxyl group of the substrate,[82] because of the correspondence of their structure to the conformation of arachidonic acid bound to the enzyme.



(A)

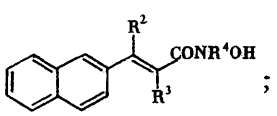
(LXXVII)

(B)



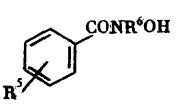
(LXXVIII)

(C)

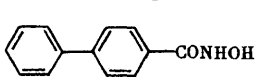


The hypothetic conformation (A) of arachidonic acid at the active site[22,79] is shown above together with the "superposition" of simpler aromatic hydroxamates on it in (B) and (C). It is clear that in case (C) the "superposition" is considerably more precise, which is in agreement with the experimental results.[79] In selecting inhibitors, the authors have attempted, other conditions being equal, to give preference to those compounds and their isomers which occupy the volume in the inner region to a lesser extent.

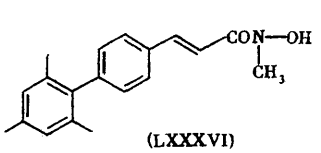
ω-Phenylalkyl- and ω-naphthylalkyl-hydroxamates were studied as inhibitors of this type (sources of enzyme activity—supernatant RBL-1), and the latter were, as a rule, more active,[79] which is consistent with a greater affinity of the enzyme towards more lipophilic compounds. The introduction of a methylene group between the benzene ring and the carboxyl group increased the activity of the compounds. A study of the effect of substituents in the aromatic systems showed that derivatives with electron-withdrawing groups are more active. Any modification of the hydroxamate function (apart from methylation) reduce the activity of the inhibitors.[79]



Thus, it was shown that even compounds with a simple structure that contain the hydroxamate group can be powerful inhibitors of 5-LO:



(LXXIX), $R^1 = O(CH_2)_3CH_3$;
(LXXX), $R^1 = O(CH_2)_2CH{=}CH(CH_2)_4CH_3(Z)$;



(LXXXI), $R^2 = CH_3$, $R^3 = H$, $R^4 = CH_3$,
(LXXXII), $R^2 = H$, $R^3 = H$, $R^4 = Ph$;

(LXXXIII), $R^5 = p$-(1-naphthyl);
$R^5 = p$-(2,4,6-trimethylphenyl);

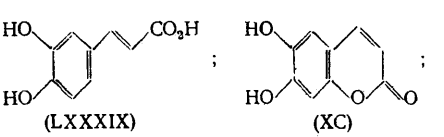
(LXXXV)

(LXXXVI)

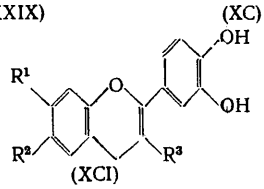
Compound	(LXXIX)	(LXXX)	(LXXXI)	(LXXXII)	(LXXXIII)	(LXXXIV)	(LXXXV)	(LXXXVI)
IC_{50}, μM	6.5	2.9	0.12	0.052	0.18	0.29	0.41	0.022

Compound (LXXXVI) is one of the most active inhibitors of 5-LO to be studied.[78,79]

Sulphur-containing polyunsaturated acids can also be grouped with inhibitors that chelate with iron.[48] In the opinion of Funk et al.,[48] the effect of these compounds is derived from a similarity in their structure to substrates of LO as well as their ability to chelate with Fe(III):



(LXXXVII)



(LXXXVIII)

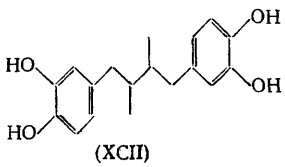
13-Thia-9*Z*,11*E*-octadecadienoic acid (LXXXVII) and 13-thia-9*E*,11*E*-octadecadienoic acid (LXXXVIII) were tested as inhibitors of soybean 15-LO and they exhibited the properties of competitive inhibitors.[83]

The ability of caffeic acid (LXXXIX) and its derivatives,[84] esculetin (XC),[85] and certain flavonoids (XCI) [86] to form chelate complexes with Fe(III) is known, their activity as inhibitors of 5-LO being related to this:

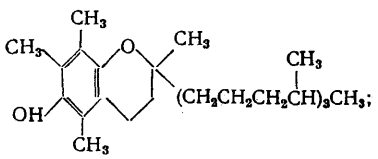
(LXXXIX) (XC)

(XCI)

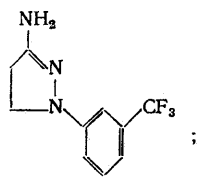
cirsilol $R^1 = H$, $R^2 = OCH_3$, $R^3 = OCH_3$ (a);
pedalitin $R^1 = H$, $R^2 = OH$, $R^3 = OCH_3$ (b);
quercetin $R^1 = OH$, $R^2 = H$, $R^3 = OH$ (c).



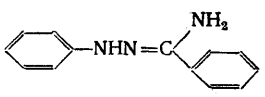
The mechanism of complexation of flavonoids with Fe(III) is unclear, it is also possible that they act through a dual mechanism—as chelating agents of Fe(III) and as antioxidants, which they behave as at the same time (see below).[7,86]



It should be mentioned, however, that 5-LO is definitely not the only iron-containing enzyme of the arachidonic acid pathway (cyclooxygenase, 12-LO, and 15-LO also contain it).[7,31,75,87] Hence there is no reason to expect high specificity from inhibitors of this type.

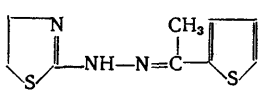


4. Antioxidants

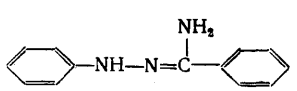


Since the lipoxygenase reaction is, in essence, the oxidation of acid substrates with oxygen, it was natural that many antioxidants should prove to be inhibitors.

Virtually all known antioxidants inhibit 5-LO to a given extent, these include sterically hindered phenols [nordihydroguaiaretic acid (NDGA)] (XCII), α-tocopherol (XCIII), flavonoids (XCI),[88] etc.



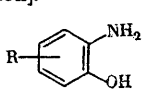
(XCII)



(XCIII)

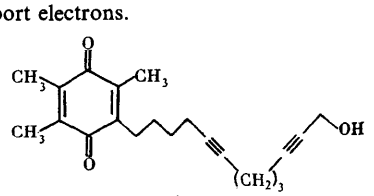
(XCIV)

(XCV)



A separate group is made up by the hydrazone antioxidants BW-755C (XCIV) [89] and CBS-1114 (XCV) [90] and hydrazones (XCVII) and (XCVIII):[91]

(XCVI)



(XCVII)

A characteristic feature of these inhibitors is the absence of selectivity towards LO. Thus, compounds (XCVII) and (XCVIII) inhibit 5-LO, 12-LO, and cyclooxygenase to virtually the same extent.[91]

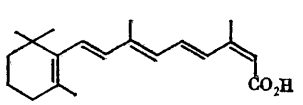
o-Aminophenols with the general structure (XCVIII) have also been reported[92] as antioxidant inhibitors of 5-LO. However, a dual mechanism, similar to that for flavonoids, cannot be excluded for their mode of action [chelation with Fe(III) and inhibition of oxidation].

(XCVIII)

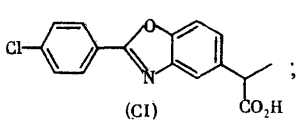
A special group of antioxidants is made up by the so-called Takeda quinones,[93] which are similar to ubiquinones in structure. There is most interest in quinone AA-861 (XCIX), which has the highest selectivity in this series and inhibits 5-LO (IC_{50} = 1 μM) without having any significant effect on cyclooxygenase and 12-LO at concentrations up to 10 μM (when 5-LO retains only 3% activity). This compound has passed clinical trials as a potential drug for the treatment of bronchial asthma.[7] Its mode of action has not been established, although ubiquinone is known for its ability to transport electrons.

(XCIX)

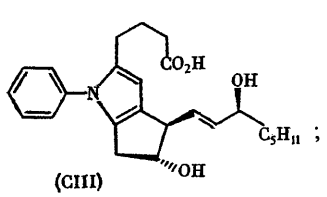
A correct interpretation of the role of antioxidants as potential pharmacological drugs should evidently be made on the basis of recently published reports concerning the role of the so-called active forms of oxygen—AOS (active oxygen species) (superoxide anions, peroxides, hydroxyl and ferryl radicals, etc.)[94] in diseases such as cancer, cardiovascular disorders, allergic and inflammatory processes. Thus, it is thought, for example, that the ferryl radical (the hypothetical intermediate in lipoxygenase catalysis) damages the active sites of a number of enzymes, lipid membranes, DNA, etc. Although the mechanism of these processes is not known, AOS can apparently give rise to rearrangement of regions of the membrane, affect the transport of Ca^{2+} and the activation of phospholipases, and cause the release of eicosanoids, which in turn can produce a whole series of biochemical changes.



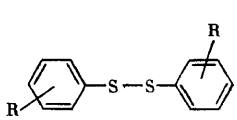
5. Certain other inhibitors



There are many compounds that inhibit LO (mainly 5-LO) for which the mechanism is not known and there is no reasonable theory for combining them into classes. There are also many individual reports about inhibitors which do not belong to any of the groups described above.

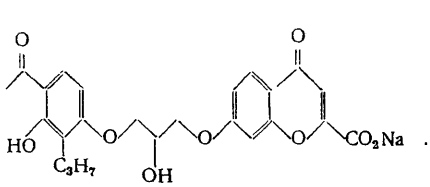


Thus, the ability of retinoids to inhibit 5-LO selectively has been established,[95] the most active being 13*Z*-retinoic acid (C).



Benoxaprofen (CI), a non-steroid antiinflammatory drug used for the treatment of psoriasis, is a non-selective inhibitor of 5-LO whose mode of action is unclear.[96]

Aryl disulphides (CII), reported by research workers from Merck as a new class of selective inhibitors of 5-LO, are able to reduce the level of hydroperoxides needed for enzyme activation.[75,96,97]



(C)

(CI)

(CIII)

(CII)

Compound U-60,257 (CIII) is an inhibitor which acts simultaneously at several points of the arachidonic acid pathway. Thus, it was described originally as an inhibitor of glutathione transferase. However, it was subsequently shown to have the ability to deactivate 5-LO and have the properties of a peptidoleukotriene antagonist.[98] Another active antagonist, SRS-A-FLP-55712 (CIV), which had already been adopted for medical use and was widely used for biochemical studies of the effects caused by LTC_4,[99] also proved to be an inhibitor of 5-LO (IC_{50} = 20 μM).[100]

(CIV)

An interesting example of an inhibitor that acts as a suicide substrate is phenylhydrazine (CV), which irreversibly deactivates soybean 15-LO.[101] It was established that deactivation is dependent on phenyldiazine (CVI) formed by autoxidation of phenylhydrazine:

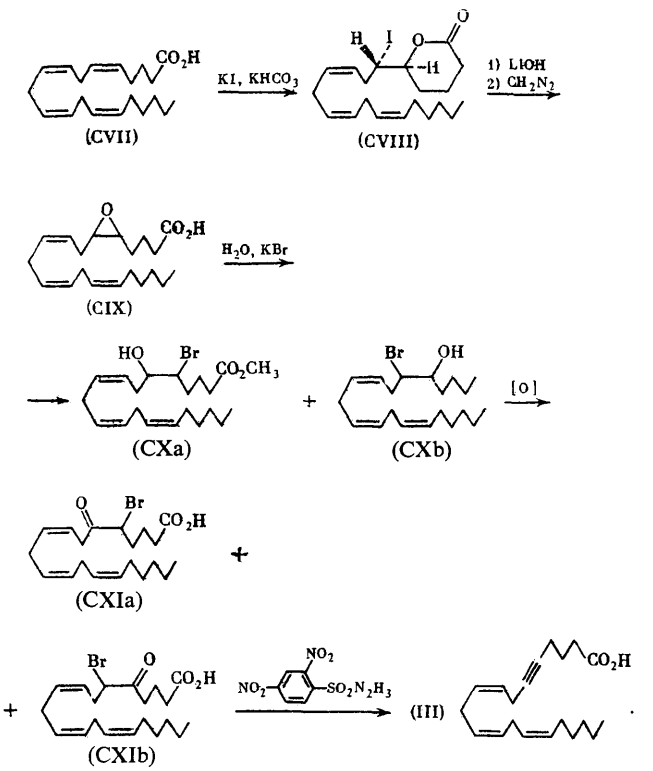
$$\underset{\text{(CV)}}{PhNHNH_2} \xrightarrow[M^{n+}]{O_2} \underset{\text{(CVI)}}{RhN{=}NH} + H_2O_2, \quad (1)$$

$$\underset{\text{(CVI)}}{PhN{=}NH} + Fe\,(III) \rightarrow Ph^{\cdot} + N_2 + Fe\,(II). \quad (2)$$

The Fe(III)-enzyme is sensitive to phenyldiazine formed non-enzymatically according to Eqn. (1). However, deactivation is related not only to the conversion of the enzyme to a Fe(II)-containing inactive form, since excess 13*S*-HPOD does not cause the enzyme to be reactivated and the Fe(II)-enzyme is also irreversibly deactivated by phenylhydrazine.[101]

The activity exhibited by the haloethane 1,1,1-trifluoro-2-bromoethane is difficult to explain in terms of its structure. This compound (widely used in anaesthesia) suppresses the synthesis of leukotrienes and hydroxy acids by 5-LO in leucocytes.[102] Inhibition is reversible (removal of the inhibitor reactivates the enzyme) and depends on the dose. It was also established that this haloethane blocks the release of arachidonic acid from phospholipids and the synthesis of LTC_4 by glutathione transferase.[102] Its mode of action remains unclear, but it is evident that this compound acts at the second or even third stages of the enzymatic pathway.

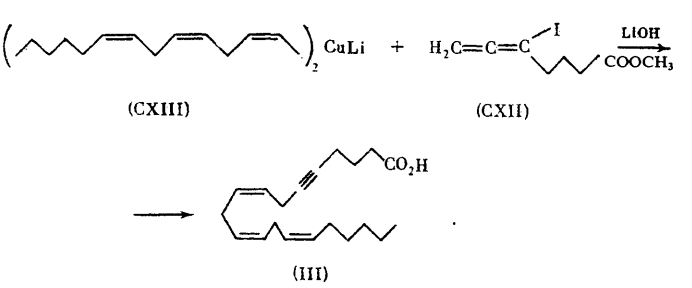
Thus, the suppression of lipoxygenase activity may occur as a result of the effect of very different factors, which have still in part not received a rational explanation. Thus, it was established that the selective suppression of the 5-lipoxygenase activity of alveolar macrophages occurs during smoking.[103] Selective suppression only occurred for 5-lipoxygenase products (LT and 5-HETE) while TXB_2 and PGE_2 were formed in unchanged quantities. The mechanism of inhibition has not been established but it is thought to be related to the effect of free radicals generated by smoking on the active site of 5-LO.[103] However, this does not explain the selectivity of inhibition.



IV. The chemical synthesis of lipoxygenase inhibitors

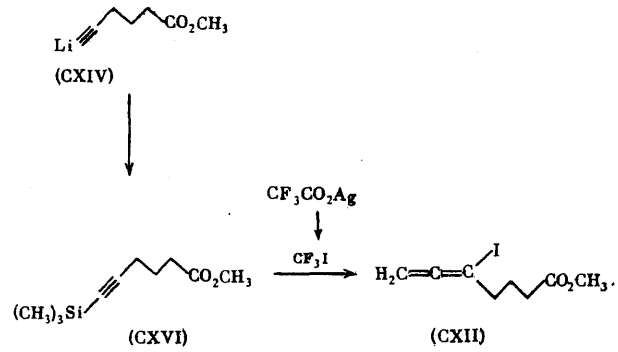
The majority of the inhibitors of lipoxygenase oxidation of polyenoic acids examined are polyunsaturated systems containing double (separated by methylene groups, conjugated or cumulated) and triple bonds. Their synthesis is related, on the one hand, to the formation of a given carbon skeleton and, on the other hand, to the introduction (including during the build-up stage) of double bonds of a given configuration and triple bonds.

The following methods have been used to produce triple bonds in inhibitor molecules: 1) from the epoxide of the corresponding polyenoic acid;[67,104] 2) by condensing iodo- or bromo-allene with suitable lithium derivatives;[27,105] 3) by the reaction of metal acetylides with halogen derivatives.[106,107]

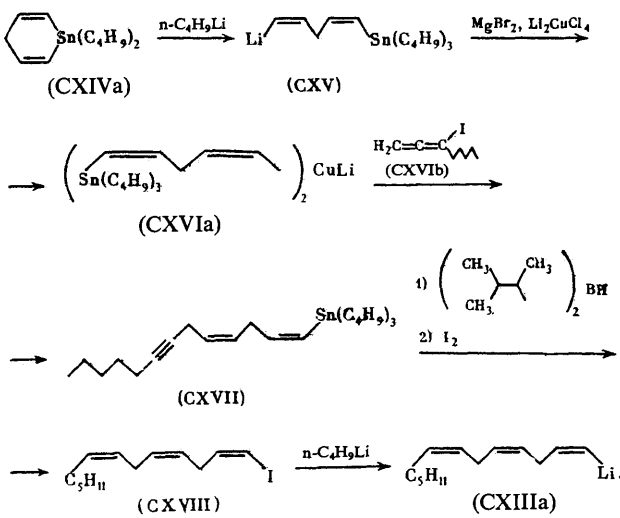


The application of these three approaches to the synthesis of acetylenic inhibitors can be conveniently examined in the case of 5,6-dehydroarachidonic acid.

Thus, the first synthesis of 5,6-DHA from arachidonic acid (CVII) was carried out by converting it to a lactone and then to epoxide (CIX) by the action of lithium hydroxide,[68] Epoxide (CIX) was converted to a mixture of isomeric bromohydrins (CXa, b) followed by a Jones oxidation to form a mixture of bromoketones (CXIa, b). Reaction of the isomeric mixture (CXIa, b) with 2,4-dinitrobenzene-sulphonyl hydrazone yielded the methyl ester of 5,6-DHA (IIIa):[67]

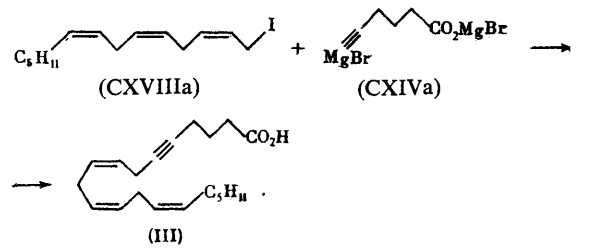


8,9-, 11,12-, and 14,15-DHA were obtained similarly via the respective epoxides.[67,108]

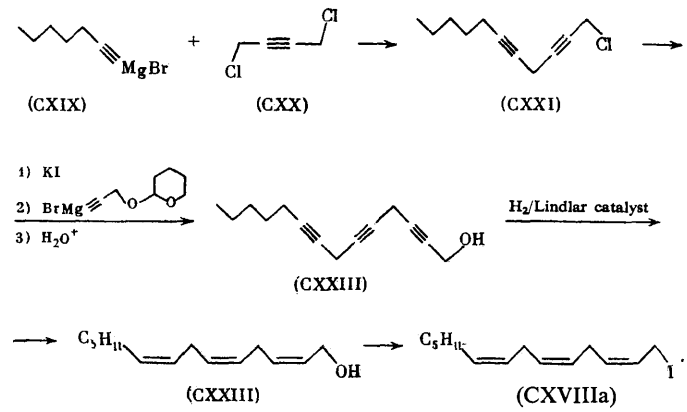


5,6-Dehydroarachidonic acid (III) may also be obtained by a complete synthesis, the key components of which are methyl 5-iodo-5,6-heptadienoate (CXII) and the lithium derivative of tridecatriene (CXIII):[27]

Iodoallene (CXII) is obtained by silylation of the lithium derivative of methyl 5-hexynoate (CXIV) with trimethylsilyl chloride in THF–HMPT followed by a reaction with silver trifluoroacetate in methylene chloride:

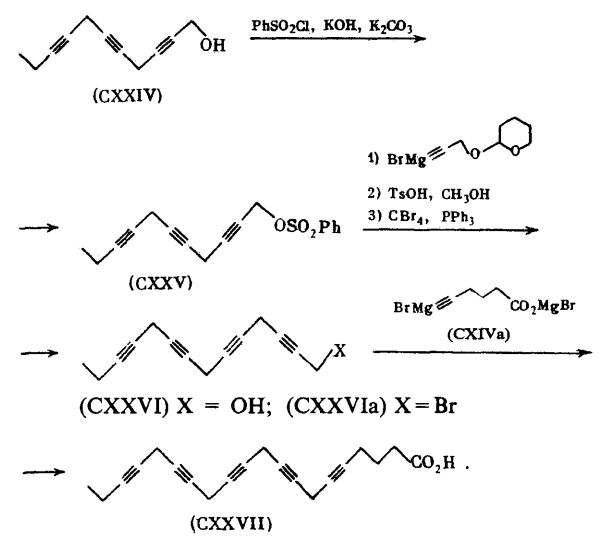


The synthesis of 1-lithio-1,4,7-tridecatriene (CXIII) is carried out by ring opening of 1,1,-di-n-butyl-1-stanna-2,5-cyclohexadiene (CXIVa) with n-butyllithium followed by extension of the carbon chain through the reaction of 1-lithio-5-tributylstannyl-1,4-pentadiene cuprate (CXVIa) with 3-iodo-1,2-octadiene (CXVIb), obtained in a similar manner to iodoallene (CXII):



The triple bond in (CXVII) formed as a result is reduced with disiamylborane to a *cis*-double bond.[27]

The synthesis of 5,6-DHA from acetylenic compounds was achieved by cross-combining propargyl- and allyl-type halides (tosylates) with ω-acetylenic compounds.[107] 1-Iodo-2*Z*,5*Z*,8*Z*-tetradecatriene (CXVIIIa) and 5-hexynoic acid (CXIVa) were selected as the key synthons:



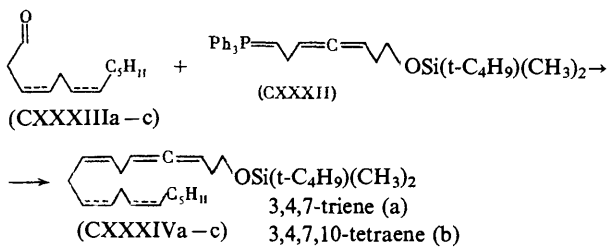
The triene iodide was synthesised by starting from 1-heptyne (CXIX), which was condensed with 1,4-dichlorobutyne (CXX) to give 1-chloro-2,5-undecadiyne (CXXXI):

Iodide (CXXIa), obtained from the diyne chloride (CXXI), was condensed with protected propargyl alcohol followed by removal of the protecting group and hydrogenation on a Lindlar catalyst. The triene alcohol (CXXIII) obtained in this manner was converted to the corresponding iodide (CXVIII) via the mesylate.

Another example of the successful application of a method for the preparation of eicosapolyynoic acids from acetylenic compounds is provided by a novel synthesis of 5,8,11,14,17-eicosapentaynoic acid (CXXVII)—a potential LO inhibitor.[108] The starting material for this was 2,5,8-undecatriynol (CXXIV),[109] conversion of which to the benzenesulphonate (CXXV) and condensation with the magnesium bromide derivative of protected propargyl alcohol gave 2,5,8,11-tetradecatetraynol (CXXVI). Subsequent replacement of the hydroxyl group in this compound by bromine gave 1-bromo-2,5,8,11-tetradecatetrayne (CXXVIa). The latter condensed with 5-hexynoic acid to form the required acid (CXXVII):

This type of approach to the synthesis of the pentaynoic acid (CXXVII) was also known previously,[110] but the use of propargyl halides to form polyacetylenic structures (in particular for the preparation of 5,8-nonadiynoic acid)[110] resulted in relatively low yields. Therefore, the tetrayne bromide (CXXVIa) and 5-hexynoic acid (CXIV) were selected by the authors as key components. The use of the benzenesulphonate (CXXV) instead of the corresponding bromide[111] made it possible to conduct the reaction under milder conditions (20 °C) and led to an increase in yield by 10–20%.

The double bonds in inhibitor molecules (both *cis*- and *trans*-) have been formed, as a rule, by means of the Wittig reaction.[35,36,38,39,48,82] Moreover, as has already been demonstrated, *Z*-double bonds may be obtained by the reduction of triple bonds on a Lindlar catalyst,[34,59,107] disiamylborane,[27] R1 or R2 nickel[112] (the use of the latter has only been reported for systems containing no more than two triple bonds).



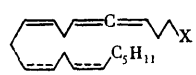
A significant disadvantage of the Wittig reaction is its low stereoselectivity.

The stereochemical result of the reaction is affected by the presence of lithium salts, which causes an increase in the proportion of *trans*-alkenes in the same reactions when the synthesis is conducted in non-polar solvents.[113] On the other hand, by using HMPT in the Wittig reaction it is possible to increase the proportion of the *cis*-isomer from 85 : 15 (*cis* : *trans*) to virtually pure *Z*.[54]

The Wittig reaction may be accompanied by side reactions, for example, isomerisation of the neighbouring double bond.[114] By using phosphonates (Wittig–Horner reaction) it is possible to improve the stereoselectivity of condensation slightly in favour of the formation of *trans*-alkenes. Attempts to increase the proportion of *Z*-products proved largely unsuccessful.[113,115,116]

Despite all these disadvantages the Wittig reaction remains the main method for forming double bonds in modified acid inhibitors (mainly the *Z*-configuration).[38,39,54]

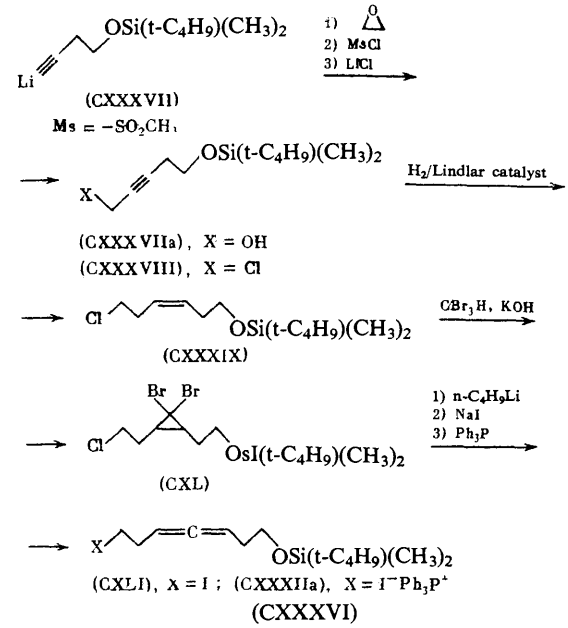
Thus, the synthesis of 4,5-eicosaallenic acids is based on the stereoselective Wittig condensation of the allenic ylide (CXXXII) with the respective aldehyde (CXXXIIIa–c), the products of which are the nonadecasilyl ethers (CXXXIVa–c):[54]



(CXXXIIIa–c) (CXXXII)

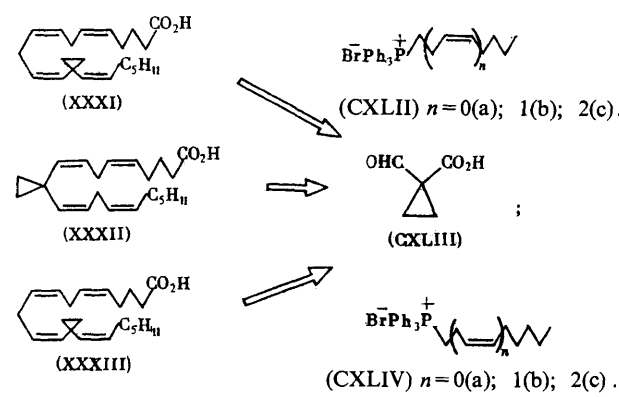
(CXXXIVa–c)

3,4,7-triene (a)
3,4,7,10-tetraene (b)
3,4,7,10,13-pentaene (c).



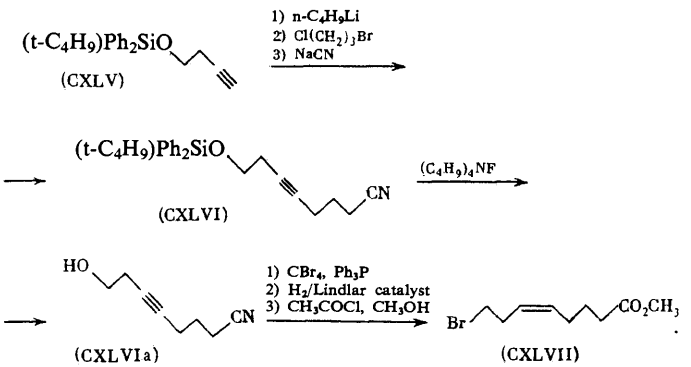
The subsequent conversion of the silyl ethers to bromides (CXXXVa–c) and the reaction of the Grignard reagents obtained from them with carbon dioxide gave 4,5-alleneicosanoic acids (IVa–c):

(CXXXVa–c) X = Br
3,4,7-triene (a)
3,4,7,10-tetraene (b)
3,4,7,10,13-pentaene (c)



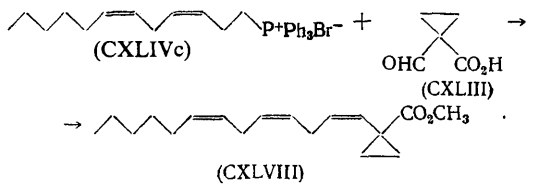
(IVa–c) X = CO_2H
8*Z*-eicosa-4,5,8-triene (a);
8*Z*,11*Z*-eicosa-4,5,8,11-tetraene (b);
8*Z*,11*Z*,14*Z*-eicosa-4,5,8,11,14-pentaene (c).

A common intermediate in the synthesis of allenic acids (IVa–c) is [7-(t-butyldimethylsilyloxy)-hepta-3,4-dien-1-yl]triphenylphosphonium iodide (CXXXVI), which was obtained from the lithium derivative of 3-butynyl t-butyldimethylsilyl ether (CXXXVII) by alkylation of the latter with ethylene oxide to form the monoprotected diol (CXXXVIIa), which was then converted to the chloride via the mesylate. Catalytic reduction of the triple bond of the chloride gave 6-chlorohexen-3*Z*-yl t-butyldimethylsilyl ether (CXXXIX), which was then converted to the corresponding dibromocyclopropane (CXL) by reaction with bromoform and potassium hydroxide in the presence of a phase-transfer catalyst. Conversion of the cyclopropane (CXL) to 1-chlorohepta-3,4-dien-6-yl t-butyldimethylsilyl ether (CXLI) by reaction with n-butyllithium and the subsequent replacement of chlorine by iodine and quaternisation led to the required component (CXXXVI):

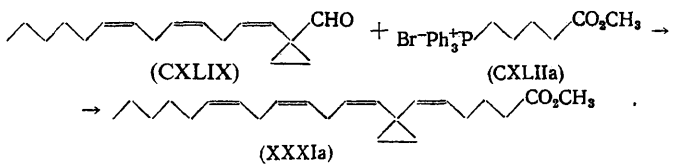


(CXXXVII)
Ms = $-SO_2CH_3$
(CXXXVIIa), X = OH
(CXXXVIII), X = Cl
(CXXXIX)
(CXL)
(CXLI), X = I ; (CXXXVIIa), X = $I^-Ph_3P^+$
(CXXXVI)

For a number of syntheses of polyenoic lipoxygenase inhibitors construction of the carbon skeleton using condensations of terminal acetylenic compounds with propargyl (allyl) halides (followed by selective reduction) as well as the formation of double bonds by the Wittig reaction is typical. This approach was used in the synthesis of the so-called ethanoarachidonic acids (XXXI)–(XXXIII).[38,39] Retrosynthetic analysis led Nicolaou et al.[38,39] to the phosphonium bromides (CXLIIa–c), (CXLIVa–c), and the cyclopropane derivative (CXLIII):

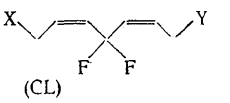


(XXXI) (CXLII) *n* = 0(a); 1(b); 2(c).
(XXXII) (CXLIII);
(XXXIII) (CXLIV) *n* = 0(a); 1(b); 2(c).



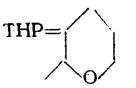
The synthesis of phosphonium salt (CXLIIb) was carried out by alkylation of the lithium derivative (CXLV) with chlorobromopropane followed by replacement of bromine by a cyano group, giving nitrile (CXLVI), which after desilylation, bromination, and reduction was converted to methyl ester (CXLVII)—the direct precursor of the required compound:

Phosphonium salts (CXLIVa–c), formed in a similar manner from the corresponding terminal alcohols, were used for subsequent condensation with the cyclopropane derivative (CXLIII):



Subsequent conversion of methyl ester (CXLVIII) to an aldehyde and its condensation with phosphonium salt (CXLIIa) gave ethanoarachidonic acid (XXXI):

As has already been indicated, a versatile approach to the synthesis of methylene-separated polyene and polyenyne structures is a method which has already become established and the basic principles of which were previously developed by Osbond.[117] This method is based on the successive build-up of the carbon skeleton by condensation of magnesium halide derivatives of terminal acetylenic compounds with propargyl halides followed by reduction of the complete polyyne system or its individual parts. However, in a number of cases this method proves to be unacceptable despite the formal correspondence of the structure to what is required.



Thus, the synthesis of fluorine-containing analogues of arachidonic acid (XXII)–(XXV) is based on a substantially different approach to the formation of a methylene-separated polyene structure.[34,59] The starting point in this approach is formation of the difluoroallyl system (CL), which is carried out by means of a chain reaction involving an acetylene anion containing substituents X and CF_2ClBr:[34]

(CL)

X = OTHP, Y = OSi(t-C4H9)(CH3)2

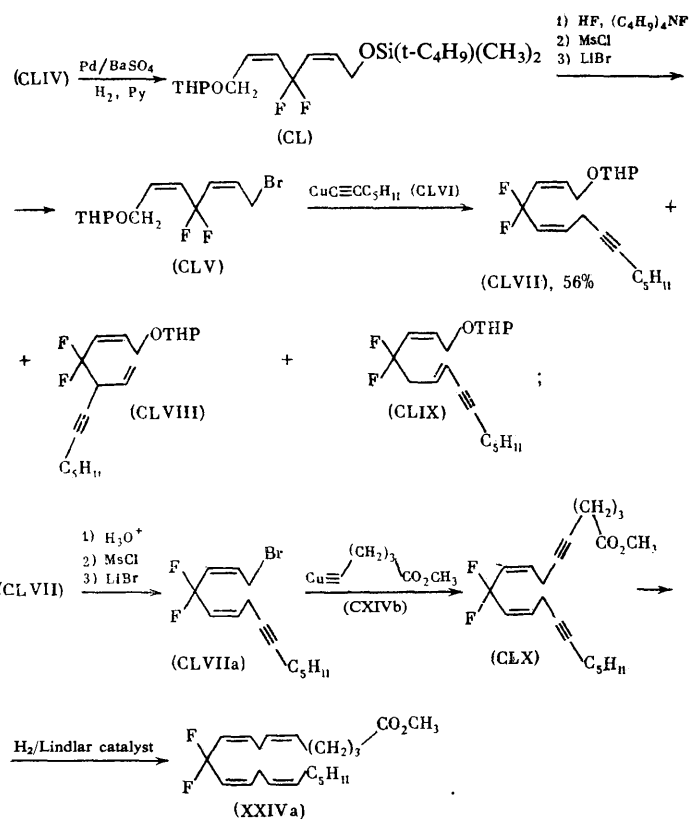
$$\underset{\text{(CLI)}}{THPOCH_2C{\equiv}CLi} \xrightarrow[THF,\ -80\ ^\circ C]{CF_2ClBr} \underset{\text{(CLII), 52\%}}{THPOCH_2C{\equiv}CCF_2Br} + \underset{\text{(CLIII), 25\%}}{THPOCH_2C{=}CBr}.$$

(3)

The following mechanism for an ionic chain reaction has been proposed:[34,39]

$$\text{Initiation } Nu^- + BrCF_2Cl \rightarrow NuBr + CF_2Cl^-,$$

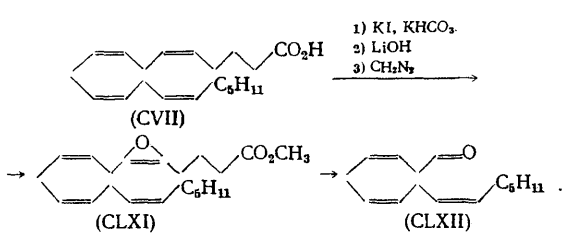
$$\text{Chain growth} \begin{cases} CF_2Cl^- \rightarrow :CF_2 + Cl^-, \\ Nu^- + :CF_2 \rightarrow NuCF_2^-, \\ NuCF_2^- + BrCF_2Cl \rightarrow NuCF_2Br + CF_2Cl^-, \end{cases}$$



which is supported by the formation of bromide (CLIII) in reaction (3). By subsequently converting difluorobromide (CLII) to the corresponding iodide, it was possible to carry out a second condensation with acetylide anion as in (4), leading to the formation of the asymmetric difluorodiyne (CLIV):

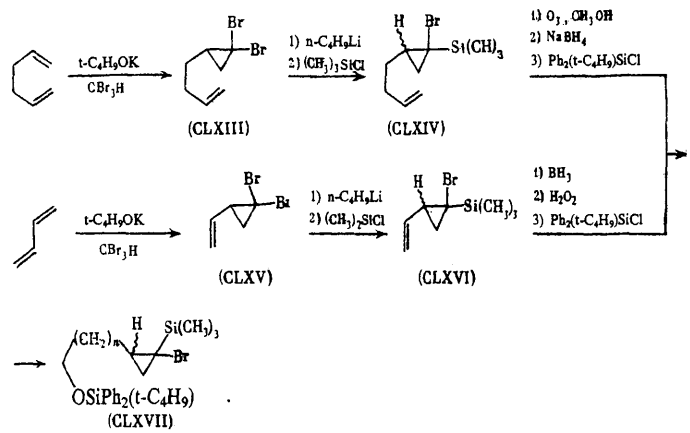
$$\underset{\text{(CLIIa)}}{THPOCH_2C{\equiv}CCF_2I} + \underset{\text{(CLIa)}}{LiC{\equiv}CCH_2OSi(t\text{-}C_4H_9)(CH_3)_2} \rightarrow$$

$$\rightarrow \underset{\text{(CLIV)}}{THPOCH_2C{\equiv}CCF_2C{\equiv}CCH_2OSi(t\text{-}C_4H_9)(CH_3)_2}. \quad (4)$$

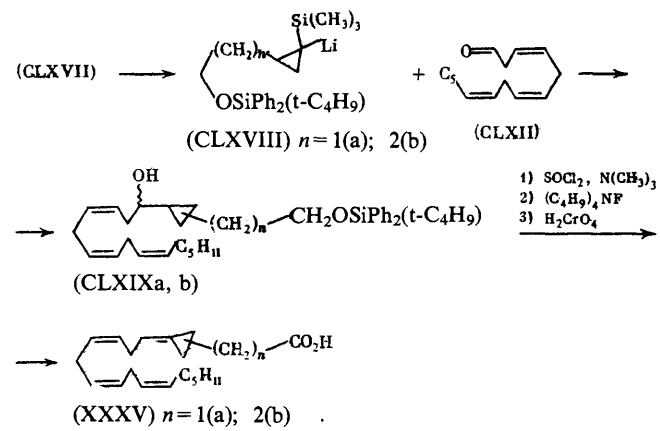


Reduction of difluorodiyne (CLIV) over $Pd-BaSO_4$ in pyridine yielded the key intermediate—difluoro-*Z*-diene (CL). After this there was the problem of forming two different carbon bonds with the respective substituents. This only proved possible with the use of cuprate reagents. Thus, condensation of the allyl bromide (CLV) with the heptynyl cuprate (CLVI) gave difluorodienyne (CLVII) (56% yield). There are different opinions in the literature about the possibility of using a diyne bromide (CLIVa) in a condensation.[34,118] The condensation is accompanied by the formation of branched (CLVIII) and conjugated (CLIX) enynes. Subsequent condensation with the cuprate of methyl hexynoate led to the dienyne (CLX),

which was hydrogenated on a Lindlar catalyst to give the required acid (XXIVa):[34]

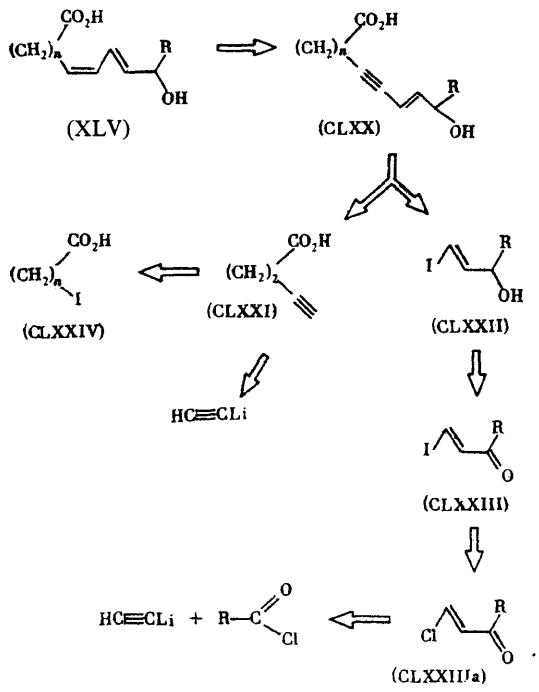


A widely used method for the synthesis of derivatives of arachidonic acid involves its direct conversion to the required compounds or the formation from it of separate residues of the final structures.

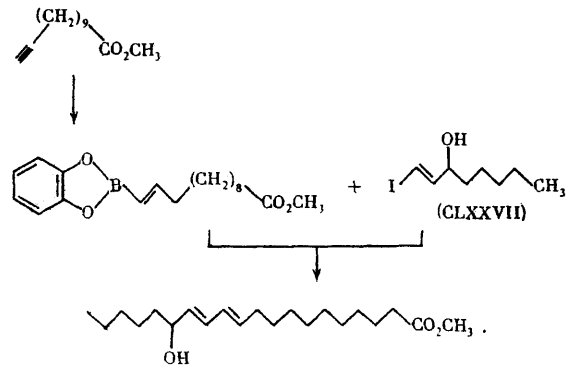


Thus the synthesis of methylenecyclopropane analogues of arachidonic acid[57] was achieved by iodolactonisation of the latter with subsequent conversion to an epoxide (in a similar manner to the approach of Corey et al.[67]) and its oxidation to an aldehyde:

The starting compounds in the synthesis of the methylenecyclopropane residue were 1,3-butadiene and 1,4-heptadiene:



Metallation of (CLXVII) and reaction with aldehyde (CLXII) gave a mixture of four diastereomers (CLXVIIIa, b) which after chromatographic separation were converted to the silanes (CLXIXa, b). Desilylation and oxidation of the latter yielded the required acids (XXXVa) and (XXXVb):



The synthesis of inhibitor analogues of lipoxygenase metabolites is carried out using similar synthetic methods.

Retrosynthetic analysis of 15-hydroxy-11*Z*-13*E*-dienoic acid (XLV) [64] shows that a reasonable method of building up this structure involves the condensation of ω-acetylenic acid (CLXXI)

with hydroxyvinyl halides to form the hydroxyenyne intermediates (CLXX), which are then reduced to the final (*Z*,*E*)-dienes:

Condensation was carried out by using tetrakis(triphenylphosphine)palladium(0) and cuprous iodide in triethylamine. By modifying the conditions it was possible to obtain the (*E*,*E*)-dienes, which were synthesised using 11*E*-carbomethoxy-1-undecylpyrocatechinborane (CLXXVI) and 3-hydroxy-1*E*-octenyl iodide (CLXXVII):

A detailed examination of the methods for synthesising inhibitors and antagonists with a different structure to that of the analogues of acid substrates and lipoxygenase metabolites (monocyclic and condensed heterocycles, phenol derivatives, etc.) is beyond the scope of the present review. These topics are covered in several publications.[119–124]

V. Conclusion

It is clear from the information given in this review that a large number of effective lipoxygenase inhibitors and antagonists of the corresponding metabolites with different chemical structures have been developed up to the present time. However, only a few of them have been used as antiallergic and antiinflammatory drugs;[7,50,93,125] without exception, all of these compounds in terms of their structure are far removed from lipoxygenase substrates and metabolites.

Heterocyclic lipoxygenase inhibitors acting as antioxidants, chelating agents of Fe(III) and via other, often undetermined mechanisms[7,88,90,91,129] have become quite widespread. A number of compounds that have been isolated from plants and microorganisms belong to this group.[126–128]

The synthesis of analogues of the precursor acids of eicosanoids is a promising trend for the development of compounds with antilipoxygenase activity, even though they are generally inactive *in vivo* and cannot be used as drugs. Compounds of this type can be used for a detailed study of the mechanism of conversion of eicosapolyenoic acids by LO and for obtaining information about the nature of groups forming part of the active site.[25,31,32,54]

Special mention should be made concerning inhibitors that do not have direct structural similarities with natural lipoxygenase substrates but with a good isosteric correspondence to the active site of the enzyme, which have been developed with the aid of three-dimensional computer models.[64,65,79]

Antagonists of lipoxygenase metabolites constitute an important independent group of antilipoxygenase compounds whose activity is determined by their ability to block the receptor interactions of eicosanoids.[40–43,72,73,112,123]

Thus, the problem of pharmacological regulation of the arachidonic acid pathway and its lipoxygenase metabolism in particular is an extremely complex, multilevel question and may be resolved only by the continuation of studies in all the existing areas of research into fundamentally new antilipoxygenase agents and factors as well as combining the separate research efforts on the basis of a common approach.

Selective replacement of hydrogen at a saturated carbon atom under the action of oxidising agents

L S Boguslavskaya, A V Kartashov, N N Chuvatkin
Scientific-Research Institute for Polymers, Dzerzhinsk

ABSTRACT. Data have been correlated for the heterolytic substitution reaction of hydrogen atoms in saturated hydrocarbons and also in some ethers and esters under the action of oxidising agents, viz. halogens, nitronium salts, halogen fluorides and ozone. Alternative schemes of electrophilic and nucleophilic substitution of hydrogen at an sp^3-hybrid carbon atom are considered.

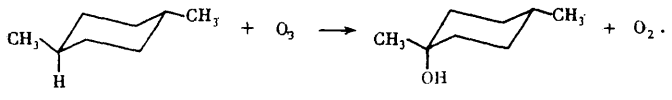
I. Introduction



It was shown recently that halogen atoms in alkyl halides are selectively substituted by other functional groups under the action of various oxidising agents with the formation of extremely valuable final products. Proof has been presented of the fact that all these reactions are linked by a general mechanism and may be considered as oxidative nucleophilic substitutions of halogen at a saturated carbon atom.[1]

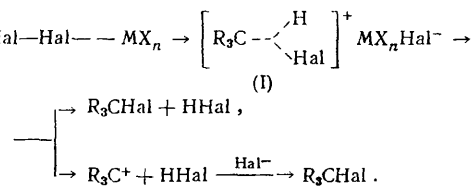
In recent years it has been reported that similar oxidising agents are capable of selectively replacing hydrogen atoms (mainly at tertiary carbon atoms or α-hydrogen atoms in ethers). Typical examples of such reactions are:

$$CH_3CH_2CH(CH_3)(CH_2)_5CH_3 + F_2 \rightarrow CH_3CH_2CF(CH_3)(CH_2)_5CH_3 + HF,$$

$$(CH_3)_2CHCO_2R_F + BrF_3 \rightarrow (CH_3)_2CFCO_2R_F + HF + Br_2,$$

Many investigators of these reactions have considered the development of preparative methods of 'functionalising' organic compounds by replacement of hydrogen at a saturated carbon atom to be an extremely promising direction and the selection of conditions at which the yield of substitution product reaches 50–60% to be a great success. Since low temperature non-radical oxidative substitution processes for hydrogen atoms are a very important type of chemical conversion of organic compounds and are seemingly fairly widely distributed in nature, it seemed expedient to us just now to correlate all the available information on such processes. We are confident that analysis of such data will permit formulation of a fairly objective representation of the overall rules of oxidative substitution of hydrogen atoms and planning of routes for further investigation of the problem.

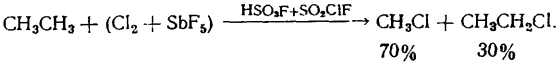
Table 1. Halogenation of alkanes by molecular halogen in the presence of Lewis acids in CH_2Cl_2.[9,10]



No.	Alkane	Halogen	Lewis acid	Molar ratio Hal:Lewis acid:alkane	Temp. °C (time, min)	Reaction products (yield[a], %)
1	Isobutane	Cl_2	$AlCl_3$[b]	1:0.1:1	25 (960)	over 20 products[c]
2	Isobutane	Cl_2	$AgSbF_6$	0.5:0.1:1	−15 (10)	t-butyl chloride (7)
3	Isobutane	Br	$AgSbF_6$	0.5:0.1:1	−15 (10)	isobutyl bromide (84) t-butyl bromide (11) 2,3-dibromoisobutane (6)
4	Cyclohexane	Cl_2	$AgSbF_6$	0.5:0.1:1	15 (10)	cyclohexyl chloride (5)
5	Cyclohexane	Br_2	$AgSbF_6$	0.5:0.1:1	25 (15)	cyclohexyl bromide (27)
6	Norbornane	Cl_2	$AlCl_3$	1:0.1:1	25 (960)	*exo*-2-chloronorbornane (17) *endo*-2-chloronorbornane (8) 7-chloronorbornane (4)
7	Norbornane	Br_2	$AgSbF_6$	0.5:0.1:1	25 (15)	*exo*-2-bromonorbornane (71) *endo*-2-bromonorbornane (12) 7-bromonorbornane (12)
8	Adamantane	Cl_2	$AlCl_3$	1:0.1:1	25 (1260)	1-chloroadamantane (63) 2-chloroadamantane (3)
9	Adamantane	Cl_2	$AgSbF_6$	0.5–0.1:1	−45 (5)	1-chloroadamantane (62) 2-chloroadamantane (1) 1-hydroxyadamantane (36)

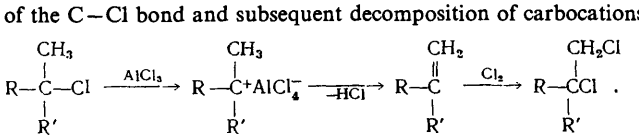
[a] In the case of $AlCl_3$ catalyst the yield is given on Cl_2 taken, in the case of $AgSbF_6$ on catalyst.
[b] Reactions were carried out without solvent.
[c] t-Butyl chloride and isobutyl chloride were absent from the products.

The numerous reactions for the oxidation of hydrocarbons by transition metal salts and by chromic and manganic acids are not considered in the review. The ample material on this type of side-chain oxidation of alkylaromatic compounds is correlated in a review paper[2] and in a monograph.[3] Preparative possibilities and proposed mechanisms of oxidation of saturated hydrocarbons by chromic acid and by transition metal salts have been described.[4–7]



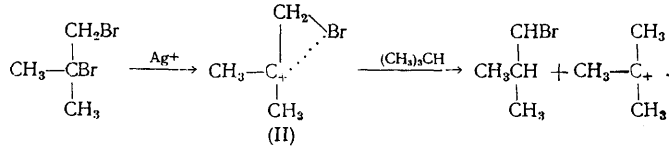
II. Reactions of saturated hydrocarbons with Hal_2–Lewis acid (Hal = Br, Cl) systems and other oxidising agents

The first attempts to effect the preparative replacement of hydrogen atoms at a saturated carbon atom by electrophilic oxidising agents under conditions excluding the possibility of free radical reactions were undertaken by G Olah in the seventies.[8–10] It was shown that Cl_2 and Br_2 in the presence of SbF_5, $AlCl_3$ and $AgSbF_6$ were able to interact at low temperature in the dark with saturated hydrocarbons to form alkyl halides (Table 1). He proposed that positively polarised halogen effected a frontal electrophilic attack on the C–H bond forming a pentacoordinate carbenium ion (I) which may then be converted into an alkyl halide by two routes: first, by ejection of a proton and formation of a bond between the carbon atom and the attacking halogen atom or second, by transfer of a hydride ion to the oxidising agent with subsequent capture of the resulting carbocation by halide anion.



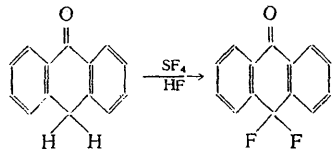
(I)

The use of antimony pentafluoride, the most powerful chlorination catalyst, in chlorination reactions led not only to hydrogen atom replacement (chlorination) but also to cleavage of a σ C–C bond in the alkane (chlorolysis). Thus the reaction of ethane in the Cl–SbF_5 system at room temperature gave methyl chloride and ethyl chloride in the ratio 70:30



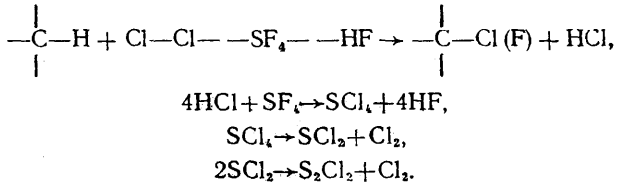
In the presence of the weaker catalysts $AlCl_3$ and $AgSbF_6$ no chlorolysis was observed. All types of σ C–H bonds (primary, secondary, tertiary) were chlorinated on catalysis by aluminium chloride, in addition the resulting alkyl halides were converted into products of further chlorination as a result of the ease of heterolysis of the C–Cl bond and subsequent decomposition of carbocations.

Thus isobutane gave more than 20 products in the presence of $AlCl_3$ (Table 1, compound No. 1). Since the elimination of a proton and double bond formation at a bridgehead is impossible for norbornane and adamantane, the chlorination of these compounds gave appreciable quantities of the corresponding monochlorides (Table 1, compounds No. 6, 8).



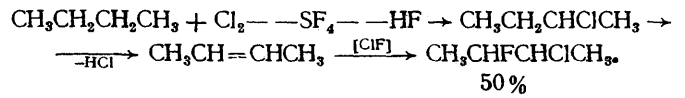
The Hal_2–$AgSbF_6$ systems possess even lower electrophilicity and correspondingly greater selectivity towards the C–H bond. Only isoalkanes and cyclic hydrocarbons (see Table 1) react in these systems at low temperature. In the presence of $AgSbF_6$, alkyl chlorides are less inclined to further conversion than with aluminium chloride. Thus only t-butyl chloride is formed from isobutane (Table 1, No. 2). In contrast to chlorination the bromination of isobutane gave isobutyl bromide, t-butyl bromide and 2,3-dibromobutane (Table 1, No. 3). The fact that the main bromination product of isobutane is not t-butyl bromide but isobutyl bromide is explained by transfer of a hydride ion from isobutane to the carbocation (II) which was formed by heterolysis of the tertiary C–Br bond in 2,3-dibromobutane:

(II)



This was confirmed by special experiments on the bromination of a mixture of 2,3-dibromobutane and isobutane in the presence of $AgSbF_6$.

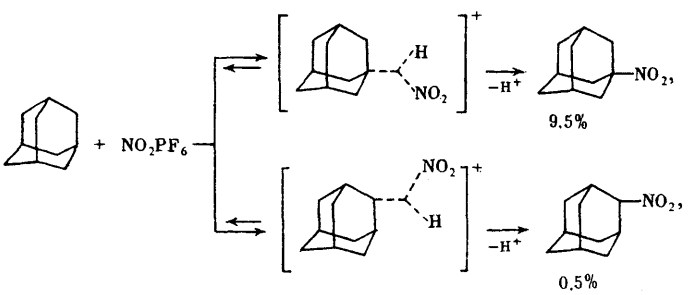
Interesting communications have appeared recently on the influence of small additions of Cl_2 on the ability of SF_4–HF systems to replace hydrogen at a saturated carbon atom by fluorine.[11,12] It was known previously that these systems replace hydrogen atoms in anthrone and adamantane by fluorine at moderate temperatures (60–70 °C):[13,14]



85%

It was shown[11] that after careful purification from traces of Cl_2 and SCl_2 (the initial product in SF_4 synthesis) sulphur tetrafluoride was unable to replace hydrogen in adamantane. Consequently it was concluded that Cl_2 was a necessary component of this system but the effectiveness of the action of traces of sulphur chlorides is linked with the generation of molecular chlorine in this system by the reaction sequence:[12]

On introducing large quantities of chlorine into the SF_4–HF system (molar component ratios 2:1:5 respectively) it was possible to effect substitution of hydrogen in n-butane even at 20 °C. The following reaction sequence was proposed to explain the observed facts:[12,15]

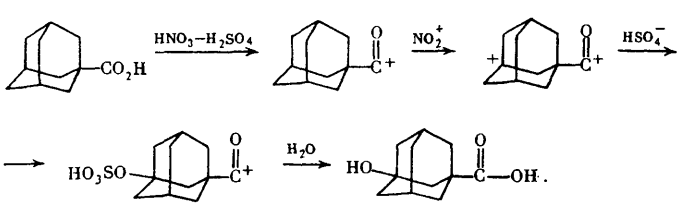


50%

However such an explanation is unconvincing since it is not very likely that dehydrochlorination of 2-chlorobutane may occur under these conditions. It is possible that alkenes are formed by loss of a proton from the intermediate carbenium ion resulting in transfer of hydride ion to the oxidising agent.

$$CH_3CH_2CH_2CH_3 + Cl_2 - - SF_4 - - HF \rightarrow [CH_3CH_2\overset{+}{C}HCH_3] \xrightarrow[-HCl]{} CH_3CH{=}CHCH_3 \xrightarrow{[ClF]} CH_3CHFCHClCH_3.$$

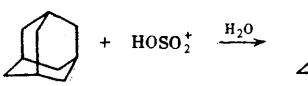
Oxidative replacement of hydrogen atoms in alkanes may be effected by various systems containing the nitronium cations.[16–19] On reaction of nitronium hexafluorophosphate with saturated hydrocarbons in an aprotic solvent at 25 °C nitroalkanes are formed although fission of σ C–C bonds has also been observed in addition to replacement of hydrogen atoms.[16] The yield of nitroalkanes in these reactions is extemely low, in the case of acyclic compounds the yield of products did not exceed 2–5%. The best result was obtained in the reaction of adamantane when 1- and 2-nitroadamantanes were isolated in 10% total yield.



In the authors' opinion the main obstacle to achieving preparative yields is the high basicity of the solvent, containing atoms with unshared electron pairs, in comparison with the basicity of the σ C–H bond. A mixture of concentrated nitric and sulphuric acids may be used in place of nitronium salts in nitration reactions.[16] On nitrating isobutane with this mixture the following set of products was obtained: CH_3NO_2 (28%), $CH_3CH_2NO_2$ (5%), $(CH_3)_2CHNO_2$ (1%), $(CH_3)_3CNO_2$ (66%).

However carrying out the reaction in a mixture of strong acids was complicated by protolytic cleavage of the secondary and tertiary nitroalkanes.

$$(CH_3)_3CNO_2 \overset{H^+}{\rightleftarrows} (CH_3)_3CNO_2H^+ \rightarrow (CH_3)_3C^+ + HNO_2.$$



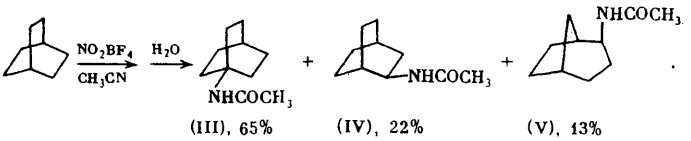
The interaction of 1-nitro-2,2-dimethylpropane with benzene and toluene in the presence of strong acids led only to the t-butyl derivatives of benzene and toluene.

On reacting 1-adamantanecarboxylic acid with a mixture of nitric and sulphuric acids no nitro derivatives were detected but 3-hydroxy-1-adamantanecarboxylic acid was obtained in high yield.[17] The authors proposed a reaction scheme including removal of the hydride ion by the nitronium cation with subsequent capture of the resulting carbocation by the hydrogen sulphate anion.

Analogous replacement of a hydrogen atom occurred on reaction of adamantane with 90–100% nitric acid and mixtures of it with acetic anhydride[18,19] or a mixture of 96–98% sulphuric acid with trifluoroacetic anhydride.[20] Thus on reacting adamantane with 90% HNO_3 the nitrate of 1-hydroxyadamantane was obtained in 50–65% yield.[18] It was proposed that in a $H_2SO_4/(CF_3CO)_2O$ mixture the active species is the $HOSO_2^+$ cation.[20] SO_2 is separated in the oxidation process.

$$H_2SO_4 + (CF_3CO)_2O \rightleftarrows HOSO_2^+ + CF_3CO_2^- + CF_3CO_2H,$$

$$H_2SO_3 \longrightarrow SO_2 + H_2O.$$



Evidently the oxidation of hydrocarbons by concentrated sulphuric acid occurs in a similar manner:[7]

$$RH + H_2SO_4 \rightarrow [R^+HSO_4^-] + SO_2 + H_2O.$$

On oxidation of adamantane with nitronium salts the magnitude of the kinetic isotope effect was 1.86,[21] of isobutane with a mixture of nitric and sulphuric acids 2,[22] and of 1,3,5-trimethyladamantane 4.4.[18] The kinetics of the oxidation of adamantane, and its derivatives substituted in the angular positions, by nitric acid in methylene chloride solution have been investigated.[23] It was established that the rate constants were linked linearly to the rate constants for solvolysis of the corresponding bromo derivatives and to the Taft induction constants. This is also in agreement with a mechanism including as limiting stage the removal of a hydride ion by the oxidising agent with the formation of the adamantyl cation. Evidence in favour of the mechanism involving the formation of carbenium ions was obtained not only in the oxidation of adamantane but also of other saturated organic compounds.[21,24] Thus on oxidation of 2-methylbutane with nitronium fluoroborate in acetonitrile at room temperature 2-acetamido-2-methyl-3-nitrobutane was obtained in good yield. Since this compound is also obtained by the addition of nitronium fluoroborate to trimethylethylene in acetonitrile medium the reaction sequence depicted in the scheme may be the sole explanation:

$$(CH_3)_2CHCH_2CH_3 \xrightarrow{NO_2BF_4} (CH_3)_2\overset{+}{C}CH_2CH_3 \xrightarrow{-H^+} (CH_3)_2C{=}CHCH_3 \xrightarrow[CH_3CN]{NO_2BF_4} (CH_3)_2CCHNO_2CH_3 \xrightarrow{H_2O}$$
$$\rightarrow (CH_3)_2CCHNO_2CH_3.$$
$$\quad NHCOCH_3$$

The interaction of bicyclo[2.2.2]octane with nitronium fluoroborate led to the formation of a mixture of acetamides (III–V) in 73% total yield.

(III), 65% (IV), 22% (V), 13%

The ratio of unrearranged acetamide (IV) to rearranged amide (V) was close to 2:1 as in the solvolysis of bicyclo[2.2.2]octyl bromobenzenesulphonate.[25] On oxidation of adamantane under

these conditions N-(1-adamantyl)acetamide (88%) was obtained. Norbornane gave exclusively N-(*exo*-2-norbornyl)acetamide (78%). The ease of transfer of hydride ions from adamantane, bicyclo[2.2.2]octane and norbornane was in direct relation to the stability of the corresponding carbenium ions.[26] Proof of the fact that nitro derivatives are not formed as intermediates on reaction of alkanes with nitronium fluoroborate in acetonitrile was the inertness of 2-methyl-2-nitropropane and 1-nitroadamantane towards the reagent at 25 °C.[21]

Trifluoroacetyl nitrate formed *in situ* in the reaction of ammonium nitrate and trifluoroacetic anhydride is also an efficient oxidising agent for saturated hydrocarbons:[24]

$$NH_4NO_3 + (CF_3CO)_2O \rightleftarrows CF_3CO_2NO_2 + CF_3CO_2NH_4.$$

Oxidation was carried out in trifluoroacetic acid medium at 25–40 °C. It was proposed that the active electrophile in this system was protonated trifluoroacetyl nitrate $[CF_3CO_2NO_2H]^+$. Under these conditions cyclooctyl trifluoroacetate was obtained in good yield (50%) from cyclooctane and also *exo*-2-trifluoroacetoxynorbornane (52%) and *exo*-2-norbornyl nitrate (23%) from norbornane.

III. Heterolytic oxidation of ethers

The α-hydrogen atoms of amyl ethers are replaced significantly more readily than hydrogen atoms in alkanes since the ether oxygen atom facilitates both the radical and ionic replacement of α-hydrogen atoms while stabilising the resulting free radical or carbocation intermediate.[27] Oxidation proceeds according to a free radical or ionic mechanism depending on the type of oxidising agent and on the conditions of carrying out the reaction. The classical oxidation reaction of ethers by atmospheric oxygen has been well studied and its free radical mechanism is not in doubt. On UV irradiation and also at elevated or room temperatures many alkyl ethers interact energetically with elementary chlorine by a free radical mechanism.[27,28] However dark low-temperature halogenation of ethers evidently proceeds according to a heterolytic mechanism and leads to replacement of hydrogen atoms by chlorine exclusively at the position α to the alkoxy group.[28–30] α-Chloroethyl ether (42%) and α,α′-dichlorodiethyl ether (57%) are obtained as a result of the chlorination of diethyl ether at –20 to –30 °C. But even at –5 to +5 °C more extensive chlorination occurs principally at the β-position.[28]

Due to the fact that the alkoxy group effectively stabilises carbenium ions, attack by the oxidising agent at the σ-bond of the α-hydrogen atoms leads to transfer of hydride ion to the oxidising agent with the formation of resonance-stabilised carbocation (VI):[27,29]

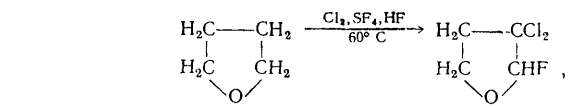
$$Hal{-}Hal + H{-}\underset{|}{\overset{|}{C}}{-}OR \rightarrow Hal^- + $$

$$+ HalH + \left[\underset{|}{\overset{|}{C}}{=}\overset{+}{O}R \;\; (VI)\right] \xrightarrow{Hal^-} Hal{-}\underset{|}{\overset{|}{C}}{-}OR,$$

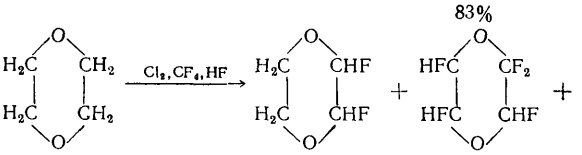
Hal=Cl, Br.

Probably other oxidising agents may react under milder conditions with ethers by the same mechanism. Chlorine monofluoride is a reagent for which all descriptions of reaction with organic compounds bear a clearly marked heterolytic character.[12] At low temperature in HF medium it readily replaces an α-hydrogen atom in the ethyl group of 1-chloro-2,2-difluoro-3-oxapentane:[30]

$$CH_2ClCF_2OCH_2CH_3 + ClF \rightarrow CH_2ClCF_2OCHFCH_3.$$



Bromine trifluoride at room temperature in the absence of solvent replaces a hydrogen atom in the methyl group of ether (VII) and an α-hydrogen atom in the ethyl group of compound (VIII):[31]

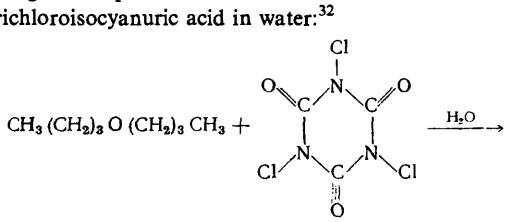


$$\underset{(VII)}{(CF_3)_2CHCF_2OCH_3} \xrightarrow[20°C]{BrF_3} \underset{48\%}{(CF_3)_2CHCF_2OCH_2F},$$

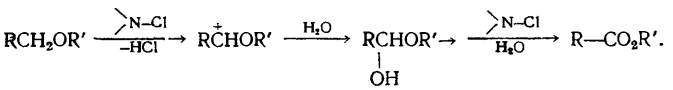
$$\underset{(VIII)}{(CF_3)_2CHCF_2OCH_2CH_3} \xrightarrow{BrF_3} \underset{74\%}{(CF_3)_2CHCF_2OCHFCH_3}.$$

Since the electron-donating ability of the oxygen atom is strongly reduced in a polyhalogenated alkoxy group, the ionic and radical halogenation of ethers of type (VII, VIII) proceeds with difficulty. Thus radical chlorination of similar compounds occurs only on UV irradiation. The use of such powerful electrophilic oxidising agents as ClF and BrF_3 permits heterolytic replacement of α-hydrogen atoms. The system Cl_2-SF_4-HF effectively fluorinates ethers at moderate temperatures.[6,10,14] In this way more extensive halogenation occurs, viz. replacement of β-hydrogen atoms predominantly by chlorine:

$$CH_3CH_2OCH_2CH_3 \xrightarrow[50°C]{Cl_2,SF_4,HF} \underset{89\%}{CCl_3CHFOCH_2CH_3},$$

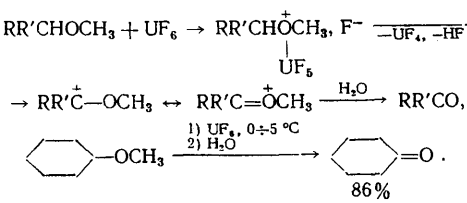


+ $CF_3CHFOCH_2CH_2F$.

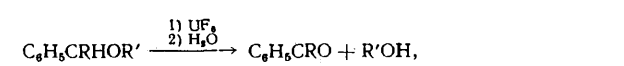


These reactions probably occur by the initial oxidative replacement of α-hydrogen atoms by fluorine according to a heterolytic mechanism analogous to that presented above. However as a result of the extreme instability of α-fluoroethers[28] the products of mild monofluorination are not isolated. Under more forcing conditions further fluorination and chlorination of the α-fluoroethers occur. The polyhalogenated ethers obtained in this way are then completely stable since the nucleophilic replacement of α-fluoro atoms occurs with more difficulty as a result of the electron-accepting influence of the vicinal halogens.

One further interesting example of the selective replacement of α-hydrogen atoms in ethers under the action of oxidising agents containing electropositive chlorine is the reaction of dibutyl ether with trichloroisocyanuric acid in water:[32]

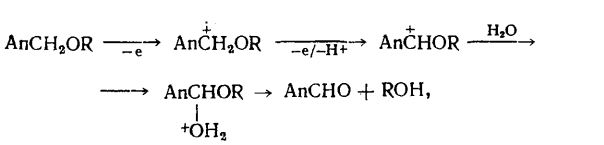


→ $CH_3(CH_2)_2CO_2(CH_2)_3CH_3$.

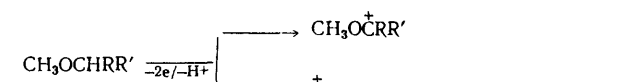


This reaction may be represented as follows:

Uranium hexafluoride has been proposed for the selective oxidation of ethers and certain other organic compounds.[33] Carbonyl compounds and alcohols are formed as a result of the oxidation of unsymmetrical ethers. In the case of methyl ethers the reaction proceeds regioselectively. The authors put forward a scheme assuming initial attack of uranium hexafluoride at the oxygen atom:



Aromatic compounds and aliphatic alcohols are formed on oxidation of alkyl benzyl ethers and benzhydryl ethers:



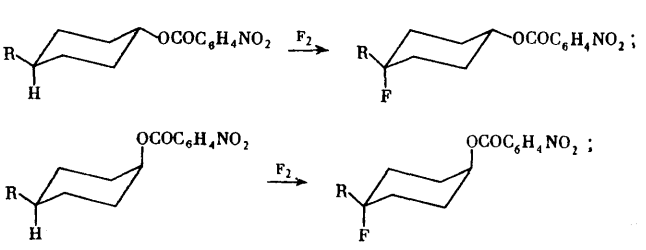
R = H or C_6H_5; R′ = alkyl, cycloalkyl.

It is interesting that extremely similar results were obtained on electrochemical oxidation of alkyl benzyl ethers.[34,35] An especially good yield (74 to 98%) was observed in the case of *p*-methoxybenzyl ethers. A mechanism was proposed for these reactions.[36]

An = anisyl.

By electrochemical oxidation of ethers it is possible to obtain orthoesters, acetates of hemiacetals or acetals which are readily hydrolysed in aqueous acidic medium and give the corresponding aldehydes in good yield.[34,37,38] The regioselectivity on electrochemical oxidation is the same as on oxidation by uranium hexafluoride and is determined by the ability of substituents at the reaction centre to stabilise the positive charge formed by elimination of the α-hydrogen atom:

R = H, alkyl; R′ = alkyl.



Consequently the hydrogen atoms of CH_3 groups are not affected during oxidation of mixed alkyl methyl ethers. For the same reason selective replacement of benzylic hydrogen atoms occurs for alkyl benzyl ethers having no electron-accepting substituents in the aromatic ring.[33,38]

IV. Selective fluorination of organic compounds containing tertiary and secondary hydrogen atoms, with elementary fluorine and halogen fluorides

Elementary fluorine reacts vigorously with organic compounds under the usual conditions which frequently leads to destruction of the hydrocarbon skeleton.[39] During the last 10 years Rozen and co-workers have developed preparative methods of replacing tertiary hydrogen atoms by fluorine using low temperature fluorination with elementary fluorine.[40–48] Fluorination was effected by passing a gaseous mixture of F_2 and N_2 containing 1 to 10% fluorine through a strongly diluted (0.1–0.3%) solution of the substrate in a mixture of $CFCl_3$–$CHCl_3$ (1:1) at –75 to –78 °C. Chloroform was a necessary component of the solvent, in Freon alone fluorination did not take place.[46]

Exhaustive data on fluorination by this means including literature since 1985 have been presented in a review.[49] We will give only the most typical examples illustrating the possibilities of this method.

Best results (70–90% yield) were obtained for cyclic hydrocarbons (Table 2, compounds 2–6). Evidently these results are not explained by their hydrogen atoms reacting more readily with F_2 but by the greater stability of such alkyl fluorides compared with acyclic fluorides. A special feature characteristic of oxidative fluorination is the possibility of replacing the hydrogen atom at position 1 of the norbornane system (Table 2, compounds 7, 8) in which the formation of carbenium ions is extremely disfavoured. 1-Fluorocamphane and 2-(1-norbornyl)ethyl acetate were obtained in low yield (15–20%). Electron-accepting substituents hampered replacement, consequently tertiary hydrogen atoms furthest removed from such substituents were replaced more readily. Thus a better result was obtained with a steroid diol diacetate than with the ditrifluoroacetate (Table 2, compounds 9, 10), in both cases the hydrogen atom replaced was that located furthest from the acceptors. Similarly the tertiary hydrogen atom in the position γ to the ester group was replaced in better yield than that in the β position (Table 2, compounds 11, 12). The presence of two electron-accepting substituents in the position β to hydrogen hindered replacement so much that the yield of the corresponding fluoride was extremely low (Table 2, compound 13). The stereochemistry of replacement of tertiary hydrogen atoms by fluorine in cyclohexane derivatives has been investigated.[47] Replacement occurred with retention of configuration in all cases.

R = CH_3, $(CH_3)_3C$.

On fluorinating bicyclo[2.2.2]octane by this method a rearrangement

was observed typical of a reaction proceeding with the formation of carbenium ions.[48]

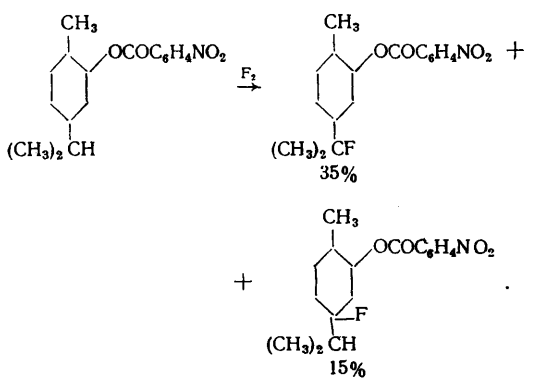
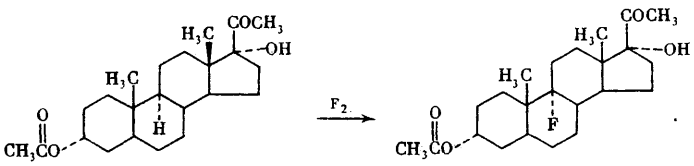
[a] Depending on the reactivity of starting material from 1 to 100 moles fluorine were passed in per mole substrate.
[b] Starting materials differed in that hydrogen replaces fluorine.
[c] Yield calculated on substrate.

1-Fluorobicyclo[2.2.2]octane and 2-fluorobicyclo[3.2.1]octane (rearrangement product) were obtained from the reaction. The authors proposed a scheme explaining the formation of these products. In the first stage a pentacoordinated carbonium ion (IX) is formed which is in equilibrium with the non-classical ion (X) having 8 electrons at each carbon atom. However such an explanation is hardly acceptable since conversion of ion (IX) to any other carbonium ion may only be effected by direct elimination of proton with subsequent protolysis of other σ bonds. Just such a scheme has been proposed for the isomerisation of saturated hydrocarbons in strongly acidic medium.[50] It is probable that the rearrangement product may be formed only from ion (XI) which has a strong electron-accepting substituent (fluorine atom) in the β-position and consequently must be less stable than ion (IX).



(XI)



A relationship was found between the contribution of the *p*-orbitals to the C–H bond and the ease of replacement of the hydrogen atom; the greater the contribution of *p*-orbitals then the easier substitution occurred.[46] According to semi-empirical calculations by the PRDDO method the contribution of *p*-orbitals to the C(1)–H bond is 2.7 and C(4)–H and C(8)–H about 2.9. The product with substitution at C(8) was obtained preferentially.

The fact that substitution did not occur at C(4) was explained by the authors by the fact that fluorine approaches the reaction centre accompanied by at least one molecule of chloroform and the C(4) atom is the most sterically hindered. If the ester substituent is removed then the hydrogen atom at C(4) is also replaced.

However in our opinion it is more certain that this fact is explained by the deactivating influence of the electron-accepting ester group on the vicinal hydrogen atom of compound (XII). The synthesis of fluorosteroids is the most useful preparative application of the selective replacement of hydrogen atoms with elementary fluorine.[38] It was recorded that in all cases replacement occurred with retention of configuration. As a rule yields of products were not large (20–30%) but for 5α-pregnane-3α,17α-diol-20-one 3-acetate (XIII) the yield of 9α-fluorosteroid (XIV) reached 60%.

(XIII) (XIV)

The selectivity of the replacement attracts attention. Of the three tertiary hydrogen atoms in compound (XIII) only the 9α-hydrogen, which is furthest from the electron-accepting substituents, is replaced by fluorine.

The fact that fluorination takes place with complete retention of configuration and also the absence of typical carbocation rearrangements (excluding bicyclo[2.2.2]octane) and the absence of proton elimination reactions indicated, in the authors' opinion,[46] against a hydride transfer mechanism:

$$R_3CH + F_2 \rightarrow R_3C^+ + HF \xrightarrow{F^-} R_3CF.$$

They ascribed the selective fluorination to a type of electrophilic substitution at the saturated carbon atom proceeding through a pentacoordinated carbonium ion (XV) (Olah mechanism):

$$R_3CH + F_2 \rightarrow \left[R_3C\text{-}\overset{H}{\overset{\diagup}{\underset{F}{\diagdown}}}\ F^- \text{---} HCCl_3\right] \xrightarrow{-HF} R_3CF.$$

In this reaction chloroform is a trapping agent for free radicals and a source of protons and serves as an acceptor of fluoride anion through a hydrogen bond which lowers the energy of the transition state.

It has recently been shown that not only elementary fluorine but also halogen fluorides may be used for the selective replacement of hydrogen atoms by fluorine.[51–53] Both tertiary and secondary hydrogen atoms are replaced by this method. Chlorine trifluoride in an inert solvent (Freon 114, 112, liquid CO_2) at −75 °C fluorinates hydrocarbons in good yield on observing experimental conditions such that ClF_3 itself and inorganic byproducts are in the reaction zone for no more than 2 min.[51] Reaction proceeds according to the scheme:

$$-\overset{|}{\underset{|}{C}}-H + ClF_3 \rightarrow -\overset{|}{\underset{|}{C}}-F + HF + ClF.$$

The formation of chlorine monofluoride as an inorganic byproduct was established by trapping it with cyclohexane or ethylene. Under these conditions first tertiary and then secondary hydrogen atoms are preferentially replaced. Methane and 2,2,3,3-tetramethylbutane, having only primary hydrogen atoms do not react. Since in the case of 2,2-dimethylbutane and 2-methylbutane products are obtained with 1,2-migration of methyl groups the authors preferred a heterolytic mechanism for the replacement of hydrogen by fluorine:

$$(CH_3)_3CCH_2CH_3 + ClF_3 \rightarrow ClF + HF + F^- + (CH_3)_3C^+CHCH_3 \rightarrow$$
$$\rightarrow (CH_3)_2C^+CH(CH_3)_2 \xrightarrow{F^-}$$
$$\rightarrow \underset{55\%}{(CH_3)_2CFCH(CH_3)_2} \xrightarrow{ClF_3} \underset{22\%}{(CH_3)_2CFCF(CH_3)_2},$$
$$(CH_3)_2CHCH_2CH_3 \xrightarrow{ClF_3} \underset{33\%}{(CH_3)_2CFCH_2CH_3} \xrightarrow{ClF_3}$$
$$\rightarrow \underset{5\%}{CH_3CF_2CH(CH_3)_2}.$$

Bromine trifluoride in a Freon medium at room temperature is also capable of replacing a hydrogen atom by fluorine. Reaction was carried out by direct addition of liquid BrF_3 to a 5–20% solution of substrate in Freon.[52,53] The process occurs according to the scheme:

$$R_3CH + {}^2/_3BrF_3 \rightarrow R_3CF + HF + {}^1/_3Br_2.$$

Selective fluorination of esters containing tertiary hydrogen atoms was effected by such a method.

$$(CH_3)_2CHCH_2OCOCF_3 + BrF_3 \rightarrow \underset{47\%}{(CH_3)_2CFCH_2OCOCF_3}.$$

Bromine trifluoride in the presence of anhydrous hydrogen fluoride (60 mol%) is capable of replacing tertiary hydrogen atoms in the position α to an ester group, which was unsuccessful with elementary fluorine.

$$(CH_3)_2CHCO_2R_F + BrF_3 \xrightarrow[\text{Freon 113}]{HF} \underset{50\%}{(CH_3)_2CFCO_2R_F} +$$
$$+ \underset{8\%}{CH_2BrCFCO_2R_F},$$
$$\quad\ \ CH_3$$

$$R_F = CH_2(CF_2)_2H.$$

On replacing hydrogen atoms with bromine trifluoride the formation of cationoid moieties at the stage determining the reaction products was confirmed by the observation of a methyl group 1,2-migration in the reaction with 2-fluoro-2-methylbutane:[53]

$$(CH_3)_2CFCH_2CH_3 + BrF_3 \rightarrow$$
$$\rightarrow \underset{85\%}{CH_3CF_2CH(CH_3)_2} + \underset{15\%}{(CH_3)_2CFCHFCH_3}.$$

On extended reaction of bromine trifluoride with polyhaloalkanes in a Freon medium nonselective replacement of hydrogen atoms by fluorine was observed:[54]

$$CH_2FCHFCH_2Cl \xrightarrow[\text{Freon 112}]{BrF_3} \underset{29\%}{CH_2FCHFCH_2F} + \underset{35\%}{CHF_2CHFCH_2Cl} +$$
$$+ \underset{6\%}{CH_2FCF_2CH_2Cl} + \underset{29\%}{CHF_2CHFCH_2F}.$$

It should be mentioned that replacement of chlorine atoms in haloalkanes under the action of BrF_3 is catalysed by $SnCl_4$ and $SbCl_5$ (Lewis acids forming complex salts with BrF_3) while replacement of hydrogen atoms is catalysed by anhydrous HF.[55]

$$CH_2ClCHFCH_2Cl \begin{cases} \xrightarrow[SnCl_4(1\%)]{BrF_3} \underset{28\%}{CH_2ClCF_2CH_3} + \underset{43\%}{CH_2ClCHFCH_2F}, \\ \xrightarrow[HF]{BrF_3} \underset{30\%}{CH_2ClCF_2CH_3} + \underset{15\%}{CH_2ClCHFCH_2F} + \underset{25\%}{CHF_2CHFCH_2Cl}. \end{cases}$$

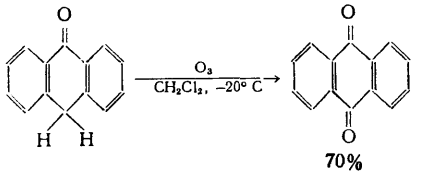
On fluorinating 1,3-dichloro-2-fluoropropane in Freon 113 in the presence of $SnCl_4$ only products of chlorine replacement were obtained while in HF 3-chloro-1,1,2-trifluoropropane, the product of replacing a hydrogen atom, was also obtained.

It has been shown[1] that in oxidative replacement of halogen atoms in organic halo-derivatives, halogen fluorosulphates are closest in reactivity to halogen fluorides. Consequently it might be expected that these reagents will also efficiently oxidise ether C–H bonds. However a single example of oxidative replacement of a hydrogen atom under the action of bromine trisfluorosulphate has been described in the literature.[56]

$$Cl(CF_2)_4H + Br(OSO_2F)_3 \rightarrow Cl(CF_2)_4OSO_2F + BrOSO_2F + HSO_3F.$$
65%

It is difficult to agree with a study[57] which considered that halogen fluorosulphates are inert towards C–H bonds at room temperature and only replace halogen atoms. In the case in question the matter consists not in the inertness of halogen fluorosulphate towards C–H bonds but in the fact that iodine and bromine atoms in alkyl halides are oxidised significantly more slowly than hydrogen atoms. The absence of data on reactions of halogen fluorosulphates with saturated hydrocarbons is also seemingly linked with the extremely low stability of alkyl fluorosulphates which complicates the isolation of the primary substitution products.

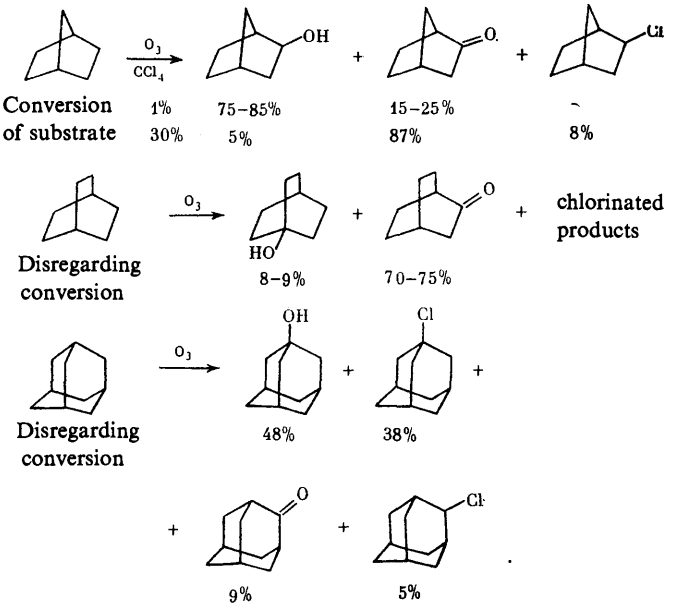
V. Reactions of saturated organic compounds with ozone



Linked with the current ecological concern about the opacity of the Earth's ozone layer, significant attention has been paid to the reaction of ozone with saturated hydrocarbons[58–70] and at the present time this is the most studied class of reactions for the oxidative replacement of hydrogen atoms. The reaction of ozone with σ C–H bonds leads to the formation of hydrotrioxides (XVI) as initial products which at temperatures greater than −40 °C readily decompose with the formation of alcohols and carbonyl compounds.

$$R_2CH_2 + O_3 \rightarrow \underset{(XVI)}{R_2CH_2OOOH} \rightarrow [R_2CHO^{\cdot} + {}^{\cdot}OOH]$$

$$\downarrow \qquad\qquad \downarrow \qquad\qquad \downarrow$$



$$R_2CHOH + O_2 \qquad R_2C{=}O + H_2O_2 \qquad RCHO + R^{\cdot}.$$

$R_2CH\dot{O}$ and $\dot{O}_2H$ radicals escaping from the cage initiate radical processes. Usually ozonation of saturated hydrocarbons is effected by passing ozone diluted with nitrogen or oxygen into a solution of substrate in an inert solvent (CCl_4, CH_2Cl_2, Freons) at a temperature between −78 and +25 °C. Ozonation of anthrone carried out by this method leads to the formation of anthraquinone in 70% yield.[58]

70%

The authors showed that 2 moles O_3 were consumed and 2 moles O_2 were liberated on oxidising 1 mole anthrone confirming the sequential replacement of two atoms of hydrogen. An investigation of the oxidation products of norbornane, bicyclo[2.2.2]octane and adamantane has been described.[59] Both the tertiary hydrogen atoms at the bridge-head and the secondary hydrogen atoms were replaced in adamantane and bicyclo[2.2.2]octane but only secondary atoms in norbornane.

An interesting method of hydroxylation of tertiary C–H bonds has been developed.[60] Ozonation was carried out by absorbing substrate (1%) on silica gel and passing a stream of ozone (3% in O_2) at −45 °C. Rupture of C–C bonds was observed in addition to replacement of hydrogen atoms. Thus interaction of 2,3-dimethylbutane with O_3 led to the following set of products:

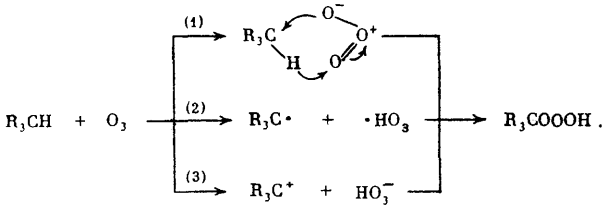
$$(CH_3)_2CHCH(CH_3)_2 \xrightarrow{O_3}$$

$$(CH_3)_2\underset{\displaystyle OH}{\underset{|}{C}}H(CH_3)_2 + (CH_3)_2\underset{\displaystyle O}{\underset{\|}{C}}HCCH_3 + (CH_3)_2CO.$$

35% 28% 37%

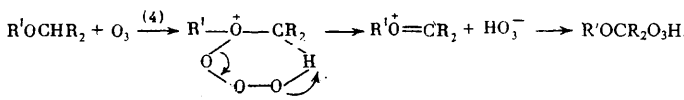
The total yield of ozonation products was 80–90%. The authors noted that on ozonation in Freon 112 solution at −45 °C the conversion of substrate was significantly less but the composition of products was the same as on silica gel. Thus on ozonation of 3-methylpentane the yield of products was only 6%.

Hydrotrioxides stable at low temperatures were obtained on ozonation of acetals with ozone and were characterised by their NMR spectra.[61] The hydrotrioxides decomposed by a radical mechanism to oxygen and the corresponding hydroxy derivatives, which gave esters and alcohols on acidic catalysis:



$$CH_3\underset{\displaystyle H}{\underset{|}{C}}(OR)_2 \xrightarrow{O_2} CH_3\underset{\displaystyle O_3H}{\underset{|}{C}}(OR)_2 \rightarrow$$

$$\rightarrow O_2 + CH_3\underset{\displaystyle OH}{\underset{|}{C}}(OR)_2 \xrightarrow{H^+} CH_3CO_2R + ROH.$$



Replacement of hydrogen atoms at a saturated carbon atom by ozone occurs pre-eminently with retention of configuration. Thus on ozonation of *cis*- and *trans*-1,4-dimethylcyclohexanes 80–90% retention of configuration was observed,[62] oxidation of *cis*- and

trans-decalins to the corresponding 9-decalols occurred with complete retention of configuration.[63]

Many studies have been devoted to the kinetics and mechanism of ozonation of C–H bonds.[59,64–70] Three possible mechanisms have been proposed for the first stage of the oxidation of saturated hydrocarbons with ozone:

A mechanism with initial attack of ozone at the oxygen atom is possible for ethers and acetals in addition to those indicated above:

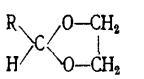
However it was shown that on oxidation of t-butylbenzyl ether[64] and also of a series of hydrocarbons[65,66] the kinetic isotope effect was approximately 4. These data make it possible to consider scheme (4) unlikely.

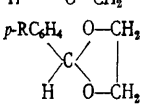
An assessment has been carried out of the possible routes of the ozonation reaction of saturated hydrocarbons by empirical calculation methods in the application of transition state theory based on recent thermochemical data.[62] It was shown that the most probable mechanism involved transfer of hydride ion and the formation of a tight ion pair:

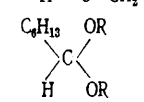
Table 3. Relative rates of ozonation,[67,68] bromination[71] and solvolysis.[72]

Type of C–H bond	O_3	Br·	Solvolysis[a]
Primary	0.003	0.005	—
Secondary	1	1	1
Tertiary	100	88	$10^{7.8}$

[a] Solvolysis rate in 80% alcohol of 2-bromoadamantane and 2-bromo-2-methyladamantane.







However study of the kinetics of oxidation of saturated hydrocarbons place the hydride ion transfer mechanism in doubt.

Relative rates of ozonation of primary, secondary and tertiary C–H bonds are shown in Table 3 as are relative rates of the free radical bromination and solvolysis.

The observed ratios of ozonation rates showed that a significant positive charge is not generated on the α-carbon atom in the transition state as in that case the difference in reactivity would be significantly greater. Since nucleophilic assistance by the solvent is absent from solvolysis of adamantane derivatives the ratio shown in Table 3 reflects the stability of transition states close in structure to a carbocation. It should be mentioned that ozonation is closer to free radical bromination in selectivity (a polar transition state is characteristic of the latter) than to a carbocationic reaction.

A kinetic study of oxidation processes with a change of substituent for various systems showed that the logarithm of the relative rate constants correlated well with the Hammett and Taft constants (Table 4).

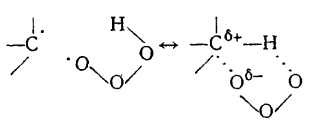


Table 4. Correlation of kinetic data and Hammett and Taft constants.[69,70]

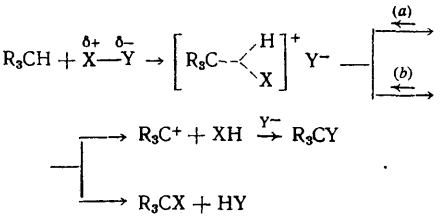
No.	Substrate	ρ
1		−1.16
2		−1.10
3		−1.31
4	p-$RC_6H_4CH_3$	−2.07
5	p-$RC_6H_4CH_3$[a]	−1.42

[a] Reaction parameter for free radical bromination.[71]

The small values of ρ obtained for acetals were explained either by the fact that the positive charge in the transition state is stabilised by the acetal oxygens and to a significantly lesser degree by the substituents or by the fact that a small positive charge is generated in the transition state. For comparison values of ρ in acid hydrolysis reactions of acetals were from −3.6 to −4.2.[73] Comparison of ozonation and free radical bromination shows (Table 4, Nos. 4, 5) that oxidation with ozone proceeds through a more polar transition state than does bromination. The effect of solvent polarity on the ozonation rate of C–H bonds has been investigated.[68,69] It was shown that the oxidation rate of 2-hexyl-1,3-dioxan with ozone in acetic anhydride was two times greater than in n-hexane.[69] A similar increase in rate of 2–2.5 times on going from carbon tetrachloride (ε = 2.24) to acetonitrile (ε = 38) was observed on oxidation of a series of ethers. For comparison the solvolysis rate of t-butyl iodide was increased by more than one order of magnitude on going from benzene (ε = 2.28 to benzonitrile (ε = 25).[71] Thus the available data permit the view that the ozonation of C–H bonds proceeds through fairly polar transition states, however the charge separation in the transition state does not reach values characteristic of carbocationic reactions.

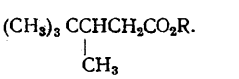
Activation parameters have been determined for the ozonation of a series of saturated hydrocarbons, ethers and acetals.[68,69] The energy of activation of these reactions is between the limits of 5 to 15 kcal/mol, the pre-exponential multiplier varies from 6 to 8. The values obtained for the pre-exponential factor are somewhat greater than would be expected for an insertion mechanism (log A < 7) [74] and less than for the usual radical reactions (log A = 8−11).[71] However the fact that ozonation proceeds through a more polar transition state than free radical substitution should be taken into consideration and this must lead, especially on carrying out the reactions in non-polar solvents, to an increase in the negative entropy of activation. Further the pre-eminent retention of configuration characteristic of ozonation may be explained not only by the insertion mechanism but also by the rapid collapse of the free radical pair in the solvent cage. Such an explanation of the pre-eminent retention of configuration was proposed[75] for the oxidation of saturated hydrocarbons by chromic acid to the corresponding alcohols. The mechanism of direct insertion of oxidising agent at a C−H bond is unlikely since it was shown that the sterically more hindered triethylmethane is oxidised 1.5 times more rapidly than isobutane. Thus the transition state in the ozonation reaction is most probably described by two resonance structures.



VI. General rules and mechanisms for oxidative replacement of hydrogen in saturated hydrocarbons

The experimental data considered in the previous sections show that in practice all strong oxidising agents, viz. elementary fluorine, ozone, nitronium salts or halogen fluorides are capable at low temperature in the liquid phase of selectively attacking a σ-C−H bond leading to the replacement of hydrogen by another element or functional group. The following factors are capable of increasing the selectivity of the oxidative replacement of hydrogen: 1) there must not be many C−H bonds in the substrate molecule of identical reactivity and 2) the more reactive the substrate the greater the dilution by inert solvent of substrate and reagent is required to bring about a selective reaction. An increase in electron density of the C−H bond favours attack by oxidising agent since the following series of C−H bond reactivities was observed for all the reactions considered in the previous sections: tertiary > secondary ≫ primary. Correspondingly the introduction of electron-accepting substituents into the substrate molecule deactivates the neighbouring C−H bond and in this way the selectivity of replacing more distant hydrogen atoms is increased.

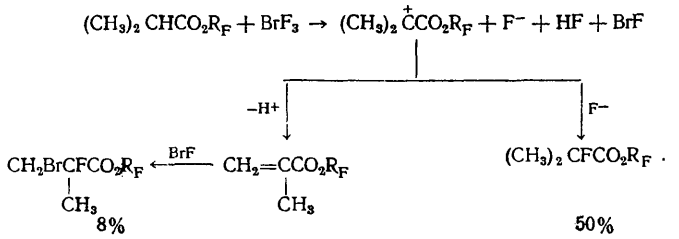
In the general case the non-radical reaction pathway of replacing hydrogen atoms under the action of oxidising reagents may be described by the scheme proposed by G Olah (Scheme 1).[50] Simple C−H bonds possess the ability to give a bonded electron pair to an electrophilic reagent with the formation of two-electron three-centre bonds. The electrophile attacks covalent bonds just from the front not the rear, and those portions of the covalent bond orbitals play a relatively small role. Subsequent breakdown of the three-centre bond in the pentacoordinate carbonium ion (XVII) may lead either to the formation of trivalent carbenium ions (route *a*) or directly to bonding carbon with the electrophile and ejection of a proton (route *b*).



Scheme 1

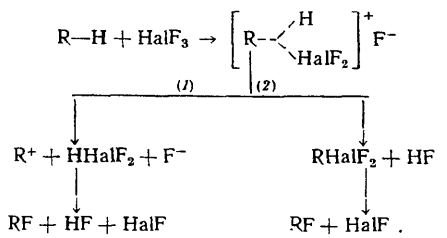
Replacement of hydrogen atoms by scheme 1*a* should be referred to as a nucleophilic substitution reaction and by scheme 1*b* as a direct electrophilic replacement at a saturated carbon atom. At the present time it appears extremely difficult to choose between these directions for the majority of oxidative replacements of hydrogen. Thus in the case of homoatomic oxidising agents (F_2, O_2, Hal_2−Lewis acids) it is impossible to make this choice on the basis of the nature of the products since in both cases the same products will be formed. Consequently the scheme of direct electrophilic replacement quoted for these reactions in the fundamental publication[76] does not have adequate foundation.

The authors present a series of arguments in favour of electrophilic substitution as the course of the reaction of elementary fluorine with hydrocarbons, however in our view it is impossible to regard the mechanism of this reaction to be unequivocally established.



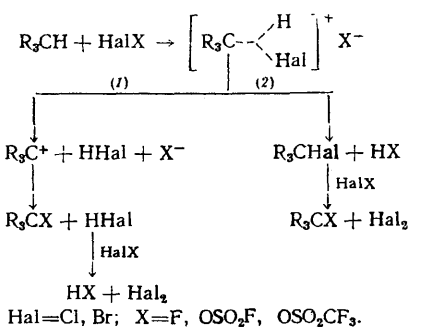
The first argument is the absence of rearrangements characteristic of carbenium ions. This principle, discovered by the authors, is not unexpected since only tertiary hydrogen atoms were subjected to substitution and rearrangements are not characteristic for tertiary carbocations. It would be extremely interesting to investigate fluorination of substrates for which rearrangements are possible, for example:

The second argument is the absence of elimination reactions. Proceeding from the general reaction rules of carbenium ions obtained from study of solvolysis reactions it would certainly be expected that unsaturated compounds would be formed on carrying out a fluorination reaction through a carbenium ion, especially in a non-polar solvent. However under these conditions the resulting olefins will be subjected to further fluorination and consequently small quantities of difluoro adducts will be difficult to detect among products of radical fluorination.



Further it should be mentioned that the formation of olefins is not a characteristic of hydrogen replacement reactions under the action of ClF_3 and BrF_3, although tertiary carbocations are formed in these reactions. Probably this is linked with the small steric volume of the nucleophile (fluorine anion) and also with conducting these reactions at low temperatures. Nonetheless in the reaction of fluoroalkyl isobutyrate with BrF_3 in addition to the main product, fluoroalkyl 2-fluoroisobutyrate, a small quantity of fluoroalkyl 2-fluoro-3-bromoisobutyrate was isolated[52] which was

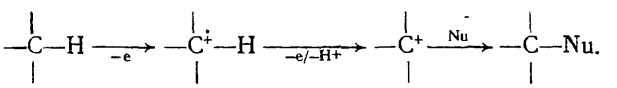
probably formed as a result of bromofluorination of the unsaturated ester:



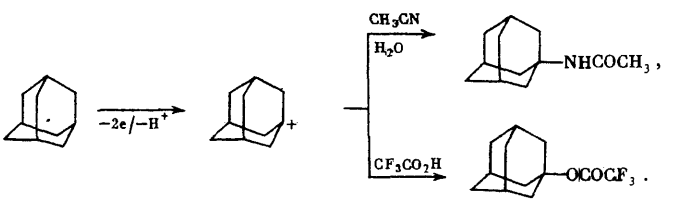
The main argument in favour of electrophilic substitution is the formation of products with complete retention of configuration from optically active substrates. However these results were obtained for conformationally stable cyclohexane derivatives, there are no data on the stereochemistry of oxidative substitution of hydrogen atoms in aliphatic compounds. It is known that the replacement reaction may proceed with the formation of carbenium ions and is accompanied by retention of configuration in the case when the reaction proceeds in a tight ion pair.[71]

In hydrogen replacement reactions with halogen fluorides (ClF_3, BrF_3) the formation of carbocationic intermediates at the stage determining the reaction products has been unambiguously confirmed by the observation of 1,2-migration of methyl groups. However two reaction routes may be proposed in this case:

Conversion of alkylhalogen(III) difluoride into final product may be accompanied by rearrangements. Thus dissociation of neopentyliodine(III) difluoride occurs with methyl group migration and the formation of t-amyl chloride and trimethylethylene derivatives.[1]



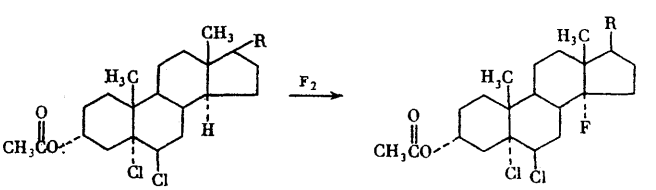
On the whole, for any oxidising agent containing an electropositive halogen atom, it is impossible to draw a conclusion as to the direction (route *1* or *2*) of the reaction based on the reaction products. At present it is well known that such oxidising agents preferentially attack the unshared electron pairs of halogen atoms covalently bonded to carbon rather than a C—H bond in identical surroundings.[1] Consequently if the reaction also proceeds according to route *2* then the product obtained R_3CHal will be slowly converted into product R_3CX undergoing in this route all the rearrangements and migrations typical of this reaction.



Therefore irrespective of the reaction route the final products of the interaction of hydrocarbons with halogen-containing oxidising agents will be the same.

It might have seemed that reasoned conclusions on the possible routes of hydrogen replacement by scheme 1 may be drawn on the basis of results of nitronium salt oxidation of hydrocarbons. In a non-nucleophilic medium (CH_2Cl_2, sulpholan) nitro derivatives are obtained in low yield the formation of which may be explained by electrophilic substitution (route *b*). The formation of 1-nitroadamantane shows that attack at a C—H bond is effected from the front since attack from the rear is impossible for adamantane. However on carrying out these reactions in nucleophilic solvents (CH_3CN, CF_3CO_2H) the corresponding acetamides and trifluoroacetates were formed in high yield which, together with the observed sextet rearrangements and elimination reactions, points in favour of splitting off a hydride ion with the formation of carbenium ion (route *a*).

The great similarity between the results of the hydrogen replacement reactions under the action of oxidising agents and the results of electrochemical oxidation of similar compounds has attracted attention.[34,77–79] In the light of modern ideas the formation of a carbenium ion in electrochemical oxidation of saturated hydrocarbons occurs as a result of two sequential one-electron oxidations, which is formally equivalent overall to hydride ion elimination by the reagent, i.e. the oxidising agent:[34]



Depending on the solvent and electrolyte used, corresponding functional derivatives are formed, for example:

Yields of trifluoroacetates and acetamides were 50—90%.[69,77] As indicated previously similar results were obtained with nitronium salts.

It should be added that if terminology is applied strictly then the proposed elimination of hydrogen by an electron pair under the action of an oxidising agent cannot be called hydride ion elimination since the attacking electrophilic particle (E) possesses more strongly electron-accepting properties than hydrogen and a molecule with an electropositive hydrogen atom is the leaving group.

A particular special feature may be noted for certain oxidising agents containing electropositive oxygen or fluorine atoms, viz. their greater affinity towards hydrogen than towards chlorine (in the same environment). Such data are rare at present but they merit attention.

Oxidising agents with an electropositive halogen oxidise chlorine atoms under identical conditions.[1]

$$CH_3(CH_2)_5Cl + BrF_3 \rightarrow CH_3(CH_2)_3CHFCH_3.$$

The oxidising replacement reactions for hydrogen considered have one further special feature concerning their preparative use. Although tertiary and secondary C–H bonds are readily oxidised some final substitution products are unstable under the usual conditions in the case of simple hydrocarbon substrates. Thus secondary and tertiary fluorides, fluorosulphates and related compounds are readily decomposed especially in the presence of traces of strong acid. However introduction of electron-accepting substituents into a substrate increases the stability of such compounds and under these conditions interesting preparative applications may be considered for the oxidative hydrogen replacements.

Summarising the results considered the following conclusions may be drawn:

1. At the present time there are no conclusive data confirming the possibility of electrophilic substitution of hydrogen at an sp^3-hybrid carbon under the action of oxidising agents.

2. Carbenium ions are formed at the stage determining the products of oxidative replacement of hydrogen.

Further investigations are necessary for a deeper understanding of the mechanism of the above reactions. In particular it is necessary to expand ideas on the oxidation of C–H bonds at sp^3-hybrid carbon atoms by reagents such as halogen fluorides, hypohalites of strong acids and nitronium salts.

In conclusion it would be desirable to record that at present chemists have available a large selection of oxidising reagents for the selective functionalisation of saturated hydrocarbons and it may be expected that in the next few years the preparative potential of these reactions will be appreciably expanded.

Reactions of pyridines, pyrimidines and 1,3,5-triazines with nucleophilic reagents

N V Alekseeva, L N Yakhontov
S. Ordzhonikidze All-Union Scientific-Research Institute for Pharmaceutical Chemistry, Moscow

ABSTRACT. Literature data published since 1971 on the addition of nucleophiles to the C=N bond of the most studied π-deficient six-membered heterocycles, viz. pyridine, pyrimidine and 1,3,5-triazine leading to their transformation have been examined and correlated. Possible applications and proposed mechanisms for the considered processes have been discussed.

The bibliography contains 169 references.

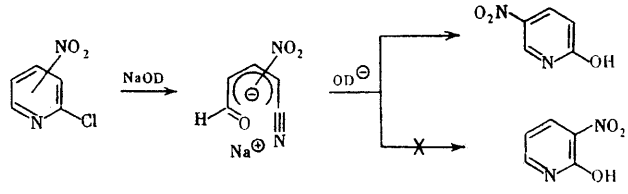
I. Introduction

Nitrogen atoms of the pyridine type in six-membered nitrogen-containing aromatic compounds redistribute the electron density such that the carbon atoms in the heterocycle are depleted of electrons.[1,2] The maximum deficiency of negative charge is formed in the positions *ortho* and *para* to the hetero atom.[2] The angle between the valence bonds of nitrogen and carbon in heterocycles of such type differ from 120°.[3] The above mentioned reasons facilitate the addition of nucleophilic reagents at the C=N bonds of these rings. Among the considered compounds the uncondensed azines lie in the series 1,3,5-triazine > pyrimidine > pyridine in reactivity towards nucleophiles in accordance with the decrease in π-deficiency.[1]

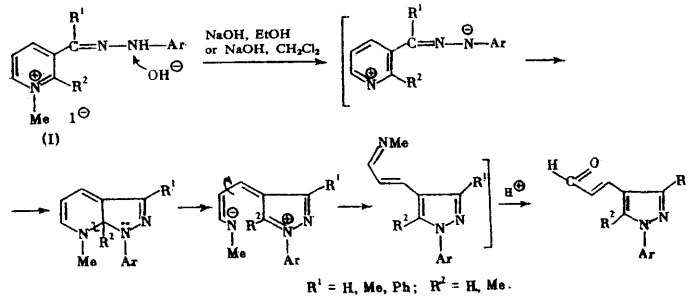
In several cases the addition of nucleophiles to these heterocycles leads to transformations of the latter.

Conversions of heterocycles known up to 1971 have been collated in a review.[4] Separate problems on recyclisation under the action of certain nucleophilic reagents have been considered in reviews for pyridines,[7,13] pyrimidines[5,6,10,12] and other azines.[8,9,11]



A large number of studies has been published in the chemical literature in the last decade on such transformations the analysis and correlation of which for uncondensed pyridines, pyrimidines and 1,3,5-triazines is the subject of the present review.

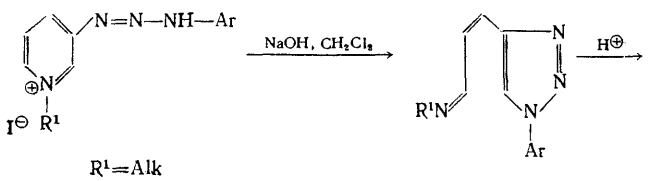
II. Recyclisation of pyridines, pyrimidines and 1,3,5-triazines under the action of water, alkali, amines, and strong acids



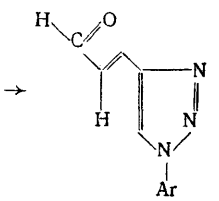
Pyridines, having only one nitrogen atom, are the most 'aromatic' among the compared heterocycles and are least inclined to interact with nucleophiles. In order to facilitate addition of nucleophilic reagents at the C=N bond of the pyridine ring their quaternary salts are usually used.[3,7,13] An analogous method is frequently applied in the case of pyrimidine compounds characterising high reactivity towards nucleophiles. The three nitrogen atoms of 1,3,5-triazines show such high overall electron-accepting action that these molecules are sufficiently activated for reaction with nucleophiles without quaternisation.

The products of cleaving pyridinium salts by nucleophiles are derivatives of glutaconic aldehyde which are used in organic synthesis for cyclisation into derivatives of pyridine and other heterocycles.[13]

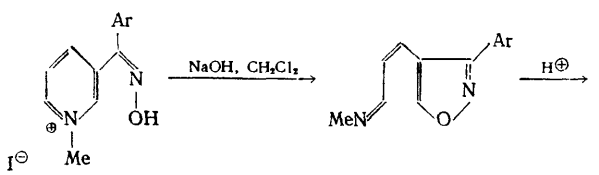
Derivatives of glutaconic aldehyde are formed on heating 2-chloropyridines having a nitro group in the 3 or 5 positions with alkali. However these cyclise once more into a pyridine compound but only a 5-nitropyridine derivative.[14]



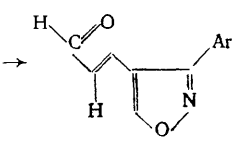
3-Arylhydrazonomethyl-1-methylpyridinium iodides (I) are converted into acroleylpyrazoles in the presence of base. According to the proposed mechanism, under the action of base a negative charge arises on the nitrogen atom of the hydrazone fragment in (I) and this aids intramolecular cyclisation. Rupture of the pyridine ring then occurs and a pyrazole derivative is formed.[15,16]



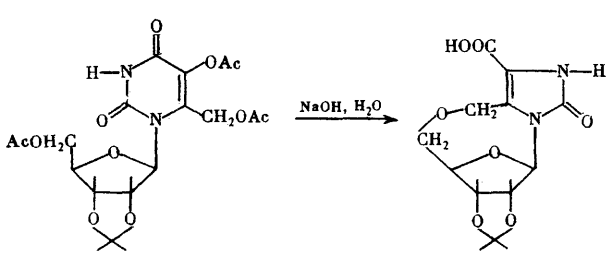
As might have been expected from the conversion scheme electron-donating substituents R^1 in (I) reduce the yield of pyrazole derivative. A substituent R^2 in (I) also shows a negative effect on the course of the reaction due to steric hindrance when forming the intermediate bicyclic compound.



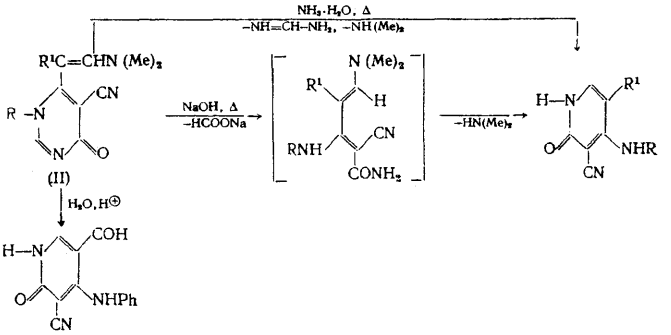
If the $R^1-C=$ fragment in the pyridine salt (I) is replaced by nitrogen then the 3-(3′-aryl-1′-triazenyl)-1-methylpyridinium salt is converted under the above conditions by an analogous scheme into a 1,2,3-triazole derivative.[16,17]



R^1=Alk

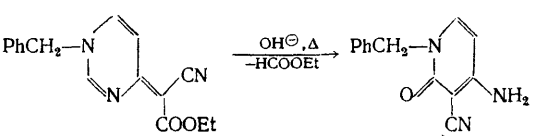


Derivatives of isoxazole are formed by a similar reaction from oximes of 3-benzoyl-1-methylpyridinium iodides in 10% yield.[16,17]



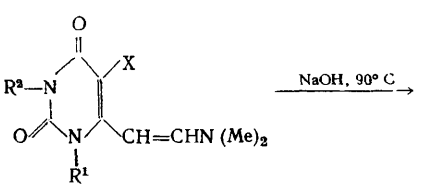
Uracil compounds are converted by alkali into imidazolones which are used in nucleic acid chemistry.[18]

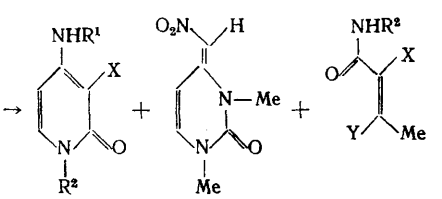
Similar conversions of the pyrimidine nucleus into imidazolones occur in aqueous solutions of amines or alkali and also in the case of pyrimido[4,5*e*]1,2,4-triazines.[19,20]



1,6-Disubstituted 5-cyano-4-oxo-1,4-dihydropyrimidines (II) are decomposed on boiling in dilute alkali with fission of the C(2)–N(1) and C(2)–N(3) bonds with separation of formic acid salts. Cyclisation of the resulting intermediate occurs through the dimethylaminovinyl fragment with cleavage of dimethylamine.[21–24] A similar conversion of (II) (R = $PhCH_2$, R^1 = H) occurs on boiling with aqueous ammonia with cleavage of formamidine.[25]

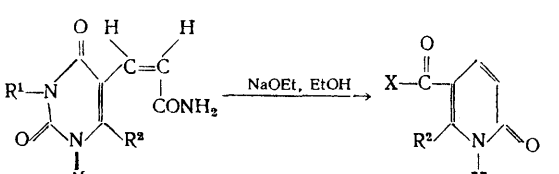
In the case of hydrolysis of (II) (R = Ph, R^1 = H) with acid the recyclisation product was 3-cyano-5-formyl-2-oxo-4-phenylamino-1,2-dihydropyridine.[26]





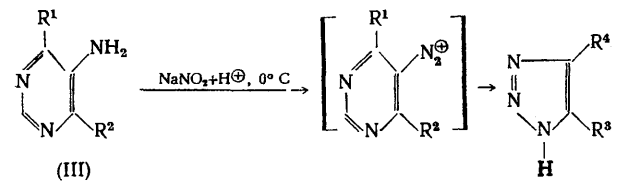
R^1, R = $-(CH_2)_n-$, n = 2,3; R = $PhCH_2$, Ar, cyclohexyl, R^1 = H.

Alkaline hydrolysis of 1-benzyl-4-(ethoxycarbonylcyanomethylene)-1,4-dihydropyrimidine also led to a 2-pyridone derivative.[27]



6-Dimethylaminovinylated derivatives of uracil are converted on heating in alkali into 2-pyridone derivatives with the formation of pyrimidines and acyclic compounds as side products.[28,29]

X=NO_2, CN; Y=R^1NH, OH;
R^1=Me, Ph, $PhCH_2$; R^2=Me, $C_6H_{11}Ar$

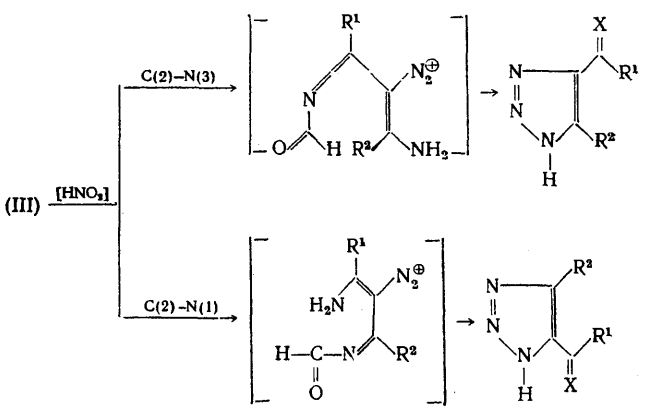


5-(2′-Carbamoylvinyl)uracils with sodium ethoxide in ethanol form 5-carbamoylpyrid-2-ones the ratio of which depends on the amount of water added to the reaction mixture.[30]

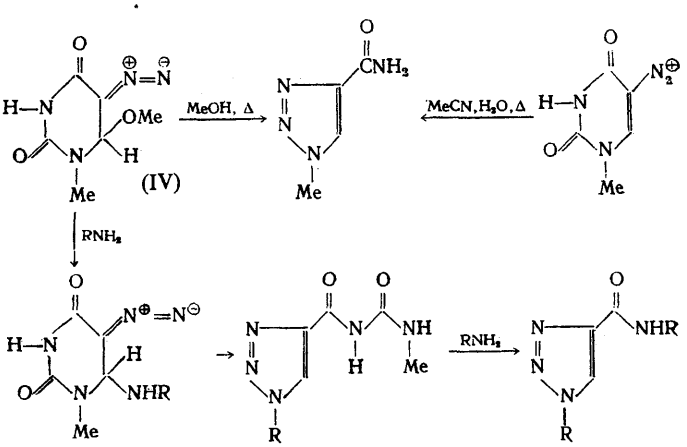
R^1R^2=H, Alk; X=R^1NH, OEt.

Unsubstituted pyrimidine is converted into 5-ethyl-2-methylpyridine on heating with aqueous methylamine in a sealed tube.[31]

4,6-Disubstituted 5-aminopyrimidines containing no labile hydrogen atoms in the 4 and 6 positions form 4,5-disubstituted 1,2,3-triazoles on treatment with nitrous acid.[32–35]



(III)

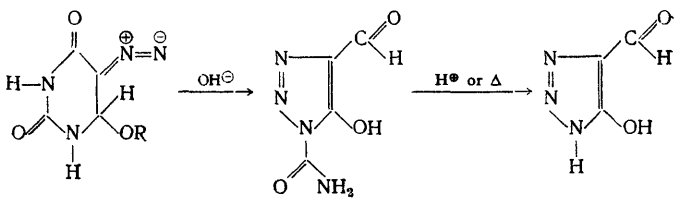


R^1=OMe, $N(Me)_2$, OEt; R^2=SAlk, SAr, SHetar, $N(Me)_2$, Cl, OMe, OEt; R^3=R^2, CN, $C(=Y)R^2$, where Y=NH, O;

R^4=COOMe, COOEt, CN, $C(=O)SR$.

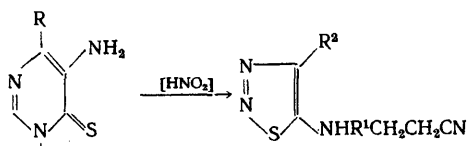
It is presumed that diazonium salts are formed initially which are subjected to covalent hydration at position 2 of the pyrimidine ring. The presence of a methyl group in the second position of (III) had no effect on the course of hydration. Then either the C(2)–N(1) or the C(2)–N(3) bond in the pyrimidine ring may break. The obtained intermediates are cyclised into 1,2,3-triazole derivatives.[32–35]

Diazonium salts of the uracil series are converted on heating in methanol or aqueous acetonitrile by fission of the N(1)–C(2) bond of the pyrimidine nucleus into 4-carbamoyl-1-methyl-1,2,3-triazole.[36,37]



(IV)

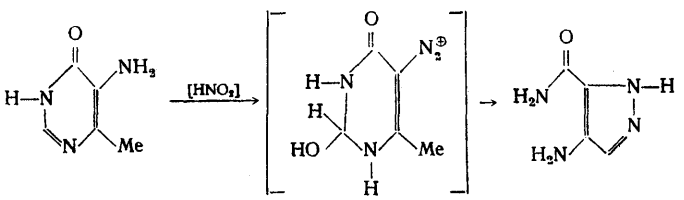
R=Alk, $-CH_2CH=CH_2$, $-(CH_2)_3N(Me)_2$.



Compound (IV) forms 1,2,3-triazoles by reaction with various primary amines.[38,39] Possibly primary amines initially replace the alkoxy residue of (IV) and then fission of the C(6)–N(1) bond occurs with closing of the five-membered 1,2,3-triazole ring and inclusion in it of the amino group nitrogen. Similar reactions take place for 3-methyl and 1-desmethyl derivatives of (IV).

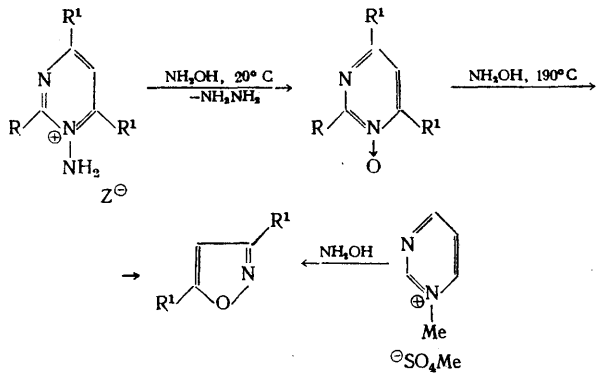
Alkaline hydrolysis of 5-diazouracils leads to 1,2,3-triazoles in 60–90% yield.[40]

Conversions of 5-diazouracils into compounds of the 1,2,3-triazole series are used in nucleic acid chemistry.[37,41]



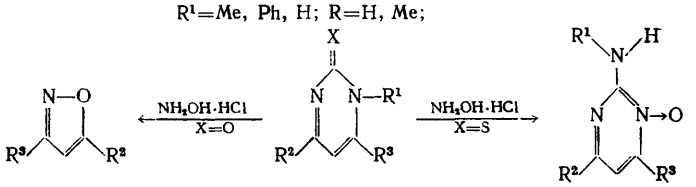
4-Substituted 5-amino-1-(β-cyanoethyl)-1,6-dihydropyrimidine-6-thiones, in contrast to 6-alkylthio derivatives are converted by diazotisation into 5-amino-1,2,3,thiadiazoles.[34,35,42]

R=Cl (a), OMe (b)



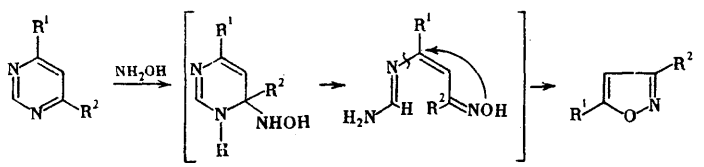
R^1=CN, R^2=CHO (a), R^1=COH, H; R^2=COOMe (b)

In the case of 5-amino-4-methyl-6-oxo-1,6-dihydropyrimidine, the acyclic intermediate formed under conditions of diazotisation is cyclised to a pyrazole derivative owing to the presence of the methyl group.[34,35]

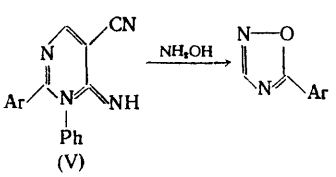


N-Dinitrophenylpyridinium salts give pyridine *N*-oxide on interaction with hydroxylamine through a glutaconic aldehyde derivative.[7,13]

Interaction of pyrimidine compounds with hydroxylamine usually leads to an isoxazole derivative or pyrimidine *N*-oxide.[43–45]

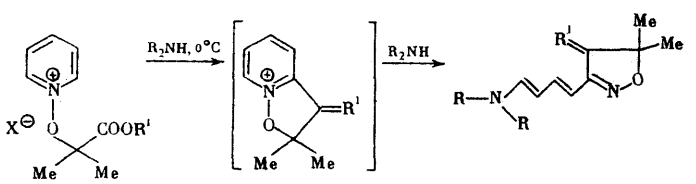


R^1=Me, Ph, H; R=H, Me;

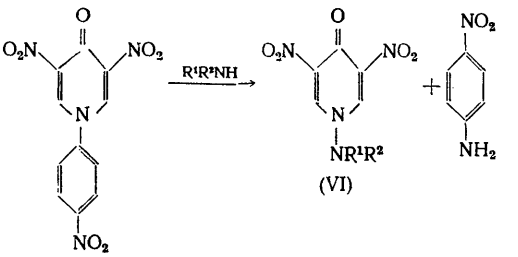


R^1, R^2, R^3=Me, Ph, Ar.

It is assumed that in these reactions hydroxylamine is added at the 1,6-position of the pyrimidine nucleus after which the ring breaks. The intermediate cyclises to an isoxazole compound containing the C(4)–C(5)–C(6) fragment of the initial pyrimidine.[43]



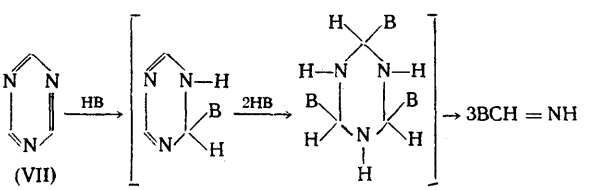
Pyrimidine compound (V) is converted under the action of hydroxylamine into a 1,2,4-oxadiazole derivative.[10,46]



(V)

Alkoxypyridinium salts are recyclised in methanol with amines into isoxazole derivatives.[47] The isolation of the bicyclic intermediate from the reaction mixture confirmed the proposed scheme.[47]

R^1 = OEt(a), Ph(b), R^1 = O(a), Ph, OH(b) R^1 = O(a), Ph, OH(b)

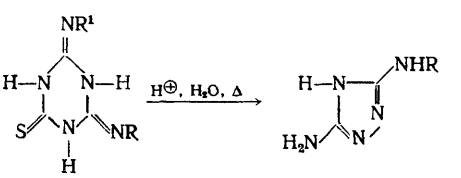


When 3,5-dinitro-1-(4-nitrophenyl)pyrid-4-one reacts with amines recyclisation occurs with the formation of 4-nitroaniline and the corresponding 1-amino substituted pyridone (VI).[48] This reaction (55–100% yield) is used for replacing amino groups in amino acids. The free amino acid is obtained by reacting (VI) with stronger bases. Racemisation of the amino acid was not observed.[49]

(VI)

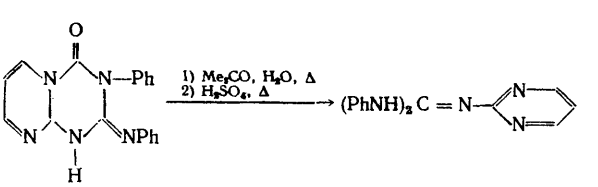
R^1, R^2 = $-(CH_2)_5-$; R^1 = H, R^2 = Alk, amino acid.

In contrast to pyridines and pyrimidines unsubstituted 1,3,5-triazine (VII) is able to add up to three molecules of nucleophile with the formation of an adduct which is decomposed into three molecules of amine by the following scheme.[50]



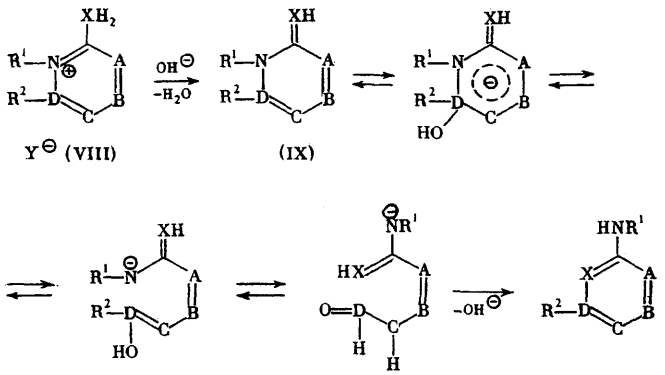
(VII)

HB – nucleophile



The ability of (VII) to be decomposed into three fragments by the action of nucleophiles is used in various syntheses for introducing a methylenimine group.[51–56]

Unsymmetrically substituted 1,3,5-triazines may be recyclised in a more complex manner under the action of nucleophilic reagents.[57]

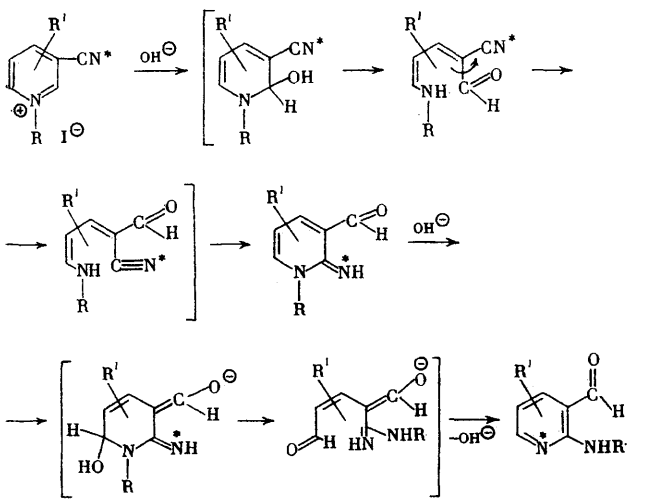


R = H, Ph; R^1 = H, NH.

Condensed pyrimido[1.2a]1,3,5-triazines are split in a stepwise manner. Initially the pyrimidine ring is cleaved on boiling in aqueous acetone and a 2-acroleylamino-1,3,5-triazine derivative is obtained. Boiling in sulphuric acid causes opening of the 1,3,5-triazine ring and splitting away of the acroleylamino residue. Subsequent cyclisation leads to a pyrimidine derivative.[58]

III. The Dimroth and Kost–Sagitullin reactions

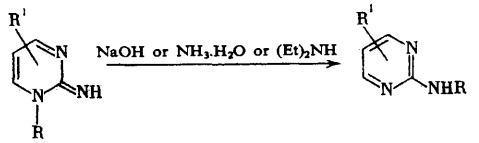
Rearrangements are often observed in the reaction of nucleophiles with electron-deficient nitrogen-containing rings. A general mechanism for this is given in the scheme.[59,60]



$Y^{\ominus}$ (VIII) (IX)

X, A, B, C, D = N or CH.

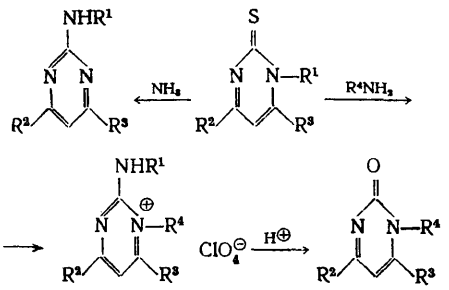
A quaternary salt of the heterocycle (VIII), its anhydro base or imino form (IX) adds nucleophile (hydroxyl ion, amine or hydroxylamine) and is converted into a new heterocyclic system. If a new C–N bond is formed as a result of recyclisation the reaction is called a Dimroth rearrangement.[61] If a new C–C bond is formed on recyclisation and the obtained heterocycle contains one atom of nitrogen less than the initial (VIII) such a rearrangement is called a Kost–Sagitullin rearrangement.[8,60] The presence of labile exocyclic α-atoms of hydrogen is one of the conditions for these reactions.[59]



The Kost–Sagitullin rearrangement is characteristic of pyridinium and pyrimidinium salts[9] and the Dimroth reaction is a feature of pyrimidines and 1,3,5-triazines[61] but is rarely met in pyridines.[62]

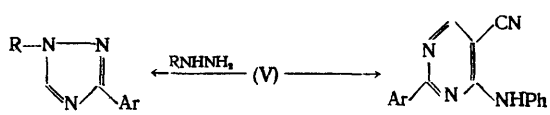
1-Alkyl-3-cyanopyridinium iodides are converted in alkaline solution first into derivatives of 1-alkyl-2-aminopyridine which are recyclised once more into 2-alkylaminopyridines. To detect the indicated conversions it was helpful to introduce ^{15}N into the cyano group of the initial pyridine and study the subsequent behaviour of the label.[62]

R = Me, R^1 = H(a); R = Et, R^1 = 5-Me(b); N* – ^{15}N-labelled atom.



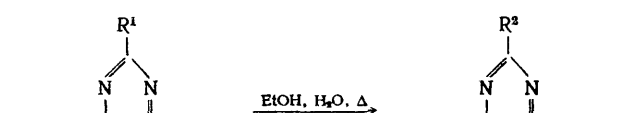
The Dimroth rearrangement for pyrimidines usually takes place in protic solvents in the presence of base. 1-Substituted 2-amino-1,2-dihydropyrimidines take part in it particularly readily[61] and are converted into 2-alkylaminopyrimidines.

R = Alk, CH_2COOEt; R^1 = Alk, Hal, NO_2, $N(Et)_2$.



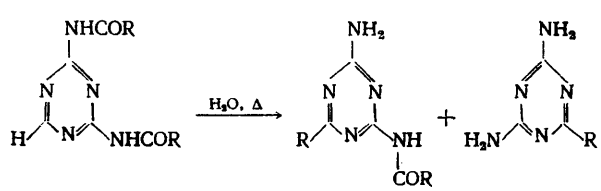
The reaction does not take place in aprotic solvents, a change of protic solvent may influence the course of the rearrangement.

1,4,6-Trisubstituted 2(1H)-pyrimidinethiones react with ammonia in a sealed tube by a type of Dimroth rearrangement. The presence of perchlorate anion is necessary for the analogous rearrangement with primary amines. The resulting salts are readily hydrolysed by acid to 2-pyridones.[63]



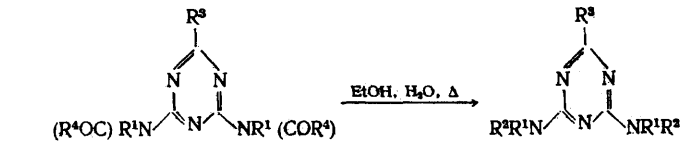
R^1, R^3 = Me, Ar, Ph; R^2 = Me; R^4 = Alk.

Reaction of pyrimidines (V) with guanidine, ethylenediamine or thiosemicarbazide gives 2-aryl-5-cyano-4-phenylaminopyrimidines, the products of Dimroth rearrangement.[10,46] When a bulky substituent is present in the nucleophile recyclisation leads to a 1,2,4-triazole derivative.[10,46]



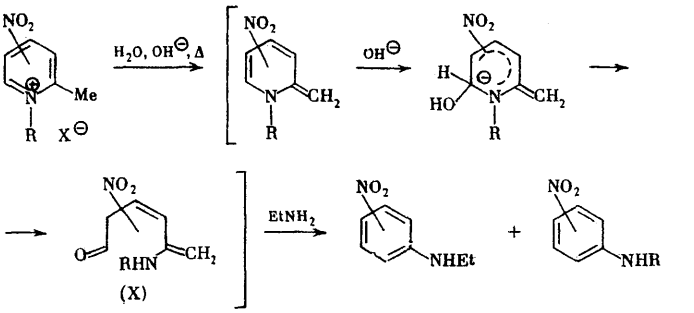
R = Ar, Ph, H

2,4-Diacylamino-1,3,5-triazines undergo a Dimroth rearrangement on heating in aqueous alcoholic solution.[64,65]



R^1 = H, Me; R^2 = Ph, Ar.

Two products are formed in the case of aliphatic *N*-acyl residues[66] and the processes proceed more rapidly than for the corresponding aromatic acyl derivatives.



R = Alk

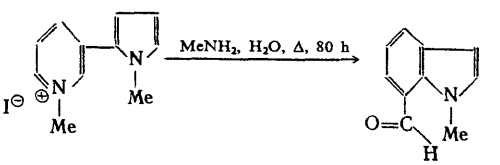
2,4-Di-(*N*-alkyl, *N*-acylamino-1,3,5-triazines undergo a double Dimroth rearrangement on boiling in aqueous alcohol.[67] The reaction proceeds twenty times more slowly with *N*-alkylated *N*-acylaminotriazines than with *N*-unalkylated compounds.

R^1 = Alk; R^2 = H; R^3, R^4 = Me, Ph, Ar, H.

The simplest example of a Kost–Sagitullin rearrangement is the recyclisation of pyridines[68] and their quaternary derivatives[69–74] on heating in aqueous solutions of ammonium salts and alkali to give substituted alkylanilines.

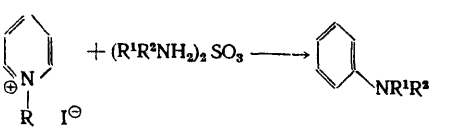
Recyclisation is assisted by electron-accepting substituents in positions 3 and 5 of the pyridine ring,[69–72] by the presence in the α-position to nitrogen of groups capable of deprotonation with the formation of anhydro bases and by the presence of amine as cyclising agent in the reaction mixture.

If the substituents in the amine and at nitrogen of the pyridinium ring are different then transamination at the stage of the acyclic intermediate (X) and the formation of several recyclisation products is possible.



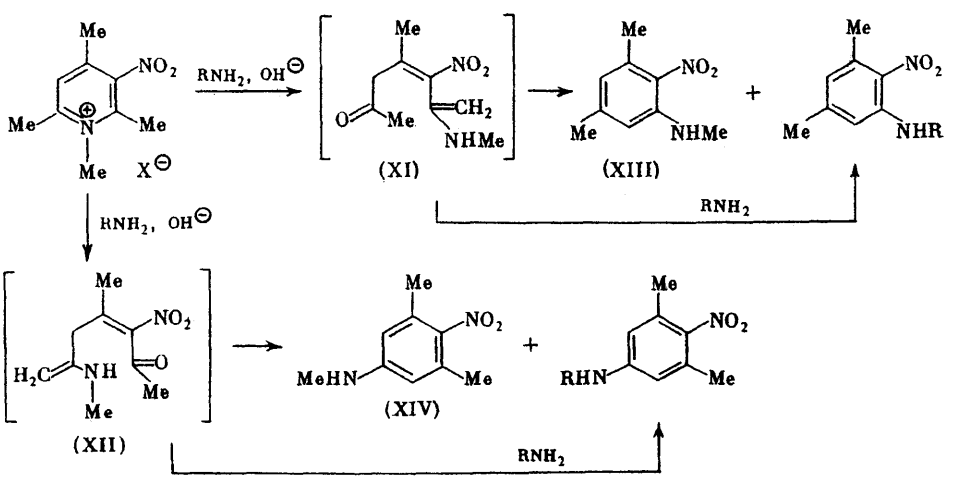
The presence of groups with labile hydrogen atoms at positions 2 and 6 of the pyridine leads to the formation of two anhydro bases (XI) and (XII) and as a result two isomeric anilines (XIII) and (XIV) are generated in the presence of methylamine.[70,72,73]

The ratio of (XIII) and (XIV) is determined by the degree of preference of attack of hydroxyl ion on the initial pyridine at the position *para* to the nitro group compared to the formation of *ortho* isomer (XII). However transamination of the acyclic intermediate (XI) is hindered. Consequently *para* isomer (XIV) predominates in the transamination products (except when R = Me).[75]



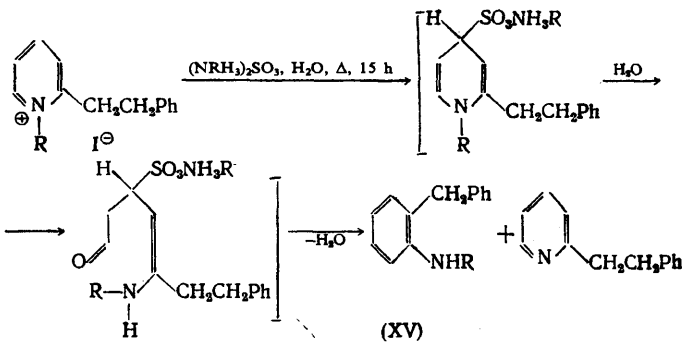
When the chain length of the *N*-alkyl substituent in the pyridinium salts reaches C_{12}, in the author's opinion, micelle formation takes place in the aqueous solution in which the pyridine bases are disposed on the micelle surface.[76,77] As a result the approach of water molecules to the recyclisable product and ring opening are facilitated and the approach of amine is hindered and transamination practically does not occur.

The Kost–Sagitullin rearrangement is also used for introducing an aromatic residue into other heterocycles[78–81] and the preparation of aromatic amines.[8,82–88]

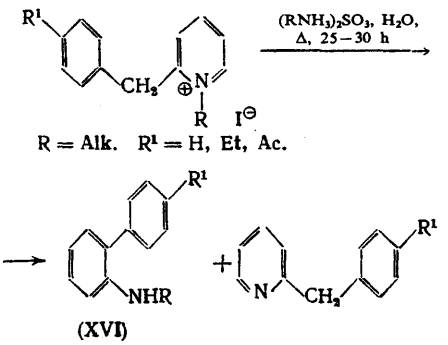


Thus heating nicotine methiodide at 150 °C with methylamine leads to recyclisation to 7-formyl-1-methylindole.[79]

Alkylpyridinium salts form arylamines under the conditions of the Kost–Sagitullin reaction.[82]

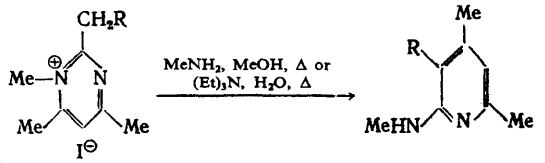


R, R^1, R^2 = Alk.



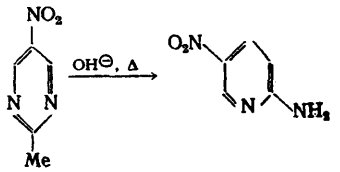
R = Alk

Similarly 2-(2-phenylethyl)pyridinium salts form *ortho*-alkylaminodiphenylmethanes (XV).[83,84]



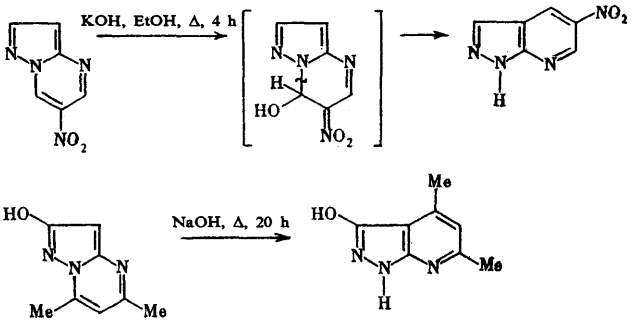
Benzylpyridinium salts form 2-aminobiphenyls (XVI).[85,86]

N-Dealkylation products are formed in these reactions together with (XV) and (XVI).[83–86]

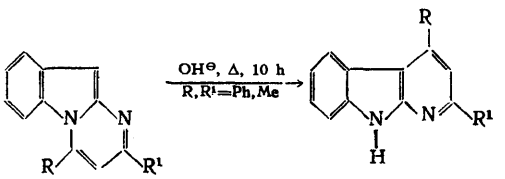


Transamination may occur at the ring opening stage if the R substituent in the pyridinium salt and in the alkylamine sulphite are different. Yields of biphenyl recyclisation products (XVI) are reduced with increasing volume of the *N*-alkyl group, or with the introduction of substituents into the α and β positions of the pyridine nucleus which hinders the addition of sulphite anion, or by introducing electron-donating residues into the phenyl nucleus impeding intramolecular cyclisation of intermediates.

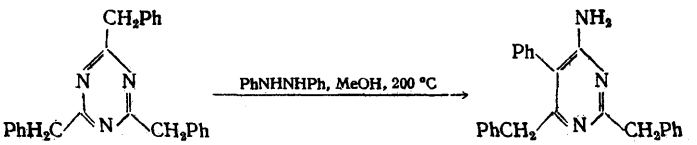
Pyrimidinium salts readily add nucleophiles under conditions of the Kost–Sagitullin reaction and are converted into α-aminopyridine derivatives.[89]



R = Ph, COOEt

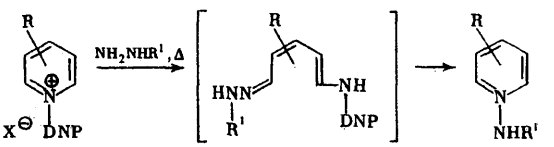


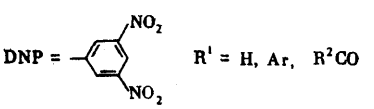
A nitro group in the pyrimidine ring facilitates these reactions and recyclisation of 2-methyl-4-nitropyrimidine is possible without obtaining the quaternary salt.[90]



Condensed systems such as pyrazolo[1,2a]pyrimidines are recyclised into pyrazolo[3,4b]pyridines on heating with alkali. The presence of a nitro group in the starting material facilitates the reaction.[91]

Pyrimido[1,2a]indoles are converted into α-carbolines on boiling in alkali.[92]

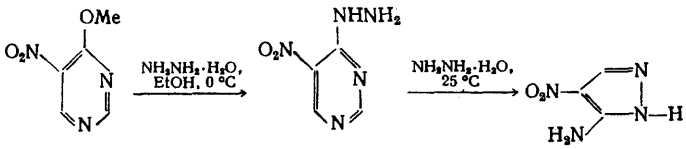




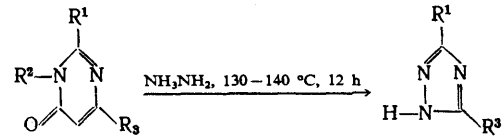
The Kost–Sagitullin rearrangement recalls the conversion of 2,4,6-tribenzyl-1,3,5-triazine into a pyrimidine derivative on heating with hydrazobenzene in methanol.[93]

IV. Recyclisations during hydrazinolysis

The interaction of pyridines, activated by donating-accepting substituents or transformed into quaternary salts, with hydrazine[7,13] proceeds with recyclisation of the pyridinium ring into an *N*-aminopyridinium ring.

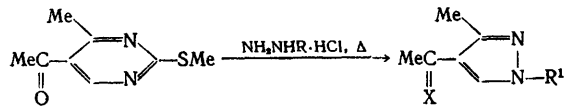


Many studies have been devoted to the hydrazinolysis of pyrimidine derivatives[35,90,94–104] mainly to pyrazoles[90,94–104] and to 1,2,4-triazoles.[35,95,102]



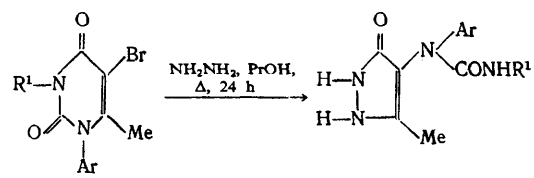
If there are substituents in the pyrimidine ring capable of interacting with hydrazine then at low temperature (<0 °C) hydrazinopyrimidines are formed.[94,96,99,101] and on increasing the temperature (occasionally to room)[99] and using an excess of

hydrazine, addition of one further molecule of hydrazine to the pyrimidine[96,99,101] and recyclisation were observed.



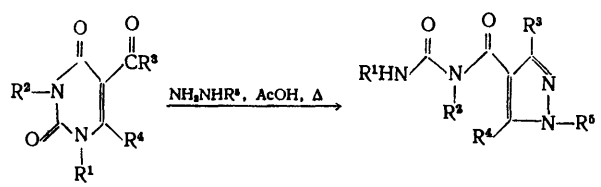
4-Methoxy-5-nitropyrimidine forms 4-hydrazino-5-nitropyrimidine with hydrazine hydrate in alcohol at 0 °C, which at room temperature and with an excess of hydrazine is converted into 3-amino-4-nitropyrazole.[96]

Analogous reactions proceed above 100 °C in the absence of the nitro group.[102]



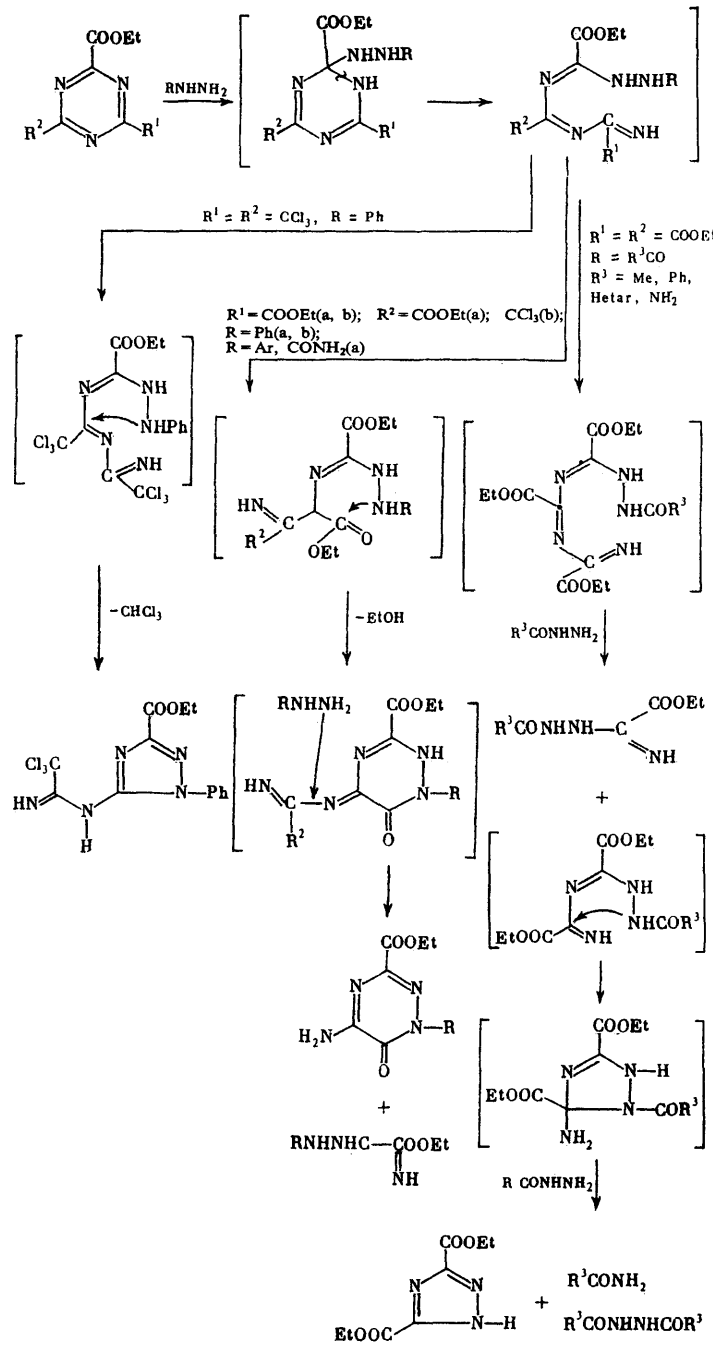
Heating 5-acetyl-4-methyl-2-methylthiopyrimidine with hydrazine hydrochlorides leads to pyrazole derivatives.[101]

R = H, Me, Ph, C(=NH)NH$_2$, CONH$_2$, CSNH$_2$;



X = O, NH$_2$; R^1 = R, H

On heating 1,3-disubstituted 1-aryl-5-bromo-6-methyluracils with hydrazine in isopropanol they recyclise into 4-substituted 3-pyrazolones.[97,98]



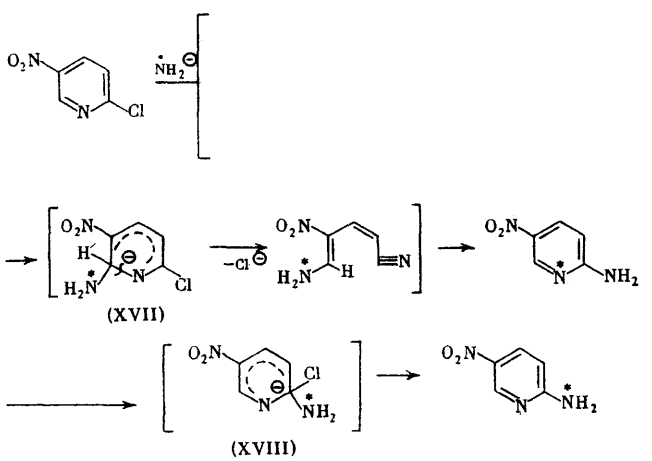
R^1 = Alk, —CH$_2$—CH=CH$_2$.

Hydrazinolysis of uracil derivatives in acetic acid also leads to pyrazoles.[99,100]

R^1, R^4 = H, Me, Et; R^2, R^3, R^5 = H, Me.

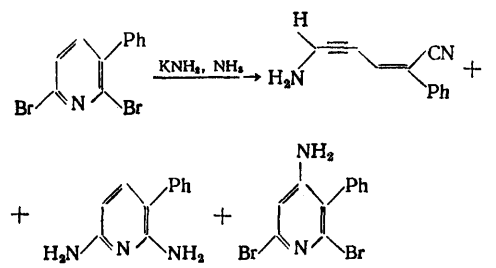
By reaction with aryl-, acylhydrazines, semicarbazide or thiosemicarbazide 2,4,6-triethoxycarbonyl-1,3,5-triazines are converted into derivatives of 1,2,4-triazine or 1,2,4-triazole depending on the nucleophilicity of the hydrazine derivative nitrogen atoms. Acyclic products were also isolated from the reaction mixture the formation of which is in agreement with the proposed scheme.[105–109] The conversion of 1,3,5-triazines containing both trichloromethyl and ethoxycarbonyl groups goes by a similar scheme under the action of phenylhydrazine.[109] On reducing the nucleophilicity of the hydrazine (isoniazide) the reactions with 1,3,5-triazines containing ethoxycarbonyl and trichloromethyl groups did not go.

V. Reactions with alkali metal amides in liquid ammonia



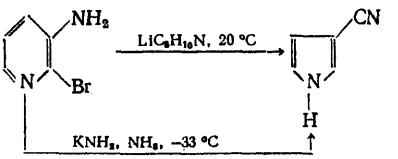
The reaction of nitrogen-containing heterocycles with potassium amide in liquid ammonia has been studied principally by van der Plas.[110,111,113,115–131] Depending on the structure of the

starting material and the concentration of potassium amide conversions may proceed both by an S_N(AE) and by an S_N(ANRORC) mechanism.



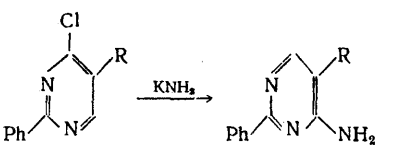
If the reaction is accompanied by recyclisation then the product may be both the initial ('degenerate recyclisation')[6] and a transformed heterocycle. Degenerate recyclisations were detected with an ^{15}N label in the potassium amide or in the heterocycle.[104,115–119,126,131]

The reaction of pyridine with potassium amide in liquid ammonia may proceed by an S_N(AE) mechanism (Chichibabin amination)[132] or with recyclisation of the pyridine nucleus.[110–115] In both cases the process starts with the formation of a σ complex of pyridine with amide anion. Electron-accepting substituents in the pyridine molecule facilitate the formation of a σ complex, opening of the ring and subsequent recyclisation.



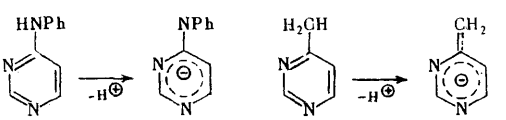
2-Chloro-5-nitropyridine forms two σ complexes (XVII) and (XVIII) with amide anion, the nitro group in the *ortho* position enables breaking of the C(2)–N(1) bond and the resulting intermediate is cyclised to 2-amino-5-nitropyridine. The second σ complex (XVIII) splits off chloride anion and is also converted into 2-amino-5-nitropyridine.[110] To discriminate between the resulting pyridines was possible with the aid of potassium amide labelled with ^{15}N. Steric hindrance occurred in the formation of σ complex (XVIII) consequently 75% σ complex (XVII) was formed.

It was possible to form three products under the same conditions from 2,6-dibromo-3-phenylpyridine, viz. an acyclic compound, 2,6-diamino-3-phenylpyridine [(S_N(ANRORC) mechanism] and 4-amino-2,6-dibromo-3-phenylpyridine [S_N(AE) mechanism].[111]

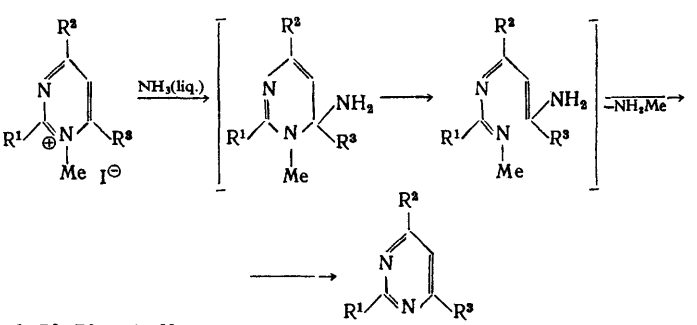


3-Amino-2-bromopyridine is converted into 3-cyanopyrrole with potassium amide in liquid ammonia at −33 °C or with lithium piperidinide at 20 °C.[114]

In pyrimidines as in pyridines the interaction with potassium amide in liquid ammonia may occur with a 'degenerate recyclisation'.[115–127] The course of the reaction is principally determined by the structure of the initial pyrimidine.



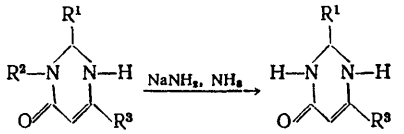
5-Substituted 4-chloro-2-phenylpyrimidines form σ complexes with amide anion at positions 4 and 6, position 2 is sterically hindered. On breaking the pyrimidine ring bonds C(4)–C(5) and C(5)–C(6) respectively were severed.[120]



R = OMe, SMe, Ph, OEt.

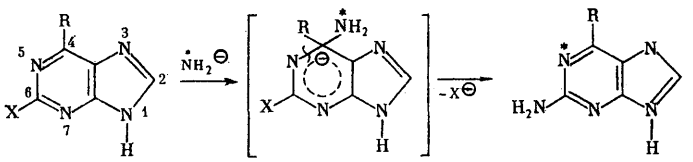
In order that the interaction of pyrimidines with amide anion should go by an S_N(ANRORC) mechanism it is necessary to observe the following conditions.[120–123] There must be the possibility of forming a σ complex able to open the pyrimidine ring. With unsubstituted pyrimidines a σ complex is formed at position 2. In substituted pyrimidines several σ complexes may be formed.[120,122,123] For 2-fluoro substituted pyrimidimes the splitting away of fluoride ion occurs after the formation of σ complex with amide anion at position 2 and the reaction goes by the S_N(AE) mechanism.[123]

Substituents at positions 4 and 6 of the pyrimidine nucleus must not have an acidic proton capable of forming stable anions of type (XIX) and (XX) hindering attack of the nucleophile.[121]



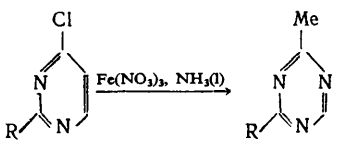
Dealkylation of *N*-alkylpyrimidinium salts in liquid ammonia may occur at an S_N(ANRORC) mechanism.[79,124]

R¹, R², R³ = H, Me.



6-Ethoxy-1,3-diethyl-4-oxo-3,4-dihydropyrimidinium tetrafluoroborate is dealkylated in liquid ammonia to 3-ethyl-6-ethylamino-4-oxo-3,4-dihydropyrimidine.[125]

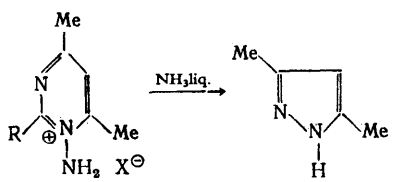
The interaction of 4,6-disubstituted 3-alkyl-2-pyrimidones with sodium amide in liquid ammonia also leads to dealkylation at nitrogen.[102]



R^1 = iso-Pr, Ph; R^2 = H, Me, Et; R^3 = Me, Et.

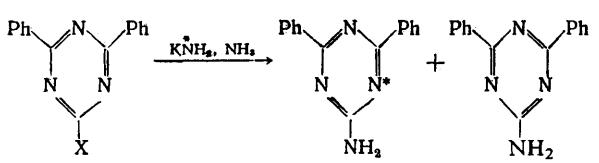
The reaction of 2-substituted purines with potassium or sodium amides in liquid ammonia is accompanied by the formation of a complex at position 6 with subsequent conversion of the pyrimidine nucleus.[126,127] If position 6 in the purine is occupied by a methyl group amination goes by an S_N(AE) mechanism.

X = Hal, SMe; R = H, Me.



!,3,5-Triazines[128] and five-membered nitrogen-containing rings[129] may be obtained by the recyclisation of pyrimidines in liquid ammonia.

R = Alk; Ph, N(Me)$_2$

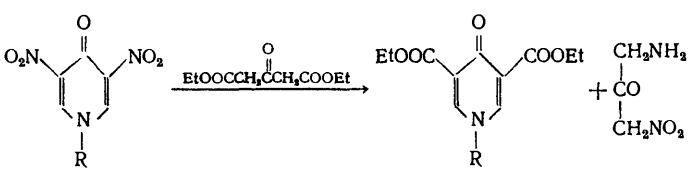


It was established by ^{14}C labelling that the C(5)–C(6) bond in the pyrimidine ring was severed.[128]

N-Aminopyrimidinium salts were converted into liquid ammonia into 3,5-disubstituted pyrazole.[129]

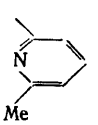
R = H, Me.

The interaction of substituted 1,3,5-triazines with potassium amide in liquid ammonia may be accompanied by a 'degenerate recyclisation'. Whether the amination reaction has an S_N(ANRORC) or S_N(AE) mechanism depends on the potassium amide concentration and the nature of the leaving group.[130,131]



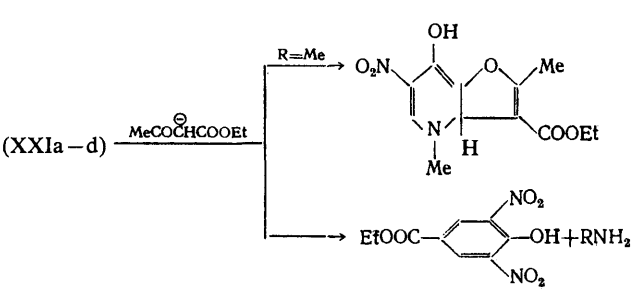
X = H, Cl, SMe.

VI. Conversions with CH-acids and ambident nucleophiles



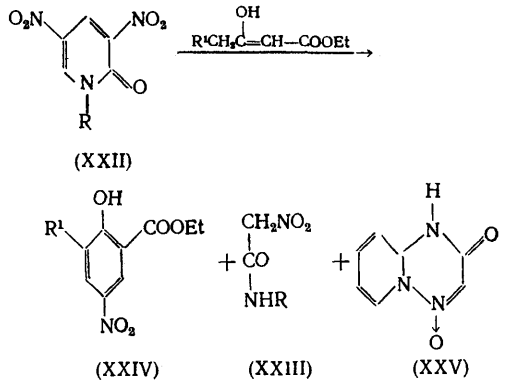
It was considered previously that the general mechanism for the reaction of nitrogen-containing π-deficient heterocycles with anions of CH-acids or ambident nucleophiles consisted of addition of anion to the heterocycle with the formation of a Meisenheimer complex, opening of the heterocycle and closure of a new ring with replacement of a portion of the ring atoms by a residue of the ambident nucleophile or CH-acids [S_N(ANRORC) mechanism]. The formation of a Meisenheimer complex is facilitated if the heterocycle is activated by an electron-accepting substituent.

Recent work has shown that the formation of bridge structures is occasionally possible for ambident nucleophiles on reaction with a heterocycle. In some cases these structures have been successfully established.[11,134,135,151,159,161,169] To establish non-cyclic intermediates and σ adducts is more difficult since they are unstable and their further conversion by ring opening and rapid recyclisation are thermodynamically favourable.



1-Substituted 3,5-dinitro-4-oxo-1,4-dihydropyridines (XXIa–e) with acetonedicarboxylic acid diethyl ester form 1-substituted 3,5-diethoxycarbonyl-4-oxo-1,4-dihydropyridines (58–85% yield) and 3-amino-1-nitropropan-2-one.[133,134]

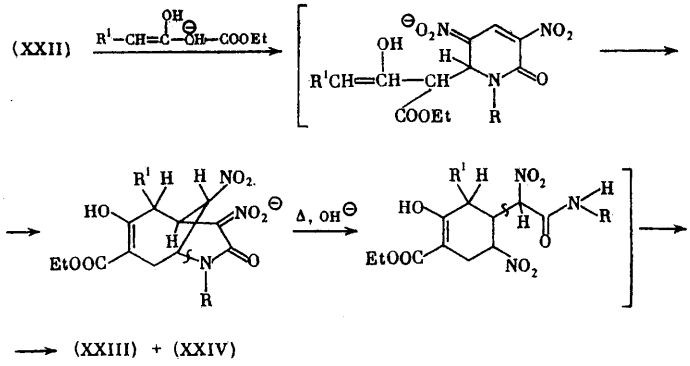
(XXI а — д)



R = Me (a), 3-Py (b), 4-Py (c),  (d), H (e).

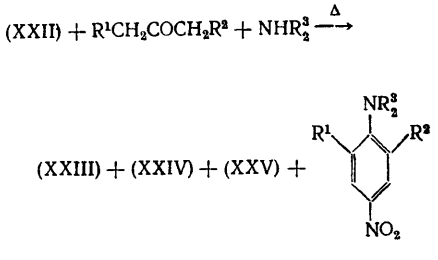
The interaction of (XXIa–d) with the sodium derivative of acetoacetic acid ester in alcohol depends on substituent R at the nitrogen atom in (XXIa–d). The reaction product is a furano-[2,3b]pyridine for the electron-donating R = Me (XXIa). In the case of electron-accepting substituents (XXIb–d) the reaction product was 4-hydroxy-3,5-dinitrobenzoic acid ethyl ester.[134]

The interaction of 1-substituted 3,5-dinitro-2-oxopyridines (XXII) with the sodium derivative of acetoacetic ester (R^1 = H) or acetonedicarboxylic acid ethyl ester (R^1 = COOEt) depending on the character of the substituents R and R_1 leads to *N*-substituted



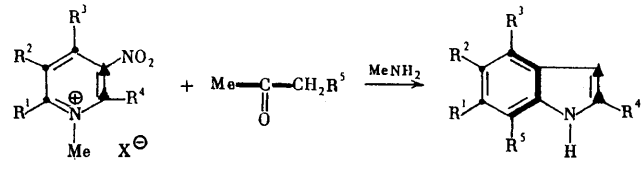
α-nitroacetamide (XXIII), a derivative of 5-nitrobenzoic acid ethyl ester (XXIV) and bicyclic derivatives (XXV).[133–137]

(XXII) (XXIV) (XXIII) (XXV)



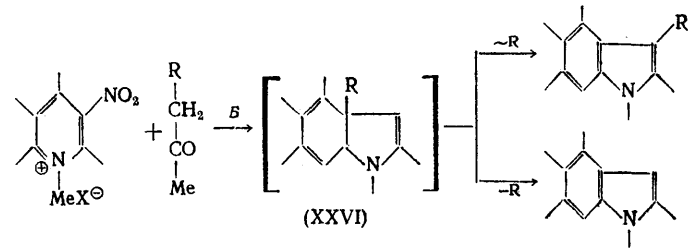
R = Me, CH_2Ar, CH_2Hetar, H, OMe, 2-Py; R^1 = H, COOEt.

Conversion of pyrid-2-ones (XXII) to *para*-nitrophenols (XXIV) may go through an anionic σ adduct and then through a bicyclic derivative according to the scheme.[134–137]

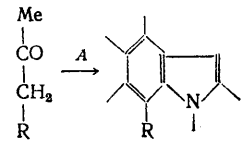


(XXII) → (XXIII) + (XXIV)

On reacting pyrid-2-one (XXII) with ketones in the presence of amines condensation of amine with ketone and further reaction of the resulting activated enamine with pyridone (XXII) may occur. Consequently *N*-substituted *para*-nitroaniline is present in the reaction products in addition to *para*-nitrophenol (XXIV).[137]



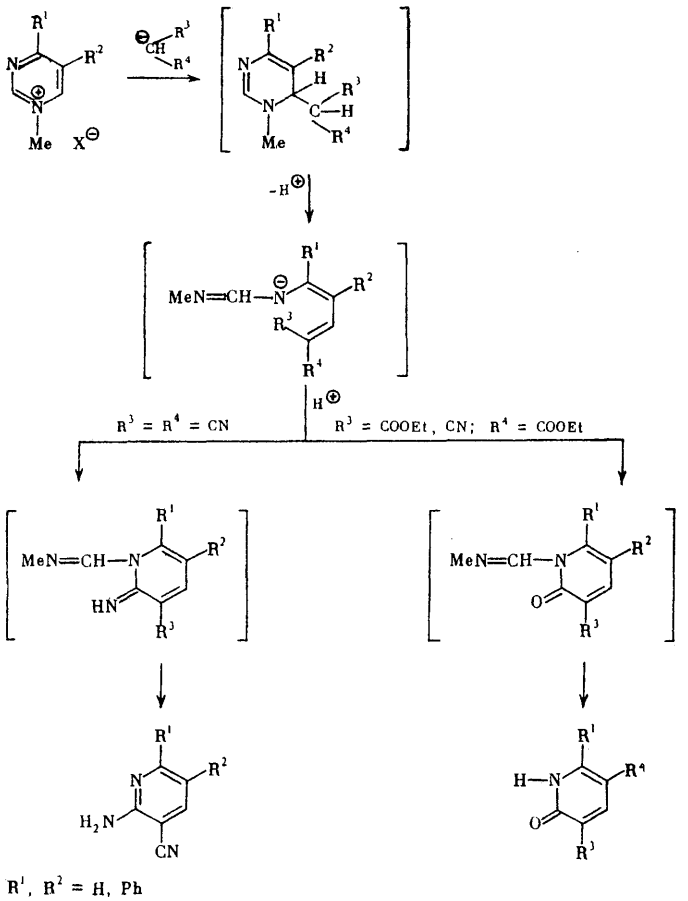
R^1, R^2 = H, Me, COOEt; NR^3_2 = 



It was discovered recently tht 3-nitropyridinium salts are converted into indole derivatives on reaction with ketones in the presence of amines.[138,139] A specially developed spectroscopic procedure made it possible to establish the structure of the products formed and to suggest structural rules for the construction of the indole molecules ('diazine' process).[140]

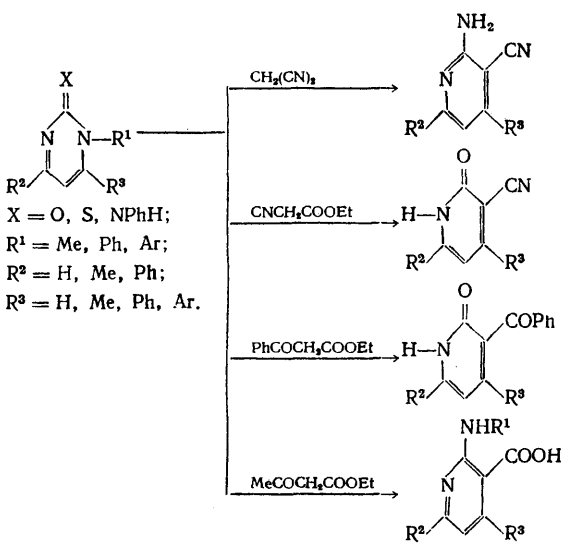
The reaction seemingly begins with condensation of ketone or ketimine with the pyridinium salt and the formation of a bicyclic derivative in which the C(3)–C(4) and C(6)–N(1) bonds of the pyridinium nucleus are broken. A three carbon fragment of the ketone is introduced between the fragments of the pyridine ring. The proposed scheme was confirmed by the detection by chromatomass spectrometry of the two different directions (A and B) for the process linked with the orientation of the ketone on reaction with the pyridinium salt.[141]

(XXVI)



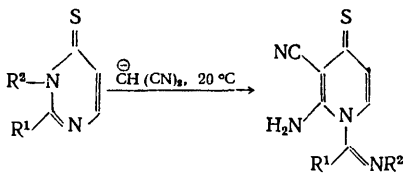
Route A leads to an indole of normal structure. In the case of route B intermediate (XXVI) may be aromatised by migration of R or by its elimination.

The use of prepared ketimines (in place of a mixture of ketone and amine) and polar aprotic solvents in the reaction improves yields (up to 80%) and simplifies the isolation process of the indole.[142,143]



Many recyclisations of the pyrimidine ring on reaction with CH-acids and ambident nucleophiles are known.[144–172] To facilitate these reactions the pyrimidine derivatives are usually converted to quaternary salts,[145] and are then converted into substituted pyridines on reaction with the sodium derivatives of malonic ester, malondinitrile or cyanoacetic ester by replacement of the N(1)–C(2) fragment of the pyrimidinium system by a two-carbon fragment of the CH-acid. In the case of cyanoacetic ester closing of the acyclic intermediate as shown in the scheme goes through the ester and not

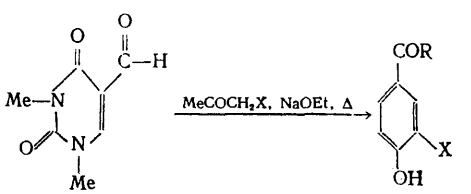
through the cyano group.[145]



R^1, R^2 = H, Ph

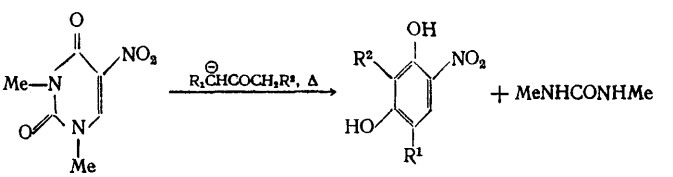
The interaction of 2,4,6-trisubstituted 2,3-dihydropyrimidines with compounds having an active methylene group at room temperature in the presence of sodium ethoxide leads to pyridines.[146] In this the C(6)–N(1) bond in the initial pyrimidine is broken and yields of the pyridine derivative are determined by steric hindrance in the formation of a σ complex with the CH-acid at position 6 of the pyrimidine ring.

X = O, S, NPhH;
R^1 = Me, Ph, Ar;
R^2 = H, Me, Ph;
R^3 = H, Me, Ph, Ar.



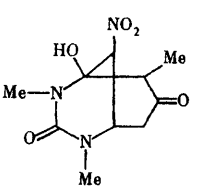
Interaction of 2,3-disubstituted 4-thio-3,4-dihydropyrimidines with malondinitrile in the presence of sodium ethoxide also goes with the formation of pyridine derivatives. Because of steric factors the CH-acid is added at C(4) of the pyrimidine nucleus and the C(4)–N(3) bond of the pyrimidine ring is broken.[147]

Three atoms of the pyrimidine ring may be replaced by three atoms of the nucleophilic reagent.[144,148–153]



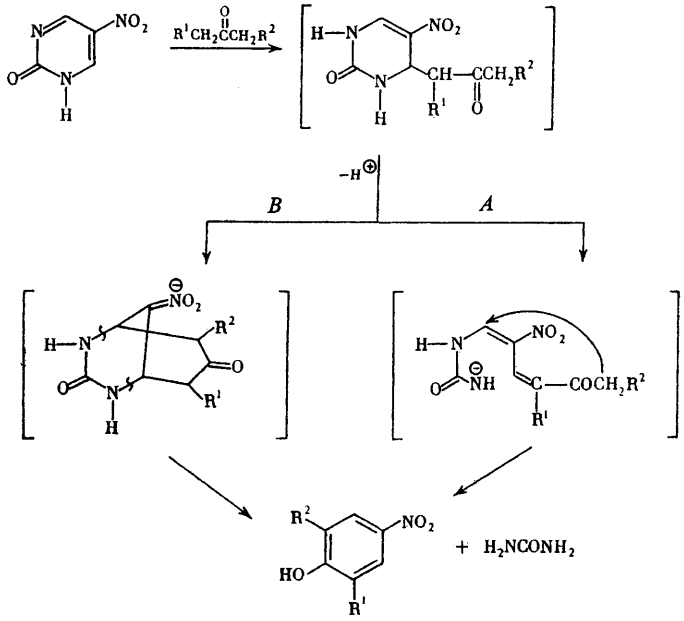
If the N(1)–C(2)–N(3) fragment of the pyrimidine nucleus is replaced by a C–C–C or C–C–N residue from an ambident nucleophile then benzene derivatives are formed in the first case[144,148–152] and pyridine derivatives in the second.[144,148,151,153]

On boiling 5-formyl-1,3-dimethyluracil with CH-acids in alcoholic sodium ethoxide derivatives of *p*-hydroxybenzoic acid are formed.[148,149,152]



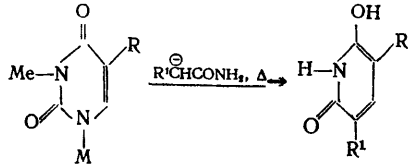
X = COMe, $CONH_2$, Ph, COOEt; R = OEt, NHMe.

1,3-Dimethyl-5-nitrouracil with ketones in boiling alcoholic alkali is recyclised to nitroresorcinol derivatives.[150]



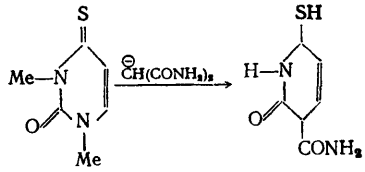
R^1 = COOEt, H, Me; R_2 = H

With unsymmetrically substituted ketones (R_1 = Me, R^2 = H) a mixture of two final products is formed because of the possibility of forming σ complexes at the different CH-groups.[150] A bicyclic product was isolated from the reaction mixture in the case of butanone.

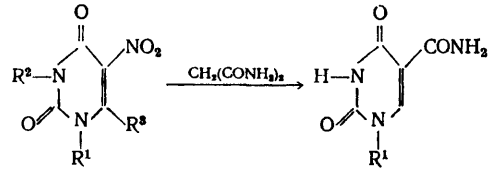


Similar bicyclic structures were successfully established in the reaction of ketones with 5-nitro-2-oxo-1,2-dihydropyrimidines. The final products of this reaction were *para*-nitrophenol derivatives.[151] Conversion of the pyrimidinium nucleus into benzene occurs in two directions, an S_N(ANRORC) (route *A*) and through

the formation of a bicyclic structure with subsequent splitting away of a urea derivative (route *B*).[151]

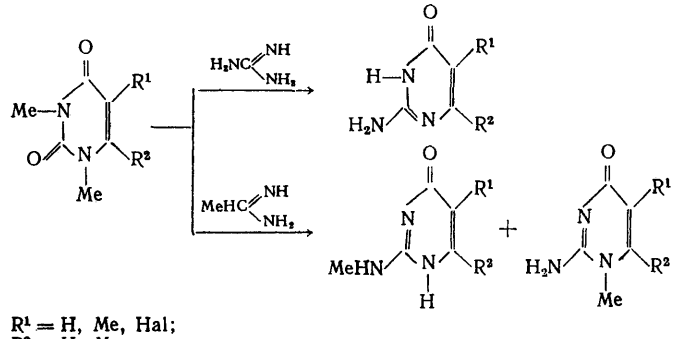


Reaction of 1,3-dimethyluracils with α-substituted acetamides in alcoholic sodium ethoxide leads to pyridine derivatives.[148,149,152,153]

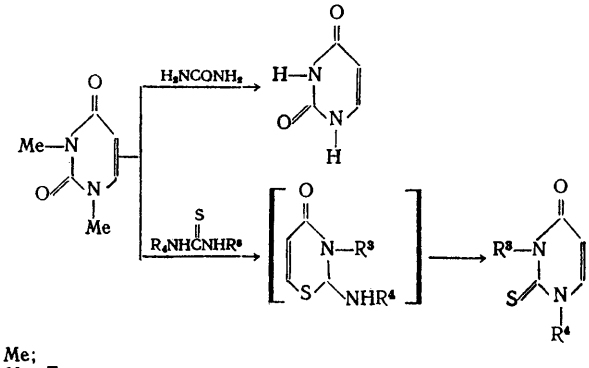


R = H, Me, CN, F,  ; $R^1 = CONH_2$, **CN**, COMe, Ph.

A 2-hydroxy-6-mercaptonicotinamide is formed from 1,3-dimethyl-6-thiouracil by an analogous reaction.[153]

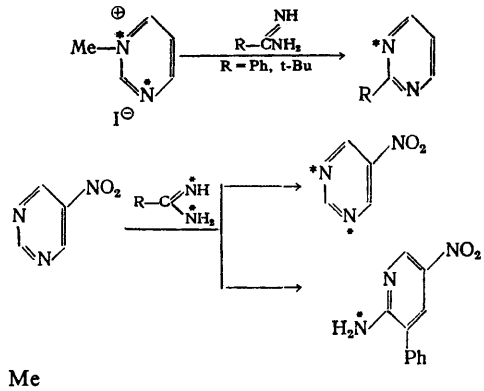


Reaction of 5-nitrouracils with malondiamide in alcoholic sodium ethoxide leads to 5-carboxamidouracils.[154,155] In this case the C–C–N residue of the nucleophile replaces C(5)–C(4)–N(3) of the pyrimidine ring. The reaction does not take place when the substituents at the uracil nitrogen atoms $R^1 = R^2 = H$ since the anionic form of the initial uracil is not able to add nucleophile.



R^1, $R^3 = H$, Me, C_6H_{11}; $R^3 = H$, Me.

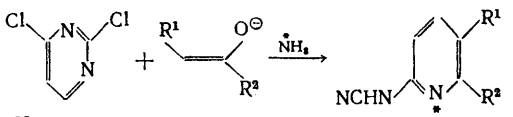
A 'degenerate recyclisation' occurs when the N(1)–C(2)–N(3) fragment of the pyrimidine is replaced by the N–C–N fragment of the nucleophile. Derivatives of guanidine, urea and thiourea are used as nucleophiles. Similar conversions of pyrimidine bases are used in nucleic acid chemistry.[144,148,149,156,157]



$R^1 = H$, Me, Hal;
$R^2 = H$, Me

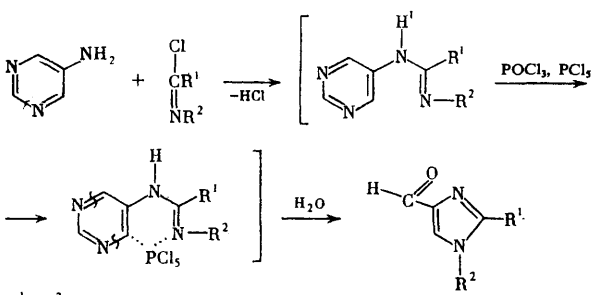
$R^3 = H$, Me;
$R^4 = H$, Me, F.

6-Methyluracil derivatives (R^2 = Me) do not react with ureas due to the impossibility of forming a Meisenheimer complex at position 6. Electron-accepting substituents at position 5 of the pyrimidine facilitate the reaction.[157]



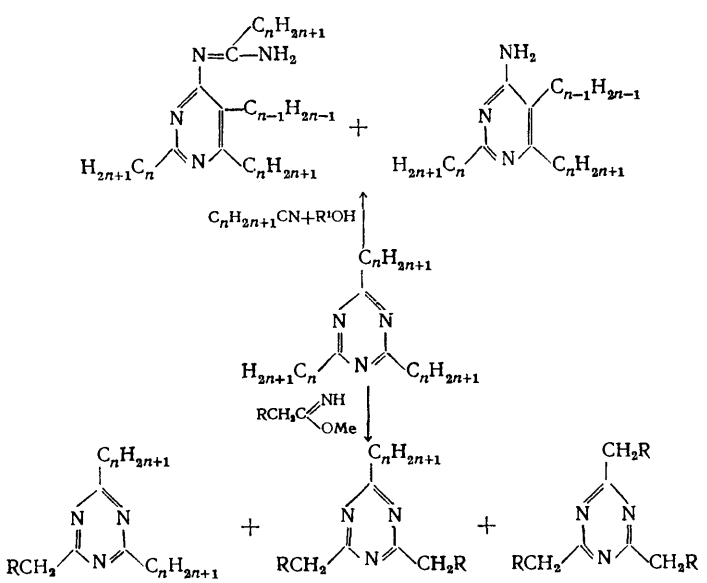
Recyclisation of quaternary salts or pyrimidines activated by a nitro group goes ambiguously with the formation of pyrimidines and pyridine (demonstrated by ^{15}N NMR).[158–161]

R = Ph, t-Bu, Me



Reaction of 2,4-dichloropyrimidine with the potassium enolates of ketones in liquid ammonia leads to recyclisation to 2-cyano-pyridine. The N(1)–C(2)–N(3) fragment of the pyrimidine nucleus is

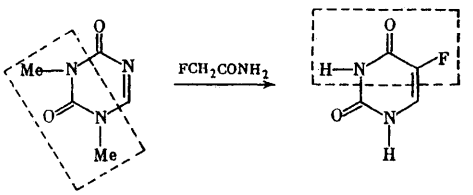
replaced by the C–C fragment of the ketone and a nitrogen from the ammonia (demonstrated by ^{15}N NMR).[162]



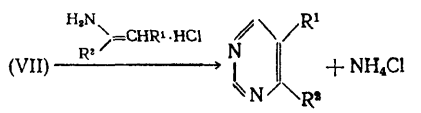
R^1, R^2 = Alk, H.

The conversions of pyrimidines considered above by reaction with ambident nucleophiles occur with the formation of six-membered heterocycles. Reaction of 5-aminopyrimidine with imidoyl chlorides in the presence of phosphorus oxychloride or pentachloride leads to 1,2-disubstituted 5-formylimidazole.[163] Phosphorus oxychloride or pentachloride is necessary to activate the nitrogen atoms, initially the side chain nitrogen is activated and then that in the pyrimidine ring.[163]

R^1, R^2 = H, Alk, Ph



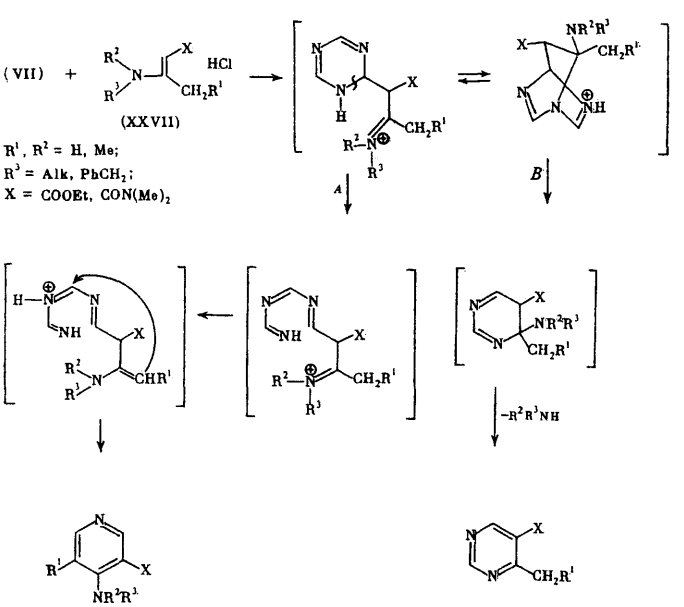
The reaction of 2,4,6-trialkyl-1,3,5-triazines with nitriles in alcohol at 100–150 °C under pressure is seemingly effected by conversion of nitrile into iminoether which replaces a portion of the triazine molecule. The reaction product may react with a further molecule of imidate and it is possible to obtain a completely transalkylated triazine.[164] A reaction was also possible under the same conditions in which pyrimidine derivatives are formed.[165]



n = 1, 2; R = Me, Ph, Ar, Hetar; R^1 = H, Me, Et.

A similar process was evidently observed in the reaction of 2,4,5-trisubstituted 1,3,5-triazines with ammonia and nitriles in the presence of catalyst.[166]

With 1,3-dimethyl-5-azauracil fluoroacetic acid amide replaces the N–C–N fragment of the 1,3,5-triazine by a C–C–N fragment of the nucleophile with the formation of 5-fluorouracil. The reaction goes by an S_N(ANRORC) mechanism.[167]



Heating 1,3,5-triazine (VII) in acetonitrile with an activated enamine hydrochloride leads to a 4,5-disubstituted pyrimidine.[168]

R^1 = Alk; R^2 = COOEt, MeCO.

However on boiling (VII) in acetonitrile with enaminoketone (XXVII) pyrimidine derivatives constitute a reaction by-product (5–10% yield). The formation of 4-aminopyridines containing electron-accepting substituents is the main direction (30–45% yield).[169] The ability of (XXVII) to insert three of its carbon atoms into the pyridine ring is unusual. An *N*-phenyl substituent in (XXVII) impedes the reaction.

It was proposed that (VII) is protonated by the action of (XXVII) hydrochloride, its nucleus is activated towards nucleophilic attack by the β carbon atom of (XXVII) and simultaneously towards recyclisation into a bicyclic adduct. An equilibrium mixture of intermediates is present in the mixture at the first stage of the reaction of (VII) and (XXVII). One of them is converted by route *A* [S_N(ANRORC) mechanism] into a pyridine derivative and the other proceeds by a reverse Diels–Alder reaction by route *B* with the formation of a pyrimidine derivative.[169]

Generation and reactions of silylenes in the gas phase

E A Chernyshev, N G Komalenkova
State Scientific Research Institute for the Chemistry and Technology of Heteroorganic Compounds, Moscow

ABSTRACT. Results of the investigations in recent years on the gas phase thermal reactions of both inorganic and organic silylenes have been correlated. Particular attention has been paid to the sources used for generation of these unstable intermediates and also to methods of obtaining and to the properties of cyclic silylenes.

The bibliography contains 62 references.

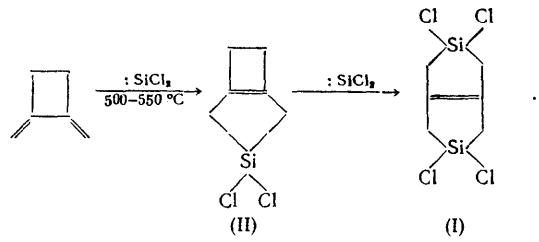
I. Introduction

Much attention has been paid in recent years to the study of the synthetic possibilities of using unstable derivatives of divalent silicon, viz. the silylenes, in gas phase pyrolytic reactions and also to the search for accessible sources of these molecules.[1–16] Recent achievements in the chemistry of gas phase reactions of silylenes, which are most interesting in the authors' view, have been correlated and systematised in the present work.

II. Reactions of silylenes generated from substituted di- and polysilanes

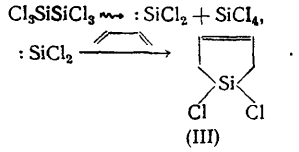


1. Addition of silylenes to multiple bonds

Thermal decomposition of various substituted disilanes in the gas phase is one of the most convenient and sufficiently general methods of generating silylenes. It was shown recently[17,18] that methyl and methylphenyl substituted cyclohexasilanes are also sources of organic silylenes in thermal reactions.

(a) Inorganic silylenes

Spectrometric investigations of gas phase reactions of addition of dichlorosilylene, generated from hexachlorodisilane, to the multiple bonds of acyclic and cyclic dienes have permitted on the one hand a significant broadening of the synthetic possibilities of the gas phase technique of thermal cyclisation and on the other the obtaining of data on the relative reactivity of various classes of compounds towards $:SiCl_2$.

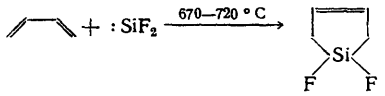


Addition of $:SiCl_2$ to such a specific diene system as 1,2-dimethylenecyclobutane leads to the formation of an unsaturated bicyclic compound with two silicon atoms in the ring, viz. 3,3,7,7-tetrachloro-3,7-disilabicyclo[3.3.0]oct-1,5-ene (I).[19] The sequence of conversions may be represented by the scheme:

(II) (I)

Seemingly the first product of addition of $:SiCl_2$ to the initial diene is the heterocycle (II) which then undergoes further insertion of $:SiCl_2$ into a C–C bond of the strained four-carbon ring. At a reagent ratio of Si_2Cl_6 : diene equal to 2 : 1 the yield of heterocycle (I) was 70%. On reducing the quantity of $:SiCl_2$ in the reaction mixture by half the yield of heterocyclic compounds fell to 25–30%.

A new method of generating dichlorosilylene by decomposing hexachlorodisilane radiochemically has been proposed.[20] 1,3-Butadiene was used as active intercepting agent for dichlorosilylene.



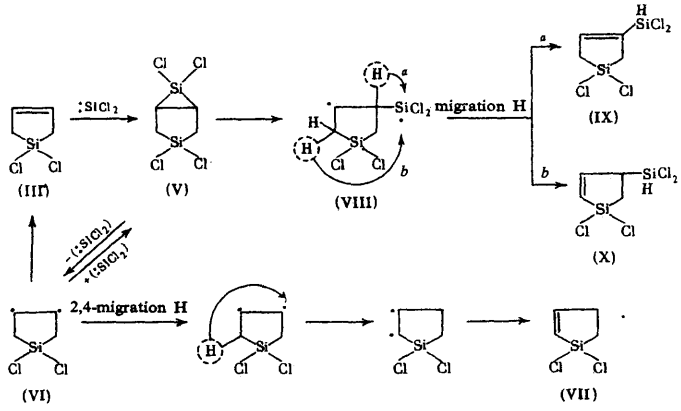
(III)

Under static conditions using an ELV-8 electron accelerator with a 30 kV beam as source of ionising radiation 1,1-dichloro-1-silacyclopent-3-ene (III) was formed at lower temperatures (200 –300 °C) than without irradiation (> 350 °C).

There is significant practical interest in the thermal interaction of perchloropolysilanes containing hydrochloropolysilanes with various acyclic 1,3-butadienes leading to the formation in almost quantitative yield of 1,1-dichloro-1-silacyclopent-3-ene or derivatives of it.[21] This method permits the use of still residues formed in processes of hydrochlorinating silicon as a source of dichlorosilylene in place of hexachlorodisilane.

The interception reaction of the highly reactive monomeric :SiF_2 in gas phase pyrolysis of hexafluorodisilane in an excess of 1,3-butadiene has recently been effected successfully.[22]

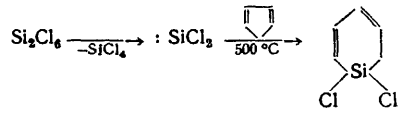
$$Si_2F_6 \rightarrow : SiF_2 + SiF_4,$$



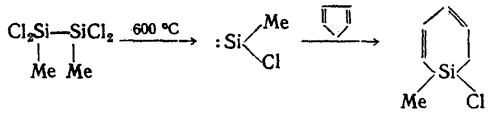
(IV), 56—75% .

The process was carried out in a flow system with a reactant contact time of 0.01—0.02 sec.

Study of the gas phase thermal isomerisation of 1,1-dichloro-1-silacyclopent-3-ene (III) into 1,1-dichloro-1-silacyclopent-2-ene in the presence of added hexachlorodisilane showed the essential role of dichlorosilylene in this process.[23] Thus isomerisation of the heterocycle in the absence of a source of :$SiCl_2$ began only at 480—500 °C but introduction of added hexachlorodisilane (4.86—16.4 mol%) into the reaction zone accelerated the isomerisation of compound (III) and reduced the temperature for the start of reaction to 380—400 °C. With an increase in the quantity of added hexachlorodisilane, and therefore an increase in :$SiCl_2$ concentration in the reaction zone, the extent of isomerisation of heterocycle (III) was increased. To explain the accelerating influence of dichlorosilylene a scheme was proposed for the isomerisation with the initial addition of :$SiCl_2$ to the olefinic bond of 1,1-dichloro-1-silacyclopent-3-ene (III).

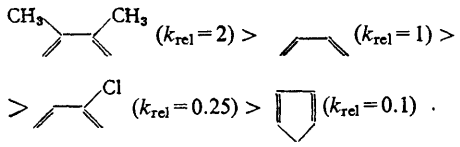


Scheme 1

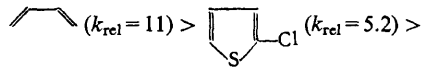


On adding :$SiCl_2$ to the multiple bond of heterocycle (III) the bicyclic compound (V) is formed which has an unstable silacyclopropane ring the decomposition of which at both intracyclic Si—C bonds leads to biradical (VI) which is subsequently converted either to the initial heterocycle (III) or (with 2,4 migration of hydrogen) to heterocycle (VII).

The proposed Scheme 1 is also in good agreement with the formation of dichlorosilyl substituted dichlorosilacyclopentenes in this reaction. Fission of one Si—C bond of the silacyclopropane ring of bicycle (V) leads to biradical (VIII) and then to a mixture of silyl-substituted heterocycles with Si—H bonds (IX) and (X) as a result of intracyclic hydrogen migration.

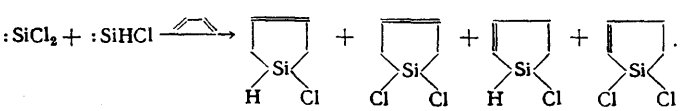


Such cyclic diene systems as cyclopentadiene (or its dimer) proved to be interesting subjects for studying the addition reaction. Reaction of hexachlorodisilane with cyclopentadiene leads to 1,1-dichloro-1-silacyclohexa-2,4-diene in 45—50% yield.



The procedure, published in our studies[2,3,5,6,24] on the thermal synthesis of this previously unavailable monocyclic silicon compound, has been reproduced repeatedly.[25,26] Thus Barton and Banasiak[27] synthesised 1-methyl-1-chloro-1-silacyclohexa-2,4-diene by thermal interaction of tetrachlorodimethyldisilane with cyclopentadiene.

A similar reaction has also been carried out in vacuum (650 °C, 10^{-2} Torr).[28] Communications have appeared recently for the first time on the relative reactivity of various classes of compounds towards :$SiCl_2$ generated thermally from hexachlorodisilane.[19,29,30] The following series of relative activities of various dienes for :$SiCl_2$ adding to multiple bonds has been established using competing reactions (flow reactor, 500 °C).[19,29]



The relative reactivities of 1,3-butadiene, 2-chlorothiophen, chlorobenzene and hydrogen chloride towards :$SiCl_2$ have also been determined (flow reactor, 420—440 °C).[30]

$> C_6H_5Cl$ ($k_{rel} = 1$) < HCl ($k_{rel} = 0.33$) .

It follows from the obtained data that aromatic chlorides are poorer acceptors of :$SiCl_2$ than 1,3-butadiene. The least effective acceptor of dichlorosilylene proved to be HCl. Its reactivity was 30 times lower than that of 1,3-butadiene.

Hexachlorodisilane and its mono- and dihydro derivatives were formed on pyrolysis of trichlorosilane in the presence of added chloroform (quartz flow reactor, 450—600 °C, 1 mol% $CHCl_3$ relative to $HSiCl_3$).[31,32] Thus at 350 °C the content of tetrachloro-, pentachloro- and hexachlorodisilanes in the pyrolysate was ~15%, and of $SiCl_4$ 25%. It is possible that the decomposition products of chloroform are capable of forming these compounds. Interaction of dichloro- and chlorosilylenes generated from the disilanes indicated above with 1,3-butadiene yields a mixture of mono- and dichlorosilacyclopentenes.[32] The maximum overall yield of chloro-substituted silacyclopentenes (21% on initial trichlorosilane) was observed at 550 °C.

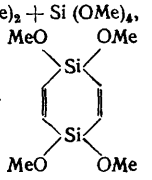
It should be mentioned that monochlorosilacyclopentenes (11%) are formed at a lower temperature (510 °C).

(b) Organic silylenes

Investigations carried out recently on the study of gas phase addition reactions of organic silylenes generated from various di-, poly- and cyclohexasilanes with organic substituents on the silicon atom encompass processes both at atmospheric pressure and at high vacuum. Mainly alkynes and conjugated dienes were used as active 'interceptors' of silylenes. The principal directions of the work were as follows. At the theoretical level kinetic data were obtained on gas phase reactions of the pyrolytic formation of silylenes and the mechanisms of the reactions involving them were studied. At the synthetic level new sources for generating organic silylenes have been sought.

Among the kinetic investigations which should be mentioned is the determination of rate constants and activation parameters for gas phase reactions for the pyrolytic formation of silylenes from 1,2-dimethoxytetramethyldisilane, methoxypentamethyldisilane, 1-methoxy-1-propyltetramethyldisilane and 1,2-dimethyldisilane (pyrolysis in a nitrogen stream, 304–450 °C, ~1000 Torr).[33] The reactions studied were first order with respect to disilane. The majority of experiments with disilanes were carried out in an excess of 1,3-butadiene as a trap for silylenes to suppress secondary reactions.

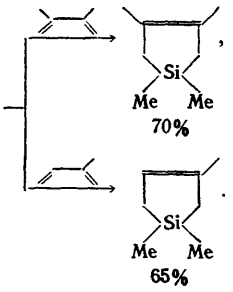
There are interesting data on the reaction mechanism for the addition of $:SiH_2$ generated on pyrolysis of disilane to ethylene.[34] The obtained results made it possible to consider the interaction of $:SiH_2$ with ethylene in the gas phase as a sequential stepwise process comprising the initial formation of a silacyclopropane intermediate and subsequent conversion of it either into the starting materials or into ethylsilylene and vinylsilylene.



$$H_3SiSiH_3 \longrightarrow :SiH_2 + SiH_4,$$

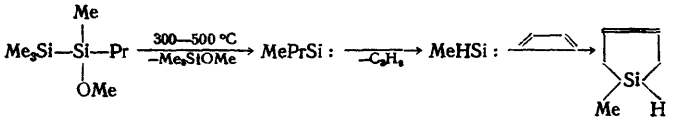
$$:SiH_2 + CH_2{=}CH_2 \rightleftharpoons H_2C(CH_2)SiH_2 \longrightarrow C_2H_5\ddot{S}iH \quad / \quad \longrightarrow CH_2{=}CHSiH_3.$$

Hexamethoxydisilane is a good source of dimethoxysilylene in the gas phase.[35] Copyrolysis of this disilane with acetylene leads to 1,1,4,4-tetramethoxy-1,4-disilacyclohexa-2,5-diene in 56% yield.

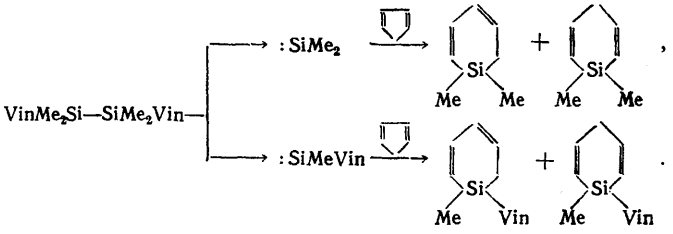


$$(MeO)_3SiSi(OMe)_3 \xrightarrow{\Delta} :Si(OMe)_2 + Si(OMe)_4,$$

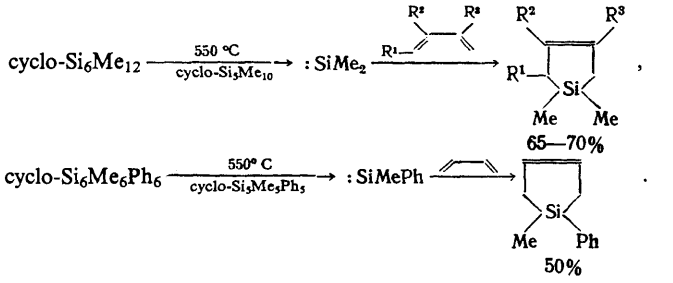
$$:Si(OMe)_2 + CH{\equiv}CH \xrightarrow{370\ ^\circ C}$$



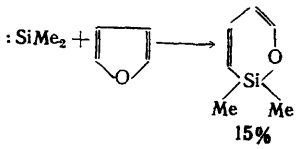
The addition of dimethylsilylene, generated thermally from 1,2-dimethoxytetramethyldisilane, to acyclic 1,3-dienes both at atmospheric pressure[36] and in vacuum[37] has been described.



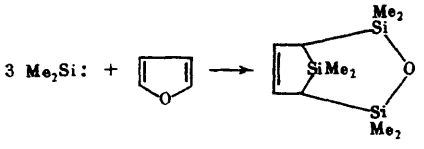
$$(MeO)\,Me_2Si{-}SiMe_2(OMe) \xrightarrow[-(MeO)_2SiMe_2]{450\ ^\circ C/2\ Torr} Me_2Si:$$



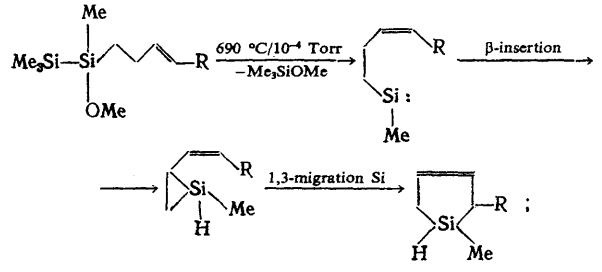
On pyrolysis 1-methoxy-1-propyltetramethyldisilane first forms PrMeSi: which is rapidly decomposed into MeHSi: and propene.[33,38]



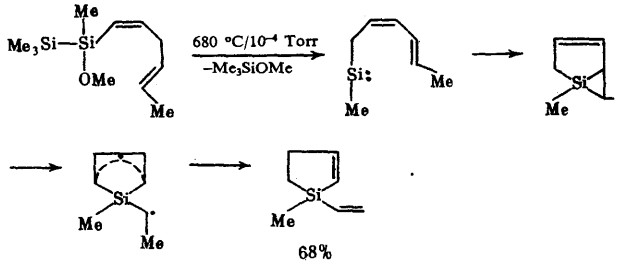
Thermal decomposition of 1,2-divinyltetramethyldisilane occurs non-selectively with the formation of dimethyl- and methylvinylsilylenes. Thus on copyrolysis of 1,2-divinyltetramethyldisilane with cyclopentadiene (650 °C, 10^{-2} Torr) substituted silacyclohexadienes are formed which are products of addition of both organic silylenes in approximately equal amounts.[39]



Studies on the thermal generation of dimethyl- and methylphenylsilylenes from dodecamethylhexaphenylcyclohexasilanes deserve special attention. These compounds were known to date only as photochemical sources of silylenes and were regarded, evidently due to their low volatility, as unsuitable for thermal reactions.[17,18] It has been shown that these cyclohexasilanes were capable of decomposing in the gas phase to the corresponding cyclopentasilanes and silylenes (flow reactor, 500–550 °C, contact time 40–60 sec).[17]

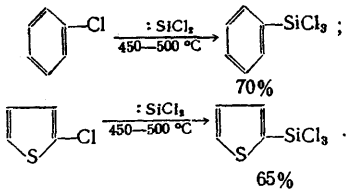


The formation of silylenes in these reactions was confirmed by the formation of silacyclopent-3-enes in the presence of 1,3-butadienes. The reaction of intercepting $:SiMe_2$, generated by pyrolysis of dodecamethylcyclohexasilanes, by furan (flow system, 500 °C) at atmospheric pressure has been studied for the first time.[18] Among the main reaction products 2,2-dimethyl-2-sila-1-oxacyclohexa-3,5-diene and the product of addition of three molecules of dimethylsilylene to furan were detected.

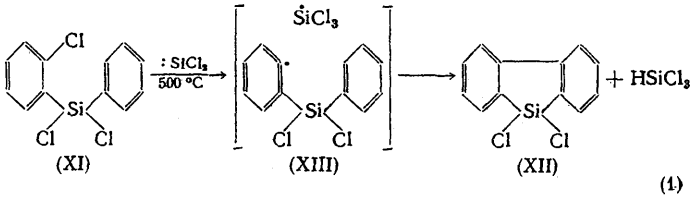


The reactions indicated above were carried out with dimethylsilylene generated by reaction of dimethyldichlorosilane with Na or K vapour at 400–500 °C.[18]

A new direction in the 'high temperature' chemistry of organic silylenes was the investigation of their intramolecular conversions. A method has been proposed for the intramolecular interception of silylenes generated from a series of methoxytetramethyldisilanes containing butenyl or pentadienyl groupings.[39] Reactions were carried out under high vacuum when generating such silylenes with a view to limiting the contribution of intermolecular reactions and secondary processes.



R = H, 56%; R = Me, 30%.

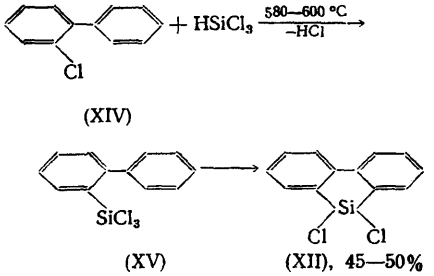


2. Gas phase thermal cyclisation reactions involving :$SiCl_2$

It was recorded previously that processes introducing dichlorosilylene, generated on pyrolysis of hexachlorodisilane, into a $C_{Ar}-Cl$ bond differ widely in selectivity.[2,4–6] They seemingly occur through a fission-recombination stage as in the reaction of singlet carbenes with the C–Cl bond.[40] Singlet :$SiCl_2$ removes a chlorine atom from the starting material with the formation of a pair of radicals. Recombination of the radicals with one another leads to the corresponding aryltrichlorosilane (separation of the radical pair is atypical for this interaction).

On studying the gas phase interaction of (*o*-chlorophenyl)phenyldichlorosilane (XI) with hexachlorodisilane (500 °C, reactant ratio 1 : 1) it was established unexpectedly that the main reaction product was 9,9-dichloro-9-silafluorene (XII) (90% yield).[41,42] The formation of a product of insertion of :$SiCl_2$ into a $C_{Ar}-Cl$ bond of the starting material did not occur in this case. It is interesting that compound (XI) in the absence of a source of dichlorosilylene was not subject to intramolecular dehydrochlorination with the formation of heterocycle (XII) in the range 400–550 °C and at 680 °C the yield of the latter did not exceed 18%.[43] The suggestion was made that the role of dichlorosilylene in the reaction studied is reduced merely to fission of a chlorine atom from the initial (XI) which permits intramolecular cyclisation, :$SiCl_2$ itself does not enter into the composition of the resulting reaction products.[3,5,6,43]

(1)

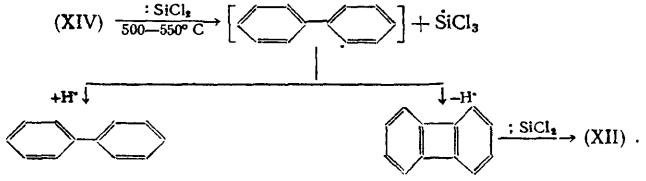


Evidently recombination of the radical pair did not occur in this case because of the increased tendency of radical (XIII) towards intramolecular cyclisation. It is extremely informative that the intermediate formation of a free radical with an unpaired electron solely at the ortho carbon atom, when the radical centre and the aromatic system are sterically close together, leads to an intramolecular cyclisation.

The interaction of (*p*-chlorophenyl)phenyldichlorosilane with hexachlorodisilane under the conditions studied leads only to the formation of (*p*-trichlorosilylphenyl)phenyldichlorosilane (30% yield).[42] *o*-(Trichlorosilylphenyl)phenyldichlorosilane, the product of inserting :$SiCl_2$ into the $C_{Ar}-Cl$ bond of compound (XI), was obtained by a different reaction;[43] up to 500–550 °C it did not undergo thermal conversions and at 680 °C cyclised by a different scheme with the formation of 9,9,10,10-tetrachloro-9,10-disila-9,10-dihydroanthracene (30% yield).

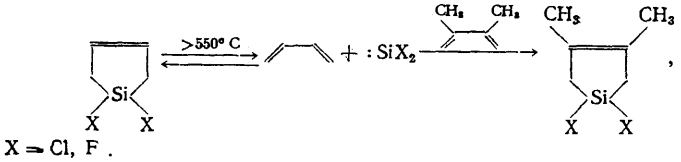
It should be noted that this gas phase reaction also occurs on using other sources of :$SiCl_2$, such as trichlorosilane and 1,1-dichloro-1-silacyclopent-3-ene in place of hexachlorodisilane.[42]

The observed gas phase reaction of dichlorosilylene has possibly no analogy in carbene chemistry and is the basis of a new general method of forming a series of silicon-containing heterocyclic systems.[3,5,6,44]



Recently this reaction was extended to ortho substituted aromatic hydrocarbons, particularly to *o*-chlorodiphenyl.[45] Formerly the high temperature synthesis of the heterocycle (XII) from *o*-chlorodiphenyl (XIV) was carried out in the presence of trichlorosilane.[46,47] It was shown that the initial step of the reaction was homolytic silylation of *o*-chlorodiphenyl (XIV) with subsequent intramolecular cyclisation of the resulting *o*-trichlorosilyldiphenyl (XV).

The significant role of temperature was noted. Heterocycle (XII) was formed only at 680–700 °C, at lower temperatures (580–600 °C) only the silylation product (XV) was detected.



On thermal interaction of compound (XIV) with hexachlorodisilane heterocycle (XII) was formed under milder conditions and its yield was 75–80%. Diphenyl was the main byproduct. Compound (XV), which may be regarded as the product of inserting

$:SiCl_2$ into the $C_{Ar}-Cl$ bond of the initial *o*-chlorodiphenyl (XIV), was also isolated in insignificant yield (5–7%). A suggestion as to the possible cyclisation of compound (XV) at lower temperatures (500–550 °C) in the presence of hexachlorodisilane was not confirmed experimentally. These circumstances made it possible to propose another scheme for forming heterocycle (XII) through biphenylene in the reaction in question.

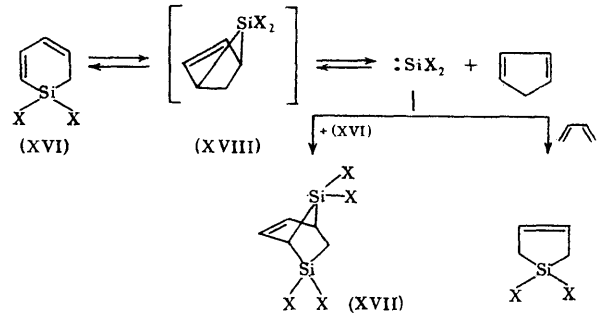
III. Generation of dihalosilylenes on thermal decomposition of 1,1-dichloro(difluoro)silacyclopent-3-enes and 1,1-dichloro(difluoro)silacyclohexa-2,4-dienes

The retrodiene decomposition of 1,1-dichloro- and 1,1-difluoro-1-silacyclopent-3-enes under high temperature conditions has been reported previously.[5,6,48]

X = Cl, F .

The use of the method of 'chemical trapping agents' has made it possible to obtain proof of the intermediate formation of dihalosilylenes in this reaction.

The formation of dichlorosilylene on pyrolysis of 1,1-dichloro-1-silacyclopent-3-ene (800–1400 K, pressure 10^{-1} to 10^{-2} Torr) was shown with the aid of IR spectroscopy in a solid argon matrix.[49] The direct mass spectrometric detection of primary products of vacuum pyrolysis of 1,1-dichloro- and 1,1-difluoro-1-silacyclopent-3-enes, viz. 1,3-butadiene and dihalosilanes was also effected with the aid of vacuum pyrolytic mass spectrometry.[50]

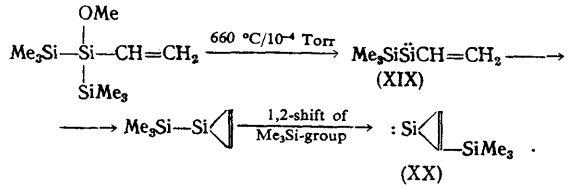


The formation of 1,1-dichloro-1-silacyclopent-3-ene in the gas phase from $:SiCl_2$ and 1,3-butadiene is thermodynamically favoured in the temperature range 300 to 1000 K.[51]

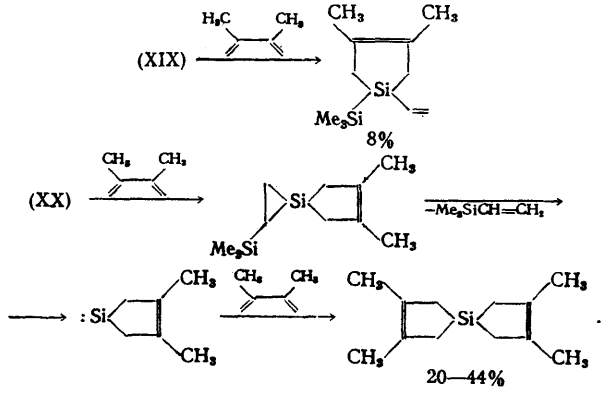
The successful demonstration of the thermal retrodiene decomposition of 1,1-dichloro-1-silacyclopent-3-ene forms a basis for the hypothesis that the gas phase interaction of $:SiCl_2$ with *symm-cis*-1,3-butadiene corresponds formally with the Diels–Alder reaction and therefore proceeds by a concerted 1,4-cycloaddition mechanism.

Pyrolysis of dihalo substituted silacyclopent-3-enes is an efficient means of generating not only dichloro- but also difluorosilylene. The preparation of monomeric $:SiF_2$ by other methods is very difficult.

1,1-Dichloro(1,1-difluoro)-1-silacyclohexa-2,4-dienes (XVI) are also capable of decomposing on pyrolysis (500–650 °C, flow system) by a retrodiene scheme with the formation of cyclopentadiene and dichloro(difluoro)silylene. The thermal decomposition of the difluoroderivative requires higher temperatures (600–650 °C).[29,52] The primary content of the pyrolysis products of these heterocycles has been studied by vacuum pyrolytic mass spectrometry.[50] Chemical proof has been obtained of the formation of dihalosilylenes on pyrolysis of these heterocycles. Thus copyrolysis of dienes (XVI) with 1,3-butadiene leads to the formation of the corresponding 1,1-dihalo-1-silacyclopent-3-enes. Pyrolysis of individual compounds (XVI) alone leads to the formation of cyclopentadiene and the 1,4-cyclo adduct (XVII) of $:SiX_2$ with the initial heterocycles probably by the following Scheme (Scheme 2).

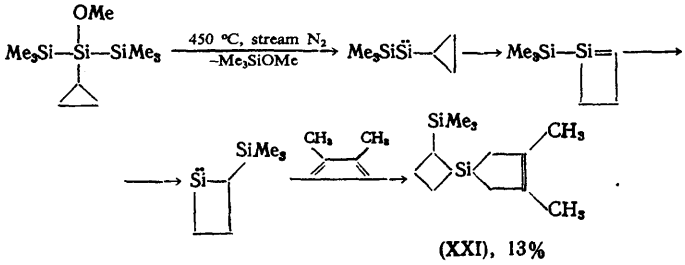


Scheme 2



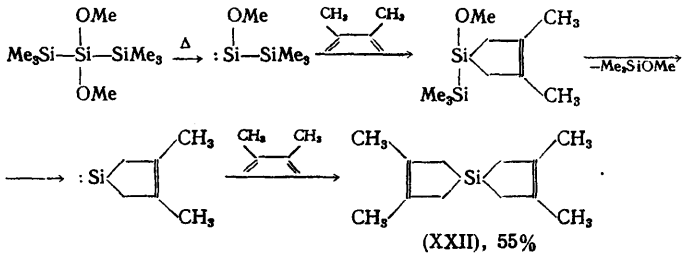
Mass spectrometric investigation of the decomposition routes of heterocycle (XVI) under electron impact also confirmed the possibility of forming the bicycle (XVIII) under these conditions.[53] The results obtained testify in favour of a 1,4-addition mechanism of $:SiCl_2$ to cyclopentadiene, however further study is required.

IV. Methods of preparation and reactions of cyclic silylenes

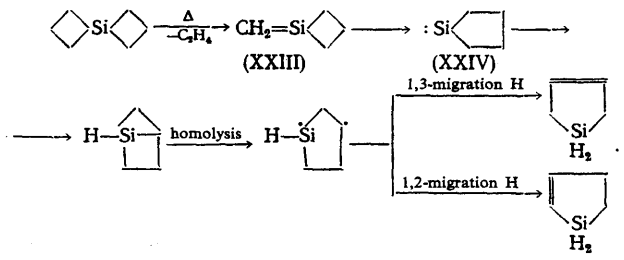


Two main routes for obtaining cyclic silylenes have been contemplated up to the present time: 1) thermal decomposition (at atmospheric pressure in a nitrogen stream or at high vacuum) of difficultly available organosilicon compounds undergoing complex intramolecular rearrangements[54–59] and 2) the use of gas phase dehalogenation of available dichloro substituted silacycloalkanes and silacycloalkenes with alkali metal vapour.[60–62] An interesting vinylsilylene intramolecular rearrangement was discovered on studying the pyrolysis of 2-methoxy-2-vinylhexamethyltrisilane.[54]

The existence of intermediates (XIX) and (XX) was confirmed by reaction of the initial trisilane with 2,3-dimethyl-1,3-butadiene.

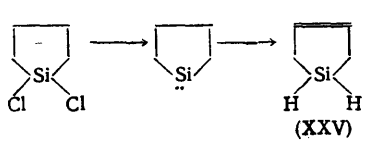


The formation of spiro compound (XXI) on copyrolysis of 2-cyclopropyl-2-methoxyhexamethyltrisilane with an excess of 2,3-dimethyl-1,3-butadiene was explained by the occurrence of a complex silylene–silene–silylene rearrangement including the formation of silacyclobutanylidene.[55]



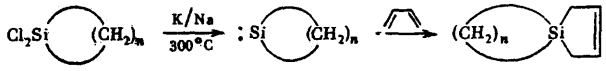
(XXI), 13%

Pyrolysis of 2,2-dimethoxyhexamethyltrisilane (450 °C, nitrogen stream) may be considered a convenient method of generating 3,4-dimethyl-1-silacyclopent-3-en-1-ylidene. Conducting the reaction in the presence of the trapping agent 1,3-dimethyl-1,3-butadiene leads to the formation of spiro compound (XXII).[56]

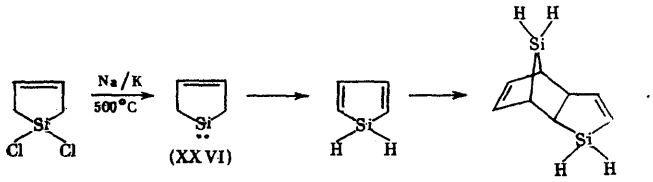


(XXII), 55%

Interesting results were obtained when studying the vacuum thermal decomposition of 3,3-silaspirocycloheptane.[57–59] It was assumed that the first stage of this process was the formation of silene (XXIII) which underwent rearrangement into silylene (XXIV) and subsequent intramolecular conversion as a result of which 1-silacyclopent-2-ene or 1-silacyclopent-3-ene were formed.

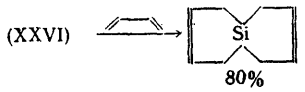


A gas phase method of generating silacycloalkanylidenes by reaction of dichlorosilacycloalkanes with alkali metal vapour (K/Na, 280–300 °C, 10^{-1} to 1.0 Torr) has been described,[60,61] for example:



(XXV)

The formation of (XXV) is explained by intramolecular insertion of the initially formed unstable silacyclopentanylidene into the β C–H bond and subsequent conversion of the bicyclic intermediate. The cyclic silylenes obtained by dehalogenation are able to participate in [1 + 4] cycloaddition reaction with dienes such as 1,3-butadiene.



$n = 3 - 5$

The availability of the initial reactants makes the dehalogenation of organochlorosilanes by K/Na vapour a convenient method of generating cyclic silylenes and synthesising various spirane compounds with a central silicon atom.[62] For example reaction of 1,1-dichloro-1-silacyclopent-3-ene (500 °C, atmospheric pressure, argon atmosphere) with an excess of sodium or potassium leads to the formation of 1-silacyclopent-3-en-1-ylidene (XXVI).

The formation of (XXVI) was proved by trapping it with 1,3-butadiene.

80%

Investigation of the gas phase reactions of silylenes is developing intensively at the present time. In this project the thermal method must be considered as one of the most promising and hopeful, the wide use of which will lead to the discovery of both still unknown properties of silylenes and of sources for their generation.

Cyclic mono- and diphosphazenes

R I Tarasova, V V Moskva
S M Kirov Kazan Chemico-Technological Institute

ABSTRACT. Methods of synthesis of 5- and 6-membered heterocyclanes with one or two endocyclic P=N bonds (cyclomono- and cyclodi-phosphazenes) have been considered. Types of reaction common to acyclic analogues and specific types of reaction have been separated. The change of electronic structure and geometry of the P=N bond on changing from linear to cyclic phosphazenes are clearly displayed in the special features of their chemical behaviour.

I. Introduction

The beginning of the seventies was a period of explosive development in investigations on phosphocyclanes in the chemistry of organophosphorus compounds.[1] This phenomenon also applies to heterocyclic compounds with an endocyclic P=N bond (cyclomono- and cyclodiphosphazenes). Acyclic phosphazenes were described for the first time by Staudinger in 1919,[2] however their systematic study began in 1950 with the work of Kirsanov and collaborators.[3–5] The first syntheses of six-membered cyclomono- and cyclodiphosphazenes appeared in the next decade,[5,6] as did those of five-membered analogues with dicoordinated[7] and tetracoordinated phosphorus atoms.[8,9]

The intensive investigations on organic cyclophosphazenes undertaken since the beginning of the seventies are reflected in a series of reviews published mainly in the foreign press.[10–14] Certain problems of the chemistry of these compounds have been touched upon in part.[15,16]

Interest in this area was caused by the special features of the structure and numerous chemical conversions of phosphacyclanes with a P=N bond, revealing broad vistas for the synthesis of various classes of *P,N*-containing compounds available for practical use.

A significant contribution has been made by Soviet investigators in the development of organic cyclophosphazene chemistry as is evident from an analysis of the literature.[6,10,11,14–16] There has been no correlation of these achievements in the domestic literature to date. Studies on heterocyclanes with one or two endocyclic P=N bonds are included in the present review. The cyclotriphosphazenes, having their own fairly complete literature converage,[17] have not been considered by us.

In contrast to acyclic compounds with a P=N bond, the nomenclature of which has an arbitrary character to a significant extent,[5,6,10,14] the naming of the corresponding cyclic organophosphorus compounds (OPC) is more uniform and corresponds to contemporary IUPAC rules.

This system will mainly be used in the present review. However it is convenient to use 'phosphazene' nomenclature, which has been widely adopted for some time, for linear and cyclic analogues as a general class of compounds with a P=N bond.[17] This nomenclature will be used for the general naming of the extensive series of compounds with a P=N bond.

The chemistry of heterocyclanes with a P=N bond is constructed on the basis of the experimental and theoretical developments of the acyclic phosphazenes. Consequently the synthetic methods for acycylic analogues are the basis for many means of obtaining cyclophosphazenes. Five of the basic reactions used for obtaining acyclic phosphazenes may be noted.[5]

The Staudinger reaction[2] comprises the reaction of organic azides with derivatives of tricoordinated phosphorus.

$$R_3P+R'N_3\rightarrow R_3P{=}NR'. \quad (1)$$

The reaction of dihalophosphoranes with compounds containing a primary amino group (the phosphazo reaction)[3–5]

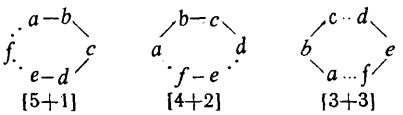
$$R_3PX_2+R'NH_2\rightarrow R_3P{=}NR'. \quad (2)$$

The reaction of derivatives of tricoordinated phosphorus with compounds containing an amino group with two labile bonds (oxidation imination)[5,18]

$$R_3P + R'N\begin{matrix}X\\ \diagup\\ \diagdown\\ Y\end{matrix} \rightarrow R_3P{=}NR'. \quad (3)$$

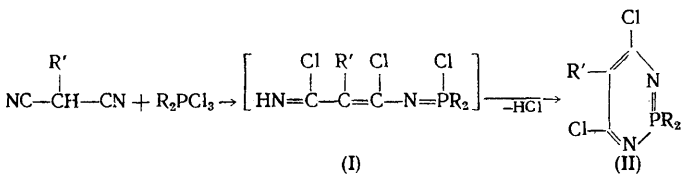
An elimination reaction for compounds with a P–N bond[19–21]

$$R_3P\!-\!N\begin{matrix}R'\\ \diagdown\\ \diagup\\ Y\end{matrix} \rightarrow R_3P{=}NR'. \quad (4)$$
$$\quad\quad\quad



II. Preparative methods

1. Cyclocondensation reactions

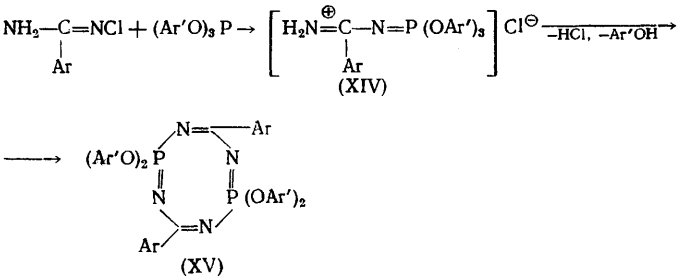


(a) Synthesis of hetero-1,2σ^4-azaphosphorines

The investigations of the Kiev school in conjunction with those of Kirsanov[6] and of Schmidpeter and colleagues[30] have made an important contribution to the development of the synthesis of six-membered cyclophosazenes. The reaction of nitrogen- and phosphorus-containing reactants by the phosphazo reaction with a subsequent cyclocondensation stage was a characteristic of all the proposed methods.

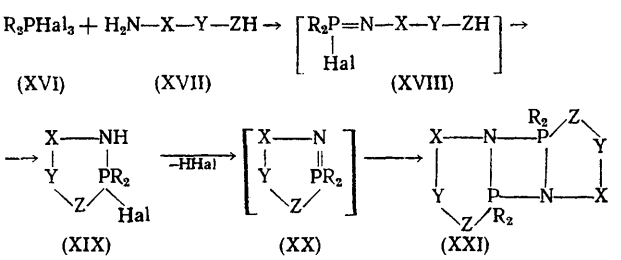
The synthesis of six-membered cyclophosphazenes may be formally represented as a number of elements participating in ring formation by [5 + 1]-,. [4 + 2]- and [3 + 3]-cyclocondensation reaction schemes.

One of the first representatives of the organic cyclophosphazenes, viz. 1,3,2-diazaphosphorine (II), was obtained by the interaction of malonic acid dinitrile with phosphorus pentachloride.[6]



The authors suggested that the formation of a linear phosphazene (I) precedes the concluding stage. Study of the structure and routes of formation of diazaphosphorine (II) by the application of quantum chemical calculation methods has been carried out.[31]

Variants of the [5 + 1] scheme are the reaction of phosphorus pentachloride and certain trichlorophosphoranes with 1-amino-2-cyanoethylenes, *N*-cyanoamidines[6] and acetylurea[32] (Table 1, examples 1a, 1b, 2, 3a). Depending on the structure of the amino-containing reactant 1,3,2- (II) and 1,3,4-diazaphosphorines (III) or 1,3,5,4-triazaphosphorines (IV) were obtained. For [3 + 3] type cyclocondensations *P*-trichloro-*N*-dichloroalkylphosphazenes (VII)[6] and certain *N*-phosphorylated phosphazenes (IX), (X)[33–40] were reacted with nitriles, amidines and their salts. The structure of the resulting phosphorines (II), (IV), and (V) containing one or two P=N bonds was determined by the choice of phosphorus-containing reactant (Table 1, examples 1c, 3b, 4a, b). Triazamono- (IV) and triazadiphosphorines (V) were also obtained by a [4 + 2]-cyclocondensation of linear phosphazenes (VIII) and (XI) (Table 1, examples, 3c, 4c).[42]



The multistage process of interacting *P*-trichloro-*N*-dichloroalkylphosphazene (VII) with ammonium chloride was carried out through the intermediate formation of alkylidenediphosphazene salts (XII) with isolation of triazadiphosphorine (V) [33,43,44] or a mixture of it with triazaphosphorine (IV) [6] (Table 1, example 4d). The synthesis of thioanalogues (VI) of triazadiphosphorines by a [5 + 1] scheme has been described.[45–50]

It is interesting to note the [4 + 4]-cyclocondensation reaction of hydrochloride salts of *P*-triaryloxy-*N*-iminoarylphosphazenes (XIV) as a rare example of the formation of 1,3,5,7,2,6-tetra-azadiphosphorine (XV).[51]

b) Synthesis of hetero-1,2σ^4-azaphospholes

Many methods of obtaining five-membered cyclophosphazenes are based on the interaction of halophosphoranes (XVI) with amino-containing compounds (XVII).

It is possible to represent the process by a single scheme, the initial stage of which is the formation of a linear phosphazene (XVIII). The latter undergoes intramolecular cyclisation into azaphospholine (XIX) with a pentacoordinated phosphorus atom. Further conversion of phosphacyclanes (XIX) occurs with elimination of hydrogen halide and the formation of 1,2σ^4-azaphospholes (XX) or their dimers (XXI).

The type of azaphosphole ring is determined mainly by the amino-component of the reaction for which oxalic acid diamides,[52] 2-aminoalkyl nitriles,[53] 4,5-diaminopyrimidines,[54] amidrazone hydrochlorides,[55,56] 1,2-aminophenols[57–60] and hydrazides of carboxylic[61–63] and thiocarboxylic acids[64] have been studied. The reaction of numerous reactants with phosphorus pentachloride or trichlorophosphoranes leads to the formation of 1,3,2σ^4-diaza- (XXII), (XXIII), 1,2,3,4σ^4-triaza- (XXIV), (XXV), and also isomer (XXVI), 4,5-benzo-1,3,2σ^4-oxaza- (XXVII), and 1,3,4,2σ^4-oxadiaza- (XXVIII) phospholes (Table 2).

In the majority of cases hetero-1,2σ^4-azaphospholes are unstable in the monomeric forms, they rapidly dimerise at the moment of formation. Exceptions are certain representatives of triazaphospholes (XXIV) and spirobis(triazaphosphole) (XXV). The latter is formed from triazaphosphole (XXIV) with an excess of amidrazone hydrochloride (XXIX).[65] 4,5-Pyrimidino-1,3,2-diazaphosphole (XXIII), characterised as the monomer,[54] seemingly exists in the dimeric form.

The problem of the stability of the monomeric and dimeric forms of hetero-1,2,-azaphospholes and the reason which causes a mixture of them in equilibrium has been discussed in several papers by Schmidpeter[53–57,64] and in detail in a review.[14] These problems will be considered in the present review only within the limits necessary for the characterisation of the chemical behaviour of the azaphospholes.

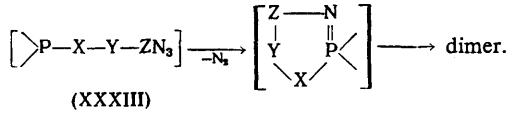
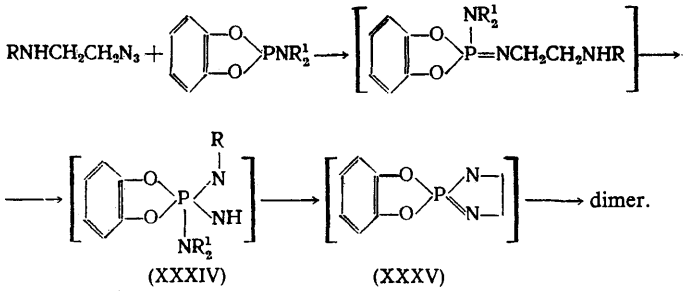
*D — dimer; **M — monomer.

The interaction of carboxylic acid hydrazides with halophosphoranes was historically the first and has been studied in most detail. The final result of the reaction depends mainly on the ratio of the initial reactants. At an equimolar ratio the process proceeds in accordance with the presented overall scheme and leads to dimers of 1,3,4,2σ^4-oxadiazaphospholes (XXVIII) (route a).[61,62] Hydrazides of thiocarboxylic acids reacted similarly at a 1 : 1 ratio.[64] At a two- and three-fold excess of phosphorus pentachloride decomposition of the intermediate oxadiazaphospholine (XIX) occurs (route c),[66] and in the case of a two-fold excess of hydrazide (XVII) spirodi(oxadiazaphospholines) (XXXI) were isolated.[63]



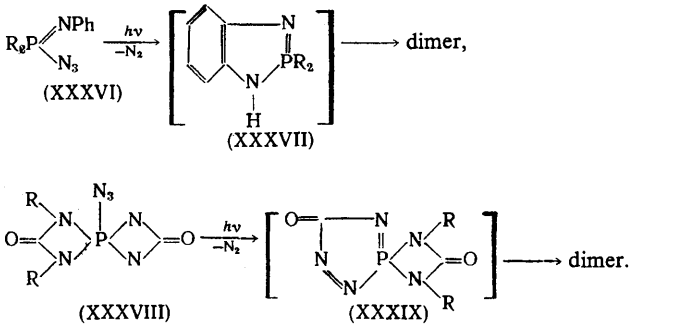
The acid chlorides of P(IV) acids or their thio analogues[61–64,67] were also used in reactions with carboxylic acid hydrazides (XVII). The latter were reacted at a ratio 1 : 1 and the former 1 : 3. In both cases dimers of 1,3,4,2σ^4-oxadiazaphospholes (XXVIII) were isolated as in the reactions with phosphoranes.[67]

The original method of synthesis of hetero-1,2,σ^4-azaphospholes was proposed in studies.[68–71] The authors used the high lability of the proton on the endocyclic nitrogen atom of 4,5-benzo-1,3,2-oxazaphospholanes (XXXII). As a result reaction was effected with acrylonitrile[68,70] and bisdiethylaminomethane[71] with the formation of 4,5-benzo-1,3,2-oxazaphospholes (XXVII), existing in the dimeric form.



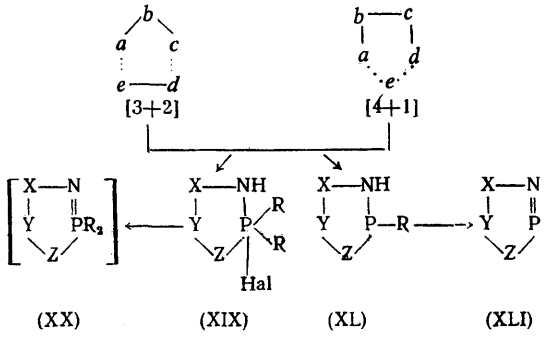
Analogous dimers of 4,5-benzo-1,3,2-oxazaphospholes (R = X = Ph) were formed from 4,5-benzo-2-methoxy-1,3,2σ^5-oxazaphospholanes by removing methanol thermally.[72] The course of the reaction through the unstable form (XXVII) was shown by reaction with aldehydes.

Intramolecular cyclocondensation of the Staudinger reaction type has also been studied with the aim of synthesising hetero-1,2-azaphospholes. In this scheme reaction was carried out between 2-hydroxyphenyl azide and diethylchlorophosphine[57,58] (Table 2, example 3c) and between 2-azidoalcohols and 1,2,4,3σ^2-triazaphospholes.[73] In both cases the 2-azidoaryl or 2-azidoalkyl derivatives of P(III) acids of the (XXXIII) type formed in the first step were subject to intramolecular cyclisation with separation of nitrogen.



On interacting *N*-(2-azidoethyl)alkylamines with cyclic phosphites the first step was a Staudinger reaction completed by intramolecular cycloaddition and the formation of spirophosphoranes (XXXIV).[74]

The reaction led to the isolation of dimers of 1,3,2σ^4-diazaphospholines (XXXV). One of the alternative routes of forming them, proposed by the authors, may be the elimination of amine from a molecule of spirophosphorane (XXXIV).

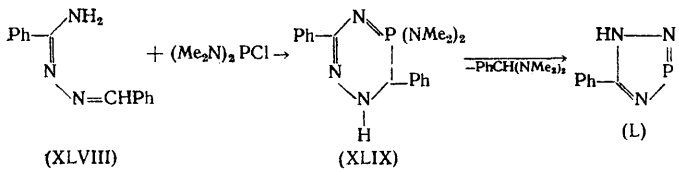


Azides of P(IV) (XXXVI) and P(V) (XXXVIII) derivatives may also be starting materials for obtaining dimers of hetero-1,2σ^4-azaphospholes (XXXVII) and (XXXIX). Photolytic decomposition of the azides was effected with simultaneous intramolecular cyclisation in the first case at the *ortho* position of the phenyl group and in the second at the nitrogen of the diazaphosphetidine ring.[12]

c) Synthesis of hetero-1,2σ^2-azaphospholes

The cyclocondensation reaction involving compounds of tricoordinated phosphorus is a source of many five-membered cyclophosphazenes with the coordinated of phosphorus equal to two. The first information on cyclophosphazenes with a low phosphorus coordination was published in 1963,[7] however the purpose directed synthesis of hetero-1,2σ^2-azaphospholes began to be intensively developed only after the work of Charbonnel and Barrans.[75]

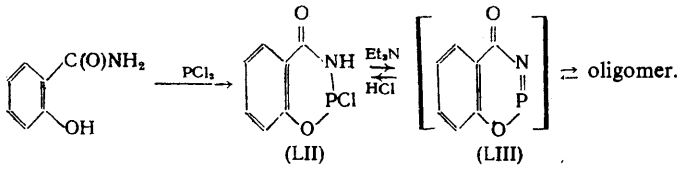
When developing the analogy between the syntheses of hetero-1,2σ^4- and 1,2σ^2-azaphospholes it should be noted that the precursors of the desired products in both processes are unstable intermediates of type (XIX) or (XL). They may be formed by [3 + 2]- or [4 + 1]-cyclocondensation schemes. Conversion of the intermediates into 1,2σ^4- (XX) or 1,2σ^2-azaphospholes (XLI) respectively occurs with loss of one of the exocyclic substituents at phosphorus and by reduction of the phosphorus coordination to 4 or 2.



(XX) (XIX) (XL) (XLI)

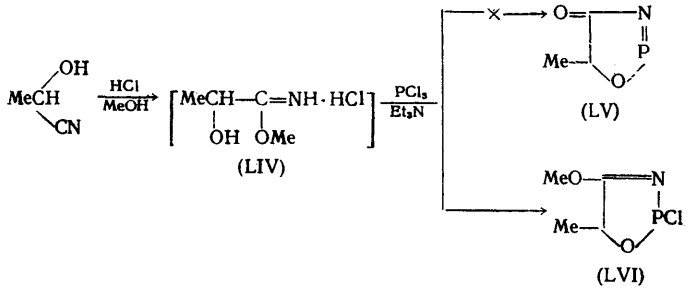
The types of hetero-1,2σ^2-azaphospholes (XLIII)–(XLVII), (LI) and (LVII) synthesised on the basis of cyclocondensation reactions are shown in Table 3. As is seen from Tables 2 and 3 the synthesis of hetero-1,2σ^4-azaphospholes proceeds mainly by a [4 + 1] scheme but a [3 + 2]-cyclocondensation scheme also occurs for hetero-1,2σ^2-azaphospholes. In addition to these, intramolecular cyclocondensation (Table 3, example 1b)[13] and 'reductive elimination' (example 1c)[34] reactions have been developed for 1,3,2σ^2-diazaphosphole (XLIII).

The first representative of the azaphospholes, viz. 4,5-benzo-1,3,2σ^2-azaphosphole (XLV),[7] as shown by later investigations,[76] exists in crystals in the form of a tetramer.



1,2,4,3σ^2-Triazaphospholes (XLVI) and (XLVII) were obtained by reacting methylimidates with chlorophosphines.[75] This reaction takes place through a stage of forming phosphinoimidates[77] (Table 3, example 2a). The latter react with monosubstituted hydrazines with the separation of two regioisomers α-(XLVI) and β-(XLVII) possessing different thermal stabilities. Only one α-isomeric form (XLVI) was isolated from the reaction of amidrazone hydrochlorides with tris(dimethylamino)phosphines[77,78] (example 2b).

An unusual method of obtaining *N*-protonated 1,2,4,3σ^2-triazaphospholes (L) has been described.[79] It is based on the reaction of tetramethyldiaminochlorophosphine with azine (XLVIII), the resulting 1,2,5,4σ^4-triazaphosphorine (XLIX) is converted into triazaphosphole (L) with separation of aminal.



(XLVIII) (XLIX) (L)

In contrast to the stable monomeric diaza- and triazaphospholes described above (Table 3) 1,3,2σ^2-oxazaphosphole (LI) was obtained as the tetramer (Table 3, example 3).[84] Similarly reaction of salicylic acid amide with phosphorus trichloride is terminated by the formation of an oligomer of 4-keto-5,6-benzo-1,3,2σ^2-oxazaphosphorine (LIII).[85] On treatment with hydrogen chloride the oligomer is converted once again into oxazaphosphorine (LII) evidently through the monomeric form (LIII).

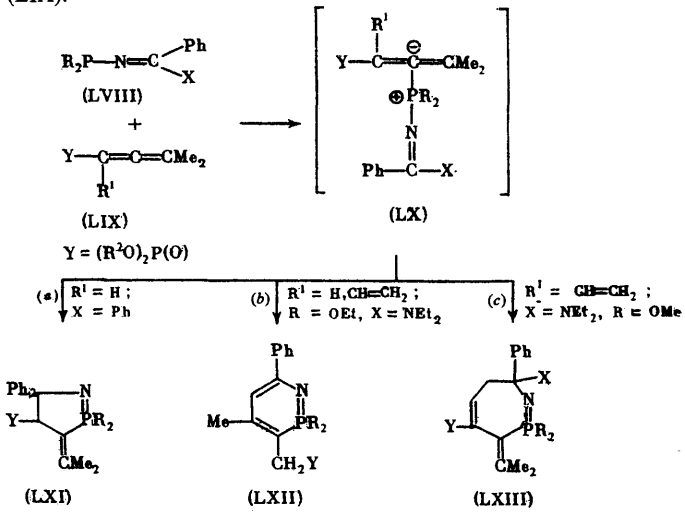
(LII) (LIII)

Unsuccessful attempts to obtain 4-keto-1,3,2σ^2-oxazaphosphole (LV) also point to the low thermodynamic stability of the endocyclic O–P=N system.[86] 1,3,2σ^3-Oxazaphospholine (LVI) was isolated in place of the desired product from the reaction of imidate hydrochloride (LIV) and phosphorus trichloride.

(LIV) (LV) (LVI)

The reaction of tetrachloromethylenediphosphine with hydrazine led to the formation of 1,2,3,5σ^2-diazadiphosphole (LVII) which is the first representative of a diphospha-1,3-diene system (Table 3, example 4).[87]

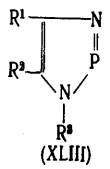
2. Cycloaddition reactions

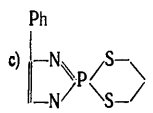


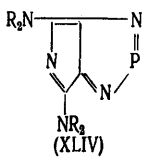
Cycloaddition reactions have a significant role in the chemistry of heterocyclic compounds. Development of these reactions applied to the P=N bond systems has opened new prospects for the synthesis of five- and six-membered cyclophosphazenes. The use of 'non-classical' 1,3-dipoles =P–X=Y (or =P–X≡Y) for the construction of phosphorus-containing rings has been considered.[9,88] Experimentally these ideas were confirmed by the synthesis of [3 + 3]-cyclic adducts with a P=C bond,[16,89] and also of [3 + 2]-cyclic adducts[8,9,90] and [3 + 3]-cyclic adducts[91,92] with P=N bonds.

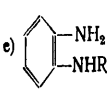
Cycloaddition reactions involving heteroatomic 1,3-dipoles have been considered in reviews,[15,16] the few examples of obtaining cyclophosphazenes up to that time are included there. Of the approximately 35 types of cyclophosphazenes known today more than half were synthesised by cycloaddition reactions.

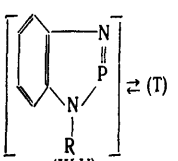
a) Synthesis of hetero-1,2σ^4-azaphosphorines

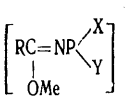


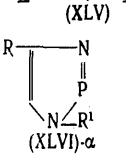


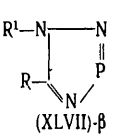


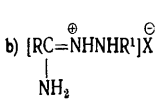


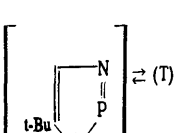


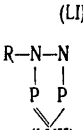












Both [3 + 3]- and [4 + 2]-cycloaddition reactions are used in methods of synthesising the indicated cyclophosphazenes (Table 4).

1,2-Azaphosphorines (LXII) were isolated from the reaction of methyleneaminophosphines (LVIII) and allenylphosphonates (LIX).[93–96]

(LVIII) (LIX) (LX) (LXI) (LXII) (LXIII)

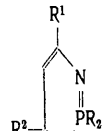
*T — tetramer.

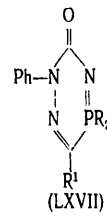
Two possible reaction routes have been established for α-unsubstituted ($R^1 = H$) allenylphosphonates, viz. a [3 + 2]-cycloaddition (route a) and a [3 + 3]-cycloaddition (route b).[93,94] The presence of a readily removable group X on the methylene carbon of the methylenaminophosphine (LVIII) is very important for the success of the reaction route.

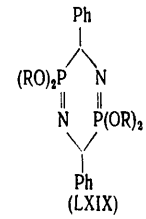
In the case of α-vinylallenylphosphonate [$R^1 = (CH=CH_2)$] two dipolarophilic centres capable of participating in cycloaddition are competing.[95] The reaction proceeds by routes (b) or (c) depending on the nature of the alkoxy substituents at the phosphorus of methylenaminophosphorine (LVIII). Data from kinetic measurements and quantum chemical calculations were in agreement with the proposed two-stage reaction mechanism through the initial formation of the dipolar ion (LX).[96]

As mentioned above the first [3 + 3]-cycloaddition reaction of phosphorus-nitrogen-containing 1,3-dipoles was carried out for the reaction of diphenylisocyanatophosphine (LXV) with nitrilimines (LXVI) (Table 4, example 2).[91,92] The activity of the phosphorus-containing dipoles in reactions with such classical 1,3-dipoles fell according to the following series.[97,98]

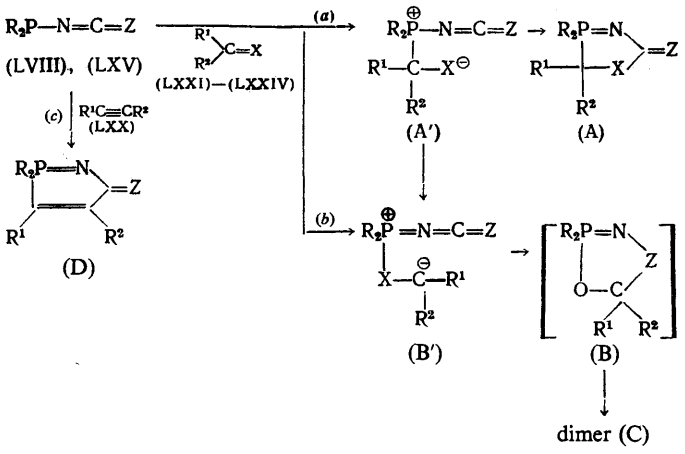
$$ArPNCO > (ArO)_2PNCO > R_2PN{=}C\begin{matrix}R^1\\R^2\end{matrix}$$







In contrast to methylenaminophosphines (LVIII), which have two alkyl or aryl substituents at the methylene carbon, benzylidene-aminophosphine (LXVIII) possessed increased activity.[99] At the moment of preparation it rapidly dimerised by [3 + 3]-cycloaddition with the formation of 1,4,3,6-diazadiphosphorine (LXIX) (Table 4, example 3).



The Diels-Alder reaction has also been investigated with a view to synthesising 1,2-azaphosphorines.[100] The linear phosphazene (LXIV), obtained by reaction of phosphines with alkene azides, was used as diene in this reaction. The [4 + 2]-cycloadduct from the reaction of diene (LXIV) with alkynes was not isolated but was converted into the more stable 1,2-azaphosphorine (LXII) (Table 4, example 1b).

b) Synthesis of hetero-1,2σ^4-azaphospholes and azaphospholines

Like the syntheses of 1,2-azaphosphorines described above, the [3 + 2]-cycloaddition reaction leading to the formation of five-membered cyclophosphazenes has been studied in detail mainly for two phosphorus-nitrogen-containing 1,3-dipoles, viz. methylen-aminophosphines (LVIII) ($Z = R^1, R^2$) and isocyanatophosphines (LXV) ($Z = O, S$) (Tables 5, 6). Reaction of these 1,3-dipoles proceeded with the formation of cyclic adducts of types (A)–(D) depending on the nature of the dipolarophile.

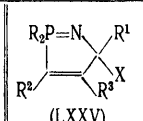
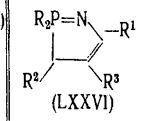
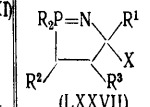
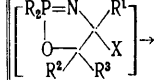
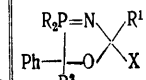
The [3 + 2]-cycloaddition of phosphorus-containing 1,3-dipoles to dipolarophiles (LXXI)–(LXXIV) was characterised in the majority of studies as a two-stage process, beginning with nucleophilic attack of the phosphorus atom on the electrophilic centre of the dipole (route a).[11,16,97] After formation of the bipolar ion (A′) conversion proceeds further to cyclic adduct by direct cyclisation to azaphospholine (A) or through first isomerisation into ion (B′) and subsequent cyclisation to the unstable azaphospholine (B) which dimerises.[11] An alternative route (b) was proposed for the reaction of methylenaminophosphines with 4-nitrobenzaldehyde.[101] It is quite probable that the interaction of substituted alkynes (LXX) (route c) may proceed via a concerted cycloaddition mechanism; however, there are no kinetic data to date on this type of reaction. It should be noted that not all the studied combinations of 1,3-dipoles and dipolarophiles lead to the isolation of cyclophosphazenes (A) or (B). In many cases the formation of cyclic adducts is accompanied by their further conversion. They will be considered in more detail when discussing the chemical properties of the five-membered cyclophosphazenes.





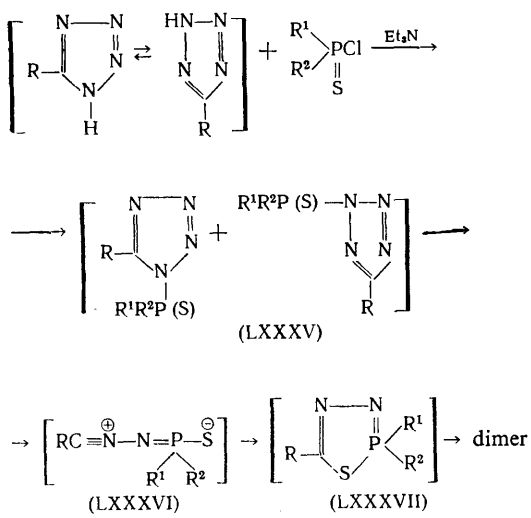






Various structures for the synthesised heterophosphacyclanes (LXXV)–(LXXXIV) were achieved by varying the dipolarophile component of the reaction.

As is seen from Tables 5 and 6 a wide range of dipolarophiles of the classes of unsaturated and carbonyl compounds (LXX)–(LXXIV) was investigated in the reactions with phosphorus- and nitrogen-containing 1,3-dipoles. Analysis of the experimental data showed that a decisive role in determining the course of the processes and also the formation of regioisomers is played by the initial step comprising nucleophilic attack by the phosphorus atom of the 1,3-dipole on the electrophilic centre of the dipolarophile. This was confirmed by the observation that cycloaddition reactions are accelerated with an increase in the nucleophilicity of the phosphorus atom.[96,97,128] and also the order of addition to substituted alkenes,[9,102,104,119] aldehydes[121–128] and other dipolarophiles.[129–131] Consequently structures (E) and (F) of the resonance structures of 1,3-dipoles make the major contribution.



In this case the order of addition of certain carbonyl compounds requires particular consideration. The reaction of these compounds proceeds with the formation of monomers of type (A) or the regioisomeric cyclic adducts (B), which exist in the form of dimers (C). The different order of addition is explained by isomerisation of the bipolar ion (A′) into ion (B′) (see general scheme.[11] However in certain cases with an insignificant difference in structure of dipolarophile (examples 4, 5 in Table 5, examples 4c, 5a in Table 6, etc.) the process is directed either towards 1,4,3-oxazaphospholines (LXXIX), (LXXXIII), or towards 1,3,2-oxazaphospholines (LXXVIII), (LXXXIV) or their dimers. There is still no complete explanation for this.

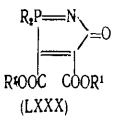
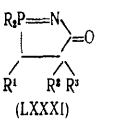
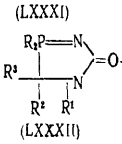
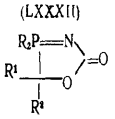
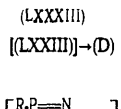
Of other cycloaddition reactions it is possible to cite the method of obtaining dimers of 1,3,4,2-thiadiazaphospholes (LXXXVII) from thiophosphorylated tetrazoles (LXXXV).[64] Pyrolysis of the latter leads to ring opening and the formation of a linear phosphazene (LXXXVI) which undergoes rapid intramolecular cycloaddition and dimerisation.











(LXXXV)

(LXXXVI) (LXXXVII)

The $1,2\sigma^2$-azaphospholes, which retain their endocyclic P=N bond during several transformations, may be starting materials for obtaining hetero-$1,2\sigma^4$-azaphospholes. [4 + 1]-Cycloaddition reactions of α-dicarbonyl compounds[133] and esters of azodicarboxylic acids[134] to $1,2\sigma^2$-azaphospholes are known. A series of spirocyclic phosphazenes was obtained in this way both in the dimeric[134] and in the monomeric form.[133]

Several other reactions of $1,2\sigma^2$-azaphospholes and also the conversions of $1,2\sigma^4$-azaphosphole dimers, described in part III of the present review, may be considered as sources for obtaining five-membered cyclophosphazenes.

Only one type of four-membered cyclophosphazene is known as yet, viz. diazadiphosphetine (XC), obtained by photolysis of diisopropylphosphine azide (LXXXVIII).[12,135,136] Reaction occurred through a reactive intermediate (LXXXIX) which was dimerised already at −42 °C.

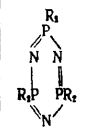
$$[(\text{iso-Pr})_2\text{N}]_2\text{PN}_3 \xrightarrow{h\nu} \{[(\text{iso-Pr})_2\text{N}]_2\text{P}{\equiv}\text{N}\} \rightarrow \{[(\text{iso-Pr})_2\text{N}]_2\text{P}{=}\text{N}\}_n$$

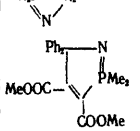
(LXXXVIII) (LXXXIX) n = 2 (XC); 3 (XCI).

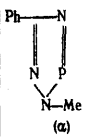
The molecular structure of dimer (XC) was demonstrated by X-ray structural analysis.[135] Trimerisation of the intermediate (LXXXIX) was observed in addition to dimerisation. The formation of diazadiphosphetine (XC) (42% yield) was preferred in comparison with triazatriphosphorine (XCI) (3% yield).

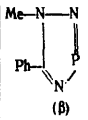
III. Special features of structure and reactivity

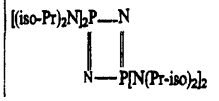
Much attention has been paid in recent years to the clarification of the special features of the electronic structure of the P=N bond. The data obtained enable an understanding of the peculiarities of the structure and chemical behaviour of phosphazenes when compared with their heteroanalogues. It is known that in their properties phosphazenes occupy an intermediate position in the series of compounds with isoelectronic groups P=X (X = C, N, O, S).[28,29] They have a higher bond order than phosphorus ylids which was confirmed by their higher ionisation potentials[138] and by the P=N bond lengths.[137]











A model molecule $Me_3P{=}NH$ was assigned to the π-type from the results of HOMO quantum chemical calculations and this was confirmed experimentally by photoelectron spectroscopic data.[138] At the same time the P=N bond is significantly more polarised than the phosphoryl or thiophosphoryl bonds.[139–141]

The special features found for the P=N bond, particularly the double bond character with a significant contribution of polar structure and its ready polarisability, mainly predetermine the chemical behavior of acyclic and cyclic phosphazenes. However a change in the electronic properties of the P=N group and the geometry of its components caused by the presence of a ring introduce specific features into their chemical behaviour. A theoretical analysis of the structure of acyclic and five-membered cyclic phosphazenes with a tetracoordinated phosphorus atom has been carried out.[14] In comparison with acyclic analogues[137] transition into a cyclic phosphazene is accompanied by a significant reduction in the endocyclic angles at phosphorus and nitrogen (Table 7). As a result of the angular strain in the five-membered phosphazene ring there is an increase in the *p*-character of the valence orbitals of the phosphorus atom and in the lengths of the endocyclic bonds with neighbouring atoms. The changes in structure and electronic properties are displayed in an increase in the electrophilicity of the phosphorus atom, an increase in the polarity of the P=N bond,[14] and a tendency to transition of the five-membered cyclophosphazenes into phosphacyclanes with pentacoordinated phosphorus. In the latter the gain in energy is explained by the small structural changes required for conversion of σ^4- into σ^5-phosphacyclanes.[57,142]

Conclusions on the specific features of the P=N bond in five-membered rings were confirmed by the accumulated experimental

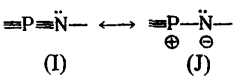
material both on some of their physical properties and on their chemical behaviour. The value of the screening constant of the phosphorus atom nucleus was an indicator in this respect. A very broad range for the chemical shifts of the ^{31}P nucleus (δ_P + 40 to −98 p.p.m.) was characteristic of acyclic phosphazenes with tetracoordinated phosphorus. Their values were in a complex non-additive dependence on the nature of the substituents at phosphorus and nitrogen.[143–147]

Table 7. Structural parameters of the endocyclic Y−P=N−X fragment of cyclophosphazenes.

No.	Compound	Bond length P=N, Å	Angle P=N−X, deg	Angle Y−P=N, deg	Refs.
1		1.54–1.60	120–148	115–126	[17]
2		1.579	111.5	98.6	[142]
3	 (α)	1.616	108.9	92.4	[154]
4	 (β)	1.627; 1.637	106.6	97.0; 97.0	[155] [156]
5		1.651	85.0	95.0	[135]

The screening constants for five-membered cyclophosphazenes lie within much closer limits and depend to a lesser degree on the environment of the phosphorus atom. For example, for the most studied 1,2σ^4-azaphospholes and 1,2σ^4-azaphospholines the resonance signals were observed in the region δ_P 76 to 48 p.p.m. (Tables 5, 6) and for 1,3,2σ^4-diaza- and 1,2,4,3σ^4-triazaphospholes were in the region 83 to 61 p.p.m.[30] It is characteristic that this region of appearance in low field is comparable with that for acyclic phosphazenes with a polarised P=N bond.[28,137,141,143–146]

The narrow range of values for the ^{31}P nuclear screening constants in the hetero-1,2σ^4-azaphospholes and -azaphospholines may serve as a diagnostic tool when establishing the structure of these cyclanes. The exceptions were the five-membered spirocyclophosphazenes in which the chemical shift of the ^{31}P nucleus was displaced towards higher field (50 to 15 p.p.m.).[60,73,133]



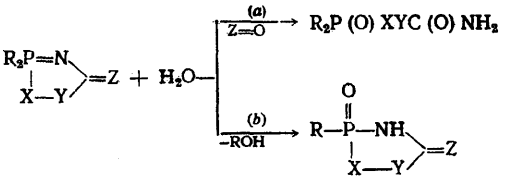
The ^{31}P nuclear resonance signals for hetero-1,2σ^4-azaphosphorines were observed within the limits δ_P 14 to 57 p.p.m. (Tables 1, 4). The breadth of the limits and the displacement towards higher field indicate the less polar character of the P=N bond in six-membered cyclophosphazenes. This conclusion was confirmed by the chemical behaviour of the azaphosphorines, distinguished by high stability. The changes mentioned in the character of the phosphazene bond were the result of a reduction of the angular stress in the six-membered ring and its partial aromaticity due to the delocalisation of π-electrons in the endocyclic P=N−X system.[6,17,34] The degree of delocalisation of π-electron density and the conductance of the electronic influence of the P=N−X fragment of diaza- and triazaphosphorines has been studied[148,150] using the ^{35}Cl NMR method and quantum chemical calculations.

In contrast to hetero-1,2σ^4-azaphospholes the corresponding phosphacyclanes with a dicoordinated phosphorus atom possess a lower inclination to react at the P=N bond.[13,77,151–153] The increased stability of the 1,2σ^2-azaphospholes is explained by the presence of aromatic character in these heterocycles. The molecular structure of 1,2σ^2-azaphospholes demonstrates the closeness of the configuration of the valence *p*-orbitals of the phosphorus atom to an ideal orthogonal configuration (Table 7).[154–158]

The resonance region of the dicoordinated phosphorus atom nucleus was specific (Table 3). It is easily possible to distinguish hetero-1,2σ^2-azaphospholes from the corresponding compounds of tetracoordinated phosphorus by ^{31}P NMR spectral data. Important characteristics were obtained by NMR spectral methods (^{31}P, ^1H, ^{13}C) and were used for the identification of the structures of these cyclanes.[13] A correlation of ^{15}N and ^{31}P nuclear chemical shifts has been carried out.[159]

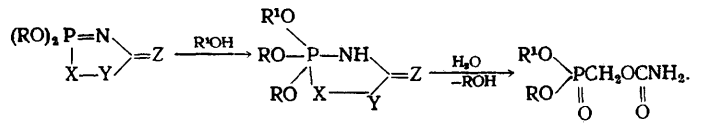
1. Interaction with nucleophilic and electrophilic reagents

The nucleophilic character of the phosphazene bond is explained by the contribution of both the resonance structure (I) and structure (J). In addition it is known that compounds with a P=N bond also possess electrophilic properties in the display of which a significant role is played by the contribution of structure (J).[137,138,141]



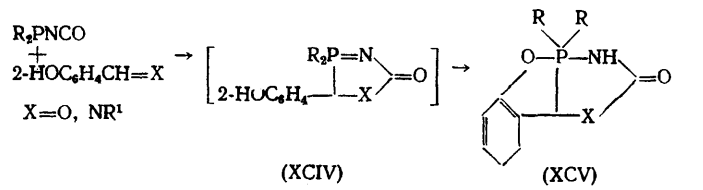
(I) (J)

The stability of acyclic phosphazenes $R_3P{=}NR^1$ towards the action of nucleophilic reagents depends on the substitutents R and R_1 and varies within wide limits.[5,28,29,137]



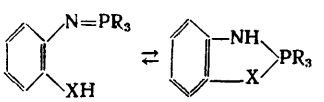
Regarding the polar character of the P=N bond the cyclophosphazenes are more stable to the action of water, alcohols, amines and other reagents with labile protons.

Hetero-1,2σ^4-azaphospholes and -azaphospholines are readily, partially at the time of isolation, subject to hydrolysis. This reaction occurs in the majority of cases with opening of the ring at the P=N bond (route *a*), however there are examples of ring retention (route *b*).



1,2-Azaphospholes,[90,111] azaphospholines,[93–95] and 1,3,4-oxazaphospholines[122–128] react by route (*a*). A wide range of *C*-phosphorylated carbamates has been obtained based on this and investigated.[121,125,160–163] A course of hydrolysis by route (*b*) has been recorded for 1,2,4,3-triazaphospholes,[56] phosphorylated 1,2-azaphospholes[94] and 1,3,4-diazaphospholines.[164]

The interaction of five-membered cyclophosphazenes with alcohols is readily effected. Relatively stable addition products (XCII) were successfully obtained for 1,3,2σ^4- [101] and 1,3,4-σ^4-oxazaphospholines.[165] These were rapidly hydrolysed with the isolation of carbamates (XCIII) with mixed substituents on phosphorus.[166]

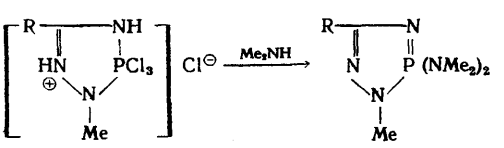


Z=O, (R^2, R^3) (XCII) (XCIII)

The thermodynamically more stable cyclic phosphoranes (XCV) were obtained on interacting isocyanatophosphines with ortho-hydroxysubstituted aromatic aldehydes [167,168] and amines,[169] and also with fluorinated acetylacetone.[170]

(XCIV) (XCV)

The intermediate formation of cyclic adducts (XCIV) was not recorded either during the reaction process or in solutions of phosphabicyclane (XCV).[168] In contrast to this it was possible to observe the tautomeric equilibrium of phosphazene and phosphorane structures in a series of linear *N*-2-hydroxy(amino)phenyl-phosphazenes (XCVI).[171–173]

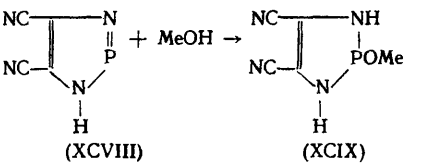


(XCVI)

This fact, and also the examples given above of reactions with water and alcohols demonstrate the low thermodynamic stability of five-membered rings with a P=N bond, being subject to facile conversion into phosphacyclanes with a pentacoordinated phosphorus atom.

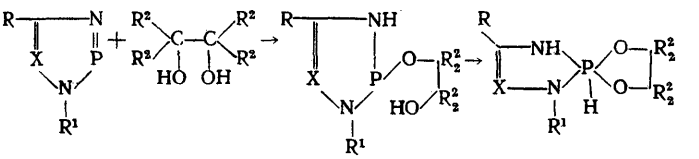
The reactions of dimeric five-membered cyclophosphazenes with water and alcohols seemingly occur through the monomer formation stage. The presence of the monomer even in infinitesimally small concentration enables rapid flow of the process because of its high reactivity. The hydrolysis of 1,3,2σ^4-diazaphosphole dimers [52,53] and the reaction of 1,2,4,3σ^4-triazaphospholes with *p*-cresol [56] proceed in this way.

Five-membered cyclophosphazenes are more stable towards the action of amines. Treatment of 1,2,4,3σ^4-triazaphospholine salts (XCVII) or its dimer with a secondary amine leads only to replacement of chlorine atoms at phosphorus and isolation of free triazaphosphole (XXIV).[56] Products of addition at the P=N bond were not observed.



(XCVII) (XXIV)

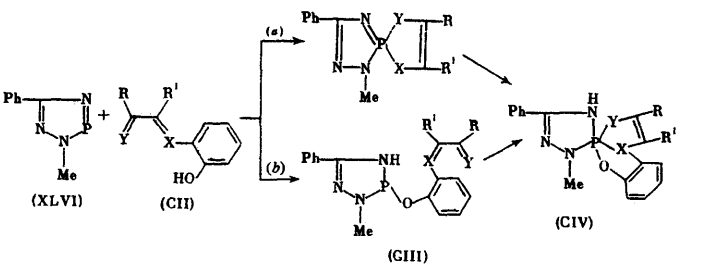
The low reactivity towards amines made it possible to develop a synthesis of monomeric spirocyclophosphazenes (XXV) based on the reaction of triazaphosphole dimers (XXIV) with *N*-methyl-benzamidrazone hydrochloride (XXIX) [65] (Table 2, example 2b).



In contrast to the dimers of triazaphospholes (XXIV) the dimers of oxa- and thiadiazaphospholes (XXVIII) react with diethylamine in the dimeric form. Replacement of chlorine at phosphorus was readily effected in this way.[64]

The reactivity of hetero-1,2σ^4-azaphospholes was reduced in comparison with their analogues with a tetracoordinated phosphorus atom and depended on the degree of aromaticity of the azaphosphole ring. 1-Methyl-5-phenyl-1,2,4,3σ^2-triazaphosphole (XLVII) (β-isomer), possessing little aromaticity, did not react with alcohols or amines, but 2-methyl-5-phenyl-1,2,4,3σ^2-triazaphosphole (XLVI) (α-isomer) adds alcohols, primary and secondary amines at the P=N bond.[77] However such weak nucleophiles as carboxylic acids, aromatic amines or β-naphthol did not react with the α-isomer. Alcohol added more readily to 1,3,2σ^2-diazaphosphole (XCVIII) with the formation of the corresponding 1,3,2-diaza-phospholine (XCIX).[81]

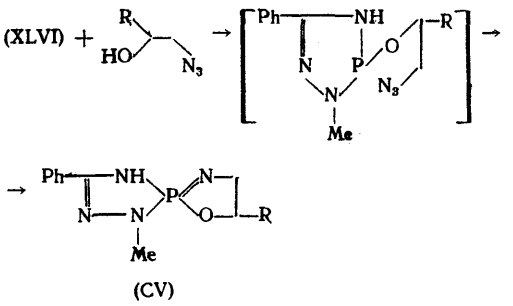
(XCVIII) (XCIX)



The reaction of 1,2-diols with 1,2,4σ^2-triaza- (XLVI) [77] and 1,3,2σ^2-diazaphosphole (XLIII) [81] was accompanied by subsequent cyclisation at the tricoordinated phosphorus atom of intermediate (C) with the formation of spirophosphoranes (CI).

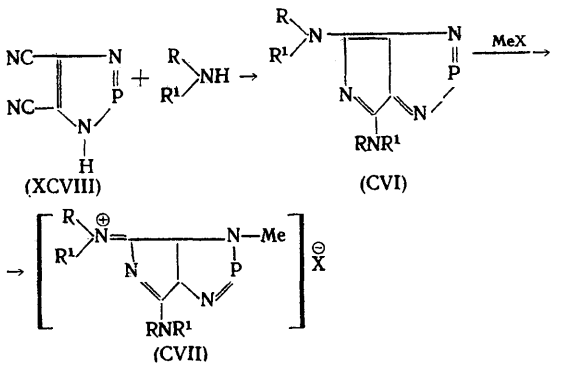
(XLIII), (XLVI) (C) (CI)

1,2-Aminoalcohols and 1,2-diamines reacted in a similar manner.



The reaction of 2-methyl-5-phenyl-1,2,4,3σ^2-triazaphosphole (XLVI) with phenols (CII) containing a diene grouping in the ortho position has been studied.[153]

(XLVI) (CII) (CIII) (CIV)

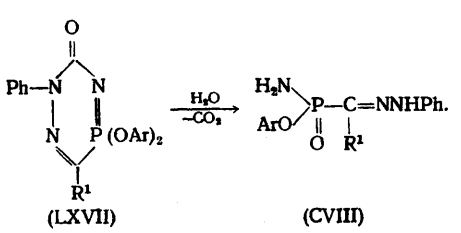


The authors claimed that of the two possible routes the process is effected by route (*b*) with the initial 1,2-addition of the hydroxyl group of reactant (CII) and subsequent intramolecular [4 + 1]-cycloaddition of the intermediate (CIII). The interaction of triazaphosphole (XLVI) with azido alcohols is assigned to the same type.[73] As in the reactions shown above the present process does not stop at the stage of addition of the P=N bond. Cyclisation is

further brought about by a reaction of the Staudinger type with the formation of a new spirocyclophosphazene (CV).

(CV)

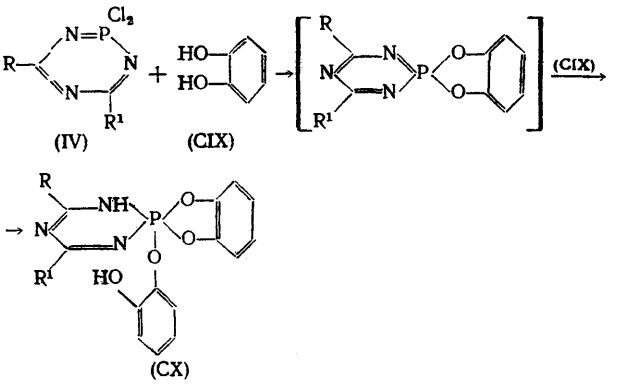
Interesting results have been obtained on reacting 1,3,2σ^2-diazaphosphole (XCVIII) with secondary amines.[80–83] The presence of a diazaphosphole ring activated the nitrile group. The latter proved to be capable of adding amine with the formation of 4,5-pyrrolo-1,3,2σ^2-diazaphosphole (CVI). In this the (σ^2) P=N bond was retained.



(XCVIII) (CVI) (CVII)

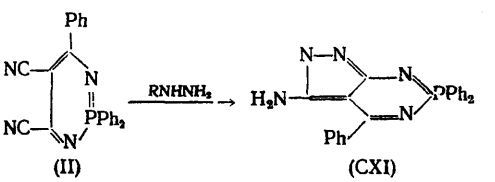
Alkylation of the product (CVI) with the formation of salt (CVII) was carried out on the diazaphosphole ring with retention of the phosphorus coordination.

The six-membered cyclophosphazenes occupy an intermediate position between the five-membered analogues and cyclotriphosphazenes in regard to the action of nucleophiles. Their reactivity is determined to a significant degree by the nature of the substituent at phosphorus. Thus 1,3,5,2,4-triazadiphosphorine (V) (Table 1, example 4) with methyl substituents at phosphorus dissolves readily in cold water without decomposition.[36,42] The corresponding chloro derivatives (V) are hydrolysed under these conditions, the authors claim, at one of the phosphazene bonds without ring scission,[34] but heating 2,2,4,4-tetraphenyl-1,3,5,2,4-triazadiphosphorine with water led to rupture of the ring.



An unusual course for the reaction with water was found for 1,3-aryl-6-oxo-1,2,5,4-triazaphosphorine (LXVII) hydrolysis of which was accompanied by decarboxylation and led to the *C*-phosphorylated hydrazone (CVIII).[97]

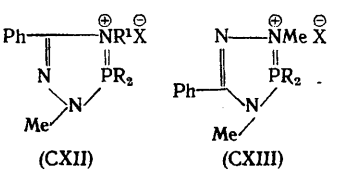
(LXVII) (CVIII)



1,2-Azaphosphorines (LXII) (Table 4)[6,93] and eight-membered cyclophosphazenes (XV) [51] are hydrolysed at the P=N bond with retention of the ring.

The reaction of 2,2-dichloro-1,3,5,2-triazaphosphorines (IV) with diols in the presence of base occurs with substitution of chlorine and retention of the phosphazene bond in the ring.[174] However on using ortho-hydroquinones 1,2-addition at the P=N bond was observed in addition to substitution and spirophosphoranes (CX) were obtained.

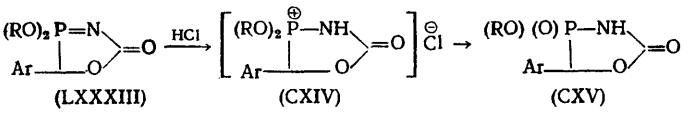
(IV) (CIX) (CX)



Chloro-substituted 1,3,2-diaza- (II) and 1,3,5,2-triazaphosphorines (IV) enter into exhaustive substitution reactions with aliphatic amines, phenoxides and alkoxides. The P=N bond is not affected by this. 4-Chloro-5-cyano derivatives of (II) react with *N*-substituted hydrazines with the formation of condensed heterocycles (CXI) without participation of the P=N bond.[6]

(II) (CXI)

In contrast to the acyclic phosphazenes[28,29,137,175–178] there are no systematic investigations on the basicity of the cyclophosphazenes which is seemingly connected with their low stability. Nonetheless examples have been described of the formation of cyclophosphazene salts in reaction with hydrogen chloride and with alkyl halides.



Salts of 1,2,4,3-triazaphospholes (CXII) and (CXIII) have been established by ^{31}P NMR. By removing hydrogen chloride, salt (CXII) (R^1 = H) is readily converted into the corresponding azaphosphole or its dimer.[56]

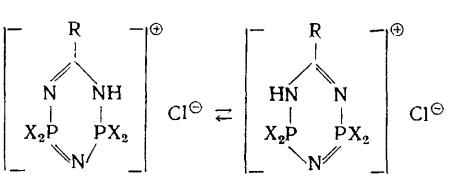
(CXII) (CXIII)

Alkylation of 1,2,4,3-triazaphospholes (XLVI) and (XLVII) has been carried out with the formation of salts of analogous structure. It was noted that azaphospholines (LXXVII) were more basic than 1,2-azaphospholes (LXXV) (Table 5) in reaction with hydrogen chloride.[179] 1,4,3-Oxazaphospholines (LXXXIII), with alkoxyl substitutents at phosphorus, were readily converted by hydrogen

chloride into oxazaphospholidines (CXV). The reaction evidently proceeds through the formation of phosphonium salt (CXIV).[180]

(LXXXIII) (CXIV) (CXV)

Similarly the monomeric product of addition of the P=N bond appeared on reaction of dimeric 1,3,2-oxazaphospholes (LXXVIII) (Table 5) with hydrogen chloride and was decomposed further with rupture of endocyclic bonds at phosphorus.[67]

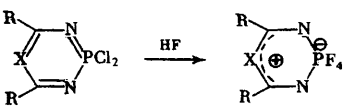


The basic properties of hetero-1,2σ^2-azaphospholes are weakly expressed because of the less polar character of the P=N bond. Thus 1,2,4,5σ^2-triazaphospholes possess such a low basicity that they are not protonated by acetic or trichloroacetic acids and do not give salts with methyl iodide.[77] 1,3,2σ^2-Diazaphospholes display acidic properties with strong bases. Their ammonium and potassium salts react with methyl iodide at the nitrogen atom neighbouring the P=N bond.[81–83] In all these conversions the coordination of phosphorus is retained equal to two.

Hydrogen chloride adds at the P=N bond of hetero-1,2σ^2-azaphospholes. This reaction is the reverse of the dehydrochlorination of 1,2σ^3-azaphospholidines which leads to the formation of azaphospholes with dicoordinated phosphorus.[56,77,81,83,85]

Bromination and chlorination of 1,2,4,3σ^2-triazaphospholes takes place with retention of the P=N bond and leads to the dimer of 1,2,4,3σ^4-triazaphospholes (XXVI) (Table 2).[55,56,77] The authors claim that the target products were the result of a more complex process than a 1,2-addition reaction at the (σ^2) P atom.[13]

Organomagnesium compounds react with 1,2,4,3σ^2-triazaphospholes (XLVI) at the P=N bond, electrophilic attack at the (σ^2) P atom is effected in this.[181]



The basicity of hetero-1,2-azaphosphorines is determined by the nature of the substituent at phosphorus as in the reactions with nucleophiles described above. So 2,2,4,4-tetrachloro-1,3,5,2,4-triazaphosphorines (V) are not alkylated by alkyl halides.[33] Replacement of the chlorine atoms at phosphorus by aryl groups leads to a strengthening of the basic properties of the triazaphosphorines (V). In the case of the 2,2,4,4-tetraphenyl derivatives fairly stable hydrochloride salts (CXVI) were obtained, the structure of which has been investigated by NMR spectroscopy (^{31}P, ^{1}H).[34] It was shown that protonation of the nitrogen takes place at position 1 or 5 but the phosphorus atoms in cations (CXVI) are magnetically equivalent. This corresponds to the presence of degenerate tautomerism of both protonated forms.

(CXVI)

Salts (CXVI) were hydrolytically less stable than the free bases, they were readily hydrolysed or alcoholised with ring rupture between nitrogen and phosphorus at positions 1 and 2.[35]

1,3,2-Diaza- (II) and 1,3,5,2-triazaphosphorines (IV) add two molecules of hydrogen fluoride with simultaneous exchange of halogen at phosphorus. The final product was cyclic salt (CXVII) in the molecule of which the negative charge was localised at the (σ^6) P.[182]

(II), (IV) (CXVII)

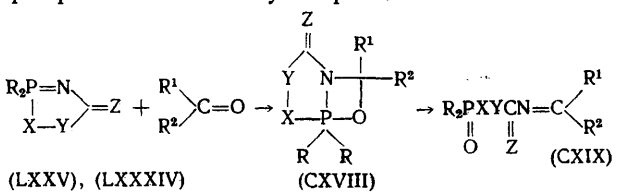
X = CCl, CH, N

2. Cycloaddition reactions

Cycloaddition reactions have been best studied for five-membered cyclophosphazenes with a tetracoordinated phosphorus atom. This clearly marked trait of their chemical behaviour is caused by the polar character of the P=N bond and an inclination towards transition to the energetically more favourable cyclanes with a pentacoordinated phosphorus atom.

Dimerisation reactions are a characteristic of many types of hetero-1,2σ^4-azaphospholes and azaphospholines. The reasons influencing the position of the equilibrium between monomeric and dimeric forms have been fairly well studied to date.[14,55–58,64] Among azaphospholines and azaphospholes structures have been found for which the position of the equilibrium is shifted either towards the monomeric or the dimeric forms. If attention is paid only to the nature of the endocyclic atoms in the N=P–X fragment then the inclination towards dimerisation of five-membered cyclophosphazenes grows along the series X = C < N < O.[56,57] There are only a very few cyclophosphazenes with an endocyclic P–C bond existing in the dimeric form. 1,3,4σ^4-Oxazaphospholines (LXXXIII) with electron-accepting exocyclic substituents at phosphorus[114–116] and 2-oxo-1,3,4-diazaphospholines (LXXXII) (Table 6, examples 3b 4c, d)[129–131] belong to these.

The preferential existence of cyclanes with an N=P–C fragment in the monomeric form is explained by the transition to the dimer being disadvantaged by the high activation energy of the process. The increase in energy is linked with the need for such a configuration of the dimer when the five-membered ring is forced to occupy a diequatorial position due to the weak apicophilicity of carbon. The indicated transition is unfavoured especially in the presence of apicophilic exocyclic substitutents at phosphorus.[14]



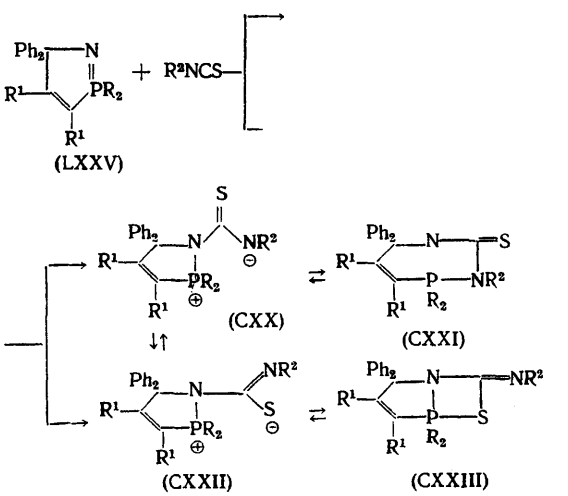
When the neighbouring atom X in the endocyclic N=P–X fragment is nitrogen the position of the monomer⟷dimer equilibrium depends on the fine balance of electronic and steric influences of the exocyclic substituents.[14] Representatives existing only in the form of monomers[56,65,133] or dimers[52,53,56,67,134] are found among this type of 1,3,2σ^4-diazaphospholes.

When an endocyclic N=P–O fragment is present the five-membered cyclophosphazenes exist in the crystal almost exclusively in the dimeric form.[57–60,68–70,73,107,108,110] There is only one example of the monomeric form for 1,3,2σ^4-oxazaphospholine (LXXXIV) in the solid state (Table 6, example 5c).[118]

The possibility of conversion into the monomeric form in solution has been proposed to clarify several chemical properties of the cyclophosphazene dimers. Such a conversion has been observed for dimers of 1,3,2-oxazaphospholines (LXXXIV) in solution.[68,73] The presence of the monomeric form in solution was confirmed experimentally in competing [2 + 2]-cycloaddition reactions.[56,67,72]

In addition to dimerisation five-membered cyclophosphazenes with a tetracoordinated phosphorus atom readily participate in [2 + 2]-cycloaddition reactions with several compounds with

multiple bonds. In contrast to acyclic phosphazenes[5] primary products of cycloaddition (CXVIII) with pentacoordinated phosphorus were isolated or established in the majority of reactions of cyclophosphazenes with carbonyl compounds.

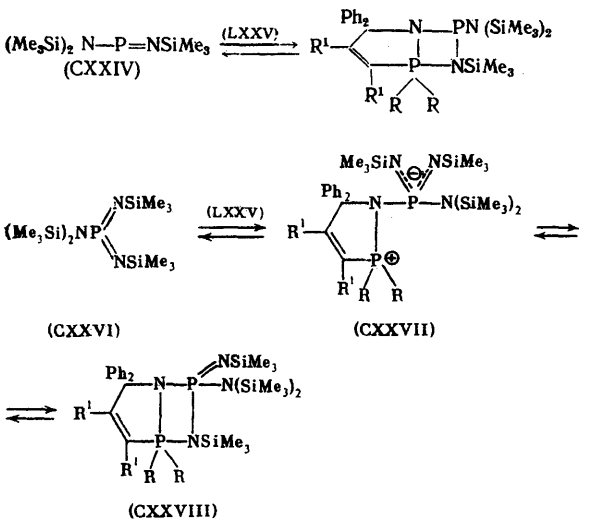


(LXXV), (LXXXIV) (CXVIII) (CXIX)

The interaction of 1,3,2σ^4-oxazaphospholine (LXXXIV) (Table 6, example 5b) with hexafluoroacetone has been described.[120] Stable bicyclic adducts (CXVIII) were successfully isolated and studied by X-ray analysis in reactions of 1,2-azaphospholes (LXXV) (Table 5, example 1c) with ketones.[142,183] On heating, bicyclanes (CXVIII) were converted into linear imines (CXIX).

The same, but less stable, bicyclic adducts of type (CXVIII) were obtained by reaction of 1,2-azaphospholes (LXXV) with chloroacetone.[184] The formation of intermediates (CXVIII) was not observed in analogous reactions with aldehydes, linear imines (CXIX) were isolated directly as final products.[101,183] However, on using chloral, bicyclanes (CXVIII) stable at low temperature were established spectrally.[180]

Dimers of 1,3,2σ^4-oxazaphospholes (LXXXIV) have been successfully introduced into competing [2 + 2]-cycloaddition reactions due to their partial dissociation in solution. A bicyclic adduct of type (CXVIII) was isolated on reaction with methyl isocyanate,[67] but an imine of type (CXIX) on reaction with ketones.[72] Similarly dimers of triazaphospholes (XXVI) (Table 2, example 2) reacted with phenyl isocyanate through the monomeric form with the formation of bicyclic adduct (CXVIII).[56]

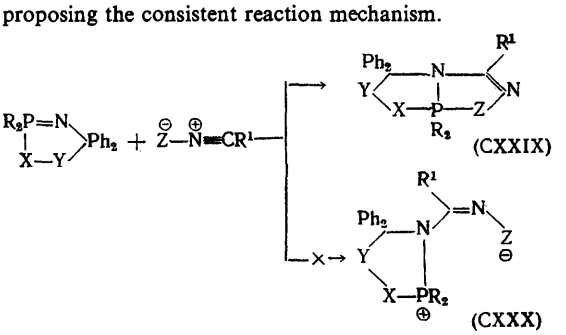


The [2 + 2]-cycloaddition of isothiocyanates to 1,2-azaphosphole (LXXV) occurred by two routes with the participation of both heteroatom double bonds.[185]

(LXXV) (CXX) (CXXI) (CXXII) (CXXIII)

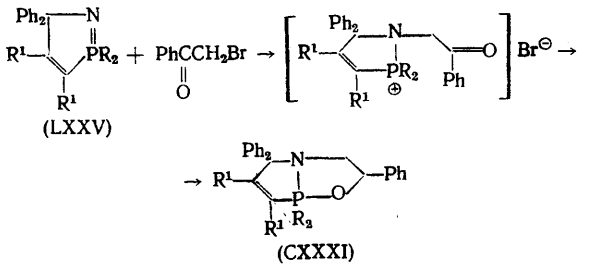
The course of the process along one or the other route was determined by the substituent on the isothiocyanate group. Methyl isocyanate reacted with the C=N bond with the formation of a stable bicyclic adduct (CXXI). Isothiocyanates with more electron-accepting substituents [R^2 = $Ph_2P(S)$; PhC(O)] led to the product of cycloaddition at the C=S bond (CXXIII). When the dipolarophilic activity of the isothiocyanate double bonds [R^2 = $Me_2P(S)$; Me] was the same, reaction occurred simultaneously by the two routes. The composition of the resulting mixture of cyclic adducts depended on the nature of the solvent and on concentration. The latter fact, in the authors' opinion, indicates the presence of a labile equilibrium between the final cyclic adducts (CXXI) and (CXXIII), and their ionic forms (CXX) and (CXII). The presence of such an equilibrium was confirmed spectroscopically.

In addition to carbonyl compounds, linear $\sigma^2\lambda^3$-diazaphosphazene (CXXIV) and $\sigma^3\lambda^5$-triazaphosphazene (CXXVI) have also been used in cycloaddition reactions of 1,2σ^4-azaphospholes (LXXV).[186] Cyclic adducts (CXXV) and (CXXVIII) were found in solution in equilibrium with the starting materials, and in the case of triazaphosphazene (CXXVI) the bipolar ion (CXXVII) also participated in the equilibrium.



(CXXIV) (CXXVI) (CXXVII) (CXXVIII)

The spectrally observed formation of bipolar ion (CXXVII),[186] and also the possibility of transition of cyclic adducts through bipolar ions (CXXI)⇄(CXX)⇄(CXXII)⇄(CXXIII) [185] point in favour of a stepwise mechanism for the [2 + 2]-cycloaddition reaction of 1,2σ^4-azaphospholes.

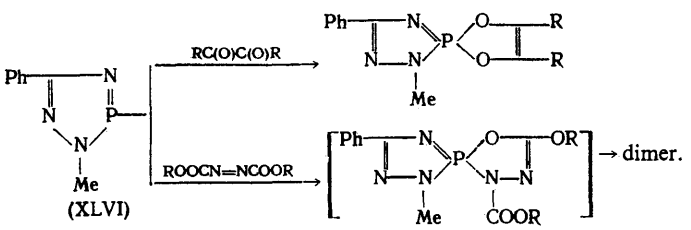


It should be mentioned that the reverse reaction, viz. dissociation into starting materials, is observed for many five-membered cyclophosphazenes and the products of their [2 + 2]-cycloaddition in solution.[123,126,179,183–186] In the majority of cases the process is reversible.

Hetero-1,2σ^4-azaphospholes and azaphospholines take part in [3 + 2]-cycloaddition reactions with such classical 1,3-dipoles as nitriloxide, nitrilimines and nitrones.[179] In all cases, except for 3,4-dihydroquinoline *N*-oxide, the formation of stable crystalline cycloaddition products (CXXIX) was recorded. Checking the reaction by ^{31}P NMR spectroscopy failed to detect the presence of bipolar ion (CXXX) as a possible intermediate which was a basis for proposing the consistent reaction mechanism.

(CXXIX) (CXXX)

In contrast to that given above the reaction of 1,2σ^4-azaphosphole (LXXV) with bromoacetophenone occurred through the stage of a phosphonium intermediate.[184]

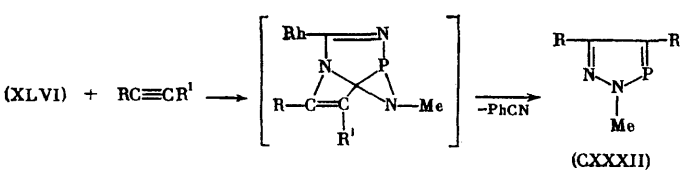


(LXXV) (CXXXI)

The formation of bicyclic adducts analogous to (CXXXI) was also observed in the reaction with styrene oxide. It is impossible to attribute reaction with the latter two reactants to the classical [3 + 2]-cycloaddition reaction.

1,2σ^2-Azaphospholes proved to be less inclined towards dimerisation and cycloaddition reactions due to the aromatic character of the azaphosphole ring and the lower polarity of the phosphazene bond.

Of the known types of hetero-1,2σ^2-azaphospholes (Table 3) 4,5-benzo-1,3,2σ^2-diazaphospholes (XLV) and 1,3,3,σ^2-oxazaphospholes (LI) exist in the form of tetramers, however they readily pass into the monomeric form in solution or on heating.[7,76,84]

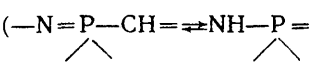


The reduced activity of 1,2,4,3σ^2-triazaphospholes (XLVI) was displayed in reactions with 1,2-diketones[133] and esters of azodicarboxylic acid[134] which reacted according to a [4 + 1] type of cycloaddition at the phosphorus atom without participation of the phosphazene bond.

(XLVI)

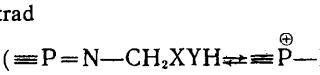
The reactions shown demonstrate the possibility of using 1,2,4,3σ^2-triazaphospholes for the synthesis of the corresponding spirocyclophosphazenes with a tetracoordinated phosphorus atom. However, 1-phenyl-1,2,3,5σ^2-diazadiphosphole (LVII) did not react with diacetyl by the reaction indicated.[87]

There are data on the participation of triazaphosphole (XLVI) as dienophile in a [4 + 2]-cycloaddition reaction with a substituted acetylene.[187] The authors claimed the intermediate formation of cyclic adducts the observation of which was unsuccessful. Diazaphospholes (CXXXII) with a (σ^2) P=C bond were isolated by elimination of nitrile.



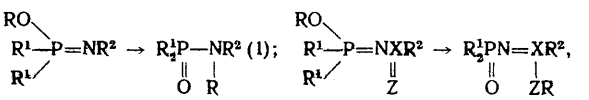
(CXXXII)

A similar reaction has also been described for 1,3,2σ^2-diazaphospholes (XLIII).[82]



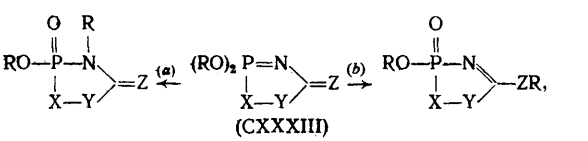
3. Rearrangements in the cyclophosphazene series

Several types of rearrangement and heterotropic conversion have been found for acyclic phosphazenes. Reversible and irreversible silylotropic rearrangements are known[188–193] as are prototropic tautomeric conversions in triad



[194–197]

and tetrad

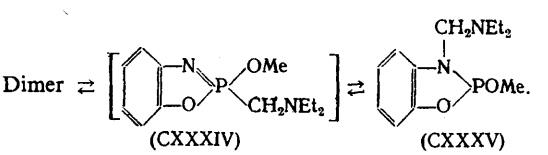


[198–200]

systems. The ring-chain tautomeric equilibrium in compounds with a P=N bond may also be assigned to the latter system.[171,172,200] The imide–amide (1) and imide–imide (2) rearrangements of acyclic phosphazenes have been considered in a review.[27]

X=C, P; Z=O, S.

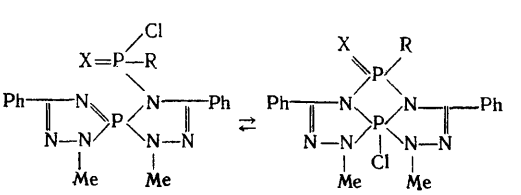
Two reactions of the latter type in the cyclophosphazene series have been studied widely and systematically by Pudovik and Konovalova and their co-workers.[11,15] The subjects of the investigation, viz. hetero-1,2σ^4-azaphospholines (CXXXIII), were rearranged thermally without isolation by routes (*a*) or (*b*) in the majority of cases.[115,201–209]



(CXXXIII)

Z=O, S, (R^1, R^2).

Frequently both processes occurred simultaneously,[210–212] although rearrangement by route (*b*) was more characteristic for thione derivatives of (CXXXIII).[213–215]

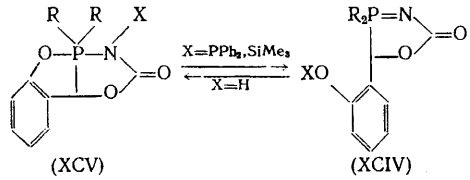


In contrast to compounds (CXXXIII) 4,5-benzo-1,3,2-oxazaphospholine (CXXXIV) underwent an imidophosphonate–amidophosphite rearrangement under distillation conditions.[70,71]

(CXXXIV) (CXXXV)

Oxazaphospholine (CXXXV) formed on distillation is slowly (60 days) transformed at room temperature once again into the dimer evidently through the monomeric form (CXXXIV).

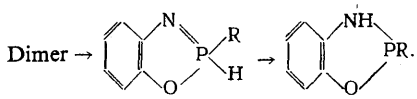
A new type of chlorotropic ring–chain tautomerism has been described for *N*-substituted 3,3-spiro-di(1,2,4,3σ^4-triazaphospholes) (CXXXVI).[65]



(CXXXVI) (CXXXVII)

X=O, unshared electron pair.

The position of the (CXXXVI)⇄(CXXXVII) equilibrium depends on the electron-accepting properties of the substituent at phosphorus. The equilibrium is completely displaced either to the left or to the right for the extreme members of the series R = Ph, Me_2N, PhO, Cl (X = unshared electron pair), Cl (X = O), an equal mixture of tautomers was observed for an average member.

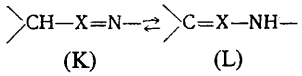


An irreversible phosphoro- and silylotropic transition (σ^5)→(σ^4) P was found in the triad system of oxazaphosphabicyclooctane (XCV).[169]

(XCV) (XCIV)

Structure (XCV) with a pentacoordinated phosphorus atom was more stable as the protonated derivative.[167,168]

On the other hand 4,5-benzo-1,3,2-oxazaphospholine (CXXXVIII) was subject in solution to irreversible transition into a form with a lower phosphorus coordination.[68]



(CXXXVIII) (CXXXIX)

No prototropic conversions have been found in the triad

in the five-membered cyclophosphazene series. 1,2σ^4-Azaphospholines[102–105] and 1,3,4 σ^4-oxazaphospholines[121–128] exist only in the imide form (K). In addition the carbocyclic pyrrole[102] and oxazol-2-one[216] analogues of these compounds have the enamine structure (L).

(K) (L)

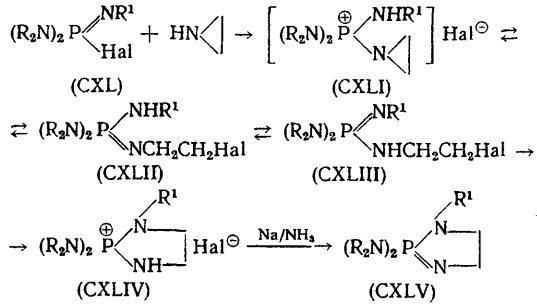
4. Complex-forming reactions

The electron-donating character of the phosphazene bond is determined by the extent of hybridisation and other electronic parameters of the orbitals occupied by the unshared electron pair of nitrogen.[137] As has been shown in a series of investigations complex formation of linear phosphazenes with salts of mercury and cadmium,[217] Lewis acids,[218–221] iodine[222] and metal carbonyls[138] leads to coordination at nitrogen.

Complexes of 3,3-diphenyl-1,4,3-oxazaphospholines with stannic chloride of composition 1:1 are known in the cyclophosphazene series with tetracoordinated phosphorus.[128] Complex formation in the ligand is effected at the nitrogen atom according to IR spectral data.

Complex formation of hetero-1,2-azaphospholes with a dicoordinated phosphorus atom has been studied most. Competition of both donor centres is possible in the presence of unshared electron pairs on the phosphorus and nitrogen atoms in the 1,2,3σ^2-azaphosphole molecule. Diaza- and 1,2,4,3σ^2-triazaphospholes gave complexes with metal carbonyls where the dicoordinated phosphorus atom was the donor.[223,224] It has been recorded that 1,2,3σ^2-diazaphospholes display weaker donor properties than triazaphospholes. This is linked with the change in degree of orbital hybridisation of the unshared electron pair at phosphorus which is reflected in the size of the endocyclic angles being reduced on going from a triaza- to a diazaphosphole.

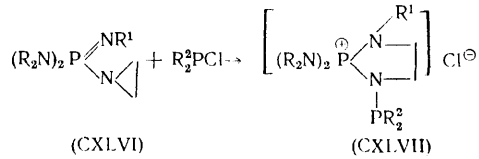
Coordination at phosphorus was observed when forming a complex of 2-methyl-5-phenyl-1,2,4,3σ^2-triazaphosphole (α-isomer) with compounds of trivalent gold.[225] However the phosphazene bond does not participate in complexes of the β-isomer and the role of donor is played by the neighbouring nitrogen atom. Seemingly, complex formation of 1,2,4,3σ^2-triazaphosphole with boron trifluoride also occurs without participation of σ^2-phosphorus.[75,77,226,227]



Salts of copper, mercury and cadmium gave solid complexes with 1,2,4,3σ^2-triazaphospholes which have not been studied in detail.[77]

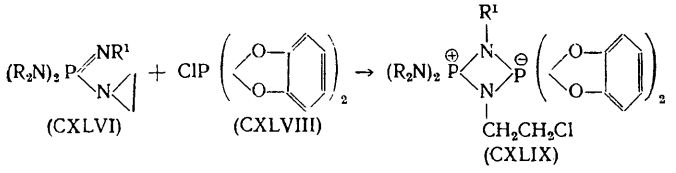
Significant success in developing the chemistry of cyclophosphazenes has been achieved in a comparatively short period. To date the main synthetic routes and chemical transformations of five- and six-membered representatives of these cyclanes have been determined. Rules for the display of their reactivity as a function of structure have been elucidated. There is no doubt that investigations will be extended to larger and smaller rings. There is interest both for the development of theoretical organic chemistry and for purpose-directed hetero-organic synthesis.

* *
*



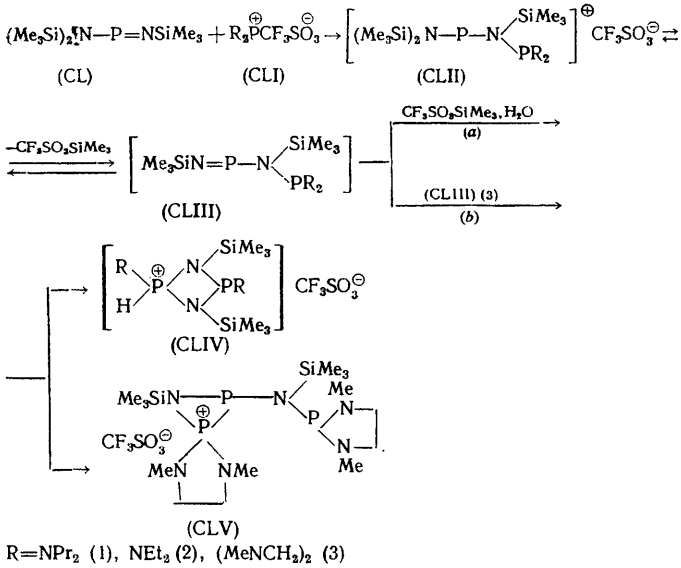
Since preparing the manuscript for printing additional information has appeared on the problem under consideration.

Synthesis of 5-membered cyclophosphazenes. A set of studies has been published recently by Pinchuk, Marchenko and co-workers on the synthesis of 1,3,2-diazaphospholines (CXLV).[228–232] The proposed method is based on the reaction of halodiaminophosphazenes (CXL) with ethylenimine.



(CXL) (CXLI) (CXLII) (CXLIII) (CXLIV) (CXLV)

Bromodiamidophosphazenes (CXL) are significantly more reactive than the corresponding chloro derivatives. It was shown using the latter that the formation of diazaphospholidinium salts (CXLIV) was a complex process of reversible conversions of the intermediates (CXLI)–(CXLIII).[228] A modification of the indicated reaction was the interaction of aziridinodiaminophosphazene (CXLVI) with a P(III) monoacid chloride.[232]

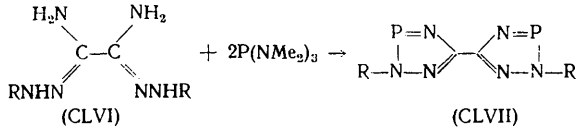


(CXLVI) (CXLVII)

However chlorophosphorane (CXLVIII) unexpectedly adds to phosphazene (CXLVI) with the formation of bonds directly onto the two nitrogen atoms, viz. the imidine and the aziridine.[233]

(CXLVI) (CXLVIII) (CXLIX)

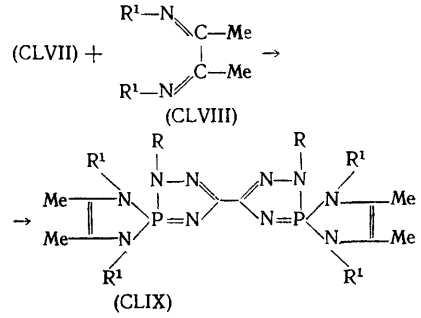
Compounds (CXLIX) represent a new type of diazaphosphetidine containing differently charged tetra- and hexacoordinated phosphorus atoms. The reaction between phosphazenes (CXLVI) and P(III) diacid chlorides proceeds by the same route with the formation of diazaphosphetidines containing tetra- and tricoordinated phosphorus atoms.[234] The reaction of acyclic phosphazene (CL) with phosphenium trifluoromethylsulphonate (CLI) leads to the analogous heterophosphocyclane (CLIV).[235]



(CL) (CLI) (CLII) (CLIII) (CLIV) (CLV)

R=NPr$_2$ (1), NEt$_2$ (2), (MeNCH$_2$)$_2$ (3)

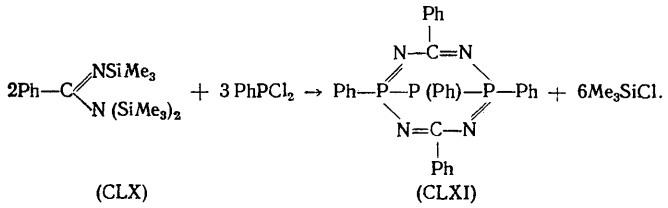
Compounds (CXLIV), (CXLVII), (CXLIX), (CLIV) and (CLV) are salts of the corresponding five- and four-membered cyclophosphazenes with a significantly polarised P=N bond. The fairly high stability of the indicated salts supports this.



Investigations on the synthesis of hetero-1,2σ^4-azaphospholines by the [3 + 2]-cycloaddition of isocyanates of P(III) acids to dipolarophiles have continued. Examples of the latter which have been studied are chloro-substituted acetaldehydes,[236] hexafluoroacetone, esters of trifluoropyruvic acid,[237] diphenylcarbodiimide[238] and a series of other reactants containing a C=N bond.[239]

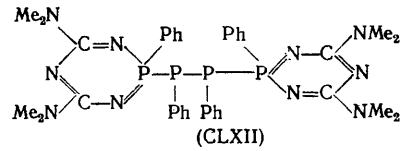
New bicyclic 1,2,4,3σ^2-triazaphospholes (CLVII) have been obtained in [4 + 1]-cycloaddition reactions.[240] The skeleton of bicycle (CLVII) is constructed on the basis of the diamidrazone molecule (CLVI), both ends of which are subject to cyclisation under the action of a triaminophosphine.

(CLVI) (CLVII)



Triazaphospholes (CLVII) react further with di-imines (CLVIII) with retention of the P=N bond and the formation of new bis-spirobicyclophosphazenes (CLIX).

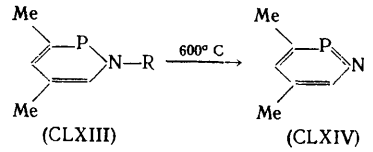
(CLVII) (CLVIII) (CLIX)



Synthesis of 6-membered cyclophosphazenes. The interaction of *C,N*-diarylnitrilamines with isocyanatophosphites has been studied in continuation of investigations on the [3 + 3]-cyclocondensation reaction.[241,242] New representatives of 1,2,4,5σ^4-triazaphosphorines (LXVII) (Table 4, example 2) have been obtained.

An interesting type of bicyclic diazatriphosphorine (CLXI) is formed by the reaction of phenyldichlorophosphine with silylated amidines (CLX).[243]

(CLX) (CLXI)



The reaction of phenyldichlorophosphine with dimethylguanidine hydrochloride in the presence of triethylamine leads to an analogous compound.[243] Bicyclic triazaphosphorine (CLXII), in which the rings are separated by a chain of four phosphorus atoms, was described in the same paper.

(CLXII)

The molecular structure of the triazaphosphorine ring in 2,2-bis(aziridinyl)-4,6-bis(trifluoromethyl)-1,3,5,2-triazaphosphorine has been studied.[244]

Synthesis of six-membered cyclophosphazenes (CLXIV) with dicoordinated phosphorus has been effected by vacuum thermolysis of azaphosphorine (CLXIII).[245]

(CLXIII) (CLXIV)

R = t-Bu, t-BuCH$_2$CH$_2$CMe$_2$.

In addition to the synthesis of cyclothiophosphazenes (VI) (Table 1, example 5) new types have been isolated by the reaction of lithium enolates of acetaldehyde with triazathiodiphosphazenes.[246]

Some problems of the chemistry of cyclophosphazenes, viz. isomerisation and tautomerism, have been considered in a review.[247]

Perfluorinated carbon-chain copolymers with functional groups and cation exchange membranes based on them: synthesis, structure and properties

Yu E Kirsh, S A Smirnov, Yu M Popkov, S F Timashev
L Ya Karpov Scientific-Research Institute of Physical Chemistry, Moscow

ABSTRACT. The review is devoted to perfluorinated polymers with sulphonic and carboxylic acid groups and to cation exchange membranes based on them. The synthesis is described of copolymers of tetrafluoroethylene with perfluorovinyl ethers containing functional groups by radical copolymerisation in an organic medium and in aqueous emulsions. Special features of the copolymerisation and approaches to obtaining copolymers with set characteristics are discussed. Data are presented on the structure and physicochemical properties of the polymeric films. Attempts to form membranes from the polymers obtained, the means of strengthening them and methods for chemical modification are described. Data are correlated on the influence of structure and polymer composition and the nature of the functional groups on the electrochemical characteristics of membranes. Special features of the functioning of perfluorinated membranes in the process for making chlorine and alkali by the electrolysis of sodium chloride solution are considered.

The bibliography has 104 references.

I. Introduction

Perfluorinated carbon-chain polymers occupy an important place in the wide range of carbon chain polymers. The presence of fluorine atoms in the main chain causes unique chemical stability and high thermal sturdiness for materials prepared from these polymers. The combination of such properties has aided wide application of perfluorinated polymers (PFP) [primarily polytetrafluoroethylene and copolymers of tetrafluoroethylene (TFE)] in various areas of science and technology.[1]

The creation of ion exchange materials based on copolymers of TFE with perfluorovinyl ethers (PFVE) containing functional groups has extended the areas of application of PFP still more. With the aid of cation exchange membranes (CEM) prepared from PFP a process has been established for obtaining alkali and chlorine by the electrolysis of concentrated aqueous solutions of sodium or potassium chloride (the so-called "chlorine–alkali" electrolysis) by membrane technology. This process has given the most powerful impulse to the development of cation exchange membranes from PFP, to the technology of preparing them, and also to the investigation of the structure and properties of such materials. The problem posed was therefore that of developing CEM with a high chemical stability and mechanical sturdiness, low electrical resistance and high selectivity.

The results of such developments are reflected in the large number of patents published in the seventies and eighties by several companies from the USA (Dupont) and Japan (Asahi Chemicals, Asahi Glass, etc.). The total energy consumption on obtaining chlorine and alkali in an electrolysis plant using CEM is 25–40% less than in traditional methods of electrolysis with mercury and diaphragms.[2] The replacement of mercury by membranes in plant is exceptionally important from the ecological point of view apart from anything else.

The use of perfluorinated CEM is not restricted solely to the chlorine–alkali electrolysis process. They are used in a whole range of electrochemical processes[3,4] and their sphere of application is widening precipitately.

The correlation of information enabling a linking of the special features of membrane function in various processes with the structure and properties of the polymers from which they were prepared and with the conditions of forming and modifying films of these polymers, will stimulate further development of new polymers and membranes and will enable the limits of their application in practice to be extended.

II. Synthesis and macromolecular characteristics of copolymers with functional groups

The creation of CEM both for chlorine–alkali electrolysis and for other processes is a complex problem. It comprises a series of necessary and inseparably linked steps. The first is the synthesis of suitable perfluorinated monomers with functional groups, the second is the development of conditions for the copolymerisation of TFE with these monomers, the third is the obtaining of membranes from the prepared polymers, including stages of making the films, strengthening them and modifying them chemically.

1. Selection of monomers

The synthesis of monomers for obtaining PFP with ion exchange groups is a vast self-contained area of organofluorine chemistry in which intensive investigations are being conducted continuously. Several tens of monomers have been patented but only a few of them are used in practice.

PFVE of the following general formula are used as monomers with functional groups and are copolymerised with TFE:

$$CF_2=CF-O-(CF_2-\underset{\displaystyle CF_3}{\underset{|}{CF}}-O)_m-(CF_2)_n-X \quad \text{(A)}$$

where usually m = 0 to 2, n = 1 to 4, X is SO_2F, SCH_2H_5, $COOCH_3$. The group X then changes to the ionic form SO_3^- or COO^- in the obtained copolymers.

The first PFVE of the indicated type was perfluoro-(4-methyl-3,6-dioxa-7-octene)sulphonyl fluoride (I):

$$CF_2=CF-O-CF_2-\underset{\displaystyle CF_3}{\underset{|}{CF}}-O-CF_2-CF_2-SO_2F \quad \text{(I)}$$

The sulphonic cation exchange membrane 'Nafion' was made based on its copolymers with TFE. Monomers developed later have also acquired great practical importance, e.g. methyl perfluoro-(5-oxa-6-hepten)oate (II),

$$CF_2=CF-O-CF_2-CF_2-CF_2-COOCH_3, \quad \text{(II)}$$

methyl perfluoro-(6-methyl-5,8-dioxa-9-decen)oate (III)

$$CF_2=CF-O-CF_2-\underset{\displaystyle CF_3}{\underset{|}{CF}}-O-CF_2-CF_2-CF_2-COOCH_3 \quad \text{(III)}$$

perfluoro-(4-oxa-5-hexene)sulphonyl fluoride (IV)

$$CF_2=CF-O-CF_2-CF_2-CF_2-SO_2F, \quad \text{(IV)}$$

and perfluoro-(5-methyl-4,7-dioxa-8-nonene)sulphonyl fluoride (V):

$$CF_2=CF-O-CF_2-\underset{\displaystyle CF_3}{\underset{|}{CF}}-O-CF_2-CF_2-CF_2-SO_2F \quad \text{(V)}$$

The routes of synthesis of the main monomers have been published.[5]

In addition to those listed PFVE containing two carboxyl groups,[6] and perfluoroallyl ethers with functional groups[7] have been proposed in the patent literature. Several other monomers described in patents do not introduce any changes in principle into the composition and structure of the ion exchange materials based on them compared with polymers synthesised from compounds (I)–(V) and differ only in method of synthesis. For example it has been proposed to use PFVE for the synthesis of ion exchange materials which have formula (A) where X is a ketone of structure $-C(O)-CF_3$ or $-C(O)-CH_3$ [8] or X is ω-hydroperfluoropropylvinyl ether $CF_2=CF-O-CF_2-CF_2-CF_2H$.[9] The side groups of the units of these monomers were oxidised to carboxyl groups in the copolymers obtained with TFE.

The preparation of PFVE containing ionogenic groups for phosphonic acids has been described.[10] However the complexity of synthesising such monomers precludes discussion of their practical application at present. Finally PFVE have been patented[11] differing in the replacement of the CF_3 group in them by CF_2Cl which affords additional possibilities for modifying the obtained PFP.

As a third comonomer the use of PFVE containing no functional groups, e.g. $CF_2=CF-O-CF_2-CF_2-CF_2-CF_3$, has been recommended in the copolymerisation of functional PFVE with TFE. Their introduction improves the physico-mechanical properties of films.[12–14] The possibility of using ethylene or other olefins as a third comonomer has been mentioned.[15]

The method of strengthening the polymeric material of membranes by cross-linking by introducing perfluorinated compounds with two vinyl groups as comonomer with PFVE at the polymerisation stage has been discussed in many patents.[13,16–18] However this method has not been used in practice probably because of the difficulty of forming films from the cross-linked polymers and also because of the poor availability of monomers of that kind.

2. Special features of the radical copolymerisation of vinyl ethers with tetrafluoroethylene

Copolymers of PFVE and TFE are obtained by radical copolymerisation. Vinyl ethers, particularly when perfluorinated, have an extremely low reactivity on copolymerisation with TFE. The shape of the curve describing the dependence of copolymer composition on the composition of the monomeric mixture (Fig. 1) indicates that on copolymerisation (II) and (III) require to be in considerable excess in relation to TFE in order to obtain polymers with an appreciable content of PFVE units. The curves for the dependence of polymer composition on the composition of the monomer mixture when copolymerising TFE with PFVE (IV) or (V) have a similar shape.[20] The copolymerisation constants calculated by the Fineman–Ross method for ethers (II) and (III) were 0.14 and for TFE 7.0.[19] Close values for the copolymerisation constants were also obtained for sulphonyl fluoride monomer (V) and TFE, 0.08 and 8.0 respectively.[5] Calculation of the parameters of the Alfrey–Price equation gave values of Q (a parameter proportional to the degree of double bond conjugation with substituents) and of e (a parameter reflecting the excess charge of the monomer caused by the polarising influence of the substituents) for carboxyl-containing PFVE equal to 0.0057 and 1.08 while values for Q and e for TFE were 0.089 and 1.22 respectively.[21] Such appreciable differences in the size of parameter Q, i.e. in the activity of TFE and ether,

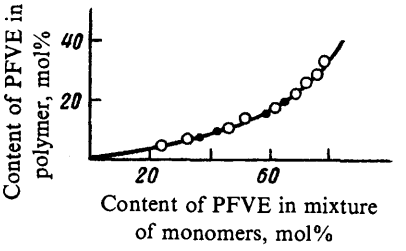

Figure 1. Dependence of copolymer composition on the composition of the mixture of monomers in the copolymerisation of PFVE (II) or (III) with TFE alone at 70 °C.[19]
○ Experimental data for PFVE (II), ● ditto for PFVE (III).

significantly complicate the synthetic process for copolymers of a given composition and demand careful observation of the experimental conditions, particularly the maintenance of a precise concentration ratio between the comonomers during the whole experiment.

Another special feature of the process of copolymerising PFVE with TFE, which is essentially reflected in the molecular weight (MW) and molecular weight distribution (MWD) of the obtained polymers, is linked with a fragmentation reaction of the radical of the terminal unit of a monomer ether:

$$\sim CF_2-\dot{C}F \longrightarrow \sim CF_2-\underset{\displaystyle O}{\overset{\displaystyle \|}{C}}-F + R_f-\dot{C}F_2 .$$
$$\quad\quad\quad

pressure limit indicated in patents is 0.7 MPa but mostly copolymerisation in an emulsion is carried out at a TFE pressure of 1.4–2.0 MPa.[17]

The most important advantage of emulsion copolymerisation over polymerisation in an organic medium is the possibility of conducting the process up to a high conversion of the ether monomer. At conversions above 45% polymerisation at constant TFE pressure does not provide consistency of composition for the obtained polymer. This consistency may be achieved only in a regime of an automatically regulated reduction in TFE pressure according to the reduction in PFVE concentration.[21]

It should be noted that the emulsion polymerisation process makes it possible to obtain copolymers with a higher MW and provides a better reproducibility of results compared with polymerisation in non-aqueous medium. However it presents exceptionally high requirements both in precision of maintaining technological parameters and in the purity of all components.

One of the requirements is the maintenance of the necessary pH value of the aqueous phase since the extent of hydrolysis of the ester groups on the functionalised monomer depends on it (Fig. 2). The appearance of carboxyl groups in the polymer as a result of hydrolysis leads to an abrupt worsening of its reprocessability by reason of an appreciable increase in pour point due to generated hydrogen bonds. Carboxyl groups may also be formed on hydrolysis of the terminal acyl fluoride groups resulting from rearrangement of the ether monomer radical as a result of the fragmentation reaction (1). Consequently, before reprocessing, copolymers obtained by the emulsion method are treated with methanol[28] with the aim of re-esterifying carboxyl groups.

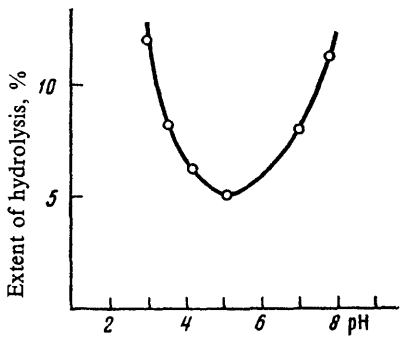

Figure 2. Influence of aqueous phase pH on the extent of hydrolysis of monomer (II) ester groups during emulsion copolymerisation.[21]

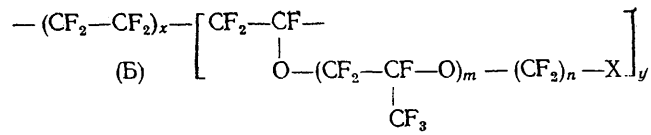

The regulation of copolymer MW is achieved by introducing aliphatic hydrocarbons or alcohols into the medium,[18] i.e. by methods traditional for obtaining fluoropolymers. Agents for chain transmission reduce the contribution of the fragmentation (1) of the growing radical. Stable hydride groups, viz.-CF_2H, are formed in place of terminal acid fluoride groups.[1]

On isolating the polymer obtained by emulsion polymerisation quantitative extraction of unreacted PFVE with freon CF_3CCl_3 from the latex has been proposed[21] followed by purification by distillation with addition of agents preventing thermal polymerisation. Treatment of the latex with freon has a second purpose, viz. removal from the copolymer of its lowest molecular portion.[29]

The emulsion copolymerisation of TFE and sulphonyl fluoride monomers has been patented very recently.[30–33]

5. Copolymer composition

The composition of copolymers used as materials for making perfluorinated CEM is expressed by the following formula:

where x and y are the molar fractions of TFE and PFVE units respectively. Due to the low reactivity of functionalised PFVE, units of it are distributed statistically in the copolymer on polymerisation and do not form blocks.

The ratio of TFE and PFVE units determines the whole complex of physicochemical, mechanical and electrochemical properties of the membranes prepared from the obtained copolymers. The molar proportion of the units of functionalised monomer in the copolymer may be varied over extremely wide limits from 5 to 30 mol.%.[18] The optimum content of PFVE with ionogenic groups in copolymers was from 8 to 15 mol.%. At a lower content membranes have high electrical resistance and low ion exchange capability. The preparation of films of such copolymers is difficult due to the high reprocessing temperature. Films of copolymers with a content of PFVE units bearing ion exchange groups greater than 20% swell excessively in solutions of electrolytes.

The homogeneity of macromolecules of the obtained copolymer is important. The content of ionogenic units in a copolymer must not deviate more than 0.3 mol.% in either direction for reproducibility of the electrochemical characteristics of membranes obtained from various batches of copolymer.[21]

If a non-ionogenic perfluoroalkylvinyl ether is introduced into the copolymer its molar proportion comprises from 2 to 20%.[18] It was shown in the same study that the molar ratio of units of ethylene or other olefin to TFE may be varied from 1:9 to 6:4.[18]

The terms "equivalent weight" (EW) and "exchange capacity" (EC) are used for the characterisation of the composition of copolymers of TFE and PFVE with ion exchange groups. The equivalent weight is the molecular weight of polymer corresponding to one ion exchange group and the exchange capacity is the quantity of milligram-equivalents of ion exchange groups contained in 1 g dry polymer. The exchange capacity of a copolymer is greater the greater the molar portion of monomer with ion exchange groups in it, and at equal molar proportions of such units the EC grows with the reduction in MW of the functionalised monomer. The equivalent weight and exchange capacity are inversely proportional, EC = 100/EW. The values of EW lie as a rule in the range 500–2000 and of EC 0.5–2.0 mg-eq/g.

6. Molecular weight and molecular weight distribution of copolymers

There are practically no data in the literature concerning the macromolecular characteristics of copolymers of the described type which is due, firstly, to the considerable methodological difficulties in determining them and secondly to the fact that not all the scientific results obtained in the industrial laboratories of companies are reflected in publications.[12]

Methodological difficulties are caused by the difficulty of obtaining solutions of copolymers which are suitable for MW determinations. Some results of MW determinations have been reported.[21] According to the report MW values of copolymers of (II) with TFE lie within the limits 10^5-10^6, however these data also were obtained by an indirect route. The copolymer of TFE with (II) is insoluble in accessible solvents but the copolymer of TFE with $CF_2=CF-O-(CF_2)_3-COOC_{10}H_{24}$ is soluble in chlorobenzotrifluoride. The MW of the copolymer containing decyl groups may therefore be measured by osmometry. The values of copolymer MW obtained in this way were extrapolated to the copolymer of (II) with TFE which was synthesised under analogous conditions and used in membrane preparation.

As a result of the difficulty of determining MW directly for copolymers of PFVE with TFE the size of T_Q, linked with the melt viscosity, was introduced for assessing practically the MW of carboxyl-containing copolymers.[16] T_Q is the temperature at which the polymer melt flows at a rate of 100 mm^3/sec through a nozzle of diameter 1 mm and length 2 mm at a pressure of 3.0 MPa. A linear relationship was established between T_Q and log MW of the copolymer determined by the indirect method indicated above (Fig. 3). For polymers used for obtaining cation exchange membranes T_Q lies within the limits 180–300 °C.[17] Polymers with a lower T_Q, i.e. with a lower MW, do not give films with a sufficiently high mechanical strength and polymers with higher T_Q values are difficult to reprocess.

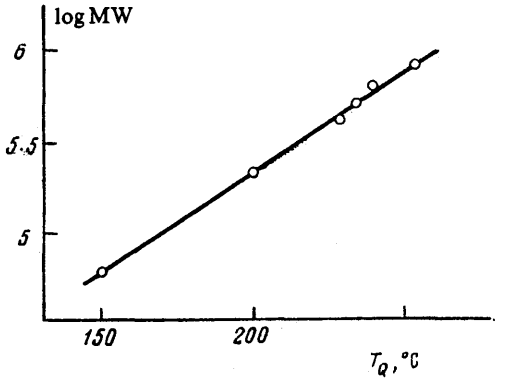

Figure 3. Relationship between T_Q of copolymers of (II) with TFE and their MW.[21]

There are no literature data on the MW of copolymers with sulphonyl fluoride or sulphide groups. It transpired that copolymers used for preparing membranes must possess high MW.[5,12] The required order of MW has been assessed[27] at the same value as in the case of carboxyl-containing polymers, i.e. 10^5-10^6.

There is even less information on the MWD of ion exchange PFP although this parameter may influence in a significant way the physico-mechanical and electrochemical properties of the membranes obtained from them. There are only hints that the synthesised PFP must have a narrow MWD. One of the purposes of MW regulators is to reduce the polydispersity of macromolecules.[18] The extraction of a copolymer with boiling freons under pressure enables removal of low molecular fractions and a narrowing of the MWD of a sample which improves the technological characteristics of the obtained membranes.[29]

III. Physicochemical properties of copolymers

The structure, physicochemical and electrochemical properties of perfluorinated CEM with sulphonyl groups based on copolymers of (I) with TFE (Nafion) have been investigated to a much greater extent than have the properties of other copolymers with carboxyl and sulphonyl groups developed later. The results of investigations of physicochemical properties of copolymers have been correlated.[34] Crystallinity, physico-mechanical properties and hydrophilicity exert an appreciable influence on the operating characteristics of CEM.

1. Crystallinity

The methods of investigating the supramolecular structure of the CEM Nafion (low-angle scattering of X-radiation and neutrons, IR spectroscopy, NMR) and the data obtained have been discussed.[35] A study has been devoted to the application of the X-ray diffraction method to the investigation of the structure of perfluorinated CEM with sulphonyl and carboxyl groups based on copolymers of TFE with (I).[36] Comparison of the results obtained for copolymers as sulphonic acids and for the same polymers in which the terminal $-CF_2SO_3H$ groups have been converted into carboxyl groups (Table 2) show that firstly the copolymers with sulphonyl groups with the same content of functionalised monomer units and identical length of side chain carrying the ion exchange group have a lower crystallinity than carboxyl containing copolymers. This may be linked with the stronger electrostatic repulsion of the sulphonyl groups characterised by a lower pK_a compared to carboxyl groups.[21] Secondly the degree of crystallinity of a copolymer falls with an increase in the content of PFVE units.

Table 2. Extent of crystallinity of copolymers of (I) and TFE as a function of their composition and type of ion exchange group.[36]

Composition		Extent of crystallinity (%) of copolymers with groups	
EW	(I), mol%	$-CF_2SO_3H$	$-COOH$
1100	13.3	12	18
1150	12.5	—	20
1200	11.7	19	23
1400	9.5	20	27
1500	8.7	22	28

Data on large-angle X-ray diffraction for copolymers of (II) with TFE also show a reduction in the degree of crystallinity with an increase in the proportion of ether monomer units.[37] Copolymers containing more than 20 mol.% monomer (II) are almost completely amorphous.

Crystallinity falls on hydrolysis of the nonionic ($-CF_2SO_2F$ or $-COOCH_3$) to the ionic form of the functional groups. The copolymers of (II) or (III) with TFE have a higher crystallinity as methyl esters than as sodium salts (Fig. 4).

Data on large-angle X-ray diffraction permit the conclusion that the crystal lattice of PFP with functional groups is, in essence, a crystal lattice of polytetrafluoroethylene with large disturbances of packing and is built of consecutive TFE units in the chains of the macromolecules.[21,38] This confirms the dependence of the degree of

crystallinity of copolymers on the proportion of TFE units in them recorded above. As analysis showed,[39] the copolymers are characterised at room temperature by larger intermolecular distances in the crystalline phase than polytetrafluoroethylene. It has been established[40] that these distances are reduced on increasing the EW of the copolymer, i.e. on reducing the PFVE portion, to a value close to 0.566 nm which is characteristic of the crystal lattice of polytetrafluoroethylene at room temperature.

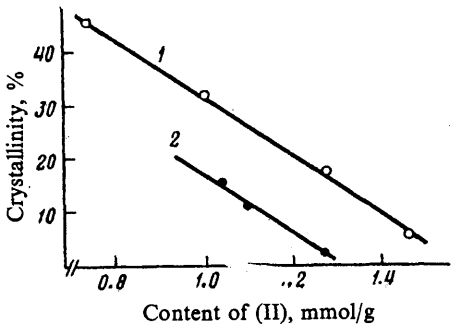

Figure 4. Relationship of crystallinity of copolymers of (II) with TFE on PFVE (II) content.[21]
1, Copolymers with $COOCH_3$ groups; *2*, copolymers with COONa groups.

Attempts to construct a model of the submicro structure of perfluorinated CEM based on the various experimental data, primarily on low-angle X-ray diffraction data, have arisen in the work of Gierke.[41] He has proposed a so-called cluster-channel model according to which hydrated ionogenic groups and counter ions form fairly voluminous (~5 nm in size) associates ("clusters"). Separate hydrated functional groups, forming "ion channels", participate in the transfer of ions and water molecules between such associates. This model has been developed subsequently.[42–44]

An alternative model of the submicro structure of perfluorinated CEM is based on representations of the comb-shaped structure of the copolymers comprising them.[45]

It was shown[46] that the structure of the sulphocation exchange membranes based on copolymers of (I) with TFE does not depend on the presence of low molecular polymer fractions. The latter are concentrated in the amorphous portion of the matrix from where they may be extracted with solvent (freon).

2. Physico-mechanical properties

The physico-mechanical properties of copolymers (viscosity, strength, elasticity) influence in an appreciable way both the processes of forming membranes based on them and on the operating characteristics of membranes.

The dependence of melting point of copolymers of (I) with TFE on content of TFE units proved to be linear (Fig. 5). Extrapolation of the line to 100% TFE content gave a value close to 326 °C, the melting point of polytetrafluoroethylene.

The viscosity of polymers is extremely sensitive to the presence of intermolecular bonds. The appearance in PFP molecules of carboxyl groups able to form hydrogen bonds sharply increases the temperature required for reprocessing and the melting point of such polymers becomes greater than their decomposition points.[21]

Physico-mechanical properties and their link with the supramolecular structure of polymers serving as material for Nafion membranes have been studied in detail.[47] Films of perfluorinated carboxyl-containing copolymers possess several better mechanical properties in comparison with the corresponding copolymers containing sulphonyl groups (Table 3).

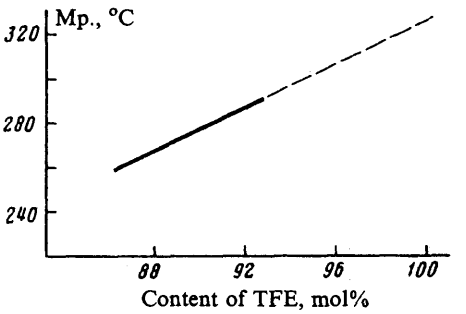

Figure 5. Relationship of melting point (Mp) of copolymers of (I) with TFE to TFE content according to differential scanning calorimetry data.[40]

Table 3. Mechanical properties of films of copolymers of (I) and TFE as a function of the type of ion exchange group.[5]

Property	Ion exchange group	
	$-CF_2SO_3H$	$-COOH$
Tensile strength, kg/cm²	224	236
Specific elongation at break, %	155	253
Modulus of tensile strength, kg/cm²	791	1560

Footnote. Ion exchange capacity of copolymer was 0.03 mg-eq/g, content of monomer (I) units was 0.3 mol.%. Measurements were conducted in aqueous medium at 25 °C.

The high mechanical properties of non-crosslinked perfluorinated copolymers are determined by the crystallites which are formed from sequences of TFE units belonging to different macromolecules. Such crystals with a characteristic spacing ~10 nm provide physical reinforcement to the perfluorinated matrix.[45] In this way the values of the intermolecular distances existing in the crystal at room temperature are achieved in crystals of pure polytetrafluoroethylene at enhanced temperature (200–220 °C).[48] The presence of ionic groups impedes a tighter packing of the indicated fragments in the copolymers. A third monomer, a non-ionogenic perfluoroalkylvinyl ether such as $CF_2 = CFO(CF_2)_3CF_3$, is introduced into the copolymers to reduce the wedging influence on crystals.[49] The relatively long perfluorinated radical in this comonomer causes

buffer zones containing ionogenic groups to form between the crystal and amorphous portions which improves the mechanical properties of membranes.

The form of the functional group proves to have a strong influence on the mechanical properties of functionalised PFP. Thus the strength of carboxyl-containing copolymers as sodium salts is greater than as methyl esters and this difference is increased significantly with an increase in temperature (Table 4). It is seen in Fig. 6, where the specific elongation at fixed tension is shown for these polymers, that at identical load the extension of films of copolymers with terminal $-COOCH_3$ groups is substantially greater than for films of copolymers having $-COONa$ as terminal groups.

Table 4. Tensile strength of films of copolymer of (II) and TFE in relation to temperature and the form of the functional groups.[37]

Temperature, °C	Tensile strength, kg/cm²	
	–COONa	$-COOCH_3$
25	320	250
50	250	40
90	230	7

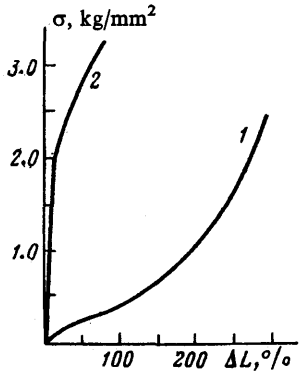

Figure 6. Relationship of stress (σ) and specific elongation (ΔL) for copolymers of TFE with (II) in the form of its *1*, methyl ester and *2*, sodium salt.[37]

Mechanical relaxation spectra permitting determination of phase transition temperatures have been studied for copolymers of (I) with TFE[47] and for copolymers of (II) and (III) with TFE.[50] The glass point of copolymers also depends primarily on the form of the functional group. It is increased substantially on going from copolymers with –COOMe groups to copolymers with –COOH groups and especially with –COONa groups. The glass point falls with increasing content of the number of PFVE units in the copolymer. Thus copolymers of (II) with TFE with –COOMe groups for which EC = 1.25 mg-eq/g has a glass point of 30–35 °C and the same copolymers with EC = 1.80 mg-eq/g only 14–21 °C. These same copolymers with COOH groups have glass points close to 70 °C and its reduction with growth of EC is less significant in this case.

3. Hydration of perfluoropolymers with ion exchange groups

The functional properties of perfluorinated CEM during chlorine–alkali electrolysis are determined to a significant degree by the amount of water absorbed by the membrane since the latter proved to be decisive in the selectivity of the CEM. In the case of a high degree of hydration a reversible migration of hydroxyl ions from the catholyte to the anolyte may occur together with transfer of sodium ions through the hydrated ion channels of the membrane. Water molecules are grouped in the membrane in amorphous regions near ionogenic groups so that the process of water molecule aggregation is determined by the types of ionogenic groups and counter ions (cations) and their interaction (Table 5). In this way the hydrophobic matrix also proves to influence the state of the water molecules in the membrane. IR spectroscopic data make it possible to draw conclusions about the presence of water molecules in perfluorinated CEM which enter hydrate coatings of ions ("bound water") and that found between them ("free water").[38]

The dependence of membrane water content on the type of ionogenic group has paramount importance. Since the electrical polarisability of the COO^- group is greater and of the SO_3^- less than that of a water molecule, COO^- anions (in contrast to SO_3^-) are able to displace water from the hydrated environment of cations.[51] As a result carboxyl containing perfluorinated CEM absorb a substantially lower quantity of water than do sulphonic cation exchange resins (Table 6).

Table 5. Equilibrium water content in copolymers of (I) and TFE with exchange capacity of 1100 for various forms of ion exchange groups.[36]

Ion exchange group	Water content	
	as% polymer dry weight	as number of molecules per ion exchange group
$-CF_2SO_3H$	32	19.6
$-CF_2SO_3Na$	27	16.9
$-CF_2SO_3Cs$	13	8.9
$-CF_2SO_3NHR$	3	2.0
–COOH	6	3.6

Table 6. Equilibrium water content in copolymers of (I) and TFE as a function of their composition and type of ion exchange group.[36]

Composition		Water content			
EW	(I), mol%	% polymer dry weight		number of molecules per ion exchange group	
		$-CF_2SO_3H$	–COOH	$-CF_2SO_3H$	–COOH
1100	13.3	32	6	19.6	3.6
1150	12.5	23	5	14.7	3.1
1200	11.7	20	4	13.3	2.6
1400	9.5	10	3	7.8	2.3
1500	8.7	8	4	6.7	3.0

The reduction in hydrophilicity of copolymers with increase in their EW is linked with the increase in content of hydrophobic TFE units participating in the establishment of the crystal structure.[5,36]

It is seen from Table 5 that sulphonamide groups formed on treating sulphonic cation exchange membranes with amines have a substantially lower degree of hydration (10-fold in comparison with the initial $-CF_2SO_3H$).

A reduction of the length of the side group in PFVE lowers the hydrophilicity of its copolymers with TFE.[52] Therefore copolymers of TFE and $CF_2 = CFOCF_2CF_2SO_2F$ with an EW 800–1300 in the $-CF_2SO_3H$ form contain from 11 to 18 water molecules per ion exchange group in the swollen state which is substantially less than for copolymers of TFE and (I).[53] Such a reduction in hydrophilicity causes a somewhat better selectivity of membranes in the electrolysis process. However copolymers containing $-OCF_2CF_2.SO_3H$ as side group have not been widely adopted due to the complexity of synthesis of the corresponding monomer and due to the occurrence of a cyclisation side reaction in the course of its copolymerisation with TFE.[54]

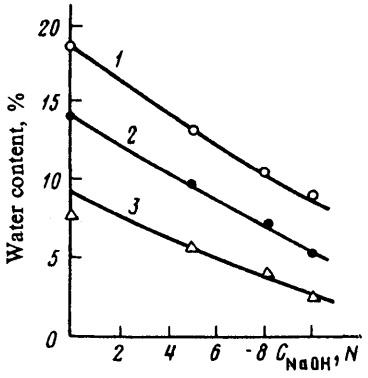

Figure 7. Water content of perfluorinated carboxyl-containing CEM based on modified copolymers of (I) and TFE with EW of: *1*, 1100; *2*, 1200; *3*, 1350 as a function of NaOH concentration.[5]

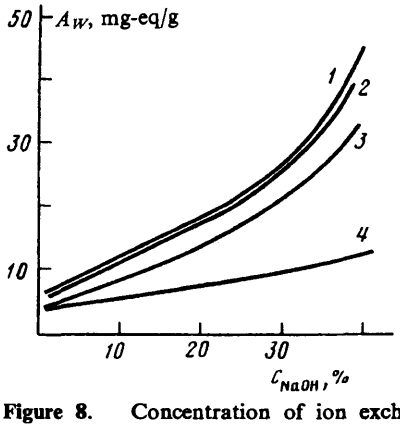

Figure 8. Concentration of ion exchange groups (in mg-eq per gram absorbed membrane water A_W) as a function of alkali concentration for copolymers of (II) and TFE with *1*, EC 1.23 mg-eq/g and *2*, EC 1.44 mg-eq/g, for copolymers of (III) and TFE with *3*, EC 1.21 mg-eq/g and for copolymers of (I) and TFE with *4*, EC 0.82 mg-eq/g.[37]

With an increase in alkali concentration the water content of the swollen polymer is reduced and this effect is strongly expressed for copolymers with a large EC (Fig. 7). Correspondingly with an increase in alkali concentration the effective concentration of ion exchange groups is increased (the mean distance between adjacent ion exchange groups is reduced) due to the reduction in membrane swelling and volume. This effect is displayed more strongly for carboxyl-containing membranes (Fig. 8).

4. Solutions and dispersions of copolymers

The problem of obtaining solutions of perfluorinated copolymers with functional groups is extremely important. Apart from the question of determining copolymer MW and MWD which was referred to above this problem has great value in applications. When solved it would be possible to form membranes by glazing from a solution. In addition the repair of membranes would be substantially simplified. Consequently much attention has been paid to the search for methods of dissolving perfluorinated copolymers. Publications have been devoted to the study of the solubility of copolymers of (I) with TFE and of the swelling of membranes based on these copolymers.[55,56]

Copolymers with CF_2SO_2F and $COOCH_3$ groups pass into solution with great difficulty. They dissolve successfully only in perhalogenated oligomers, perfluorinated kerosenes[57,58] and in perhalogenated compounds with polar groups, such as carboxyl and tertiary amino groups, at high temperatures of 170–220 °C.[58] On cooling these solutions the polymer separated in the form of a solid or gel. At room temperature stable solutions of such copolymers were obtained in saturated perhalogenated ethers simulating the structure of the ether unit of the polymeric chain.[59,60] However similar compounds are expensive and inaccessible.

Conversion of the functional groups ($COOCH_3$ or CH_2SO_2F) into the ionogenic form is alleviated by obtaining solutions of copolymers. Their ability to dissolve increases with an increasing content of ionogenic groups. Thus the hydrolysed copolymer of (I) and TFE containing 16 mol.% monomer (I) units (EW 970) dissolves in ethanol.[61] Copolymers of such type with EW 1100–1200 [11.7–13.3 mol.% of (I)] passed into solution on heating at 250 °C in water–alcohol mixtures under pressure.[61] After cooling to room temperature a 1% solution of copolymer was obtained. It was established that destruction of the polymer did not occur on solution under such forcing conditions. Concentrated (25% or more) solutions of carboxyl-containing copolymers with COOH groups were obtained at room temperature using a mixture of hydrophilic solvents (alcohols, glycols, acetone, methylpyrrolidone, etc.) with a small quantity of water (between 0.05 and 20%).[62] Polymers did not pass into solution in non-aqueous solvents nor on replacing COOH groups by CO_2Me.

Under certain conditions such as when making films, it is possible to use dispersions of polymers in hydrophilic solvents in place of solutions. A method of making such dispersions has been proposed and consists of replacing water in the emulsions obtained after polymerisation by a hydrophilic solvent.[63] Removal of water was effected either by centrifugation before introducing the solvent or after introducing solvent by freezing or by evaporation if the solvent used has a boiling point above that of water. Another method consists of treating the polymer with an aqueous alcoholic mixture at high temperature (180–300 °C) under pressure, the higher the water content in the mixture the higher must be the temperature.[64] The polymer concentration in the dispersion obtained in this way may amount to 2 to 18%.

IV. Membrane formation

The performance of perfluorinated CEM was established at each manufacturing stage including the step of making films from copolymers.

1. Single layer films

The making of films from perfluorinated copolymers is effected before conversion of their functional groups into an ionogenic form since otherwise the temperature required for processing is substantially increased and may reach the decomposition point of the polymer. Preparation of the films is effected by methods traditional for polyfluoroethylene resins. Extrusion at 180–220 °C, i.e. close to T_Q for carboxyl containing polymers, is usually used. Methods of hot pressing or rolling are rarely used.

The thickness of a membrane has almost no influence on its selectivity however to decrease resistance and the resultant energy losses it is desirable to reduce the thickness of a film. Here the mechanical strength proved to be the limiting factor.

The problem of mechanical strength is usually solved by introducing a reinforcing base into a film. Polytetrafluoroethylene fabric is used as such a base for reasons of chemical stability. The film thickness (usually 150–250 μm) must be sufficient such that the reinforcing fabric is encapsulated in the film without disturbing its integrity. The fabric is combined with the film by hot pressing. Such a reinforcement doubles the tensile strength of the membrane with a simultaneous 3- to 4-fold reduction in its ability to stretch (specific elongation at break).[65] Flakes of microporous polytetrafluoroethylene of thickness 13–75 μm and pore size 3–15 μm have been used in place of fabric.[66]

The presence of non-ion exchange strengthening material increases the electrical resistance of the membrane so that one of the problems is to reduce the volume fraction of such material in the membrane. The original method of reinforcing films was suggested in a patent.[67] The copolymer was mixed with a small amount (2–3%) of fibrilar polytetrafluoroethylene, extruded and the obtained film stretched, as a result of which the polytetrafluoroethylene forms an oriented structure confering high stability towards bending and punching to the membrane and the required mechanical strength.

The possibility of using chemical cross-linking for strengthening films has been indicated in several patents, however there are no data on the practical application of this method.

2. Multilayer membranes

The perfluorinated CEM used in the chlorine–alkali electrolysis process consist, as a rule, of two or more layers. There are three main methods of preparing multilayer films.

The first, the chemical modification of the surface layer of one prepared film, will be considered in detail in the next chapter. The second method is the lamination of two or several films. The advantage of the lamination method is that the layers of the ensuing membrane may be prepared separately and independently of one another and each of them may set desired characteristics. This explains the wide application of such a method. The disadvantage of laminated membranes is the risk of their separation during operation. Since one of the layers usually contains a copolymer with carboxyl groups and the other one with sulphonic acid groups, then to reduce the differences (in swelling ability for example) between these layers and to improve adhesion it is possible to introduce between them a layer of a mixture of such copolymers,[68] or to laminate films in one of which the sulphonate groups have been converted into carboxyls.[69] The problem of obtaining multilayer membranes stable towards separation remains, as before, a real one.

The third method of preparing multilayer films, viz. the application onto the surface of an initial film of a glazing from solution, has been used only recently in connection with the successful resolution of the problem of preparing sufficiently concentrated solutions of perfluorinated polymers with ionogenic groups. Thin layers of polymer, not exceeding 15–20 μm as a rule, are usually applied in this way.[68,70,71] Dispersions of polymers may be used in place of solutions, the methods of obtaining them have been discussed above. All three methods enumerated may be applied simultaneously for preparing multilayer membranes.[68]

The reinforcement of twin- or multilayer membranes is usually effected at the lamination stage, by packing the polyfluoroethylene between the two films. In membranes prepared without lamination the reinforcing material is introduced into the thickest layer by hot pressing.

With the aim of reducing the voltage in the electrolytic cell the distance between the electrodes and the membrane is minimised so that electrolysis occurs in the vicinity of the membrane surface. However at a distance of less than 1 mm between membrane and cathode it becomes difficult to remove bubbles of nascent hydrogen which have a tendency to stick to the membrane and lead to an increase in electrolysis voltage.[20] In order to prevent gas bubbles, primarily of hydrogen, sticking to the membrane on its cathode side, membranes for chlorine–alkali electrolysis have recently come to be prepared with rough surfaces. The beneficial effect of a rough membrane surface on the anode side on selectivity, because such a surface aids creation of a thicker diffusion layer, has been described.[72] Many methods of creating a rough surface on perfluorinated CEM have been patented.[15] Best results were given by incorporating fine particles of non-oxide ceramics, usually silicon carbide, into the surface layer on the cathode side and titanium dioxide or zirconium dioxide on the anode side.[68,73,74]

V. Chemical modification of membranes

The functional groups of the PFVE used are in the non-ionogenic form, viz. $-CF_2SO_2F$, $-CF_2SR$ or $-COOR$, at the stages of polymerisation and film formation. Conversion of them into an ionic form is usually brought about after membrane formation by hydrolysis with water or alcoholic alkali. The hydrolysis kinetics of copolymers with sulphonyl fluoride [copolymers of TFE with (I)][75] and with carboxyl groups [copolymers of TFE with $CF_2=CFO(CF_2)_5COOCH_3$][76] have been studied by IR spectroscopy. The energy of activation of the hydrolysis reaction has been determined and is 100 kJ mol^{-1} for copolymers with sulphonyl fluoride groups[75] and 105–140 kJ mol^{-1} for copolymers with carbomethoxy groups depending on the chemical nature of the alkali taken.[76] Moist morpholine was used in place of a solution of alkali for the hydrolysis of the copolymer of TFE with (I).[77] In this case the formation of sulphonamide groups simultaneously with hydrolysis was observed to a small extent.

Chemical modification of polymeric films is also as a rule effected in addition to hydrolysis. The aim of such modification is to enhance the selectivity of membranes by preventing migration of hydrated hydroxyl ions along hydrophilic channels of the membrane from the catholyte to the anolyte. This was sought by creating on the cathode side of the membrane a thin (~2–10 μm) surface barrier layer with a relatively small moisture content.

1. Copolymers with sulphonyl fluoride groups

The first method proposed for modifying membranes of copolymers of TFE with (I) was treatment of their surface (before or after hydrolysis) with ammonia[78] or primary amines.[79] In this the formation of relatively hydrophobic sulphonamide groups (see Table 5) occurs in the surface layer of the film of thickness usually ~10 μm, by the following reaction:

$$R_f—SO_2F + RNH_2 \rightarrow R_f—SO_2—NHR + HF,$$

or, for a polymer previously hydrolysed and converted into the sulphonic acid form,

$$R_f—SO_3H + RNH_2 \rightarrow R_f—SO_2—NHR + H_2O.$$

The use of di- and polyamines permits subsequent cross-linking of the polymer on heating to 100–200 °C by the reactions:

$$R_fSO_2F + NH_2—R—NH_2 \rightarrow R_fSO_2—NH—R—NH_3^+F^-,$$

$$2R_fSO_2NHRNH_3^+F \xrightarrow{\text{heat}} R_fSO_2NHRNHRNHSO_2R_f + HF + NH_4F,$$

$$R_fSO_2NHRNH_3^+F^- + R_fSO_2F \xrightarrow{\text{heat}} R_fSO_2NHRNHSO_2R_f + HF.$$

The formation of a cross-linked structure increases the strength of polymeric films. The course of the indicated reactions has been investigated in detail by IR spectroscopy.[82] The sulphonamide groups resulting from amination have pK_a 8–9 and are completely ionised at pH > 10. In the process of electrolysing a NaCl solution this condition is known to be fulfilled for the aminated layer in the vicinity of the surface facing the cathode. However in electrolysis it is necessary to acidify the anolyte with hydrochloric acid for complete neutralisation of the hydroxyl ions penetrating there. As a result of the proton currents generated in the membrane by this the amino groups in the depth of the aminated layer may appear with a lower effective pH value. The electrical resistance of the membrane then increases sharply. For this reason the use of aminated membranes in chlorine–alkali electrolysis prevents acidification of the anolyte and as a result the chlorine obtained contains no less than 2% oxygen from oxidation of hydroxyl ions at the anode.[5] In addition the sulphonamide groups proved to be insufficiently stable chemically on contact with concentrated alkali.

A method of converting sulphonic acid into carboxyl groups proved to be far more promising from the point of view of improving the electrochemical characteristics of perfluorinated CEM.[5,83] The reaction of sulphonamide groups with anion radicals, for which complexes of sodium with aromatic hydrocarbons such as naphthalene serve as sources, has been proposed for such conversions.[84] Under the action of anion-radicals decomposition of sulphonamide groups occurs with elimination of sulphur dioxide but the generated primary fluorinated amines are unstable and immediately dehydrofluorinate to nitriles which are then subjected to hydrolysis:

$$\sim CF_2SO_2NH_2 \xrightarrow{\text{anion-radicals}} [\sim CF_2NH_2] \rightarrow \sim CF_2N \xrightarrow{\text{hydrolysis}} \sim COOH.$$

This laborious method is however not used in practice.

Many other methods of converting sulphonyl fluoride groups of perfluorinated copolymers into carboxyls have since been patented.[5,83] The most widespread is chemical modification through a sulphinic acid as follows:

$$\sim CF_2SO_2F \underset{(a)}{\rightarrow} \sim CF_2SO_3H \underset{(b)}{\rightarrow} \sim CF_2SO_2Cl \underset{(c)}{\rightarrow} \sim CF_2SO_2H \underset{(d)}{\rightarrow} \sim COOH \qquad (3)$$

The first step [step (*a*)] is usually hydrolysis of the sulphonyl fluoride. Then the $-SO_3H$ group is converted into the relatively more reactive, in comparison with sulphonyl fluoride, sulphonyl chloride by treatment of the polymer with a solution of PCl_5 in $POCl_3$ under fairly forcing conditions (temperature > 110 °C, treatment time > 20 h) [step (*b*)].[85] Step (*c*) proceeds under the action of a reducing agent. Some groups of reducing agents have been proposed, viz. metal hydrides and borohydrides, atomic hydrogen, organometallic compounds, lower valency transition metal salts, etc.[86] The reaction stops at the formation of sulphinic acid when using a weak reducing agent. When using a strong reducing agent and forcing conditions step (*d*), carboxyl group formation, is also effected straight away. We point out that in this case also conversion occurs through the intermediate step of sulphinic acid. A small quantity of sulphinic acid groups is present in the modified polymer and is then oxidised to sulphonate groups with sodium hypochlorite or hydrogen peroxide.[85] The detailed mechanism for step (*d*), the splitting off of two fluorine atoms from the terminal carbon atom under the action of a reducing agent and the formation of a carboxyl group, remains as yet unclear.

A whole series of modifications of the presented scheme exists in which the separate steps may be combined or brought about. Thus the sulphonyl fluoride has been reduced directly to CF_2SO_2H groups with hydrazine, the copolymer with sulphinic acid groups was then subjected to oxidation with molecular oxygen catalysed by variable valency metal ions.

Conversion of sulphonyl chloride to carboxyl groups may be carried out using an oxidising agent and not a reducing agent thus avoiding the sulphinic acid step,[88] for example with molecular oxygen in alcohol medium at high temperature (110–150 °C). Oxidation under forcing conditions, such as with nitrogen oxides or oxygen with UV irradiation at 140–150 °C or a mixture of oxygen and fluorine, permits a one-step process for converting sulphonic acid to carboxyl groups.[88,89]

One further route to obtain carboxyl groups may be represented by the following scheme:[5]

$$\sim CF_2SO_2Cl \xrightarrow[-SO_2]{X_2} \sim CF_2X \xrightarrow{\text{UV + oxidising agent}} \sim COOH, \qquad (4)$$

where X is iodine or bromine. In all cases the mechanism of the final step, in which two fluorine atoms are split off and a carboxyl group is generated, is unclear.

The advantage of the method of modifying functional groups by scheme (3) with reduction of sulphonyl chloride through the step of forming sulphinic acid is its high selectivity.[5] The use of concentrated hydriodic acid in glacial acetic acid as a reducing agent provides a smooth reduction in the proportion of carboxyl groups from 100% to zero in the surface layer of the modified film with a gradient of less than 12% in 1 μm.[85] The gradual change in content across the thickness of the film effectively increases the stability of the membrane towards separation. The kinetics of the chemical modification by the indicated method have been investigated by IR spectroscopy and the energies of activation of the individual steps of the process have been determined.[90]

The chemical modification of copolymers with alkyl sulphide groups (in place of sulphonyl fluoride) is not different in principle. These groups are readily converted by chlorine and oxygen to sulphonyl chloride or may be oxidised directly to sulphinic or sulphonic acid groups.[27]

It should be noted that in the course of converting a sulphonyl fluoride to a carboxyl group a reduction of one occurs in the

sequence of CF_2 units between the ion exchange group and the ether oxygen in the PFVE fragment. Thus from a copolymer of (I) with TFE a polymeric material with $-OCF_2CO_2H$ groups is formed. It has been shown that when only one CF_2 unit is present between the ether oxygen and the carboxyl group stable operation of membranes over an extended period in chlorine–alkali electrolysis is not provided.[5] The reason for this is as yet unclear. It may be connected either with the chemical stability of the terminal groups or with special features of the physical structure of the polymeric material.[5] This has served as a stimulus for the development of new sulphonyl fluoride monomers, including (IV) and (V). After their industrial manufacture was effected, copolymers of (I) with TFE have ceased to be used in practice for obtaining carboxyl-containing ion exchange materials employed in chlorine–alkali electrolysis. At the present time these copolymers are used in chlorine–alkali electrolysis but mainly as sulphonic acids for other purposes.

2. Carboxyl-containing copolymers

Membranes of carboxyl-containing perfluorinated copolymers may be used without any preliminary chemical modification. A procedure for converting carboxyl groups of PFP into sulphonic acid groups has no practical application since the initial monomers with sulphonyl fluoride groups remain more accessible than those containing carboxyl groups.[90]

It is necessary to consider that the pK_a of carboxyl groups of polymeric perfluorocarboxylic acids is 1.9 and membranes of carboxyl-containing PFP may provide cation exchange only at a pH less than 3.[91] Therefore the possibility of adding hydrochloric acid to the anolyte is limited when using cation exchange membranes prepared only from carboxyl-containing polymers in the electrolysis of NaCl solution. Consequently in this case the chlorine obtained contains a certain amount of oxygen as when using membranes with sulphonamide groups. In addition chlorate ion accumulates in the anolyte and is extremely difficult to remove from the brine. Finally the evolution of oxygen at the anode reduces the life time of the latter. On the strength of the above mentioned factors monolayer membranes of carboxyl-containing copolymers are being superseded at the present time by multilayer membranes in which a layer of copolymer with sulphonyl groups possessing high acidity is facing towards the anode.

Polymeric perfluorocarboxylic acids are unstable towards the action of alkali of concentration above 40%.[16] The chemical mechanism of their decomposition under the action of alkali has not been described but it has been reported that sodium carbonate has been detected in the products of decomposition by concentrated sodium hydroxide and $-CF_2H$ groups are found in the polymer.[92] It has also been recorded that with a rise in temperature the alkali concentration sufficient for decomposition is reduced. This effect has been used for generating a surface layer, by short term treatment with concentrated NaOH solution, with a reduced concentration of carboxyl groups facing towards the cathode and consequently with a reduced moisture content. This may be carried out directly in the electrolyser.

3. Other procedures for chemical modification

A whole series of procedures for the chemical modification of perfluorinated CEM has been proposed in the patent literature. In some patents[13,93,94] it is recommended to impregnate membranes carrying sulphonyl groups on one side with carboxyl-containing monomers of various nature (carboxyl-containing dienes[93] or perfluoroacrylic acid[94]) in order to increase their selectivity. Polymerisation is then carried out afterwards. The proposed method[13] of copolymerising TFE simultaneously with other monomers carrying functional groups of a similar nature was ineffective since in this case a uniform material was obtained instead of a twin-layer membrane with a barrier layer.

Many attempts have been undertaken to use graft copolymerisation when obtaining and modifying perfluorinated CEM. The preparation of material for membranes by grafting monomers with ionogenic groups onto PFP, particularly polytetrafluoroethylene primarily by radiation grafting, is tempting in its simplicity. The grafting procedure has been patented.[95] However the most important disadvantage of this method is its non-selectivity. It was recorded[16] that copolymers prepared in this way did not possess the supramolecular structure which makes their use in membranes possible. Radiation grafting has been suggested for use only for modifying fabricated membranes. Thus the selectivity of perfluorinated sulphonic acid membranes is increased by grafting perfluorobutenoic acid on one side of their surface.

The introduction of the other halogens, chlorine, bromine and iodine into polymers as reactive groups in place of fluorine opens further possibilities for the chemical modification of membrane materials. They may be introduced, as indicated in Chapter II, at the monomer synthesis stage. However such a route is extremely laborious and furthermore the reactive groups may prove to have a negative influence on the polymerisation process, by playing a chain transfer role. Consequently it is expedient to carry out such chemical modifications on an already prepared polymer.

Thus a portion of the $-CF_2SO_2F$ groups in the copolymer (up to the stage of forming CH_2SO_2Cl groups) are replaced by $-CF_2I$ or $-CF_2Br$ and then initiation is carried out with peroxides grafting on carboxyl-containing monomers.[97] A similar result was desired when using the reaction of labile halogen atoms with radical initiators containing terminal carboxyl groups.[98] As a result the carboxyl-containing fragments of the initiator are linked with the polymer. Cross-linking of the polymer by the action of peroxide radical initiators at $-CF_2I$ and $-CF_2Br$ groups in place of grafting has been sought.[99] The preparation of a cross-linked structure in copolymers of (I) with TFE using di- and polyamines has been mentioned above.

All the methods enumerated in this section have not as yet been applied in practice to any extent.

VI. Electrochemical properties of membranes

The electrical resistance of membranes used in electrolysis processes must be as low as possible. The electrical conductivity of films and the quantity of water absorbed by them increase simultaneously with increasing content of ion exchange groups in the polymer but with growth in water content the selectivity of the membrane is reduced. The electrical conductivity and selectivity are in inverse relationship. Optimisation of these two parameters is the most important problem in the development of ion exchange membranes.

1. Film conductivity and composition

The dependence of the electrical conductivity of perfluorinated polymeric films on their composition is represented in Fig. 9. Films from carboxyl-containing copolymers have a lower electrical conductivity in comparison with films from copolymers with sulphonic acid groups at a given content of ion exchange groups in

the polymer. It is also evident that at constant EC some increase is observed in specific conductivity with increased comonomer molecular weight. This may be partially linked with the fall in copolymer crystallinity which shows up not only in the mechanical but also in the electrochemical properties of films.[12]

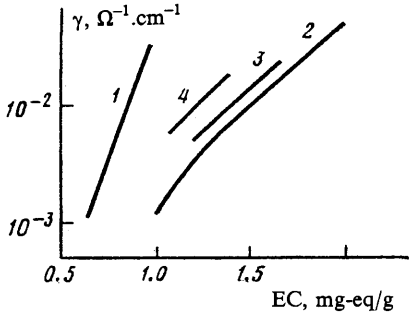

Figure 9. Dependence of electrical conductivity γ of polymeric films on their composition for copolymers of TFE *1*, with (I) in SO_3H form, *2*, with (II), *3*, with $CF_2 = CFO(CF_2)_4COOCH_3$ and *4*, with (III). Curves *2*–*4* in –COOH form.[37]

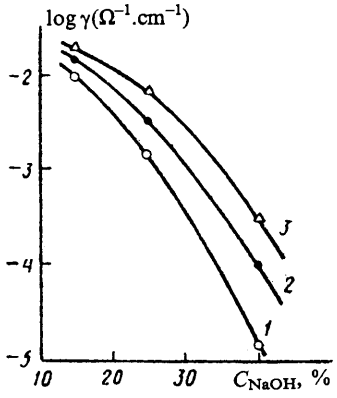

Figure 10. Dependence of electrical conductivity (γ) of carboxyl-containing membranes on NaOH concentration at temperatures of: *1*, 52; *2*, 72; *3*, 90 °C.[37]

The electrical conductivity of perfluorinated CEM depends markedly on the external conditions, viz. alkali concentration and temperature (Fig. 10). The activation energy for the transfer of Na^+ through a membrane of carboxyl-containing polymers at NaOH concentrations of 14, 25 and 40% were 16.4, 38.2 and 71.5 kJ/mol respectively.[37] Such an increase in activation energy with growth in alkali concentration is linked primarily with the reduction in membrane water content, mentioned in Chapter III, depending on the alkalinity of the medium as a result of which the diffusion coefficient of ions is sharply reduced.[38] The indicated effect supersedes the increase in electrical conductivity caused by the increase in mobile ions in the polymer as a result of the non-exchange absorption of electrolyte.

2. Membrane selectivity

The selectivity of perfluorinated CEM has a key significance in their use. The efficiency of using electrical energy, i.e. the proportion of electric current consumed in obtaining the desired products (the so-called yield on current) and also their purity, depends primarily on membrane selectivity in the process of chlorine–alkali electrolysis.

The selectivity of perfluorinated CEM is determined by the degree of "reversible" migration of hydroxyl ions through the membrane from the catholyte into the anolyte which itself depends primarily on the concentration of non-exchange absorbed electrolyte in the membrane. This concentration is significantly lower in the less hydrophilic carboxyl-containing polymers than in copolymers with sulphonic groups particularly at high alkali concentrations (Fig. 11). Since the equilibrium Donnan concentration of hydroxyl ions in the membrane grows with increasing NaOH concentration, cation exchange membranes intended for obtaining electrolytically more concentrated alkali must have a higher density of fixed ionogenic groups. This dependence has been confirmed experimentally. Maximum yield on current is achieved for membranes of higher EC in the case of a higher concentration of alkali in the catholyte.[5,19,83] It has been recorded[16] that membranes of carboxyl-containing copolymers operate with the highest efficiency (yield on current 96–97%) when the concentration of carboxyl groups in the surface layer of the swollen membrane facing the cathode in relation to the water absorbed by it is equal to the alkali concentration in the catholyte. This may be explained by the fact that under such conditions the transfer of Na^+ ions from membrane to catholyte is not accompanied by a change in its degree of hydration. On the basis of this relationship membranes have been developed with various EC of the surface layer for obtaining alkali of various concentration.[93]

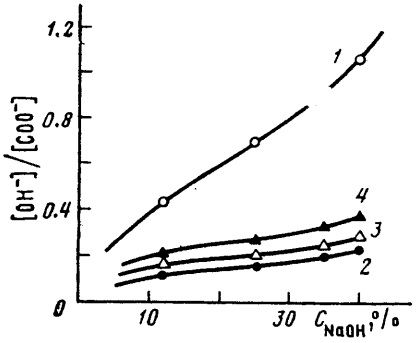

Figure 11. Dependence of hydroxyl ion concentration on alkali concentration at Donnan equilibrium in cation exchange membranes prepared from copolymers of: *1*, TFE and (I) with EC 0.82 mg-eq/g; *2*, TFE and (II) with EC 1.23 mg-eq/g; *3*, TFE and (II) with EC 1.44 mg-eq/g; *4*, copolymers of TFE and (III) with EC 1.21 mg-eq/g.[37]

It is evident from Fig. 11 that films of PFP with sulphonic groups may not possess high selectivity, particularly at high alkali concentrations, and require chemical modification to increase their selectivity or must be used in multilayer membranes having a barrier

layer of polymer with lower water content. The first attempt to prepare such membranes by laminating two layers of copolymers of (I) with TFE having different EC, such as with EM 1100 and 1500,[101] where the second of these layers fulfills a barrier role, was unsuccessful. The selectivity of such membranes was inadequate for their use in industry.[12] Later the analogous method of combining two films of different EC was used to increase the selectivity of membranes prepared from copolymers with carboxyl groups.[102] However as a rule polymer layers bear ionogenic groups of different types in multilayer membranes prepared both by chemical modification and by the lamination method.

Methods of chemical modification of films of ion exchange PFP have been considered in Chapter V. As already mentioned the route to increasing the selectivity of sulphonic cation exchange membranes, by carboxylation of a thin surface layer facing the cathode when fixed in an electrolytic cell, has displaced the method of aminating the surface of these membranes because of the inadequate chemical stability of sulphonamide groups, the increased electrical resistance of the aminated membranes and the difficulties of using them which are linked with the high pK_a of sulphonamide groups. The placing of a barrier layer of carboxyl groups on the surface of the sulphonic cation exchange membrane sharply increases its selectivity without an appreciable increase in electrical resistance. It is shown in Fig. 12 that a barrier layer of thickness 6–8 μm provides optimum selectivity and a further increase in the thickness of this layer did not increase further the yield on current. However the term "thickness of carboxylated layer" remains incompletely defined.[5,83] It is unclear what extent of conversion of sulphonic acid into carboxyl groups is applied as the border of this layer.

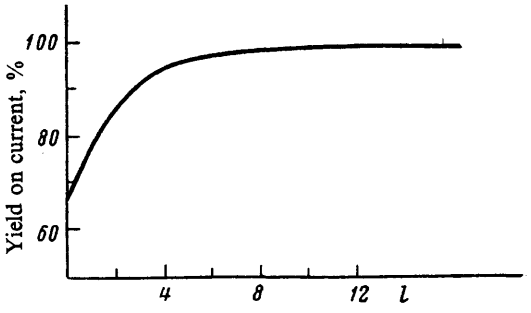

Figure 12. Influence of thickness (l) of carboxylated layer of sulphonic cation exchange membranes on yield on current when using them in the electrolysis of NaCl.[5]

All the highly selective perfluorinated CEM developed recently have a multilayer structure.[68,70,71] Their basic layer, having high EC and consequently low resistance, may be prepared from copolymers both with sulphonic acid[70] and with carboxyl groups.[68,71] In the latter case an additional layer of polymer with sulphonic groups possessing high acidity is placed on the side facing the anode. A relatively thin (10–40 μm) barrier layer of carboxyl-containing copolymer with reduced EC is placed close to the cathode. In membranes intended for preparing alkali of concentrations greater than 40% a further thin layer (~6–20 μm) of polymer with sulphonic groups was created on the side facing towards the cathode in order to protect the carboxyl-containing polymer of the barrier layer from decomposition by the concentrated alkali. It has been applied from a solution but chemical modification procedures may also be used for this purpose.[71] Across such a surface layer a fall of hydroxyl ion concentration occurs to values safe for the carboxyl-containing polymer. It is possible to introduce one more layer to improve the adhesion between layers of polymers of different chemical nature on lamination.[68] The membranes obtained in this way combined high selectivity, low electrical resistance, chemical strength and stability towards film separation.

VII. Conclusion

Great success has been achieved in the last fifteen years in the area of developing perfluorinated CEM as a result of which the industrial process for obtaining alkali and chlorine by membrane technology has been successfully put into practice. At the present time the efforts of many investigators have as usual been concentrated on improving the individual steps of this technology, on simplifying and making more economical the methods of synthesis of monomers used in the manufacture of membrane materials, on the development of methods of obtaining polymers with the desired characteristics by copolymerisation and polymer-like conversion reactions and also on the further development of procedures for fabricating membranes capable of working for an extended time with high efficiency under drastic conditions, on giving them a surface structure providing minimum energy losses during electrolysis, and optimising the parameters of membrane–electrode assemblies, etc. The synthesis of new functionalised perfluorinated monomers remains an urgent problem.

Expansion of the manufacture of perfluorinated cation exchange polymeric materials permits substantially the extension of investigations of their structure and physicochemical properties and, based on this, finding new areas for applying them.

Membranes of PFP with sulphonic groups having strongly acidic properties and providing a high proton mobility were already applied long before chlorine–alkali electrolysis as solid electrolytes in hydrogen–oxygen and hydrogen–halogen fuel cells. With the growth of hydrogen power the use of perfluorinated membranes in the electrolysis of water, where they are able to provide high current density and process efficiency, is extremely promising.[3] One more region for the application of perfluorinated sulphonic cation exchange membranes is that of ion selective electrodes.[4] A review[35] has been devoted to the use of perfluorinated sulphonic cation exchange polymers and 'Nafion' membranes based on them as catalysts. Possessing high acidity they may successfully replace traditional acid catalysts in such processes as hydration, esterification and the alkylation of benzene and its homologues. The use of catalysts based on ion exchange PFP containing metal ions has been considered in a review.[103] There have been communications on the use of perfluorinated CEM for drying gases[4] and for gas distribution.[104]

The uniqueness of the properties of cation exchange PFP and the intensity with which they are being investigated makes it possible to predict with confidence further extension of their spheres of application and an increase in their role in chemical technology.

αββ-Trifluorostyrene and polymers based on it

T S Nikitina
Karpov Physicochemical Institute, Moscow

ABSTRACT. The literature data on the synthesis, properties, and applications of αββ-trifluorostyrene and the polymers based on it are surveyed. The characteristic features of the polymerisation and copolymerisation of αββ-trifluorostyrene, the methods of preparation of ion-exchange materials based on polytrifluorostyrene, and their characteristics and applications are examined.

Certain aspects of the effect of fluorine atoms in the vinyl group of αββ-trifluorostyrene on its reactivity and physicochemical properties are discussed. The applications of polytrifluorostyrene-based materials and their advantages are indicated.

The bibliography includes 136 references.

I. Introduction

Among the large series of fluorine-containing compounds capable of polymerising, αββ-trifluorostyrene (TFS) occupies a special position by virtue of the combination in its molecule of the perfluorinated vinyl group and the aromatic ring. As a result of this, TFS can be regarded both as a phenyl derivative of tetrafluoroethylene and as a styrene with a perfluorinated vinyl group. Such combination of properties is responsible for a number of characteristic features and for the differences between this monomer and its two analogues both in polymerisation and when they are involved in different chemical reactions.

The polymer obtained on polymerisation of TFS, namely polytrifluorostyrene (PTFS), belongs to the class of thermally and chemically stable materials: it contains a perfluorinated main chain, which is resistant to thermal oxidation, and phenyl substituents. In contrast to polytetrafluoroethylene and the majority of its derivatives, which do not dissolve in any solvent, PTFS is readily soluble in many organic compounds, which permits its processing in different solutions. The presence of the benzene ring in the PTFS molecule ensures the possibility of introducing into it various functional groups and the preparation on its basis of modified materials. This renders PTFS particularly promising for the development of various ion-exchange and other materials with enhanced thermal and chemical stability.

The combination in the TFS molecule of the electronegative fluorine atoms, the vinyl group, and the benzene ring makes it an extremely interesting object for the theoretical study of the effect of electronic structural factors on the reactivity of the unsaturated and aromatic components of this compound and on its physicochemical properties and also on the properties of the monomers based on it.

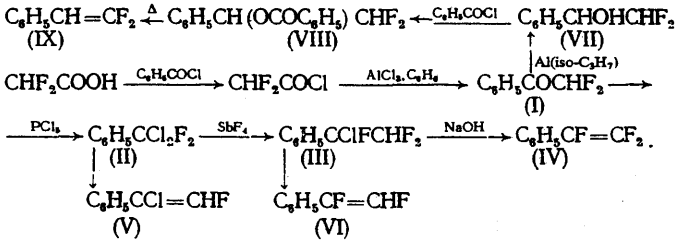
II. Synthesis and properties of αββ-trifluorostyrene

1. Methods of synthesis of αββ-trifluorostyrene

The first mentions of the synthesis of αββ-trifluorostyrene, a new fluorine-containing monomer, dates back to the end of the 1940s and the beginning of the 1950s when the study by Cohen, devoted to a multistage method of synthesis of this compound, was published.[1,2] The starting materials in this synthesis were the salts or the chlorides or chlorofluoro- or trifluoro-acetic acids:

$$CF_3COCl \xrightarrow[AlCl_3,CS_2]{C_6H_6} C_6H_5COCF_3 \xrightarrow{PCl_5} C_6H_5CCl_2CF_3 \xrightarrow{SbF_3} \rightarrow C_6H_5CFClCF_3 \xrightarrow[\text{abs. ethanol}]{Zn} C_6H_5CF{=}CF_2 .$$

The synthesis is based on the Friedal–Crafts reaction, which results in the formation of the corresponding trifluoroacetophenone or chlorodifluoroacetophenone. The overall yield of TFS does not exceed 30% and the main difficulty is the reaction involving the abstraction of ClF in the last stage of the process.

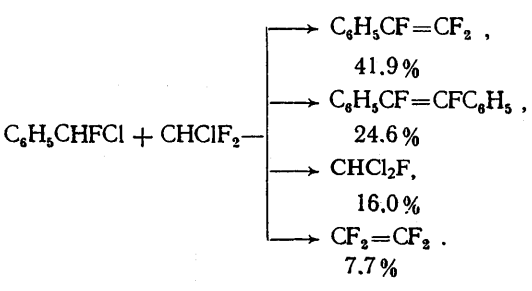


$$C_6H_5COCF_2Cl \rightarrow C_6H_5CCl_2CF_2Cl \rightarrow C_6H_5CFClCF_2Cl \rightarrow C_6H_5CF{=}CF_2 .$$

Table 1. Polymerisation of αββ-trifluorostyrene and its derivatives.[3]

Monomer	Initiator	c_{in}^{*}, %	Polymer, %	T_{soft}^{**}, °C
$C_6H_5CF{=}CF_2$	BP***	9.7	2.9	185–190
(TFS)	BF_3	1.2	0	—
$C_6H_5CH{=}CF_2$	BP	0.4	3.5	176–180
(ββ-DFS)	BF_3	0.4	2.4	127–130
$C_6H_5CF{=}CHF$	BP	0.7	2.7	—
	BF_3	30.0	2.8	225–230
$C_6H_5CCl{=}CHF$	BP	2.7	0	—
	BF_3	3.2	0	—

*c_{in} = initiator concentration.
**T_{soft} = softening temperature of the polymer.
***BP = benzoyl peroxide.



The synthesis of TFS in Prober's study,[3] also dating back to the 1950s, is a development and modification of the method described above. Together with TFS, its derivatives with chlorine and hydrogen atoms instead of fluorine in the vinyl group are obtained by this procedure. These processes can be represented schematically as follows:

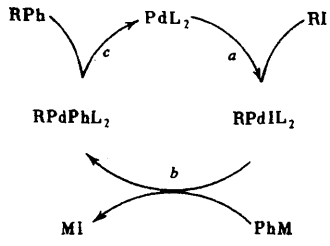
All the monomers obtained, with the exception of the chlorine-containing compound (V), are capable of polymerising with formation of polymeric compounds. Table 1 presents data on the polymerisation of these monomers and on the softening temperatures of the polymers based on them.

Prober also developed a direct method of synthesis of TFS from chlorotrifluoroethylene and benzene when they are jointly pyrolysed[4,5] in the temperature range 550–600 °C. There is an indication that this reaction can be accelerated by various acid compounds (for example BF_3) and substances with a high specific surface (activated charcoal, $PbMe_4$, etc.).[4] In this method, the reaction mixture is repeatedly circulated through a hot zone with successive enrichment of the mixture in TFS; the mixture is then distilled through a fractionating column with a large number of theoretical plates. A low yield of the final product (not exceeding 30%) and the large amount of side products, which are difficult to remove from TFS because of their ability to form azeotropic mixtures with the latter, must be included among the disadvantages of this procedure (as in the previous methods of synthesis).

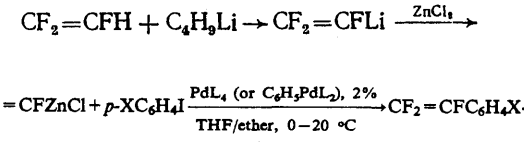
Yet another method of the pyrolytic synthesis of TFS consists in the copyrolysis of C_6H_5CHFCl and $CHClF_2$ at 600–800 °C in a stream.[6] The gaseous products obtained are absorbed in scrubbers using water and are fractionated. For the initial proportions of 68.5 mol% of C_6H_5CHFCl and 31.5 mol% $CHClF_2$, the following mixture of products is obtained:

A change in the initial reactant ratio affords other proportions of the final products.

A procedure is also known for synthesising TFS by the reaction of solid PhNa with C_2F_4 in a heterogeneous liquid–solid system containing a solvent for C_2F_4.[7] The reaction is carried out in the presence of an excess of C_2F_4 (whose amount is 50–500%) at a pressure of $(0.7-14)\times10^5$ Pa and in the temperature range from −30 to −100 °C:



One of the most widely known methods of synthesis of TFS and its derivatives is Dixon's method in which it is obtained via organolithium compounds.[8,9–13]

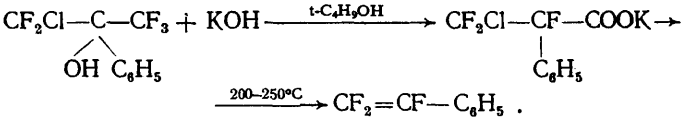


In this procedure, 1 mol of the organolithium compound under an inert atmosphere and in dry diethyl ether at −80 °C is added slowly to 1.2 mol of the fluoroalkene. The yield of TFS by this method also does not exceed 20–30%, since the main product is 1,2-difluorostilbene,[11–14] but the TFS obtained is much purer and its isolation is much simpler.

In order to obtain TFS derivatives with substituents in the benzene ring, substituted benzene derivatives were used as the initial organolithium compounds. The corresponding phenyl-lithium derivatives were obtained from them.[13]

Finally a method of synthesis of TFS and its derivatives in a high yield (≥87%) from trifluorovinyl derivatives of lead and zinc and iodobenzene derivatives in the presence of palladium complexes was described recently.[15,16] The method is based on cross-coupling reactions which are known to involve several stages: oxidative-reductive addition (a), transmetallation (b), and reductive elimination (c):[17]

When applied to the synthesis of TFS and its derivatives, this process can be expressed by the general scheme



$$X = H,\ CH_3,\ CH_3O,\ Cl.$$

The catalytic reaction involving the coupling of CF_2 = CFZnCl to ArI can be represented as the successive interaction of $ArPdI(PPh_3)_2$ with CF_2 = CFZnCl (exchange reaction) leading to the formation of the complex $ArPd(CF=CF_2):(PPh_3)_2$, which is converted as a result of reductive elimination into the zerovalent palladium complex $Pd(PPh_3)_2$ and CF_2 = CFAr. After the oxidative addition of ArI, the initial complex $ArPdI(PPh_3)_2$ is regenerated.[16] These processes take place in solution in different solvents, the yield of the products increasing as a function of their nature in the following sequence: HMPA ≃ DMF > DMSO > THF > C_6H_6 > $C_2H_4Cl_2$.[15]

In addition, a procedure is known for the synthesis of highly pure TFS using chlorinated 2-phenylperfluoro-2-propanol, from which $CF_2ClCF(C_6H_5)COOK$ is obtained. The latter compound is decomposed at 200–250 °C and 20 mmHg. For example, the synthesis of 1-chloro-2-phenylperfluoro-2-propanol proceeds as follows:

When this method is used, TFS without any impurities is obtained.[18,19]

2. Physicochemical properties of αββ-trifluorostyrene

TFS is a colourless liquid with a specific smell. When stored in air, it gradually decomposes to benzoic acid with liberation of HF.[20] A cyclic dimer is formed readily. This will be described in detail below.

In order to characterise the monomer with the aid of spectroscopic data, one usually employs the UV absorption maximum at 240 nm,[27] the IR absorption band at 1752 cm^{-1} due to the C=C (vinyl) group,[9,27,28] the 1650 and 2000 cm^{-1} bands due to the ring-monosubstituted derivatives, the 690 and 755 cm^{-1} deformation vibration bands,[24] and the 1075 and 1175 cm^{-1} bands due to the CF and CF_2 groups.[24] Table 2 presents certain characteristics of TFS taken from different sources.

Table 2. Physicochemical characteristics of TFS and PTFS.

TFS			PTFS

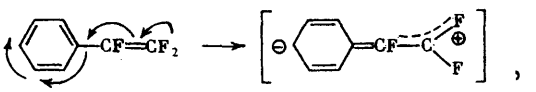
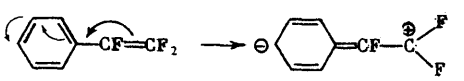
Dipole moment μ	1.98 D	[21, 26]			

*Barb[21] used the method of the LSP-limit of the softening point.
**Brown[23] determined the glass point T_g using a scanning calorimeter.



It is known that all non-aromatic fluoroethylene derivatives are coplanar, i.e. all the fluorine atoms lie in the same plane as the double bond.[25,26] On the other hand, the TFS molecule has a non-planar, non-coplanar structure. The *cis*-β-fluorine atom and the *ortho*-hydrogen atom of the benzene ring do not lie in the same plane because the distance between the centres of the hydrogen and fluorine atoms (1.6 Å) is smaller than the sum of their van der Waals radii.[25,26,29]

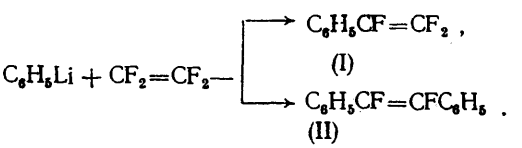
The results of geometrical calculations are confirmed satisfactorily by the dipole moment of TFS (1.98 D), which indicates the rotation of the trifluoroethylene group relative to the benzene ring and the absence of π-electron interaction between them, as a consequence of which the dipole moment of TFS is identical with those of other fluorinated alkenes, for example, 1,1,2-trifluorooct-1-ene (1.97 D).[25,26] Calculation of the dependence of the dipole moment on the angle between the planes of the benzene and perfluorinated groups showed that the angle in TFS is close to a right angle.[30,31]



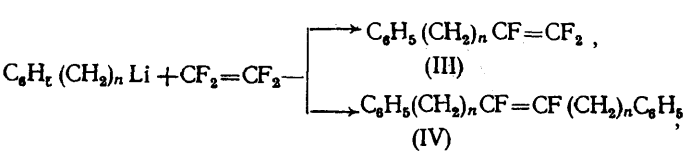
The breakdown of coplanarity in the TFS molecule is also indicated by UV absorption spectroscopic data for this compound. The study of the UV absorption spectra of mono-, di-, tri-, and tetra-substituted derivatives of TFS also lead to the conclusion that the conjugation between the perfluorinated vinyl group and the benzene ring breaks down, which indicates the non-coplanarity of these molecules.[30,31]

One can postulate on the basis of the foregoing that the nature of the effect of fluorine on the electronic structure of the C=C bond in fluorinated ethylenes and fluorinated styrenes is the same. However, analysis of different data permits the conclusion that the fluorine atoms are involved in the π-conjugation of the perfluorovinyl group with the benzene ring. This is demonstrated by the difference in the character of the sulphonation reactions of TFS and PTFS. Whereas the former compound is sulphonated directly with extreme difficulty and the process requires very severe conditions, PTFS can be sulphonated under relatively mild conditions (for example, with chlorosulphonic acid or SO_3 in dry hydrocarbon solvents at temperatures in the range 20–50 °C) (see Section IV).

The presence of conjugation leading to an increased reactivity of the C=C bond, which can be represented schematically by the formula

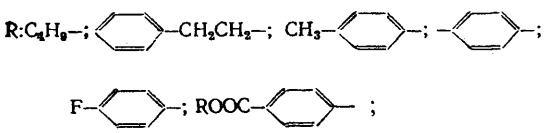


[Presumably intended scheme is:



(Ed.)]

is believed to be one of the causes of the low yield of TFS (I) in its synthesis via phenyllithium as a consequence of side reactions which result in the formation of a stilbene (II):[11–13]



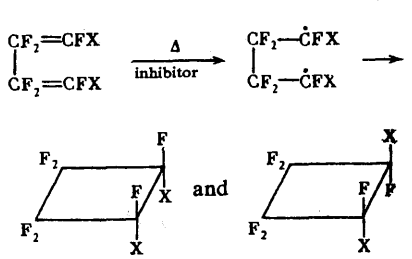
For example, this has been established when one or two methylene groups were introduced into $Ar(CH_2)_nLi$ or when polymethyl derivatives of phenyllithium $(CH_3)_nC_6H_5Li$, where $n > 1$ and CH_3 in in one or two *o*-positions, are used. Judging from the ratio of the products (III) and (IV) obtained by the reaction

when conjugation breaks down, the reactivity of the C=C bond in compound (III) falls, so that the compounds resemble the alkylfluoroethylenes AlkCF = CF_2.[14]

Data concerning the presence of conjugation between the perfluorinated vinyl group and the benzene ring in TFS have also been obtained by spectroscopic methods and have been interpreted on the basis of the available data for the effect of substituents on the electronic spectra and π-donor properties of benzene derivatives.[32]

Interesting data, associated with the presence of conjugation between different groups, have been obtained in the study of the structures, steric effects, the parameters δ and *j*, and other characteristics of TFS by the ^{19}F NMR method.[33–37] Analysis of the NMR spectra of a series of RCF = CF_2 derivatives showed that the change in the δ_{F_1} and δ_{F_2} (β-fluorine atoms) signals is associated with the inductive-resonance effect of the substituents. Thus the shifts of δ_{F_2} diminish in the following sequence:

δ_{F_2}: −7.0 −7.5 −16.3 −17.4 −17.7 −20.8.



Comparison of the shifts δ_{F_2} for the compounds RCF = CF_2, where R = C_4H_9 or $C_6H_5CH_2CH_2$, with the remaining compounds shows that the greatest changes occur for the β-fluorine atoms (F_1 and F_2) as a result of the additional delocalisation of the π-electrons of the phenyl group associated with the conjugation effect.[14,35]

However, in certain chemical reactions of TFS conjugation is only weakly manifested. For example, the chlorination and bromination of $C_6H_5CF = CF_2$ afford $C_6H_5CFCl-CF_2Cl$ and $C_6H_5CFBr-CF_2Br$ respectively in 94–95% yields, i.e. the main process involves the ethylenic double bond, as for similar non-aromatic derivatives.[38]

αβ-Difluorostilbenes and their derivatives, which are obtained simultaneously with TFS and its derivatives in the synthesis via organolithium compounds, are also non-coplanar. The non-coplanarity of the structures of these compounds has been demonstrated by UV and ^{19}F NMR spectra; despite this, the conjugation effect does occur in molecules of this kind.[39]

3. Dimerisation of αββ-trifluorostyrene

Fluoroalkenes are known to exhibit a characteristic behaviour in polycentre reactions and, in contrast to the non-fluorinated monomers, they readily dimerise or react with other olefinic compounds, forming cyclobutanes by 1,2-addition.[40] The polarisation of the double bond does not affect their cyclodimerisation, which rules out an ionic mechanism. It has been suggested that the 1,2-addition reactions proceed via a two-step radical mechanism. A biradical, in which rotation about the C(1)–C(2) bond is possible, arises in the first stage:[40]

The coupling of fluoroalkenes in the first stage of the reaction proceeds in such a way that a radical centred on the carbon atom linked to the smallest number of fluorine atoms is produced. The "head to head" cyclodimerisation is not stereospecific and in the case of asymmetric fluoroalkenes leads to the formation of *cis*- and *trans*-isomers.

The tendency of TFS towards dimerisation is extremely pronounced. In all the early studies on the synthesis and polymerisation of TFS, it was already stated that this monomer readily dimerises.[3,24] Subsequently the dimerisation reaction and the dimer itself were investigated in fair detail.[29,41–48]

It is now regarded as generally recognised that TFS dimerises via a biradical two-step mechanism, illustrated schematically above. It has also been confirmed that this reaction is not stereospecific—the dimer is always formed as a mixture of *cis*- and *trans*-isomers. Their amounts in the mixture depend little on the process conditions and can be approximately equal.[29,42,48–51] In order to identify and establish the structures of these products, different methods have been used: spectroscopic, ^{19}F NMR, mass-spectrometric, chromatographic, etc. The results have been unambiguous.

From an analysis of NMR spectra, it has been suggested in recent years that the transition state in the dimerisation of TFS has symmetrical polarity and that the double bonds are polarised. A linear relation has been obtained between the Hammett constant σ and the ^{14}F NMR parameters and it has been suggested that the deformation of the π-electron clouds is caused by mutual repulsion and polarity.[41,46,47]

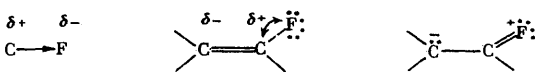
It has been demonstrated that heating of TFS in bulk or in hydrocarbon solvents in the absence of material initiators leads to the formation of dimeric products alone[29] and that this process is a second-order reaction: $V_{dim} = K_{dim}[M]^2$.[25,26,29] A relation has been derived for the determination of the dimerisation rate constant, which is $K = 1.5 \times 10^7 e^{-17652/RT}$.[49]

Table 3. The rate of dimerisation of TFS in bulk and in different solvents at 50 °C.[29]

System	TFS concentration, M	V_{dim}^*, % h^{-1}
In bulk (pH 6.0)	7.88	0.62
In bulk (pH 1.0)	7.88	0.64
Triethylamine (0.63 M)	7.28	0.66
Diethyl ether (0.22 M)	7.60	0.60
p-Benzoquinone (0.001 M)	7.60	0.65
In solution in cumene	3.06	0.72
In solution in toluene	2.84	0.76
In solution in toluene	6.27	0.70

*V_{dim} is the rate of dimerisation (adjusted to the TFS concentration in bulk).

The dimer is a mixture of a colourless oily liquid with a crystalline phase (the *trans*-isomer). The dimer completely freed from the monomer has no smell. On heating, one isomeric form of the dimer is converted into the other (*cis*–*trans* interconversion).



The dimer is extremely stable chemically but above 250 °C it decomposes back to the monomer: T_b = 120–121 °C at 6 mmHg, n_D^{20} = 1.4973;[3] n_D^{20} = 1.4954, d_4^{20} = 1.3884.[24] The rate of dimerisation of TFS depends only temperature[52] and the process is not inhibited or accelerated in the presence of various additives. Table 3 presents some results for the dimerisation of TFS in different systems.

III. Polytrifluorostyrene and αββ-trifluorostyrene copolymers

1. Polymerisation of αββ-trifluorostyrene

The presence of fluorine atoms in the TFS molecule leads to the specific behaviour of this monomer in polymerisation processes. We shall consider the causes of this behaviour.

The introduction of fluorine (the most electronegative element) atoms as substituents into the molecule of a saturated organic compound (at a carbon atom in the sp^3-state) usually leads to the appearance of a negative inductive effect ($-I_{eff}$). If the fluorine atom is linked to an sp^2-carbon atom of an unsaturated π-electron system, it exhibits the opposite effect, consisting in the repulsion of the π-electrons ($+I_{eff}$), which is due to the presence of three unshared electron pairs in the outer shell of the fluorine atom. A strong repulsion arises between the pairs of 2p electrons of the fluorine atoms and the pairs of $2p_\pi$ electrons at a neighbouring carbon atom. This effect, associated with the extremely strong influence on the reactivity of fluorine-containing monomers, is usually referred to as the "resonance-donor effect" or the R effect:[53]

$-I$ effect $+I$ effect $+R$ effect.

As a consequence of the $-I$ effect, the electronegative fluorine atom generates on the neighbouring carbon atoms an excess positive charge δ+. The pair of π electrons is then subject to the field of the positively charged carbon atoms which increases the Coulombic interaction of the π-electrons with the nuclei of these atoms. This alters their energy state and the symmetry of the distribution of electron density. As a result of this, the deformed cloud of π electrons becomes more extended along the C=C axis, binding more strongly the carbon nuclei.

For fluorinated styrenes, the change in the distribution of electron density on the C=C bond also entails a significant decrease in the conjugation of the π-electron double bond with the π electrons of the benzene ring (20%). The IR and Raman spectra of a series of fluorinated styrenes in the region of the C=C bond stretching vibrations indicate a greater strength of this bond compared with styrene.[54] Analysis of data on the copolymerisation of TFS with other monomers[55–57] shows unambiguously that TFS is more reactive than styrene.

As a consequence of the non-coplanarity of the TFS molecule, which was discussed in detail above, the effect of the polar factor for this compound is dominant and is hardly distorted by the effect of the conjugation with the benzene ring. Therefore the decrease in the reactivity of β-substituted fluoro-monomers is apparently caused precisely by the polar effect of the substituents.

The low reactivity of the TFS molecule and also the presence of fluorine atoms in it introduce definite characteristic features into the polymerisation of this monomer. The attempts to obtain the polymer by the traditional radical polymerisation in bulk and in solution, made in a number of studies, did not lead to the desired results.[3,29,58–60] The main reaction product under such conditions is a dimer, which consists of a mixture of isomers of diphenylperfluorocyclobutane, and a small amount of a low-molecular-weight polymer (oligomeric products with molecular weights in the range 1500–2000).[29] In such systems, the polymerisation of TFS involves the occurrence of two parallel and independent processes: dimerisation and oligomerisation.[29] The activation energy for the first process is then 58.58 kJ mol^{-1} and that for the second is 79.5–87.8 kJ mol^{-1} depending on the type of initiation.[29,52] When the process is carried out in solution, an increase in the dielectric constant of the medium leads to an increase in the molecular weight of the oligomer. Table 4 presents certain results for the polymerisation of TFS in different solvents.

Table 4. The rates of oligomerisation (V) of TFS in different solvents at 50 °C (AIBN*, 0.076 M).[29]

Solvent	ε	TFS concentration, M	$10^4 V$, mol litre^{-1} min^{-1}		Molecular weight
			Experimental	adjusted to concentration in bulk**	
In bulk	—	7.88	2.30	2.30	1 200
Cumene	2.23	3.06	0.94	2.42	1 100
Toluene	2.23	2.84	0.92	2.54	1 200
Toluene	2.23	6.27	2.23	2.27	1 170
Ethyl methyl ketone	18.0	4.88	3.36	5.26	2 000
N-Methylpyrrolidinone	31.0	3.14	2.02	5.05	4 300
Dimethylformamide	36.7	5.07	4.78	7.45	7 200
Sulpholan	44.0	4.23	10.72	20.17	10 000

*AIBN = azobisisobutyrodinitrile—the initiator.
**The rate adjusted to the concentration in bulk on the assumption of a linear dependence of the rate of oligomerisation on the TFS concentration.

Nor can the high-molecular-weight polymer be obtained in an appreciable yield on polymerisation via ionic and ionic-coordination mechanisms in the presence of BF_3, $SnCl_4$, and Ziegler–Natta catalysts.[24,49,55,59,67]

A high-molecular-weight PTFS can be obtained only by emulsion polymerisation, which was first achieved by Prober in 1953.[3] The method of emulsion polymerisation still remains the only procedure for the synthesis of PTFS with a fairly high molecular weight and a high degree of conversion. Studies in this field can be divided into two groups: the study of the kinetics of the emulsion polymerisation of TFS in order to create a basis for the specific synthesis of PTFS[4,29,62,63] and the synthesis of PTFS with a specified set of properties.[3,24,55,59,60,64]

The first studies in this field already showed that the yield of the polymer and its molecular weight are affected to an appreciable extent by the nature of the emulsifying agent and its concentration

(the ratio of the phases comprising the aqueous solution of the emulsifying agent and the monomer) and also by the initiating system.[3,24,55,59] More detailed studies showed that a change (increase) in the rate of polymerisation and especially in the molecular weight on passing from the polymerisation of TFS in bulk to its polymerisation in emulsion has no analogues among other vinyl monomers. Thus for TFS the rate increases under these conditions by approximately a factor of 30 and the molecular weight increases by three orders of magnitude. Table 5 presents for comparison the corresponding data.[52] The polymerisation rate constant, activation energies, and pre-exponential factors for TFS and its *p*-methyl derivative using different polymerisation procedures were determined from the kinetic data. The data are presented in Table 6.[64] The ratio of the chain propagation and termination rate constants (k_p/k_t) for styrene proved to be greater by a factor of 4 than for TFS, while the chain propagation rate constant for styrene is greater by a factor of 400 than the value for TFS.

Table 5. Polymerisation of TFS under different conditions (0.5% BP relative to weight of monomer, 50 °C).[52]

Polymerisation conditions	Conversion, %	$10^3 V$, min^{-1}	M_n (ebullioscopic)
In bulk	12.0	2.1	1236
In bulk + 3.0 wt.% E-30	10.9	2.1	1200
TFS + water (phase ratio 1:7)	12.0	2.2	930
TFS in emulsion (phase ratio 1:7, 3.0 wt.% E-30)	24.0	63.0	$9 \cdot 10^{6}$*

*The molecular weight was determined by the light scattering method.

Table 6. Kinetic characteristics of the polymerisation of fluorostyrenes and their comparison with data for styrene.[64]

Polymerisation conditions, monomer	k_{60}, s^{-1}	E, kJ mol^{-1}	A, litre $mol^{1/2}$ $s^{1/2}$
TFS (in emulsion)	$4 \cdot 10^{-6}$	82.4	$3.5 \cdot 10^{7}$
p-Methyl-αββ-trifluorostyrene (in solution)	$0.9 \cdot 10^{-6}$	85.8	$2.6 \cdot 10^{7}$
p-Methyl-αββ-trifluorostyrene (in emulsion)	$2.6 \cdot 10^{-6}$	100.4	$1.3 \cdot 10^{9}$
Styrene (in solution)	$3.2 \cdot 10^{-6}$	88.7	$3.7 \cdot 10^{9}$
Styrene (in emulsion)	$16.0 \cdot 10^{-4}$	94.5	$6.0 \cdot 10^{11}$

However, one should note that the complete removal of HF from the reaction mixture makes it possible to obtain in bulk a polymer with a molecular weight of 30000 – 50000 at a system pH of 7.[29]

One of the distinctive features of the emulsion polymerisation of TFS is the marked dependence of the rate of the process and of the molecular weight of the polymer on the topochemistry of the initiation process. It has been established that only water-soluble initiators (of the type of persulphates) or oxidation-reduction systems whose components are soluble in different phases are capable of ensuring the maximum rates of reaction and the maximum molecular weights of the polymers obtained.[29,52,60,62,65]

Detailed study of the emulsion polymerisation of TFS made it possible to develop effective methods for the synthesis of this polymer in a form suitable for practical purposes.[29,52,62,65] It is noteworthy that TFS polymerises only when hydrocarbon emulsifying agents are used and that the best results are obtained in the presence of anionic emulsifying agents of the type of E-30 (sodium salt of $C_{15}-C_{16}$ alkanesulphonates) and their mixtures with non-ionic emulsifying agents of the type of hydroxyethylated alcohols.[29,52,60,62,65] The attempts to use for emulsion polymerisation of TFS fluorinated emulsifying agents—the salts of fluorocarboxylic acids which are widely employed in the polymerisation of many fluorine-containing monomers, did not yield positive results in the given instance.[66]

The emulsion system also affords fully cross-linked polymers when TFS is polymerised in the presence of polymeric peroxides.[63]

The attempt to obtain a high-molecular-weight PTFS in a high yield not in an emulsion system but by carrying out the process at a high pressure (up to 2000 MPa),[67] which likewise failed to give satisfactory results, should also be noted.

2. Physicochemical properties of PTFS and its structure

The PTFS obtained by emulsion polymerisation is a white powder (d_4^{20} = 1.4903 g cm^{-3}) readily soluble in organic solvents—benzene, diethyl ether, acetone, ethyl methyl ketone, tetrahydrofuran, ethylene chloride, etc.—and also in aprotic solvents. Transparent films can be obtained from solutions, their strength amounting to 100 MPa but their relative elongation does not then exceed several per cent. The brittleness of the films greatly limits the application of this polymer, although its high thermal and chemical stability combined with its ability to undergo modification by the introduction of various groups into the phenyl units makes this polymer extremely promising for the preparation of functional polymeric materials. PTFS is an amorphous polymer, but the X-ray diffraction pattern of an extended specimen reveals a weak tendency towards texture formation. The reflections corresponding to 2.35 and 4.66 Å are concentrated along the meridian. Such a picture for an extended specimen indicates a definite degree of orientation but does not confirm the presence of a crystalline phase. The orientation of the extended specimens is also demonstrated by the high degree of double refraction in crossed polarisers.[24]

It has been suggested that the PTFS molecules have the form of a distorted C–C–C zig-zag. The attempt to construct a model on the basis of this hypothesis demonstrated that, as a consequence of steric hindrance, isotactic disposition of the benzene rings is impossible. The molecule can exist only in the syndiotactic version.[29] The NMR study of the structure of the *p*-methyl-αββ-trifluorostyrene homopolymer showed, however, the presence of non-equivalent CF groups of three types, which it has been suggested refer to the isotactic, syndiotactic, and heterotactic sections of the polymer chain.[68]

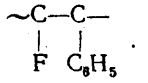
It has also been established that vitreous PTFS has different mechanical properties depending on the formation conditions of the specimens (from the melt or from solution), similarly to what has been observed for crystalline polymers.[69] It has been noted that certain important properties of the polymers (for example, their brittleness) depend on the supermolecular structure formation which

develops very slowly. This plays an especially notable role for the sulphonated PTFS, in which the formation of structural elements leads to an appreciable improvement of the strength characteristics but develops extremely slowly. The introduction of small amounts (up to 4%) of certain low-molecular-weight additives (for example, dibutyl phthalate) greatly accelerates the structure formation and leads to the strengthening of the polymer.[69] A change in the structure occurs also at low temperatures (in the range 4.2–300 K and for 1–2 Hz).[70]

Light scattering and viscometric studies of PTFS solutions showed that this polymer has chains with an enhanced rigidity and occupies an intermediate position between flexible chain and rigid chain polymers.[71] The increased skeletal rigidity of the PTFS chains is probably induced by the appreciable retardation of the internal rotation caused both by the increasing steric hindrance to their rotation owing to the large van der Waals radius of fluorine and by the dipole–dipole interaction of the polar C–F bonds. It is noteworthy that the comparatively high rigidity of the PTFS molecules (greater by a factor of four than that of styrene) is not caused by a secondary structure but is due to the true skeletal rigidity of its single-stranded chain.[29]

PTFS is an infusible polymer and cannot be worked in the molten state. Certain data on the softening temperature as well as the dielectric characteristics of PTFS films are presented in Table 2. PTFS has low dielectric losses over a wide frequency range[24] and some of its copolymers are polymeric dielectrics with an enhanced thermal stability.[72] However, the thermal stability of PTFS is appreciably lower than that of polytetrafluoroethylene (PTFE),[73] although in terms of its decomposition products (the yield of the pure monomer) PTFS is closest to PTFE. Thus the yield of the pure monomer on thermal degradation of PTFE, PTFS, poly(chlorotrifluoroethylene), poly(trifluoroethylene), poly(vinyl fluoride), and poly(vinylidene fluoride) is respectively M > 95, 75, 28, <1, <1.[74] According to mass-spectrometric data, the content of the monomer in the degradation products is 73.6%, while 26.4% corresponds to heavy fragments with an average molecular weight of 458.

On irradiation of PTFS with ^{60}Co γ-rays at a dose of 10^{22} eV g^{-1}, the radiation-chemical yield $G_{\text{cross-link}}$ does not exceed one, which indicates an appreciable radiation stability of the polymer, similar to that of the usual styrene.[75]



During recent decades, TFS together with other monomers and compounds which are difficult to polymerise has been polymerised in plasma. Films with improved thermal stability and containing oxygen were obtained on its surface.[76,77] The rate of formation of polymer films in a discharge plasma is 54 Å s^{-1} for TFS against 132 Å s^{-1} for styrene.[77]

3. Copolymerisation of αββ-trifluorostyrene

As already mentioned, the introduction of fluorine atoms into the vinyl group of styrene leads to specific features in the polymerisation of TFS. The copolymerisation reaction of this monomer is of interest from the standpoint of the effect of the fluorine atoms on the reactivity of TFS. It too constitutes a method of synthesis of new polymeric materials based on it and is a procedure for the modification of PTFS.

Data on the radical copolymerisation of fluorostyrenes confirm that the effect of fluorine atoms on the conjugation energy in these compounds is low. Systematic studies on the effect of the location of fluorine atoms on the reactivity of these monomers have made it possible to arrange fluorostyrenes in terms of their increasing reactivity in the following sequence:[57] ββ-difluorostyrene < β-fluorostyrene < αβ-difluorostyrene < TFS < pentafluorostyrene < 2,4-difluorostyrene < *p*-fluorostyrene.

The decrease in the reactivity of β-substituted fluoro-monomers can be attributed only to the polar effect of the substituents, since the effect of fluorine on the conjugation energy in the monomer is very insignificant and may be neglected. Being an electron acceptor, the fluorine in the β-position diminishes the electron density on the double bond and the monomer plays the role of an electron-donating partner in copolymerisation reactions. However, the decrease in the reactivity of the monomer is not compensated, as for the α-substituted monomers, by the increase in the reactivity of the radical, because the substituent in the radical formed is separated from the radical centre by the aliphatic C–C chain:[57]

As a result of all these factors, the constant for the copolymerisation of β-substituted styrenes [M_2] is low or even zero.

Table 7 illustrates the effect of the β-substitution of fluorine atoms on the parameters of the copolymerisation of styrene with fluorostyrenes. Thus, in the copolymerisation of styrene with *p*-fluorostyrene, the copolymerisation constants are very similar for both monomers, which is evidently caused by the weak inductive effect of the fluorine in the aromatic ring on the double bond. In the case of the styrene–2,4-difluorostyrene pair, there is some enrichment of the copolymer in styrene. The conjugation in the molecule of 2,4-difluorostyrene partly compensates for the polar effect of the fluorine atoms and the constants therefore differ insignificantly. Pentafluorostyrene enters into the polymer chain much less effectively. This is apparently caused by the steric hindrance due to the presence of the cumbersome perfluorovinyl groups and/or the effect of the polar factor.

Table 7. Copolymerisation of styrene with fluorinated styrenes.[57]

Monomer	r_1	r_2	Q	e
p-Fluorostyrene	0.7	0.9	0.83	−0.12
2,4-Difluorostyrene	1.05	0.75	0.65	−0.32
Pentafluorostyrene	1.53	0.62	0.22	0.52
β-Fluorostyrene	5.96	0.01	0	—
ββ-Difluorostyrene	10.4	0	0	—
αβ-Difluorostyrene	2.44	0.04	0.1	0.94
TFS	3.5	0.15	0.15	—

Remarks. r_1 and r_2 are copolymerisation constants, Q is a quantity characterising the reactivity of the monomer, and e is the polar factor.

In the case of β-fluorostyrene, the reactivity of the monomer diminishes very greatly. This is a result of the polar effect of the fluorine atom and not of steric hindrance. In the copolymerisation of ββ-difluorostyrene, the polar effect is manifested even more sharply and the homopolymerisation of styrene actually takes place.

The introduction of a fluorine atom into the α-position in β-fluorostyrene activates the monomer. Thus αβ-difluorostyrene and TFS are more reactive in copolymerisation than ββ-difluorostyrene or β-fluorostyrene.[55]

Table 7 presents quantities characterising the copolymerisation of styrene with these fluorine-containing compounds.[57] Attempts to obtain copolymers of TFS with other monomers containing, and not containing, fluorine atoms have been made since the 1950s. The aims of these studies were various. The task in most of them was the synthesis of new chain materials with improved thermal and chemical stabilities, modification (improvement of physicomechanical properties of PTFS), and the introduction of functional groups into the copolymers in order to obtain mainly ion-exchange materials. Quite a few studies have also been devoted to theoretical aspects of problems of the reactivity of the monomers, as already pointed out.

The copolymerisation reactions of TFS with styrene, its derivatives, and methyl methacrylate under various conditions have been studied in greatest detail.[24,29,55,56–72,78–85] The properties of the copolymers and their molecular weights were varied within wide limits, which determined to a large extent the properties of the materials obtained. Table 8 presents certain data for such copolymers.[78]

Table 8. Copolymerisation of αββ-trifluorostyrene and its derivatives.[78]

Copolymer	Copolymerisation time, h	Yield of copolymer, %	Composition of copolymer, mol%		[η]* (in benzene)
			M_1	M_2	
TFS [M_1]–styrene [M_2]	8	74	28.53	71.47	2.7
	7	70	39.77	60.23	2.8
	8	60	48.53	51.47	1.8
	8	40	53.75	46.24	0.9

	4	50	60.77	39.23	0.6
TFS [M_1]–methyl methacrylate [M_2]	6	—	43.29	56.71	0.4
	11	41	53.88	46.22	0.2
m-Methyl-αββ-TFS [M_1]–styrene [M_2]	2.5	40	46.27	53.73	0.5
o-Methyl-αββ-TFS [M_1]–styrene [M_2]	33	11	50.41	49.59	0.5
p-Methyl-αββ-TFS [M_1]–styrene [M_2]	7	55	46.97	53.03	2.0
	7	64	36.77	63.23	1.4

*[η] is the intrinsic viscosity measured in benzene.

Comparison of the thermal stabilities of different copolymers of TFS with styrene and its derivatives showed that the highest thermal stability (190 °C) is exhibited by TFS–2,5-dimethylstyrene copolymers.[72,79] Certain other characteristics of copolymers based on TFS have also been determined.[79,86]

Attempts have likewise been made to obtain ternary TFS–styrene–diene copolymers.[82,84,85,87,88]

Among other monomers which copolymerise with TFS and its derivatives, the greatest interest attaches to monomers based on acrylic and methacrylic acids and their derivatives.[78,88–94]

The copolymerisation of TFS with divinylbenzene, leading to the formation of cross-linked insoluble polymers, has been carried out mainly in order to obtain on subsequent sulphonation ion-exchange materials with improved thermal and chemical stabilities.[88,95–99] This is described in greater detail below.

The attempt to obtain a peroxide oligomer by the copolymerisation of TFS with a redox initiating system containing diene or vinyl units is also noteworthy. Such oligomers are used to vulcanise rubbers in order to obtain chemically stable vulcanised materials.[100]

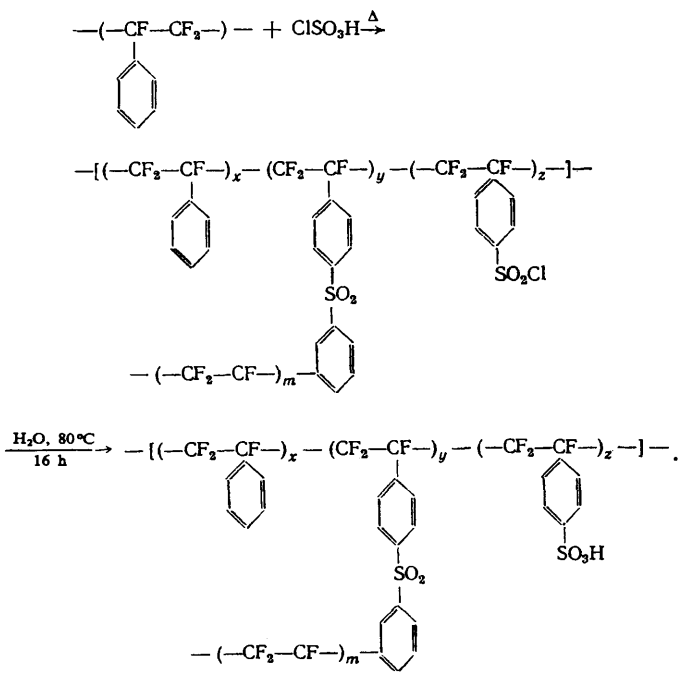
Among all the possible TFS copolymers, its copolymer with tetrafluoroethylene would be of greatest interest. Such a copolymer would possess unique properties—high chemical and thermal stabilities since it would have a fully fluorinated main chain, effective physicomechanical properties as a result of the introduction of flexible TFE units, and the ability to dissolve owing to the presence of phenyl groups. However, it is extremely difficult to achieve such copolymerisation for a number of reasons, although in principle, it should be possible. Hitherto, there have been only isolated mentions of the synthesis of such copolymers.[101,102] The copolymer is obtained, for example, by emulsion polymerisation with radical initiation in the presence of dodecylamine hydrochloride or sodium lauryl sulphate in an autoclave. Table 9 presents the characteristics of this copolymer obtained by the emulsion method.[102]

As can be seen from the results in Table 9, the rate of copolymerisation of TFS with TFE and the yield of the copolymers are extremely low. Depending on the composition of the initial mixtures and the excess of TFE, their content of TFE:TFS units can vary from 2:95 mol% to 95:5 mol%. The copolymers obtained have low molecular weights, are soluble, and form fairly satisfactory films.

IV. Ion-exchange materials based on polytrifluorostyrene. Their synthesis and properties

The presence in each monomer unit of PTFS of a benzene ring makes possible the introduction into the latter of different functional groups with retention of the main perfluorinated chain. The introduction of ionogenic groups (sulphonic and carboxylic acid groups, phosphorus-containing groups, amino-groups, and certain others), which lead to the formation of valuable ion-exchange materials with improved resistance to corrosive influences, is most promising in this respect. The commonest method for the introduction of such groups is sulphonation of PTFS, which affords ion-exchange materials with good electrochemical characteristics.

1. Homogeneous cation-exchange membranes



Numerous studies have been devoted to the sulphonation of PTFS in order to obtain cation-exchange materials with improved resistance to the action of corrosive media.[59,103–112] The sulphonation is usually carried out with chlorosulphonic acid or SO_3 in a dry halogen-containing solvent (usually chloroform) in the presence of an excess of the sulphonating agent. This results in the

Table 9. Copolymerisation of αββ-trifluorostyrene with tetrafluoroethylene.[102]

Remarks. The copolymers obtained are soluble in acetone, from solutions in which transparent flexible films can be cast.

formation of a polymer with different degrees of sulphonation and having both linear and cross-linked structures.

Depending on the sulphonation conditions and the presence of an excess of the sulphonating agent, the ratio of the linear and cross-linked sulphonated PTFS can be various.

There also exists a method for the synthesis of PTFS which is fully linear with a controllable number of sulpho-groups and which is in addition soluble in different solvents. The method reduces to sulphonation in solution with constant removal of the solvent whilst maintaining a constant concentration of the sulphonating agent.[113] In this way, it is possible to obtain sulphonated PTFS ranging from a water-soluble polymer [in the presence of a high content of sulphur-groups (>30 mol%)] to a polymer soluble in different hydrocarbon solvents (when the content of sulphur-groups is <10 mol%) and which can be worked in such solvents. The films obtained from the sulphonated PTFS can be used as ion-exchange membranes with high exchange capacity (>1 mequiv./g of polymer) and a low specific resistance. However, such films have low strength characteristics and are very brittle in the dry state.

Table 10 presents the sulphonation conditions (concentration of the sulphonating agent, its excess, and reaction time and temperature) and the characteristics of homogeneous ion-exchange membranes based on sulphonated PTFS for a large number of specimens sulphonated to different extents.[103] It follows from the analysis of the data presented that a low concentration of the sulphonating agent (<0.1 M) and a ratio of the sulphonating agent and the phenyl groups below the stoichiometric value ensure the formation of a non-cross-linked sulphonated PTFS with a fairly high degree of sulphonation (up to the presence of a sulpho-group in each benzene ring) and an exchange capacity >1. With increase in the concentration of the sulphonating agent to a value close to 1 M and above and when its excess relative to the phenyl groups is by a factor of several units, the sulphonation process affords a cross-linked product insoluble in all solvents and characterised by an approximately uniform exchange capacity (Table 10). This shows that it is undesirable to increase the excess of the sulphonating agent, although this permits a reduction of the process temperature. It

Table 10. Preparation and properties of sulphonated polytrifluorostyrene and homogeneous ion-exchange membranes based on it (PTFS with a molecular weight of 125000 was used).[103]

follows from the data presented that all the parameters affect to some extent the characteristics of the sulphonated PTFS and hence the method of synthesis of ion-exchange materials from it.

2. Heterogeneous cation-exchange membranes

Heterogeneous membranes with good electrochemical parameters and better, compared with homogeneous membranes, physicochemical characteristics are also obtained from sulphonated PTFS. Such membranes are prepared either by mixing solutions of the corresponding polymers or by blending solid powdered polymers

with subsequent manufacture of the membranes from them.[103] These membranes are characterised by lower exchange capacities compared with the homogeneous membranes as a consequence of their appreciable content of an inert polymer but are more promising both in view of their improved physicomechanical properties and by virtue of the possibility of using different inert polymers depending on the operating conditions. Blends of polymers can also be used as neutral components of membranes of this kind; in such cases the heterogeneous membranes are obtained by blending three and more polymers.[104] The ionogenic component in the heterogeneous membranes is cross-linked sulphonated PTFS having the following structure:

$x = 2.3$.

Table 11 presents examples of different compositions of heterogeneous membranes and some of their electrochemical characteristics.[103]

Table 12. Surface modification of heterogeneous ion-exchange membranes based on sulphonated PTFS.[110]

Solutions of reactants (parts by weight)	Reaction conditions		ρ, Ω cm²	Transport number	Current yield, %	Concentration of NaCl in 5 M NaOH, M

Without treatment	—	—	6.0	0.84	77	0.03

Like the best ion-exchange membranes available at present, which are based on a material of the Nafion type, the homogeneous and heterogeneous ion-exchange membranes obtained from sulphonated PTFS are designed for use under severe conditions (mainly in chlorine electrolysis in electrolytic cells). In terms of their electrochemical properties, these membranes are indistinguishable or differ little from the corresponding membranes based on the Nafion type material but are appreciably inferior to them as regards mechanical properties.

In order to improve certain electrochemical parameters, such membranes are subjected to surface modification which can be readily carried out using the Friedel–Crafts reaction by introducing various groups into the benzene rings of PTFS. Table 12 presents the changes in the current yield and in the selectivity of the membranes obtained by blending 30 parts by weight of the sulphonated and cross-linked PTFS with 70 parts by weight of a fine poly(vinylidene fluoride) powder (Kynar) using a blending and pressing procedure.[110]

3. Grafted cation-exchange membranes prepared using sulphonated polytrifluorostyrene

Membranes based on sulphonated PTFS, which have good thermal and chemical stabilities, are particularly valuable ion-exchange materials which are resistant to corrosive influences. However, such membranes, especially homogeneous ones, are characterised by inferior physiochemical parameters compared with membranes of the Nafion type. One of the most promising procedures for overcoming these disadvantages proved to be the grafting of TFS onto different films (usually fluorine-containing polymers) with subsequent sulphonation of the resulting graft copolymers or by introducing other ionogenic groups into their benzene rings.[99,101,114–125] The grafting is carried out as a rule by a radiation method.

Films made up of polyethylene, polytetrafluoroethylene, poly(chlorotrifluoroethylene), the ethylene–TFE copolymer, the propene–TFE copolymer, poly(chloroethylene), the hexafluoropropene–vinylidene fluoride copolymer, the heptafluoropropene–TFE copolymer, the copolymer of TFE and perfluorinated vinyl ethers (Nafion), and other materials are used as inert supports. The irradiation dose is 1–30 Mrad. The films are irradiated in air and in oxygen or inert media. This results in the formation of radicals whose lifetime in an inert atmosphere is up to two weeks at 0 °C, up to seven days at 10 °C, and 2–3 days at room temperature.[118,119] In order to obtain graft TFS polymers on different supports, the irradiated films are placed in TFS or its solutions in chloroform, tetrachloroethane, CCl_4, Freon 113, or benzene and are kept there at a temperature of 10–90 °C for 1–50 h. The degree of grafting is 10–50%. The characteristics of such membranes are quite good and are comparable with those of ion exchange membranes based on Nafion. Comparative data for ion-exchange membranes based on the ethylene–TFE copolymer on which TFS has been grafted with subsequent sulphonation and for Nafion 120 membranes[119] are presented below.

Membrane	Exchange capacity, mequiv g^{-1}	ρ, in 0.5 M KCl, Ω cm²	Extensibility	Transport number, 0.5 M KCl/1 M KCl
With grafted TFS	0.61	1.71	3.4—4.5	0.94
Based on Nafion	0.83	1.48	4.0	0.93

Such membranes can be used as diaphragms for any purposes (the electrolysis of water, NaCl, and the Glauber salt, low-temperature dialysis, etc.). The methods employed provide for the irradiation of only the initial films, while TFS is not irradiated. They are economical and readily applied. Table 13 presents the characteristics of certain cation-exchange membranes obtained by grafting TFS onto different 100 μm supports with subsequent sulphonation in the

course of 40 min with chlorosulphonic acid in CCl_4 or tetrachloroethylene at 40 and 135 °C respectively.[119]

Table 13. Cation-exchange membranes obtained from different polymers by the radiation grafting of TFS and subsequent sulphonation.[119]

Support	Degree of grafting, %	Degree of sulphonation, %	Characteristics of membrane			Resistance to action of oxidant (weight loss)
			exchange capacity, mequiv. g^{-1}	ρ, Ω cm^2	transport number, 0.5 M KCl/1 M KCl	
Polyethylene (low density)	23	95	1.5	1.4	0.9	15
Poly(vinylidene fluoride)	20	60	0.6	3.2	0.93	10
TFE–ethylene copolymer	21	90	1.0	—	—	3
TFE–ethylene copolymer	16	80	0.7	3.5	0.93	3
Polytetrafluoroethylene	—	—	—	4.0	0.93	1

*Treatment with 3% H_2O_2 containing 4 p.p.m. of Mohr's salt at 70 °C for 24 h.

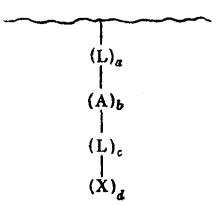
There is also a radiation method for grafting TFS onto inert films by irradiating the latter in a solution of the monomer. In this case, the degree of grafting for identical doses is regulated by the TF concentration in solution in different solvents and depends on the nature of the latter. Table 14 present data for the grafting of TFS onto the TFE–hexafluoropropene (HFP) copolymer in different solvents.[115] TFS was grafted onto a film which was placed in the form of a roll into the corresponding TFS solution, the chamber was evacuated or filled with an inert gas, and the temperature was kept at a level such that the solvent did not evaporate.

Table 14. Degree of radiation grafting of TFS at a dose of 2.59 Mrad.[115]

TFS concentration, %	Benzene, %	Degree of grafting, %	TFS concentration, %	Methylene chloride, %	Degree of grafting, %
10	90	1.4	10	90	2.5
30	70	8.2	30	70	9.7
50	50	14.3	50	50	17.6
70	30	24.0	70	30	27.1

4. Anion-exchange and other membranes prepared using grafted αββ-trifluorostyrene

Films with grafted TFS can be used after the appropriate treatment not only as cation-exchange membranes with sulphonic and carboxylic acid or phosphorus-containing groups but also as anion-exchange membranes after appropriate amination or as neutral membranes.[119]



Anion-exchange membranes obtained by the radiation grafting of TFS onto different supports with subsequent chloromethylation and the preparation of quaternised aminated derivatives are of great interest. The reagents used for this purpose are CH_3OCH_2Cl, paraformaldehyde $(CH_2O)_3$, and HCl with which the grafted films are treated in the presence of $AlCl_3$ or $ZnCl_2$ as catalysts at 40 to 80 °C. The films are then treated with 5–50% aqueous solution of trimethylamine, triethylamine, or 2-hydroxyethyl(dimethyl)amine. Such anion-exchange membranes have good electrochemical parameters and an improved resistance to hydrolysis. The relevant data are presented in Table 15.[119]

Table 15. Anion-exchange membranes prepared from different polymers with radiation grafted TFS and subsequent chloromethylation and amination.[119]

Support	Degree of grafting, %	Degree of chloromethylation, %	Characteristics of membranes			Resistance to hydrolysis*
			exchange capacity, mequiv.g^{-1}	ρ, Ω cm^2	transport number, 0.5 M KCl/1 M KCl	
Polyethylene (low density)	23	80	0.86	4.2	0.92	without changes
Poly(vinylidene fluoride)	20	78	0.75	5.0	0.93	ditto
TFE–ethylene copolymer	18	80	0.70	4.8	0.94	»
Polytetrafluoroethylene	18	80	0.71	6.0	0.93	»

*Hydrolysis in distilled water at 95 °C for six days.

An interesting method of synthesising ion-exchange materials involves radiation cografting of a mixture of vinyl monomers and dicarboxylic acids onto a perfluorinated base. TFS can also be used as the vinyl monomer. Such ion-exchange materials can be represented schematically as the main perfluorinated chain with grafted side groups of the type[126]

where $a \geqslant 1$, $b \geqslant 0$, $c = 0.1$ or above, and $d \geqslant 1$, L represents the vinyl monomer residue, A represents active groups (dicarboxylic acids or their derivatives), and X is the polymer chain, capable of being terminated, or a fluorinated hydrocarbon polymer.

Insoluble cation-exchange resins with different exchange capacities have been obtained by copolymerising TFS with divinylbenzene and then sulphonated.[95,97,103,109]

V. Other aspects of the applications of polytrifluorostyrene

Together with the well known applications of PTFS as ion-exchange materials resistant to the action of corrosive media, this polymer is used for a number of other purposes. The use of PTFS for the preparation of an ultrafine fibrous filtering material FSPF (fluorostyrene Petryanov filter) proved to be the most promising application. This material is capable of withstanding repeated sterilisation with hot steam up to a temperature of 150 °C without change in filtration efficiency (99.99% with respect to an oil mist) and in physicomechanical parameters. The FSPF material is designed for use in bacterial filters sterilised by hot steam whose purpose is to free air from microorganisms in the microbiological, medical, and food industries and in health service establishments.[127–129]

Sulphonated PTFS can be employed as a catalyst in the synthesis of esters from neoalkylpolyols and aliphatic acids, its use greatly improving the properties of the products synthesised and simplifying their isolation from the reaction masses.[130] PTFS sulphonated to different extents can be used also in highly sensitive elements for a gravimetric hygrometer[131] and as a complex-forming material with a high selectivity in the separation of certain mixtures.[132]

The PTFS base material FC-430 is introduced in small amounts into compositions for the protection of films against electrochemical corrosion.[133]

PTFS-based materials with effective adhesion and antistatic properties are also employed to coat the grains of a photographic material.[134]

It has recently been reported that polymeric optical fibres, with excellent optical properties and a high capacity for the transmission of light have been prepared using PTFS.[135] PTFS is employed as their core. The losses in light transmission in such fibres are 130 dB km^{-1} (at 660 nm), 280 dB km^{-1} (at 780 nm), and 440 dB km^{-1} (at 850 nm).

PTFS has found recently an extremely interesting new application in the formation of negative electronic resistors with a high sensitivity, high chemical and thermal stabilities and a satisfactory resistance to dry etching.[136] In order to obtain such coatings, a solution of PTFS in chlorobenzene is deposited onto a silicon plate. On irradiation with a stream of fast electrons and subsequent treatment, coatings having a surface relief with a high resolving capacity, good adhesion, and a high resistance to dry etching are obtained.

X-Ray diffraction studies on electron density in organic crystals

P M Zorkii, A E Masunov
Lomonosov Moscow State University

ABSTRACT. The review presents the advances in precision X-ray diffraction studies on electron density in organic crystals carried out during the last several years. The methods for the elimination of and allowance for experimental errors, procedures used to interpret the results, and the characteristic features of the distributions of the deformation electron density in organic molecules are discussed.

The bibliography includes 126 references.

IV. Trends in the distributions of deformation electron density 599

I. Introduction

The spatial distribution of electron density $\rho(\mathbf{r})$ in a crystal was initially the principal result of X-ray diffraction analysis (XRDA). However, it was not until the middle of the 1960's that an increase in the experimental accuracy (automatic diffractometers), the correct allowance for systematic errors, the improvement of models (anisotropic thermal parameters), and the creation of special sets of programs made it possible to formulate the problem of the real physical significance of the asymmetry of the ρ maxima.

The first X-ray diffraction studies on organic crystals, whose authors claimed to have achieved an objective description of the details of the electron density distribution $\rho(\mathbf{r})$, were published in 1966–1967.[1–5] This was associated with the use in Fourier synthesis of thermal parameters obtained from neutron diffraction data or data on the large angle scattering of X-rays. Thus the effects of the non-sphericity of the distribution of valence electrons were successfully separated from the effects of thermal motion. The redistribution of electron density on formation of chemical bonds was represented by the deformation electron density $\delta\rho(\mathbf{r})$:

$$\delta\rho(\mathbf{r}) = \rho(\mathbf{r}) - \rho_0(\mathbf{r}) = \sum_{\mathbf{q}} (F(\mathbf{q}) - \tilde{F}(\mathbf{q})) \exp(i\mathbf{rq}), \quad (1)$$

where ρ_0 is the electron density of the "precrystal" made up of spherically symmetrical non-interacting atoms, which are distributed and vibrate as in the crystal, $\mathbf{q}$ the radius-vector of the inverse lattice site, $\tilde{F}(\mathbf{q})$ the structural amplitudes of the "precrystal", and $F(\mathbf{q})$ the structural amplitudes of the crystal with the initial phases taken from $\tilde{F}(\mathbf{q})$.

Nevertheless, the procedures available to the investigators in the 1960's at best yielded a first aproximation to the solution of this fundamental problem. In subsequent years the improvement of various aspects of the method of determination of the functions ρ and δρ made it possible to achieve reproducible (similar in analogous cases) results: δρ maxima of reasonable size were usually observed in the internuclear space of chemically bound atoms and it was usually possible to detect also peaks corresponding to lone electron pairs (LEP) and to discover the characteristic features of the distribution of δρ in the regions of hydrogen bonds.

The outcome of the studies of the charge distributions in organic crystals during the period from 1966 to 1984 was summarised in a review.[6] In recent years, new steps of fundamental importance were taken in this research field. Here we have in mind (1) the improvement of the method of determination of experimental data, (2) progress in the interpretation of the distributions of ρ obtained, and (3) the accumulation of information about the distributions of δρ for a wide variety of chemical compounds, which makes it possible to discuss successfully detailed features of chemical bonds. The aim of the present review is a consistent discussion of these three aspects of the latest studies on precision XRDA of organic crystals. The main outcome of the research under consideration apparently consists in the fact that, whereas previously mainly qualitative aspects of the subject were investigated, it has now become possible to guarantee the quantitative reliability of the details of charge distributions discussed.

II. Determination of the experimental distributions of ρ and δρ

The characteristic features of the precision X-ray diffraction experiment, the principles governing the construction of the distributions of ρ and δρ, and also the errors of these distributions have been examined in a review.[7] Certain methods reducing the errors in the determination of experimental data and in their subsequent treatment and the latest examples of their application, demonstrating the great sensitivity of δρ maps to such correction, are presented below. The wide-scale use of the function δρ is due to two causes. Firstly, the difference between two convergent series (1) converges faster than either individual series and the termination of the series therefore affects δρ less than ρ. Secondly, the distribution of ρ requires some kind of procedure for primary interpretation[8] while the distribution of δρ is a result of one of the versions of such interpretation.

In order to obtain ρ, it is necessary in the first place to convert correctly the experimental intensities into the moduli of structural amplitudes, which involve the introduction of a series of corrections for systematic experimental errors.[7] These are for example, the

allowance for the anomalous and thermal diffuse scattering, extinction, and absorption.

Allowance for anomalous scattering is essential in the presence of heavy element atoms and is not usually carried out in their absence. Thus in the case of sulphur (thiourea) it causes little change in $\delta\rho$.[9] Allowance for thermal diffuse scattering is extremely important.[10] Without it, the thermal parameters of atoms proved to be too low (for example, by 12% in oxalic acid), but this is not reflected in the qualitative features of the distributions of $\delta\rho$ in the region of chemical bonds and lone pairs.[11]

The greatest difficulty arises in allowing for the extinction contribution. Although at the present time methods are available for such allowance, the introduction of the appropriate corrections for single crystals of different size and shape leads to appreciable differences in the heights and positions of the $\delta\rho$ maxima.[12] The intensity and small wavelength of synchrotron radiation make it possible to investigate single crystals whose diameter is less than 0.1 mm. The small size of the crystals diminishes the influence of extinction and absorption.[13] These and other advantages of synchrotron radiation (the possibility of reducing anomalous scattering by modifying the wavelength, the increased accuracy of the analysis of the peak profile by virtue of the small divergence of the beam) make its use in precision X-ray diffraction analysis extremely promising.

Appreciable changes in $\delta\rho$ maps (especially near the nuclei) occur even after small changes in the scaling factor and it is therefore refined separately with respect to the entire set of structural amplitudes, with the remaining variable parameters fixed. Recently an alternative procedure has also been used—the determination of the scaling factor from hard γ-ray diffraction data[14] or from neutron diffraction data.[15]

As already stated, the distribution of $\delta\rho$ is less subject to the influence of the termination of the series than the distribution of ρ, but in the case of $\delta\rho$ it is more difficult to apply the corresponding correction. There is a prospect that in the solution of this problem (both for ρ and $\delta\rho$) it will be possible to abandon the traditional Fourier method, having replaced it by the entropy maximisation method. The latter makes it possible also to reduce the role of random errors, which increases the resolution of the electron density maps.[16,17] The essential feature of the method of Kuz'min et al.[18] consists in the fact that the coefficients of the series, corresponding to weak reflections and assumed to be zero in the usual XRDA scheme, are found from the conditions

$$S = -\int \frac{\rho(\mathbf{r})}{F(000)} \ln \frac{\rho(\mathbf{r})}{F(000)} d\mathbf{V} \to \max.$$

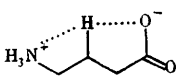
Here the function $\rho(\mathbf{r})$ is regarded as the distribution of the probability density, the best distributions being selected from all the distributions agreeing with the available information. The application of this procedure requires, however, a large amount of computer time.[16]

Hitherto we have spoken of the improvement of the determination of the moduli of structural amplitudes. Another possibility of refining the distributions of ρ obtained from a diffraction experiment consists in improving the calculation of the initial phases. In the standard XRDA, they are calculated in the anisotropic harmonic approximation of spherically scattering atoms. In order to obtain accurate distributions of ρ, use is made of better models: the *L*-shell method (the cleaved atom method), the κ-method, the two-centre models of charge clouds on bonds and lone pairs (Stewart, Hellner), and different versions of the multipolar models (Coppens, Hirshfeld, Stewart, Tsirel'son). All these methods, which are mentioned in order of increasing complexity, have been described in a review.[7] The importance of allowing for the anharmonicity of thermal vibrations has been confirmed[19] in relation to γ-aminobutanoic acid. The methods listed have been compared in two communications.[20,21]

The most complex (and because of this the most flexible) of the models enumerated contain a large number of parameters, which sometimes reaches the number of the accessible independent structural amplitudes. The problem of eliminating the correlations between these parameters has therefore arisen. Here the use of neutron diffraction and spectroscopic data as well as the superposition of additional physical conditions, in particular the determination of the relation between the distribution of ρ and the one-determinant wave function of the crystal, are helpful. One of the new examples of this approach has been provided by Frichberg.[22]

A relatively new step has been the use of experimentally measured initial phases. The anomalous scattering effect can be used for this purpose. In recent years, such studies have been carried out. In the presence of heavy atoms, anomalous scattering can be optimised by adjusting the wavelength of the synchrotron radiation.[23] It has also been suggested[24] that the initial phases be determined from intensity measurements at two wavelengths close to the characteristic wavelength, the wavelength of the X-ray generated by the electron beam directly in the crystal investigated being determined by the angle of incidence of the electrons relative to the modal plane. This method is applicable also to substances without heavy atoms, for example, to oxygen-containing organic compounds.

The method based on analysis of three-wave diffraction profiles under the conditions of the Renninger effect (interference occurring when two series of planes assume simultaneously the reflecting position) has been applied in practice.[12,25,26] This method makes it possible to determine experimentally the initial phases of certain reflections. A precision study of the Si crystal (involving measurement of the intensities and determination of the initial phases of the "forbidden" reflections) made it possible to increase by an order of magnitude the accuracy of the determination of $\delta\rho$ [mean square error $\sigma(\delta\rho) \simeq 0.005$ e Å^{-3}] [25] and to discover on the pseudostatistical $\delta\rho$ distribution map a fine effect involving the splitting of the peak on the Si—Si bond into two components.[26]



The experimental determination of the initial phases on the basis of three-wave diffraction apparently represents the most promising aspect of studies of this kind. However, despite the clear advantages of the direct experimental methods for the determination of the initial phases listed above, they still remain too complex to hope for their rapid and extensive application on a large scale.

III. Primary interpretation of electron density distributions

The distribution of the total electron density contains in principle exhaustive information about the nature of intramolecular and intermolecular interactions[10] (and also about all the one-electron properties of the system[7]), but its direct interpretation is difficult.[8] To facilitate the use of such information, additional procedures and concepts are introduced. They will be examined in the present Section (in relation to examples taken from studies in recent years).

The simplest numerical characteristics of continuous distributions of ρ are the effective point moments, in particular the atomic and bond charges. They can be obtained not only at the refinement

stage (in the model of multipolar pseudoatoms or charge clouds) but also subsequently from the $\delta\rho$ distribution constructed. For example, it has been proposed[27] that $\delta\rho$ peaks be fitted by ellipsoids of rotation and that the bond charge be calculated by integration with respect to the entire volume of the ellipsoid. Different procedures for the separation of $\delta\rho$ into contributions corresponding to individual atoms have been compared in another communication.[28] Atomic charges are useful in the calculation of the properties of the crystal (for example, in the calculation of the electrostatic field gradients at nuclei[7] or of the Coulombic components of the intermolecular interaction[6]) and in the analysis of the "electronic structure" of molecules. Thus the employment of pseudoatomic charges, determined from diffraction data, made it possible to detect the inductive effect in molecules of barbital[29] and tetrafluoroterephthalodinitrile[30] and an unusual methylene hydrogen bond in γ-aminobutanoic acid:[9]

In order to weaken the dependence of the effective atomic charge on the method used to subdivide the continuous distribution, it has recently been suggested[31] that the charge of a "local region", defined as the sum of the effective charges on a given atom and on the neighbouring atoms linked directly to it, be brought into correspondence with each atom. This approach yields more "reasonable" values. For example, the carbon atoms of an aromatic nucleus in the naloxone ion $C_{19}H_{22}NO_4^+$ have been found to carry a larger negative charge than the aliphatic carbon atoms, the nearest N and O atoms carrying the greatest negative charge.

Pseudoatomic moments can also be used to bring the parametric description of ρ closer to orbital ideas.[32] The calculation of the electron populations of the *d*-orbitals of Fe^{2+} in the porphyrin complex with the aid of a multipolar model yielded values close to those expected for the high-spin $^5F_{2g}$ configuration. The observed deviations indicate the presence of dative bonds with the ligands.[33] A more general approach consists in the application of the valence form-factors, i.e. the atomic scattering factors, taking into account the valence state and not averaged with respect to orientations: this approach also yields *p*-orbital populations.[34]

Another way of interpreting the distribution of ρ in chemical terms involves the density matrix method.[7] In this method the calculation of the elements of the bond charge-order matrix elements involves adjustment to X-ray diffraction data. An unambiguous calculation is achieved by imposing an additional condition involving the minimisation of the energy functional.[35] However, the finite nature of the basis set makes it possible to obtain satisfactory results even without this requirement.[36] An alternative way of finding the wave function from the distribution of ρ^{stat} is described at the end of this Section.

The rigidity of the multipolar pseudoatoms[7] (i.e. the independence of the populations of the thermal parameters) gives rise to the possibility of separating the effects of chemical bonds from the thermal "spreading" of ρ and of constructing the pseudostatic electron density ρ^{stat}. When such construction is entirely adequate, the results should be independent of the experimental temperature. So far it has not been possible to achieve this.[37] A more detailed analysis of the influence of thermal motion on the distribution of ρ has been described.[38–40]

According to certain investigators, the clearest form in which the results of a precision X-ray diffraction analysis can be represented is in terms of the electrostatic potential φ and the deformation electrostatic potential $\delta\varphi$.[41] The application of this method to organic crystals is extremely fruitful in the analysis of the effects of the chemical bond, intermolecular interaction, and reactivity. These questions have been discussed in other reviews,[42,43] where the principal formulae can be found.

We may note the latest studies in this field. A method for the subdivision of the crystal space into molecules with the aid of the electroneutrality principle has been proposed[44] and applied to dicyanodiamide. The $\delta\varphi$ distribution maps for the $C_{13}H_8N_2$ molecule have made it possible[45] to discover the weakest bond in the cyclopropane ring: whereas on other bonds the deformation potential $\rho\varphi$ has a negative minimum, on this bond it is close to zero. This agrees with the chemical properties; even at room temperature, the substance undergoes unimolecular isomerisation with dissociation of the given bond.

The study of phosphorylethanolamine $C_2H_8NO_4P$ [46] showed that the large (in absolute magnitude) negative potential in the region of the ester oxygen atom of the phosphate group is not saturated even on formation of a hydrogen bond by the other oxygen atom of the same group. The layer made up of such molecules serves as a model of a phospholipid membrane and near the surface has regions of positive and negative potential, which enables the molecules of the layer to form hydrogen bonds with both donors and acceptors. Such "amphoteric" behaviour was not predicted in quantum-chemical calculations for an isolated molecule.

The study of the molecular complex of thiourea with parabanic acid $CH_4N_2S.C_3H_2N_2O_3$ [47] revealed saddle points in the φ distribution of approximately equal height in the regions of the N–H...O and N–H...S hydrogen bonds formed by the molecules of this layer. It was concluded on this basis that the energies of the two bonds are similar despite the considerable difference between their lengths (0.27 Å). It has also been shown that the interaction of molecules of different layers does not take place as a result of charge transfer but involves short contacts between the S atoms and the C–C bonds: there is a broad saddle point in the distribution of φ in this region.

The electrostatic potential of the molecule permits a correct inference about its intermolecular interactions only in those cases where interactions involving monopoles predominate in electrostatic forces (for example, on protonation). The "dipolar electrostatic potential",[48] which describes the optimum orientation and energy of a single dipole located at a certain point in the electron distribution (in particular on the van der Waals surface of the molecule) is more suitable for characterising the interaction with a polar uncharged molecule. Such maps show, for example, that the preferred direction along which a nucleophile approaches a formaldehyde molecule does not lie in the plane of this molecule.[48]

The force density method,[49] consisting in the analysis of the distribution of the modulus of the electrostatic force density $f_A(\mathbf{r}) = \rho(\mathbf{r})/(\mathbf{r} - \mathbf{R}_A)^2$, acting on the nucleus A, located at the point $\mathbf{R}_A$, from the side of the electron density at the point $\mathbf{r}$ and diminishing (or intensifying) the destabilising repulsion from other nuclei, is close to the electrostatic potential method. For example, the function $f_N(\mathbf{r})$ for the N_2 molecule has peaks at the centre of the bond (stabilisation) and on the line obtained by producing the bond to the rear at the given atom (destabilisation). In the LiF molecule, similar $f_F(\mathbf{r})$ peaks have been displaced towards the F nucleus, while $f_{Li}(\mathbf{r})$ has a single peak coinciding with the centre of the F atom. Apart

from the differences between covalent and ionic bonds, the force density method makes it possible to investigate the character of the chemical bond in complex polycyclic structures.

However, analysis of the φ and f distributions as well as the use of local (effective) electrostatic characteristics apparently solves only a limited range of specific problems. The most universal and most widely used means for the primary interpretation of the distribution of ρ is provided by the deformation electron density $\delta\rho$ function, which is extremely sensitive to details of the electronic structure of molecules and crystals. The regions of positive values of $\delta\rho$ are those where electron density accumulates compared with the precrystal, consisting of non-bonded atoms. However, the absence of positive $\delta\rho$ maxima on the bond (and even the negative values of $\delta\rho$), which sometimes occur in the case of bonds formed by electronegative atoms (N, O, F, etc.), by no means imply the absence of a bond.

One of the causes of such anomalies consists in the fact that thermal motion "blurs" the $\delta\rho$ map. Thus the dynamic function $\delta\rho$ for crystals of *p*-nitropyridine *N*-oxide $C_5H_4N_2O_2$ [50] has low values in the region of the $\rangle N\rightarrow O$ bonds and the lone pairs of the O atom, whereas considerable peaks appear in these regions on maps which are constructed with the aid of the multipolar resolution and afford a pseudostatic picture. Furthermore, the large angle procedure for the refinement of thermal parameters can lead to the smoothing of the anisotropy of the electron distribution. This effect causes a particularly marked reduction of the height of the LEP peaks, which are located closer to the nucleus than the peaks on the bonds.[51]

However, the type of bond has a decisive influence on the height of the $\delta\rho$ peak. The causes of the redistribution of electron density, arising from the preparation of the atoms of the premolecule for bonding (promotion of electrons, orientation, polarisation, and hybridisation of orbitals) and from the formation of bonds proper (interference of the orbitals and charge transfer) have been listed[52] in terms of hybrid orbitals (HO).

We shall consider initially the effects due to the formation of bonds. For a bond between atoms 1 and 2, the bonding molecular orbital, made up of the singly populated HO ψ_1 and ψ_2, assumes the following form in terms of the LCAO MO approximation:

$$\Psi = (1+2\lambda S+\lambda^2)^{-1/2}(\psi_1+\lambda\psi_2),$$

where S is the overlap integral. The electron density of this orbital is

$$\rho_{MO} = 2\Psi^2 = (1+2\lambda S+\lambda^2)^{-1}(2\psi_1^2+2\lambda^2\psi_2^2+4\lambda\psi_1\psi_2) =$$
$$= (\psi_1^2+\psi_2^2)+(1+2\lambda S+\lambda^2)^{-1}(4\lambda\psi_1\psi_2-2\lambda S(\psi_1^2+\psi_2^2))+$$
$$+(1+2\lambda S+\lambda^2)^{-1}(1-\lambda^2)(\psi_1^2-\psi_2^2) = \rho_0+\Delta\rho_i+\Delta\rho_{ct}.$$

For HO with similar energies, $\lambda \simeq 1$ and $\Delta\rho_{ct} \simeq 0$. The deformation density is then $\Delta\rho_i$ and is approximately proportional to the overlap density $\psi_1\psi_2$ at the maximum. By analogy with the interaction of light waves, this effect is referred to as interference. With increase in bond length, the overlap density and hence $\Delta\rho_i$ diminish. Furthermore, for large bond lengths (especially between transition metal atoms), electron correlation, not taken into account in the MO method, makes an appreciable contribution to the decrease of $\Delta\rho_i$.[51]

If the interacting HO are identical, then the quantity $\Delta\rho_i$ is a maximum at the centre of the bond. On the other hand, if they have similar energies but different extents in space, the greatest overlap density (and hence the $\Delta\rho_i$ maximum) should be attained closer to the centre of the more compact orbital. Even greater changes in elecron density are induced by differences between the orbital energies. The energy of the HO diminishes with increase in its electronegativity and s character. If the energy of ψ_2 is greater than that of ψ_1, then $\lambda < 1$ and the charge transfer effect $\Delta\rho_{ct} \simeq \psi_1^2 - \psi_2^2$ arises. Ultimately the $\Delta\rho$ peak shifts in the direction of the atom 1.

We shall now consider a hypothetical distribution of electron density of the premolecule on transition of the atoms to the valence state (i.e. during the preparation of the atoms for the formation of a bond). According to the concept of hybridisation, when a HO is formed with participation of the atomic s and p orbitals, the populations n_s and n_p change (electrons are promoted from the s sublevel to the p sublevel). In particular, in the case of ideal sp^3-hybridisation of the C atom, $n_s = 2$, $n_p = 2/3$, and $n_s' = n_p' = 1$; for the O atom, $n_s = 2$, $n_p = 3/4$, and $n_s' = n_p' = 6/4$. This leads to some transfer of the electron density of a spherical atom from its centre to its periphery. The subsequent orientation of the HO is determined by the nearest neighbours of the atom in the premolecule and fixes both the position of the singly populated HO involved in the bonds and the doubly populated HO (i.e. lone pairs). After the orientation of the HO, the change in the population of the p orbital directed along the bond line is

$$\Delta n_p = {}^3/_4 + {}^1/_{12}(n_2+n_3+n_4) - n_p,$$

where the numerical coefficients correspond to the contributions of the p orbital to the sp^3-HO with the populations n_i. For the carbon and oxygen atoms, $\Delta n_p = 0.33$ and -0.17, i.e. ρ accumulates between carbon atoms and diminishes between oxygen atoms, while between oxygen and carbon atoms the electron density shifts from oxygen to carbon. Electrons always accumulate in the direction of the LEP.

$$\Delta n_p' = {}^3/_2 + {}^1/_{12}(n_2+n_3+n_4) - n_p.$$

However, the simple scheme described does not take into account certain fairly important effects. For example, under the influence of the environment the atomic orbitals undergo a change in shape (are polarised). In particular, the 1s orbital of the H atom contracts slightly on formation of the bond. Furthermore, the differences between the electronegativities of the substituents or steric stresses can lead to deviation of the hybrid orbitals from the ideal sp^3, sp^2, and sp orbitals. Finally, the populations of the interacting orbitals can differ from unity. Thus, in the $Mn_2(CO)_{10}$ dimer examined below, the population of the d orbitals forming the Mn–Mn bond diminishes under the influence of the ligand field, which is in fact the main reason for the absence of the $\delta\rho$ peak on this bond.[51] However, despite the above stipulations and effects due to the formation of bonds, the height of the $\delta\rho_{max}$ peak usually varies in parallel with the quantity $n_p' - n_p$ according to Angermund et al.;[10] this indicates the predominance of the orientation effect.

In order to isolate the chemical bond effect in a pure form, the sum of the electron densities of the oriented atoms $\rho_0^{(or)}$ was subtracted[52,53] from the total function ρ; the resulting function was called the chemical deformation density $c\delta\rho = \rho - \rho_0^{(or)}$.

When the functions $c\delta\rho$ are used, we in fact abandon a universal reference standard. The next step in this direction is taken when the "fragment-formation" density $f\delta\rho$ is introduced;[54] this is obtained when the electron density of the fragments is subtracted from the total function ρ. The $f\delta\rho$ maps can be used to investigate the redistribution of electrons when the reacting species interact.

In particular, in the study of coordination compounds, it is natural to differentiate the central atom and the ligands as the fragments. This was done in a quantum-chemical study of the distribution of ρ in the $Co_2(CO)_8$ molecule,[54] which showed that the interaction of a CO molecule with a metal atom leads to the outflow of electron density from the C–O axis into the region of the *p* orbitals of oxygen and carbon perpendicular to this line. The function $f\delta\rho$ makes it possible to observe the redistribution of electrons on formation of a covalent bond between radicals or molecules. The peak due to the Mn–Mn bond, which is absent from δρ maps, and also the displacement of the lone electron pairs of the oxygen atoms in the equatorial CO groups in the direction of the "foreign" Mn atom can be seen on the $f\delta\rho[Mn_2(CO)_{10}-2Mn(CO)_5]$ map constructed[54] from the results of non-empirical calculations, while on δρ maps the differences between the electron distributions of the axial and equatorial ligands are inappreciable.

It has been shown[55] with the aid of $f\,\delta\rho$ that, on formation of the $H_3N{\rightarrow}BH_3$ donor–acceptor bond, an appreciable decrease in electron density is observed in the first place in the region of the p_σ orbital of the B atom, extended along this bond, with the simultaneous decrease in electron density on the corresponding orbital of the N atom and on the ammonia H atoms (the σ-donor effect of nitrogen) and in the second place there is a small transfer of electron density from the perpendicular p_π orbital of the B atom to the orbital of the N atom oriented in parallel (the π-acceptor effect).

The above examples of quantum-chemical calculations indicate the possibility of the effective employment of the $f\delta\rho$ function also for the primary interpretation of the experimental distributions of ρ.

With the aid of difference functions, it is possible to discover also the redistribution of electrons under the influence of external forces. Thus the change in electron density in the H_2O molecule under the influence of an external homogeneous electrostatic field is demonstrated by "polarisation" deformation density $p\,\delta\rho$ maps.[56] In order to discover the effects of the ionic environment in the H_2O molecule and in the $HC_2O_4^-$ ion, the distributions of the "double" deformation density $d\delta\rho = \delta\rho' - \delta\rho$ were constructed, the $\delta\rho'$ distributions being obtained by means of a non-empirical calculation modelling the influence of the crystal structure by point charges.[57]

In the study of intermolecular interactions (including hydrogen bonds and other specific contacts), the "molecular-deformation" density $m\,\delta\rho$ (the difference between the experimental function ρ in the molecular crystal and the superposition of the molecular distributions of ρ calculated for the experimental geometry of the molecules) may prove useful. The $m\,\delta\rho$ maps, constructed for formamide[58] and oxalic acid,[59] reflect the influence of intermolecular interactions, not only on the atoms involved in hydrogen bonds, but also on the inner parts of the molecule.

A fundamentally different and extremely promising procedure for the primary interpretation of the function ρ (topological analysis) was developed by Bader and co-workers (see Refs. 60–62 and the bibliography quoted therein); this method provides one of the possible justifications of the qualitative concept of the classical theory of molecular structure. The principles of Bader's theory are described below and the results of the latest studies of his group as well as the applications of this approach to the experimental distributions of ρ are examined.

The topological properties of the function $\rho(\mathbf{r})$ are revealed in the analysis of the vector field of the gradient $\nabla\rho(\mathbf{r})$. Here one uses a series of auxiliary concepts (they are illustrated by Fig. 1, where the vector field of the $CH_2{=}CHF$ molecule is presented as an example).

1. The surface *S*, at each point of which the vector flux of the gradient is zero [i.e. $\nabla\rho(\mathbf{r}).n(\mathbf{r}) = 0$, where *n* is the normal] is called the zero flux surface.

2. The curve such that the tangent to each point on it coincides with the direction of the gradient vector is referred to as the trajectory or gradient line. Each trajectory is one of the solutions of the equation $d\mathbf{r}(s)/ds = \nabla\rho[\mathbf{r}(s)]$ and is specified by the formula

$$\mathbf{r}(s) = \mathbf{r}_0 + \int_0^s \nabla\rho(\mathbf{r}(t))\,dt.$$

3. The point at which the gradient $\nabla\rho(\mathbf{r})$ becomes zero is called critical (the point $\mathbf{r}_c$). This point is characterised by the rank λ and the symbol σ. The rank λ is equal to the number of non-zero values of the curvature matrix (Hessian) with the elements

$$H_{ij} = (\partial^2\rho/\partial\mathbf{r}_i\partial\mathbf{r}_j)\,\mathbf{r}=\mathbf{r}$$

and the symbol σ represents the difference between the number of positive and negative eigenvalues.

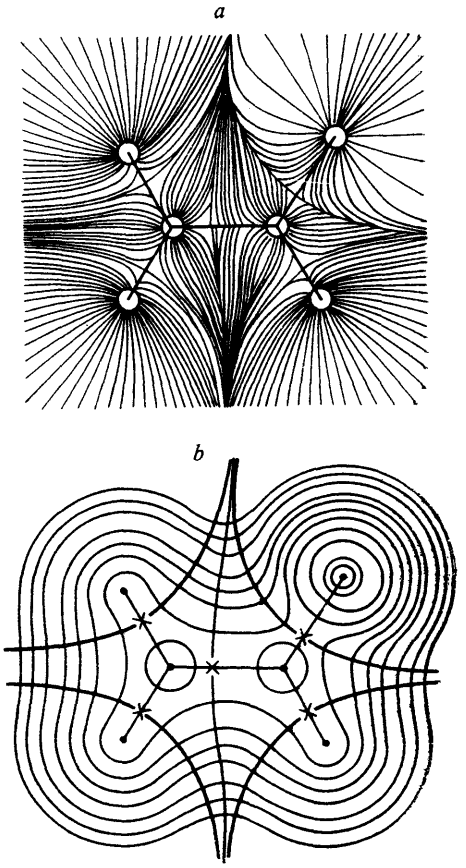


Figure 1. Topological analysis of the vector field of the $CH_2{=}CHF$ molecule (section coinciding with the plane of the molecule): (*a*) gradient lines terminating at the atomic nuclei, bond lines, and zero flux surfaces dividing the basins of the atoms are shown; (*b*) the critical points (3, –3) and (3, –1), the bond lines, and the zero flux surfaces against the background of the distribution of electron density are shown.

The critical points (λ, σ), for which $\lambda < 3$, are degenerate (unstable): for any change in the function $\rho(\mathbf{r})$, induced by the shift of the nuclei, these points either vanish or break up into a certain number of non-degenerate (stable) critical points. Such points are encountered rarely but play an important role because they indicate the possibility of structural changes in the system.

Non-degenerate critical points (for which $\lambda = 3$) can refer to one of four types: (3, −3) (maxima), (3, −1) and (3, +1) (saddle points), (3, +3) (minima).

The critical point of the type (3, −3) represents a set of ends ($s \to \infty$) of gradient trajectories which do not lie on the surfaces S; thus the role of "sinks" (attractors) of the vector field $\nabla\rho$ is attributed to these points.

The set of trajectories terminating at the given attractor forms the "basin" of this attractor. Two neighbouring basins are separated by the surface S, on which is located the critical point of the (3, −1) type [crossing point (pass)]. The trajectories located on the surfaces S terminate at the critical points (3, −1); a pair of trajectories, terminating at two neighbouring attractors and forming the "bond line", arise from each such point. Along this line, the electron density ρ is a maximum, i.e. small displacements perpendicular to this line lead to a decrease in ρ.

In Bader's theory, it is assumed that the minima in the function ρ coincide with the atomic nuclei.† Nuclei are then connected by bond lines; the assembly of nuclei and bond lines forms a molecular graph. The atom is defined as a combination of the attractor (nucleus) and its basin.

Bader's theory also includes the analysis of the "structural stability" of molecular systems, whose description is outside the scope of the present review.

Various methods for detecting the location of atoms in a molecule have been described in the literature.[64,65] However, the condition of the fulfillment of the principle of minimum action not only for the entire system (molecule) but also for its subsystems (atoms) requires that atoms be bounded by zero flux surfaces, as is done in Bader's theory. In this case, the atom in a molecule is described by the same equations of motion and theorems (for example, the virial theorem or the Ehrenfest theorem) as those applicable to the total system. Any property of an atom (charge, dipole moment, kinetic and potential energies) is calculated as the average value of a one-particle operator, which, however, is averaged only with respect to the volume of the atomic basin and not the entire space.

The topographical characteristics proposed by Bader also make it possible to describe important properties of interatomic bonds. The ratio of the bond length l to the length of the internuclear vector and the distance from the corresponding critical point (3, −1) to this vector serve as a measure of the curvature of the bond in molecules with steric strain or in non-equilibrium molecular systems. The degree of angular strain is measured as the difference between the angle between the bond lines and the angle between the bond axes.

The energy of the AB bond is defined as

$$E_{AB} = \alpha N_{AB} / (\mathbf{R}_A - \mathbf{R}_B)^2,$$

where α is a dimensionless coefficient (it is assumed that it is equal to 3 for the bonds in alkanes) and N_{AB} is a measure of the number of bond electrons. The latter quantity is assumed to be zero for free atoms, while for the deformed atoms in the molecule

$$N_{AB} = (\mathbf{R}_A - \mathbf{R}_B) \oint \rho(\mathbf{r})\, \mathbf{n}_A(\mathbf{r})\, dS_{AB},$$

where S_{AB} is the area of the zero flux surface separating two basins and $\mathbf{n}_A(\mathbf{r})$ is the unit vector of the normal to S_{AB} directed from the atom A to the outside.

Important conclusions about the character of the bond can be reached from the analysis of the distribution of ρ in the region of the critical point (3, −1). By definition, the Hessian at the critical point has two negative ($|\lambda_1| \geqslant |\lambda_2|$) and one positive ($\lambda_3$) eigenvalue, each of which defines the curvature of ρ along the corresponding eigenvector, i.e. at right angles to the bond (λ_1 and λ_2) and along the bond (λ_3). The multiplicity n of the C−C bond can be calculated from the electron density $\rho(\mathbf{r}_c)$ at this point. This is done by interpolating between the values of $\rho(\mathbf{r}_c)$ in the C_2H_6, C_6H_6, C_2H_4, and C_2H_2 molecules, for which $n = 1$, 1.5, 2, and 3. The corresponding relation is expressed by the formula $n = \exp[6.458(\rho_c - 0.252)]$.

The bond ellipticity ε [where $\varepsilon = (\lambda_1/\lambda_2) - 1$] is a measure of the deviation of the charge distribution along the bond trajectory from radial symmetry. This quantity is sensitive to the amount of "π character" of the bond. If a single bond is conjugated with a double bond, then calculation for the former yields $n > 1$ and $\varepsilon > 0$.

However, the presence of the critical point (3, −1) is only a necessary but not a sufficient condition for the existence of the covalent bonds between two atoms: such points exist in ion pairs, in molecular complexes with hydrogen bonds and charge transfer, and also in premolecules. The predominance in the internuclear region of the potential energy of the electrons (negative in sign) over the positive kinetic energy has been postulated as a sufficient condition. This empirical postulate has different mathematical expressions. Bader uses for this purpose the "charge concentration function": $g = -\nabla^2\rho$, where $\nabla^2\rho$ is the Laplacian of the electron density ($\nabla^2\rho = \partial^2\rho/\partial x^2 + \partial^2\rho/\partial y^2 + \partial\rho/\partial z^2$), expressing the overall curvature at the point with the coordinates x, y, and z and equal, according to the virial theorem, to twice the sum of the kinetic and total energies of the electrons at this point. Other workers[66] consider the total energy of the electrons (the sum of the kinetic and potential energies) at the critical point of the bond.

If $g(\mathbf{r}_c) > 0$, then the quantity ρ at the critical point exceeds its average value in a small region near this point, i.e. the charge accumulates in the internuclear space and the bond is regarded as covalent. The only exception is the F_2 molecule, which can be explained by the anomalously high intraatomic correlation of the electrons. For an ionic bond, $g(\mathbf{r}_c) < 0$. Here the function ρ exhibits a plateau in the plane perpendicular to the bond line and the positive values of g are localised near the nuclei on either side of the plane. The same picture is observed for hydrogen bonds and van der Waals interactions.

More detailed topographical analysis of the function g also yields useful results. In an isolated atom, the maximum values of g are observed at the point corresponding to the nucleus and on $n - 1$ concentric spheres, where n is the principal quantum number. Since an evident analogy with the shell model of the atom is to be seen

† In a recent non-empirical study of free Na_m clusters ($m = 2$, 4),[63] ρ maxima were observed between nuclei, the Na atoms forming bonds only via these "pseudoatoms". Apparently this feature is characteristic of a metallic bond and the experimental observation of ρ maxima at the centres of the vacancies in spherical packings is to be expected, for example, for crystals of alkali metals and beryllium.

here, the outer sphere with an increased charge concentration is referred to as the valence shell. When the atom forms chemical bonds, the valence shell is distorted and loses the constancy of g at each of its points; local g maxima appear on it, i.e. two dimensional attractors (2, –2) and between them saddle points (2, 0) appear on it. The trajectories ∇g, originating from the saddle points, divide the valence shell into two-dimensional basins each of which contains one maximum. If $g > 0$ at a given maximum, then a region of increased charge concentration, i.e. a region where $g > 0$, corresponds to it (evidently such regions can overlap).

In Bader's view, analysis of maps of the distribution of the function g provides a physical justification of the concept of electron pairs. Furthermore, the number, positions, and dimensions of the regions with an increased charge concentration agree with Gillespie's ideas[67] of the repulsion of localised pairs, explain Pearson's theory of hard and soft acid and bases,[68] and can serve as a basis for the determination of the direction of electrophilic and nucleophilic attack on the orientation of the reacting molecules at the start of the reaction. Bader believes that this approach is more correct than the electrostatic models usually employed nowadays, because molecules approaching one another "see not the charges on the atoms and not the distribution of the electrostatic potential but the system of local discharge and charge concentration centres described by the electron density Laplacian". The predictions of the intramolecular and intermolecular interactions, presupposing the mutual attraction of regions with different signs of g, have therefore proved to be extremely successful.

Thus the minimum in g on the valence shell surface of the carbonyl carbon atom is located in the direction forming an angle of 110° with the C=O bond. Accordingly, in crystal structures with shortened contacts between oxygen and carbonyl carbon atoms the O...C=O angle is usually close to this value.

When the molecule contains competing active centres, analysis of the function g makes it possible to predict the preferred direction of the reaction. For this purpose, one uses the concept of the "hardness" of the active centre.[68] The interaction of "like with like", i.e. of a harder nucleophile with a harder electrophile and conversely, is found to be preferred. According to Bader, the hardness of the nucleophile (electrophile) increases with decrease in the distance between the maximum (minimum) and the nucleus and also with increase in the absolute magnitude and curvature of g at the extremum.

The approach developed by Bader and co-workers has been used recently to interpret the results of non-empirical quantum-chemical calculations for an increasing range of molecular systems (hydrocarbons, carbonium ions, carbenes, complex compounds, "non-rigid" molecules, molecular dimers). With the aid of this approach, it is possible to investigate intermolecular and intramolecular hydrogen bonds and the effects of hyperconjugation and heteroaromaticity. It has been shown[69] that the properties of atoms and bonds and the influence of substituents on the position of the critical point can be associated with simple orbital models. The fact that the electron distribution in the premolecule ρ_0 contains valuable chemical information is somewhat unexpected: in particular, it makes it possible to divide the molecule into pseudoatomic fragments.[70]

It was noted previously that the Bader approach is promising not only as regards the calculated theoretical distributions $\rho(\mathbf{r})$ but also as regards their experimental values. The first studies on these lines[71,72] confirmed this conclusion. The ethane molecule in a crystal was investigated on the basis of the topographical analysis of the experimental function ρ taking into account the specific limitations of the experiment.[71] In contrast to the free molecule, here one observes a non-zero ellipticity of the C–C bond, which can be treated as partial double bond character due to the influence of the environment. However, this effect can be explained also by the imperfection of the method: the static distribution of ρ in the molecule is regarded as the sum of the static function ρ_0 of the premolecule and the dynamic function $\delta\rho$, which precludes the complete exclusion of the influence of thermal motion. A $\nabla^2\rho$ map has been used[72] to describe non-classical many-centre bonds in the pseudocubic V_4S_4 cluster. The conclusion that the V–V and V–S bonds are covalent, reached on its basis, served as a significant complement to the $\delta\rho$ map.

Thus topographical analysis of the distribution of ρ is a powerful instrument and reveals many hidden features of electron density. However, like any universal method, it does not enable one to discover fully the chemical individuality of the compound. Comparision of the distributions of ρ for the given substance and its chemical analogues helps to view this individuality from different aspects.

The necessity for a quantititative comparison of two charge distributions arises also in other cases (comparison of theory and experiment, comparison of the results of two different calculations or two experimental studies, etc.). Such comparison can be carried out on three levels: (1) the integral level (the outcome is expressed by a single parameter); (2) the local level (the outcome is represented by a set of values); (3) the continuous level (the outcome of the comparison is a continuous function).

The Carbo index serves as an integral characteristic of molecular similarity.[73] For isoelectronic molecules, it can be reduced to the generalised Polanski number:

$$K_{12} = \frac{\int \rho_1\rho_2 dV}{\left(\int \rho_1^2 dV\right)^{1/2}\left(\int \rho_2^2 dV\right)^{1/2}} \simeq \frac{N}{2} tr\,(P_1P_2),$$

where N is the number of electrons and P_1 and P_2 are the density matrices of the molecules 1 and 2 formulated in terms of a single basis set. The quantity K_{12} depends on the method used to superimpose the molecules. On the basis of the similarity index for the reactants and products, it is possible, for example, to predict the stereospecificity of pericyclic reactions.[74]

Without dwelling in detail on the local comparison of the distributions of ρ, we shall mention only that the discrete characteristics, listed at the beginning of this section, or the properties of atoms and bonds considered by Bader can serve as parameters of such comparison.

Continuous comparison yields most information but is usually carried out at a qualitaltive level involving the visual comparison of two $\delta\rho$ maps. For example, the differences between two crystallographically independent thiourea molecules (the reasons for the differences were not discovered)[21] and three forsterite crystals (the reason is the inadequate allowance for the extinction manifested in different ways)[12] were observed in precisely this way.

A more complete and objective result is provided by a quantitative continuous comparison involving the construction of difference density maps. However, even for small differences between geometrical parameters of the molecular systems 1 and 2 compared, such constructions become ambiguous. Even in the simplest case, involving the comparison of two N_2 molecules with internuclear distances of 1.09 and 1.11 Å, one can superimpose either the centres of gravity or one pair of nuclei. In the former case, the

difference density map[75] shows the accumulation of ρ between the nuclei as the latter approach one another, while in the second it shows the accumulation of ρ in the postnuclear region and in both cases there is a pair of intense peaks (positive and negative) corresponding to the nuclear displacements. The "point" generalised-difference density $\Delta\rho'$ makes it possible to avoid the latter false effect and at the same time to discover the first two. Such density was derived by Steiner:[75]

$$\Delta\rho'(\mathbf{R}) = \rho_1(\mathbf{f}_1(\mathbf{r})) - \rho_2(\mathbf{f}_2(\mathbf{r}')).$$

where $\mathbf{r}$ and $\mathbf{r}'$ are the coordinates of the points corresponding to one another in the molecules 1 and 2 and $\mathbf{R} = \mathbf{f}(\mathbf{r})$ is the function of the change of variables mapping the coordinates of the nuclei of the first molecule $\mathbf{r}_i$ on the ideally disposed reference points $\mathbf{R}_i$. The integral of ρ with respect to the volume of the molecule, which is equal to the number of electrons, must be invariant relative to such change of variables:

$$\int \rho(\mathbf{r})\, d\mathbf{r}^3 = \int \rho''(\mathbf{R})\, d\mathbf{R}^3 = \int \rho''(f(\mathbf{r}))\left|\frac{d^3\mathbf{R}}{d^3\mathbf{r}}\right| d\mathbf{r}^3.$$

In order to take into account this factor, a "volume" generalised-difference density $\Delta\rho''$ was constructed:

$$\Delta\rho''(\mathbf{R}) = \rho_1(\mathbf{r})\left|\frac{d^3\mathbf{f}_1(\mathbf{r})}{d^3\mathbf{r}}\right| - \rho_2(s)\left|\frac{d^3\mathbf{f}_2(\mathbf{r}')}{d^3\mathbf{r}'}\right|,$$

where $|d^3\mathbf{f}_1(\mathbf{r})/d^3\mathbf{r}|$ is the Jacobi determinant.

In the case of the N_2 molecule, the distribution of $\Delta\rho''$ on approach of the nuclei proved to be similar to the distribution of δρ and was interpreted as partial transfer of electrons from the p_π to the p_σ orbital. A similar electron redistribution was noted also in the case of ethane on transition from the eclipsed to the hindered configuration. This effect is not manifested in the rigid rotation of methyl groups and has been observed only with the aid of generalised-difference maps.[75] A significant disadvantage of the study described is an extremely artificial and ambiguous construction of the function $\mathbf{f}$ by the method of segmental-linear interpolation along each coordinate of the Cartesian system. This led to breaks on the $\Delta\rho''$ maps and to a dependence of $\Delta\rho''$ on the choice of direction of the axis.

The coordinate transformation method was also used[76] for the solution of the problem of recovering the wave function from precision XRDA data. The change of variables leaves the nuclei in place and distorts the electron density of the premolecule ρ_0 until it coincides fully with the experimental density:

$$\rho(\mathbf{r}) = \left|\frac{d^3\mathbf{f}}{d^3\mathbf{r}}\right| \rho_0(\mathbf{f}(\mathbf{r})).$$

The transformation $\mathbf{f}$ found from this condition is then applied to the wave function of the precrystal in order to obtain the wave function of the crystal. A local-scaling transformation, in which $\mathbf{r}\|\mathbf{f}(\mathbf{r})$ is used as $\mathbf{f}$. By applying the approach described to the problem of the construction of the generalised-difference density, one can ensure the uniqueness of the function of the change of variables by the requirement for the complete coincidence of the electron densities of the premolecules of the systems being compared.

Another procedure for the quantitative comparison of the charge distributions w_1 and w_2, where $w = \rho, \varphi, \delta\rho, c\,\delta\rho, \nabla^2\rho$, etc., which also ensures the uniqueness of the function $\mathbf{f}$, has been proposed.[77] In particular, it was noted that, in constructing $\mathbf{f}$, it is essential to take into account a series of factors dictated by the physical significance of the problem: the movement of the region near the nuclei without deformation, a strong dependence of the changes in electron density on the changes in the electrostatic potential and the smooth (non-oscillatory) character of these changes. Mathematically the uniqueness of the function $\mathbf{f}$ is ensured by minimising a functional for which one can use the measure of the distortion of space[77] or the information entropy. In the comparison of the distributions of ρ in systems 1 and 2, the function $\mathbf{f}$ can be conveniently represented as a homeomorphism mapping the trajectories $\nabla\rho_1$ onto the trajectories $\nabla\rho_2$. (For molecules or molecular fragments having equivalent structures according to Bader,[60] such homeomorphism exists by definition). In the latter case it is reasonable to impose the requirement that the function $\mathbf{f}$ should bring into coincidence not only the nuclei but also other critical points, as well as the zero flux surface and bond lines.

If a comparison is carried out in order to interpret chemical effects, it is essential to take into account the difference between the thermal vibrations in the systems being compared. Within the framework of the Debye–Waller approximation,[7] this can be done in two ways: by constructing the pseudostatic densities ρ^{stat} or by blurring ρ_2 by the thermal vibrations characteristic of system 1 (with the aid of a convolution transformation) within the framework of the multipolar pseudoatom or solid state models. The function $\Delta\rho''$ constructed reflects the influence of the environment and the substituents on the distribution of ρ in the molecules.[77]

Thus the quantitative comparison of the charge distributions makes it possible (after the appropriate choice of the objects to be compared) to characterise comprehensively the chemical individuality of the molecules and to extract fundamentally new information from X-ray diffraction data.

IV. Trends in the distributions of deformation electron density

Hitherto deformation density maps have been constructed for more than 120 organic compounds. The list, which includes 96 organic substances investigated in this way, has been published in a review.[6] Table 1 lists the organic substances investigated most recently (from 1983 to 1987); among them, one may encounter compounds mentioned in the review of Tsirel'son and Zorkii[6] but reinvestigated recently. The most complex structural formulae of the compounds in Table 1 are shown in Fig. 2.

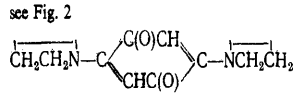
The available experimental data make it possible to note the following qualitative feature of the distributions of δρ:

(1) the presence of a peak on the covalent bond line (the exceptions are discussed below);

(2) dependence of the form of this peak on the π character of the bond;

(3) the shift of the peak away from the bond axis in sterically strained systems;

(4) asymmetry of the peak of a polar bond;



(5) the shift of the peaks of electron-deficient bonds to the bisector of the bond angle (up to the fusion of these peaks);

(6) the presence of a single peak or two peaks in the region of lone electron pairs of the heteroatom;

(7) the slight deformation of the LEP peak on formation of weak and moderately strong hydrogen bonds;

(8) approximate symmetry of the strong hydrogen bond X–H...Y relative to the centre of the XY section.

Table 1. The list of substances investigated.

Empirical formula	Name of substance	Structural formula	Structural class	Refs.
CH_4N_2O *	Urea	$(H_2N)_2CO$	$P\bar{4}2_1m$, $Z = 2(2mm)$	[9]
CH_4N_2S *	Thiourea	$(H_2N)_2CS$	$Pnma$, $Z = 4(m^s)$	[9, 21]
$CH_4N_2S \cdot C_3H_2N_2O_3$	Thiourea–parabanic acid complex	$(H_2N)_2CS \cdot \overline{C(O)NHC(O)NHC(O)}$	$P2_1/m$, $Z = 2(m, m)$	[47]
$C_2H_2O_4 \cdot 2H_2O$ *	α-Oxalic acid dihydrate	$(COOH)_2 \cdot 2H_2O$	$P2_1/c$, $Z = 2(\bar{1}; 1)$	[11, 59, 78]
$C_2H_6NO_2 \cdot Br^-$	Glycinium bromide	$[H_3NCH_2COOH]^+Br^-$		[79]

*Compounds already mentioned in an earlier review[6] but reinvestigated.

The height of the covalent bond peak

In general, the height of the $\delta\rho_{max}$ peak is not an unambiguous characteristic of the bond strength. Firstly (as a consequence of the lack of standard methods), the differences between the experimental conditions and the refinement procedures lead to a dependence of the results on the method in which it was obtained.[6] Secondly, the thermal vibrations of the molecules and atoms in different structures can "blur" the $\delta\rho$ peaks to different extents, while the static distributions of $\delta\rho$ depend on temperature and the model used as a consequence of the insufficiently accurate allowance for thermal

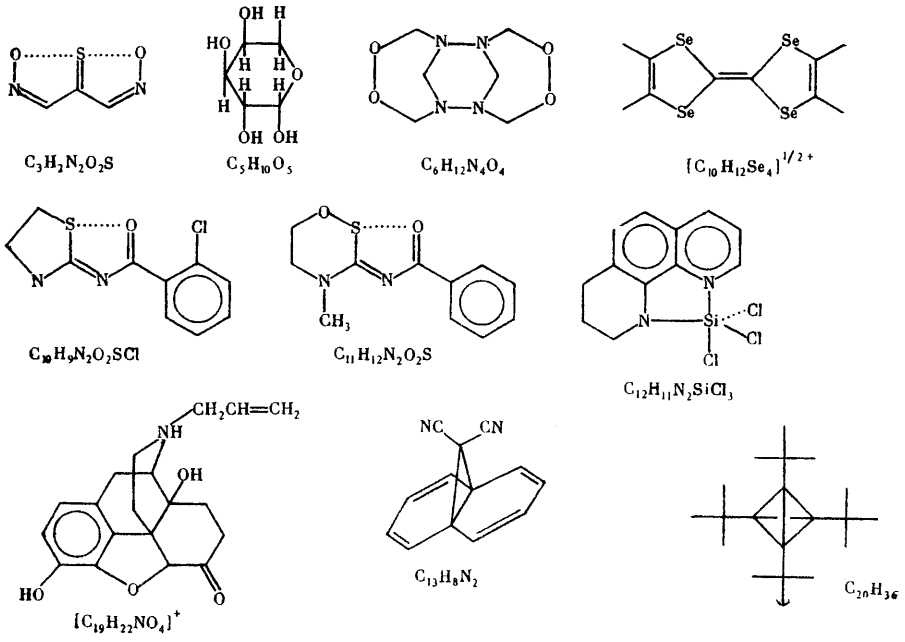

Figure 2. Structural formulae in Table 1.

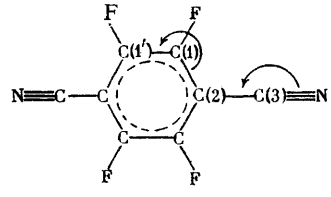
motion.[21,37] Thirdly, as regards bond strength, the comparison of the deformation densities on bonds of this type (for example, O–O and N–N) is known *a priori* to be incorrect.[87]

However, the differences between the values of $\delta\rho_{max}$ in a single molecule can indicate the non-equivalence of isotypical bonds, which has been confirmed both theoretically and experimentally. For example, in the case of 9-t-butylanthracene $C_{18}H_{18}$, the values of $\delta\rho_{max}$ are approximately proportional to the overlap populations[10] calculated with the aid of the extended Hückel method. The extremely small value of $\delta\rho_{max}$ on the elongated C–C bridge bond in the compound $C_{13}H_8N_2$ [45] indicates that this is the weakest bond in the molecule. This conclusion is fully confirmed by chemical properties.



In certain cases, $\delta\rho_{max}$ proved to be smaller than the background level; one then speaks of the absence of a peak on the bond. The bond between inverted carbon atoms in the propellane derivative $C_{17}H_{19}N$, having the normal length, has been examined as an example in a review.[6] Theory describes such a bond with the aid of sp^4-hybrid [sic] orbitals whose overlap is indeed small.[110]

The causes of the systematic absence of peaks on bonds of the C–F and O–O types as well as certain others[7] were indicated above in Section III. The splitting of the peak on bonds formed by a silicon atom (Si–Si,[26] Si–Cl,[102] and Si–C [108]) is sometimes also observed.

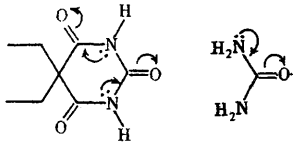
The form of the covalent bond peak

Single, double, and triple bonds differ, apart from the values of $\delta\rho_{max}$, by the form of the equal deformation density surfaces. In the ideal case, single and triple bonds are manifested as peaks having the shape of ellipsoids of rotation (the axis of rotation is extended along the bond axis) with different ratios of the longitudinal and transverse half-axes.[111] The peak of the double bond in ethylene is extended at right angles to the plane of the molecule.[112] When single and multiple bonds alternate in the molecule, conjugation arises: the density of π-electrons is displaced from the multiple to the single bond (the mesomeric effect is designated in the structural formula by a curved arrow). This is reflected in the shape of the deformation density peaks.

A characteristic example is provided by tetrafluoroterephthalodinitrile $C_8N_2F_4$:[30]

The form of the peaks due to different bonds on the 0.1 e Å^{-3} multipolar pseudostatic δρ distribution surface is characterised by the following values (in Å).

	C(1')—C(1)	C(1)—C(2)	C(2)—C(3)	C(3)—N
Maximum width in the molecular plane (d_1)	0.89	0.89	0.93	1.30
Maximum width at right angles to the plane (d_2)	1.41	1.28	1.02	1.23
Bond length	1.38	1.40	1.43	1.15



The sizes of the peaks confirm the existing ideas about the mesomeric effect and show that the π character of the bonds diminishes monotonically in the sequence C(1')–C(1), C(1)–C(2), C(2)–C(3), since the quantity d_2/d_1 diminishes (the latter is confirmed also by the increase in bond length). This means that the structure of the six-membered ring approaches the quinonoid structure, while the linear C(2)C(3)N fragment approaches the

cumulene type. We may note that the dynamic δρ distribution does not exhibit the quantitative features described. The existence of the inductive effect (transfer of electron density from C to F atoms and from the C atom to the N atom) follows from the atomic charges: F 0.13 e; C(1) 0.13 e; C(2) 0.05 e; C(3) 0.11 e; N 0.15 e.

The alternation of charges in a chain of four carbon atoms, which agrees with the ideas about the inductive effect, has been discovered also in the molecule of barbital $C_8H_{12}N_2O_3$.[113]

Polar bonds exhibit asymmetry in the δρ peak relative to the centre of the A–X internuclear section. For single bonds, having no π-component, the following regular feature is observed. If the bond polarity, measured by the quantity $\Delta q_{AX} = q_A - q_X$ (where q is the atomic charge) is large (of the order of 1 e), the δρ maximum is displaced towards the nucleus of the electronegative atom X, the function δρ diminishing faster in the direction of the X nucleus than in the opposite direction.‡ In organic molecules, purely single and at the same time polar bonds are encountered rarely; there are virtually no such bonds among organic substances for which carefully constructed δρ maps exist, (only in this case is there any point in discussing such fine details). Therefore examples of the features described can be more easily found among inorganic substances (the B–N bond in the cubic BN,[115] the Si–O bond in coesite,[116] and the Te–Cl bond in $C_2H_2TeCl_2$ [81]). Weakly polar bonds (for example, N–O, C–N, and C–O in $C_6H_{12}N_4O_4$ [95]) do not exhibit such asymmetry.

The characteristic features of bonds with a definite contribution of the π-component can be clearly seen in relation to barbital $C_8H_{12}N_2O_3$.[116] A shift of the charge on the C–N and C–O bonds in the π-region towards N and O bonds and in the plane of the molecule towards C bonds is observed in this instance. In the π-region, a similar feature, confirmed by theoretical calculations, is shown also by the carbonyl group in the urea CH_4N_2O molecule. Such behaviour of the π-charge can be explained by the schematic illustration of the mesomeric shift of electrons:

Hence it is clear that the population of the p_π orbitals of the N and O atoms is greater than unity and that of the C atom does not exceed unity. The differences between the orbital populations induce the asymmetry of the δρ peaks in the π-region. As regards the σ-charge, the example of parabanic acid $C_3H_2N_2O_3$,[47] two investigations of which led to completely different forms of the δρ peak in the σ-region of the C–N bond, makes it necessary to exercise caution in drawing inferences about the shape of the multiple bond peak in the molecular plane.

The asymmetry of the δρ peak for non-equivalent N–Si bonds in the compound $C_{12}H_{11}N_2SiCl_3$ [102] with a trigonal-bipyramidal coordination of the Si atom is manifested in different ways (Fig. 3). On the N_e–Si bond with an equatorially coordinated nitrogen atom, an appreciable displacement of the σ-density towards the Si atom and of the π-density towards the N_e atom is observed. The long bond with the axially coordinated nitrogen atom ($N_a \rightarrow Si$), which is formed by a donor–acceptor mechanism, exhibits different features. Its σ-component is displaced from the centre to the N_a atom and the π-component is virtually absent. Similarly to the single bonds discussed above, the quantity δρ diminishes in this instance from the maximum towards the N_a atom much more steeply than in the opposite direction.

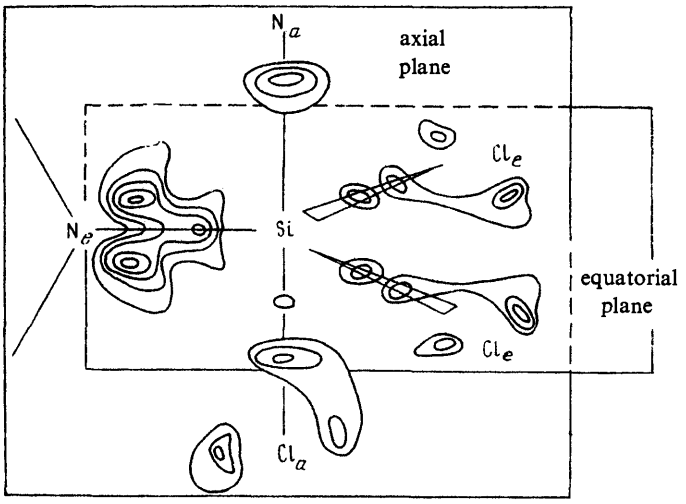


Figure 3. Schematic representation of the distribution of the deformation electron density in the SiN_2Cl_3 system.

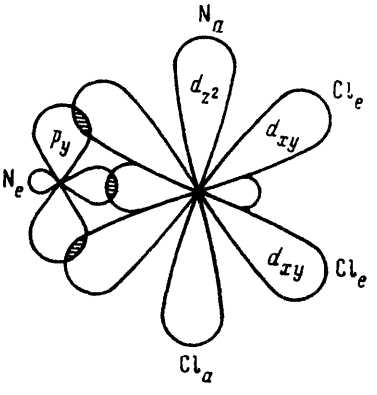

Figure 4. Interpretation of the electronic structure of the SiN_2Cl_3 system with the aid of atomic orbitals.

These facts can be explained with the aid of simple orbital ideas (Fig. 4). In the equatorial plane, the Si atom forms with the aid of sp^2-hybrid orbitals three σ-bonds (with the N_e atom and two Cl atoms). The N_e atom donates the electron pair occupying the p_y

‡We may note that the shift of the symmetrical peak to one of the nuclei can be induced not [only] by the bond polarity but by the difference between the sizes of the principal atomic regions (an example is provided by the C–S bond in the thiazolidine ring[114]).

orbital to the unoccupied d_{xy} orbital of the Si atom and forms a π-bond. The bond with the axial Cl atom is produced by the p_z orbital of the Si atom and the LEP of the N_a atom is transferred to the unoccupied d_{z^2} orbital. The extent of the atomic 3*d* orbitals in space explains the large distances from the Si nucleus to the peaks of the donor–acceptor bonds.

We may note that non-equivalence of the axial bonds is observed also in the trigonal-bipyramidal phosphorus compound C_2Cl_9P.[83]

The position of the covalent bond peak

In sterically strained systems, the δρ peaks deviate significantly from the bond lines in order to compensate for the decrease in the bond angle compared with the angle between the hybrid orbitals.[6]

The δρ map in the plane of the cyclopropane ring has been incorporated in textbooks and has become the classical image of banana bonds.[117] Another example is the cyclobutadiene fragment of the $C_{22}H_{32}S_2$ molecule, in which the following features of the δρ distributions have been observed.[118] In the plane passing at right angles through the centre of the C=C bond, there is in this instance a two-humped peak and the saddle section of the peak, corresponding to the σ-component, is further away from the ring axis than the maxima corresponding to π-electrons; for a single bond, δρ is close to zero at the analogously located points (at the same distances from the plane of the ring where the double bond gives rise to δρ maxima). The observed picture can be explained as a result of the superposition of distributions characteristic of a bent σ-bond and the usual π-bond, but non-empirical quantum-chemical calculation, performed for cyclobutadiene, did not lead to the observation of the double-humped peak described.

In compounds with electron-deficient bonds, a trend has been noted towards a shift of the δρ peaks into the inner region of the angle between such bonds.[119] Under these conditions the peaks fuse or a bridge is formed between them. Apart from inorganic compounds (metals, oxides) such features are observed in carbaboranes[120] and other boron compounds. Theory describes these compounds with the aid of three-centre two-electron orbitals localised at the centre of a three-membered ring made up of boron atoms.

Peaks in the region of unshared electron pairs

The height and shape of such peaks depend on the type of atom, its valence state, and the immediate environment.[6] Non-valence interactions or conjugation with π-bonds usually greatly influence the LEP peaks.

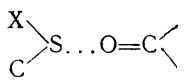
The N(III) atom has a single LEP. The corresponding δρ peak is manifested most clearly in the case of *sp*-hybridisation in the $-C\equiv N:$ group (for example, in $C_8N_2F_4$ [30]). The LEP of the angular dicoordinate nitrogen, occupying an sp^2-hybrid orbital, is also clearly manifested, for example, in the $C=\ddot{N}-C$ group (4-methylpyridine C_6H_7N [92]) and the $C=\ddot{N}-O$ group ($C_2H_6N_2O_2$ [80]). However, in the case of nitrogen with a planar ternary coordination, where the LEP occupies a *p* orbital, the maximum in the non-valence region is absent or is weak (in diformylhydrazine,[121] acetamide,[122] etc.). This is associated with the delocalisation of electrons on conjugation with double bonds. In the case of pyramidal coordination (in the compounds $C_6H_{12}N_4O_4$ [95] and C_3H_9N [86]), a diffuse LEP peak, occupying an sp^3 hybrid orbital, is observed near the N atom.

The two LEP of the oxygen atom give rise to two peaks located at an angle of ~130° in the case of sp^2-hybridisation. For sp^3-hybridisation, these LEP are usually manifested as a single longish peak (which agrees with non-empirical calculations for the H_2O molecule), but the intermolecular interactions sometimes lead to the splitting of this peak into two components. Numerous examples have been discussed in a review.[6] Here we shall only note that the peak corresponding to a single LEP can also be split, as has been observed for TeO_2.[123]

The remaining heteroatoms have been less thoroughly investigated. The unshared electron pairs of sulphur(II) usually behave like the oxygen LEP, but sometimes the height of their peak is comparable to the error of the determination of the δρ.[6] In the pyramidal SO_3^{2-} ion, the single LEP of sulphur(IV) has been observed at the apex of the pyramid.[124] The LEP peaks of the halogen atoms X (X = F, Cl) are manifested by a torus, whose axis coincides with A–X bond line and whose centre is displaced towards the A atom.[83,94,102] More rarely they appear in the form of three lobes directed at right angles to this axis.[89] Furthermore, there are negative minima in the direction opposite to the A–X bond line indicating the participation of the p_σ orbital of the atom X in the formation of this bond. A minimum is also observed on the C–F bond itself.[30,97]

Characteristic features of δρ in the region of hydrogen bonds

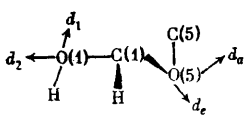
It was noted previously[6] that the δρ distribution along strong hydrogen bonds is approximately symmetrical relative to the midpoint despite the differences between O–H and O...H distances, while in the case of weak and moderately strong hydrogen bonds the δρ distributions are close to the superposition of δρ fragments.



However, in a more detailed analysis of strong N–H...N interactions, it was noted[102] that the δρ distributions along the N...H bond and along the covalent N–H bond[89] differ somewhat. In the former case, the δρ peak is polarised (it descends gently) in the direction of the H atom, while in the latter case it is polarised in the direction of the N atom. It has also been noted that the steepness of the peak of the LEP not involved in the intermolecular interaction is approximately the same on the side of the nucleus and on the opposite side. The polarisation of this peak indicates a weak hydrogen bond. The specific C–H...N interactions in the 1,2,3-triazine crystal were in fact discovered on the basis of this feature[10] (*a priori* the appearance of such hydrogen bond was regarded as unlikely).

The redistribution of δρ on formation of hydrogen bonds has been frequently studied theoretically. Comparison of non-empirical calculations for the H_2O molecule in a free state and in a cluster, modelling the unit cell, indicates[125] an increase in the polarity of the O–H bonds and the transfer of electron density from the LEP and the hydrogen atoms to the O atom. On the other hand, the presence of short contacts (the formation of strong hydrogen bonds) increases the LEP peak. In the presence of several nearest neighbours, the changes in δρ are superimposed. For this reason, an increase in the number of neighbours blurs the characteristic features of the δρ distribution.

Thus according to the data presented, the idea that the δρ in weak and moderately strong hydrogen bonds is the sum of the deformation density of the LEP and the covalently bound hydrogen appears to be fairly approximate.



Redistributions of δρ induced by specific non-valence interactions

As an example of the influence of non-valence interactions on δρ, we shall present the results of a study[94] in which the intramolecular

interactions in the $C_{10}H_9N_2OSCl$ and $C_{11}H_{12}N_2O_2S$ molecules were compared (the lengths of the S...O contacts are 2.68 and 2.52 Å respectively). In the former case, two peaks of the LEP of the carbonyl O atom can be seen in the δρ distribution, while the peaks near the S atom are absent. In the latter case, the peaks due to the LEP of oxygen have almost completely vanished, while the S atom is surrounded by an intense δρ halo. Model calculations carried out with the aid of the extended Hückel method have shown that the order (covalence) of the bond between the atoms involved in these contacts reaches 4 and 25% respectively (compared with the covalent S–O bond).§ This can be explained by the fact that the interaction of the LEP of the O atom and of the antibonding molecular orbital of the S–X bond intensifies with increase in the electronegativity of the atom X.

Yet another example of specific non-valence interactions is provided by the anomeric effect in β-DL-arabinose,[15] which has been detected in the molecular fragment

where the letters *d* denote the LEP. It was established that the heights of the δρ peaks, corresponding to the unshared electron pairs d_a, d_e and d_2 are similar. For the d_1 pair, this quantity is smaller, because this LEP interacts with the C(1)–O(5) bond. It has also been noted that the δρ peaks on the "anomeric" C(5)–O(5) and O(1)–H bonds are significantly lower than on other bonds.

Manifestations of intermolecular specific non-valence interactions have been observed[81] in $(CH_3)_2TeCl_2$ crystals. Here the orbital of one molecule, occupied by the unshared pair of the Cl atom, interacts with the antibonding orbital of the Te–C bond of another molecule, which increases the level of δρ on the Te...Cl section.

From the standpoint of δρ distributions, the non-specific intermolecular interactions in organic crystals have so far been scarcely investigated. The effects associated with them are found at the limits of accuracy of the precision X-ray diffraction analysis but non-empirical quantum-chemical study of the intermolecular forces appears even more complex. It is therefore possible that new results, of fundamental importance for the theory of the structure of molecular condensed phases, will in fact be obtained in this precise region.

Low-temperature X-ray diffraction analysis: possibilities in the solution of chemical problems

M Yu Antipin
Nesmeyanov Institute of Organoelement Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The possibilities of the modern precision X-ray diffraction method for the determination of the exact geometry, the characteristics of the thermal vibrations, and the distribution of electron density in the crystals of molecular compounds are examined in relation to a number of examples. The role of such investigations in the solution of chemical problems is demonstrated.

The bibliography includes 134 references.

I. Introduction

The development of the X-ray diffraction method for the investigation of the structures of single crystals has been marked in recent years by a significant acceleration and simplification of the procedure used to obtain experimental diffraction data and to elucidate and refine crystal structures. At the same time there has been considerable growth also in the analytical possibilities of the method, which has proved extremely important for the actual solution of many chemical problems. In particular, use of low-temperature recording during a diffraction experiment (T < 100–150 K) made it possible to establish the structures of many fundamentally important simplest low melting and/or thermally labile compounds, including chemically unstable intermediates in chemical reactions,[1–3] which significantly extended the scope of X-ray diffraction analysis.

Acceleration of the measurement of structural data and the extension of the analytical scope of the method and in a certain sense of its routine applications (this includes low-temperature experiments) proved possible by virtue of the development of modern automatic diffractometers with appropriate attachments and highly effective sets of programs for crystal structures calculations on latest generation computers. The considerable increase in the number of structural studies throughout the world on molecular carbon-containing compounds is indicated, in particular, by the fact that the Cambridge Structural Data Centre contains at present information about the structures of more than 73,000 compounds[4] and the Centre receives annually approximately 6000–7000 new structures. Thus X-ray diffraction analysis has become one of the most important and useful methods for the study of structure in modern chemistry.

On the other hand, there has been an appreciable growth in recent years also in the real accuracy of the X-ray diffraction method. This has made it possible to extract from its results information of a new type, namely one can now establish detailed features of the steric structures of molecules and crystals, to discover the characteristics of atomic thermal vibrations, and also to investigate experimentally the distribution of electron density in crystals. In particular, the attainment of a precision in the determination of interatomic distances to within 0.002–0.003 Å permits a reliable detection of different electronic effects in molecules (the anomeric effect, the presence and absence of conjugation, etc.), which alter their geometry.

We emphasise that the standard errors in the interatomic distances obtained on refining crystal structures by the least squares method (LSM) fairly often have similar values. However, in the usual ("routine") experiments a whole series of factors (absorption, extinction, and diffuse scattering of X-rays, the asphericity of the electron distribution of atoms, the librations of the molecules and atomic groups in the crystals, the possible types of disorder, etc.) are not as a rule taken into account. These can introduce errors into the structural, including geometrical, parameters, which can sometimes be several times greater than the standard errors of the LSM. The correct allowance for these factors or reduction of their influence and hence the determination of the most reliable and accurate diffraction data and structural characteristics of the molecules and crystals is the task for modern precision X-ray diffraction analysis which has greatly developed in recent years.[5,6]

In the case of molecular crystals, which include almost all the crystals of organic, organoelement and organometallic compounds, one of the main and in many cases the principal condition governing the measurement of precise diffraction data involves the use of low temperatures (T < 100–150 K)† in X-ray diffraction experiments.[7] The increase in the accuracy of the X-ray diffraction analysis on reducing the temperature is mainly associated with the decrease in the amplitudes of atomic vibrations. The decrease in these amplitudes leads to a sharp rise in the intensities of the diffraction maxima, which permits in practice their measurement with a high statistical accuracy. On cooling molecular crystals to the

† In the vast majority of low-temperature devices, cold nitrogen vapour is used as the cooling agent (T_b = 77 K). X-Ray diffraction studies at helium temperature have so far been few in number (see, for example, Henriksen et al.[8]) in view of the complexity of the corresponding devices.

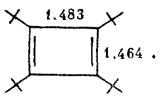
temperatures indicated, the greatest increase in the intensity of the large angle of reflections ($\sin\theta/\lambda > 0.6-0.7$ Å^{-1}) takes place. They are in fact largely determined by the scattering of X-rays by the electrons of the inner shells of the atoms, which are little perturbed on formation of chemical bonds and therefore the inclusion of such reflections in the LSM refinement of structures is extremely important and leads to the measurement of more correct thermal and positional parameters of atoms which have not been displaced as a result of chemical bonding effects. Such effects can incidentally be considerable for crystals made up of molecules containing multiple bonds of the type C≡C or C≡N. The refinement of structures of this kind only on the basis of "near" reflections, which is frequently the case when the experiments are carried out at room temperature where "far" reflections are absent due to intense thermal vibrations, can lead to a systematic shortening of such bonds by 0.01 Å and more, although the error, determined by the LSM, in the interatomic distances can be almost an order of magnitude smaller.[9]

At low temperatures, where the possibility of a reliable measurement of large angle reflections arises, it is possible to avoid this source of systematic error as a result of the appreciable increase in the contribution of such reflections to the X-ray scattering, which corresponds to a large extent to scattering by spherically symmetrical atoms—this is one of the main approximations in the X-ray diffraction analysis. The cooling of crystals and the associated decrease in the atomic vibration amplitude lead also to a decrease in a series of other effects (anharmonicity, diffuse thermal scattering, the "freezing out" of certain low-frequency vibrations), which also affect the thermal and geometrical parameters. Furthermore, on cooling, there is an increase in the radiation and chemical stabilities of the crystals. In particular, in the case of molecular crystals, a decrease in temperature to 100–150 K decreases the librations of the molecules or their fragments in crystals as a whole and hence there is an appreciable decrease in the so called "librational" shortening of bonds—an effect attaining 0.02–0.03 Å at ~300 K. On the other hand, the introduction into the diffraction data obtained at the usual temperature of corrections applied to the bond length is not always effective, because the corresponding mathematical models, used in the structural analysis for the description of thermal movements and for the calculation of these corrections,[10] are frequently themselves correct only at low temperatures (since they are based on the small displacement approximation). In addition, it is evident that in many cases the determination from X-ray diffraction data (for molecular crystals) of correct values of the parameters of the anisotropic thermal vibrations (more precisely the mean square displacements) of the atoms is in many cases possible only at low temperatures.[11,12] The progress achieved in recent years in the determination of physically significant parameters of atomic mean square displacements or thermal ellipsoids and the development of methods for the theoretical calculation of these parameters[13,14] and of different criteria of their reliability[15,16] have made possible the extraction from the results of the precision X-ray diffraction experiment of additional new information associated in particular with the determination of the types and energy characteristics of different intramolecular movements in crystals (including movements due to the conformational changes in the molecules) and with the study of the nature of the disorder and phase transitions.

The possibility of obtaining accurate X-ray diffraction data, characterised by the accuracy of the determination of the correct set of kinematic structural amplitudes to within ~1–2% makes it possible to find from the experimental X-ray diffraction data the electron density distribution function for the crystal $\rho(r)$.[17–19] It is important to emphasise that this function defines uniquely the structure and physicochemical properties of the test system (the Hohenberg–Kohn theorem[20]). The latter factor provides a basis for the formulation in the language of electron distribution of various chemical problems (together with other problems), the most important of which involves the establishment of the nature of the chemical bond in compounds of different classes. Here too the experimental determination and visualisation of the characteristic features of the function $\rho(r)$, for example, in the form of electron density distribution maps, makes it possible to obtain valuable information about the nature of the chemical interaction and reactivity of molecules.

The method most widely used in such investigations involves the construction and analysis of maps of the so called deformation electron density (DED), defined as the difference $\delta\rho(r) = \rho(r) - \rho^0(r)$, where $\rho(r)$ is the total electron density of the crystal derived from the experiment, while $\rho^0(r)$ is the calculated electron density of spherically symmetrical non-interacting atoms (of the "premolecule"). The function $\delta\rho(r)$ thus describes the character of the redistribution of electron density on formation of chemical bonds between the initially non-interacting atoms, i.e. permits the "visualisation" of the formation of such bonds. It is significant that DEP maps can be constructed from the results of the X-ray diffraction experiment alone, while the quantity $\rho^0(r)$ can be calculated from the results of the large angle refinement of structures by the least squares method (the so called "$X-X$" method for the construction of DED maps). Bearing in mind that the function $\delta\rho(r)$ generally represents a small difference between two large quantities $\rho(r)$ and $\rho^0(r)$, the experimental determination and calculation of the latter should be carried out with a high accuracy, which can be achieved for molecular crystals in most cases only by using low temperatures and by applying the corrections listed above (for absorption, extinction, etc.) to the diffraction data obtained. This review deals with certain examples of the results of precision (low-temperature) X-ray diffraction analysis for the solution of various chemical problems, mainly associated with the determination of the accurate geometry of the molecules and of the detailed features of the steric structure and the characteristics of thermal vibrations in molecular crystals and also with the establishment of the character of the distribution of electron density.

The review does not consider methodological questions involving the employment and application of various low-temperature devices in X-ray diffraction experiments (such devices have already been considered[7,21]) as well as questions associated with the use of low temperatures for the investigation of low melting and/or metastable compounds (other reviews[1,22] have been devoted to these problems). The principal task of this review is the elucidation and consideration, in relation to a number of examples, of the potential of the method associated with its increasing true accuracy in the low-temperature study of crystals of molecular compounds.



II. Determination of the exact molecular geometry

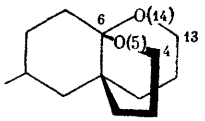
We shall consider certain examples of studies of molecular crystals carried out in order to obtain the exact molecular geometry (with an error of the determination of the interatomic distances between non-hydrogen atoms in the range 0.001–0.003 Å) from diffraction data.

Such studies are extremely important for the development of modern structural chemistry, since they permit a reliable determination of very detailed and in many instances fundamentally important features of the structures of molecules and crystals. As already mentioned, the use of low temperatures is one of the main conditions for the determination of accurate structural results, because it is then possible to measure a sufficient number of "large angle" reflections.

In particular, a recent low-temperature (123 K) study[23] of tolane Ph−C≡C−Ph established that the length of the C≡C triple bond is 1.211(2) Å according to the results of the large angle refinement ($\sin\theta/\lambda > 0.65$ Å^{-1}), whereas refinement of the structure only in terms of the near reflections, which is equivalent to the employment in the experiment of Cu radiation for which $\sin\theta/\lambda < 0.65$ Å^{-1}, yielded a significantly smaller length of this bond: 1.196(2) Å. Thus the effective shortening of the triple bond in the usual experiment is by 0.015 Å for tolane, which is comparable or can even be greater than the real change in the length of this bond due to the electronic conjugation effects.

An X-ray diffraction study of tetra(t-butyl)cyclobutadiene (I) at room temperature[24] showed that the central ring has a nearly square planar geometry.

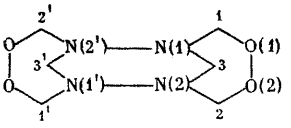
(I)



This conflicted with many other experimental (including X-ray diffraction) and calculated data and forced the authors to postulate the presence of dynamic or static disorder in the crystal of compound (I), leading to the superposition of two orientations of the central rectangular (and not square) ring, differing by a rotation in the plane by 90°. A reinvestigation of compound (I) at 123 K [25] confirmed the existence of such disorder and its diminution at a low temperature led to a decrease in the contribution of the alternative form to 15−30%, which made it possible, in its turn, to establish more correct bond lengths in the ring [1.441(2) and 1.527(2) Å; for other known cyclobutadiene derivatives in which there is no disorder the corresponding distances are 1.34 and 1.60 Å]. We may note that the partial disorder in the molecule of compound (I) at low temperatures can be clearly discovered by means of a detailed analysis of the parameters of atomic thermal displacement (see below).

Other examples are associated with the study of the geometry of arene or other π-complexes of transition metals with cyclic polyene ligands. Quantum-chemical calculations have shown[26] that in the case of such π-complexes of the type $(\eta^n\text{-}C_nH_n)M(CO)_m(XY)$ (n = 3−7, m = 1−3, XY = CO, N_2, NO, CN, M = transition metal) the electronic influence of the metal should reduce the symmetry of the coordinated η^n-cyclic ligand and should give rise to a characteristic change in its geometry. In particular, the alternation of the C−C bond lengths in the benzene ring should be observed for η^6-arene complexes.

Indeed, the alternation of C−C bonds in a six-membered ring was observed in a low-temperature study (77 K) of benzenechromium tricarbonyl $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ the C−C bond eclipsed by CO groups are lengthened compared with the other bonds in the ring by 0.017(2) Å. This small change in molecular geometry is correlated with the characteristics of the electron distribution maps near the Cr atom.[28] Subsequently the effect was confirmed[29] also in a low-temperature diffraction study of similar complexes $(\eta^6\text{-}C_6Me_6)Cr(CO)_3$ [Δ = 0.021(4) Å] and $(\eta^6\text{-}C_6Me_6)Mo(CO)_3$ [Δ = 0.036(9) Å]. However, we emphasise that, as a consequence of the considerable librations of η^6-linked rings at room temperature, this extremely fine electronic effect, which is of fundamental importance for the understanding of the nature of the chemical bond in transition metal π-complexes, could not be recorded experimentally in any of the three compounds indicated.



The effects associated with the manifestation of the so called orbital n,σ^*-interactions belong to the class of important stereoelectronic effects which determine to a large extent the characteristic features of the structure and reactivity of certain molecules of organic and organoelement compounds.[30] Interactions of this type can affect also the geometrical characteristics of the molecules. In particular, according to the results of quantum-chemical calculations for methanediol and methoxymethanol[31,32] in the synclinal (*sc*) and antiperiplanar (*ap*) conformations, the C−O bonds located in the *ap*-position relative to the lone electron pairs (LP) of the O atoms are lengthened relative to the other C−O bonds by 0.025−0.030 Å.

The reliable detection of small geometrical effects of n,σ^*-interactions becomes possible in highly accurate low-temperature X-ray diffraction studies. In particular, the O(5) and O(14) oxygen atoms in the structure of dihydroxypropellane ketal (II), investigated[33] at 98 K, are chemically equivalent but conformationally different: the C(6)−O(14) bond has the *sc*-orientation relative to the O(5)−C(4) bond and hence the *ap*-orientation relative to the LP of the O(5) atom; on the other hand, the C(6)−O(5) bond is characterised by the *ap*-orientation relative to the O(14)−C(13) bond and by the *sc*-orientation relative to the LP of the O(14) atom.

(II)

As a consequence of the different effectiveness of the orbital n,σ^*-interactions, the difference between the C−O bond lengths in the molecule of compound (II) is 0.026(3) Å [C(6)−O(5) = 1.412 Å, C(6)−O(14) = 1.438 Å]. A similar difference between the lengths of the chemically equivalent C(1)−N(1) and C(2)−N(2) bonds (0.025 Å) and between the C(1)−O(1) and C(2)−O(2) bonds (0.017 Å) has been observed in a study of the tricyclic compound (III) (data obtained[34] at 96 K), which is also induced by the different effectiveness of the interaction of the LP of the N(1) and N(2) atoms with the σ* orbitals of the C−O bonds:

(III)

The use of low temperatures gives rise to the possibility of investigating the manifestation of such stereoelectronic effects in crystals of the simplest molecular compounds which are in many instances liquid with low melting points or gases. The methodological questions involving the preparation of single crystals of low-melting compounds from liquids (melts) having melting points ranging from room temperature to about −150 °C needed for studies of this kind have been examined in a number of reviews[1,7,22] and will not be discussed here. We may note only that data on the structures of such usually very simple compounds are of special

interest for structural chemistry: they can be used to investigate the characteristic features of the steric structure of molecules (for example, the geometrical manifestation of various electronic effects) and crystals (the specific features of intermolecular interactions) in a "pure" form, i.e. in those cases where the molecules lack different functional substituents, which, on the one hand, enable the compounds to form crystals stable under the usual conditions, but, on the other hand, influence those properties of the test molecules which are difficult to determine beforehand.

As an example, we shall present data obtained in a recent study of the molecular structure of dimethoxyamine $HN(OMe)_2$ (IV) [35] and tetramethoxyhydrazine $(MeO)_2N-N(OMe)_2$ (V) [36]—the simplest (and low melting) alkoxyamines in which n,σ^*-interactions play an important role according to the available chemical data. The molecular structures of compounds (IV) and (V) and their principal geometrical parameters are presented in Figs. 1*a* and 1*b*.

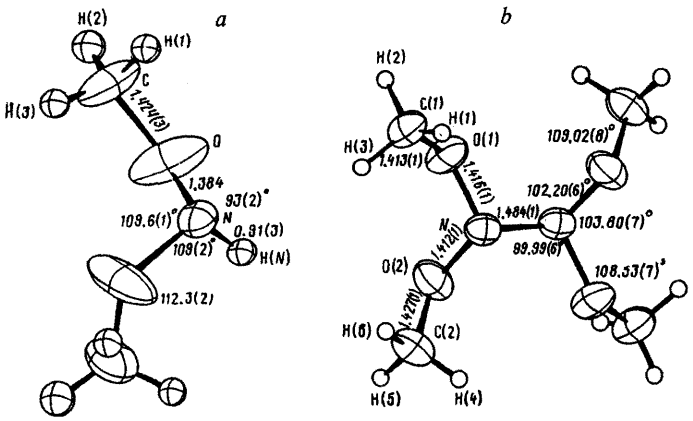


Figure 1. The crystal structure and principal geometrical parameters of the molecules of dimethoxyamine (IV) (*a*) and tetramethoxyhydrazine (V) (*b*).

It has been established that in the crystal of compound (IV) the molecules have a conformation characterised by a CONO torsional angle of 78.7°; the Me groups are then displaced from the ONO plane on either side. Electron diffraction study of this compound in the gas phase and the results of electrooptical measurements in solution established that mainly this conformation of the molecule is retained in the free state and in solution.[35] The preferred retention of this conformation is apparently determined by the fact that it is optimal for the occurrence of the stabilising $n_O-\sigma^*_{NO}$ interaction, as a result of which the N–O bond length in dimethoxyamine is reduced to 1.384(2) Å compared, for example, with 1.496(9) Å in MeO–NH(Me), where there is no such possibility. On the other hand, in the case of tetramethoxyhydrazine (V) (centrosymmetrical molecule, CONO torsional angles of 108° and −132°), the effectiveness of this interaction is smaller than in dimethoxyamine, which lengthens the N–O bonds to 1.414(2) Å. On the other hand, the conformation of compound (V) is favourable for the occurrence of another stabilising interaction of the type $n_O-\sigma^*_{N-N}$ whose occurrence is manifested by the lengthening of the N–N bond in this compound by 0.038 Å compared with hydrazine. It has been noted[37] that the ready homolysis of the N–N bond is a chemical manifestation of this electronic effect.

The interesting question of the relation between the reactivity of molecules, for example, their capacity to undergo dissociation at specific bonds, and the length of such bonds (in the ground electronic state) arises in this instance. A series of studies have been devoted to such questions.[38–42]

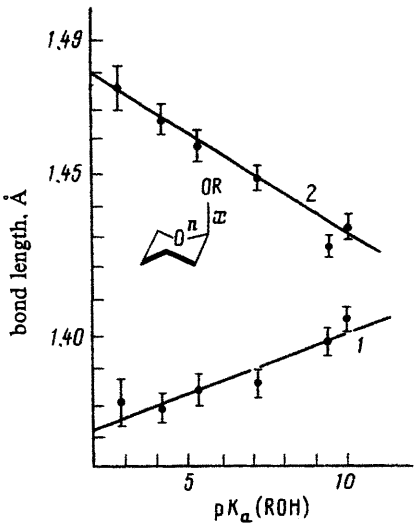

Figure 2. Dependence of the C–O bond lengths in a series of aryl derivatives of tetrahydropyranyl acetals on the pK_a for the corresponding acids ROH:[39] *1*, *n*; *2*, *x*.

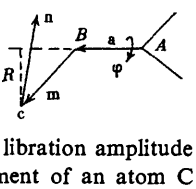
For example, structural and kinetic studies of a series of aryl derivatives of axial tetrahydropyranyl acetals established a linear correlation between the lengths of the endocyclic and exocyclic C–O and C–OAr bonds, on the one hand, and the pK_a of the corresponding conjugate acids ArOH (Fig. 2), on the other. According to Briggs et al.,[39] the pK_a determine the rate constants for the hydrolysis of the acetals, i.e. for the reactions involving the heterolytic dissociation of the C–OAr bond, and hence the free energy of activation. With increase in the effective electronegativity of the OAr substituent as a consequence of the increasing effectiveness of the $n_O-\sigma^*_{C-O}$ interaction, the endocyclic C–O bond is appreciably shortened and the axial C–OAr bond is lengthened, which increases the rate of hydrolysis. The profile of the coordinate of this reaction plotted from the experimental data using the method of structural correlations[41,42] made it possible to estimate the slope of the $\Delta E/\Delta r$ curve in the initial stage of the stretching of the C–OAr bond, which proved to be 260 ± 10 kcal mol^{-1} Å^{-1}. Thus the energy expended on the stretching of the bond of the type under consideration by ~0.01 Å is fairly large and amounts to ~3 kcal mol^{-1}, which necessitates the determination of the geometrical characteristics of the molecules with a high accuracy in studies of this kind. We may also note that, when stereoelectronic effects (for example the anomeric effect) in compounds containing elements of the Third Period (O, S, P) are considered, the corresponding effects of the substituents are much weaker. In particular, the energies and geometries of all the possible molecules of doubly substituted methanes XCH_2Y, in which the substituents X, Y = F, OH, NH_2, Cl, SH, or PH_2 contain elements of the

Second and Third Periods, have been calculated[43] by the SCF LCAO-MO method (in terms of the 3-21G* basis set). It was established that the energy of the interaction of the substituents Cl, SH, and PH_2 is significantly lower than for substituents containing the elements of the Second Period. The geometrical manifestation of these effects should also be apparently weaker; this requires an improved reliability of the structural data for their reliable identification.

III. Analysis of atomic thermal parameters

An important characteristic feature of the precision X-ray diffraction method is the possibility of extracting from diffraction data the correct values of atomic thermal parameters[6,7,9,11,16] or temperature factors.‡ Their analysis permits conclusions about the types and characteristics of the low-frequency motions and/or static atomic displacements occurring in the crystals.



In the case of molecular crystals, such analysis is usually carried out within the framework of the familiar "rigid-body" model,[10] the essential feature of which consists in the separation of atomic vibrations into "external" low-frequency and "internal" high-frequency modes and in the neglect of the contribution of the latter to the temperature factors. Here it is also assumed that static displacements, induced, for example, by the disorder among the atoms in the crystals, are absent. Evidently, as a consequence of the smallness of their amplitude the contribution of the high-frequency vibrations to the temperature factor should be much smaller than that of the low-temperature frequency vibrations. For example, typical mean square amplitudes of the stretching vibrations in organic molecules are 0.001–0.002 Å^2 for non-hydrogen atoms,[44] which is in many cases smaller by an order of magnitude than the values calculated from the experimental temperature factors. As a result, the vibrations of molecules or the vibrations of their constituent components as a whole make the main contribution to the atomic temperature factors for crystals of molecular compounds.

In conformity with the "rigid-body" model considered,[10] the harmonic movement of molecules in the crystal as a whole can be described in the general case with the aid of three tensors: the translational (**T**), librational (**L**), and translational-librational (correlation) (**S**) tensors, containing 20 independent components. The mean square displacements of any atom, i.e. the components of its temperature factor in the harmonic approximation, represented in the form of the so called thermal ellipsoid, can then be expressed in terms of these tensors and also in terms of the equilibrium position of the atom in an explicit form. Thus the description of the thermal motion of a molecule in a crystal containing n independent atoms with the aid of $6n$ temperature parameters of the ellipsoids of thermal vibrations of each atom can be reduced to the consideration of only 20 components of the three **LTS** tensors. These components are determined by the least squares method either using as the "variables" the $6n$ already refined components $U_{ij}(B_{ij}, \beta_{ij})$ of individual temperature factors or by refining the LTS-tensors directly on the basis of diffraction data.[45]

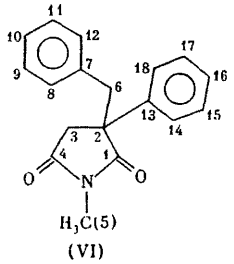
The agreement between these parameters, obtained from diffraction data (U_{ij}^{exp}) and calculated on the basis of the hard body model (U_{ij}^{theor}) is a measure of the physical significance of the temperature parameters and of the suitability of the **LTS** model. Evidently, if the difference $\Delta U_{ij} = U_{ij}^{exp} - U_{ij}^{theor}$ is small and close to the error of the experimental determination $\sigma(U_{ij})$, the temperature parameters correspond to the rigid-body model within the limits of the accuracy attained.

However, it is evident that the model is too simplified and that the discrepancy between U_{ij}^{exp} and U_{ij}^{theor} should not always be understood merely as an indication of an experimental error in the determination of U_{ij}^{exp}. The slow low-frequency ($\omega \leqslant 500$ cm^{-1}) intramolecular vibrations, not taken into account in the **LTS** model, can introduce an appreciable contribution to the values of U_{ij} and the identification of such movements, which can be precursors of conformational transformations in crystals, is in fact of significant interest. Therefore, subsequently, after the appearance of the rigid-body model, other more complex versions of the description of the thermal motion of atoms and crystals were developed. In particular, they make it possible to take into account the non-rigidity of the molecular skeleton. One of the first attempts to take into account the intramolecular movements in the description of atomic thermal parameters was the "riding" model widely used for the description of the thermal movements of terminal atoms in molecules, especially hydrogen atoms.[46] Next, mention should be made of Johnson's model which has been called the "segmented rigid-body" model[47] and was subsequently developed for the description of the thermal motion of macromolecules,[48] and of the studies of Hamilton and co-workers[49] on the torsional oscillations of methyl groups in different organic molecules (on the basis of neutron diffraction data). A method has been proposed recently for analysing the thermal parameters in which it is possible to calculate the force constants of the slow intramolecular movement. It is based on the inclusion in the least squares procedure of the parameters of the quasi-normal modes of these movements together with the simultaneous refinement of the components of the **LTS** tensors.[50] The procedure has been tested successfully in the description of thermal motion in two lipid derivatives characterised by significant torsional librations about the single bonds linking the rigid cyclic molecular skeleton to the flexible aliphatic chains.

A fairly simple one-parameter model, in which together with the calculation of the corresponding **LTS** tensors there is a possibility of taking into account and calculating the amplitudes of intramolecular torsional vibrations, has been developed in recent years for practical applications in studies of this kind.[51,52] In this model, a single parameter φ (the libration amplitude) is introduced for each atom or group of atoms which can execute torsional vibrations about the given bond (for example, the vibrations of a C atom about an A–B bond).

$$\mathbf{n} = \mathbf{m} \times \mathbf{a} / |\mathbf{m} \times \mathbf{a}|;$$
$$R = |\mathbf{m} \times \mathbf{a}| / |\mathbf{a}|.$$

If the libration amplitude is not too great, it can be regarded as the movement of an atom C in the direction of a unit vector **n**. The additional displacement of the atom C as a result of such intramolecular movement is φR and this movement is superimposed on the displacement of the molecule in the crystal as a whole. The mean square amplitude $\langle\varphi^2\rangle$ as well as the components of the **LTS** tensors are refined by the least squares method. The model

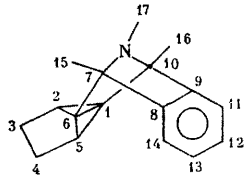


‡ It has recently become common usage to call these parameters the parameters of the mean square displacement amplitudes (the English abbreviation is MSDA), because not only atomic vibrations but also different kinds of static displacements of atoms from equilibrium positions contribute to the Debye–Waller factor (the "temperature" factor).

considered proved to be extremely efficient and suitable for the description of intramolecular movements in crystals with fairly large torsional amplitudes ($\varphi < 20-25°$).

However, in the general case, in the analysis and interpretation of the temperature parameters within the framework of the simple rigid-body LTS model or when its more complex versions are used, difficulties frequently arise which are both associated with the unduly high degree of simplification of the models and are purely mathematical.[53] Therefore, in the interpretation of the temperature parameters, the search for other criteria of their quality and reliability becomes important.

For molecular crystals, one of the ways of testing the quality of atomic thermal parameters and of discovering the types of intramolecular movements (or disorder) occurring in crystals involves the calculation of the differences Δ between the mean square amplitudes of the opposed vibrations of pairs of atoms in the direction of the chemical bond between them (the so called Hirshfeld test[15] of the "rigidity" of the bond: $\Delta_{AB} = Z^2_{AB} - Z^2_{BA}$, where Z^2 is the projection of the mean square vibration amplitudes of the atoms A and B onto the direction of the A–B bond in the compound investigated). If Δ_{AB} is small ($\lesssim 10^{-4}$ Å^2) for the given chemical bond between the atoms A and B in the molecule, which corresponds to significantly smaller amplitudes of the stretching vibrations of the atoms compared with the vibrations of the molecules in the crystal as a whole, then the thermal ellipsoids for the atoms A and B correctly reproduce the character of the atomic movement. On the other hand, if Δ is significantly greater than 10^{-4} Å^2, then some other additional atomic displacements apparently contribute to the thermal parameters of the atoms A and B or there is a systematic error in their calculation. For structurally rigid systems, for example for molecules with three-dimensional frameworks or for cyclic systems, with correctly determined thermal parameters, the values of Δ should be small also for all pairs of atoms not linked by valence bonds, confirming the rigidity of the entire molecular skeleton. However, if the test of the rigidity of chemical bonds is positive and the calculation of Δ for certain pairs of chemically non-bonded atoms in the molecule yields values of Δ much greater than 10^{-4} Å^2, this result can indicate the occurrence in the given molecule of definite types of intramolecular movements. Such calculation of the values of Δ has been frequently used recently to elucidate the types of such movements.[16]



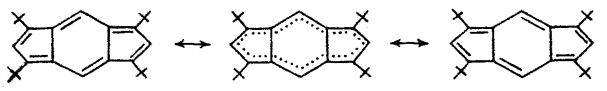
As one of the examples of the analysis of the values of Δ, we shall consider the result of the study of a crystal of 3-benzyl-*N*-methyl-3-phenylsuccinimide (VI) at 100 K:[54]

(VI)

The average value of Δ for all 23 pairs of chemically bonded atoms in compound (VI) is 21×10^{-4} Å^2, which is comparable to the values of $\sigma(\Delta) \simeq 15 \times 10^{-4}$ Å^2. The values of Δ for pairs of atoms linked by valence bonds in three fragments, namely the *N*-methylsuccinimide fragment (8 atoms), the benzyl fragment (7 atoms), and the phenyl fragment (6 atoms), are also small, amounting to 19, 24, and 11 ($\times 10^{-4}$ Å^2) respectively, which indicates their structural rigidity. On the other hand, calculation of the average values of Δ for pairs of non-bonded atoms belonging to different fragments indicates the non-rigidity of the molecular skeleton of compound (VI) as a whole: $\Delta = 71 \times 10^{-4}$ Å^2 (imide–benzyl), 38×10^{-4} Å^2 (imide–phenyl), and 44×10^{-4} Å^2 (benzyl–phenyl). This structural non-rigidity is probably due to the possibility of the torsional vibrations of the three rings relative to the C(2)–C(6), C(7)–C(6), and C(2)–C(13) single bonds of the central fragment of the molecule of compound (VI).

In the study of the structure of the [3.1.1]propellane derivative (VII), it was established (structural data for 95 K [55]) that, for all the pairs of chemically bonded atoms, the Hirshfeld test of the rigidity of the bonds is positive with a high degree of accuracy [$\Delta_{av} = 3(7) \times 10^{-4}$ Å^2], which indicates a high quality of the diffraction data. The molecule as a whole is also fairly rigid — the average value of Δ for all the pairs of atoms not linked by valence bonds [with the exception of pairs with participation of the C(17) atom of the methyl group attached to the N atom] is less than 10×10^{-4} Å^2.

(VII)



Calculation of the values of Δ for the non-bonded pairs of atoms with participation of the C(17) atom shows, however, that there is an appreciable movement of this atom relative to the C(8)–C(14) carbon atoms on the right-hand side of the molecule [displacement in the direction C(17)...C(8)–C(14)]. On the other hand, such additional countermovement has not been observed relative to the atoms in the left-hand part of the molecule [the C(1)–C(7), C(10), C(15), and C(16) atoms]:

	C(1)÷C(7), C(10), C(15), C(16)	C(8)	C(9)	C(11)	C(12)	C(13)	C(14)
Δ ($\times 10^4$ Å^2)	0–6	17	21	33	39	38	25

Thus the additional movement (detected in the thermal parameters of the structure) of the C(17) atom of the methyl group takes place along an arc around the nitrogen atom, i.e. it corresponds to the beginning of the possible route to the inversion of the configuration at this atom.

Calculation of the differences Δ for the same compound, investigated at different temperatures, makes it possible in a number of instances to establish the most readily "frozen out" types of intramolecular vibrations. In particular, a study[56] of the trigonal-bipyramidal phosphorane $Cl_3P(CCl_3)_2$ (VIII) at 153 K demonstrated the structural rigidity of the molecule: calculation of the differences Δ for all the chemically bonded and also non-bonded pairs of atoms at distances $\lesssim 3.2$ Å yields the mean square value $\Delta = 7 \times 10^{-4}$ Å^2. On the other hand, the analogous calculation using high-temperature data (300 K [57]) leads to $\Delta = 85 \times 10^{-4}$ Å^2; the pairs of atoms not linked by valence bonds and including atoms of only one of the two CCl_3 groups are characterised by the maximum values of Δ [$\Delta = (112-166) \times 10^{-4}$ Å^2]. This evidently indicates the additional libration of this group in the crystal, which was also detected from ^{35}Cl NQR data. The barrier to the rotation of this group, estimated from diffraction data, proved to be approximately 57 kJ mol^{-1}.[58] The possibility of the libration of only one of the two CCl_3 groups is due to their different environments in the crystal.

Naturally, it is difficult to establish the occurrence of a specific type of intramolecular movements (or the presence of disorder) in crystals by analysing only the values of Δ. However, calculation of Δ is a very simple and reliable criterion for discovering the presence of these effects. For example, in the study of the cyclobutadiene derivatives (I) at 123 K [25] already mentioned, the presence of residual ring disorder is manifested by the relatively large value of $\Delta_{C,C}$ (compared with other values) for the carbon atoms of the central ring ($\Delta_{C,C} = 19 \times 10^{-4}$ Å^2). On the other hand, the study of the structure of the derivative of S-indacene (IX) at room and low (100 K) temperatures showed[59] that the molecule in the crystal has the intrinsic D_{2h} symmetry of the carbocycle, which corresponds to the equalised structure (B) and agrees with ^{13}C NMR data:[60]

(IX, A) (IX, B) (IX, C)

Analysis of the differences $\Delta_{C,C}$ for the ring carbon atoms in the molecule of compound (IX) confirmed its structural rigidity ($<\Delta^2_{C,C}>^{1/2} = 7 \times 10^{-4}$ Å^2), which rules out the possibility of the coexistence of the valence isomers (A) and (C) in the crystal. This result forced the authors[59] to put forward the hypothesis that in the case under consideration there is a possibility either of the stabilisation in the crystal of the delocalised non-aromatic 12 π-electron system or the geometry of the molecule corresponds to the transition state of the valence isomerisation reaction stabilised by crystal packing.

In view of the foregoing, it appears useful to analyse the values of Δ for crystals of different tautomeric compounds and also for crystals of compounds with strong hydrogen bonds (for example, of the type O−H...O) and a central H atom. Such analysis makes it possible to discover the contribution to the structure observed in the crystal by possible "limiting" valence forms.

More important information about the intramolecular movements is obtained (which makes it possible to establish not only a qualitative but also a quantitative measure of such movements) using the one-parameter model discussed above,[51,52] on the basis of which it is possible to calculate the mean square amplitudes of the intramolecular torsional vibrations $<\varphi^2>$. Next, it is possible to calculate, using familiar formulae, the force constants f and other characteristics of such movements:[16,61]

$$f = kT/\langle\varphi^2\rangle. \quad (1)$$

Strictly speaking, in the calculation of the libration force constant ($f = 4\pi^2 I\nu^2$, where I is the moment of inertia and ν is the frequency in cm^{-1}), one should use a quantum-chemical expression for $<\varphi^2>$:

$$\langle\varphi^2\rangle = \frac{h}{8\pi^2 I\nu^2}\,\mathrm{Coth}\left(\frac{h\nu}{2kT}\right). \quad (2)$$

However, it has been shown[61] that Eqn. (2) reduces to the classical Eqn. (1) to within at least 1% for frequencies $\nu < 0.2\ T$ (ν is expressed in cm^{-1} and T in K), which is valid at normal temperatures for almost all groups except $-CH_2$, $-CH_3$, $-NH_2$, and $-NH_3$. Having specified the usual form of the rotational potential V [$V = B(1 - \cos n\varphi)/2$], where B is the height of the potential barrier, and having expanded V in series, we obtain

$$V = \frac{B}{2}[1 - (1 - n^2\varphi^2/2 + \ldots)] \simeq \frac{Bn^2\varphi^2}{4}. \quad (3)$$

Having set this expression equal to $V = f\varphi^2/2$, we have in the classical limit

$$B \simeq 2f/n^2 = 2kT/n^2\langle\varphi^2\rangle. \quad (4)$$

Thus, not only the frequencies and force constants but also the heights of the barriers to slow intramolecular vibrations in crystals can be estimated from the values of $<\varphi^2>$ determined from diffraction data. On the assumption that the selected form of the cosinusoidal potential is valid, Eqn. (4) proved to be sufficiently accurate (the error is less than 10%), provided that the height of the barrier B exceeds $12kT/n^2$,[61] i.e. provided that the mean square amplitude $<\varphi^2> < 0.17$ rad^2 ($\varphi < 25$ °C). The possible barriers B as well as the frequencies and force constants for more than 300 groups have been estimated[61] on the basis of the corresponding calculations of the quantity $<\varphi^2>$ from the experimental temperature parameters $U_{i,j}$ for 125 different structures of molecular crystals using data from the Cambridge Crystallographic Data Centre. Certain results, including those obtained recently,[58,62] are presented in Table 1, which shows that the calculated barriers fall within the range found by means of other methods. Such estimates may prove useful, particularly in the absence of the corresponding experimental data obtained by other methods (non-elastic scattering of neutrons, relaxation NMR methods, NQR spectroscopy, etc.), or in comparing the results obtained by different methods. In this connection, we may note the tabulated (Table 1) estimates of the barriers to the rotation of the cyclopentadienyl and permethylated cyclopentadienyl rings in metallocenes, for which a good agreement has been observed with the results found by NMR relaxation methods, as well as the data for the barriers to rotation in phosphazo-compounds, which agree with the studies of these compounds by the NQR method.

Table 1. The barriers to the intramolecular movements of certain atomic groups in crystals estimated from X-ray diffraction data.[58,61,62]

Group	Atom linked to group	Height of barrier, kJ mol^{-1}	
		calc. by Eqn. (4)	from data obtained by other methods
$-CH_3$*	Trigonal C, N Tetrahedral C, N, P O	B_3 = 1.5–9.6 B_3 = 4–26 (cf. Ref.11) B_3 = 1–9 (cf. Ref.4)	1.2–8.5 (crystal) 12–22 (gas) 4.5 (CH_3OH gas) 15–19 (crystal)
$-CF_3$	Trigonal C Tetrahedral C	B_3 = 4–10 (cf. Ref.7) B_3 = 8–66 (cf. Ref.25)	4–7 (gas) 13–25 (gas) 11–17 (crystal, NMR)
$=PCl_3$	Trigonal N in phosphazo-compounds $Cl_3P=NR$	B_3 = 31–58	21–38 (crystal, NQR, NMR)
η^5-C_5H_5	Transition metals, Fe, Ni, Rh, Ru, Os	B_5 = 7–23	10–25 (crystal, NMR non-elastic neutron scattering)
η^5-C_5Me_4	Transition metals, Fe, Ru, Os	B_5 = 9–19	10–30 (crystal, NMR)

*From neutron diffraction data.

Multitemperature studies have played an important role in the investigation of the characteristics and features of the thermal vibrations of atoms in crystals. In the first place, such studies make

it possible to investigate the nature of the disorder,[7] revealing its static (associated with the coexistence in the same positions in the crystal of several different molecular orientations or conformations or with the multidomain nature of the specimen) or dynamic (associated with slow intramolecular movements characterised by a high amplitude) character. Such separation of the different types of ordering is naturally arbitrary because it can be determined only by the height of the barrier separating the crystal different orientations and conformers located in the same position in the crystal; furthermore, there is also a possibility of the presence in the crystal of both types of disorder.

Under the conditions of disordering of a static type, cooling of the crystals to specified temperatures should not lead to a consistent decrease in the temperature factors of the atoms in the disordered groups, which is natural since in the given instance large temperature parameters usually reflect only the presence in the crystal of molecules (or their fragments) with other orientations and conformations and not the occurrence of any atomic movement. On the other hand, in the study of systems with dynamic disorder one may expect a fairly sharp decrease in the temperature parameters of certain atoms in the structure when the temperature is reduced, since usually this type of disorder is associated with movements characterised by a fairly large amplitude and a low frequency, i.e. with the most readily "frozen out" types of vibrations. Certain examples of the use of low-temperature data in order to reduce disorder were examined above.

One may also note that the energy characteristics of the process considered can also be estimated from the analysis of the temperature variation of the populations of the individual sites in dynamically disordered structures. Thus a multitemperature study of 1,3,5-tribenzyl-1,3,5-triazacyclohexane (X) at 293, 268, 250, and 127 K [63] showed that the populations of the axial and equatorial positions of the N atoms change consistently with temperature, which corresponds to their inversion. The values of ΔH° and ΔS° for the inversion of the N atoms were calculated from diffraction data. Other examples of similar estimates were considered elsewhere.[11]

In a number of instances, interesting qualitative conclusions about the character of the conformational and sometimes chemical transformations of molecules in crystals can be reached only by analysing the shape of the thermal atomic ellipsoids. For example, in crystals containing molecules and complexes with saturated flexible five-membered rings, including metallocycles, one observes fairly frequently at room temperature a conformational disorder of the latter as a result of which two conformers coexist in the crystal (each has the half-chair form). The transition between them takes place via a pseudorotation mechanism.[64]

Numerous ethylenediamine complexes of metals constitutes a large group of such compounds. The individual orientations of the rings on electron density maps for such systems are usually not observed and disorder is as a rule manifested by the significant extension of the ellipsoids of the thermal vibrations of the C atoms of the ethylenediamine (en) ligands at right angles to the plane of the effectively flattened five-membered ring. The calculated effective amplitudes of the vibrations of the C atoms at right angles to the plane of the ring are anomalously large and amount to 0.3–0.4 Å; the C–C single bond then proves unrealistically short (~1.4 Å).[64] This disorder evidently has a dynamic nature, since, on cooling the crystals of these compounds, the metallocycles exhibit the half-chair conformation characteristic of them and the geometry of the ring becomes "normal". A similar change has been observed in a study of the complex $Cr(en)_3(SCN)_3.0.75H_2O$ in the temperature range 293–133 K,[65] the transition being fully reversible and continuous in character.

A similar disorder of the five-membered pyrrolidine ring has been observed in an X-ray diffraction study of sodium pyrrolidine-1-carbodithioate dihydrate $Na[S_2CN(CH_2)_4].2H_2O$ (XI) at 295, 150, and 27 K.[66] At 295 K, the ring is effectively flattened [the displacements of the C(4) and C(5) atoms from the plane of the S(1), C(1), and N atoms are 0.245(5) and −0.151(7) Å respectively], and thermal ellipsoids of the C(4) and C(5) atoms are greatly extended in the direction at right angles to the plane of the ring (Fig. 3), and, as a consequence of conformational disorder, the C(4)–C(5) single bond is unrealistically short: its length is 1.394(8) Å. At 150 K, the disorder is only partly frozen out [the displacements of the C(4) and C(5) atoms from the above plane are 0.269(6) and −0.259(6) Å respectively and the bond length C(4)–C(5) = 1.419(8) Å], in agreement with the height of the barrier to the pseudorotation of the pyrrolidine ring, which is commensurate with kT at 150 K. Complete ordering of the structure takes place at 27 K: the ring has the half-chair conformation, the displacements of the C(4) and C(5) atoms from the plane are 0.328(7) and −0.373(7) Å, and the bond length C(4)–C(5) = 1.511(10) Å, i.e. has the usual value for a $C(sp^3)–C(sp^3)$ single bond.

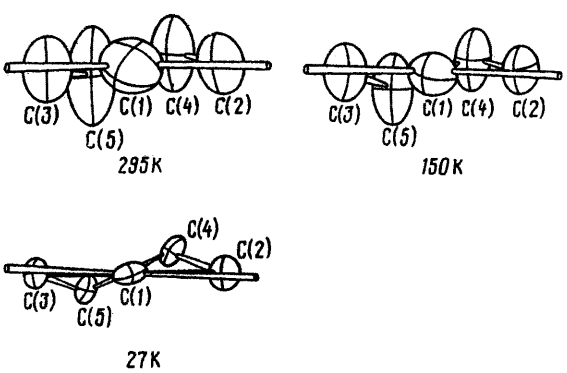


Figure 3. General form of the pyrrolidine ligand along the C(1)–N bond in the structure of sodium pyrrolidine-1-carbdithioate dihydrate (XI) at three temperatures (295, 150, and 27 K); the atoms are represented by thermal vibration probability ellipsoids.[66]

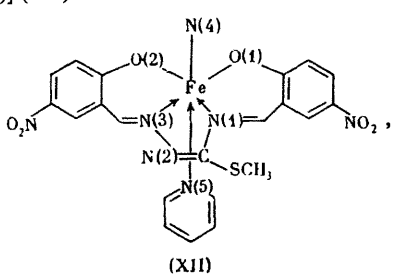
Analysis of the parameters of the atomic thermal displacements has also proved important in the study of many physical properties of crystals,[11] in particular in the study of the mechanisms of the structural and magnetic (spin) phase transitions, in the study of the properties of the liquid crystal state (the mesogen molecules are usually characterised by the presence of a hard central core and mobile side groups, which in the crystal execute much more vigorous vibrations than the central core of the molecule[67]), and in the study of biological macromolecules.[68,69]



As an example, we shall consider the interesting type of disorder in a crystal, observed in the study of complexes containing Jahn–Teller ions (for example, Cu^{2+}) or compounds with spin transitions of the type "high-spin–low spin" in different octahedral iron complexes.

The degenerate electronic ground state ^2E_g of the Cu^{2+} ion for the ideal octahedral coordination of $[CuL_6]^{2+}$ (L is any ligand) is known to be unstable as a consequence of the Jahn–Teller effect, as a result of which the symmetry of the ion is reduced in order to remove the degeneracy.[70] The octahedral coordination of the ion is distorted, for example, to the tetragonal coordination, and these distortions actually lead to the disordering of the structure (because the tetragonal distortion axis can be any of the three directions in the octahedron). However, these distortions can be frequently small and they can therefore be detected only from the anomalous values of the temperature parameters of the $[CuL_6]$ fragment, which retains the average symmetry of the octahedron. Such anomalies are observed in the calculation of the differences Δ between the mean square "opposed" amplitudes of the atomic vibrations mentioned above. Table 2 presents data[42] for two isostructural compounds of the type $K_2PbM(NO_2)_6$ (M = Cu, Ni) characterised by the ideal octahedral symmetry of the anions $[M(NO_2)_6]^{4-}$ (all the M–N bonds are crystallographically equivalent).[42] The significant difference between the structures consists, however, in the fact that the Cu^{2+} complex is characterised by Jahn–Teller distortions and the existence of the ideal octahedron is therefore impossible for such an ion and the structure observed in the crystal is in essence disordered. As a consequence of this, the differences $\Delta_{M,N}$ for two the isostructural compounds differ almost by an order of magnitude: 0.0208(20) and 0.0022(10) Å^2. The magnitude of the Jahn–Teller distortion can be calculated from these differences (~0.14 Å).

Table 2. The mean square amplitudes U(Å^2) of the vibrations of the M (Cu, Ni) and N atoms in the direction of the bonds between them in the octahedral anions $[M(NO_2)_6]^{4-}$, the differences between them $\Delta_{M,N}$, and the distances R_{M-N}.[42]

Parameter	$[Cu(NO_2)_6]^{4-}$	$[Ni(NO_2)_6]^{4-}$
U_N	0.0380 (20)	0.0132 (9)
U_M	0.0172 (1)	0.0110 (1)
$\Delta_{M,N}$	0.0208 (20)	0.0022 (10)
R_{M-N}, Å	2.111 (4)	2.080 (2)

The study of an octahedral iron complex with a tetradentate asymmetric *S*-methylisothiosemicarbazide ligand L, i.e. [Fe(Py)(L).(NCS)] (XII)

(XII)

at 293 and 163 K showed[71] that, when the temperature is reduced, there is an appreciable change in the geometry of the coordination unit of the Fe atom, which can be caused by the transition of the metal atom to a low-spin state on cooling the specimen.

According to EPR and Mössbauer spectroscopic data, the Fe(3+) atom in compound (XII) is in a high-spin (S = 5/2) state at room temperature, while on cooling the compound a continuous phase transition to a low-spin (S = 1/2) state takes place, the transition being completed only at ~80 K. According to the results of Mössbauer analysis, the content of the high-spin form at 163 K (the temperature of the diffraction experiment) diminishes to ~20%, which alters significantly the geometry of the Fe octahedron: it contracts and the Fe–N bond involving the N(5) atom of the Py ligand is shortened by 0.105(4) Å; the decrease in the length of other Fe–N bonds is by 0.045–0.076(4) Å. At 163 K, the geometrical parameters of the FeN_4O_2 units are found to be close to those characteristic of the corresponding low-spin Fe(3+) complexes. However, the "failure" of the spin transition to reach completion at 163 K, i.e. the presence in the crystal of a residual disorder, is manifested distinctly by the anomalous values of the atomic thermal structural parameters at a low temperature. Thus the average value of the Hirshfeld differences Δ for the Fe–N and Fe–O bonds at 293 K (100% of the high-spin form) is 31 × 10^{-4} Å^2, whereas at 163 K (20% of the high-spin form and 80% of the low-spin form) this value increases by a factor of 3 to 91 × 10^{-4} Å^2. There is a corresponding sharp impairment at 163 K also of the formal parameters of the **LTS** model (R = 5.6% at 293 K and R = 18.6% at 163 K). (In the calculation of the **LTS** tensors, account was taken only of the atoms in the immediate environment of the metal.) The examples presented show that the parameters of the atomic thermal displacements can serve as reliable "indicators" of fine structural changes in crystals, in particular those associated with different phase transitions.

In conclusion of this part of the review, we may note that a real possibility of the extraction from precision X-ray data of quantitative information about the effective (one-particle) potentials of atoms in crystals has appeared recently.[72] The individual atomic temperature factors T(**q**) (**q** is the scattering vector) are Fourier transforms of the distribution function $P(R)$ (the probability density function) of the positions of the nuclei or electron density centroids (in neutron and X-ray diffraction respectively). In the classical high-temperature approximation, the function $P(R)$ can be written in the form

$$P(R) = \exp[-V(R)/kT] \Big/ \int \exp[-V(R)/kT]\, dR, \qquad (5)$$

where $V(R)$ is the potential energy of an atom vibrating in the effective field of its neighbours. Series expansion of $V(R)$ in powers of the displacement relative to the equilibrium position and the use of the quasi-harmonic approximation[72] makes it possible to recover the effective potential of the given atom in the crystal from the coefficients of the expansion. The expansion coefficients are usually refined by the least squares method. It is significant that the expansion need not necessarily be restricted to the harmonic members of the series; within the framework of this approach, it is also possible to take into account the anharmonicity of the atomic vibrations.

The first calculations of the effective atomic potentials were associated with the study of ionic conductivity[73] and the precision study of the electron distribution and anharmonicity of the atomic vibrations in the crystals of simple inorganic compounds.[74] Subsequently this approach was extended to studies on more complex compounds, in particular it was used to calculate the effective potentials of copper atoms in high-temperature

superconductors.[75] On the other hand, the concept of effective atomic potentials can prove useful also for the solution of various crystal-chemical problems. In particular, the force constants and the characteristic frequencies of the chemical bonds are related to the parameters of such potentials. The determination of the specific character of such a bond will probably make it possible to investigate at a higher level the different dynamic processes in crystals.

IV. Study of the distribution of electron density in crystals

The experimental determination of the distribution of electron density $\rho(r)$ in crystals and the discovery of the fine electronic structure of the chemical bond are some of the most important aspects of modern X-ray diffraction analysis.[6,17–19,76] Such studies make it possible to examine the principal ideas, which have become traditional, concerning the nature of the chemical bond in the language of the observed distribution $\rho(r)$. As already mentioned, the commonest method of investigation of the characteristics of the function $\rho(r)$ is the analysis of maps of the deformation electron density $\delta\rho(r)$ (DED), which has a simple significance. In particular, the form, position, and height of the $\delta\rho(r)$ maxima and/or minima relative to the atomic nuclei and lines connecting the chemically bound atoms make it possible to "visualise" the most important features of the electronic structure of molecules and crystals in the region of chemical bonds of different types.

The main principles of the interpretation of electron distribution maps have been described in a number of reviews[76–79] and monographs[17–19] and therefore there is no need to dwell on them in detail. We shall confine ourselves to characteristic examples of studies in recent years, referring mainly to the precision low-temperature study of the distribution of electron density in the crystals of simplest (usually low-melting) molecular compounds as well as certain more complex compounds of new types for which experimental electron distribution data were lacking until recently.

The importance of such investigations of the simplest compounds is determined primarily by the possiblity of carrying out for the purpose of such research of non-empirical quantum-chemical calculations of the electron distribution with a high level of accuracy, which makes it possible to compare theoretical and experimental data and to test the principal theoretical concepts developed for the description of the nature of the chemical bond. A critical comparison of such theoretical and experimental results has been made.[80,81] In addition, the fraction of valence electrons is frequently a maximum precisely in the crystals of the simplest compounds and the corresponding characteristic features of the DED maps, associated with the redistribution of the outer electrons of the atoms and the formation of chemical bonds, can therefore be recorded experimentally with a high accuracy and reliability.

We may note that the modern non-empirical calculations for molecules with a small number of electrons ($\sim$20–25) make it possible to evaluate the electron density in the internuclear space to within 0.05–0.10 e Å^{-3}. The possibilities of the diffraction experiment in the determination of the function $\rho(r)$ are somewhat greater — the accuracy of the determination of electron density in the region of the chemical bond reaches 0.02–0.04 e Å^{-3}.[18]

Apart from this, the X-ray diffraction method is applicable to the study of the electron distribution in complex polyatomic crystals and also in crystals containing the atoms of heavy elements ($Z < 70$). Non-empirical quantum-chemical calculations for such compounds, which require a high level of accuracy, are so far extremely laborious and few have been performed. Because of this, the precision X-ray diffraction method frequently proved to be the only available procedure whereby data can be obtained on the electron distribution in the study of complex compounds. The latter factor is extremely significant in the investigation of the distribution of electron density and of the characteristic features of the chemical bond in crystals of compounds of new types.

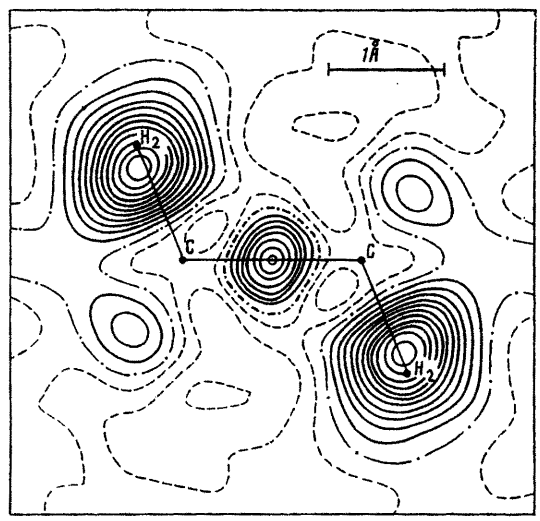


Figure 4. DED section through the transoid H–C–C–H fragment of the ethane molecule.[82] In this and subsequent figures, the continuous contours on the DED maps correspond to positive DED, the dashed lines correspond to negative DED, and dot and dash lines correspond to zero DED. The isolines are drawn at 0.05 e Å^{-3} intervals. [In the calculation of the DED for the ethane molecule, the electron density of the H atoms was not subtracted from the total density $\rho(r)$.]

Examination of the characteristic DED maps in the region of different chemical bonds can be usefully begun with the analysis of the results of the study of ethane, ethylene, and acetylene crystals — the simplest organic molecules containing single, double, and triple bonds between carbon atoms.[82] For the ethane molecule (data at 85 K), the DED section in the plane of the H–C–C–H transoid fragment is characterised by the presence of a distinct symmetrical maximum 0.35(4) e Å^{-3} high and located midway between the C atoms (Fig. 4). This result is consistent with the concept of the formation in ethane of a single covalent σ-bond (the C–C bond length in the crystal is 1.532 Å). In ethylene, the DED maximum on the C=C double bond with a length of 1.313 Å (data at 85 K) is characterised by a greater height (0.50 e Å^{-3}, Fig. 5*a*) and the presence of the π-component in the bond is manifested by a distinct extension of the DED maximum in the direction at right angles to the plane of the molecule and the bond line (Fig. 5*b*). The effectiveness of this π-interaction can probably be estimated from the degree of elongation of the ellipsoidal section (the ratio of the half-axes of the ellipse) in the plane at right angles to the

bond line. It is of interest to compare the result with the value of the so called bond "ellipticity" (ε) in ethylene $\varepsilon = \lambda_1/\lambda_2 - 1 = 0.74$, calculated quantum-chemically from electron density $\rho(r)$ data, where λ_1 and λ_2 are the eigenvalues of the $\rho(r)$ Hessian matrix in two mutually perpendicular directions at right angles to the bond line.[83]

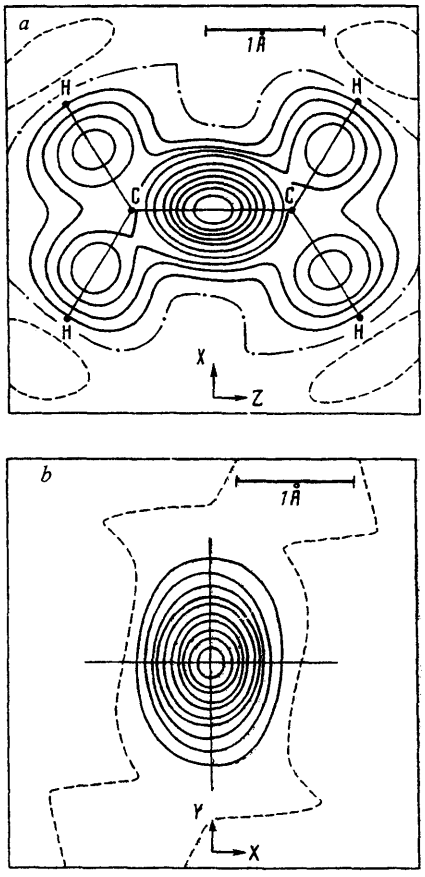

Figure 5. DED sections through the ethylene molecule in the plane of the latter (*a*) and in the plane perpendicular to the C—C bond and passing through its centre (*b*). The contours are drawn at 0.05 e Å^{-3} intervals.

The DED sections through the acetylene molecule (data at 141 K) are presented in Figs. 6*a* and 6*b*. The height of the DED maximum at the centre of the C≡C triple bond (1.182 Å) is 0.60 e Å^{-3} and the DED map actually coincides quantitatively with the results of the theoretical calculation for C_2H_2.[82] We emphasise that, since two π-bonds are formed in ethylene in mutually perpendicular directions, it follows that in the section normal to the C≡C bond line the characteristic ellipticity of the DED maximum is no longer observed (Fig. 6*b*).

The DED section in the plane of the C atoms of the cyclopropane molecule is illustrated in Fig. 7 (structural data[84] obtained at 94 K). It is characterised by the presence of distinct maxima located between the nuclei of the C atoms and displaced from the C—C bond line to the outer side of the triangle. The magnitude of the

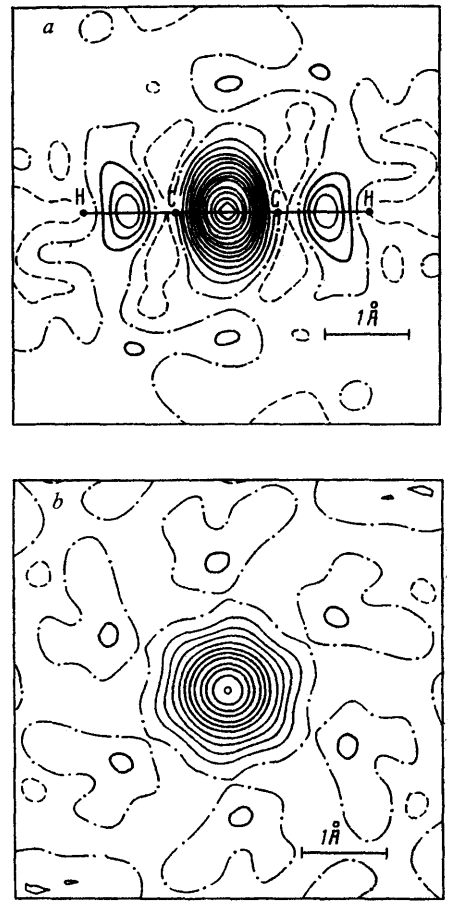

Figure 6. A DED map for the acetylene molecule (*a*) and the section in the plane perpendicular to the triple bond and passing through the centre of the molecule (*b*). The contours have been drawn at 0.05 e Å^{-3} intervals.

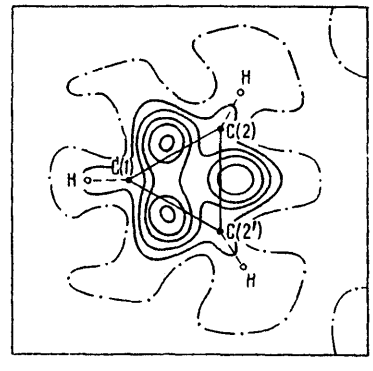

Figure 7. DED section through the plane of the C atoms of the cyclopropane molecule. The contours have been drawn at 0.05 e Å^{-3} intervals.

displacement is ~0.20 Å which constitutes clear confirmation of the ideas concerning "bent" bonds in strained small rings. A similar displacement of the DED maxima from the C–C bond line has been observed also in a series of other investigations of compounds with small rings or with strained three-membered frameworks. For example, in the tetra(t-butyl)tetrahedrane molecule, the DED maxima are displaced to the outer side of the tetrahedral molecular framework by 0.36 Å.[85] In perfluorotricyclooctane C_8F_{12} (XIII) (Fig. 8), investigated[86] at 163 K and containing condensed saturated four-membered rings, the DED maxima are displaced from the C–C bond line to a much lesser extent (~0.15 Å), which indicates a smaller bond strain in four-membered carbocycles compared with the three-membered rings.

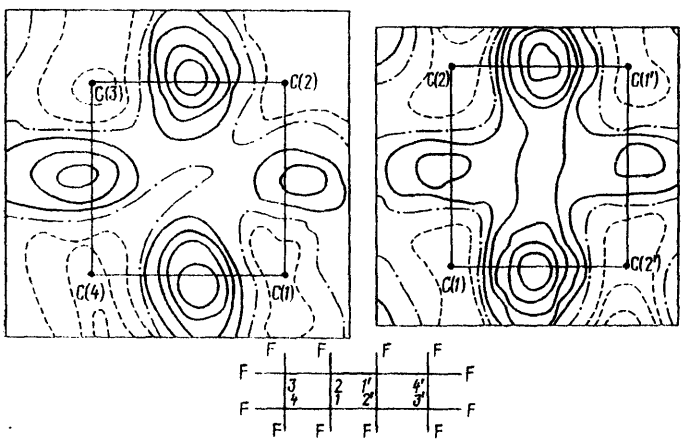

Figure 8. DED section in perfluorotricyclooctane (XIII) drawn through the planes of the four-membered rings of the molecule. The contours have been drawn at 0.1 e Å^{-3} intervals.

The examples considered above referred to molecules of organic compounds whose chemical bonds can be described within the framework of ideas concerning the formation of such compounds via the generation of localised two-centre bonds in them. In compounds where significantly **many-centre bonds with electron delocalisation** are formed according to existing ideas (for example in the molecules of borane or carbaboranes and in the cluster compounds of metals), the distribution of DED in the region of the bond is different. Figs. 9*a* and 9*b* present DED maps in sections drawn through the carbaborane nucleus (Fig. 9*a*) and the triangular B_3 and B_2C faces (Fig. 9*b*) of the icosahedron in the structure of 9-azido-*m*-carbaborane (XIV) [87] (the structural data were obtained at 163 K). In compound (XIV), the DED maxima are not distinctly localised on the B–B and B–C edges of the icosahedron or near the line connecting the atomic nuclei, as happens in the examples considered above. The excess (positive) DED is in fact distributed continuously in the region of the triangular faces but with a slight displacement of the DED on the B_2C face in the direction of the more electronegative C atom. The section through the centre of the icosahedron (Fig. 9*a*) shows that within the carbaborane framework the DED has a negative value (–0.16 e Å^{-3}) and the entire excess electron density is concentrated in a small spherical surface layer of the icosahedron and its distribution is virtually continuous. Thus, judging from the DED maps, the bonds in carbaboranes are formed as a result of the surface delocalisation of electron density, which agrees with the theoretical ideas put forward previously.[88]

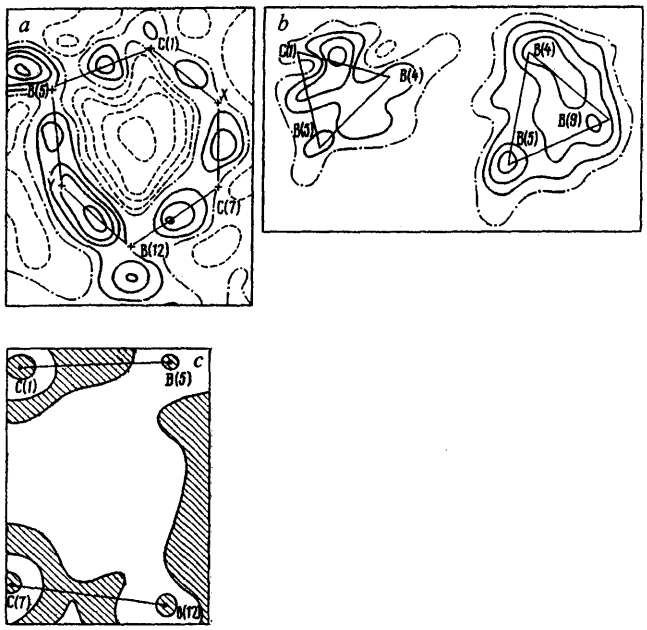

Figure 9. Distribution of electron density in 9-azido-*m*-carbaborane (XIV): *a*, DED section through the centre of the icosahedron passing through the C(1), B(5), C(7), and B(12) atoms and the centres of the B(2)–B(3) (*X*) and B(9)–B(10) (*Y*) bonds (the contours have been drawn at 0.04 e Å^{-3} intervals); *b*, DED section through the B_3 and B_2C triangular faces; *c*, $\nabla^2\rho(r)$ Laplacian section through the centre of the icosahedron passing through the C(1), B(5), C(7), and B(12) atoms (in the shaded regions, $\nabla^2\rho < 0$).

An additional confirmation of the results for compound (XIV) is provided by the calculation from the experimental data of maps of the electron density Laplacian $\nabla^2\rho(r)$ characterising the curvature of the function $\rho(r)$ in three mutually perpendicular directions. By definition, the Laplacian of the function $\rho(r)$ is the sum of the second partial derivatives:

$$\nabla^2\rho(r) = \frac{\partial^2\rho}{\partial x^2} + \frac{\partial^2\rho}{\partial y^2} + \frac{\partial^2\rho}{\partial z^2}, \qquad (6)$$

and, in conformity with the local formulation of the virial theorem for the energy of electrons $2E_{kin}(r) + E_{pot}(r) = {}^1/_4\nabla^2\rho(r)$,[89,90] the negative values of the function $\nabla^2\rho(r)$ in the molecular systems correspond to the parts of the space in which the local electron density is enhanced and in which the contribution of the potential energy stabilising the system predominates. Compared with the difference DED maps, the $\nabla^2\rho(r)$ maps have an important advantage: their construction does not necessitate the calculation of the electron density of the reference state

$$\rho^0(r) = \sum_{at} \rho^0_{at}$$

(of the premolecule), which is subtracted from $\rho(r)$ in the calculation of DED. For this reason, the $\nabla^2\rho(r)$ maps constitute an important and sometimes even a more informative complement of the DED maps used in the study of the electron distribution in crystals.[18] Fig. 9*c* presents the $\nabla^2\rho(r)$ map (the section was drawn through the carbaborane nucleus) of the molecule of compound (XIV), characterised by a wide range of positive values of the Laplacian within the carbaborane nucleus, i.e. the concentration of electron density is reduced within the nucleus, which is consistent with the form of the analogous DED map (cf. Fig. 9*a*). We also emphasise that in the vicinity of the C atoms there are in Fig. 9*c* regions $\nabla^2\rho(r) < 0$, i.e. regions of a local enhanced concentration of $\rho(r)$, which agrees with the greater electronegativity of these atoms compared with B atoms.

In the study of the electron distribution in compounds containing atoms with filled or more than half-filled valence shells (N, O, F, P, S, Cl, etc.), DED maxima are frequently observed near such atoms. They can be attributed to the sites where **the lone electron pairs (LEP) of these atoms are located.** Depending on the nature of the atom and the molecule and on the character of the crystal structure, the DED maxima can have significantly different heights, orientations relative to other bonds in the molecule, and degrees of diffuseness.

The characteristics of the manifestation of the lone electron pairs of the N and O atoms on the DED maps have been investigated frequently and in detail (see, for example, Breitenstein et al.[81]). These LEP are in fact always clearly seen on electron density maps and conclusions about the degree of hybridisation of the corresponding atoms can be reached from the character of their disposition.

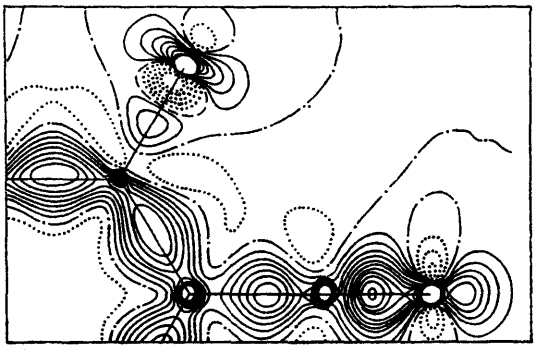

Figure 10. A static DED map in the plane of the $C_6F_4(CN)_2$ molecule (multipolar model). The contours have been drawn at 0.1 e Å^{-3} intervals.

We shall consider the characteristic features of the electron distribution in the region of LEP of halogen atoms. In the vicinity of the fluorine atoms, the LEP are as a rule manifested less distinctly, particularly in the construction of the DED maps by the traditional "$X-X$" method (see above), which is partly caused by their location near the F nuclei, where the error of the experimental determination of $\delta\rho(r)$ is large. Nevertheless, when more flexible, for example multiparameter multipolar models are used for the representation of DED, excess density maxima are observed near the F atoms and are disposed at right angles to the bond lines involving these atoms. As an example, one may quote data[91,92] obtained in the study of the electron distribution in a tetrafluoroterephthalodinitrile $C_6F_4(CN)_2$ (XV) crystal at 98 K [the error of the determination of the DED in compound (XV) in the region of chemical bonds is 0.02 e Å^{-3}; the DED maps were constructed using Hirshfeld's model[93] (Fig. 10)].

We may note that, in constructing the $\delta\rho(r)$ maps using the different multipolar models mentioned above, the electron density of the crystal is represented analytically by an expansion of $\rho(r)$, for example, in terms of angular harmonics or their combinations. The parameters of this expansion (the populations of the multipoles and the exponential multiplier in their radial components), as well as all the remaining positional and thermal parameters of the structure are refined by the least squares method. The first term in the expansion of the function $\rho(r)$ corresponds either to the electron density of the free atom $\rho^0(r)$ (Hirshfeld's deformation model[93]) or to the electron density $\rho_{int}(r)$ of the atomic core (the Stewart[94] or Hansen–Coppens[95] model).

More complex models for the analytical representation of $\rho(r)$ have also been proposed recently (see Porai-Koshits's review[18]) and it is significant that the analytical representation of the functions $\rho(r)$ and $\delta\rho(r)$ does in fact simplify the problem of the calculation of the properties of crystals which depend on these functions.[79] On the other hand, the multipolar representation of electron distribution data requires the refinement of a much greater number of independent parameters in least squares schemes. As a result of this, the use of low-temperature diffraction data in such studies on molecular crystals is sometimes essential, since only this makes it possible to secure a sufficient number of reflections (including large angle reflections) which are necessary for a significant refinement of additional multipolar parameters.

Characteristic examples are provided by data for $LiNO_3.3H_2O$ (at 295 and 120 K [96]) and imidazole (at 293 and 103 K [97]) crystals in which electron density was modelled with the aid of the Hirshfeld and Stewart multipoles respectively. In both cases, the authors pointed out the inadequate accuracy and amount of experimental data obtained at room temperature, which distorted the picture of the electron distribution.

Near the nuclei of covalently bound Cl atoms, the peaks corresponding to the LEP of the latter are shown clearly. In particular, in the study of the phosphorane $Cl_3P(CCl_3)_2$ at 153 K [56] the presence of effectively localised positive DED maxima, with a height of 0.2–0.3 e Å^{-3}, was established in the vicinity of the nuclei of Cl atoms. The maxima are at distances of 0.7–0.8 Å from these nuclei and are oriented in directions at right angles to the P–Cl and C–Cl bonds (Fig. 11).§ In terms of the character of their dispositions, these peaks should correspond to the LEP of Cl atoms having an appreciable p character. Furthermore, beyond the nuclei of the Cl atoms on the lines obtained by producing the P–Cl and C–Cl bonds, there are DED minima indicating the involvement of the p_σ orbitals of the Cl atoms in the formation of the corresponding bonds. We may also note an interesting feature of Fig. 11 associated with the presence on the axial "hypervalent" P–C bonds in this

§ The study of compound (VIII) at room temperature[57] indicated appreciable intramolecular vibrations of the CCl_3 groups, which hindered a reliable determination of the characteristic features of the DED maps.

compound of two intense DED maxima with heights of 0.35 and 0.40 e $Å^{-3}$. The presence of these maxima is consistent with the known fact that the axial disposition of electronegative substituents in pentacovalent phosphoranes is preferred.

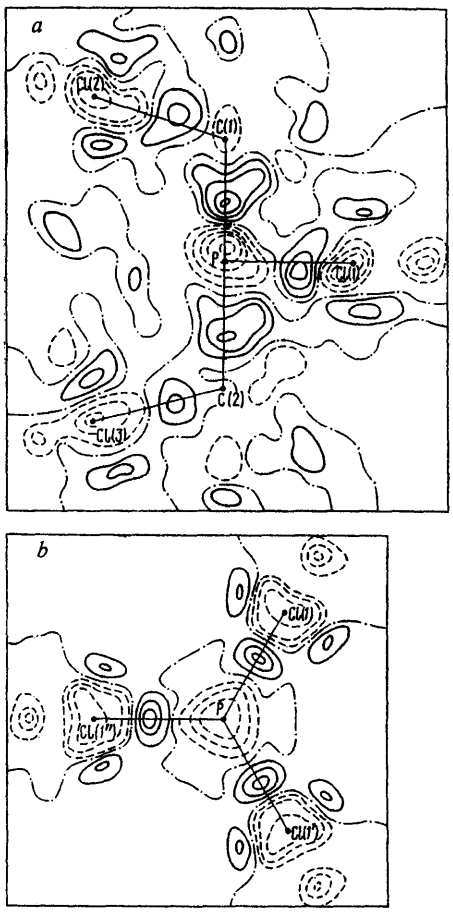

Figure 11. DED sections in the axial (*a*) and equatorial (*b*) planes of the phosphorane $Cl_3P(CCl_3)_2$ (VIII) molecule. The contours have been drawn at 0.1 e $Å^{-3}$ intervals.

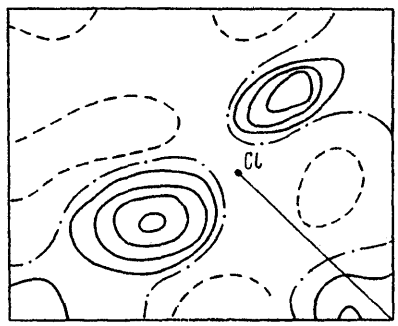
An interesting example of the manifestation of the LEP of the Cl atoms on the DED maps has been observed in a study of the crystal of difluorochloronium tetrafluoroborate $ClF_2^+BF_4^-$ (data obtained[98] at 153 K). At room temperature, this readily hydrolysed compound consists of an equimolar mixture of gaseous ClF_3 and BF_3. On the DED map drawn in the bisector plane of the "angular" ClF_2^+ cation (with the angle F–Cl–F = 96.4°), there are in the vicinity of the Cl atom two maxima located at an angle of ~150° (Fig. 12), whose positions can be attributed to the localisation of the two LEP of the Cl atom. By building up the electron environment of the central atom to a distorted tetrahedron, these LP should occupy (according to Gillespie's ideas about the repulsion of electron pairs of the chemical bonds and the LP [99]) a larger solid angle in space than the electrons of the Cl–F bonds, which in fact increases the LP–Cl–LP angle in the ClF_2^+ cation compared with the tetrahedral value.

The data obtained agree with the results of a quantum-chemical calculation[100] of the positions of the regions of local higher concentration of electron density, i.e. with the calculation of the distribution of the Laplacian $\nabla^2\rho(r)$, according to which the angle between the minima in $\nabla^2\rho(r)$ in the region of the Cl–F bonds is 99° (the location of the valence electrons of the Cl–F bonds is consistent with this), while the angle between the $\nabla^2\rho(r)$ minima in the bisector plane of the cation is ~143° (the distance from the nucleus of the Cl atom to the centres of these minima is 0.604 Å).[100] Certain new data obtained in calculations of the $\nabla^2\rho(r)$ maps in order to locate the electron pairs of the halogen atoms have been discussed.[101]



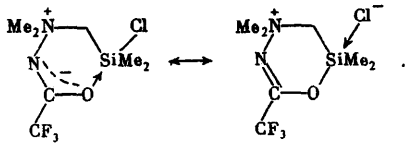


Figure 12. DED section in the structure of $ClF_2^+BF_4^-$ in the plane at right angles to the plane of the ClF_2^+ cation along the bisector of the F–Cl–F angle (the right-hand line). The contours have been drawn at 0.07 e $Å^{-3}$ intervals.

As a result of the improvement of the experimental diffraction method as well as the advances in the synthesis of compounds of fundamentally new types, which are frequently extremely unstable and have an unusual and complex structure, it has been possible in recent years to expand the research into the electron distribution in such compounds. In many cases, their great complexity precludes quantum-chemical calculation of the distribution of electron density in compounds of this kind, which makes the determination of experimental characteristics of their electronic structure of current interest. We shall consider examples of such studies in the series of **organoelement compounds.**

The study of the DED distribution in the trigonal-bipyramidal derivative of pentacoordinate silicon (XVI) was undertaken[102] as part of systematic structural investigations[103] of organosilicon compounds with additional intramolecular Si...O coordination in the "hypervalent" [O–Si–X] fragment. A precision study of compound (XVI) at 163 K showed that the Si atom is involved in trigonal-bipyramidal coordination with an axial disposition of the Cl and O atoms (the Cl–Si–O angle is 172° and the deviation of the Si atom from the equatorial plane of the three C atoms in the direction of the O atom is 0.076 Å). The Si–Cl = 2.434(1) Å bond in the molecule of compound (XVI) is very greatly lengthened, while the Si–O = 1.880(1) Å bond is close to the length of the covalent bond, although its length still exceeds somewhat the typical value for this bond. The C=O carbonyl bond in compound (XVI) has been lengthened to 1.285(2) Å, while the C=N = 1.289(1) Å bond actually corresponds to a double bond of the type $-N=C(sp^2)$.

The results suggest that the electronic structure of the molecule of compound (XVI) can be represented by the superposition of the "limiting" valence forms (A) and (B):

(XVI, A) (XVI, B)

The DED section in the axial plane of the molecule containing Cl, Si, O, and C(1) atoms shows (Fig. 13*a*) that one of the DED maxima near the O atom, whose height is 0.24 e Å^{-3} and which is usually attributed to the LP of this atom, is oriented precisely in the direction of the Si—O axial bond. On the other hand, an individual maximum was not observed on the Si—O bond, although its appearance might have been expected in the case of the formation of the usual covalent Si—O bond in compound (XVI). On the other Si—Cl bond, distinct positive DED peaks are visible only in the immediate vicinity of the nucleus of the Cl atom, while in the centre of the Si—Cl bond the DED is close to zero. In this respect, the DED map in the region of the bonds under consideration differs significantly from that found for similar but shorter (2.09—2.15 Å) Si—Cl bonds in the previously investigated trigonal-bipyramidal trichlorosilyltetrahydrophenanthroline derivative of pentacoordinate silicon.[104] The DED map in the region of the Si—Cl bond in this compound contains distinct maxima on the Si—Cl lines as well as maxima in the region of the LP of the Cl atoms located at right angles to the Si—Cl bond.

A similar picture of the DED distribution, characteristic of a covalently bound Cl atom, has been observed also in the region of the P—Cl and C—Cl bonds in the phosphorane (VIII) (Fig. 11). The data obtained for compound (XVI) evidently show that the Si—Cl bond in compound (XVI) can no longer be regarded as appreciably covalent and it is more likely that in this case a coordination interaction $Cl^- \rightarrow Si$ is observed [contribution by the form (B)]. This conclusion agrees with the increased length of the Si—Cl bond in compound (XVI) and also with the known fact[105] that, in nucleophilic substitution at a tetracoordinate silicon atom, the Cl atom is a "readily eliminated group" (as the Cl^- anion) from the axial position in the trigonal bipyramid of silicon.

The degree of electron delocalisation in the N(1)—C(1)—O amide group of compound (XVI), between the atoms of which there is a possibility of π-conjugation, can be estimated from the form of the DED sections passing at right angles to the C(1)—O and N(1)—C(1) bonds through their midpoints (Figs. 13*b* and 13*c*). A characteristic feature of these sections is the ellipsoidal form of the DED maxima, extended along the (*ab*) and (*cd*) lines perpendicular to the N(1)—C(1)—O plane illustrated by dashed lines in Figs. 13*b* and 13*c*. The form of the maxima constitutes clear confirmation (cf. the analogous section for ethylene—Fig. 5*b*) that the π-component contributes to the formation of the bonds under consideration and that in the case of the N(1)—C(1) bond this component is much more distinct than for the C(1)—O bond [contribution by the form (B)]. Thus the character of the electron distribution in the molecule of compound (XVI) clearly indicates the possibility of representing its electronic structure by a superposition of the forms (A) and (B) presented above. The data obtained from the analysis of the DED maps in compound (XVI) can be evidently used to model the character of the distribution of the electron density of the "transition state" of a S_N2 substitution reaction at the tetrahedral Si atom, which proceeds via the formation of intermediate trigonal-bipyramidal structures.

Another example is associated with the study of the electron distribution in a derivative of dicoordinate phosphorus in the phosphaalkene $(NMe_2)_2C{=}P{-}H$ (VIII) (structural data obtained[106] at 163 K). Phosphaalkenes—compounds with the $>C{=}P$-group are a comparatively new class of phosphorus derivatives and their simplest representatives, including compound (XVII), are as a rule low-melting and unstable. X-Ray diffraction study of a large group of phosphaalkenes demonstrated previously the high tendency of these compounds to conjugate the P=C double bond with the substituents at the P and C atoms,[107] which can lengthen appreciably the double bond to ~1.76 Å [in compound (XVII), the bond length P=C = 1.740(2) Å compared with the usual value of ~1.66 Å in the absence of conjugation]. In order to determine the qualitative characteristics of the electron distribution in phosphaalkenes, DED maps were constructed[106] in the region of the P=C and C—N bonds of the molecule of compound (XVII). Fig. 14*a* illustrates the DED section in the H—P=C plane [the displacement of the N(1, 2) from this plane is ±0.3 Å]. A characteristic feature of this map is the presence of the DED maximum on the P=C bond with a height of 0.39 e Å^{-3} and located approximately in the middle of the bond, and

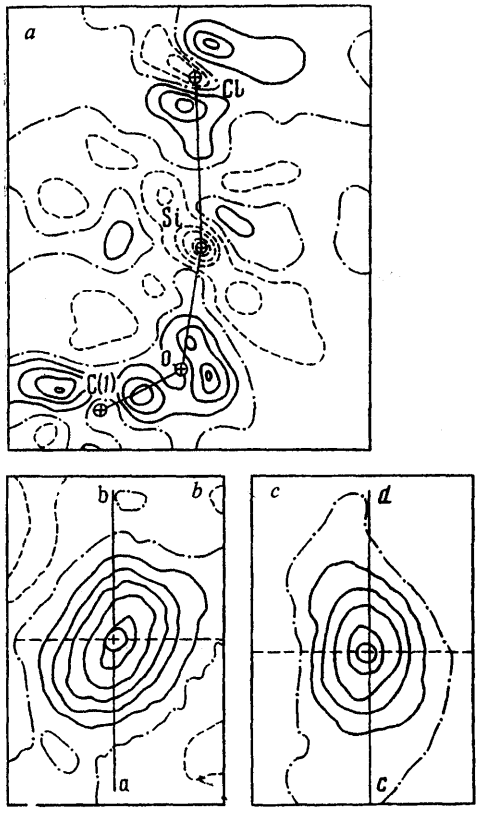

Figure 13. DED sections in the molecule of compound (XVI): *a*, in the axial plane through the Cl, Si, O and C(1) atoms (the contours have been drawn at 0.07 e Å^{-3} interval; *b*, and *c*, at right angles to the C(1)—O and C(1)—N(1) bonds and through the centres of the latter. The contours have been drawn at 0.05 (*b*) and 0.07 (*c*) e Å^{-3} intervals.

also of a maximum A (0.18 e Å^{-3}) located beyond the nucleus of the P atom at a distance of ~0.65 Å, lying in fact on the prolongation of the C=P bond line. In the plane of the π-bond (Fig. 14*b*), the DED maximum is characterised by an appreciable ellipticity, indicating a significant contribution of the π-component to the bond. A π-component of this kind can be seen also in the single C–N(1, 2) bonds, shortened to 1.348(4) and 1.391(4) Å, which is evidence for the occurrence of conjugation in the P=C=N chain.

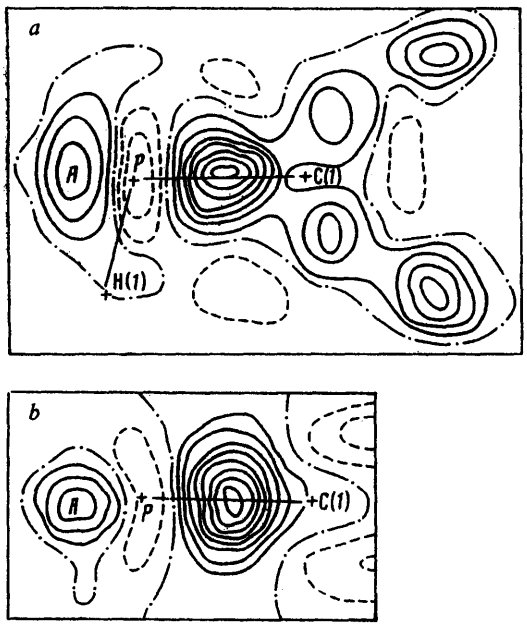

Figure 14. DED maps in the $(NMe_2)_2C=P-H$ (XVII) molecule: *a*, section in the plane of the H(1), P, and C(1) atoms (the contours have been drawn at 0.05 e Å^{-3} intervals); peak A—region of the LP of the P atom; *b*, section in the π-plane of the C=P bond (the contours have been drawn at 0.05 e Å^{-3} intervals).

The maximum A in the vicinity of the P atom is evidently associated with the location of the LP of this atom and from the character of its position one may conclude that the LP has appreciable *s* character. This conclusion agrees with the results of non-empirical quantum-chemical calculations for the simplest alkylidenephosphines.[106,108]

We may note that the significant *s* character of the LP of the P atom can explain the finding that, in the large series of structurally investigated phosphaalkenes (see the review of Chernega et al.[107]), the bond angle at the dicoordinate phosphorus atom is appreciably smaller than the value of 120° characteristic of the sp^2-hybridisation of this atom. Furthermore, the enhanced *s* character of the phosphorus LP in the compounds considered can be the reason why phosphaalkenes exhibit a lower reactivity than phosphines in oxidative addition reactions.[109]

Thus analysis of the DED maps made it possible in many instances to discover clearly the principal features of the electron distribution in the series of compounds of different types, agreeing with the traditional ideas about their electronic structure. In the language of electron distributions, particularly in terms of DED data, typical features of localised and delocalised (many-centre) bonds, strained (bent) bonds, π-bonds, hypervalent, coordinate, and dative bonds, etc. have been formulated and clear confirmation of many qualitative electron ideas used in chemistry has been obtained.

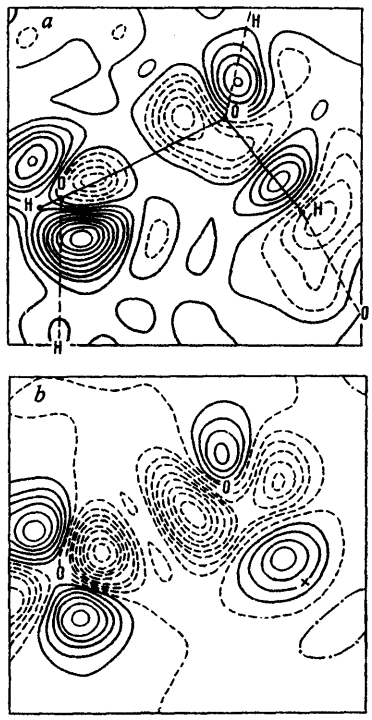

Figure 15. DED maps in the O–O–H plane of the hydrogen peroxide molecule: *a*, experimental data;[111] *b*, calculation.[113] The contours have been drawn at 0.1 e Å^{-3} intervals.

On the other hand, as DED data for different classes of compounds have accumulated, a series of **"strange" results** have appeared (see the review of Tsirel'son and Antipin[76]), which did not fit within the existing ideas about the electron distribution in the region of the chemical bond. In particular, the presence of only weak DED maxima or their complete absence from certain single covalent bonds between atoms whose valence shells are more than half-occupied proved to be difficult to understand. This result was observed in the study of the N–N bonds in a large group of hydrazine derivatives and on C–F, C–O, N–O, etc. bonds. For example, in the precision low-temperature study of 1,2,7,8-tetraaza-4,5,10,11-tetraoxatricyclo[6.4.1.1]tetradecane (III) (see above), it was found that the heights of the DED maxima on the bonds diminish systematically in the sequence C–N > C–O > N–N > O–O and in the region of the O–O bond the DED is actually negative.[110] In a series of other peroxide compounds, including hydrogen peroxide H_2O_2 (data obtained[111] at 100 K), the DED on the O–O bond is also negative (Fig. 15). These facts conflict with the traditional ideas about the formation of the covalent bond as a simple concentration of electron density in the space between nuclei, originating from early theoretical studies of the electron distribution

in the H_2 molecule; nevertheless the absence of significant DED maxima in the region of the bonds considered has been satisfactorily reproduced in quantum-chemical calculations.[81,112–114]

Detailed analysis of this problem carried out in a number of studies,[17–19,76,112–117] showed that the formation of a bond in the H_2 molecule has a number of specific features as a consequence of the absence from the molecule of steric restrictions on $\rho(r)$ imposed by the Pauli principle, and the H_2 molecule can therefore probably be regarded as a "classical" example in the study of the formation of a covalent chemical bond. The absence of DED peaks in the region of the bond considered is due to the fact that in such systems the rearrangement of electron clouds of the atom on formation of bonds proceeds in such a way that the outflow of electrons from the internuclear space as a consequence of the Pauli principle exceeds the effect associated with the increase in electron density in the same region as a result of the interference of the atomic electron clouds.[115] Since the DED maps illustrate the character of the redistribution of electron density relative to the "premolecule"[116] (an assembly of non-interacting atoms), the formation of the covalent bond proper is in many instances masked by other electronic effects (in particular, the transfer of part of the electron density from the internuclear space to the region of the LP), whose magnitude is greater the greater the degree of occupation of the valence shells of the atoms forming the chemical bond.

The foregoing permits the conclusion that the absence of positive DED in the region of the chemical bond is not essential evidence for the absence of a covalent bond and is frequently merely a result of the "oversubtraction" of the electron density, which is naturally not zero in the internuclear space of covalently linked atoms. Nevertheless, the information content of the DED maps is reduced in such cases.

We also emphasise that the presence of the DED maxima between atomic nuclei is likewise not always a sufficient condition for the formation of a covalent chemical bond.[118] In particular, the form of a theoretical DED map for the unstable Be_2 molecule does not differ qualitatively from the DED in stable diatomic molecules, for example in N_2: in both cases, $\delta\rho(r) > 0$ in the internuclear space.[119] Furthermore, even on formation of the simplest diatomic molecules, such as C_2, N_2, O_2, etc.,[84] the positive DED peaks are concentrated not only between the nuclei but also beyond them in the so called "non-bonding" regions, which diminishes, in conformity with Berlin's ideas,[120] the electrostatic forces linking the nuclei. Thus, in the analysis of DED maps and in their interpretation, it is essential to examine in detail all the positive and negative regions of such maps in the vicinity of the atomic nuclei, between which chemical bonds may (or may not) be formed.

It has been noted[118] that analysis of the changes in the electron distribution in the immediate vicinity of the atomic nuclei ($r < 0.4$ Å) is in many instances important for the understanding of the causes of the formation of a chemical bond. The electron density in these regions mainly determines the electrostatic forces acting on the nuclei, but this part of $\rho(r)$ is in fact fairly difficult to establish experimentally and theoretically with a high degree of accuracy. For example, in the multipolar analysis of the DED in the $C_6F_4(CN)_2$ (XV) molecule, it was found that the presence of a very weak $\delta\rho(r)$ maximum on the C–F bond (Fig. 10) cannot ensure the balance of electrostatic forces in the molecule required in accordance with the familiar Hellmann–Feynman theorem. In order to achieve this balance, one must take into account the polarisation of the inert electron clouds of the F atoms and, according to Hirshfeld,[92,121] such polarisation (deformation) of the atomic core can be detected experimentally when accurate X-ray and neutron diffraction data are used jointly and when the accuracy of the determination of the locations of the nuclei is to within $\sim 10^{-4}$ Å. Such an error may be attained only when diffraction data obtained at helium temperatures are used.

As a consequence of the difficulties in the interpretation of the DED maps listed above, other versions of the analysis of the experimental electron distribution data were developed in recent years, in particular methods for the calculation of maps of the **electron density Laplacian** $\nabla^2\rho(r)$ (see above) whose construction does not require the subtraction from $\rho(r)$ of the electron density of the "reference" state selected in a specific manner. Analysis of the Laplacian $\nabla^2\rho(r)$ is part of the study of the topological characteristics of the function $\rho(r)$ within the framework of Bader's theory,[88–90] which has now made possible the most rigorous definition of molecular structure, of an atom in a molecule, and of the chemical bond. A detailed discussion of the results of the analysis of the properties of the functions $\rho(r)$, $\delta\rho(r)$, and $\nabla^2\rho(r)$ within the framework of Bader's theory in relation to the study of the nature of chemical bonds of different types has been considered in a number of reviews.[18,76,83] Here we shall only emphasise that the joint analysis of the functions $\delta\rho(r)$ and $\nabla^2\rho(r)$ derived from the results of a precision diffraction experiment made it possible to deepen the existing ideas about the chemical bond.

In conclusion of the review, we shall consider briefly the possibility of using precision diffraction data, including DED maps, for the interpretation of the characteristic features of **the chemical reactivity of compounds.** We may note that so far there are few examples of such studies, although problems of the relationship between the reactivity of molecules (for example, their capacity for protonation) and their quantum-chemically calculated electrostatic properties, in particular their molecular electrostatic potential (MEP), have been considered in fair detail in the literature.[122] The MEP maps, calculated by quantum-chemical methods, have a simple physical significance, namely the MEP minima must correspond to protonation centres in the compound considered.

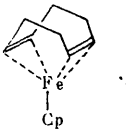
The similarities and differences between the corresponding MEP and DED maps for relatively simple molecular compounds have been investigated in a number of studies[122–125] and it has been shown that in many cases such maps are topologically similar. Thus, by formulating, using the procedure of Weber et al.,[125] the electrostatic potential $V(r)$ at a point r for the molecular system, characterised by the electron density distribution function $\rho(r)$, as the sum of the electronic and nuclear components, we have

$$V(r) = -\int \frac{\rho(r')}{|r-r'|}\,dr' + \sum_A \frac{Z_A}{|R_A - r|}, \qquad (7)$$

where Z_A is the nuclear charge of the atom A with the coordinates R_A (summation with respect to all the atoms in the molecule). After introducing the electron density of the premolecule

$$\rho^\circ(r') = \sum_A \rho_A^\circ(r'),$$

the expression for $V(r)$ can be put in the equivalent form

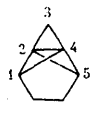


$$V(r) = -\int \frac{\rho(r') - \sum_A \rho_A^\circ(r')}{|r-r'|}\,dr' + \sum_A \left(\int \frac{-\rho_A^\circ(r')}{|r-r'|}\,dr' + \frac{Z_A}{|R_A - r'|} \right). \qquad (8)$$

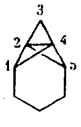
The expression in round brackets in the last sum is the atomic electrostatic potential $V_A(r)$ and Eqn. (8) can therefore be written thus:

$$V(r) = -\int \frac{\delta\rho(r')}{|r-r'|}\,dr' + \sum_A v_A(r). \qquad (9)$$

It has been shown by Politzer[126] that in the vicinity of an atom the quantity $V_A(r)$ is positive and the sign of the potential is therefore determined by the sign of $\delta\rho(r)$ (the DED function) and by the integral in Eqn. (9). It follows from Eqn. (9) that the negative regions of MEP (the possible centres for protonation or electrophilic attack) in molecules can be mutually related to regions in which there are electron density maxima on the corresponding DED maps.



We shall consider certain examples confirming the foregoing. Thus, a precision study of the DED (data obtained[78] at 100 K) of the 17-electron π-cyclopentadienyl-η^4-cycloocta-1,5-dienyl iron complex (XVIII) and its adduct with Li(TMEDA) (TMEDA = tetramethylethylenediamine) established that the Li atom in the adduct is located in the direction of the sterically most accessible (least shielded) of the group of DED maxima near the Fe atom of the initial complex (XVIII), in which these maxima, associated with the populated 3*d* orbitals of the metal atom, are arranged octahedrally.



(XVIII)

The results may indicate a significantly electrostatic character for the Fe...Li interaction and may illustrate the possible direction of electrophilic attack on the metal atom. Another similar example is a study[127] of the DED in the "cubane-like" tetrahedral chromium cluster $(\eta^5\text{-}C_5H_4Me)_4Cr_4(\mu_3\text{-}S)_4$ (XIX). On the DED map of this compound, DED maxima were observed on the outer side of the SCr_3 tetrahedra beyond the S atom. They were interpreted as corresponding to the LP of these atoms. As a result of precisely this feature of the electron distribution, the μ_3-ligand of the cluster retains the capacity for weak additional "external" S...Cu coordination in complex (XIX) with $CuBr_2$.

An interesting result has been obtained recently in a study of two highly reactive [1.1.1]propellane derivatives (XX) and (XXI) (data obtained[128] at 81 K):

(XX)

(XXI)

The lengths of the C(2)–C(4) bridge bonds between the "inverted" carbon atoms in these molecules are 1.587 and 1.585 Å, the DED in the region of the C(2)–C(4) bonds being negative and close to zero (Fig. 16). On the other hand, on the outer side of the bridge bonds near the C(2) and C(4) atoms there are DED maxima 0.10–0.15 e Å^{-3} high. Indeed, according to Wiberg et al.,[129] the ease of the protonation of [1.1.1]propellane is responsible for the marked tendency of this compound to undergo acetolysis. The presence of the above non-bonding electron density maxima at the inverted carbon atoms in propellane derivatives has been confirmed[130] by calculations of maps of the electron density Laplacian for such compounds.

A new approach to the theoretical study of the nature of chemical reactivity, based on the analysis of the characteristic features of the electron distribution $\rho(r)$ and the characteristics associated with $\rho(r)$, in the first place the Laplacian $\nabla^2\rho(r)$, was proposed by Bader et al.[100] This approach proved to be closely related to the familiar method of Fukui's "frontier orbitals".[132] It was shown that the regions where the HOMO and LUMO frontier molecular orbitals are located in space correspond in the case of many compounds to regions of local concentration or rarefaction of electron density and the positions of the latter can be determined from the analysis of $\nabla^2\rho(r)$. In particular, analysis of the characteristic features of the function $\rho(r)$ for a series of carbonyl compounds indicates the presence in the valence environment of the C atom of the so called "critical" saddle points in the distribution of $\rho(r)$, where $\nabla(\nabla^2\rho) = 0$; they are distributed near the C atoms at an angle of ~110° relative to the C=O bond line above and below the plane of the carbonyl group.[100] Nucleophilic attack on the carbon atom actually takes place at this angle, which has been confirmed by the results of structural studies.[42] In addition to the foregoing, we may note also the results of studies[133,134] in which analysis of the quantum-chemically calculated $\nabla^2\rho(r)$ maps led to a conclusion about the mechanism of the opening of the three-membered ring in the protonated dimethyloxiran $(CH_3)_2\overline{CCH_2OH}^+$ on treatment with nucleophiles.

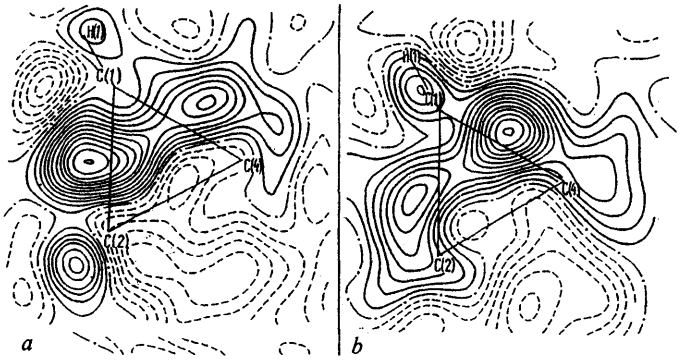


Figure 16. DED sections in the [1.1.1]propellane derivatives (XX) (*a*) and (XXI) (*b*) drawn through the C(1)–C(2)–C(4) atoms of the three-membered rings. The contours have been drawn at 0.025 e Å^{-3} intervals.

The above examples show that, in the field of study of the physicochemical properties of various compounds, the precision X-ray diffraction method can yield new interesting information about the character and features of the distribution of electron density in molecules. However, only the first steps have been taken in this direction. The expansion of the range of compounds investigated and also further improvement of the experimental accuracy of the method and of its computational techniques should evidently lead to the appearance of new and important results in the immediate future.

Characteristic features of the crystal chemistry of lanthanide molybdates and tungstates

V A Efremov
All-Union Institute of Chemical Reagents and Specially Pure Chemicals, Moscow

ABSTRACT. The review gives a systematic account and analyses the characteristic features of the chemical composition, crystal structures, and properties of lanthanide molybdates and tungstates. The structure forming role of molybdenum(VI), tungsten(VI), and the lanthanides(III) in oxide compounds is discussed within the framework of the bond valence force model and ideas concerning non-bonding intercationic interactions. The theoretical conclusions as regards the correspondence between the compositions, structures, and properties of the compounds are compared with experimental data.

IV. Structure and properties 636
V. Conclusion 638

I. Introduction

The $Ln_2O_3-EO_3$ systems, where Ln = La–Lu and Y while E = Mo and W, are the few pseudobinary systems in which the existence of a large number of intermediate compounds has been reliably established. Many molybdates and tungstates exhibit a complex polymorphism. Many of them are distinguished by qualities of practical value. Refractory, luminescent, magnetic, piezoelectric and ferroelectric, and ferroelastic properties are frequently successfully combined in a single material.[1–3] The systematic study of phase formation in the $Ln_2O_3-EO_3$ systems, initiated in the 1960s, was initially designed for applied purposes and was characterised by a combined application of methods of physicochemical analysis and the determination of physical properties.

As a result of vigorous research, the phase relations in the above systems have been elucidated schematically in broad outline but this scheme is not final owing to the contradictory interpretation of individual details of these systems by different workers. There are objective reasons for this: the experimental difficulties in high-temperature studies, the multiplicity of phase transformations in the compounds formed, the characteristic features of the kinetics of the solid-phase reactions, and the difficulty and frequently the impossibility of isolating many phases as single crystals. For example, the $La_2O_3-WO_3$ system and the compounds formed in it have been frequently studied,[4–27] but there is nevertheless no complete certainty[25–27] about the reliability of the phase diagram (Fig. 1 [23]) constructed from the results of high-temperature (up to 2000 °C) X-ray diffraction analysis and differential thermal analysis (DTA) in view of the ultrafast quenching used ($\sim 10^5$ K s^{-1} [19]). Not only the width of the phase regions but also the very fact of the formation of certain chemical compounds and their composition have been questioned. In all probability these and similar controversial questions will soon be resolved by virtue of the progressive development of methods for structural chemical analysis,[28] a number of examples of which already exist.[29–34]

Literature data are now available for more than 40 structural types of lanthanide molybdates and tungstates, 24 of which have been elucidated (Table 1). Lanthanide molybdates and tungstates resemble structurally both complex transition metal oxides and typical salt-like compounds of the type of sulphates. Their crystal structures have the same characteristic features as classical inorganic compounds. This factor is particularly valuable because it facilitates the crystal-chemical analysis of the relationship between chemical composition, structure, and properties of the test systems.

II. The structure forming role of molybdenum(VI), tungsten(VI), and the lanthanides(III) in oxide compounds

In recent years a trend has arisen in descriptive inorganic crystal chemistry towards a shift of priorities from the topological and geometrical analysis of structures to the solution of problems involving bonding and non-bonding interatomic interactions.[78–80] This has been promoted to a considerable extent by the high accuracy of the determination of the positions of atoms achieved in the structural analysis of single crystals, the high speed of such analysis, and hence the creation of an extensive and rapidly increasing stock of experimental data. All these factors create favourable conditions for far-reaching theoretical generalisations whose development is passing through the stage involving the development of empirical models describing observed phenomena with a high degree of statistical reliability.

1. The bond valence force model

In analysing the characteristic features of the structures of crystals of inorganic compounds, which possess predominantly chemical bonds of the ionic type, the concepts of the ionic radius, the coordination polyhedron, and close packing are traditionally used.[81] The characteristic features of the structures of such compounds were first treated systematically by Pauling and were formulated[82] in the form of five principles (or rules) a list of which, frequently described

rather freely, can be found in the scientific literature.[81] Since the 1970s, investigators returned to Pauling's concept because a broader significance of Pauling's postulates became apparent than the author himself imagined initially.[82] In the 1980s, a quantum-mechanical justification of Pauling's rule was discovered. This applies to the greatest extent to the so called "second rule"—the electrostatic valence principle.[83]

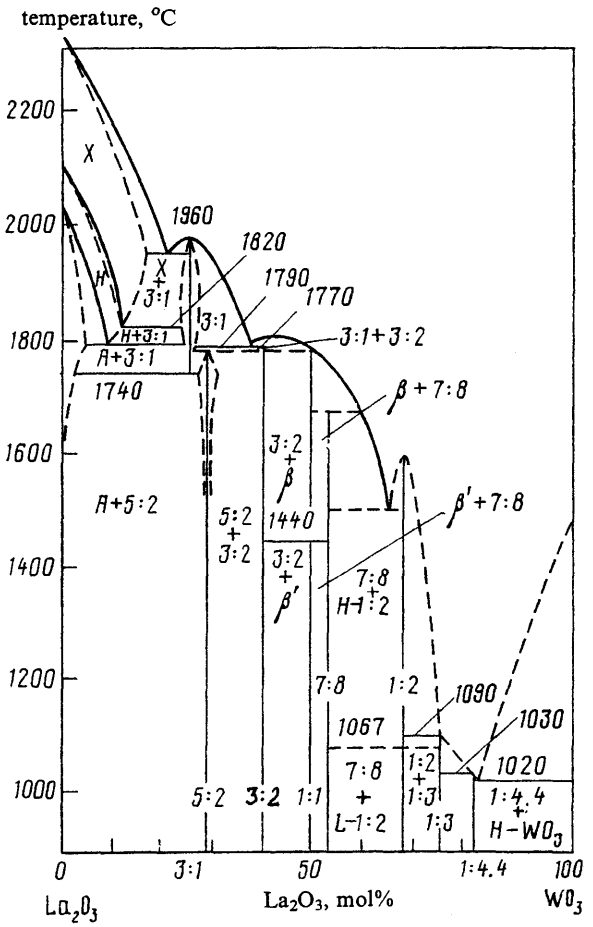

Figure 1. Phase diagram for the La_2O_3—WO_3 system.

In formulating this rule Pauling[82] introduced the concept of "bond strength". In the Soviet literature, the term "valentnoe usilie svyazi" ("bond valence force") became firmly established but the terms "sila", "prochnost'", "valentnost'" svyazi (bond "force", "strength", and "valence") are also used. Pauling's bond strength is defined as the ratio of the formal valence of the cation (V_M) to its coordination number (CN_M):

$$S = V_M/CN_M. \quad (1)$$

The original formulation of the rule was as follows:[82] in a stable coordination structure, the electrical charge of each anion tends to compensate for the force of the electrostatic valence bonds originating from the cations at the centres of the polyhedra whose vertices are occupied by the anion. Zachariasen[84] gives a somewhat different formulation: the sum of the valence forces of the bonds with the cations (pX), converging on the anion, neutralises the charge of the latter (V_X):

$$p\mathrm{X} = \sum_j S_j \simeq V_\mathrm{X}. \quad (2)$$

In such description, the rule has an "electrostatic" content but subsequently it began to be extended also to partially ionic covalent bonds.[85]

In the case of the simplest inorganic structures, in which there are anions of only one crystallographic kind, this rule is known to hold *a priori* by virtue of the requirement for the electrical neutrality of the crystal structure, but if the system is more complex, the exact or approximate fulfilment of this requirement cannot be regarded as self-evident. With increase in the number of elucidated structures, large groups of systems, for example heteropoly-compounds and isopoly-compounds,[86,87] were discovered, in which this rule breaks down. Thus, in the case of $[HN_3P_3(NMe_2)_6]_2Mo_6O_{19}$,[88] the six MoO_6 octahedra have a common oxygen vertex, i.e. when Eqns. (1) and (2) are formally applied one can arrive at the paradoxical conclusion that the nominally divalent oxygen atom is "neutralised" by six (pO = 6 × 6/6) valence units (v.u.) arising from the bonds with Mo(VI).

The objections against the rule became so strong that important advantages of the model such as the possibility of assigning with its aid the oxygen atoms in minerals to O^{2-}, OH^-, and H_2O were consigned to oblivion. It was not until the end of the 1960s that attention was drawn to the relation between the bond length R(M—O) and the sum of the valence forces [bond strengths] (pO) defined by Eqn. (1): the higher the value of pO, the greater the M—O bond length.[88] In the 1970s, this conclusion was supported by a multiplicity of data referring to reliably elucidated structures of oxide compounds of different classes. In 1970, Bauer[89] proposed the "extended electrostatic valence rule" based on the statistical analysis of 14 kinds of coordination polyhedra ranging from BO_3 to KO_8, according to which the following relation holds with a high degree of reliability (the correlation coefficients are close to 1.0):

$$R(\mathrm{M—O}) = a + b \cdot p\mathrm{O}, \quad (3)$$

where a and b are empirical coefficients having individual values for each kind of polyhedra. The empirical expression (3) for cations whose formal valence is less than 3 can be regarded as qualitative because in this case there is an appreciable scattering of data. Nevertheless, for cations with a higher valence, Eqn. (3) has great predictive power. Problems concerning the rapid testing of the reliability of structural determinations, the establishment of the presence of hydrogen bonds, and even the prediction of interatomic distances and bond angles in PO_4 tetrahedra on the basis of a qualitative scheme specifying the way in which these polyhedra are surrounded by other cations in concrete structures were solved.[90]

The numerical coefficients of Eqn. (3) have been analysed.[91] By means of elementary transformations, the authors[91] found that

$$(R_i - \bar{R})/\bar{R} = b(p\mathrm{O}_i - 2), \quad (4)$$

where R_i is the individual M—O_i bond length, R the average bond length in the polyhedron, and b an empirical constant. Eqn. (4) means that the change in the length of an individual bond in the polyhedron relative to the average value for the polyhedron is proportional to the difference between the valence of the oxygen

atom calculated by Eqns. (1) and (2) and its formal value, which is 2. Each type of polyhedra can then be characterised by a unique empirical parameter b. Formulae have also been proposed[90] for the estimation of the average bond lengths $\overline{R}(P-O)$ in the PO_4 tetrahedra, which take into account the number of cations surrounding the oxygen atoms and the distortion of the polyhedron.

Baur's model has narrow limits of applicability and is suitable only for relatively undistorted polyhedra. For example, it does not permit the description of the distortion in the structures of ferroelectrics belonging to the perovskite family, since according to Eqn. (4), one would have to expect the equality of all the isotypical bonds in the perovskite structure, whereas in reality, these bonds are not equivalent. It became clear from subsequent studies that the reason for this is the unsatisfactory linear approximation used for the dependence of the bond valence forces [bond strengths] on interatomic distance.

Pauling[92,93] initiated the use of the non-linear functions $S(R)$ and suggested that metallic and covalent bonds be described by the logarithmic relation

$$R = R_1 - A \ln n, \tag{5}$$

where R_1 is the length of a single bond, n the "bond number" defined as the number of delocalised electron pairs per bond, and A a coefficient (A = 0.30 Å for covalent bonds).

For ionic-covalent bonds, an expression of a similar form was used in the analysis of the interatomic geometry in V_2O_5 crystals as early as 1951.[94] Subsequently, a similar relation was used also to describe the Mo–O bonds.[95,96] The construction of plots of $S(R)$ without their analytical interpretation[97] is based on the concept of electron hybridisation. As a rule, the sums of the valence forces (bond orders) on the cations, determined by Eqn. (5), are close to the formal valences of the central atoms:

$$p\mathrm{M} = \sum_i S_i \simeq V_\mathrm{M}. \tag{6}$$

In the calculation of the Mo–O bond orders from the plot published by Cotton and Wing,[97] it was found that the sum of pMo appreciably exceeds the formal value of 6.

An alternative analytical expression for $S(R)$ was proposed independently by Donnay and Allmann[98] and by Pyatenko.[99] In both cases, the authors assumed that the interatomic interaction in typical inorganic structures obeys a power relation with an exponent $N > 1$ and not Coulomb's law. This approach was formulated in its final form in a study[100] where the analysis of the oxygen polyhedra in 417 reliably elucidated structures permitted the conclusion that all isotypical M–O bonds can be described by unique relations:

$$S_i = (R_i/R_1)^{-N}. \tag{7}$$

The set of empirical parameters R_1 and N was subsequently significantly extended.[101] The deviations of the values of pM calculated by Eqn. (7) from the true values of V_M are very insignificant (up to 5%). The parameters R_1 and N for the M–X bonds with X = O, F, Cl, S, P, or N, have been published.[78]

The principal qualitative feature of the model[100] consists in the fact that it does not require an "ionic" treatment of the valence balance rule and can be extended to any bonds of the ionic-covalent type. The very terms "cation" and "anion" are used not in the "electrostatic" sense but merely as designations reflecting the differences between the more electropositive partner in the chemical bond from the more electronegative one.

It has been established in recent years that the agreement with experiment achieved using the function (7) is ~30–50% worse than that obtainable with the aid of Eqn. (5), which can be written in the form[102–104]

$$S_i = \exp\left[(R_1 - R_i)/K\right], \tag{8}$$

where K and R_1 are empirical constants. The existence of a large set of experimental data, embracing 15371 polyhedra, made it possible to define the values of R_1 for the set of M–X bonds and to propose a method for the estimation of these parameters for other combinations of M and X.[103] The coefficient K was assumed to be constant for all types of bonds (K = 0.37 Å).[103] According to other data,[102,104] this parameter is specific to each set of M–X and varies in the range 0.25–0.48 Å. In view of the significant inequality of the bond lengths in the coordination polyhedron, the use of the coefficient K = 0.37 Å leads to a poorer fulfillment of the requirement for valence balance in structures than the use of values of K specific to each type of M–X bonds.[105] By virtue of the arbitrary selection of the constant of K = 0.37 Å, the empirical coefficients R_1 quoted by Brown and Altermatt[103] have values which are not entirely physically justified despite the acceptable accuracy of the results obtained by Eqn. (8).

1. In the case of polyvalent cations, the coefficients R_1 for their high oxidation states are greater than for their low oxidation states, which is itself doubtful (see also Zachariasen[84]).

2. The character of the variation of the quantities R_1 in the series of isoelectronic cations conflicts with their physical significance, since the smallest values of R_1 correspond to intermediate members of the series.

3. The previously established[100] relation between the position of the cation in the Periodic System and the values of R_1(M–O) is not manifested.

Furthermore, in the proposed method of calculation[103] no difference is drawn between transition metal cations in different spin states although the latter factor affects bond lengths.[106]

The determination of individual values of K for different types of M–X bonds involves certain difficulties, because the parameters R_1 for real structures vary in the range ±(0.015–0.020) Å relative to the statistical mean value found from the analysis of a large set of data for a wide variety of classes of compounds (simple and complex oxides, salt hydrates, complexes with involved organic ligands[105]).

The quantity R_1 depends on the characteristic features of the crystal structure.[104,105] It increases steadily with increase in the number of cations linked to the anion X participating in the M–X bond and also with decrease in their electronegativity. In the structure of hydrates, where the thermal motion of water molecules coordinated to the cation assumes significant importance, the quantity R_1 is, on the contrary, smaller than the statistical mean value. It has been suggested[105] that comparison of the values of R_1 for isotypical bonds in different structures can yield information about the effective charges of the atoms forming the bonds.

In recent years the bond valence force [bond strength] model has found a multiplicity of applications[78,98–112] by virtue of the satisfactory agreement between the results of calculations based on this simple model and experimental data. The conclusions arising from it have been confirmed by quantum-chemical methods.[83]

The model is applicable not only to the solution of traditional problems of structural analysis (including the identification of hydrogen bonds, the determination of the location of the "light" cations of the Li type,[109] the determination of the ratio of two kinds of atoms in the statistical population by the latter of one site,[100] and

the test of the validity of X-ray diffraction analysis[108]), but also to the estimation of the strengths of Lewis acids and bases[108] and the amount of ionic character of bonds.[100] Correlations have also been found between valence forces S and force constants for bond stretching[105] and the coefficients of thermal expansion of crystals.[111] Attempts have been made to use the values of S for the estimation of bond energies.[113]

Statistical studies[104,112,114] have shown that the individual values of S in the TO_4 tetrahedra, where T = Ge, P, V, S, Se, Cr, Mo, or W, obey a simple rule: they lie within the range of values from $V_T/6$ (the mean value $\overline{S}$ in the hypothetical undistorted TO_6 octahedron) and $V_T/3$ (the value of $\overline{S}$ in the hypothetical TO_3 triangle), where V_T is the formal valence of the central atom. Hence the limiting interatomic distances in these polyhedra can be found readily with the aid of Eqn. (8).

series of tetrahedra and pseudotetrahedral complexes with unshared electron pairs and the arithmetical mean values of valence forces of the bonds forming these angles. A similar relation has been found for octahedra.[104,115] Thus the method can be assessed as complementing the Gillespie method[79] for the solution of problems in coordination chemistry which has gained much popularity in recent times.

The bond valence force [bond strength] model has been used in its qualitative aspect [average valence forces determined by Eqn. (1)] for the solution of problems of the stability of crystalline substances and for the systematic treatment of data on polymorphism.[104,116]

We shall now list the principal features of the model.

1. The valence balance rule has a simple topological justification.[105] According to the principle of the superposition of the sum and of its independence of the order in which the summation is carried out, the sums ΣS with respect to all the bonds formed by any atom in the crystal structure must be equal to the formal valence of this atom. The problem thus reduces to the correctness of the determination of the function $S(R)$ and its coefficients.

2. The dependence of the individual valence forces of bonds on the length of the latter is described by an exponential law. The parameters K and R_1 in Eqn. (8) have values determined by the nature of the atoms forming the bond.

3. The "characteristic" bond valence forces (S_0) of isoelectronic cations combined with the same anion depend on the "characteristic" interatomic distances (R_0):

$$R_0 = \rho S_0^{\mu}, \qquad (9)$$

where ρ and μ are empirical constants. The term "characteristic" is applied here to the statistical mean values of R_0 and S_0. Eqn. (1) can be used to determine S_0 for a specified statistical mean coordination number CN_0. Equations of type (9) can apparently be used also for polyvalent cations.

Taking into account the information obtained using the model described above, one can formulate the following definition of the concept of the "bond valence force": bond valence forces are understood as model characteristics of interatomic interactions whose sum with respect to all the bonds formed by the given atom is numerically equal to the degree of oxidation of this atom [the number defining its oxidation state? (Ed. of Translation)].[105]

2. The structure forming role of cations

A trend has arisen in recent years to overestimate the structure-forming function of cations.[80,104,117–124] Whereas previously the analysis of crystal structures was restricted to the consideration of individual chemical bonds between atoms, i.e. to problems of coordination chemistry, nowadays the elucidation of the nature of the formation of the crystalline object as a whole has assumed decisive importance. The concept of the most compact disposition of the largest species, i.e. the largest anions and cations, has helped to some extent in elucidating the characteristics of the formation of crystal structures. However, this "packing" concept loses significance in the case of compounds with "heavy" cations.

There exist two aspects of the solution of the problem of non-bonding intercationic interactions which undoubtedly influence the dynamics of crystal lattices. Firstly, a topological approach, operating with the concept of the cationic matrix (framework, skeleton) has been developing[121] (see also Trunov et al.[104]). A method has been developed within the framework of this approach[117–124] which is based on the indentification of the planes in crystal structures most highly populated by cations. The reflections corresponding to such planes are as a rule most intense on X-ray diffraction patterns. The most compact relative disposition of cations in the planes is achieved when each cation is surrounded simultaneously by six other cations (the so-called "trigonal networks" of the 3^6 type are then formed), but there is also a possibility of "mixed" networks of the $3^3.4^2$ type with triangular and square cells, 4^4 networks with only square cells, and topologically more active networks.

It has also been suggested that individual cations can project from the planes of the networks over distances up to 0.5 Å (which amounts to 15% of the intercationic distance), while the cationic subcell sites are not subdivided as regards chemical "kind", so that vacancies can also correspond to them.[121]

According to Trunov et al.,[104] this approach can be usefully complemented by the analysis of the deformability of the cationic sublattice and the ways in which individual chemical kinds of atoms can alternate in its sites. The method for the identification of cationic motifs is used not only for the traditional classification purposes but also in considering a wide variety of solid-phase transformations, including polymorphic transformations[123] (see also Refs. 41, 46, and 48). It is also used in X-ray diffraction analysis to establish the positions of light anions if the compound includes heavy cations.[117,119]

The other approach to the analysis of the relative disposition of cations, proposed by O'Keeffe and Hyde[125,126] and by Glidewell,[127] is based on the experimentally established relatively small scatter of the "non-bond" intercationic distances when polyhedra are combined via a single common vertex regardless of the nature of the common ligand. A kind of system of "radii" has been developed, whose application ensures a satisfactory fulfillment of the additivity rule when neighbouring polyhedra are linked via a common vertex.[80] For "light" cations (including representatives of the 3*d* group of transition elements), the radii do not exceed 1.7 Å; for example, for sulphur(+6), the radius is 1.45 Å. The corresponding parameters for hexavalent molybdenum (1.90 Å) and tungsten (1.91 Å)[105] fall within the range of values 1.8–2.1 Å characteristic of the lanthanide and other "heavy" cations. When common edges are present in the polyhedra shorter (by 10–15%) intercationic contacts arise. For example, in the case of molybdenum the "intercationic interaction radius" is 1.59 Å.[105]

Thus the characteristic features of the relative disposition of cations in space are determined also by non-bonding interactions, as a result of which in the cations, with their highly developed electron core, the trend to achieve the most uniform environment comprising similar species becomes dominant, which promotes the formation of independent structural types.

We believe that the application of both schemes described above for the analysis of cationic motifs (topological and geometrical), combined with the methods of coordination chemistry (description of bonds and interbond and interligand interactions), will promote the achievement of a qualitatively new level for the consideration of the nature of the crystal structures of inorganic compounds.

3. Characteristic features of the coordination of molybdenum(VI), tungsten(VI), and the lanthanides(III) to oxgyen atoms

The crystal-chemical and stereochemical aspects of the coordination chemistry of molybdenum and tungsten compounds in the state current at the beginning of the 1970s have been described in detail.[128] During the past period, there has been a marked expansion of the number of experimental determinations and an increase in their accuracy.

A statistical survey of data on oxygen-containing molydenum(VI) and tungsten(VI) polyhedra has been carried out.[104,112] In all, information about 383 polyhedra, in which the coordination number of molybdenum varies from 4 to 7, was used. Among the total number of polyhedra, the MoO_4 tetrahedra constitute 48.6%, the MoO_5 pentagonal structures constitute 2.9%, the MoO_6 octahedra constitute 48.0%, and the MoO_7 pentagonal bipyramids constitute 0.5%. This distribution agrees with the frequency of the occurrence of particular coordinations of molydenum(VI) estimated[112] with respect to all known (including isostructural) compounds having a reliably determined coordination with respect to oxygen. The number of double molybdates alone, with heterovalent cations, taken into account in the analysis was more than 500.[104]

The tetrahedral coordination with respect to oxygen, which is so characteristic of molybdenum, is atypical for hexavalent tungsten. The WO_4 tetrahedra constitute only 10% of the total number of polyhedra, the fraction of WO_5 is 4.5%, and the fraction of WO_7 is 0.5%, so that the hexenary WO_6 coordination predominates (85%). Apart from octahedra distorted in different ways, there are also isolated examples of trigonal-prismatic coordination which occurs in similarly constructed double salts (with respect to the anion) of the type La_3WO_6X, where X = Cl_3, Br_3, or BO_3.[105]

The coefficients K and R_1 in Eqn. (8), with the aid of which the bond valence forces are determined, have the following values: K = 0.354 Å and R_1 = 1.905 Å for Mo–O; K = 0.342 Å and R_1 = 1.922 Å for W–O.[105]

The Mo–O bond lengths in the MoO_4 tetrahedra vary in the range from 1.66 to 1.91 Å, while the W–O bond lengths in the WO_4 tetrahedra vary from 1.69 to 1.92 Å. The distribution functions for the individual interatomic distances are themselves characterised by positive asymmetry[104,105] (and resemble "inverted" Morse functions) with a Gaussian "smearing" of the wings of the distributions, but the corresponding valence forces are distributed in accordance with a pseudonormal law. The most probable bond lengths in the tetrahedra are R(Mo–O) = 1.762 Å and R(W–O) = 1.775 Å (they correspond to the maxima in the distribution functions for the corresponding R_i).

The variation of the bond lengths in the tetrahedra under the influence of the "external" cationic environment are described quite satisfactorily[104] by the following expressions:

$$R(\mathrm{Mo-O}) = 1.675 + 0.186\Sigma S_{ext}, \quad (10a)$$

$$R(\mathrm{W-O}) = 1.632 + 0.272\Sigma S_{ext}, \quad (10b)$$

They take into account the contributions S_{ext}, determined from Eqn. (1), of all the "external" cations to which the given oxygen atom is coordinated. Since it is known that in the case of SO_4 tetrahedra the coefficient of ΣS_{ext} is 0.128 Å,[104] one can follow the variation of the T–O bond length in the S→Mo→W series for equal "external" influences. When the upper limit of the bond lengths in tetrahedral anions is exceeded, the coordination number of the central atom increases. This explains the low abundance of tetrahedral groups in the case of WO_4. Furthermore, it follows from Eqns. (10) presented that the formation of the "dimolybdate" groups $[Mo_2O_7]$ from two tetrahedra which are joined via one common oxygen atom, requires the formation of an Mo–O bridge bond whose length is such that it is in practice unlikely, while the formation of "ditungstate" anions appears altogether impossible. Indeed, $[Mo_2O_7]$ groups are stable only in specified instances,[129] which include, for example, the lanthanide hexamolybdates $Ln_2(Mo_2O_7)_3$,[77,112] $MgMo_2O_7$,[130] and $Ce_6(MoO_4)_8(Mo_2O_7)$,[30] which exist within narrow temperature ranges.

The length D of the O–O edges in the MoO_4 tetrahedra is from 2.66 to 3.11 Å, the statistical mean value being 2.882 Å. The distances D(O–O) are linearly related to the corresponding angles α(O–Mo–O) (correlation coefficient 0.82):

$$D(\mathrm{O-O}) = 0.25 + 0.024\alpha(\mathrm{O-Mo-O}),\ \text{Å (Ref.105).}$$

In contrast to the angles α(O–P–O) and α(O–S–O) in PO_4, SO_4, and other polyhedra, whose distortion is well described by the interbond or the non-valence interligand repulsion model,[128] the angles α(O–Mo–O) and α(O–W–O) in the MoO_4 and WO_4 tetrahedra tend to decrease as the bonds connecting these angles are shortened.[104] Under these conditions, additional oxygen atoms from the nearest tetrahedra are frequently included in the coordination sphere of Mo or W; the new atoms tend to occupy the *trans*-positions relative to the shortest Mo–O or W–O bonds in the initial polyhedron and lie over the "centres" of its expanded faces.

This feature of the distortion of the tetrahedra and the relatively high value of the parameter characterising the distance between the cations in the case of Mo and W (see the previous section) prevent the combination of the edges of the MoO_4 and WO_4 tetrahedra with other coordination polyhedra whose central atoms are high-valence ($V_M \geqslant 3$) divalent cations with an ionic radius not exceeding 1 Å. On the other hand, for sulphate ions such combination of edges is fairly typical.

With increase in the coordination number of Mo or W to 5 as a result of the approach to an O atom belonging to a neighbouring polyhedron, the dimers $[Mo_2O_8]$ or $[W_2O_8]$ are frequently formed. The length of both oxygen edges in such dimers is shortened. The pentagons usually have the form of a trigonal bipyramid in which the *trans*-influence of the axial atoms is very marked in agreement, with theory.[72,128] The bipyramids can have common oxygen edges not only with one another but also with other polyhedra.[46]

Contrary to the existing view about the similarity of the MoO_6 and WO_6 octahedra, a statistically reliably established distortion of the 2 + 2 + 2 type (gradation of the Mo–O bond lengths) is characteristic of MoO_6 octahedra.[112] Three equal-intensity maxima at R = 1.707, 1.928, 2.282 Å can be differentiated on a plot of the

R(Mo—O) distribution function. Owing to the non-linearity of the function $S(R)$ and the high degree of distortion of the polyhedra [$D_2(R)$], defined by the relation

$$D_2(R) = \left[\frac{1}{CN}\sum_{i=1}^{CN}(1 - R_i/\overline{R})^2\right]^{\frac{1}{2}}, \quad (11)$$

where $\overline{R}$ is the average bond length in the polyhedron, the arithmetical mean bond length R for the entire set of octahedra, i.e. R_m(Mo—O) = 1.973 Å, significantly exceeds the "undistorted" value R_1 = 1.905 Å. The mean distortion is $D_2(R)$ = 0.118.[112]

The WO_6 octahedra are not subject to similar "characteristic" distortions. Their average distortion is $D_2(R)$ = 0.043 and R_m = 1.940 Å for R_1 = 1.922 Å. This example is very clear, since it shows that the estimates of the size of the cations obtained using "statistical" interatomic distances may not correspond to the experimental data (including data obtained from the formula volumes of isostructural compounds) in the case of highly distorted (to different extents) polyhedra.

The "external form" of the MoO_6 and WO_6 octahedra, determined by the lengths of the oxygen edges, varies, like that of the corresponding tetrahedra,[104] to a smaller extent than all other stereochemical parameters of the polyhedra. However, whereas a unimodal distribution of the D(O—O) distances is characteristic of MoO_4, in the case of MoO_6, with the average value D_m(O—O) = 2.745 Å, a trimodal distribution is observed owing to the shortening of the lengths of oxygen edges common to other polyhedra. Three maxima can be distinguished at 2.615, 2.735, and 2.820 Å, their contributions to the overall distribution of the D(O—O) distances being 19, 35, and 46% respectively.[112] The shortest D(O—O) distances correspond to the common edges. In order to retain the average length D_m(O—O) for the octahedron, it is necessary to increase the length of the "free" edges, which is manifested by the presence of a third maximum on the distribution function curve. A similar phenomenon was also noted for GeO_6 octahedra.[114]

The average length of the edges D(O—O) in the WO_6 octahedra varies within comparatively narrow limits (2.71—2.77 Å), whereas the values of D_i specific to each individual polyhedron vary from 2.38 to 3.35 Å. The reason for this scatter is the shortening of the lengths of the common edges reflected by the appearance on the distribution function curve of a satellite maximum at 2.48 Å and a "compensating" maximum at larger distances: D(O—O) = 3.14 Å. Overall, a distortion of the external form is characteristic of the WO_6 octahedra in which there are six shortened oxygen edges and six lengthened oxygen edges in the *trans*-positions with respect to the former.

There is a strong linear correlation between the angles α(O—W—O) and the arithmetical mean values of the valence forces $\langle S$(W—O)$\rangle$ of the bonds forming this angle:

$$\alpha(\text{O—W—O}) = 51 + 39\langle S(\text{W—O})\rangle \quad (12a)$$

with a variance of ~4°. The α(O—W—O) angles range from 70° to 113°, the most acute of them being based on the common edges of the polyhedra.

A similar relation

$$\alpha(\text{O—Mo—O}) = 62 + 27\langle S(\text{Mo—O})\rangle, \quad (12b)$$

characterised by a correlation coefficient of 0.96, holds also for MoO_6.[112]

Such features of the variation of the stereochemical parameters of the octahedra make it possible to put forward two mutually consistent justifications of the small variability of the lengths of the oxygen edges D(O—O) in the absence of perturbations by additional polyhedra.

1. The increase in the angle between short bonds and the decrease in the angle between long bonds are consistent with the interbond repulsion model[79] and lead (by virtue of trigonometric relations) to similar values of D(O—O) in both cases.

2. As for the tetrahedra, the interligand non-valence interactions tend to "equalise" the lengths of the oxygen edges.

In order to account for the observed distortions of the MoO_6 and WO_6 octahedra, it is also necessary to invoke the closeness of the sums of the valence forces of the Mo—O or W—O bonds in the *trans*-positions to the value 2.0 valence units (v.u.).[104,105] This indicates the mutual dependence of the lengths of such bonds [the calculations are carried out by Eqn. (8)]. Thus in the MoO_6 octahedron the Mo atom is displaced from the centre of the polyhedron towards one of the oxygen edges, whereupon two distances R(Mo—O) are shortened compared with the "ideal" length R_1 = 1.905 Å to the "characteristic" length $R \simeq$ 1.707 Å, two R(Mo—O) distances from the molybdenum atom to the oxygen atoms on the opposite edge are lengthened to 2.282 Å, while the remaining lengths of the Mo—O bonds increase slightly to 1.928 Å. In the WO_6 octahedra, the displacements of the W atom from the centre of the polyhedron are not so marked and the cation can then be shifted not only towards two oxygen atoms forming an edge of the octahedron but also to three oxygen atoms forming one of its faces. The corresponding "short" bonds have the length R(W—O) = 1.76 Å (the W—O bond length in the "ideal" octahedron is about 1.92 Å).

This model of the distortion of the octahedra is fully consistent with the data quoted by Porai-Koshits and Atovmyan[128] and explains satisfactorily the fundamental rules governing the coupling of the MoO_6 or WO_6 octahedra formulated by the above workers[128] from the standpoint of the joint application of the concepts of the bond valence forces, the interbond repulsion and the interligand interactions.

When MoO_6 or WO_6 octahedra are combined with one another, they are grouped in such a way that the displacements of their central atoms from their geometrical centres also correspond to the intercationic repulsion model.

There are so far few experimental data on the coordination of the oxygen atoms around the lanthanide atoms and they are suitable only for a qualitative survey. A broad set of a wide variety of coordination polyhedra with coordination numbers ranging from 6 to 12 is characteristic of the lanthanides.[131] Table 2 presents the "average" coordination numbers found from statistical data for the entire set of structures known to the authors[132] in which the lanthanide atoms are coordinated only to oxygen atoms, including those incorporated in organic complex forming molecules. The "average" coordination numbers in the oxide structures proper, not containing water molecules, are also indicated in the table.[112] As a rule, the coordination number in hydrates is higher approximately by unity than in the anhydrous compounds regardless of the number of H_2O molecules. Table 2 also lists the empirical parameters in Eqn. (8) for the valence forces of the Ln—O bonds.[112]

The lower limit of the Ln—O interatomic distances is determined by the lengths of bonds having the valence force S_{max} = 0.67 v.u. [the values of R(Ln—O) can be determined from Eqn. (8)]. This valence force S_{max} corresponds to the hypothetical situation

where the oxygen atom is surrounded by only three lanthanide cations (and no other atoms). Experimental data indicate the absence of such fragments from the structures. The situation where the O atom is surrounded by Ln atoms in a tetrahedral arrangement is extremely common.[133] $S = 2/4 = 0.5$ v.u. corresponds to this situation. The coordination numbers of the lanthanide cations can then vary from 6 to 8.[105,112] For higher coordination numbers of the lanthanide atoms, such fragments are not formed.

Table 2. The average coordination numbers and parameters of Eqns. (8), (14) and (15) for the Ln–O polyhedra.[112,132]

Note. Adopted notation: n_f = number of f electrons in Ln(III); CN_1 statistical mean coordination number for the set of lanthanide compounds of different classes with Ln–O bonds;[132] CN_2 = ditto for anhydrous oxide compounds;[112] CN_3 = coordination number calculated by Eqn. (13); n_p and n_p' = numbers of polyhedra for which an analysis has been carried out; K, R_1 (Å) = individual values of the parameters of the function (8); K^f, R_1^f = the same parameters calculated by Eqns. (14) and (15).[112]

The variation of the stereochemical parameters of the LnO_n oxygen polyhedra is on the whole described satisfactorily within the framework of Gillespie's method,[79] but in the structures of complex oxides with heavy cations the distortions of the polyhedra are frequently determined by the characteristic features of the intercationic geometry.[119] The abolition of the "gadolinium break" in many series of such compounds,[104] especially for a low content of the lanthanide, is remarkable.

There is a linear relation between the coordination numbers of the lanthanides in anhydrous oxide compounds and the number of f electrons n_f of the Ln^{3+} ion:

$$CN^f = 8.31(1) - 0.11(3)\,n_f \qquad (13)$$

(the correlation coefficient is -0.95). The results of the calculations of the coordination number by Eqn. (13) are presented in Table 2. The parameters K in Eqn. (8), describing the valence forces of the Ln–O bonds, are also involved in a weak linear correlation with the number of f electrons n_f:

$$K^f = 0.310 + 0.003 n_f. \qquad (14)$$

On the other hand, if one uses the values of K^f calculated by Eqn. (14) and the coefficients R_1^f are determined from the experimental interatomic distances R(Ln–O), it is found that the coefficients R_1^f are related to n_f:

$$R_1^f = 2.220\,(6) - 0.027\,(9)\,n_f^{0.85(3)} \qquad (15)$$

(the correlation coefficient is -0.9998). The values of K^f and R_1^f calculated by Eqns. (14) and (15) are also listed in Table 2. Using the equation

$$R_0 = R_1^f - K^f \ln S_0, \qquad (16)$$

it is possible to estimate with their aid the average interatomic distances R_0 and the permissible limits of the variation of the Ln–O bond lengths for any coordination numbers of the lanthanide atoms. This requires the determination by Eqn. (1) of the average bond valence force S_0 for the corresponding coordination of the lanthanide or the substitution in Eqn. (16) of the "critical" valence force S_{max} quoted above. In the calculation of the unit cell parameters of compounds by the interpolation or extrapolation methods,[105] a more reliable procedure involves the use of Ln–O bond lengths calculated by Eqn. (16) rather than the ionic radii.[106]

The set of data presented above, characterising the features of the stereochemistry of molybdenum(VI), tungsten(VI), and the lanthanides(III) in the structures of oxide compounds, makes it possible to develop a crystal-chemical approach to the explanation of the chemical compositions, structures, and properties of the crystalline phases in the $Ln_2O_3-MoO_3$ and $Ln_2O_3-WO_3$ systems.

III. Chemical compositions of the compounds formed in the $Ln_2O_3-EO_3$ systems

When molybdenum and tungsten polyhedra are condensed into finite or infinite formations (dimers, strips, layers, etc.), the chemical composition of the latter is determined by the coordination numbers of the central atoms in the initial polyhedral "seeds" and by the way in which they are combined. As regards lanthanide cations, in the presence of a high content of the lanthanide in the oxide one may expect, with a high degree of probability, the stabilisation of the cationic tetrahedra Ln_4O around the oxygen atoms not involved in the formation of the $[MoO_n]$ and $[WO_n]$ groups. The Ln_4O tetrahedra can also be combined with one another. On combining different structural units subject to the condition that the overall electroneutrality of the model crystal is maintained, one may predict the formation of the corresponding compounds.[112] From the set of hypothetical formations, it is essential to select those which are impossible or unlikely on the basis of the known stereochemical and statistical data. Certain limitations are also imposed by the functional economy rule,[104] indicating the formation of stable crystalline structures from a minimum number of fragments with fundamentally different structures.

The only possible type of group in the octahedral coordination of Mo and W atoms when the octahedra are isolated from one another is $[EO_6]$. The $[EO_5]$ fragment can be formed in several ways, the first of which involves the isolation of the EO_5 pentagons. Two other ways reduce to the sharing of elements of the octahedra: two EO_6 polyhedra are either linked in pairs via the edges or the oxygen vertices of each octahedron are shared with two neighbouring ones: $[EO_5] = EO_{4/1}O_{2/2}$. In the latter case, an additional limitation arises from the requirement that the "bridging" oxygen atoms be located in the *cis*-positions relative to one another[128] (see also

Efremov[105]). There are also several ways of organising the $[EO_4]$ fragment. Such fragments can consist of EO_4 tetrahedra isolated from one another, paired pentagons, or chains formed by the latter, i.e. $[EO_5] = EO_{3/1}O_{2/2}$, and finally systems made up of octahedra combined with one another via the four oxygen vertices of each: $[EO_4] = EO_{2/1}O_{4/2}$. In the latter case, there is a possibility of the formation of planar layers in which each polyhedron is linked to four neighbouring ones via common vertices, the formation of zig-zag chains in which the oxygen edges of the octahedra are shared, and the formation of infinite strips in which each octahedron is linked to two neighbouring ones via vertices and with one neighbouring one via a common edge.

Naturally, when the crystal structure contains more than one crystallographic species E (E = Mo, W), the composition or structural characteristics of the fragments $[EO_n]$ can be more varied. For example, the $[E_2O_7]$ fragment can be obtained not only by the sharing of the oxygen vertices of a pair of tetrahedra (which is unlikely in the case of MoO_4 and impossible in the case of WO_4) but also as a result of the combination of the EO_4 tetrahedra and EO_6 octahedra. The overall formula $[EO_4]$ can be a result of the coupling of four EO_6 octahedra to give an isolated tetramer: $[(EO_{3/1}O_{2/2}O_{1/3}.EO_{2/1}O_{2/2}O_{2/3})_2]$.[104] An increase in the complexity of the fragment reduces the probability of its existence.

We examined above the ways in which oxygen atoms are incorporated in the $[EO_n]$ fragments. In addition, oxygen atoms can be linked to the lanthanide cations only (at least four such cations) and can form the $[Ln_qO]$ fragments. The simplest of these is the tetrahedron $[Ln_4O]$. It was noted above that the E = Mo or W cations have "non-bonding intercationic interaction radii" close to those of the lanthanides. This factor promotes the formation of the structures of lanthanide molybdates and tungstates $Ln_pE_mO_n$, where $p:m \geqslant 0.67$, which are fluorite-like or are topologically similar to fluorite.

The composition of the $[Ln_qO]$ fragments is determined by the method in which the $[Ln_4O]$ tetrahedra are joined together and by the empirical crystal-chemical rules. If the numbers of tetrahedra linked to one another in each direction in space are designated by *a*, *b*, and *c*, then the general formula of the fragment assumes the form $[Ln_{(1+a+b+c+ab+bc+ca+abc)/2abc}O]$. The valence balance rule precludes the formation of a layer infinite in two directions with a thickness corresponding to two $[Ln_4O]$ tetrahedra if Ln is in the +3 oxidation state. On the other hand, the layer with $a = b = \infty$ and $c = 1$ and with the composition [LnO] can exist. An element of this layer is an infinite column having the composition $[Ln_2O]$ with the parameters $a = \infty$, $b = c = 1$. The "double" $[Ln_3O_2]$ column with $a = \infty$, $b = 2$, and $c = 1$ is also consistent with the "economy rule". More complex ways of joining together the $[Ln_4O]$ tetrahedra lead to a considerable infringement of the economy rule and can therefore be disregarded.

We shall now consider the simplest combinations in which the anionic fragments $[EO_n]$, the cationic fragments $[Ln_qO]$, and the "free" Ln species are in proportions ensuring the overall electroneutrality of the compound. The results of such studies are presented in Table 3.[112] These data can be usefully compared with those in Table 1, where the known structural types of the binary compounds in the $Ln_2O_3-EO_3$ systems are listed. The chemical formulae of the "model" compounds make it possible to describe the majority of the phases observed in the systems. The compounds in which the functional simplicity of the structural unit is combined with the "crystallographic" ratios of the stoichiometric coefficients in the chemical formulae occur most widely and exhibit the maximum structural variety and a high thermal stability. In such cases the anion-forming elements E can form, together with the Ln cations, stable cationic structural frameworks and together with their immediate oxygen environment can play, at the same time, the role of bulky units generating the structural motif. For example, the EO_6 octahedra in the Dn_2EO_6 structures are incorporated in the cationic framework (type III) and also form two-layer arrangements of networks with trigonal 3^6 (type V), square 4^4 (type IV), and mixed $3^3.4^2$ (type VI) cells.[41]

Table 3. Models of the structures of the phases in the $Ln_2O_3-EO_3$ systems.[112]

Anion	Cation		
	Ln^{3+}	$[Ln_2O]^{4+}$	$[LnO]^{+}$
$[EO_6]^{6-}$	Ln_2EO_6 1:1 4	$(Ln_2O)_3(EO_6)_2$ 3:2 +	$(LnO)_6(EO_6)$ 3:1 1
$[E_2O_{11}]^{10-}$	$Ln_{10}[E_2O_{11}]_3$ 5:6 + (?)	$(Ln_2O)_5(E_2O_{11})_2$ 5:4 —	$(LnO)_{10}(E_2O_{11})$ 5:2 1
$[EO_5]^{4-}$	$Ln_4(EO_5)_3$ 2:3 1	$(Ln_2O)(EO_5)$ 1:1 2	$(LnO)_4(EO_5)$ 2:1 +
$[E_2O_9]^{6-}$	$Ln_2E_2O_9$ 1:2 1	$(Ln_2O)_3(E_2O_9)_2$ 3:4 —	$(LnO)_6(E_2O_9)$ 3:2 +
$[EO_4]^{2-}$	$Ln_2(EO_4)_3$ 1:3 5	$(Ln_2O)(EO_4)_2$ 1:2 +	$(LnO)_2(EO_4)$ 1:1 3
$[E_2O_7]^{2-}$	$Ln_2(E_2O_7)_3$ 1:6 1	$(Ln_2O)(E_2O_7)_2$ 1:4 0	$(LnO)_2(E_2O_7)$ 1:2 0

Note. The oxide ratio $nLn_2O_3:mEO_3$ is indicated at each position in the second row. The numeral in the third row denotes the number of elucidated structural types: the + sign indicates the possibility of the formation of the given structure and the symbol 0 indicates its impossibility. A dash means that the compound has not been detected.

In another characteristic family $Ln_2(EO_4)_3$ the isolated tetrahedral anions EO_4 either play an independent structure-forming role if lanthanides at the end of the series form part of the composition of the compounds or, together with the initial members of the series, form a fluorite-like cationic framework in several varieties of the scheelite structure.[71]

The proposed modelling procedure can be extended to compounds with more complex chemical composition containing additional cations.[104,105] By analogy with the science of living nature, one can introduce the concept of the "crystal-chemical groove",[112] which indicates the possibility of the occurrence of a particular crystal structure depending on the individual features of inorganic "building units".

IV. Structure and properties

The physicochemical and certain other structure-dependent properties of compounds in the $Ln_2O_3-EO_3$ systems are examined below. The existing information about the structure of these compounds can be subdivided into four groups of facts.

1. "Neutral" lanthanide molybdates and tungstates, having the same composition $Ln_2(EO_4)_3$ as other compounds with tetrahedral anions whose central atoms E belong to Group VI of the Periodic System, are formed in all the systems.[134]

2. All the lanthanides form the compounds Ln_2EO_6. Similar lanthanide oxytellurates have been described.[135]

3. In the regions corresponding to systems with a high Ln_2O_3 content, phases with a fluorite-like structure are formed.

4. In the $Ln_2O_3-EO_3$ systems, there is a large group of compounds of different composition in the formation of which only a limited number of representatives of the lanthanide series participate.

1. The polymorphism of $Ln_2(EO_4)_3$

In terms of their physicochemical properties, the compounds $Ln_2(EO_4)_3$, can be divided into three main groups. In the so-called *C*, *L*, and *A* families, the oxygen coordination number of the lanthanide cation is 6, 7, and 8 respectively, increasing with increase in the size of the lanthanide. The properties of the molybdates and tungstates vary in parallel. An exception is the absence from $Ln_2(WO_4)_3$ of structures with a senary oxygen coordination of the lanthanide.

As a consequence of the "lanthanide" contraction, the formula volume (V/Z) of compounds having similar structures decreases smoothly in each group with increase in the atomic number of the lanthanide. The morphotropic transition to the next group is accompanied by an abrupt increase in V/Z, which is due to the different numbers and sizes of the vacancies in the frameworks of the different structures:

$$\square Ln_2^{[8]}(EO_4)_3, \quad (A)$$
$$\square_2 Ln_2^{[7]}(EO_4)_3, \quad (L)$$
$$\square_4 Ln_2^{[6]}(EO_4)_3, \quad (C)$$

The numerals in square brackets denote in this instance the coordination number of the Ln atom and the symbol □ represents a vacant site in the cationic framework.

The lattice parameters and the values of V/Z vary smoothly without the "gadolinium break". With increase in the atomic number of the lanthanide, the melting points of the compounds (with the exception of cerium compounds) increase and the temperatures of the transitions to the higher-temperature modifications fall, which agrees with the variation of the coordination number in the series of lanthanides (Table 2). In addition, the upper limit of the stability of compounds with a coordination number of 6 for lanthanides at the end of the series should increase also as a consequence of the additional stabilisation of the LnO_6 octahedra in the ideally balanced *C*-type structure at high temperatures[104] (Fig. 2). The sequence of structural rearrangements occurring on heating corresponds to the rule that the degree of balance in the structure improves, which is expressed qualitatively by the decrease in the quantities $D_2(\overline{S})$, determined by Eqn. (11) for values of pO calculated by Eqn. (2).[104]

Within the framework of one structural group of compounds $Ln_2(EO_4)_3$, the polymorphic transitions can be classified as displacements or ordering processes. The displacements entail a gain in the degree of occupation of the crystal space, for example $C \rightarrow C1$, $L \rightarrow L1$. The simplicity of the organisation of the higher-temperature "undistorted" modification and its high symmetry permit several equivalent routes to the deformation of the structure. This is a necessary condition for the manifestation by the crystals of the properties of ferroelastic materials and, following the loss of symmetry centres, also of ferroelectric materials. Statistical data show that a high symmetry of the local environment is not characteristic of the tetrahedral MoO_4 anions at the usual temperatures.[105,112]

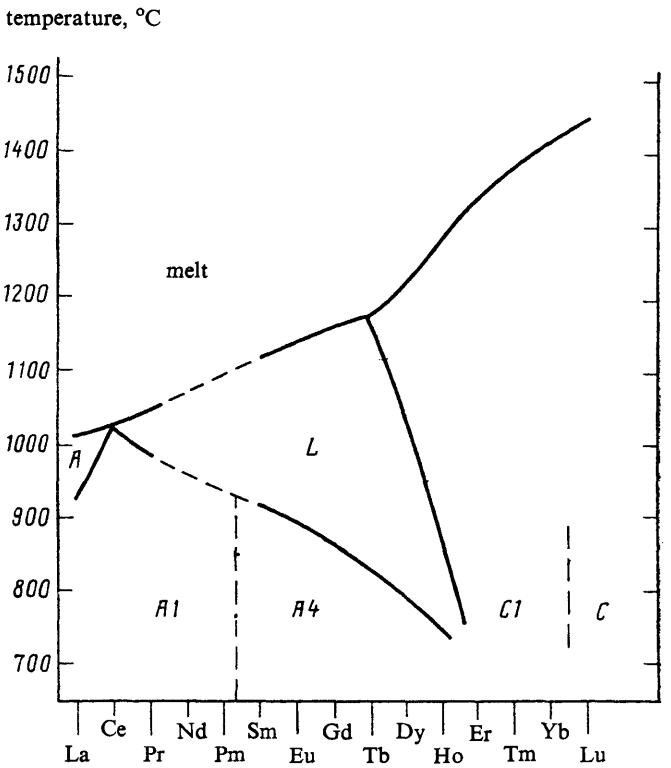

Figure 2. Temperature ranges corresponding to the existence of the polymorphic modifications of $Ln_2(MoO_4)_3$.

Another cause of such displacements of atoms relative to the initial "high temperature" structure is the endeavour by the hexavalent molybdenum and especially tungsten to increase their coordination number when the EO_4 tetrahedra are non-uniformly surrounded by highly charged cations, which is reflected in Eqns. (10). For example, the coordination number of 2/3 of the W atoms in europium tungstate (type A3) increases to 5.[62]

The next type of transformations occurring within the framework of a single structural base involves the ordering of species of different kinds, including vacancies. It proceeds via a diffusion mechanism, certain crystallographic directions proving preferable.

In practice it is frequently possible to obtain structures ordered in different ways. The scheelite-like phases (the *A* family) may serve as an example. The type of ordering can depend also on the way in which the phase is obtained, or on its previous history, and on the presence of impurity atoms in the compound.

2. Polymorphism of Ln_2EO_6

The proposed mechanism of the polymorphism is a result of systematic studies.[27,41–52] Analysis of the morphotropic transitions in this family makes it possible to discover the principal features of the variation of the structures of the most stable modifications (Fig. 3).

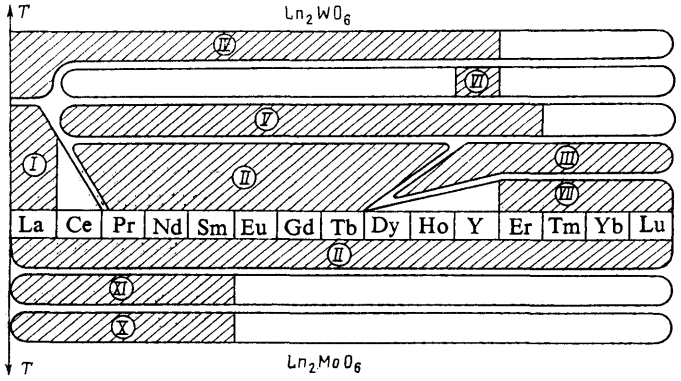

Figure 3. Schematic illustration of the polymorphism of Ln_2EO_6.

The change in the oxygen coordination number in the series of lanthanide cations is insignificant, the coordination number being in the range 8–7, decreasing from La to Lu. In structures of the intermediate members of the series, both coordination numbers occur. The coordination number of the anion-forming element (E = Mo, W) in this series show a tendency to increase from 4 (type X), through 5 (type II), to 6 (types III–VII). Lower coordination numbers are more characteristic of molybdenum in oxymolybdates than of tungsten in oxytungstates. On passing from oxymolybdates to oxytungstates in the La–Lu series, it is possible to identify changes in the structures of the compounds in which the degree of the mutual binding of the cationic tetrahedra $[Ln_4O]$—the residual units of the parent fluorite structure—is reduced. This concerns the following transitions: two-dimensionally infinite [LnO] layer in X→double $[Ln_3O_2]$ strip in II→infinite $[Ln_2O]$ column in VII→Ln^{3+} cation not involved in the formation of the $[Ln_qO]$ fragment in III–VI.

Fluorite-like cationic frameworks are characteristic of the structures of the majority of the low-temperature modifications, while the structures of the known high-temperature forms IV–VI are determined by the arrangement of large octahedral WO_6 anions which are isolated from one another.

The phase transitions between different modifications of Ln_2EO_6 are reconstructive. The reversible and readily occurring structural transformations V⇄VI⇄IV reduce to successive displacements of part of the WO_6 oxy-anions within the framework of the layer and to slight displacements of the lanthanide cations.[41] It is remarkable that all three high-temperature forms of oxytungstates are identical, whereas the low-temperature polymorphic modifications have a centrosymmetrical structure. The interconversions of the low-temperature modifications proceed via more complex pathways but they are also imagined to be subdivided into a sequence of "elementary" movements of the lanthanide cations and the elements E in steps not exceeding the typical intercationic distance of 4 Å.[46,48]

In each group of isostructural compounds, an increasing number of signs foreshadowing a change in the structural type, involving an increase in strain in contacts of the type O...O or M...M′ (M = cation), are observed as the extreme members of the series are approached. The significant shortening of one of the Ln...W edge contacts in the WO_6 and LnO_7 polyhedra on passing to the lanthanides at the end of the series is in fact responsible for the widening of the temperature range corresponding to the existence of form III with a coordination number of 8 instead of the widening of the region corresponding to the stability of structures of type V where there are seven nearest oxygen atoms in the environment of each Ln cation of both kinds.

An important structural characteristic of the majority of polymorphic modifications of Ln_2EO_6 is the presence in the latter of at least two crystallographic kinds of lanthanide atoms which in a number of instances are involved in different types of oxygen coordination. This makes it possible to "regulate" the extent of the temperature ranges corresponding to the stability of the phases on transition from the double oxides proper to the solid solutions based on them.[27]

3. Fluorite-like compounds in the $Ln_2O_3–EO_3$ systems

The most contradictory interpretation of the phase relations in the $Ln_2O_3–EO_3$ systems is in the region of a high content of the lanthanide components (in excess of 60 mol%). Compounds of several types are formed whose common feature is the involvement of fluorite (CaF_2) as the structural prototype. Whereas an octonary oxygen coordination is characteristic of the lanthanides (especially those at the beginning of the series) in the oxygen compounds (Table 2), the occurrence of coordination numbers ranging from 4 to 6 for Mo and W requires a definite rearrangement of the initial fluorite structure in order to ensure an environment characteristic of these elements. This can entail the displacements of the anions from the positions at the centres of the cationic tetrahedra to the triangular faces of the latter, the formation of anionic vacancies, and local displacements of the atoms in the non-ordered phases.

In examining the correspondence between the chemical composition of the phase and its crystal-chemical nature, one can imagine several situations.

1. Atoms of each kind wholly populate particular regular systems of points in the structures of the compounds. With the exception of the special cases of "subtraction phases" or "interstitial phases" where the ordering is complete, compounds are formed with a distinct stoichiometry and fairly narrow regions of homogeneity.

2. Anionic disordering takes place when the number of sites for the accommodation of anions, determined by the multiplicity of the regular system of points in the space group of the crystal, exceeds the actual number of anions corresponding to the chemical formula of the compound. Owing to the absence of some of the anions from the structure as a consequence of thermal motion, there is a

possibility of the migration of the remaining anions between crystallographic positions belonging to the same regular system of points. This mechanism is most probable at high temperatures. When the anions and vacancies are distributed statistically among the same positions, situations where cations of different kinds (Ln and E) are involved in oxygen coordination characteristic of them are entirely realistic.

3. Finally, at very high temperatures (in excess of 1400 °C), the crystal-chemical individuality of the cations is abolished owing to the thermal motion of the atoms, as a result of which they become statistically distributed among the sites of the initial prototype structure. The usual crystal-chemical rules which hold at the normal temperatures, apparently lose their significance under these conditions (Fig. 1).

Among the large number of "fluorite-like" phases listed in Table 1, only the structures of Ln_6EO_{12} (rhombohedral form) and $Ln_{10}E_2O_{21}$ have been reliably characterised. Furthermore, studies at high temperatures have shown that the compounds Ln_6EO_{12} give rise to broad regions of homogeneity based on the cubic fluorite structure in the vicinity of the melting points. The formation of such phases at low temperatures (1000–1200 °C) in the initial stages of the synthesis can apparently be attributed to the characteristic features of the solid-phase reactions in systems the composition of the components of which include cations with similar "radii of intercationic interactions through bonds". Such labile phases can be assessed as a kind of intermediate "activated complexes". For example, the cubic oxytungstate La_6WO_{12} in the $La_2O_3-WO_3$ system is thermodynamically stable only above 1900 °C (Fig. 1), but the synthesis from the oxides at temperatures below 1400 °C affords, as a result of the annealing of the reaction mixture for 5–20 h, a single-phase product characterised by a similar X-ray diffraction pattern.

Compounds having the approximate composition $7Ln_2O_3.4EO_3$ are in reality mixtures of phases ordered in different ways and having similar stoichiometries and fairly complex superstructures[29] like the phases in the $Ce_2O_3-CeO_2$ system.[136]

4. Compounds having other compositions

The stereochemical differences between the molybdenum and tungsten atoms coordinated to oxygen atoms begin to have an appreciable effect in the structures of lanthanide polymolybdates and polytungstates, i.e. compounds having the composition $Ln_2O_3.nEO_3$, where $n > 3$. The chemical compositions of polytungstates and polymolybdates are different. The only type of polytungstates ($Ln_{10}W_{22}O_{81}$) has a "bronzoid" structure, which consists of a complex interlinked set of WO_n pentagons, hexagons, and heptagons, each of which is joined to two similar formations via common axial oxygen vertices. This structure shows a definite similarity to that of polytantalates.[76]

Polymolybdates unexpectedly have structures which incorporate dimerised tetrahedra. The $[Mo_2O_7]$ groups can be very remote from other Mo–O anions. The temperature ranges corresponding to the stability of the compounds $Ln_2(Mo_2O_7)_3$, formed under equilibrium conditions at temperatures of the order of 650–720 °C, are extremely narrow (of the order of 30–70 °C).[77] An interesting feature of these systems is the ease of hydration of the quenched specimens (they are quenched to prevent their decomposition on cooling). Such ease is caused by the presence in their structure of large cavities combined into a single system of channels.[76] The trapped water molecules increase the coordination number of the lanthanide atoms from 8 to 9, which stabilises the structure of the monohydrate. The large hydrated crystals can be stored without change for at least 15 years.[76] On heating, the coordinated water is removed at about 280 °C, after which the compound decomposes at about 450 °C into the tetramolybdate and MoO_3; on further increase in temperature, it is reformed but this time in the region of its thermodynamic stability.[112]

In the structures of heavy lanthanide tetramolybdates $Ln_2Mo_4O_{15}$, the dimolybdate ions no longer play an independent role. They are built up to pentagonal formations by combining with neighbouring MoO_4 tetrahedra, which ultimately leads to the appearance of the $[Mo_4O_{15}]$ fragment.[75] The tetramolybdates of the lanthanides in the middle of the series contain isolated MoO_4 tetrahedra and complex polymeric fragments $[Mo_8O_{29}]$ made up of MoO_n tetrahedra, pentagons, and octahedra.[76] The formation of tetramolybdates in the structures of which there are isolated MoO_4 groups and polymer chains having the composition $[Mo_2O_7]$, made up of tetrahedra and octahedra, is characteristic of the lanthanides at the beginning of the series.[74]

On the other hand, tungstates are more widely represented when the ratios of the initial oxides are $Ln_2O_3:EO_3 > 1:3$. They contain WO_6 octahedral groups. This fact agrees well with the views described above concerning the greater tendency of tungsten(VI) compared with molybdenum(VI) to form compounds with high degrees of coordination under the influence of the "external" cationic environment. The great variety of ways in which the WO_6 octahedra can be distorted and of the types of their bonding also promotes the formation of different phases in the systems (Fig. 1).

The changes in the temperature ranges corresponding to the stability of such structures are also correlated with the degree of distortion of their constituent coordination polyhedra.

V. Conclusion

Despite the great variety of types of crystal structures of lanthanide molybdates and tungstates and the wide range of variation of the coordination numbers of E (from 4 to 7) and Ln (from 6 to 11), there is a profound relationship between the coordination numbers of the cations and their relative contents in specific structures.[112] Fig. 4 presents the changes in the "average" bond valence forces $\overline{S}_M$ in the structures of compounds of the lanthanides at the beginning, in the middle, and at the end of the series. The weighted mean value of the individual S, found by Eqn. (1), was used as $\overline{S}_M$:

$$\overline{S}_M = \left[\sum_i (n_i V_{M_i})/CN_i\right] \Big/ \sum_i n_i,$$

where V_{M_i}, CN_i, and n_i are respectively the formal valence, the coordination number, and the multiplicity of the position in the structure of each of the crystallographically different kinds of cations regardless of their chemical nature. The "generalised oxygen index" α, defined as the ratio of the number of oxygen atoms in the chemical formula of the oxide to the total number of cations, has been plotted along the abscissa axis in Fig. 4. For $Ln_pE_mO_n$, index α is equal to the ratio $n/(p+m)$; in particular, $\alpha = 2.0$ for Ln_2EO_6. The use of the index α makes it possible to compare the properties of compounds having different compositions formed in a single physicochemical system.[112]

The character of the variation of $\overline{S}_M$ with α, similar to that illustrated in Fig. 4, has been observed[112] for a wide variety of pseudobinary systems with several intermediate compounds having

known crystal structures, including compounds of the type $M_2EO_4-Ln_2(EO_4)_3$, where M is an alkali metal ranging from Li to Cs. When the compound forms several polymorphic modifications, the deviations of $\bar{S}_M$ for the high-temperature forms from the straight line joining the values of $\bar{S}_M$ for the initial components diminish.

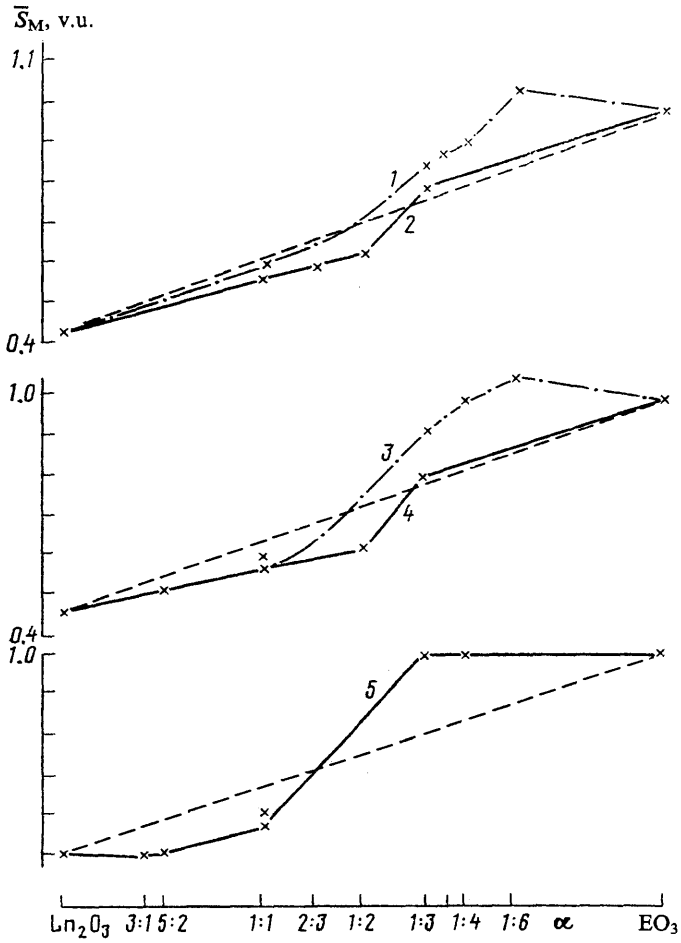

Figure 4. Variation of the quantities $\bar{S}_M$ with the oxygen index α in the structures of compounds formed in different systems: *1*, $Ce_2O_3-MoO_3$; *2*, $Nd_2O_3-WO_3$; *3*, $Sm_2O_3-MoO_3$; *4*, $Eu_2O_3-WO_3$; *5*, $Y_2O_3-WO_3$.

If the composition of the system components includes cations with very different electronegativities, then the relations considered usually becomes S-shaped (Fig. 4). On the other hand, in the case of salt systems of the type $M_2EO_4-L_2(EO_4)_3$, the curves are monotonic.

The dependence on α of the coordination numbers and the values of R_1^E averaged for cations of each kind are also smooth (Fig. 5):[104]

$$R_1^E = R_1^0 + K\ln\left[\left(\sum_{i=1}^{CN} S_i^0\right)\Big/ V_M\right],$$

where R_1^0 is the "statistical mean" value of the empirical parameter from Eqn. (8) and S_1^0 are the valence forces calculated with its aid.

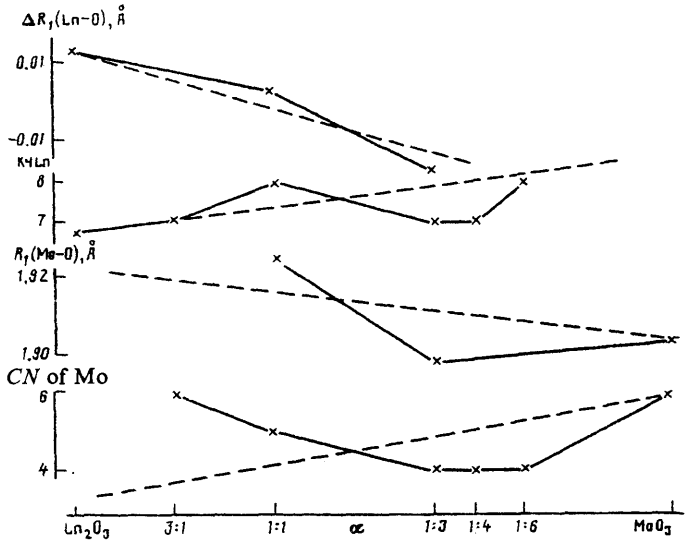

Figure 5. Dependence of the average coordination numbers and the values of R_1 in the structures of compounds of the lanthanides in the middle of the series (molybdates) on the oxygen index.

Presumably the curves illustrated in Figs. 4 and 5 reflect the competition between the cations for the fraction of bond electron density supplied by the anions. It therefore appears useful to consider jointly the results obtained using both bond valence force models as well as other methods of theoretical and experimental chemistry for a wide range of systems. This might promote a more clear-cut establishment of the limits of applicability of the valence force model which has a high predictive power. For example, by introducing hypotheses concerning the alternation of cations and concerning the intercationic distances in the Nd_2MoO_6 structure, it proved possible to determine theoretically the geometrical characteristics of the NdO_8 and MoO_4 polyhedra with approximately the same accuracy as in the experiment.[51]

In our view, the data described in this review will undoubtedly prove useful in the computer modelling of the structure of inorganic oxide compounds.

Structure of the uncharged, anionic, and cationic forms of aminoalkylcarboxylic and aminoalkylphosphonic complexones

L M Shkol'nikova, M A Porai-Koshits
All-Union Scientific-Research Institute of Chemical Reagents and Specially Pure Chemicals, Moscow
Kurnakov Institute of General and Inorganic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. This review is concerned with an analysis of the structure of aminocarboxylic and aminophosphonic acids from the data of X-ray diffraction studies. Monoamino and diamino (also triamino) complexones, the prototropic tautomerism of complexones, and the structural characteristics of their hydrohalides are examined successively.

Contents

I.	Introduction	643
II.	Main structural features of complexones	645
III.	Structure of monoamino complexones	647
IV.	Structure of diamino and triamino complexones	652
V.	Prototropic tautomerism in aminocarboxylic complexones	656
VI.	Structural features of hydrohalides of complexones	659
VII.	Conclusion	660

I. Introduction

In 1936 the company "IG Farbenindustrie" started the manufacture of two products used as water softening agents—Trilon A (nitrilotriacetic acid) and Trilon B (the disodium salt of ethylenediaminetetraacetic acid). These were the first complexones. However, complexones only gained wide acceptance at the end of the 1940s and beginning of the 1950s when their use as complexometric titrating agents for the approximate analysis of virtually all metal cations and many anions was proposed, which gave rise to the current revolution in analytical chemistry.

Schwarzenbach, Kampitsch, and Steiner[1] proposed the term "complexone". Originally it was only applied to polyaminopolycarboxylic acids that have a well-defined tendency to undergo polydentate coordination with metals.

At the present time the term "complexone" refers not only to polyaminopolycarboxylic acids ("classical" complexones) but also to compounds that combine any other basic (S and P atoms, $\rangle C-H$ or $\rangle C-N\langle$ groups) and acidic (phosphonic, arsonic, or sulphonic) sites ("modified" complexones).

In this review only aminocarboxylic and aminophosphonic complexones, whose structure has been studied much more extensively than the structure of other classes of complexones, will be examined. Replacement of carboxyl groups of methylphosphonic groups leads to considerable changes in not only the properties but also the stereochemistry of these compounds. Nevertheless, in the structure of complexones that differ in composition certain common features are retained in many cases, and the present review is to a greater extent devoted to identifying these features. From this point of view there is a discussion of intra- and inter-molecular hydrogen bonds, which play a significant role in the crystal chemistry of all complexones.

During the last ten years the practical application of complexones has extended far beyond the limits of analytical chemistry. They are used anywhere where it is necessary to eliminate the deleterious effect of a metal or, conversely, to introduce a metal into a given system—in the chemical, gas, or petroleum industries, in electrolytic metallurgy, the film industry, power engineering, building, applied bioinorganics, the food industry, agriculture, and in medicine.

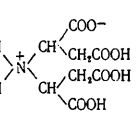
The main characteristics of complexones as ligands, making them effective in binding cations and as a result giving rise to their wide popularity in so many different areas, lies in their combination of flexibility and given geometric limitations in coordination, which differ according to the composition of the complexone. The strength of the complexes formed by them is determined, on the one hand, by the considerable covalent nature of the bonds with the metal (namely, by the nature of the active sites of the complexone together with the electronic structure of the metal), and on the other hand by the complementarity of the ligand shape of the complexone with the corresponding cation, i.e., a purely geometric factor. This latter circumstance dictates the importance of studying the stereochemistry of complexones (also metal complexonates).

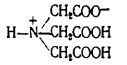
In the USSR studies on the synthesis of complexones and metal complexonates were started in the 1950s and their systematic structural analysis was initiated in about 1970 [by the group led by T N Polynova at the Chemistry Department of Moscow State University together with the Institute of General and Inorganic Chemistry, USSR Academy of Sciences and by L M Shkol'nikova's group at the All-Union Scientific-Research Institute of Chemical Reagents and Specially Pure Chemicals (VNII IREA)].

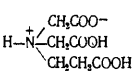
On the whole, the structural data on metal complexonates are considerably more abundant than that for complexones themselves. However, even the latter include more than 50 structural studies (two thirds of which have been carried out in the USSR), so that an examination of the results of these studies on the basis of a single approach is now suitable and timely.

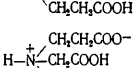
The name and standard notation of the aminocarboxylic and aminophosphonic complexes studied are given in Table 1. References to the original X-ray diffraction studies of these compounds are also given there.

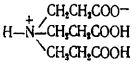
Table 1. List of complexones studied.

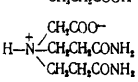


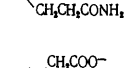


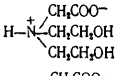


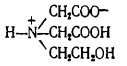


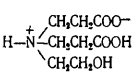


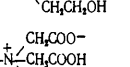


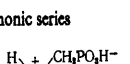












Name of compound	Standard notation	Structural formula	Refs.
Monoaminoalkylcarboxylic series

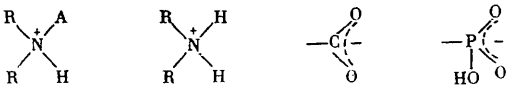
II. Main structural features of complexones

One of the general problems to be resolved from X-ray diffraction studies on the crystals of compounds that can in principle exist in different forms is the establishment of a correlation between the structure of individual molecules or molecular ions in solution (determined from a combination of physicochemical properties) and their structure in crystals, namely, under conditions of direct and constant contact in time and space between the structural units. This problem relates particularly to the determination of the structural role of separate functional groups of complex molecules under different conditions.



As far as complexones are concerned, there is first of all the question as to the predominant tautomeric form of the molecules. It is known that in aqueous solution complexones, as a rule, have a betaine structure with the positive charge on ammonium centres

(quaternised nitrogen) and the negative charge on one of the acid groups (deprotonated acid group).

Is this type of structure retained in crystals, where the tendency to form a system of N—H...O or O—H...O intermolecular hydrogen bonds can lead to tautomeric rearrangement? What is the relationship between intramolecular and intermolecular hydrogen bonding in a crystal? Would it be possible, despite the individual nature of the crystalline structure of each compound, to establish a general basis for the conformation of complexone molecules and hence to determine experimentally (without calculations) which molecular forms are the most stable? These were the main questions that were raised and resolved in a series of structural studies on complexones carried out at VNII IREA.

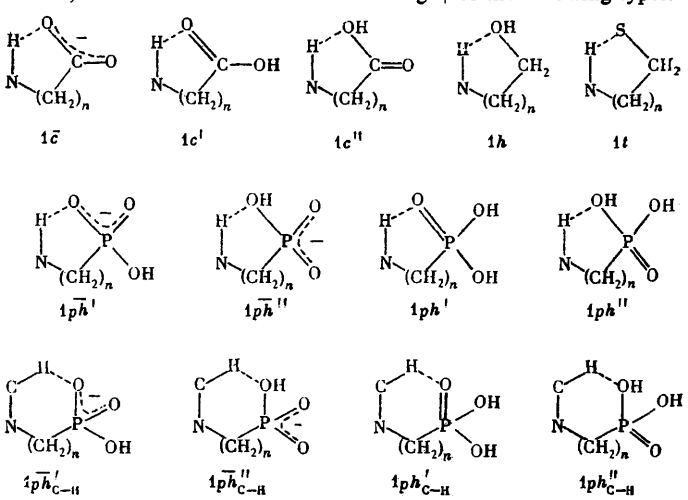
An analysis of the results of structural studies on about forty complexones based on mono-, di-, and tri-amines showed that their zwitterion structure is retained in the crystalline state. The molecules contain positively charged ammonium centres (A) or (B) and negatively charged acidic centres (C) or (D) (carboxylate or phosphonate):

(A) (B) (C) (D)

By studying the structure of molecules containing different functional groups, it was possible to establish which of the groups is most susceptible to deprotonation under competitive conditions. Naturally, the group with a higher acidity was deprotonated in all cases. In an IR spectroscopic study of phosphonomethyliminodiacetic acid (H_4phmida) in solution and its deuterium derivative in the solid state[31] it was shown that a zwitterion structure occurs via a proton from the methylphosphonic group rather than a competing acetate group. A study of crystals of H_4phmida and phosphonomethylglycine (H_3phmg) confirmed this result. It was established that in glycinopropionic (H_2gp) and nitrilopropionic diacetic (H_3npda) acids, namely, when acetate and propionate groups are present, the acetate group is deprotonated; in diethanolglycine (Hdeg) and β-hydroxyethyliminodiacetic acid (β-H_2heida) where acetate and β-hydroxyethyl groups are present, the acetate group is deprotonated; in β-hydroxyethyliminodipropionic acid (β-H_2heidp) where β-hydroxyethyl and propionate groups are present, the propionate group is deprotonated; and in iminodisuccinic acid (H_4ids), the more acidic α-carboxyl group rather than the β-carboxyl group is deprotonated. The only exception is nitrilodipropionic acetic acid (H_3ndpa), where a propionate group was found to be deprotonated when an acetate group was present. The explanation of this violation of the general rule is given below. Consequently, the functional groups can be arranged in a series representing a decreasing tendency to undergo deprotonation during competition between acidic groups (for complexones containing different functional groups:

$$CH_2PO_3H_2 > CH_2COOH > CH_2CH_2COOH > CH_2CH_2OH.$$

Thus, in all of the complexones where there are not less than two carboxyl groups per N atom, one of them is always present in the form of a deprotonated carboxylate group (C) (in the absence, of course, of the more active phosphonic group). Similarly in complexes containing not less than two diprotonated phosphonic groups $P(O)(OH)_2$ per N atom, one of them always occurs in the form of a monoprotonated (phosphonate) group (D).



Only in oxamido-*N,N'*-di-3-proprionic acid (H_2oadp) is the betaine structure absent. Nevertheless, even for this compound the formation of intramolecular N—H...O hydrogen bonds is typical (here H is a non-betaine hydrogen atom).

Since the first structurally investigated diaminocarboxylic complexes—H_4edta and H_4edds·$5H_2O$—had a symmetric bis-zwitterion structure with two quaternised N atoms and two deprotonated carboxyl groups, such a structure was also assumed for other diaminocarboxylic complexes for a long time. However, in a study of the structure of H_4cdta an asymmetric betaine structure of the molecule with only one quaternised N atom was found. The presence of another tautomer with a symmetric structure appears to be possible in solution. Incomplete quaternisation of the N atoms (two out of three) was also found in the molecule of the only structurally investigated triaminocarboxylic complexone—H_5dtpa. Incomplete quaternisation of the N atoms does not occur in the structurally investigated diaminophosphonic

complexones, which is probably due to the increased acidity of the phosphonic group compared to the carboxyl group.

The presence of a quaternised nitrogen atom and negatively charged oxygen atoms of acidic groups in complexones increases their tendency to form hydrogen bonds of the type N–H...O. These hydrogen bonds may be both intramolecular (IAHB) and intermolecular (IEHB) and together with other H-bonds they determine the overall molecular conformation, which depends in the long run on the kinetic and thermodynamic advantage for formation of a given system of hydrogen bonding during crystallisation of an acid.

The structural studies carried out indicate that complexone molecules of both monoamino and diamino types always form N–H...O intramolecular hydrogen bonds in addition to intermolecular hydrogen bonds of the type O–H...O and N–H...O, with the N–H group usually participating in IAHB simultaneously with two or three oxygen atoms, i.e., it forms bi- or tri-furcated H-bonds. As an example, the molecule of iminodisuccinic acid (H_4ids) is shown in Fig. 1. Both ammonium hydrogen atoms form bifurcated IAHB, and one of them also participates in IEHB, so that as a whole the H-bond of this N–H group becomes trifurcated. The presence of intramolecular H-rings based on N–H...X hydrogen bonds is one of the most characteristic features of the structure of complexones.[32] The most commonly occurring of them are rings that each contain one nitrogen atom. Amongst the complexes covered in the present review, are to be found mononitrilo-H-rings† of the following types:

† Several different systems of nomenclature for normal H-rings in complexones have already been put forward.[28,33,34] In order to increase their informative capacity and clarity, a new system is proposed in this review: the numeral 1 (as in the studies of Shkol'nikova et al.[28,33]) denotes that only one N atom participates in the formation of an H-ring (we will also consider below rings involving two N atoms, which will be labelled with the numeral 2); *c* denotes carboxylate; *h* is hydroxyethyl; *ph* is phosphonate; *t* is thio; ph_{C-H} is phosphonate with a C–H...O bond. A minus sign above the letters ($\bar{c}$, $\overline{ph}$) is an indication of an ionised group, a single prime against the letter (e.g., *c′*, $\overline{ph}'$) is an indication that a hydrogen bond is formed via the terminal O atom) and a double prime (e.g. *c″*, $\overline{ph}''$) is an indication of hydrogen bonding via the hydroxyl O atom as a hydrogen acceptor. The presence of a $(CH_2)_2$ group instead of CH_2 is recorded using a subscript 2 (e.g. $1\bar{c}_2$, see below).

The first three H-rings ($1\bar{c}$, $1c'$, $1c''$) are nitrilocarboxylic, the fourth ($1h$) is nitrilohydroxyethyl, the fifth ($1t$) (a special case) is analogous to the first, when an O atom is replaced by the heteroatom S. The following four H-rings (second row) are nitriloalkylphosphonic, and the last four are rarely encountered nitrilophosphonic rings with weak C–H...O hydrogen bonding. The rings $1\bar{c}$, $1\overline{ph}'$, $1\overline{ph}''$, $1\overline{ph}'_{C-H}$, and $1\overline{ph}''_{C-H}$ include deprotonated (ionised) acidic groups, the remaining rings involve protonated (formally neutral) groups. They differ from each other according to the nature of the oxygen atom participating in IAHB (while in the rings $1ph'_{C-H}$, and $1ph''_{C-H}$ they differ according to the nature of the proton donor atom). The $(CH_2)_n$ alkyl chain most frequently contains one unit (n = 1), with two units (n = 2) being less frequent.

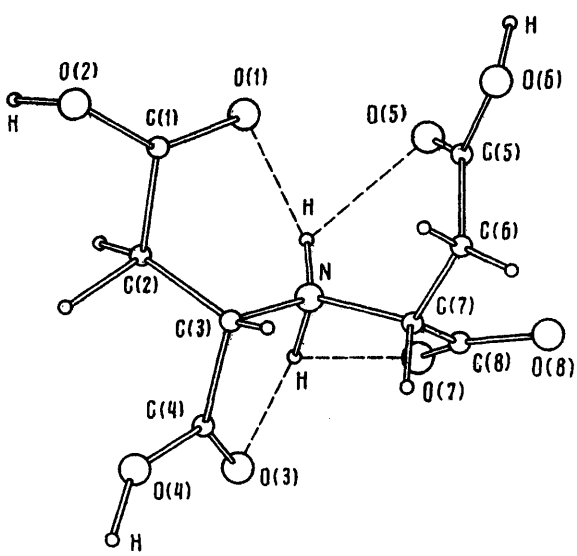


Figure 1. Structure of the iminodisuccinic acid (H_4ids) molecule.

Typical forms of H-ring that include two nitrogen atoms are examined below when the structure of di- and tri-amino complexones is discussed.

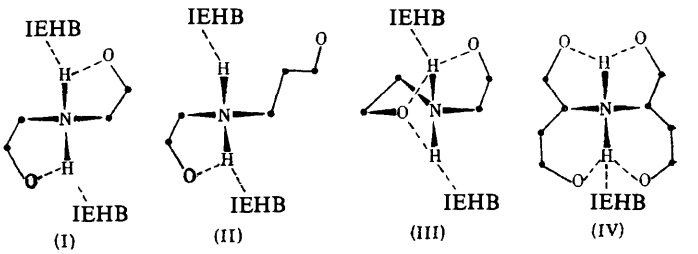
The combinations of H-rings in complexone molecules can vary considerably according to the composition of the complexone. Nevertheless, we can consider several quite standard combinations (sets) of H-rings that recur in different compounds. This is especially typical for combinations of five-membered H-rings. As a rule, five-membered H-rings have an envelope conformation, with dihedral angles between the rings lying within the comparatively narrow region of 90–130°. In this respect a clear genetic relationship can be traced between the stereochemistry of mono-, di- and tri-amino complexones.

III. Structure of monoamino complexones

Monoamino complexones can be divided into two groups in accordance with the structural nature of the central ammonium site: complexones with two H atoms on quaternised N (H_2ida class) and complexones with a single hydrogen atom on the betaine unit (H_3nta class).

In the first case, each of the two ammonium protons forms its (or their) independent H-ring, in the second case the H-rings are joined together by a common N–H bond.

The first group, in addition to the three forms of iminodiacetic acid (H_2ida), also includes H_2gp·$2H_2O$, H_3phmg, H_4idph, and H_4ids·H_2O (for labelling of the acids, see Table 1). The remaining 12 monoamino acids studied, including H_3nta itself, belong to the second group.



It is clear from the data given in Table 2 that in complexones of the H_2ida class the intramolecular H-bonds are considerably weaker than in complexones of the H_3nta class. This is especially apparent when comparing molecules that are similar in composition. In H_2ida the lengths of the intramolecular H...O bonds in all three modified forms is in the region 2.37–2.63 Å (the exception to this is one H-bond in the A form, where this distance is reduced to 2.16 Å), while in H_3nta the lengths are in the region 2.14–2.26 Å. In the glycinopropionic acid molecule (H_2gp) it is equal to 2.40 Å while in nitrilopropionic diacetic acid (H_3npda) the lengths are 2.13 and 2.27 Å. In H_3phmg the H...O distance to the O atom of the carboxyl group is 2.59 Å whereas in H_4phmida the distances are 2.38 and 2.44 Å and in H_5gdph it is 2.38 Å.‡

It also follows from the data given in Table 2 that the reduced length of the IAHB of the type N–H...O–C on going from H_2ida class complexones to H_3nta class complexones does not depend very much on the nature of the substituents R replacing the second hydrogen atom on nitrogen. Consequently, the cause of the weakening in IAHB in complexones of the first group is the very fact of increasing the number of hydrogen atoms on N. This, firstly, reduces their capacity to interact with O atoms and, secondly, increases the competitive capacity of intermolecular H-bonds, which are less rigidly restricted by the N–H...O angle. As the data of Table 2 also indicate, IEHB is much stronger than IAHB in all cases.

It is somewhat different picture with hydrogen bonding in which oxygen atoms of phosphonic or phosphonate groups participate. In this case the differences in strength of IAHB caused by the different degree of protonation of N atoms disappear, since IAHB of the type N–H...O–P is nearly always much weaker than IAHB of the type N–H...O–C.

a) Complexones of the iminodiacetic acid (H_2ida) class

Amongst the structures of monoaminocarboxylic complexones of the H_2ida class that were studied, four different combinations of IAHB and IEHB occur:

(I) (II) (III) (IV)

The structure of the H_2ida molecule in its two crystalline forms A and C is of a single type; each H forms a single H-ring and one IEHB [scheme (I)]. A similar combination occurs in the two monoaminophosphonic complexones H_3phmg and H_4idph. Replacement of the protonated acetate group by a protonated propionate group on going from H_2ida to H_2gp.$2H_2O$ (and on going from H_3phmg to H_3phma) causes the corresponding IAHB to disappear [scheme (II)]. Studies on other complexones and their cationic forms containing protonated propionate groups showed that H-rings of the type $1c'_2$ which are feasible in H_2gp and H_3phma are only formed when they are joined to other H-rings, and not in all cases (see below), whereas H-rings of the type $1c''_2$ are not formed at all.

In the two crystallographically independent H_2ida molecules with a stable B form, labelled B′ and B″ in Table 2, the formation of uniform sets of hydrogen bonds was detected, as shown in scheme (III). A characteristic of the system of hydrogen bonds here is the joining up of the $1c''$ H-rings along the line of O–C–C–N since the acceptor of IAHB that completes these rings is one and the same hydroxyl O atom of the carboxyl group.

On the whole the H...P distances (IAHB) in this class of aminocarboxylic complexones are in the range 2.37–2.63 Å and the angles at the H atoms are in the range 85–102°. Both these results indicate the weakness of such hydrogen bonds. An exception to this is one of the IAHB in the A form of H_2ida, where the H...O distance is equal to 2.16 Å and the N–H...O angle is 114°. Even less distinct are H-rings involving methylphosphonic groups. Many of them can only be regarded as hypothetical since the H...O distances in them are great as 2.60–2.80 Å, while in H_4cidph even 2.92 Å is attained.

In cyclohexyliminodimethylphosphonic acid (H_4cidph), in addition to a five-membered ring it is also possible to detect a six-membered H-ring (based on a C–H...O bond) of the type $1ph''_{C-H}$, in which the H...O distance is 2.46 Å and the C–H...O angle is 133°. In iminodimethylphosphonic acid a ring of the type $1ph'_{C-H}$ is more representative—the distance is 2.60 Å and angle is 122° (for more details about C–H...O bonds, see below). Naturally, intermolecular hydrogen bonding is much stronger in these compounds than IAHB; the H...O distances are in the range 1.80–2.01 Å (in H_4idph they are 2.12 Å) and the angles at the H atoms increase to 150–180°.

‡ It is assumed that the low accuracy in establishing the position of hydrogen atoms and the variable level of accuracy in structural studies result in a comparison of specific individual distances and angles involving hydrogen atoms not being entirely correct. Therefore, in this case and later in the text we shall examine only general trends that are sufficiently apparent without being dependent on the accuracy of individual figures.

It should be mentioned here that we recognise the actual concept of intramolecular hydrogen bonding to a sufficient extent hypothetically, without limiting the upper limits of the H...O or N...O distances to any specific value (for example, the sum of the van der Waals radii with an additional margin of 0.2 Å). The main criterion for the present authors is the degree of deviation of the C–O (or P–O) bond from the average planarity of the H-ring being formed. We consider that a hydrogen bond actually exists if on the whole the C–O (P–O) bond "faces" towards the ammonium centre of the complexone.

Table 2. Geometric properties of N–H...O hydrogen bonds in the structures of monoaminocarboxylic and monoaminophosphonic complexones.

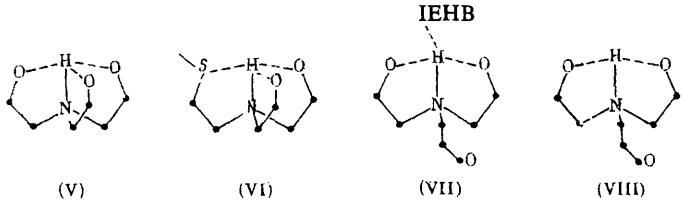
It is the weakness of IAHB (both relative and absolute) that leads to the stereochemical diversity of molecules of the H_2ida class. The molecules have a conformational flexibility and they readily change their conformation under the influence of IEHB. The existence of different crystalline forms of H_2ida is probably also a consequence of this.

Iminodisuccinic acid (H_4ids) can also formally be assigned to the H_2ida class [scheme (IV)]. The IAHB in it proved to be considerably stronger than in the remaining compounds of this class. The H_4ids molecule contains two succinate groups, which may be regarded as propionate groups with one of the H atoms replaced by a carboxyl group. It was established from X-ray diffraction studies that one of the α-carboxyl groups is deprotonated in accordance with its higher acidity compared to the β-group. In principle three ways of forming H-rings in H_4ids are possible, depending on the different combinations of IAHB involving the α- and β-carboxyl groups:



(A) (B) (C)

On crystallisation from solution, crystals in the form of (A) (Fig. 1) are isolated. The H_4ids molecule has a compact and probably the most favourable configuration energetically irrespective of intermolecular interactions, confirmation of which is its retention

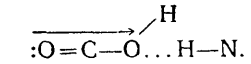
in the structure of the heteroligand complex $[Cu(H_2ids)(bipy)_2]\cdot 0.5fum\cdot 5H_2O$, where fum = fumaric acid. The H_2ids^{2-} anion retains its betaine structure with monodentate coordination to the Cu atom and has a system of IAHB similar to that of the neutral molecule (see Table 2). One H atom completes two five-membered rings and the other is included in two six-membered rings, the strength of the O...H bonds within each pair of rings being different.

b) Complexones of the nitrilotriacetic acid (H_3nta) class

The single ammonium (betaine) H atom on the N atom in complexones of the H_3nta class is highly active in forming hydrogen bonds, joining up at least two and sometimes three functional groups. Moreover, it participates in the formation of an H-bond with a heteroatom X if the latter is present in the molecule. In complexones of this class it is also possible for four different sets of H-rings to occur:

(V) (VI) (VII) (VIII)

Scheme (V) depicts the structure of $Hnta^{2-}$, H_2nta^-, H_3npda, Hdeg, β-H_2heida, β-H_2heidp, and Hndpma; scheme (VI) depicts the structure of $H_3meata.H_2O$; scheme (VII) shows the structure of H_2mida, $H_4phmida$, H_4cidph; and the structure of H_3nta, H_3ndpa, H_3ntp, and H_5gdph is shown in scheme (VIII).



The largest number of examples is included in the first group, where the trifurcated intramolecular N—H...O bond uses the oxygen atoms of all three functional groups as acceptors. Complexones which are characterised by the type of bonding in (VI), where one of the N—H...O bonds is replaced by an N—H...S, have a similar structure (concerning the similarity of the structure of this complexone and the diamino H_4cdta, see below). This type of structure can be called "closed".

Considerably different are the bonding variants (VII) and (VIII), in which one of the functional branches has a transoid rather than the usual twisted conformation relative to the N—H bond, which leads to the disappearance of one of the IAHB ("semi-closed" structure).

In complexones with a closed structure are to be found combinations of acetate groups and propionate, β-hydroxyethyl, and β-propionamide groups, or propionate groups combined with β-hydroxyethyl groups (in β-H_2heidp). It is true that H_3nta itself has a semi-closed structure (one of the two protonated acetate groups does not form an H-ring). However, the anionic forms of this acid (not only nta^{3-} and $Hnta^{2-}$ but also H_2nta^-) have a closed structure. The same applies to H_2nta^- in $Ag(H_2nta)$ and $Hnta^{2-}$ in $Ca(Hnta)\cdot 2H_2O$ and $Na[NaHnta]$.

The β-H_2heida molecule has one interesting feature. Instead of the usual $1c'$ glycine H-ring it contains an unusual $1c''$ isoglycine ring with a set of three H-rings ($1\bar{c}$-$1c''$-$1h$) being formed. It would seem that the reason for the inversion of the —COOH group might be the participation of the carboxyl O atom in an energetically more favourable intermolecular O...H—O or O...H—N interaction. However, despite the favourable configuration of the C=O group for this type of interaction, the carboxyl oxygen atom remains completely inert in relation to formation of IEHB of the type O...H—O or O...H—N but, on the other hand, participates in relatively weak IEHB of the type O...H—C.

It is known that IEHB of the type O...H—C is typical of amino acids, peptides, and other bioorganic compounds in which the N atom has an activating effect on the H atom of the neighbouring CH-, CH_2- or CH_3-group.[40] In the case of β-H_2heida the transition to a C—H...O bond, moreover, is encouraged by the weakening of the nucleophilic properties of the carbonyl O atom as a result of the withdrawal of electron density from it along the chain

A complexone which stands somewhat apart from amongst closed complexones of the H_3nta class is β-H_2heidp, in which a set of three H-rings ($1\bar{c}_2$-$1c'_2$-$1h$) is formed from two propionate groups and one hydroxyethyl group. The presence of two six-membered H-rings results in a significant weakening of the H-bond in the $1h$ ring containing the hydroxyethyl group compared to the analogous H-bonds in Hdeg and β-H_2heida, where this H-ring is combined with two five-membered rings.

The remaining complexes of the H_3nta class that were studied have a semi-closed structure. This applies not only to H_3nta itself but also to its analogue H_3ntp. Replacement of the acetate groups in H_3nta by propionate groups does not in principle change anything. Only instead of a combination of two five-membered H-rings ($1\bar{c}$-$1c'$) there is a combination of two analogous six-membered rings ($1\bar{c}_2$-$1c'_2$) (Fig. 2*a*). It is true that the conformation of the third functional group (—CH_2COOH and —CH_2CH_2COOH respectively), which does not participate in IAHB, is considerably different in the structures of the two acids; the H—N—C—C torsion angles in them are 174 and 48° respectively. But although in this first "bend" because of the small size of the torsion angle this branch in H_3ntp is capable of forming an H-ring, its second "bend", having a planar *trans* structure, turns the O atoms away from the betaine proton. The conformation of the group not participating in the formation of an H-bond is apparently determined by the packing requirements of the crystalline structure as a whole.

A similar structure occurs for nitrilodipropionic acetic acid (H_3ndpa) (Fig. 2*b*), but not for nitrilopropionic diacetic acid (H_3npda). In the latter all three H-rings are formed (Fig. 2*c*). While the semi-closed structure of H_3nta is considered to be an unusual coincidence, it may be assumed that the bifurcate nature of H-bonding in H_3ndpa and H_3ntp arises from the difficulty of forming at the same time two (even more so three) six-membered alanine H-rings because of the steric hindrance that occurs (the weakening of the H-bond involving the hydroxyethyl group in β-Heidp, as mentioned above, is an indication of this).

On the whole the observed variety of combinations of H-rings in the crystals of acids of the H_3nta class with a similar composition, and in particular in the series H_3nta—H_3ntp, is an indication of the strong dependence of the molecular conformation on apparently insignificant changes in the nature of the functional groups in the complexone. However, the possibility cannot be excluded that in solution there are different conformers, whose molecules contain a different number of H-rings. Nevertheless, it should be emphasised that in all of the complexones of this class, regardless of the nature of IAHB (bi- or tri-furcated), uniform sets of H-rings are formed. There is no doubt that the effect of intermolecular interactions is exhibited here to a very much smaller degree than in

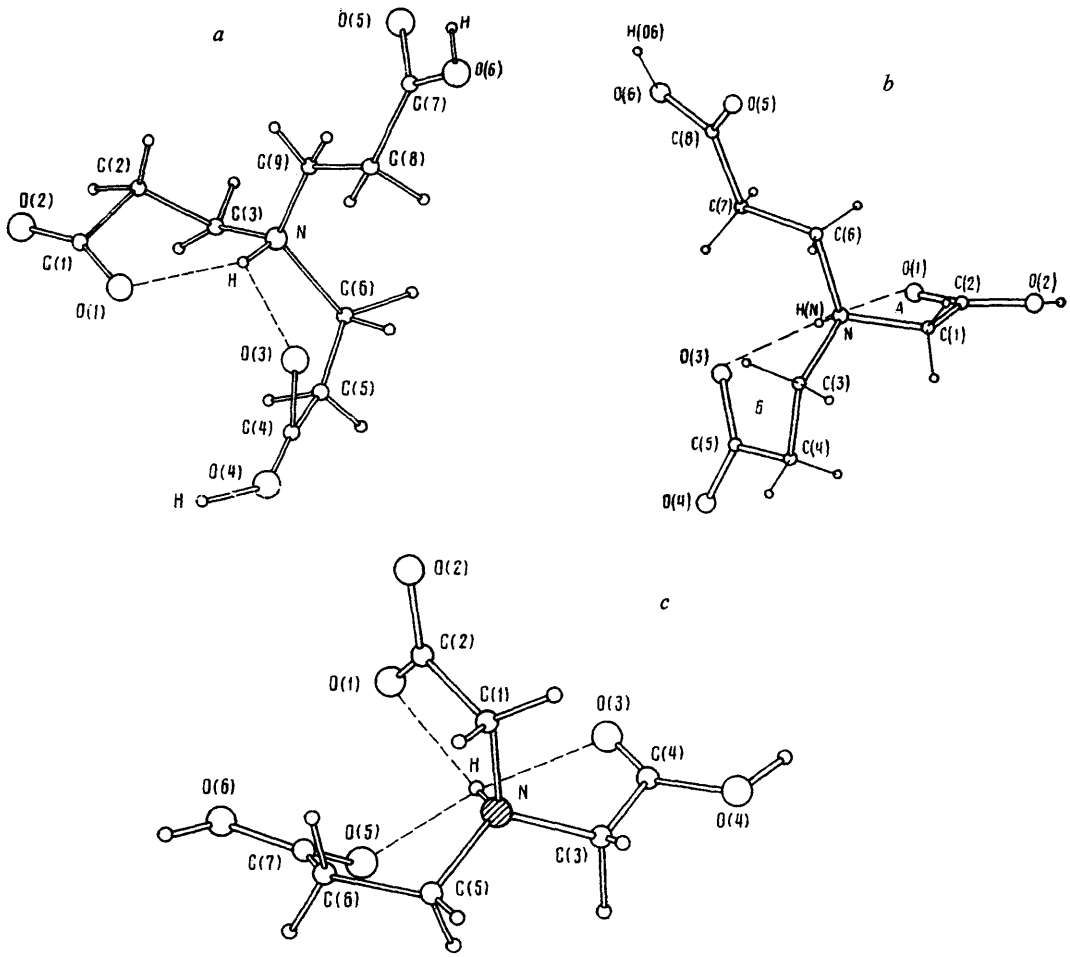


Figure 2. Structure of nitrilotripropionic acid (H_3ntp) (*a*), nitrilodipropionic acetic acid (H_3ndpa) (*b*), and nitrilopropionic diacetic acid (H_3npda) molecules (*c*).

monoaminocarboxylic complexones of the H_2ida class or in aminophosphonic complexones of both classes.

The structural data on "closed" and "semi-closed" compounds of the H_3nta class is sufficiently extensive to permit comparison between the geometric characteristics of H-rings of different types.

In rings of the type $1\bar{c}$ the H...O distances are 2.13–2.27 Å and the angles at the H atoms are 100–116°, while in rings of the type 1*c*′ these values are 2.26–2.46 Å and 97–111° respectively. These results indicate a weakening of IAHB on going from glycinate to glycine H-rings. The change from compounds with a "semi-closed" structure to a "closed" structure on deprotonation of H_3nta to H_2nta^- and $Hnta^{2-}$, for example, may be confirmation of this.

There are considerably less structural data on 1*h* and particularly 1*c*″ rings. In the 1*h* rings present in Hdeg and β-H_2heida, the H...O distances are in the range 2.21–2.31 Å and the angles at the H atom are 111–116°. In the structure of β-H_2heidp, as was indicated above, there is a pronounced weakening of the H...O bond forming the 1*h* ring (H...O distance 2.61 Å), namely, replacement of acetate groups by propionate groups causes this distance to increase by ~0.4 Å. Further replacement of a hydroxyethyl group by a propionate group in H_3ntp leads to complete ring-opening of one of the H-rings. These changes constitute a clear display of the mutual effect of the H-rings and are probably caused by steric factors.

1*c*″ H-rings were only detected in β-H_2heida and H_4phmida; the H...O distances in them are equal to 2.40 and 2.44 Å and the angles at the H atoms are 101 and 100°. Because of the lack of data, it may be concluded only provisionally that the 1*c*″ isoglycine rings have the lowest strength while the $1\bar{c}'$ glycine and 1*h* nitrilohydroxyethyl rings have approximately the same strength but lower than for $1\bar{c}$ glycinate rings.

The intermediate position of the 1*h* ring is supported by a comparison of the geometry of IAHB in Hdeg and β-H_2heida. In the first of these the H-bond involving the $1\bar{c}$ glycinate group is considerably stronger than that involving the 1*h* hydroxyethyl group, in the second the H-bond involving the hydroxyethyl group is stronger than that involving the 1*c*″ isoglycine group. The H...O distances in $1\bar{c}_2$ alanine rings are almost constant (~2.11 Å) and are virtually no different from the lower limit of the distances in $1\bar{c}$ rings. On the other hand, in $1c'_2$ alanine rings, as in 1*c*′ rings, the

H...O distances vary over a wide range and are also considerably longer than those in $1\bar{c}$ rings (2.31–2.50 Å).

The transition from five-membered to six-membered rings gives rise to considerably greater changes in the angles at the H atoms. They increase substantially (by more than 20°)—123–137° in the case of $1\bar{c}_2$ and 117–127° for $1c'_2$.

IAHB is least strong in aminophosphonic complexones. This applies primarily to the phosphonate or phosphonic groups themselves. In many cases they do not participate at all in the formation of H-rings (such as H_4phmida, H_6ntph, H_5gdph, H_4eadph, H_3phmg, and in the structure of H_3phmg·½HCl). Sometimes the formation of H-rings can only be hypothetically assumed, since the H...O distances in them increase to 2.48–2.92 Å. The other types of H-rings in these compounds also prove to be weakened, in particular for $1c'$ (in H_3phmg, H_4phmida, H_5gdph the H...O distances are 2.38–2.59 Å and the angles at the H atom are 90–106°), while a $1h_2$ ring is not formed at all in H_3phma (only intermolecular H-bonds occur in the structure). It would appear that in the case of monoaminophosphonic complexones it is only possible to indicate that there is a tendency to form H-rings, which occurs only when the molecular packing conditions are favourable.

These same groups, $-CH_2PO_3H^-$ and $CH_2PO_3H_2$, are possibly dependent on a purely conformational factor. Non-bonded interactions between the substituents in the two tetrahedral groups—phosphonic and methylene—make the most eclipsed conformation necessary for the approach of one of the atoms of the phosphonate group to the ammonium atom less favourable.

The groups described may be arranged in the following series of decreasing H-acceptor activity:

$$COO^- > COOH_{=O} > CH_2CH_2OH > COOH_{OH} > PO_3H^-,\ PO_3H_2$$

IV. Structure of diamino and triamino complexones

The list of structurally investigated diamino complexones known to the present authors includes eight diaminocarboxylic acids, four of their cationic and three of their anionic forms, three diaminophosphonic complexones and the cationic form of one of these (Table 1). The structure of a single triaminocarboxylic complexone is also known.

By analogy with monoamino complexones, diamino complexones can also be divided into two classes: those with ammonium centres each containing two hydrogen atoms [the ethylenediamine-*N*,*N'*-diacetic acid (H_2edda) class] and those with ammonium centres each containing one betaine hydrogen atom [the ethylenediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid (H_4edta) class].

Depending on the nature of the intramolecular H-rings formed, diamino complexones of both classes can be subdivided into three groups—open, semi-open, and closed. Compounds that do not form IAHB belong to the first group. In fact, this type of structure only occurs for the cationic forms of two complexones with propionate substituents—H_4eddp^{2+} and H_6edtp^{2+} as their hydrochlorides.

The second group includes compounds whose IAHB only join atoms that belong to their "own" half of the diamino complexone. H-rings characteristic of monoamino complexones are formed, and also as a rule in similar combinations, so such complexones can be called "quasi-monoamino".

The third group is made up by complexones that contain "crossed" IAHB between the atoms of the different halves of the molecule in addition to the IAHB of each monoamino moiety.

It is not difficult to realise that the formation of closed diamino complexones requires a twisted structure of the central (usually ethylenediamino) section. Complexones with a semi-open and open structure always have an unfolded transoid structure of the central section, which may be both the cause and the effect of the quasi-monoamino nature of their system of IAHB. The H_4eddp^{2+} cation, which has an open structure, and the H_2eddp molecule with a semi-open structure, are shown in Fig. 3*a* and 3*b* as examples.

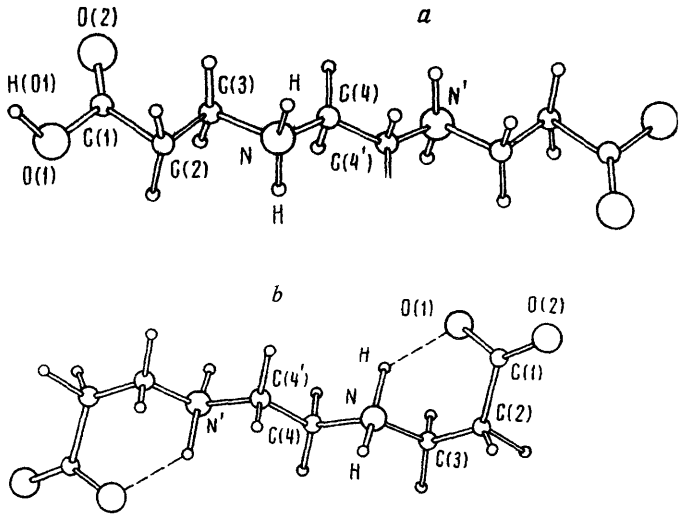

Figure 3. Structure of the H_4eddp^{2+} cation (*a*) and ethylenediamine-*N*,*N'*-dipropionic acid (H_2eddp) molecule (*b*).

In Table 3 all of the diamino complexones (and the triamino H_5dtpa) of both classes are assigned to their respective groups. It follows from Table 3 that almost all of the complexones from the H_2edda class have an open or semi-open structure. The presence of two H atoms on each ammonium centre is likely to lead to the degree of weakening of IAHB of the type N–H...O at which the strained folded structure becomes unstable. The only exception is $H_4edds·5H_2O$, which is probably related to the specific nature of the succinate groups.

Amongst those compounds that belong to the H_4edta class, all three structural variants have been found—open (in the H_6edtp^{2+} cation), semi-open (in five neutral molecules, two anions, and one cation), and closed (in five neutral molecules, one anion, and one cation).

As expected, a semi-open structure occurs in complexones with an elongated or complex hydrocarbon chain in the central section, as in H_4dbata, H_4dbeta, H_4dhobta, H_2oadp, and H_4egta (see Table 1 for structural formula), which hinders the formation of crossed hydrogen bonds. The molecules of H_2oadp§ and H_4dhobta are

§ The structure of the H_2oadp complexone is unique. This complexone is intermediate between semi-open and closed types. Its central section contains two carbonyl O atoms, so that it can form two intersecting five-membered H-rings without changing to a twisted conformation. Similar rings are also retained in the $oadp^{2-}$ anion, which is coordinated on two sides with Cu atoms in $[Cu(oadp)(bipy)(H_2O)_2]·H_2O$ (Fig. 4*b*).

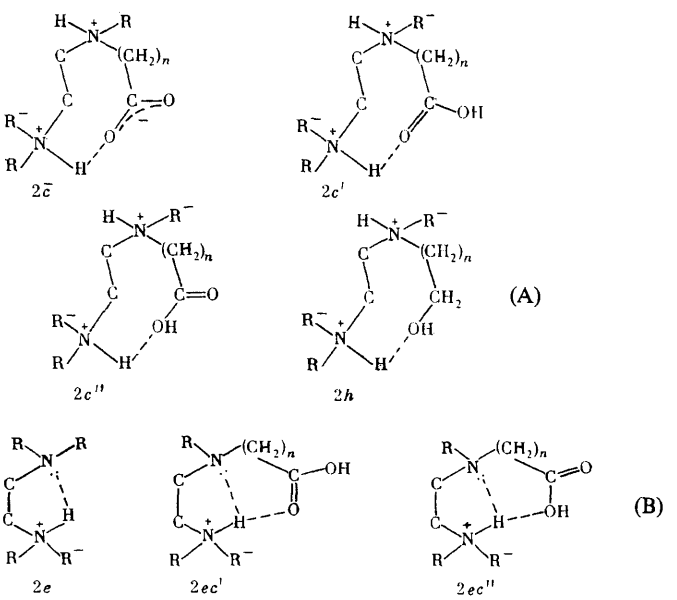

Table 3. Division of structurally investigated diamino and triamino complexones and their cationic and anionic forms into classes (H_2edda and H_4edta) and groups (different types of structure).

Group	H_2 edda class	H_4 edta class
Open structure	$[H_4eddp]^{2+}$ в $[H_2eddp]\cdot 2HCl$	$[H_6edtp]^{2+}$ в $[H_4edtp]\cdot 2HCl$
Semi-open structure (unfolded conformation of the central section)	$H_2eddp\cdot 2H_2O$ $H_4eddph\cdot 2H_2O$ $H_4eddiph\cdot 2H_2O$ $[H_6eddiph]^{2+}$ в $[H_4eddiph]\cdot 2HCl\cdot 2H_2O$ H_2oadp $oadp^{2-}$ в $[Cu(oadp)bipy(H_2O)_2]\cdot H_2O$	$[H_6edta]^{2+}$ в $[H_4edta]\cdot 2HCl\cdot 3H_2O$ $[H_2edta]^{2-}$ в $[Mg(H_2O)_6](H_2edta)$ $[H_2edta]^{2-}$ в $[Rb_2(H_2edta)]\cdot 2H_2O$ $H_4dbata\cdot 2H_2O$ $H_4dbeta\cdot 2H_2O$ $H_4dhobta\cdot 2H_2O$ $[H_5edta]^{+}$ в $[H_4edta]HBr\cdot H_2O$
Closed structure (twisted conformation of the central section)	$H_4edds\cdot 5H_2O$	H_4edta $[H_2edta]^{2-}$ в $K_2(H_2edta)\cdot 2H_2O$ $H_4cdta\cdot H_2O$ $[H_6cdta]^{2+}$ в $[H_6cdta][PdCl_4]$ H_5dtpa $H_8edtph\cdot H_2O$

depicted in Fig. 4*a* and 4*c* as examples. More curious and less easy to understand is the fact that anionic forms of the reference complexes H_2edta^{2-} in two compounds (Rb and Mg salts), in the same way as the cationic form H_5edta^{+} in hydrobromide, have an unfolded structure, while the same H_2edta^{2-} anion in the potassium salt and the acid itself (H_4edta) have a twisted conformation. This disparity evidently indicates that both forms are approximately equivalent in terms of energy and they are selected according to the specific composition of the compound as a whole. In particular, the change to a strongly acid medium, which creates the conditions for the formation of H_5edta^{+} from H_4edta, results in cleavage of the crossed N—H...O bonds, and hence leads to the conformation of the central section changing from twisted to transoid (Fig. 5*a* and 5*b*).

Finally, it is worth noting that neither the absence nor the presence of crossed IAHB are necessarily an indication of "symmetry" of the composition and conformation of the substituents of the two halves of the molecule. Symmetry in protonation of the carboxylate groups is absent, in particular in the semi-open H_4dhobta (Fig. 4*b*) and in the protonation of N atoms in H_4cdta (but not H_6cdta^{2+}) and H_5dtpa (Figs. 6 and 7). Finally, in the phosphonic complexone H_8edtph (Fig. 8), while there is complete "symmetry" of composition (see Table 3), symmetry is absent in the formation of IAHB. The structural features of these complexones will be examined below in greater detail.

In the molecules and ions with a semi-open structure, only those H-rings which are characteristic of monoamino complexones are possible. In complexones of a closed structure with crossed H-bonds, additional H-rings are formed, containing two nitrogen atoms:

The first group (A) comprises eight-membered rings (when $n = 1$) with N—H...O bonds; these are $2\bar{c}$, $2c'$, and $2c''$ H-rings based on a carboxylate substituent and a $2h$ H-ring based on a hydroxyethyl

substituent.¶ The second group (B) is made up by five-membered H-rings (when $n = 1$) with N–H...N bonds that occur when one of the two nitrogen atoms is quaternised; these are 2*e* (in a pure form), 2*ec'* and 2*ec''* (with additional expansion to eight-membered cyclic analogues of 2*c'* and 2*c''* rings). Such rings occur in the diamino H_4cdta and the triamino H_5dtpa (see structural formulae in Table 1 and Figs. 6 and 7). We should point out that the five-membered 2*e* ring may be regarded as an analogue of a 1*t* ring and hence a diamino complexone may formally be regarded as a monoamino complexone (and triamino like diamino) with an N heteroatom (carrying an unshared electron pair) as one of the substituents.

Let us pause to consider asymmetric complexones in somewhat greater detail. It is clear from Fig. 4*c* that the asymmetry of H_4dhobta arises not only because both carboxyl groups bound to one N atom are deprotonated while both of those bound to the other N* nitrogen atom are protonated. The difference also occurs because the H(N) atom takes part in the formation of a trifurcated bond with the two ionised atoms O(1) and O(3) and with the O(5) atom of the hydroxyl group in the neutral residue, while the H(N)* only participates in a bifurcated bond with the carbonyl atoms O(1)* and O(3)*. This results from the specific manner of unfolding of the successive units of the chain in the central section, leading to a convergence of the O(5) and H(N) atoms but not the O(5)* and H(N)* atoms.

The structure of the H_4cdta molecule, in which only one N(1) atom is quaternised, is depicted in Fig. 6. Its H(N1) proton participates accordingly in the formation of a trifurcated bond, forming a five-membered 2*e* ethylenediamine (*E*) H-ring and five-membered $1\bar{c}$ glycinate (*A*) and 1*c'* glycine (*B*) rings.

The structure of the triamino complexone H_5dtpa is shown in Fig. 7. Here also not all but only two of the three nitrogen atoms—the central N(1) atom and one of the lateral N(2) atoms—are quaternised, although the lateral nitrogen atoms are known to have a higher basicity than the central atom. In essence, the molecule may be regarded as a diamino complexone with a bis-zwitterion structure [the N(1) and N(2) atoms] and an analogue of H_4edta with replacement of one of the acetate groups by an ethyleneaminoacetate group. The N(2) atom, in the same way as in H_4edta, belongs simultaneously to three conjugated H-rings involving acetate groups (rings *A*, *B*, and *C* in Fig. 7), one of which (*C*) is crossed. Replacement of one of the acetate groups on the N(3) atom by an ethyleneaminoacetate group permits the H(N1) atom to form only two rings—an ethyleneamino ring (*E*), the same as in H_4cdta, and an eight-membered ring involving an acetate group (*D*), namely the combination labelled above as 2*ec'*. The geometric properties of the N–H...N bond in H_5dtpa and H_4cdta are very similar (Table 4). Thus, both the molecular geometry and the system of IAHB in H_5dtpa combine typical features of H_4edta and H_4cdta. The triaminocarboxylic complexone is made up of standard sets of H-rings that are typical of monoamino- and diamino-carboxylic complexones.

Perhaps the most individual structure is that of the methylphosphonic diamino complexone H_8edtph (Fig. 8) (for structural formula, see Table 1).

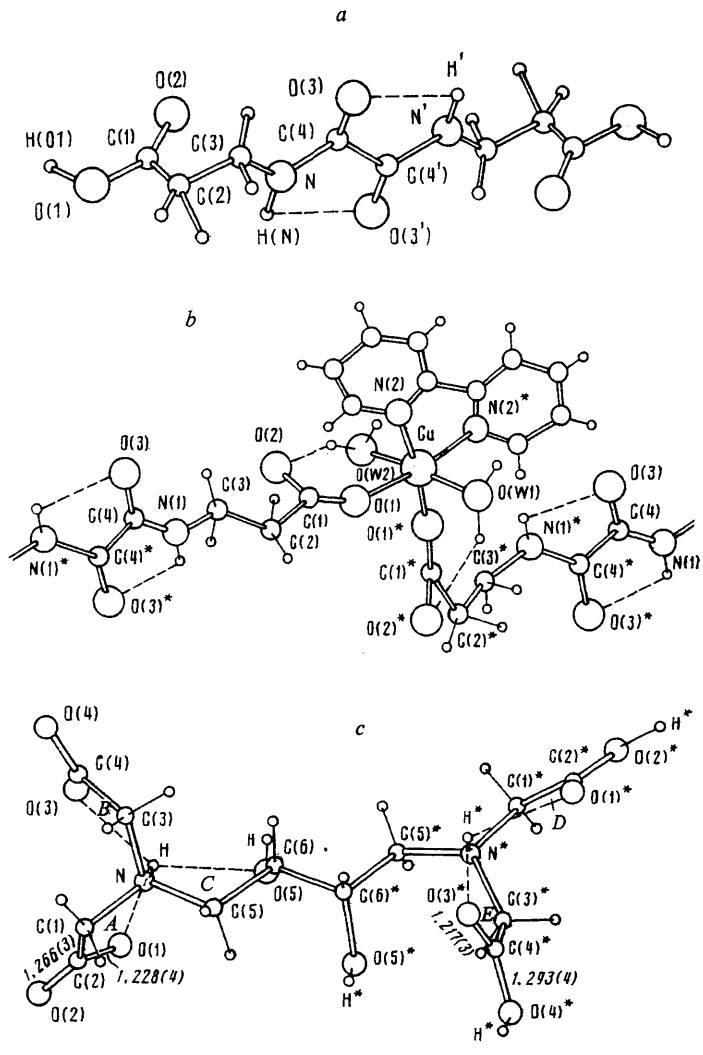

Figure 4. Structure of the oxamido-*N*,*N'*-dipropionic acid (H_2oadp) molecule (*a*), a section of the polymeric chain structure of $[Cu(oadp)(bipy)H_2O)_2]\cdot H_2O$ containing $oadp^{2-}$ anions (*b*), and the 2,3-hydroxy-1,4-butanediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid molecule (*c*). Primes are used to denote atoms that are related by symmetry elements and asterisks are used to denote crystallographically independent atoms in the second half of the molecule.

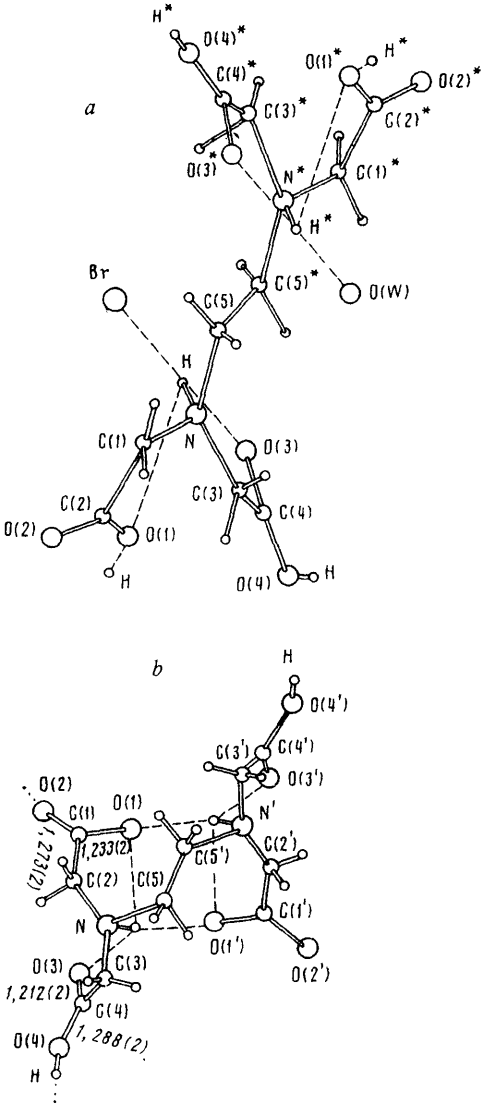
At first glance it resembles the structure of the H_4edta molecule. It has the same twisted conformation of the central ethylenediamino residue (with a dihedral angle of 86° instead of 67°), there are H-rings that include only their "own" phosphonate and also "crossed" rings that involve a "foreign" phosphonate group. In fact, however, there is only one nitrilomethylphosphonate H-ring ($1\overline{ph}$) (ring *A* in Fig. 8); the remaining three six-membered rings—$1\overline{ph}''_{C-H}$ and $1ph'_{C-H}$ (crossed) and $1ph''_{C-H}$ (terminal) (*B*, *C*, and *D*)—are formed by C–H...O bonds rather than N–H...O.

¶ Variants based on phosphonate or phosphonic groups have not been given since molecules with such types of H-ring have so far not been detected.

The specific nature of methylphosphonic complexones is manifested in this (as mentioned above in connection with similar IAHB in monoamino complexones). It is natural that the hydrogen bonds in these H-rings are some of the weakest.



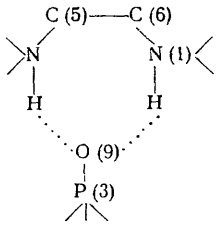


Figure 5. Structure of the H_5edta^+ cation (*a*) and ethylenediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid (H_4edta) molecule (*b*).

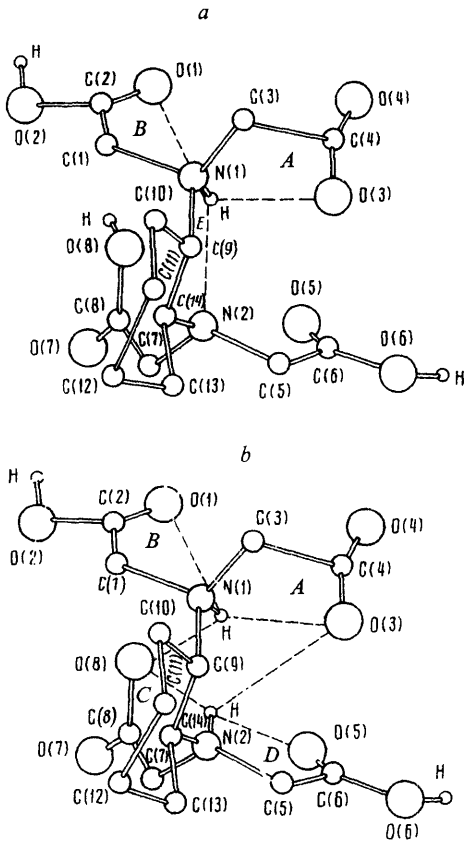

Figure 6. Structure of the *trans*-1,2-cyclohexanediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid molecule (*a*) and its hypothetical tautomeric form (*b*).

In H_8edtph there is perhaps the clearest exhibition of the tendency of methylphosphonate complexones to form intermolecular N−H...O hydrogen bonds involving the oxygen of a phosphonic or phosphonate group rather than intramolecular hydrogen bonds. An unusual feature of the crystalline structure of this compound is also that the O(9) atom of the phosphonate group of the neighbouring complexone forms an IEHB simultaneously with two

In the majority of the asymmetric complexones described there are short intermolecular hydrogen bonds of the type O...H...O, where the potential lability of the proton makes the description of the sets of H-rings in them not completely unequivocal (it opens up the possibility of a $1\bar{c}$ ring involving a COO^- group being replaced by a $1c'$ or $1c''$ ring involving a COOH group and vice versa). This question is considered in greater detail in the next section.

The geometric properties of hydrogen bonding (IAHB and IEHB) in the diamino and triamino complexones studied are given in Table 4. The labelling of the "sets"—the combinations of conjugated H-rings—is also given here.

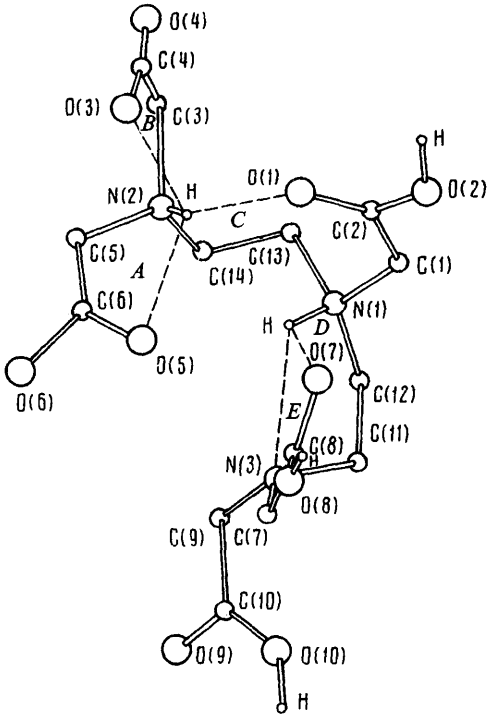

Figure 7. Structure of the diethylenetriamine-*N*,*N*,*N'*,*N''*,*N''*-pentaacetic acid (H_5dtpa) molecule.

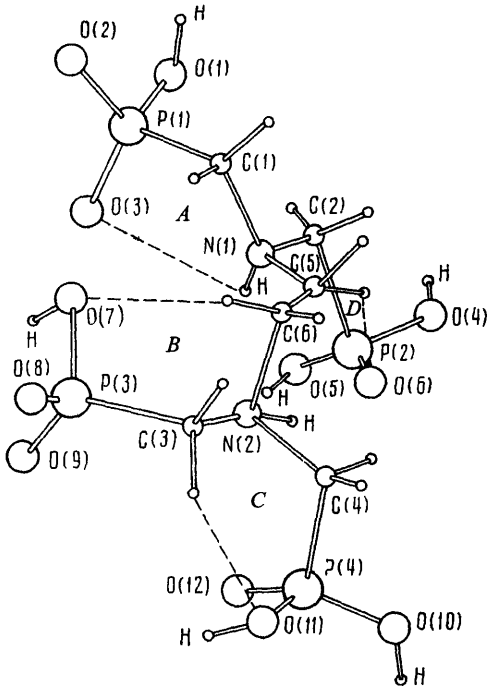
Comparison of the H...O distances and angles at the H atoms in diamino complexes is perhaps not so indicative as in monoamino complexones, mainly because of the intervention of intermolecular O...H...O bonds that increase the lability of the hydrogen atoms. If the clear examples of this type of interference are set aside (indicated by additional symbols in brackets in the labelling of the H-rings in Table 4), all of the H...O distances in rings of the type $1\bar{c}$ or $2\bar{c}$ fall within the region of 2.00–2.38 Å and the angles at the H atom are 101–132° while in rings of the type 1*c'* the distances are in the range 2.17–2.52 Å and the angles are 94–124°. In the only "pure" 1*c''* ring the O...H distance and N–H...O angle are equal to 2.42 Å and 95° respectively, while in the only 1*h* ring these values are 2.41 Å and 106°. At any rate these results are not at variance with the series of H-acceptor activity which was put forward on the basis of the structures of monoamino complexones.

Bonds of the type C–H...O (H...O equal to 2.27, 2.35 and 2.37 Å) which are found in the diamino complexone H_8edtph are somewhat shorter than the analogous bonds in monamino acids, while the angles at the H atom are greater than 140°.

V. Prototropic tautomerism in aminocarboxylic complexones

In the crystal structures of some of the mono- and diaminocarboxylic complexones discussed and also in the triamino complexone H_5dtpa short intramolecular hydrogen bonds of the type O...H...O occur (usually slightly asymmetric) with an O...O distance in the range 2.43–2.49 Å and an angle at the H atom in the range 160–180°. In certain cases studies have revealed two possible positions of the hydrogen atom between the oxygens. Short H-bonds can combine acidic groups of neighbouring molecules into dimer pairs or chains.



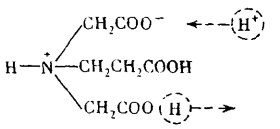


Figure 8. Structure of the ethylenediamine-*N*,*N*,*N'*,*N'*-tetramethylphosphonic acid (H_8edtph) molecule.

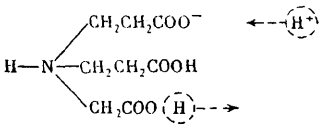
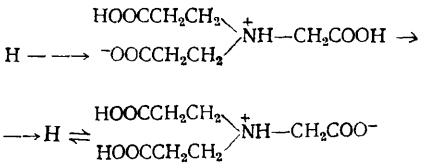


This fact suggests the possibility of tautomeric rearrangement in solution by migration of a proton or, at least, the possibility of two tautomeric forms existing in a given proportion. This suggestion is based on the somewhat unusual distribution of hydrogen atoms amongst the acid groups and on the unexpected asymmetry of some complexones.

In crystals of nitrilopropionic diacetic acid (H_3npda) one of the acetate groups is deprotonated. At the same time there is a "short" O–H...O bond of length 2.460(4) Å between the CH_2COOH groups of one molecule and CH_2COO^- groups of another [see scheme (IX) and Fig. 2*c*]. The tautomeric rearrangement on migration of a proton does not give rise to any fundamental change in the chemical structure of the molecule—deprotonated and protonated acetate groups are preserved. It is different with the

structure of nitrilodipropionic acetic acid (H_3ndpa) [see scheme (X) and Fig. 2*b*]:



(IX)

(X)

It is somewhat surprising that in the presence of the more acidic acetate group it is one of the propionate groups that is actually deprotonated. However, the short hydrogen bond of length 2.467(8) Å between the hydrogen atom of a CH_2COOH group and the oxygen atom of a $CH_2CH_2COO^-$ group suggests the possibility of a tautomeric rearrangement occurring when the molecule passes into solution to form a more stable zwitterion form:

In the structure of the semi-open diamino complex H_4dhobta (see Fig. 4*c*) the asymmetry in the arrangement of CH_2COO^- and CH_2COOH groups (two CH_2COO^- groups are situated on the N atom and two CH_2COOH groups are on the N* atom) is unexpected. However, there is a short intermolecular hydrogen bond O(4)*—H(O4)*...O(2) between the O(4)* and O(2) atoms of neighbouring molecules. The O(4)*...O(2) distance is equal to

*Random distribution of O atoms of phosphonic groups.

2.470(2) Å, the H-bond is almost symmetrical, and the C–O bonds in the groups that are linked are evidently capable of undergoing tautomeric rearrangement by delocalisation of π-interaction. In the O(1)–C(2)–O(2) group they are equal to 1.228(4) and 1.266(3) Å respectively while in the O(3)*–C(4)*–O(4)* group they are 1.217(3) and 1.293(3) Å in length. Under these conditions it is natural to expect a tautomeric change to a symmetrical form on solution:

Short O–H...O IEHB also occur in a number of closed diamino complexones, and primarily in H_4edta itself (Fig. 5*b*). The O(4)...O(2) distance in short IEHB is equal to 2.460(2) Å, and the O(4)–H and O(2)...H distances are 1.20(3) and 1.28(3) Å. It is the acetate groups that are able to undergo rearrangement (see Fig. 5*b*). In the COOH group the π-electrons are not completely localised and in the COO^- group they are delocalised. When tautomeric rearrangement occurs in both halves of the molecule the $1\bar{c}-1c'-2\bar{c}$ sets of H-rings are changed to $1c'-1\bar{c}-2c'$. The molecular symmetry as a whole is not disturbed.

The asymmetric structures of the diamino H_4cdta and triamino H_5dtpa complexones are the most interesting in relation to the present topic. It is not difficult to see (see Fig. 6*a*) that the position of one of the carboxyl groups bonded to the non-protonated N(2) atom [the group containing the O(8) and H(O8) atoms] is such that the molecule as a whole is capable of forming an O(8)...H(N1)–N(1) bond. Although the O(8)–H(N1) distance is quite long (2.62 Å), a small change in the conformation of the central section could lead to cleavage of the N(1)–H(N1)...N(2) bond and formation of an N(1)–H(N1)...O(8) bond with replacement of the $1\bar{c}-1c'-2e$ set by a $1\bar{c}-1c'-2c''$ set. If a subsequent tautomeric transfer of the H(O8) proton from the O(8) atom to N(2) is assumed, the complex would acquire a symmetrical structure similar to that of H_4edta, with $1\bar{c}-1c'-2\bar{c}$ sets (see Fig. 6*b*).

Such a possibility is supported by the completely symmetrical closed structure of the H_6cdta^{2+} cation, in which both nitrogen atoms are quaternised. Since the synthesis of $[H_6cdta]^{2+}[MCl_4]^{2-}$ complexes, where M = Pd and Pt, occurs in hydrochloric acid solutions, we can suggest the nature of the changes in the structure of H_4cdta on going from a less acidic medium to a more acidic one.

The N...N distances in H_4edta, H_6cdta^{2+}, and H_4cdta are equal to 3.195, 3.102, and 2.825 Å respectively. It may be assumed from the similarity in the general conformation of these three molecules that under certain conditions H_4edta may undergo a reverse tautomeric rearrangement, i.e., acquire the asymmetric structure characteristic of H_4cdta.

In the triamino complexone H_5dtpa both the tautomeric rearrangement characteristic of H_4edta and a rearrangement similar to that described above for H_4cdta are possible.

In fact, H_5dtpa molecules are combined in the crystalline state through the formation of IEHB similar to that found in H_4edta crystals. The O(2)...O(4) distance (between the carboxyl and carboxylate groups of neighbouring molecules) is equal to 2.455(3) Å with O...H* distances (1.24–1.25 Å) that are the same within the limits of experimental error. It is the acetate groups which are capable of undergoing rearrangement. Transfer of a proton from O(2) to O(4) does not, of course, disturb the trifurcate IAHB involving the ammonium H(N2) atom, but it changes the $1\bar{c}-1\bar{c}-2c'$ set of H-rings to $1\bar{c}-1c'-2\bar{c}$, which is exactly the same as the set in H_4edta.

The position of one of the carboxyl groups on the non-quaternised N(3) atom in H_5dtpa (it is determined from the values of the dihedral angles) is very similar to the position of the analogous group in H_4cdta, but while in H_4cdta the O(8) atom is merely capable of forming an O(8)...H(N1)–N(1) bond, in H_5dtpa the analogous O(7) atom forms such a bond and completes an eight-membered ring (in this case an H-ring of the type $2ec'$). It is also possible to admit the transfer of the H(O8) proton in the H_5dtpa molecule on to the N(3) atom with replacement of the bifurcated $2ec'$ system (containing a $2c'$ ring as a component) by a $2c'$ with an N(1)–H(N1)...O(7) bond and a $1c'$ ring with an N(3)–H(N3)...O(7) bond and with a suitable rotation of the carboxyl group containing the O(9) and O(10) atoms leading to the formation of a second ring of the type $1c'$ with an N(3)–H(N3)...O(9) bond (compare ring *D* in Fig. 6*b*).

Of course, these rearrangements can only be regarded as conjectural, but on the whole the possibility of the occurrence in complexones of tautomeric rearrangements relating to the position of "active" H atoms between different acidic groups of neighbouring molecules or to incomplete quaternisation of N atoms clearly exists.[4]

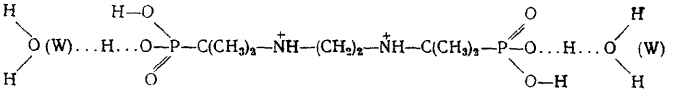
Ethylenediamine-*N,N'*-diisopropylphosphonic acid dihydrochloride dihydrate	$[H_6eddiph]Cl_2\cdot 2H_2O$	[29]

VI. Structural features of hydrohalides of complexones

The structures of hydrohalides of complexones can be used to simulate the behaviour of the corresponding complexones in strongly acidic media.[4] At the present time structural data on eight hydrohalides of aminocarboxylic complexones and two hydrohalides of aminophosphonic complexones are available (Table 5). These data relate to four hydrohalides of H_2ida (including its

hydrofluoride), dihydrochlorides of two acids containing propionate groups (H_2eddp·2HCl and H_4edtp·2HCl), and two hydrohalides of H_4edta (H_4edta·HBr·H_2O and H_4edta·2HCl·$3H_2O$), as well as phosphonomethylglycine semihydrochloride H_3phmg·½HCl and the dihydrochloride of ethylenediamine-*N*,*N*′-di(isopropylphosphonic) acid H_4eddiph·2HCl·$2H_2O$. The position of the dissociated protons of hydrohalic acids is a key feature in a discussion of the structure of compounds of this class.[4] In this case it is logical to start with the concept of a zwitterion structure of complexones in both the crystalline state and solution.

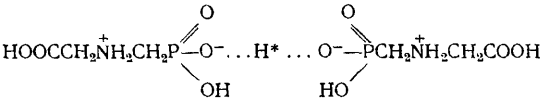
It was possible to use the structural data to establish a dependence of the crystalline structure of hydrohalides of complexones on the acidic properties of the functional groups. In cations based on weak acids the dissociated protons of the hydrohalides are clearly located on the deprotonated acid groups of the complexones, converting the molecules of the latter into cations. Strong (according to the classification of Megaw)[46] IAHB does not occur in such crystals. As an example let us examine the structure of the propionates H_2eddp·2HCl and H_4edtp·2HCl, for which precisely this type of cation-anion structure—$(H_4eddp^{2+})(Cl^-)_2$ and $(H_6edtp^{2+})(Cl^-)_2$—has been found. The cations have an open structure with the protons (from HCl) quite clearly located on the propionate groups. Although the latter could potentially participate in IAHB to form $1c'_2$ or $1c''_2$ H-rings, such rings do not occur. Even though the cations have an open structure they cannot form IEHB either between themselves or with anions.



A similar cation-anion structure also occurs for hydrohalides of H_2ida, although the acetate groups have a higher acidity than propionate groups. The absence of acceptors that are suitable for forming strong IEHB, which is supported by the completely different structure of H_2ida hydrofluoride (see below), may in this case account for the low strength of IEHB.

In cations based on fairly strong acids, the dissociated protons of the hydrohalides, on the other hand, participate in the formation of strong IEHB of the type O—H...O or O—H...X, with H-rings based on IAHB being retained, although it is true that they are sometimes in combinations that are different from those in the initial complexones. Different situations can occur depending on the nature of the acid group.

Thus in H_2ida hydrofluoride quite strong IEHB of the type O—H...F has been detected between the O atom of the carboxyl group and an F^- ion [O...F distance is 2.502(2) Å], which can be attributed to the closeness of their electronegativity values (and also the van der Waals radii), i.e., to satisfy the conditions that are necessary for the formation of strong bonds.[47] A similar pattern, namely, conversion of the complexone to a cationic form with the formation of more or less strong IEHB of the type O—H...O [length 2.51(2) Å], also occurs in the case of the above-mentioned H_4edta·2HCl·$3H_2O$, the actual formula of which is $(H_6edta^{2+})(Cl^-)_2 \cdot 3H_2O$ (1:2 composition). Protonation of all of the acid groups in the complexone eliminates its zwitterion character.



The formation of a cationic form in the hydrobromide H_4edta·HBr·H_2O (1:1 composition) occurs in a different manner. Conversion of the H_4edta molecule into an H_5edta cation does not destroy the zwitterion character of the molecule, but with this type of protonation its structure changes markedly, as has already been mentioned. The crossed eight-membered H-rings are ruptured and the central section acquires a transoid structure. At the same time the proton from dissociated HBr is not attached to any single CH_2COO^- group but is located between "semi-protonated" acetate groups of neighbouring complexones, forming strong IEHB of the type O(1)...H*...O(1)* (Fig. 5*a*) of length 2.455(5) Å with a random arrangement of two positions that are separated from each other by 0.66 Å. The resulting infinite associate that is based on this type of IEHB may be regarded as both a chain of H_5edta^{2+} cations and an alternating sequence of neutral H_4edta molecules and H_6edta^{2+} cations. It is also worth drawing attention to the fact that synthesis of this compound was carried out using excess HBr; hence the composition of the product depends on the nature of the halogen (compare with H_4edta hydrochloride).

A similar situation occurs in the structure of H_4eddiph·2HCl·$2H_2O$, where the protons from HCl are randomly distributed between monoprotonated phosphonate groups and water molecules through a strong IEHB of length 2.423(4) Å.

In this case such a structure also proves possible for a composition of 1:2 because of the increased acidity of the phosphonic group compared to the carboxyl; the pK_1 values of H_2ida and H_4idph acids are 2.54 and < 1 respectively.[48] Attachment of the proton to one of the O atoms participating in the formation of IEHB can indicate two structural variants in this case: combinations of zwitterion H_4eddiph molecules and H_3O^+ and Cl^- ions or combinations of H_6eddiph^{2+} cations, water molecules, and Cl^- anions. As in the case of H_4eddiph·$2H_2O$, the complexone in H_4eddiph·2HCl·$2H_2O$ retains a semi-open structure.

In the structure of the hydrochloride H_3phmg·½HCl, the proton that has dissociated from HCl unites two H_3phmg molecules into a dimeric associate

with a strong symmetrical IEHB O...H*...O of length 2.454(3) Å. The structure in this case is quite unambiguous; the H* protons are situated at the centres of inversion and the Cl^- anions are on double axes of symmetry. In the H_3phmg hydrochloride molecule a $1c'$ H-ring is retained and the $1\overline{ph}'$ H-ring present in the structure of H_3phmg itself has opened.

The small amount of data on the crystalline structures of hydrohalides reported in this section shows that both their composition and structure are determined primarily by the nature (acidic properties) of the functional groups of the complexone and to a considerable extent by the nature of the halogen.

VII. Conclusion

The role of crystal chemical data in the resolution of problems in basic chemistry has increased very greatly during the last ten years. Structural analysis has been introduced into the very fabric of chemical research as one of its most indispensable and important components. The significance of this component is especially great for those areas of chemistry which deal with structural units—molecules, oligomers, or polymers—consisting of residues that can undergo various ways of combining with each other.

On the preceding pages only one aspect of the structural chemistry of complexones was examined—the structure of the

molecules themselves. Questions relating to the packing of the molecules in crystals, the geometric ratios with the outer-sphere ions and solvate (hydrate) molecules have been referred to only occasionally by the present authors, in mentioning only those cases of interest for their unusual nature or of importance for an understanding of possible rearrangements on going from the crystalline state to solution.

There is no doubt that there are many different aspects of the structure of such complex compounds as polyaminopolycarboxylic acids that have not been touched upon in this review. But in any case there seems to be no doubt that even incomplete structural data on complexones are not solely of independent interest. To an even greater degree they are important as a structural basis for the interpretation of their spectroscopic parameters and for developing the most effective and adequate theoretical ideas about the relationship between structural and spectroscopic properties, for a comparison of the structure of complexones and metal complexonates in crystals and in solution under different conditions (depending on the concentration and acidity), and in the end they are important for a better understanding of reaction pathways and for directed synthesis of complexonates in solving specific practical problems. The present authors, however, have quite deliberately limited the scope of this study to purely structural material, in realising that all of these problems require further varied and thorough physicochemical studies and that to supply the overall results in this area is premature for the time being.

Spiropyrans: structural features and photochemical properties

S M Aldoshin

Branch of the Institute of Chemical Physics, USSR Academy of Sciences, Chernogolovka

ABSTRACT. The structure of photochromic systems based on different classes of spiropyrans, which are promising materials for the optical recording of information and control of luminous fluxes is examined. The structural factors which affect the photochemical activity of spiropyrans and the stability of the coloured forms derived from them have been established. It is shown that the photochemical properties of spiropyrans occurs to a considerable extent because even in the ground state the $C_{spiro}-O$ bond being cleaved on photoexcitation is weakened and elongated through specific $n-\sigma^*$ orbital interactions. The effect of the nature, electronic state, and relative orientation of the heteroatoms in the spiro centre on the efficiency of $n-\sigma^*$ interactions is analysed. The formation of different strong intermolecular associates and solvates has been found in the crystalline structure of the coloured forms of spiropyrans, which to a considerable degree determines the stabilisation of the complex resonance structure of these compounds.

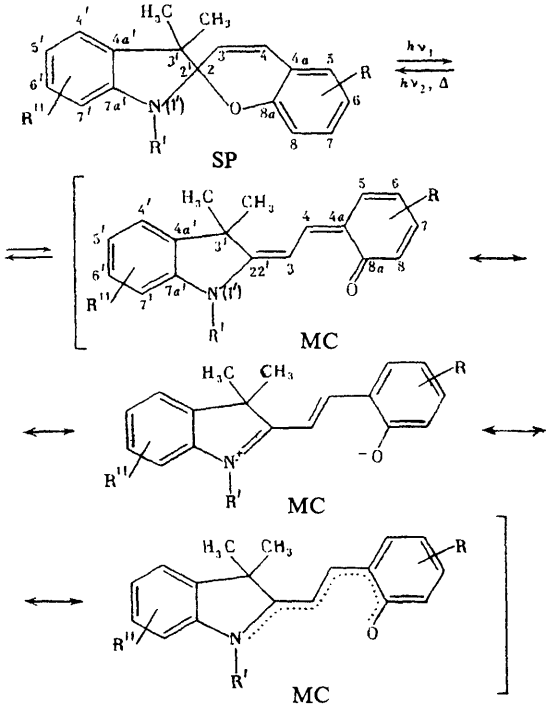
I. Introduction



Photochromic materials based on different classes of spiropyrans (SPs) are widely used at the present time for the production of light filters that regulate luminous fluxes, photochromic organic media for recording and processing optical information, and in other areas of science and technology.[1] Among the different classes of photochromic materials, indoline spiropyrans are distinguished by their high sensitivity and resolving power, and they exhibit photochromic properties in solution, in polymer matrices, and even in the solid state, which is very convenient for their practical application.

Photolysis of virtually colourless spiropyrans leads to the formation of dyes, the electronic absorption spectra of which occur in the region of ~400 to 700 nm and have a complex pattern that depends on the structure of the SP, the nature and position of the substituents, the solvents, the temperature, and other factors. Many SPs also have thermochromic properties. Despite intensive research in this field, the mechanism of photochromic SP reactions and the relationship between their structure and photochemical properties are still not fully understood.

It was established[2,3] from spectroscopic and quantum-chemical data that photo- and thermal coloration of indoline SPs is due to a valence isomerisation related to cleavage of the $C_{spiro}-O$ bond and formation of a merocyanine type of coloured structure

The photochemical activity of an SP can depend to a considerable extent on the energy of the $C_{spiro}-O$ bond and its polarity,[4] the charge distribution on the atoms of the pyran ring,[5] and the degree of electronic interaction between the indoline and pyran sections of the molecule.[6–8] The stability of the resulting merocyanine (MC) and its spectroscopic properties are related to the degree of planarity of the chromophoric chain,[9] the presence of intramolecular H-bonds stabilising the structure,[10] and the degree of equivalence of the orders of π-bonds in the chromophore.[11] These factors, which affect the photochemical properties of SPs, primarily depend on the structure of the initial SPs and the resulting MC forms.

Therefore a systematic X-ray study of these compounds is important not only for an understanding of the structural mechanism of the photochromic reactions of SPs but also for establishing the relationship between their structure and photochemical properties.

At the present time the synthesis of SPs of practical importance is related to a varied structural modification of these systems which improves their performance characteristics, such as quantum yield of photolytic conversions, lifetime of the open form, and a high number of conversion cycles without substantial decomposition of the SP. Nevertheless, X-ray diffraction studies on SPs only started in the middle of the 1970's.[12,13]

II. Structure of indoline spiropyrans

1. Effect of structure on photochemical properties

An X-ray diffraction study of the initial 1',3',3'-trimethyl-6-nitro-8-bromospiro(indoline-2,2'-[2*H*-1]benzopyran) [SP(I)] (R' = CH_3, R^6 = NO_2, R^8 = Br) and its photochemical conversion product—MC(I)—was first successfully carried out in 1980.[14] Spiropyran SP(I) has thermochromic properties and at room temperature in solution is in equilibrium with its open form. Spiropyran (I) was obtained as yellow crystals by crystallisation from toluene on irradiation with light from an incandescent lamp. The photoproduct MC(I) was isolated from ethanol as dark red crystals. The general shape of the SP(I) molecule is shown in Fig. 1. The nonplanar indoline and benzopyran residues are situated approximately at right angles to each other in the molecule. The indoline residue has a dihedral angle of 27° along the line of N(1')...C(3'), and the benzopyran residue has a dihedral angle of 16.1° along the ling of O(1)...C(3) and 6.6° along the line of O(1)...C(4). The dihedral angle between the O(1)C(22')C(3) plane of the benzopyran ring and N(1')C(22')C(3') plane of the indoline ring at the C(22') spiroatom is 87.2°. The bond lengths and bond angles in the SP(I) molecule are similar to the corresponding values in spiropyrans SP(II) and SP(III) which were studied previously (II: R' = Ph, R^8 = NO_2;[12] III: R' = Ph, R^6 = Cl, R^8 = NO_2 [13]). In spiropyrans SP(I)–SP(III) the C_{spiro}–O bond [1.492(3)–1.496(4) Å] is considerably longer than normal C–O bonds in six-membered oxygen-containing heterocycles [1.41(1)–1.43(1) Å].[15–17]

The general shape of the MC(I) molecule is shown in Fig. 2. In crystals of MC(I) isolated from a solution of non-absolute alcohol, the MC(I) molecules are solvated with water molecules. The change

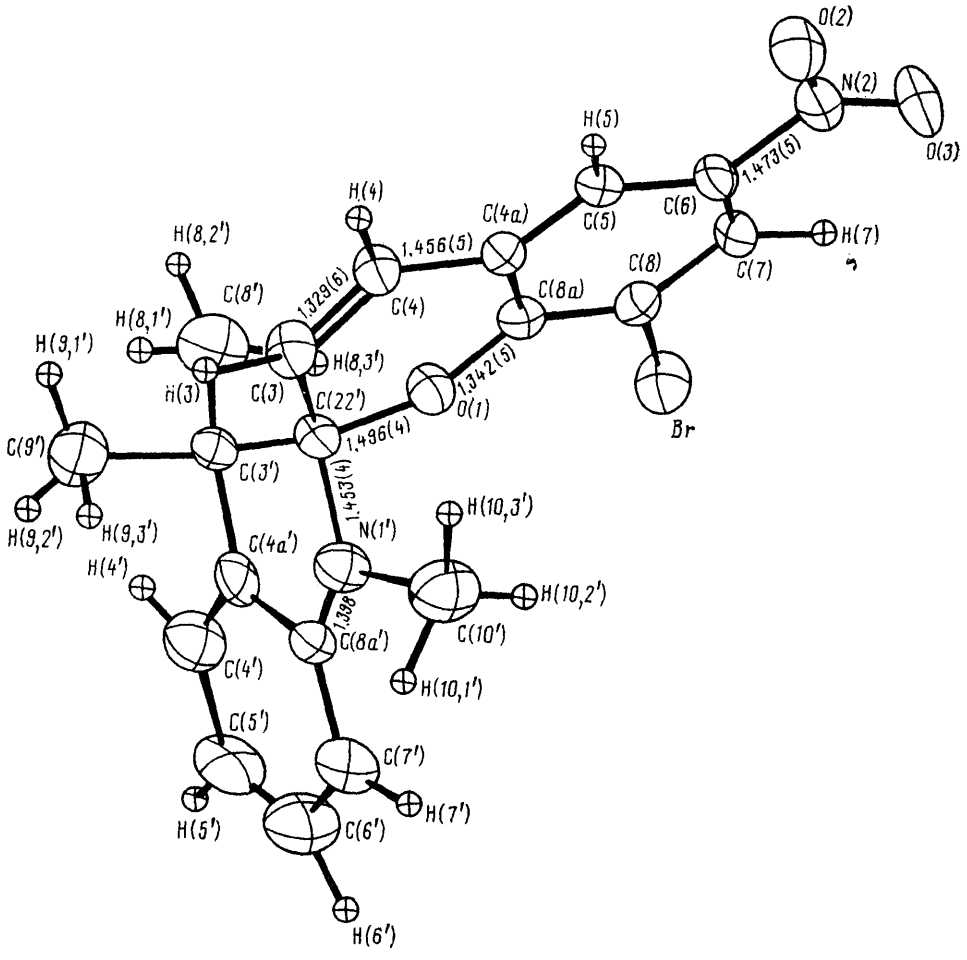


Figure 1. General shape of the SP(I) molecule.

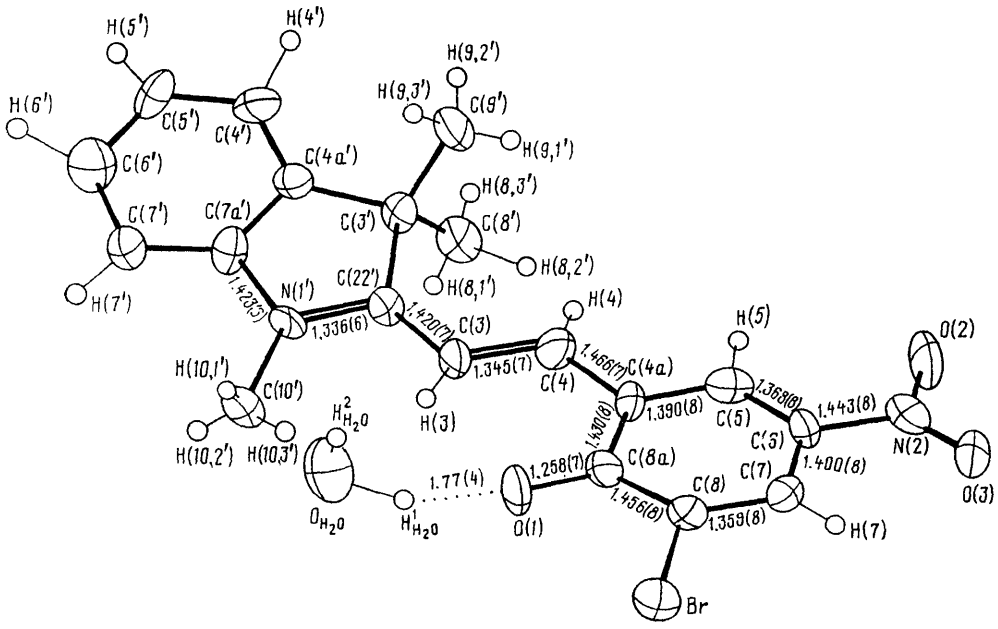

Figure 2. General shape of the MC(I) molecule.

to an open form is accompanied by a complete redistribution of bond lengths, typical for the merocyanine chromophore.[11] In this case the length of the single N(1')–C(22') bond, equal to 1.453 Å in SP(I), decreases to 1.336(6) Å in MC(I) and is of approximately the same magnitude as the length of a C=N double bond in five-membered heterocycles (1.29–1.33 Å).[15] The electrocyclic cleavage of the C_{spiro}–O(1) bond in SP(I) leads to a marked decrease in the length of the bond between the O(1) atom and the benzene ring in MC(I); the O(1)–C(8*a*) bond contracts to 1.258(7) Å. The length of this bond matches the length of the zwitterion bond in the *DL*-serine molecule, for example [1.26(1) Å].[15] The size of the C(4*a*)C(8*a*)C(8) bond angle in MC(I) [115.4(5)°] is considerably smaller than the usual value of 120°, which is an indication of the increase in σ-electron repulsion from the O(1) atom as a result of the localisation of a substantial negative charge on this atom. This type of distribution of bond lengths suggests that the MC(I) molecule has a bipolar structure [Fig. 3, form (A)]. On going from the closed form to the photoproduct the length of the C(6)–N(2) bond is reduced from 1.473(5) Å in SP(I) to 1.443(8) Å in MC(I) and at the same time the N(2)–O(2) and N(2)–O(3) bonds increase in length while the O(2)N(2)O(3) angle [122.3(6)°] decreases relative to the "equilibrium" value of 126.4° in aromatic nitro compounds[18] (see Figs. 1 and 2). This suggests that there is an increase in *s* character of the atomic orbitals of the N(2) atom participating in the formation of the C(6)–N(2) bond,[19] and is an indication of a strong resonance interaction between the NO_2 group and the benzene ring. The simultaneous elongation of the C(4*a*)–C(8*a*) and C(8*a*)–C(8) bonds and contraction of the C(7)–C(8) bond in the benzene ring (see Fig. 2) suggest that there is a significant contribution of the resonance quinoid form (B) to the structure of the *p*-nitrophenolate residue (Fig. 3).

It is also noticeable that the length of the C(5)–C(6) bond is reduced to 1.368(8) Å, which with the simultaneous contraction of the C(22')–C(3) bond [1.420(7) Å] compared to the length in SP(I) [1.483(5) Å] or even to the length of a single C_{sp^3}–C_{sp^3} bond (1.46 Å)[20] and some elongation of the C(3)–C(4) bond [1.345(7) Å] compared to the length of this bond in SP(I) [1.329(6) Å] indicate that there is an appreciable contribution of the resonance quinoid form (C) to the structure of MC(I) (Fig. 3). The mixing of structures (B) and (C) leads to delocalisation of electron density between the C(4a)–C(5) and C(5)–C(6) bonds and they decrease in length at the same time, consequently these bonds are shortened to a lesser degree than the C(7)–C(8) bond.

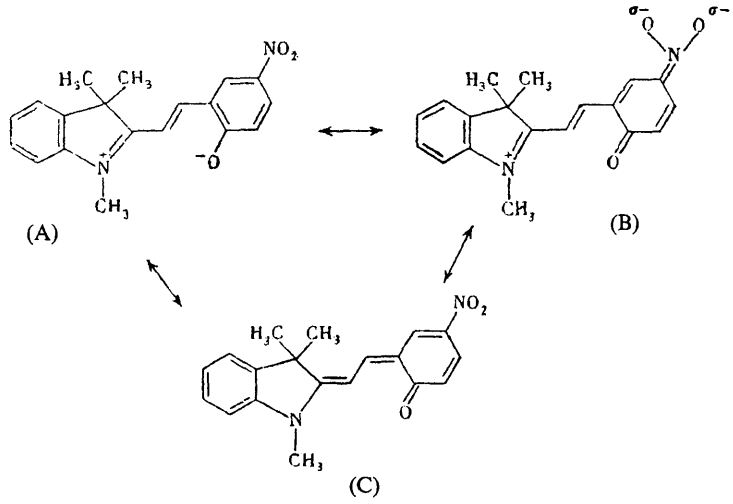

Figure 3. Resonance forms that mainly contribute to the structure of MC molecules.

Note. For numbering of the atoms, see Fig. 4, for angle notation, see text.

*1 Errors in determining the bond lengths constitute 0.003–0.006 Å.
*2 The positive angles correspond to a deflection towards the R′ substituent on the N(1′) atom, negative angles correspond to a deflection towards the *gem*-methyl groups on the C(3′) atom.
*3 Two independent molecules in the cell with a different structure.

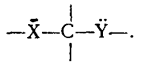
The question concerning the presence of hydrogen bonds between the O(1) and H(3) atoms remains problematic. Even though the distance of O(1)...H(3) [2.28(5) Å] is short and the H(3) hydrogen atom, as follows from quantum-chemical calculations of charges on MC(I) atoms, must be fairly acidic, the small twist about the C(4)–C(4*a*) bond and the increase of the C(3)C(4)C(4*a*) bond angle to 127.4(5)° and C(4*a*)C(8*a*)O(1) bond angle to 125.0(6)° may indicate repulsion between the O(1) and H(3) atoms. A similar repulsion evidently occurs between the H(4) and C(3′) atoms, leading to an increase in the C(3)C(22′)C(3′) bond angle to 129.5° and the C(22′)C(3)C(4) angle to 123.9(5)° and an 11.7° twist about the C(22′)–C(3) bond.

Thus, the open form MC(I) has the zwitterionic, sterically most favourable, *trans*-cisoid structure (A) with some contribution from the resonance forms (B) and (C) (Fig. 3).

The X-ray diffraction studies carried out confirmed that when an SP molecule absorbs a quantum of light the C_{spiro}–O bond is cleaved in the pyran section of the molecule. The resulting sterically most favourable *trans*-cisoid isomer of MC is further stabilised in the crystalline state through the formation of hydrogen bonds with a molecule of water of crystallisation. Solvation of the O(1) oxygen atom of the phenolate residue in solution evidently also plays a significant role, which is confirmed, for example, by the increase in proportion of the photoform on going to more polar solvents.[21] Therefore it may be assumed that in solution, as in the crystalline state, that the isomer with the structure of MC(I) is the most stable of the possible isomers. This is supported by a spectroscopic study,[22] in which it is concluded that the *trans*-cisoid form is the most stable in solution.

In the SP molecule the C_{spiro}–O bond is elongated and is evidently the weakest. Therefore cleavage of the C_{spiro}–O bond in the SP molecule may in many respects be determined by this structural factor. Particular attention will be given subsequently to the following questions: 1) the structural factors that cause the C_{spiro}–O bond to increase in length; 2) correlation between the length of this bond, its strength, and the photochemical activity of the SP; 3) a detailed study of the structural factors which stabilise the photolytic form.

2. Specific $n-\sigma^*$ orbital interactions in indoline spiropyran molecules



In this section the structural features of indoline SPs will be discussed in detail. The possible nature of the structural changes in the SP structure on photoexcitation and the effect of the structure on the quantum yield of photocoloration of these SPs are analysed, taking into account the orbital nature of the excited photochemically active states (PCAS).

a) Structural features of SP molecules in the ground electronic state

The main structural parameters of the SPs investigated are given in Table 1. In spiropyrans SP(I)–SP(IV)[12–14,23–30] the indoline and benzopyran residues of the molecules are approximately at right angles to each other but are not planar (Fig. 4). The indoline residue has the conformation of a flattened envelope with an inflection (dihedral angle α) along the line of N(1′)...C(3′) (dihedral angle α is in the range 23–30°, see Table 1). This type of structure for an indoline heterocycle is due to an essentially pyramidal

configuration of the N(1′) nitrogen atom, which reduces the conjugation between the unshared electron pair (UEP) of the N(1′) atom and the π-system of the benzene ring. In fact, the N(1′)–C(7*a*′) bond length in spiropyrans SP(I)–SP(XI), equal to 1.380(5)–1.416(5) Å, is greater than in corresponding systems with a planar trigonal structure of the N atom (1.36–1.37 Å), but matches the length of the N–Ph bond (1.39–1.42 Å) in molecules with a pyramidal structure of the N atom.[31–36] The projection of the N(1′) atom from a plane passing through the C(7*a*′) and C(22′) atoms and the carbon atom of the R′ substituent joined to the N(1′) atom is 0.12–0.34 Å. This is an indication of the substantial sp^3 character of the UEP of the N atom situated approximately perpendicular to the plane of these three atoms. The unshared electron pairs of the O atom are not equivalent;[37] they have a π- and σ-character and have different configurations. Thus, the UEP σ-electron density is situated in the plane of the C(22′)OC(8*a*) atoms while the UEP π-electron density occurs perpendicular to this plane. With such a structure of the SP the C_{spiro}–O bond of the pyran heterocycle occupies a *trans*-position relative to the UEP of the N(1′) atom and the C_{spiro}–N(1′) bond of the indoline heterocycle is *trans* relative to the π-UEP of the O atom. This type of structure can cause specific orbital interactions between the electronegative heteroatoms and the UEP of the N and O atoms bonded to a tetrahedral carbon atom (the anomeric effect).[38,39] This interaction may be described in terms of an n–σ* interaction between the UEP (n) of the heteroatom and the antibonding σ*-orbital of the adjacent polar bond located mainly on the positive carbon atom of the spiro centre[40] (Fig. 5). Since the electronegativity of the oxygen atom is greater than that of the nitrogen atom, and the UEP energy of the O atom is lower than the UEP energy of the N atom, the antibonding σ*-orbital of the C_{spiro}–O bond will be lower in energy than the antibonding orbital of the C_{spiro}–N(1′) bond, while the nonbonding orbital of the N(1′) atom will be higher in energy than the nonbonding orbital of the O atom. Consequently interactions between the n-electrons of the N(1′) atom and the σ*-orbital of the C_{spiro}–O bond are decisive in the spiro centre.[30]

Ideas about hyperconjugation have in recent years been widely used[41] to account for the structural consequences of the anomeric effect in different residues of the type

As a result of population of the antibonding orbital of the C_{spiro}–O bond, this type of interaction should lead to a strengthening of the C_{spiro}–N(1′) bond and a weakening of the C_{spiro}–O bond, which appears respectively as a contraction and elongation of these bonds. In fact, the C_{spiro}–N(1′) bond lengths in the SPs studied are in the range 1.432(4)–1.453(4) Å and prove to be considerably shorter than the normal lengths of C(sp^3)–N(sp^3) bonds (1.47–1.48 Å) in five-membered heterocycles,[15] while the C_{spiro}–O bond lengths are in the range 1.452(4)–1.497(5) Å and prove to be considerably longer than normal C–O bonds (1.41–1.43 Å)[15–17] in six-membered heterocycles.

The effectiveness of this hyperconjugation must depend to a considerable extent on the geometric configuration of the UEP of the N(1′) and O atoms and the C_{spiro}–O and C_{spiro}–N(1′) bonds on the one hand and the electronic state of the N and O atoms on the other hand. In all of the SPs studied the spiro centre has a sterically strained structure. Because of the rigidity of the tetrahedral structure of the spiro centre and the same conformation of the indoline ring, the C_{spiro}–O bond makes an angle (τ) of 165–171° with the UEP of the N(1′) atom (see Table 1).

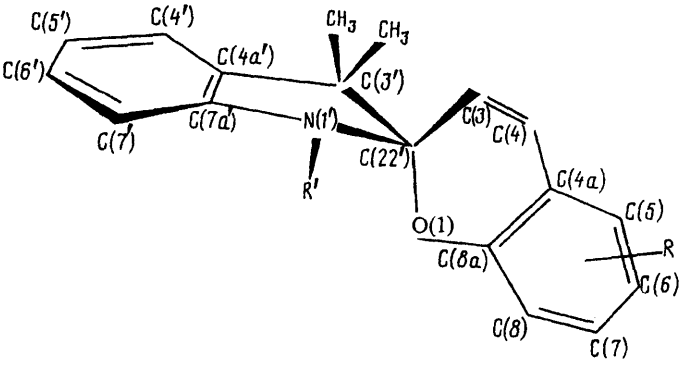


Figure 4. Schematic structure of SP molecules and the numbering of their atoms.

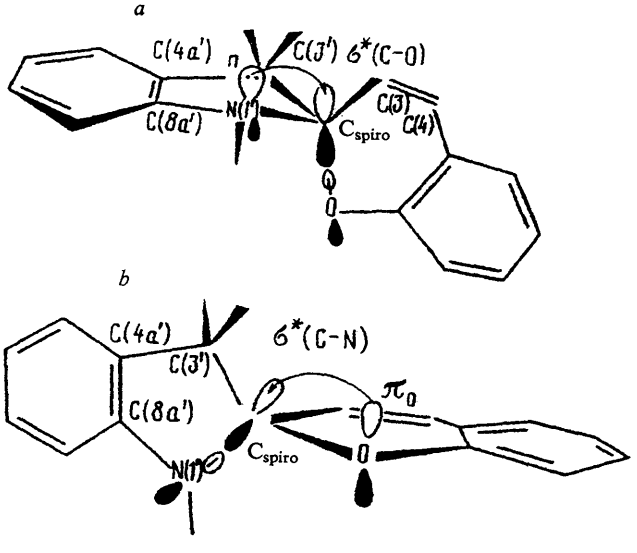

Figure 5. n[N(1)]–σ*(C_{spiro}–O) (*a*) and n(O)–σ*[C_{spiro}–N(1′)] (*b*) orbital interactions in SP molecules.

The conformation of the benzopyran residue is more flexible in these molecules. The pyran ring in an SP is nonplanar and is considerably folded along the line of O...C(3) (angle β) by 0–17° and less significantly along the line of O...C(4) (angle γ) by 0–10°. The conformation of the six-membered heterocycle in an SP is evidently determined by steric factors in the molecule and by packing effects of the molecules in the crystal rather than by the electronic effect of substituents. Confirmation of this is provided by the structure of SP(IV), in which in one of the independent molecules [SP(IV*a*)] the benzopyran ring is virtually planar while in the other [SP(IV*b*)] there are inflections with angles of 15.5° and 5.3°

respectively along the lines of O...C(3) and O...C(4). In spiropyrans SP(I), SP(IV*a*), and SP(V) the benzopyran residue is bent towards the R′ substituent while in spiropyrans SP(II), Sp(III), SP(IV*b*), SP(VI)–SP(X) it is bent towards the geminal methyl groups on the C(3′) atom.

The structural features described lead to a variable orientation of the π-electron density of the UEP of the O atom and the $C_{spiro}-N(1')$ bond (angle Δ, see Table 1). Thus in SP(II), SP(III), SP(IV*b*), SP(VI), and SP(VII) the angle between them is only 116–130°, in SP(IV*a*), SP(IX)–SP(XI) it is about 140°, and in SP(V) and SP(I) it is 145.2 and 160.2°. Thus, the $\pi(O)-\sigma^*[C_{spiro}-N(1')]$ interaction, which has an opposite effect to the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction, will strengthen with an increase in the angle Δ.

The electronic state of the N and O atoms depends on the nature and position of the substituents in the indoline and benzopyran residues. Introduction of an electron-acceptor (EA) molecule into the benzopyran residue at the *para*- and *ortho*-positions relative to the O atom should lead to an increase in conjugation of π-electron density of the UEP of the O atom with the benzene ring through further transfer of electron density from the O atom to the π-system of the phenyl group and the EA substituent. In fact, in spiropyrans SP(I) to SP(IV) and SP(VIII)–SP(XI) with EA substituents at these positions the O–C(Ph) bond lengths of 1.333(5)–1.357(5) Å and the C(Ph)–$N(NO_3)$ bond lengths of 1.459(5)–1.473(5) Å are shortened and similar to the lengths of the corresponding bonds in nitrophenols.[42,43] A decrease in electron density on the O atom causes a further polarisation of the $C_{spiro}-O$ bond, which leads to a decrease in energy of the σ*-orbital of the $C_{spiro}-O$ bond and its localisation on the C spiroatom to an even greater degree.[40] This helps to strengthen the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction and to further weaken and lengthen the $C_{spiro}-O$ bond compared to that in an unsubstituted SP, in which this bond must be stronger and shorter. Thus, as a result of specific orbital interactions in the photochromic indoline SPs, the $C_{spiro}-O$ bond, which is cleaved on photoexcitation, is the weakest and most elongated even in the ground state.

b) Nature of the structural changes in SP molecules during photoexcitation

The characteristics identified in the structure of SPs should have a substantial effect on the photochromic properties of these compounds. Since the photophysical and photochemical properties of organic molecules to a large extent depend on their structure in the excited state, we shall examine the nature of the structural changes in these molecules that take place on photoexcitation. The nature of such changes, in turn, depends on the type of electronic transition of the molecule in a photochemically active state (PCAS). The conversion of SP(I)–SP(IV) molecules to a PCAS on exposure to UV light with $\lambda > 300$ nm is caused by electronic transitions in the benzopyran part of the SP of the type $\pi l-\pi^*$ in molecules without EA substituents and of the type $\pi l-\pi^*\pi n^*$ in molecules with EA substituents in the benzopyran residue (see the review of Kholmanskii et al[44] and the references in it). It has been reliably established that these transitions constitute transitions with intramolecular charge transfer (ICT), mainly from the *l*-orbital of the oxygen atom and the π-orbital of the C(3)=C(4) bond to the phenyl group and the EA substitutent†.

† In this review[44] the π-orbital of the oxygen atom is identified as the *l*-orbital.

This ICT must lead to a decrease in electron density on the O(1) atom. Thus, for 2*H*-chromene it was found using the CNDO(S) method[45] that charge transfer from the O atom during the $S_0 \rightarrow S_3$ transition is 0.060 e. The decrease in charge on the O atom will be compensated by the σ-electrons of the $C_{spiro}-O$ bond, which should cause it to undergo further polarisation. As was shown above, this type of redistribution of electron density should lead to an increase in the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction in SP molecules and a further contraction of the $C_{spiro}-N(1')$ bond and weakening and elongation of the $C_{spiro}-O$ bond in the excited state. These conclusions are in agreement with the results of calculations using the MINDO-3 method on cleavage of the C–O bond of chromenes in an unexcited state.[46] It follows from the calculations that the length of the $C_{spiro}-O$ bond in the transition state, where cleavage of this bond occurs, is the same in all of the calculated molecules and constitutes ~1.95 Å. In the opinion of Simkin et al.,[46] the greatest proportion of the energy of activation for opening of the chromene rings is consumed on stretching the $C_{spiro}-O$ bond, the length of which at the initial stage of the reaction very accurately represents the reaction coordinate.

In spiropyran SP(V) the lowest electronically excited PCAS is the $^{1,3}(\pi l,\pi^*\pi n^*)$ state with ICT from the N(1′) atom to the phenyl residue and NO_2 group.[47] Therefore, the energy of the $n[N(1')-\sigma^*(C_{spiro}-O)$ interaction in the excited PCAS of SP(V) must be lower than in SP(IV), and the elongation of the $C_{spiro}-O$ bond in SP(V) is less than in SP(IV) (Table 1).

It has been shown[48] that a significant change in length of any bond in the excited state of the molecule assists the nonequilibrium transfer of electronic excitation energy of the molecule to the vibrational energy of this bond. Therefore, in an SP the vibrations of the weakened and elongated $C_{spiro}-O$ bond may be excited the most intensely, assisting its final heterolytic cleavage.

c) Effect of structure of SPs in the ground and excited states on their photochemical properties

Let us compare the features identified in the structure of SPs in the ground state and the nature of the structural changes in the excited state with their photochemical activity. Unfortunately, there is no information in the literature on the quantum yields of photocleavage of a bond (ν) while the quantum yields of photocoloration φ_{AB}[44] represent the efficiency of photolytic conversion without taking into account the reverse formation of the closed form of an SP (from the *cis*-cisoid isomer) directly after bond cleavage. It is evident that in general the relationship $\varphi_{AB} \leqslant \nu$ is always true.

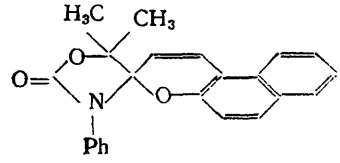
The photochemical properties of SP(I)–SP(IV) are described in detail in the literature.[44] The greatest length of the $C_{spiro}-O$ bond in the ground state, the length of which agrees within the limits of error in these SPs, has been established for these compounds. The nature of the subsequent change in length of this bond in the excited state of SP(I)–SP(IV) differs considerably. Charge transfer from the O atom to the NO_2 group will depend on the position of the NO_2 group in the benzene ring relative to the O(1) oxygen atom. The greatest transfer of charge will occur in an SP with these atoms at the *para*-position. Therefore in SP(I) and SP(IV) the $C_{spiro}-O$ bond in the excited state will be weaker and longer than in SP(II) and SP(III), which have the NO_2 group at the *ortho*-position. In accordance with this, the quantum yields of photocoloration for SP(IV) and SP(I) (0.60 and 0.45 respectively) are higher than for SP(II) and SP(III) (0.13 and 0.05).[29] Introduction of Br and Cl atoms into the benzopyran residue of the SP leads to additional ICT

from these atoms on to the π-system of the benzene ring as a result of mesomeric effects, which reduces ICT from the O atom. Moreover, Cl and Br, being heavy atoms increase the efficiency of intersystem crossing and radiationless deactivation of triplet states. Consequently, the quantum yields of the photolytic reaction of SP(I) and SP(III) are lower than for SP(IV) and SP(II) respectively.

As has already been mentioned, the $C_{spiro}-O$ bond in SP(V) in both the ground and excited states is elongated and weakened to a lesser degree than in SP(IV), and the quantum yield of photocoloration for SP(V)[47] is lower than for SP(IV). Nevertheless, this value for SP(V) is still fairly high (0.3). Kholmanskii et al.[47] believe that the high quantum yield of photocoloration of SP(IV) is due to an exchange interaction between an unpaired electron formed in the excited state on the N(1′) atom and the electrons of the σ-orbital of the $C_{spiro}-O$ bond. This type of interaction may assist cleavage of the $C_{spiro}-O$ bond.

The *cis*-cisoid isomer formed directly after cleavage of the $C_{spiro}-O$ bond in an SP is unstable and can readily revert to the initial form. In SP(I)–SP(V) the NO_2 group evidently plays a significant role in the stabilisation of the resulting intermediate. This group is known[49] to have amphi-electronic (π-acceptor and π-donor) properties depending on the electronic nature of the molecular residue of which it forms a part. In electron-rich systems the NO_2 group exhibits π-acceptor properties while in electron-deficient systems it has π-donating properties. Therefore, the NO_2 group will stabilise the open form of SP(I)–SP(IV) through delocalisation of the negative charge from the oxygen atom and formation of a quinoid structure (as was shown by Aldoshin et al.),[14] while the open form of SP(V) will be stabilised through donation of electron density to the cationic indoline part of the molecule.

Unfortunately, no information exists on the structure of unsubstituted SP. Using the arguments developed above, it may be assumed that the length of the $C_{spiro}-O$ bond in it should be intermediate between the length of this bond in SP(IV) and SP(V) and hence the quantum yield for cleavage of this bond should be high. However, the *cis*-cisoid intermediate formed by cleavage of this bond must be extremely unstable and there is a high probability that it would be converted to the initial closed form, which would significantly reduce the quantum yield of photolytic conversion of unsubstituted SP. In fact, quantum-chemical calculations on unsubstituted chromenes[46] showed that on the potential energy surface of the excited state there is no energy minimum that corresponds to a *cis*-cisoid structure.

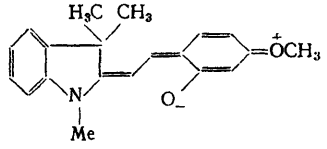


Thus, cleavage of the $C_{spiro}-O$ bond in the excited state may to a large extent be due to the further weakening and elongation of this bond during photoexcitation resulting from the same structural factors which caused the elongation and weakening of this bond in the ground state. Therefore, elongation of the $C_{spiro}-O$ bond in the ground state may serve as one of the criteria for photochemical activity in these compounds.

d) Effect of the nature and position of the substituents in SP molecules on the length of the $C_{spiro}-O$ bond

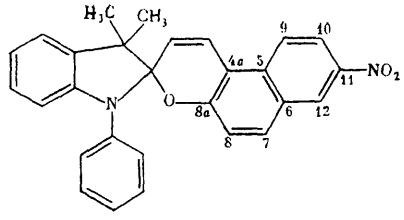
The results of X-ray diffraction analysis showed that transferring the NO_2 group from the *para*- to the *ortho*-position and also the introduction of electronegative halogen atoms into these positions actually has no effect on the length of the $C_{spiro}-O$ bond (see Table 1). At the same time, introduction of EA substituents into the indoline residue of the SP should lead to an increase in delocalisation of the UEP of the N(1′) atom in the π-system of the indoline benzene ring and a decrease in efficiency of interaction of this UEP with the σ*-orbital of the $C_{spiro}-O$ bond.

Support for this is provided by the results of an X-ray diffraction study on 1,3′,3′-trimethyl-5′-nitrospiro(indoline-2,2′[2*H*-1]benzopyran) [SP(V)] with the NO_2 group at the 5′-position of the indoline residue[24] (Table 1). In SP(V) the indoline and benzopyran parts of the molecule are also at right angles to each other. The benzopyran residue is virtually planar, as in SP(I)–SP(IV), and has the conformation of an envelope with dihedral angle along the line of N(1′)...C(3′) of 27.2°. The unshared electron pair of the N(1′) atom and the $C_{spiro}-O$ bond are at an angle of 168.8° while the π-UEP of the O atom and the $C_{spiro}-N(1')$ bond are at an angle of 145.2°. Introduction of the NO_2 group into the indoline residue at the *para*-position relative to the N(1′) atom leads to a contraction of the N(1′)–C(Ph) bond to 1.380(2) Å compared to the length of this bond [1.393(4)–1.413(5) Å] in SP(I)–SP(IV), SP(VIII), and SP(XI). The length of the N(1′)–C(Ph) bond in SP(I)–SP(IV), SP(VIII), and SP(XI) is similar to the length of the corresponding bond [1.413(3) Å] with a considerable contribution of the UEP of the N atom to the π-system of a neighbouring carbonyl group.[50] The lengths of the N(1′)–C(Ph) and (Ph)C–N(NO_2) bonds [1.380(2) and 1.461(2) Å] respectively] in SP(V) are similar to the corresponding bond lengths in *p*-nitroaniline [1.371(4)–1.380(5) Å and 1.450(5)–1.460(5) Å),[51,52] which is an indication of the increase in conjugation of the UEP of the N(1′) atom in SP(V) with the π-system of the benzene ring. As a result of this, the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction decreases and the $C_{spiro}-N(1')$ bond only decreases in length to 1.453(2) Å and the $C_{spiro}-O$ bond is only extended to 1.452(2) Å.



Confirmation of the effect of the electronic state of the N atom on the length of the $C_{spiro}-O$ bond is provided by the results of X-ray diffraction studies on SP(XXIII)[53] (SPs of this class are examined later in Section V). In SP(XXIII), as a result of the amide conjugation of the UEP of the N atom with the π-electron system of the carbonyl group, the activity of the UEP and efficiency of $n-\sigma^*$ interaction must be even lower than in SP(V). Therefore the $C_{spiro}-N$ bond (1.47 Å) becomes hardly any shorter while the $C_{spiro}-O$ bond (1.44 Å) is much less elongated than in SP(V).

SP(XXIII)



It is not possible to obtain crystals of unsubstituted SP that are suitable for X-ray diffraction analysis. The SP(VI) molecule appears to have a structure which is closest to that of unsubstituted SP.[29] The CH_3O group is known[54] to have very weak EA properties regardless of its position in the benzene ring. This group exhibits strong electron-donating (ED) properties when it is at the *ortho*- and *para*-positions of a benzene group. Thus, a CH_3O group at the 7-position of the benzopyran residue should have a weak effect on the electronic configuration of this residue and the molecular structure of 1,3′,3′-trimethyl-7-methoxyspiro(indoline-2,2′-[2*H*-1]benzopyran) (VI: $R' = CH_3$, $R^7 = OCH_3$) should be similar to the structure of unsubstituted SP.

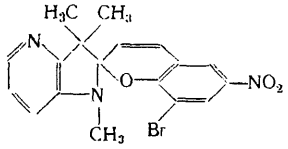
The main structural parameters of SP(VI) are given in Table 1. The structure of the SP(VI) molecule is similar to the structure of SP(II), SP(III), and SP(IV*a*). The C(7)–O(2) bond of the methoxy group is bent by 15.6° from the plane of the phenyl residue. The length of the C_{spiro}–O bond [1.471(3) Å] is intermediate between the lengths of the same bonds in SP(I)–SP(IV) [1.485(4)–1.496(4) Å] and in SP(V) [1.452(2) Å]. Thus, even if the 7-OCH_3 group is able to exert a weak ED effect on the benzopyran fragment of the SP, the C_{spiro}–O bond in unsubstituted SP will be weakened and elongated not less than in SP(VI). However, in contrast to unsubstituted SP, the 7-CH_3O group in SP(VI) stabilises the resulting MC form, being involved in conjugation as shown in the diagram

Therefore SP(VI) in solution and even in the solid state becomes coloured on irradiation with UV-light.[55]

An X-ray diffraction study was carried out[28] on 1′-phenyl-3′,3′-dimethyl-11-nitrospiro(indoline-2,2′-[2*H*-1]naphthopyran) [SP(VII)], which contains an additional benzene ring annelated at the 5- and 6-positions.

SP(VII)

The main structural parameters of SP(VII) are given in Table 1. SP(VII) has a structure which is similar to that of SP(II), but annelation of the additional benzene ring and transfer of the NO_2 substituent to the 11-position lead to a contraction of the C_{spiro}–O bond to 1.460(2) Å compared to the length of this bond [1.492(3) Å] in SP(II). Although the C_{spiro}–O bond is still longer than a normal C–O bond,[15–17] its shorter length in SP(VII) compared to SP(II) indicates that there is a weakening of the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction in this molecule. As the geometric configuration of the UEP of the N(1′) and O atoms and C_{spiro}–O and C_{spiro}–N(1′) bonds in SP(II) and SP(VII) is the same (Table 1), the decrease in $n-\sigma^*$ interaction in SP(VII) may be due to a change in the electronic state of the O(1) atom in the spiro centre. In fact, the O(1)–C(8*a*) bond in SP(VII) is longer [1.372(3) Å] than that in SP(II) [1.356(3) Å]. This suggests that there is decrease in conjugation of the π-system of the naphthalene residue with the π-UEP of the O(1) atom, leading to a reduction in polarity of the C_{spiro}–O(1) bond and a weakening of the $n-\sigma^*$ interaction. This is also supported by the contraction of the C(22′)–N(1′) bond to only 1.450(3) Å, whereas in SP(II) this bond decreases to 1.432(3) Å.



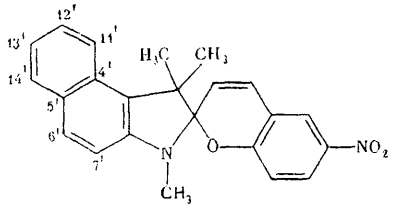
Thus, the presence of an additional benzene ring at the 5,6-position of the benzopyran residue and the transfer of the NO_2 group to the 11-position cause some contraction and strengthening of the C_{spiro}–O bond in SP(VII) compared to SP(I)–SP(VI), which in turn leads to a decrease in photochemical activity of naphthospiropyrans (NSPs).

Particular attention should be given to the fact that the quantum yield for photolytic conversion of an NSP, in contrast to SP(I), SP(III), and SP(IV), has proved very sensitive to the nature of the R′ substituent on the N(1′) atom. While replacement of R′ = CH_3 by R′ = Ph in spiropyrans has no effect on the quantum yield of photolytic conversion,[44,56] in NSPs the same change leads to a sharp fall in the value of φ—from 0.6 (R′ = Me) to 0.08 (R′ = Ph) in SP(VII).[57]

A structural analysis of the series SP(I), SP(IV)–SP(VI), SP(IX), and SP(XI) with R′ = CH_3 shows that the N(1′) atom in all of these compounds has the same pyramidal coordination and projects from the plane of the atoms bonded to it by 0.24–0.28 Å. Replacement of the CH_3 group on the N(1′) atom by the more bulky benzyl group, i.e. going from SP(IV) to SP(VIII), leads to an increase in the height of the pyramid to 0.34 Å but in other respects has no effect on the structure of the SP(VIII) molecule[25] (Table 1). Replacement of a CH_3 group by a C_6H_5 group makes it possible to conjugate the UEP of the N(1′) atom with the π-system of the benzene ring, the efficiency of which will be determined by the degree of coplanarity of the Ph-ring with the coordination plane of the N(1′) atom. In SP(II) and SP(VII), with values of the dihedral angle between these planes equal to 43.9 and 34.8° respectively, the N(1′) atom only projects from the plane of the three atoms bonded to it by 0.13 and 0.12 Å respectively, the UEP of the N(1′) atom conjugates with the π-system of the Ph substituent, and the activity of the UEP of N(1′) will therefore decrease. The fall in the quantum yield for photolytic conversion of SP(VII) may be related to weakening of the $n[N(1')]-\sigma^*(C_{spiro}-O)$ interaction. The dihedral angle between the plane of the Ph ring and the coordination plane of the N(1′) atom in SP(III) is 80° and N(1′) atom projects from the C(22′)C(7*a*)C(Ph) plane by 0.21 Å. Unfortunately, there are no data on the quantum yield for photolytic conversion of an SP(II) derivative with R′ = CH_3 and it was not possible to conduct an X-ray diffraction analysis of SP(III) and SP(VII) with R′ = CH_3 and SP(I) and SP(IV) with R′ = C_6H_5 because of the poor quality of the crystals, so the very interesting and important question concerning the effect of the degree of conjugation of the UEP of the N(1′) atom with a C_6H_5 residue on the quantum yield of photolytic conversion of SPs has no clear answer for the time being.

The synthesis of new photochromic SPs based on 4-azaindole has been reported.[58] The SPs obtained readily dissolve in polar and nonpolar solvents and some of them even in water. The small bathochromic shift of the long-wavelength absorption band of these compounds is due, in the opinion of Maisuradze et al.,[58] to the increase in EA properties of the pyridine ring in comparison to a benzene ring. The photosensitivity of azaindoline SPs towards UV radiation proved to be no lower and in some cases even higher than the photosensitivity of their indoline analogues.

The X-ray structural analysis of 1,3′,3′-trimethyl-6-nitro-8-bromospiro(4-azaindoline-2,2′-[2*H*-1]benzopyran) [SP(IX)] has been carried out.[27]



SP(IX)

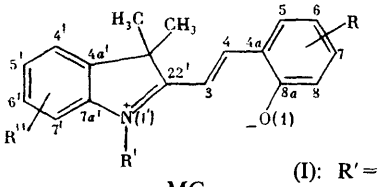
The main structural parameters of SP(IX) are given in Table 1. Since the pyridine ring has stronger EA properties than the benzene ring, the length of the N(1′)–C(7*a*′) bond [1.386(6) Å] has a

tendency to decrease and although within the limits of experimental error it matches the length of this bond in SP(I) [1.398(5) Å] and in SP(V) [1.380(2) Å], it is shorter than in SP(II)–SP(IV) and SP(VI)–SP(VIII) [1.394(3)–1.416(4) Å]. These results indicate that there is some increase in conjugation of the UEP of the N(1′) atom with the π-system of the pyridine ring. However, the $C_{spiro}-O(1)$ bond [1.486(6) Å] in SP(IX), as in SP(I) [1.496(4) Å], is still elongated, which is an indication of strong $n[N(1')]-\sigma^*[(C_{spiro}-O(1)]$ interactions in the SP(IX) molecule. Moreover, in SP(IX), in contrast to the SP(I), the benzopyran ring is virtually planar and the π-UEP of the O(1) atom makes an angle of only 139.6° with the $C_{spiro}-N(1')$ bond rather than 160.2° as in SP(I). Therefore the $n[O(1)]-\sigma^*[C_{spiro}-N(1')]$ interaction in SP(IX) will be weaker than in SP(I). This is suggested by the greater contraction of the $C_{spiro}-N(1')$bond in SP(IX)—to 1.434(7) Å compared with 1.453(4) Å in SP(I).

Thus, in SPs based on 4-azaindole, just as in their indoline analogues, $n[N(1')]-\sigma^*(C_{spiro}-O)$ orbital interactions remain strong and the $C_{spiro}-O$ bond is elongated.

As has already been mentioned above, the quantum yield of photocleavage of the $C_{spiro}-$bond in SPs in many respects depends on the length of this bond in the ground state and the degree of ICT from the oxygen atom of the pyran ring to the benzene ring in the excited state, affecting a further weakening and stretching of the $C_{spiro}-O$ bond. In order to distinguish the influence of these factors, it is necessary to study SPs whose molecules would have the same structure in the ground state but a different pattern of electronic transitions in the excited state. The subject chosen for such a study was 1′,3′,3′-trimethyl-4′,5′-benzo-6-nitrospiro(indoline-2,2′-[2*H*-1]benzopyran [SP(X)].[26] It was assumed that annelation of an additional ring at the 4′- and 5′-positions of the indoline residue would have no substantial effect on the structure of the spiro centre

SP(X)



in SP(X) relative to SP(IV), but as had been shown in two studies[8,56] would lead to intramolecular energy transfer (IET) from the pyran heterocycle to the indoline system and would lower the efficiency of photocoloration of SP(X) compared to SP(IV).

The main structural parameters of SP(X) are given in Table 1. Spiropyrans (X) and (IV) have the same structure. The benzopyran residue in SP(X) is virtually planar, as in the SP(IV*a*) molecule. The $C_{spiro}-O(1)$ bond is extended to 1.478(7) Å and within the limits of experimental error it matches the average length of this bond in SP(IV) [1.486(4) Å]. Since annelation of the benzene ring at the 4′- and 5′-positions of the indoline residue does not affect the structure of the spiro centre in the SP(X) molecule, which has the same characteristics as in SP(IV), the decrease in the quantum yield for photolytic conversion of SP(X) to 0.026, compared to 0.60 for SP(IV),[56] is evidently due solely to radiationless deactivation processes in the excited state, in particular with ICT from the pyran to the indoline ring. With such a transfer of energy, ICT from the O(1) oxygen atom to the benzene ring and the nitro group of the benzopyran residue is substantially reduced. Therefore it may be assumed that in the excited state the interaction between the UEP of the N(1′) atom and the σ*-orbital of the $C_{spiro}-O(1)$ bond will be weaker in SP(X) than in SP(IV), and although the C(22′)–O(1) bond in SP(X) is elongated and weakened in the ground state it will undergo cleavage with greater difficulty.

Another factor which has a considerable effect on the efficiency of the photochemical conversion of SPs is a process which competes with the photoreaction, namely, the radiationless deactivation of excited states through internal conversion and intersystem crossing. It is known[59] that the presence of heavy atoms substantially increases the rate of all "singlet⟷triplet" processes, and therefore heavy atoms are effective quenchers of excited states. It has already been noted in Section II.2c that the introduction of heavy Cl and Br atoms into the 6- and 8-positions of the benzopyran residue does not have any substantial effect on the structure of the SP but reduces the quantum yield of photoconversion of these compounds. This type of influence from heavy atoms in the benzopyran residue may be due either to the effect of heavy atoms increasing the radiationless deactivation of excited states or to the mesomeric donor effect of these atoms decreasing ICT from the oxygen atom to the phenyl residue. In order to study the role of heavy atoms in SP molecules, X-ray diffraction analysis was conducted on 1,3′,3′-trimethyl-4-chloro-6-nitrospiro(indoline-2,2′-[2*H*-1]benzopyran [SP(XI)],[30] which contains a Cl atom at the 4-position of the benzopyran residue. The Cl atom at the 4-position of the pyran ring does not have any marked effect on the geometry of the molecule and the distribution of bond lengths in it. The SP(XI) molecule has a structure which is the same as that of SP(IV). As in SP(IVa), the benzopyran part of the molecule in SP(XI) is virtually planar. The C(22′)–N(1′) bond length of 1.438(2) Å and C(22′)–O(1) bond length of 1.479(2) Å within the limits of experimental error match the values of these bond lengths in SP(IV) (see Table 1). Nevertheless, the photochemical activity of SP(XI) proves to be considerably lower than the photochemical activity of SP(IV). In the excited state the Cl atom at the 4-position also should not affect ICT from the O atom to the benzene ring. Therefore, the reduction in photochemical activity of SP(XI) is apparently due solely to the effect of the Cl atom as a heavy atom.

III. The structure of open merocyanine forms of indoline spiropyrans

Since one of the important characteristics of photochromic systems based on SPs is the lifetime of the open merocyanine forms of SPs, it is necessary to carry out a detailed study of the structure of MCs and to identify the structural factors which stabilise SPs in the open state. The structure of different MCs and the energy of their intermolecular interactions in crystals, and the thermodynamic and kinetic stability of the isomers identified will then be examined.

MC

(I): $R'=CH_3$, $R^6=NO_2$, $R^8=Br$;
(II): $R'=C_5H_{11}$, $R^6=NO_2$, $R^8=Br$;
(III), (IV): $R'=p\text{-}CH_3C_6H_4$, $R^6=NO_2$, $R^8=NO_2$, $R''=CH_3$;
(V): $R'=H$, $R^6=NO_2$, $R^8=NO_2$.

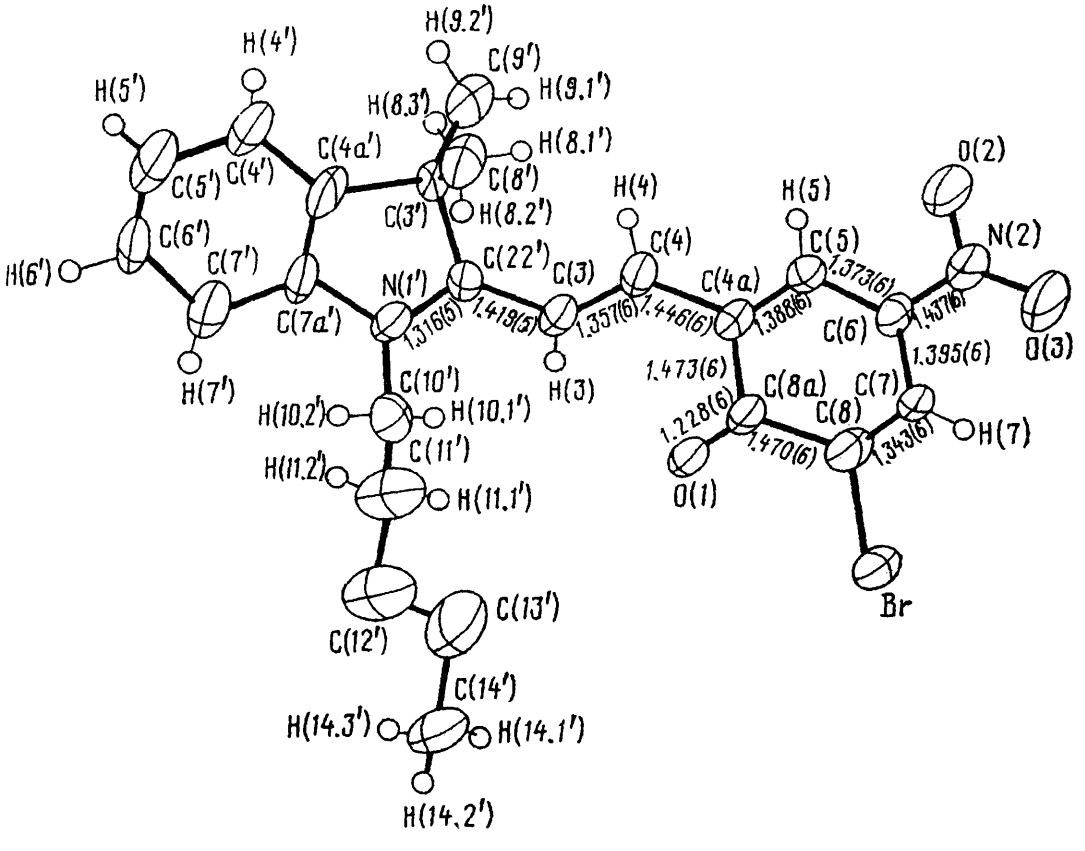
1. Molecular structure of merocyanines

In crystals of MC(I) the bipolar structure (A) appears to be stabilised to a considerable extent through solvation of the negatively charged O(1) oxygen atom by a water molecule (Fig. 2), which may substantially affect the electronic structure and stability of the MC molecule.

The crystalline structure of solvates of MC(I) provides a basis for the assumption that replacement of a methyl group on the N(1′) atom in the indoline ring by a more bulky group can inhibit solvation of the phenolate oxygen atom. In order to confirm this hypothesis, an X-ray diffraction study was carried out on the pentyl-substituted MC(II), in which the pentyl substituent on the N(1′) atom is similar to the methyl group in terms of its electronic properties.[60,61] The MC(II) molecule does not form solvates in the crystalline state. Just as in MC(I) crystals, MC(II) molecules (Fig. 6) have an almost planar *trans*-cisoid structure. The slight deviation from planarity manifests itself in twists about the C(22′)–C(3), C(3)–C(4), and C(4)–C(4*a*) bonds of 5.5, 6.7, and 8.6° respectively.

The distribution of bond lengths in the MC(II) molecule is in general terms similar to the distribution of bond lengths in the MC(I) molecule. However, the absence of solvate water molecules in MC(II) crystals leads to some redistribution of electron density in the MC(II) molecule. Thus, the length of the O(1)–C(8*a*) bond is reduced to 1.228(6) Å, which corresponds to the length of a C=O double bond.[15] Contraction of the O(1)–C(8*a*) bond in MC(II) is accompanied by a further decrease in bond angle of C(4*a*)C(8*a*)C(8) to 112.8(1)°, which is an indication of the increasing importance of σ-electron repulsion from the O(1) atom. The C(4*a*)–C(8*a*) and C(8a)–C(8) bonds are extended even more and the C(7)–C(8) bond is shorter in comparison with the lengths of these bonds in MC(I). As in the MC(I) molecule, the N(2)–C(6) bond [1.437(6) Å] is considerably shorter than this bond in the closed form,[14] the O(2)N(2)O(3) angle [121.5(5)°] being even smaller than the "equilibrium" value. This type of structure for the *p*-nitrophenolate residue suggests that there is a greater contribution of the resonance quinoid form (B) (see Fig. 3) to the zwitterion structure (A) of unsolvated MC(II) molecules compared to solvated MC(I) molecules. As in MC(I), the contribution of the canonical form (C) is appreciable in MC(II) molecules (see Fig. 3). The N(1′)–C(22′) bond in MC(II) [1.316(5) Å] is even shorter than in MC(I), which is an indication of its complete double bond character and that the positive charge is mainly located on the N(1′) atom.

Thus, the research carried out indicated that the structure of open forms of SPs can be represented by resonance forms (A) (the greatest contribution), (B), and (C), with the contribution of each of these forms varying in accordance with the nature of the substituents in the molecule. Stabilisation of open MC molecules must be related to the stabilisation of one of these resonance structures. The structure of MC(I) crystals suggests that solvation of the O(1) phenolate atom stabilises the zwitterion structure directly to a greater extent. Stabilisation of the canonical structure (C) can be achieved,



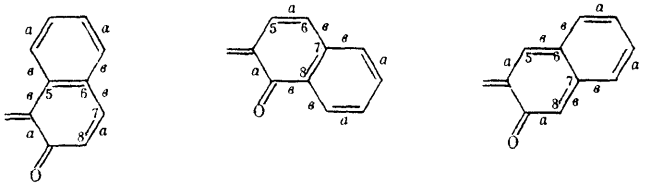


Figure 6. General shape of the MC(II) molecule.

for example, through annelation of additional benzene rings to the phenolate ring. At the same time annelation of additional benzene rings at the 5,6- and 7,8-positions will further stabilise form (C) because of the preservation of aromaticity and specificity of structure of a naphthalene residue with shortened "*a*" bonds and elongated "*b*" bonds, while annelation at the 6,7-position will lead to its destabilisation.

In MC(I) and MC(II) *p*-NO_2 substituents in the phenolate ring displace the equilibrium towards the quinoid form (B) and hence stabilise the unstable zwitterion form. It was suggested[61] that introduction of an additional NO_2 group into the *ortho*-position relative to the O(1) atom of this residue should increase the stability of the open MC form. X-Ray diffraction analysis of such a merocyanine, MC(III), showed that this compound crystallises in two polymorphic forms—monoclinic and rhombic.

In the monoclinic form MC(III) molecules have a nearly planar *trans*-structure (Fig. 7) with slight deflections about the C(22′)–C(3), C(3)–C(4), and C(4)–C(4*a*) bonds of 3.1, 4.7, and 2.7° respectively, which is similar to the structure of MC(I) and MC(II). However, in contrast to MC(I) and MC(II), the phenolate oxygen atom in MC(III) in almost equal probability occupies the *S-cis*- or *S-trans*-positions relative to the C(4)–C(4*a*) bond. Thus, the *trans*-cisoid isomer and *trans*-transoid isomer, which has been detected experimentally for the first time, occur in equal ratios in the crystalline state.

The *trans*-transoid isomer, which constitutes ~50% of a crystal, is solvated by a water molecule [O(1′)...O(H_2O) distance is 2.44 Å], which also occupies ~50% of the independent positions. The hydrogen bond formed in the solvate is one of the shortest hydrogen bonds.[62] As a result of the phenolate residue being randomly oriented in two positions, the distribution of bond lengths in it is averaged out and it is not possible to make any conclusion about the nature of the redistribution of bond lengths on introducing a second NO_2 group into the *ortho*-position relative to the O(1) atom. However, the C(6)–N(3) and C(8)–N(2) bond lengths with both nitro groups are shortened (see Fig. 7) and the O(2)N(2)O(3) and O(4)N(3)O(5) angles [121.3(6) and 120.0(6)°] are smaller than the "equilibrium" values. This suggests that there is a strong resonance interaction between these groups and the π-system of the benzene ring. The C(4*a*)–C(5) and C(4*a*)–C(8*a*) bonds are elongated while the C(6)–C(7) and C(7)–C(8) bonds are shortened (see Fig. 7) in comparison with the normal value of a bond length in a benzene ring. The remaining bond lengths in the MC(III) molecule within the limits of experimental error match the bond lengths in the MC(I) and MC(II) molecules, although the N(1′)–C(22′), C(22′)–C(3), and C(3)–C(4) bonds are somewhat longer.

X-Ray structural analysis of the rhombic form [MC(IV)] showed[61] that the two isomers—*trans*-cisoid and *trans*-transoid—also occur in crystals of this polymorph in nearly equal proportions. The pattern of distribution of bond lengths in MC(IV) within the limits of experimental error is in line with the distribution of bond lengths in MC(III).

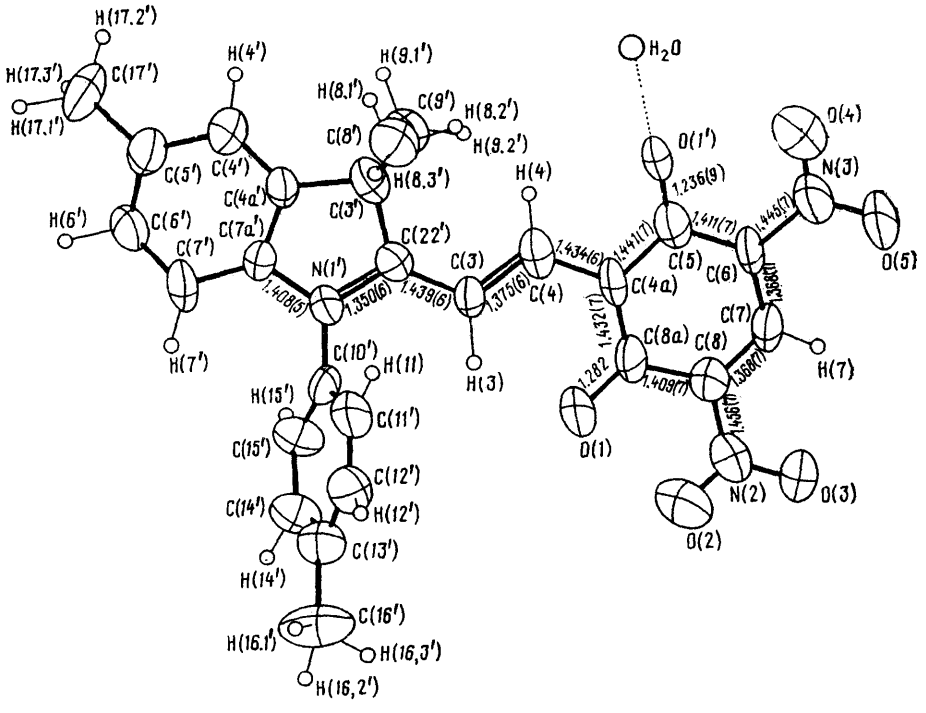

Figure 7. General shape of the MC(III) molecule.

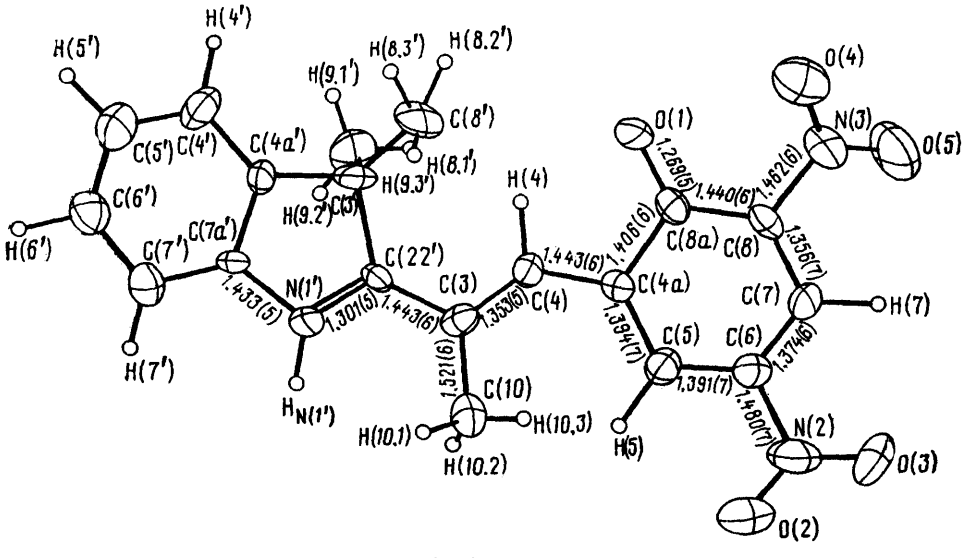
Crystals of MC(IV), like crystals of MC(III), contain solvate water molecules which occupy ~50% of the independent positions. However, in contrast to MC(III), it is the sterically less accessible O(1) atom of the *trans*-cisoid isomer that is solvated [O(1)...O_{H_2O} distance is 2.97(3) Å] rather than the O(1) atom of the *trans*-transoid isomer, which causes the phenyl substituent on the N(1′) atom to deviate from the plane of the molecule by 87.9°. In crystals of MC(IV) there are also other water molecules that do not solvate the MC molecules, and they occupy about 25% of the independent positions and are situated at an O...O distance of 2.30 Å from the solvating water molecules.

Thus, solvation of the phenolate O atom is evidently typical for MC molecules in polar solvents if steric factors do not prevent this.

The introduction of an additional NO_2 group into the phenolate residue stabilises a further isomer—the *trans*-transoid form—which evidently exists in solution in equilibrium with the *trans*-cisoid isomer, resulting in their co-crystallisation. This conclusion made it necessary to conduct a more detailed study of the structure of the *trans*-transoid isomer. An X-ray diffraction study was carried out on the *o,p*-dinitro-substituted MC(V), in which the hydrogen atom of the vinyl group is replaced by a CH_3 group, which must inhibit the formation of the *trans*-cisoid isomer. In fact, in crystals of MC(V) the molecules have a *trans*-transoid structure (Fig. 8) and are linked together in a chain via a strong O(1)...$H_{N(1')}$ hydrogen bond [1.70(4) Å]. The steric interactions which occur between the atoms of the methyl group of C(10) and the *syn* H(5) atoms "eject" the phenolate residue from the plane of the molecule by a turn of 20.3° about the C(4)–C(4*a*) bond. However, this turn is evidently not sufficient to reduce the steric strain in the molecule, and the tendency to retain a planar structure with delocalised electron density prevents a further loss of planarity by the molecule, resulting in the C(4)C(3)C(10) bond angle being distorted to 124.6(4)° and the C(3)C(4)C(4*a*) and C(4)C(4*a*)C(5) angles are even changed to 133.3(4) and 127.0(4)°. Twists of the groups about the C(22′)–C(3) and C(3)–C(4) bonds only amount to 6.1 and 8.3°. The O(1)–C(8*a*) bond length [1.269(5) Å] is similar to the length of this bond in the MC(I) molecule, where the O(1) atom, as in MC(V), particpates in the formation of a strong hydrogen bond. These bonds are longer than the O(1)–C(8*a*) bond in the MC(II) molecule, in which the O(1) atom does not participate in intermolecular hydrogen bonding. The size of the intramolecular bond angle of C(4*a*)C(8*a*)C(8) [115.4(5) Å] in MC(V) is also close to that for the same angle in MC(I), which suggests that there is the same σ-electron repulsion from the O(1) atoms in both molecules.

It was surprising to find that in MC(V) the C(6)–N(2) bond length [1.480(7) Å] within the limits of experimental error matches the lengths of the same bonds in closed SPs,[30] and is not shorter than them as in MC(I) and MC(II). The size of the O(2)N(2)O(3) bond angle [125.0(6)°] is close to the "equilibrium" value of this angle in aromatic nitro compounds.[18] All of this is an indication of the much weaker resonance interaction between the *p*-NO_2 group in MC(V) and the π-system of the phenolate residue than in MC(I) and MC(II). The length of the C(8)–N(3) bond [1.462(6) Å] is shorter than C(6)–N(2) although it is still longer than in MC(I) and MC(II). The O(4)N(3)O(5) bond angle [121.6(5)°] is also less than the "equilibrium" value. Since it was shown[18] that there is no correlation between the length of a C_{Ac}–N_{NO_2} bond and the angle of rotation of the NO_2 group about this bond, the results obtained suggest that there is a greater resonance interaction between the *o*-NO_2 group and the π-system of the benzene ring than for the *p*-NO_2 group. In the benzene ring two bonds—C(4*a*)–C(8*a*) and C(8*a*)–C(8)—are elongated while only the C(7)–C(8) bond is appreciably shortened (see Fig. 8). Taking into account this structure of the *o*,p-dinitrophenolate residue, such a distribution of



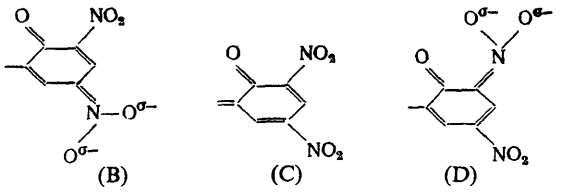


Figure 8. General shape of the MC(V) molecule.

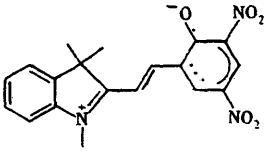
the bond lengths in the phenolate ring is unlikely to result from the contribution of the resonance quinoid forms (B) and (D) but has more complex origins.



(B) (C) (D)

The contribution of the quinoid form (C) to the structure of the phenolate residue also appears to be small, and the increase in length of the C(22′)–C(3) bond to 1.443(6) Å and the further contraction of the N(1′)–C(22′) bond to 1.301(5) Å compared to the lengths of these bonds in MC(I) and MC(II) is an indication of the decrease in contribution of this form to the structure of the complete MC(V) molecule. The overall distribution of bond lengths in the phenolate residue may occur as a result of σ-electron repulsion from the negatively charged O(1) atom and the electron-acceptor effect of the NO_2 substituents. The latter conclusion is consistent with the statistical data of Holden and Dickinson,[18] according to which the bond lengths in the benzene ring adjoining a nitro group have a tendency to shorten.

It should be noted that despite the statistical disordering of the *o,p*-dinitro-substituted phenolate residue in MC(III) and MC(IV), the distribution of bond lengths in them is similar to that found in MC(V).

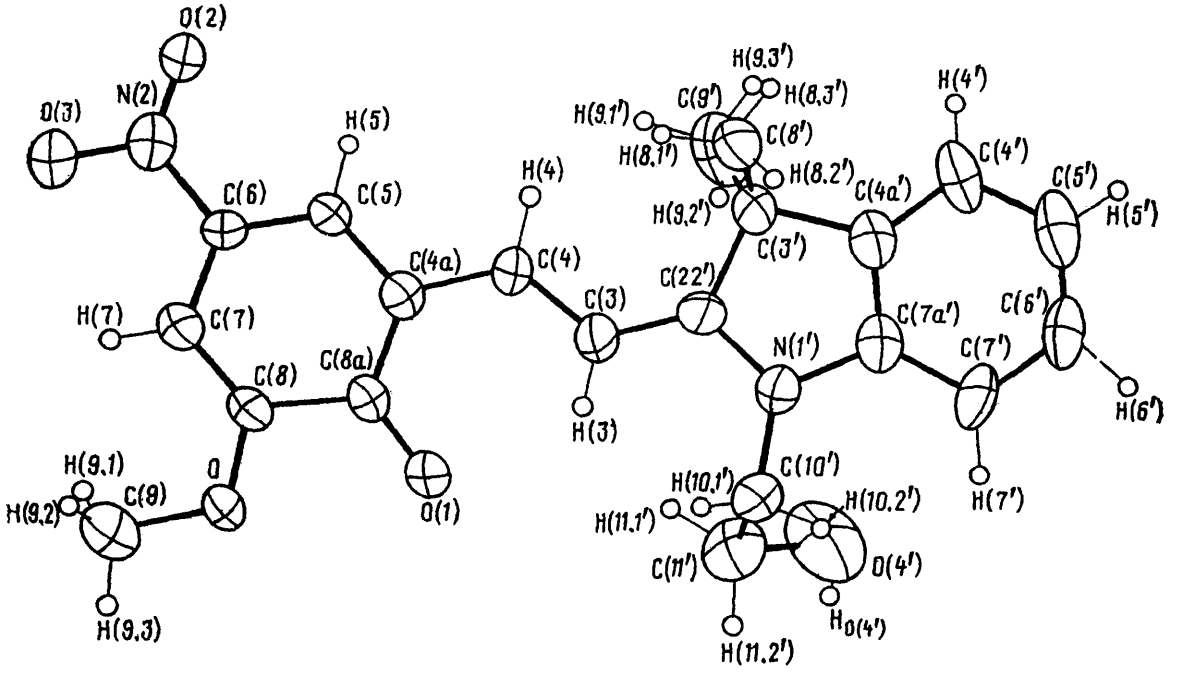
Thus, the MC(V) molecule with *o*- and *p*-NO_2 groups in the phenolate residue mainly has the bipolar structure (E) with appreciable disruption of aromaticity in the phenolate ring.

(E)

As was mentioned above, an important characteristic of an SP is the number of cycles for the photolytic conversion

$$SP \overset{h\nu}{\rightleftarrows} MC$$

without appreciable decomposition of the system. It is known[63] that SPs containing 8-OCH_3 and 6-NO_2 substituents in the benzopyran part of the molecule are more stable to decomposition. The structure of the merocyanine form of 1-hydroxyethyl-3,3′-dimethyl-6-nitro-8-methoxyspiro(indoline-2,2′-[2*H*-1]benzopyran [MC(VI)] (Fig. 9) has been studied.[64] In the crystalline state MC(VI) molecules are linked together through strong chains of hydrogen bonds of the type O(1)...$H_{O(4')}$ [1.78(3) Å] [O(1)...O(4′) = 2.64(1) Å], which results in elongation of the O(1)–C(8*a*) bond to 1.253(4) Å, which is typical for zwitterion molecules, in which the length of this bond is 1.26 Å. However, in other respects the distribution of bond lengths in MC(VI) differs substantially from



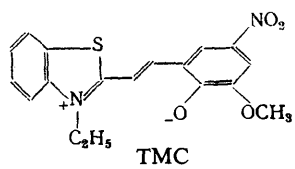


Figure 9. General shape of the MC(VI) molecule.

that in MC(I)–MC(V); the N(1′)–C(22) and C(3)–C(4) bonds [1.352(4) and 1.366(4) Å respectively] are elongated while the C(22′)–C(3) and C(4)–C(4*a*) bonds [1.403(4) and 1.444(4) Å] are shortened. This type of distribution of bond lengths in MC(VI) and at the same time the C(5)–C(6) and C(7)–C(8) bonds decreasing in length to 1.376(4) and 1.345(5) Å suggests that there is an increase in contribution of the quinoid form (C) (see Fig. 3) to the structure of MC(VI). The decrease in zwitterion character of the MC(VI) molecule and the greater contribution of the less reactive quinoid form to its structure may be responsible for the increase in stability of this system.

2. Geometric isomers of merocyanine forms

A study of the geometric isomerism and relative stability of the isomers of the open merocyanine forms is very important for an understanding of the mechanism of photochromism in SPs and to account for the spectroscopic behaviour of MCs, in particular the positions and occurrence of long-wavelength absorption, which together with the photoactivity of SPs and the stability of MCs constitute an important property which determines the practical application of SPs.[2,65] Many theoretical studies[46,66–68] have dealt with the question of the relative stability of the isomers of small model SPs and MCs and the effect of different substituents on their spectroscopic properties.

X-Ray diffraction analysis of MC(I)–MC(VI) showed that only the planar *trans*-cisoid and *trans*-transoid isomers exist in the crystalline state. The first of these occurs in crystals of MC(I)–MC(IV), MC(VI), and the open form of a benzothiazole SP–(TMC)—as studied by Miler-Strenger et al.,[69] while the second occurs together with the *trans*-cisoid isomer in crystals of MC(III) and MC(IV), whose molecules contain two nitro substituents in the phenolate residue.

TMC

It was concluded from the results of quantum-chemical calculations[61] that the *trans*-cisoid and *trans*-transoid isomers of MCs are similar in energy. In MCs with a single nitro group in the phenolate residue there is a substantial transition barrier between them, but introduction of two nitro substituents into the *ortho*- and *para*-positions of the phenolate residue lowers this barrier to such an extent that these isomers can readily undergo interconversion in solution. In fact, co-crystallisation of both isomers of the *o,p*-dinitro-substituted MC(III) and MC(IV) may also indicate that the packing energy of these isomers is virtually the same and in solution they occur in approximately equal concentrations.

The lowering of the rotation barrier about the C(4)–C(4*a*) bond when two electron-acceptor nitro groups are introduced into the phenolate residue is evidently related to the increased contribution of form (E) to the structure of this type of molecule, reducing the $\pi-\pi$ interaction between this residue and the remaining part of the molecule.

The results obtained cast doubt on the theory that the complex nature of the absorption spectrum of open merocyanine forms of SPs is due to the presence of four different stereoisomers in the solid state and in solution.[70,71] Furthermore, calculations on the absorption spectra of model isomers of 2*H*-chromenes show that these isomers are indistinguishable in the region of long-wavelength absorption.[66] In several studies[72–76] the suggestion that coloured and colourless forms of SPs are associated has been made in order to account for the spectroscopic properties of MCs. The similarity of the absorption spectra of MCs in nonpolar solvents (at low temperatures), in an amorphous state, and in thin homogeneous crystalline films suggests that the coloured form of SPs in the liquid and solid states has the same structure. Hence there is definite interest in the packing of MC molecules and energy of intermolecular interaction in crystals.

3. Nature of the molecular packing and energy of intermolecular interactions in merocyanine crystals

Since this question has been discussed by us in detail in a review article,[61] we shall only report here the main results and conclusions of this study.

The crystalline structure of open merocyanine forms of SPs is an indication of the well-defined tendency of MC molecules to form different aggregates. This is due to the planar structure and high polarity of MC molecules, and consequently, in addition to van der Waals forces, electrostatic and dipole–dipole interactions also play a significant role in the formation of aggregates. Calculations of the energy of crystalline MC structures show that the electrostatic interaction in the aggregates can amount to ~50% of the van der Waals interaction. The strongest aggregates are formed in MC(II) crystals, in which the molecules are arranged in stacks on top of each other according to the principle "head over tail". The pairing energy of the van der Waals and electrostatic interactions, without even taking account of the dipole–dipole interaction, in these stacks is approximately –26 kcal mol^{-1}. Solvated MC molecules form different aggregates through strong hydrogen bonds according to the principle "head to head" and "head to head, tail to tail".

Bulky alkyl substituents on the N(1′) atom can inhibit solvation of the *trans*-cisoid isomer of MCs, although they do not prevent the formation of "head to tail" aggregates. A methyl substituent on the N(1′) atom does not inhibit the solvation of *trans*-cisoid isomers of MCs. Solvation of a phenyl-substituted MC results in the phenyl substituent turning about 90° from the plane of the molecule and disrupting the conjugation of the UEP of the N(1′) atom with the π-system of the Ph residue, which is evidently balanced by the gain in energy from solvation of the molecule. Solvated molecules of *trans*-cisoid MC isomers form aggregates through hydrogen bonds with solvate molecules.

In the *trans*-transoid isomers the substituents on the N(1′) atom do not inhibit solvation. A solvated *trans*-transoid MC isomer can form both "head to tail" aggregates and aggregates with solvate molecules. In MC(I) crystals the aggregates comprise solvated MC molecules joined by a hydrogen bond. In these associates the molecules are arranged "head to head" at an angle of ~110° to each other, so the electrostatic attraction energy between them is reduced but the total energy of the van der Waals and electrostatic interactions is approximately –22 kcal mol^{-1}. In crystals of MC(V) the strongest aggregates (~–17 kcal mol^{-1}) are formed through the molecules being linked via hydrogen bonds in chains and also through intermolecular interactions in parallel to the molecules arranged "head to head" in layers. In the crystalline structure of MC(VI) repeating chains in which the pairing energy of intermolecular interactions is –10 kcal mol^{-1} can be distinguished.

The formation of quite strong aggregates in crystals of MC(I)–MC(VI) with different types of packing provides a basis for

the assumption that these aggregates can also be preserved in solution. In crystals only the energetically most stable forms of molecular association and those most favourable for packing usually occur, and so in MC solutions these aggregates can be even more diverse. At the same time in nonpolar aprotic solvents, for MC molecules not bound through a specific intermolecular interaction with solvent molecules formation of "head to tail" aggregates is the most probable. In protic polar solvents, formation of solvates combined into different associates through hydrogen bonds is the most probable. The formation of solvates and aggregates is a further factor stabilising the highly polar merocyanine forms and a more probable cause of the complex absorption spectrum of MCs than the proposed existence of various isomers.

IV. Effect of the nature and relative orientation of the heteroatoms in the spiro centre on the structure and photochemical properties of spiropyrans

The considerable influence of specific $n-\sigma^*$ orbital interactions of the heteroatoms in the spiro centre of indoline SPs on the structure and photochemical properties of these compounds suggests that a change in the nature and relative orientation of the heteroatoms in the spiro centre can be an effective means of modifying the structure and obtaining new classes of photochromic SPs. Therefore in this section we shall examine the structure of SPs containing different heteroatoms in the spiro centre.

1. Structural features of indoline spirothiopyrans containing S and N heteroatoms in the spiro centre

Aldoshin et al.[77] carried out an X-ray diffraction study on 1′phenyl-3,3′-dimethyl-6-nitrospiro(indoline-2,2′-[2*H*-1]benzothiopyran) [SP(XII)] (Fig. 10).

Replacement of the oxygen atom in SP(IV) by a sulphur atom [SP(XII)] resulted in a reduction of photoconversion activity of the latter at 293 K ($\varphi \approx 0.1$) compared to that of SP(IV) ($\varphi = 0.76$)[44] in solutions of dimethylformamide and toluene. At 77 K in polystyrene and polymethyl methacrylate the photochemical activity of SP(XII) increases ($\varphi = 0.7$) whereas the photochemical activity of SP(IV) ($\varphi = 0.1$) decreases markedly under the same conditions.

This type of behavioural pattern of SP(XII) compared to SP(IV) becomes clear if its structure is analysed. In SP(XII), as in other photochemically active SPs, the C(22′)–S bond [1.866(2) Å] which is cleaved on photoexcitation is considerably longer than the corresponding bonds in six-membered heterocycles (1.80–1.83 Å).[16,17] The C(22′)–N(1′) bond [1.484(3) Å] in SP(XII), in contrast to that in SP(IV), is not shortened, and its length corresponds to the lengths of normal $C_{sp^3}-N$ bonds (1.47–1.48 Å) in five-membered heterocycles.[15] Therefore elongation of the $C_{spiro}-S$ bond in SP(XII) cannot be accounted for using the concept of $n-\sigma^*$ interactions in the spiro centre proposed for SPs.

Replacement of the oxygen atom at the spiro centre by a sulphur atom, which has an ionisation potential similar to that of the nitrogen atom,[78] evidently levels out the donating capacities of the UEP of the S and N atoms. Furthermore, the C(22′)SC(8*a*) bond

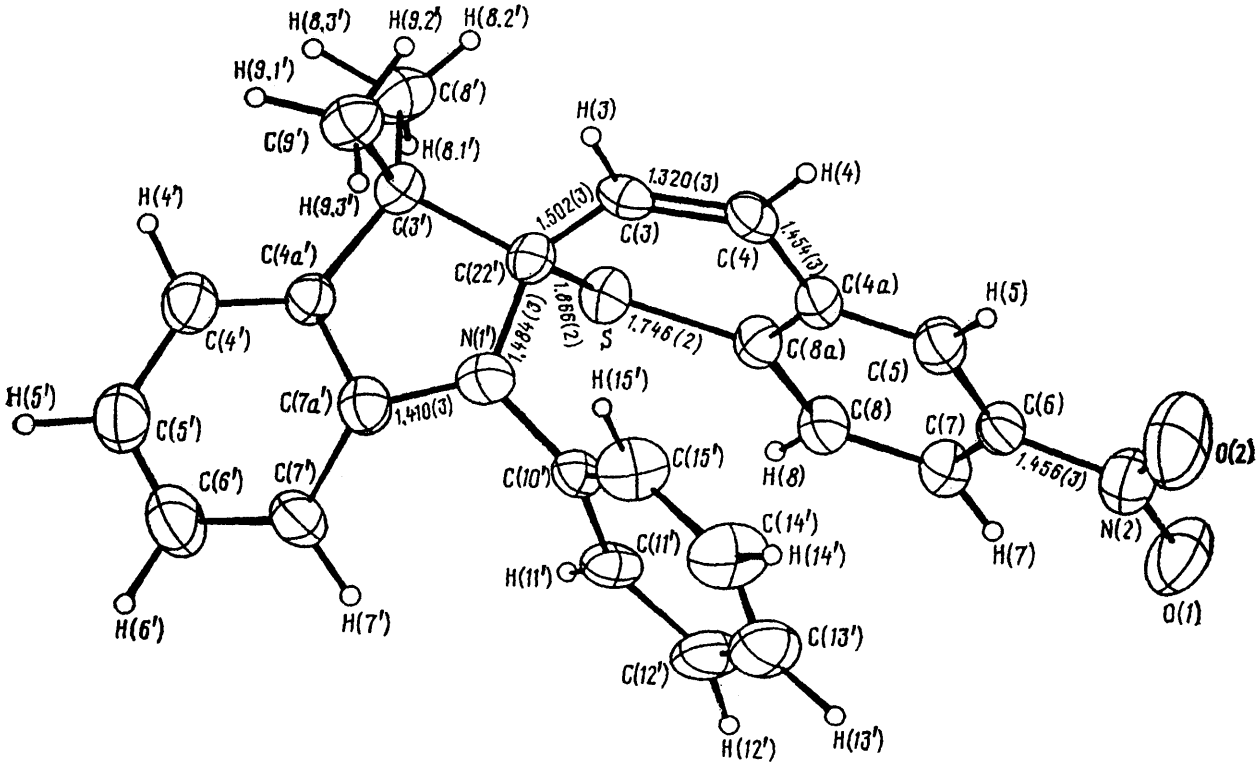

Figure 10. General shape of spirothiopyran SP(XII).

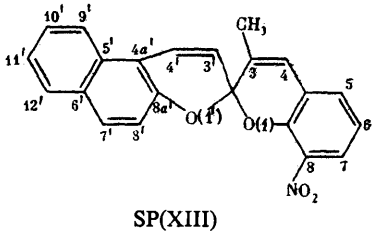
angle in SP(XII) proved to be 101.9°, whereas in SP(I)–SP(IX) the C(22′)O(1)C(8*a*) angles are in the range 120–124°. These findings could suggest that hybridisation of the S atom in SP(XII) is close to sp^3 while the O atom in SP(I)–SP(XI) is close to sp^2-hybridisation. With sp^3-hybridisation of the heteroatom there is a substantial decrease in conjugation of its UEP with the π-system of the benzene residue, hence the polarity of the C(22′)–S bond in SP(XII) will be much less than the polarity of the C(22′)–O bond in SP(I)–SP(XI) and the n[N(1′)]–σ*[C(22′)–S] interaction in SP(XII) will be weaker than the n[N(1′)]–σ*[C(22′)–O] interaction in SP(I)–SP(XI). Elongation of the C(22′)–S bond compared to the C(22′)–O bond in SP(I)–SP(XI) and the resulting withdrawal of the UEP of the S atom from the σ*-orbital of the C(22′)–N(1′) bond also reduces the n(S)–σ*[C(22′)–N(1′)] interaction, so in SP(XII) these n–σ* interactions are evidently small and balance each other.

The elongation of the C(22′)–S bond to 1.866(2) Å in SP(XII) has been attributed[77] to steric interactions between the *gem*-methyl groups and the heteroatom of the thiopyran ring. These interactions give rise to distortion of the indoline residue and its inflection along the line of C(3′)...N(1′) in the closed forms SP(I)–SP(XI), while in SP(XII), which contains the more bulky S atom compared to an O atom, the C_{spiro}–S bond is further elongated.

Because of the sp^3-hybridisation of the S atom and the weak overlap of its UEP with the π-system of the benzene ring, no significant positive charge develops on the S atom[18,56] during photoexcitation of the lowest electronic levels of the thiopyran residue in the SP(XII) molecule. Therefore, in contrast to SP(I)–SP(XI), in SP(XII) and in the excited state the n–σ* interactions will have no substantial effect on the length of the C_{spiro}–S bond and its cleavage. For this reason the mechanism of α-cleavage of this bond proves ineffective for SP(XII).[47] The observed photochemical properties of SP(XII) are evidently related to a vibrational mechanism for cleavage of the C_{spiro}–S bond, in which the electron excitation energy will be unequally converted into vibration energy of the weakest individual bonds.[48] In a spirothiopyran this is the C_{spiro}–S bond, whose vibrations should be excited more than the others. When there is steric hindrance between the S and C(8′) atoms, this results in cleavage of the C_{spiro}–S bond. Support for the decisive role of a vibrational mechanism of bond cleavage in spirothiopyrans is provided by the absence of any noticeable electronic effect from the 6-NO_2 group on their photochemical properties, in contrast to the SPs described by Betelson.[2]

Vibrational cleavage of the less polar C_{spiro}–S bond compared to C_{spiro}–O in spirothiopyrans can occur homolytically rather than heterolytically as in SP(I)–SP(IX). In contrast to SP(I)–SP(XI), the coloured form of SP(XII) is evidently not the most stable zwitterion structure but is only its thermodynamically unstable, intermediate isomer X.



$$(A) \xrightarrow{h\nu} (A^*) \xrightarrow{\varphi_{breaking}} (X) \xrightarrow{\varphi_{colour}} (B)$$

When the temperature is lowered to 77 K this isomer (X) is stabilised and the quantum yield of the reaction increases. At 293 K in solution the reverse dark reaction (X)→(A) is efficient, and the quantum yield of reaction is low, although according to the results of flash photolysis the short-lived coloured form is formed in solution (in small quantities) even at 293 K.

2. Structure of "symmetrical" spiropyrans consisting of two benzopyran residues

It was demonstrated in IV.1 that the efficiency of orbital hyperconjugation in the spiro centre, which affects the photochemical properties of SPs to a considerable extent, depends both on the geometric configuration of the UEP of the heteroatom and the adjacent bonds and on the electronic properties of the heteroatoms. Since "symmetrical" spiropyrans contain the same heteroatoms in the spiro centre, their electronic properties and the efficiency of n–σ* interactions will mainly depend on the electronic state of the heteroatoms as determined by the nature and position of substituents in the benzopyran residue.

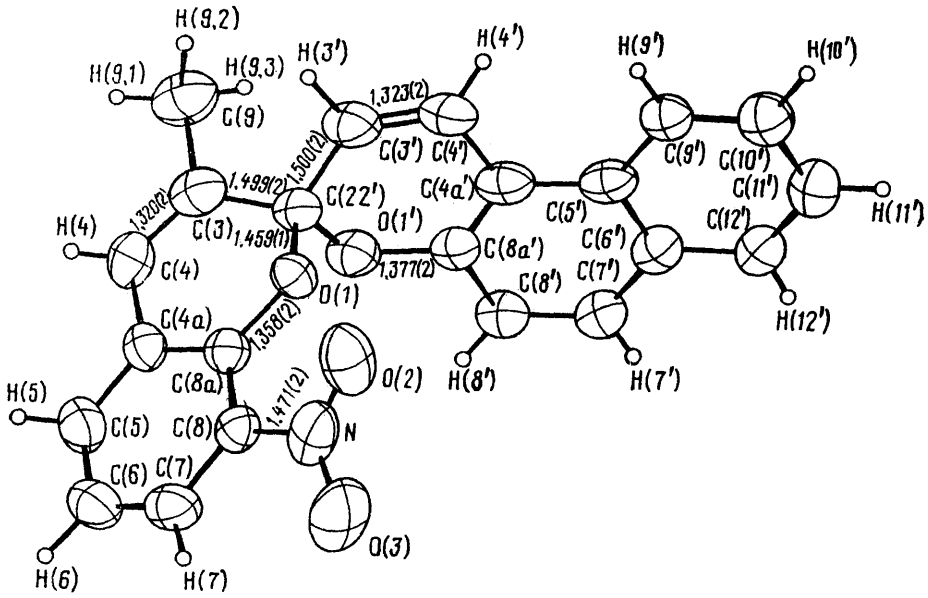
An X-ray study of SP(XIII) (Fig. 11) has been carried out.[79]

SP(XIII)

The orientation of the π-UEP of the O(1) and O(1′) atoms relative to the adjacent C(22′)–O(1′) and C(22′)–O(1) bonds in SP(XIII) is the same, with angles of 159.2 and 161.4° being formed respectively. Nevertheless, the bond lengths of C(22′)–O(1) [1.459(1) Å] and C(22′)–O(1′) [1.434(2) Å] in the spiro centre of SP(XIII) proved to be different. Introduction of the electron-withdrawing NO_2 group into the 8-position of SP(XIII) leads to a contraction of the O(1)–C(8*a*) bond to 1.358(2) Å, which, as in SP(II) and SP(III) where the lengths of these bonds are 1.356(3) Å, suggests that there is an increase in conjugation of the π-UEP of the O(1) atom with the π-system of the benzene ring.

Annelation of an additional benzene ring at the 5′, 6′-position of the benzopyran residue results in an elongation of the corresponding O(1′)–C(8*a*′) bond to 1.377 Å, which, as in SP(VII) where the length of this bond is 1.372(3) Å, suggests that the conjugation of the π-UEP of the O(1′) atom with the π-system of the naphthalene ring is weakened. With this type of structure of the spiro centre of SP(XIII), the C(22′)–O(1) bond will be more polar and the π-UEP of the O(1′) atom will be more active, so that in the spiro centre the n[O(1′)]–σ*[C(22′)–O(1)] interactions, which lead to an elongation of the C(22′)–O(1) bond, will predominate. In this case the C(22′)–O(1′) bond proves to be only slightly longer than the normal value of 1.41–1.43 Å.[15–17]

The C(22′)–O(1) bond is elongated in SP(XIII) less than in the correspondig indoline spiropyrans SP(I)–SP(IV) and its length matches the length of the C_{spiro}–O bond [1.452(2) Å] in SP(V), in which the activity of the UEP of the N(1′) atom is less than in SP(I)–SP(IV). These results suggest that the efficiency of the resulting n–σ* interactions in a spiro centre containing two heteroatoms that are both O, despite their different electronic state, is less than in a spiro centre containing O and N atoms. Nevertheless, it opens up the possibility for developing new classes of photochromic SPs containing the same heteroatoms in the spiro centre but in different electronic states. In this case the structure and hence the photochemical properties of such SPs can be regulated by changing the electronic environment of the heteroatoms.



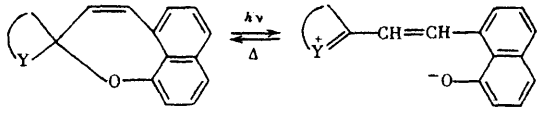


Figure 11. General shape of the "symmetrical" SP(XIII).

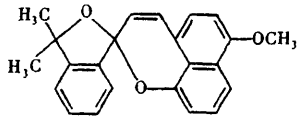
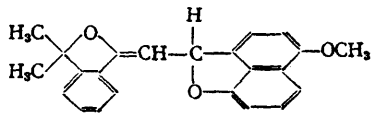


3. Structure of the first example of a spiro-2*H*-naphtho-[1,8-*bc*]oxepin

In accordance with ideas based on quantum-chemical calculations,[68] a long-wavelength band (1500–2000 nm) would be expected to occur in the electronic spectra of zwitterions X.

(Y) (X)



However, for a long time it was not possible to obtain spiropyrans (Y) containing seven-membered rings.[80] In 1986 a spiropyran of this type—SP(XIV)—was obtained for the first time and its structure studied.[81]

SP(XIV)

The general form of SP(XIV) is shown in Fig. 12. The dihedral angle between the O(1)C(22')C(3) and O(2)C(22')C(16) planes is equal to 89.9°. The oxaindan part of the molecule has an envelope configuration with a 25.0° angle of twist from the line of C(22')...C(13). Because of the rigid tetrahedral configuration of the C(22') spiroatom, the seven-membered oxepin ring is severely strained and has a distorted conformation. This type of conformation of the seven-membered ring leads to a change in the relative configuration of the π-UEP of the O(1) atom and the adjacent C(22')–O(2) bond in the spiro centre. While the π-UEP of the O(2) atom is oriented at an angle of 165.0° to the adjacent C(22')–O(1) bond and this proves to be favourable for n^{π}[O(2)]–σ*[C(22')–O(1)] orbital interaction, the π-UEP of the O(1) atom is oriented at an angle of 110.4° to the adjacent C(22')–O(2) bond, which actually suggests that there is no reverse n^{π}[O(1)]–σ*[C(22')–O(2)] interaction. Therefore, in SP(XIV) the efficiency of the interaction between the π-UEP of the O(2) atom and the σ*-orbital of the C(22')–O(1) bond increases, which results in a contraction of the C(22')–O(2) bond to 1.409 Å and an elongation of the C(22)–O(1) bond to 1.455(3) Å.

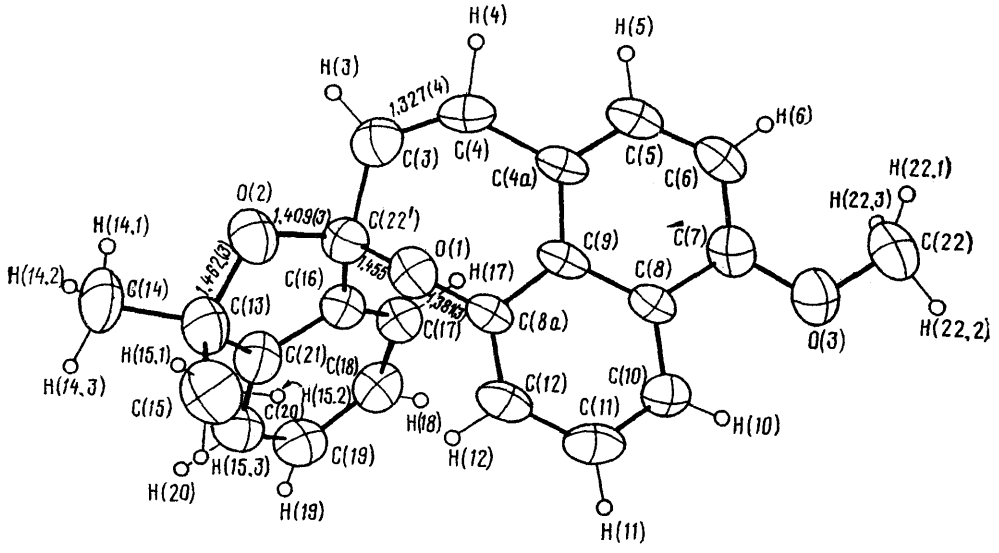
In the seven-membered ring, with an angle of deviation from the O(1)–C(8*a*) bond of 63.3°, the π-UEP of the O(1) atom is directed inside the heterocycle towards the C(4) atom, although it deviates from the line of O(1)...C(4) by approximately 38°. Taking into account the short interatomic distance of O(1)...C(4) (2.88 Å) and distortion of the C(3)C(4)C(4*a*) bond angle to 130.3°, it may be assumed that there is an attractive secondary interaction between the O(1) atom and C(4) atom destabilising the heterocycle.[79] It would appear that these structural features of SP(XIV) are responsible for its rapid conversion in solution on irradiation with a mercury lamp (313 nm filter) compound (P) rather than compound (Y).[81]

(P)

V. Structure, photo- and thermo-chromic properties of 2-oxaindan spiropyrans with polycondensed chromene residues

1. Structure of 2-oxaindan spiropyrans

It has already been mentioned, that the significant improvement in performance of SPs, and primarily the increase in stability of their



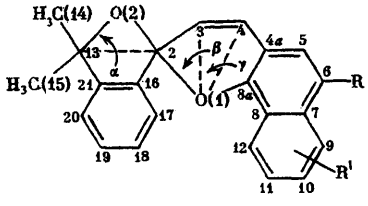


Figure 12. General shape of spiro-2*H*-naphtho[1,8-*bc*]oxepin.

photoinduced forms may be achieved by the introduction of strong electron-acceptor substituents into the benzopyran residue. However, such substituents considerably reduce the photostability of SPs,[63] thus severely limiting in scope the practical application of materials based on them.[83] Hence a study was made of the 2-oxaindan spiropyrans SP(XV)–SP(XVIII), whose photocoloured forms are stabilised through increasing the size of the π-system of the quinoid residue by means of annelation of additional arene rings to the 7,8-bond of the benzopyran part of the molecule.[84]

SP(XV)–(XVIII)

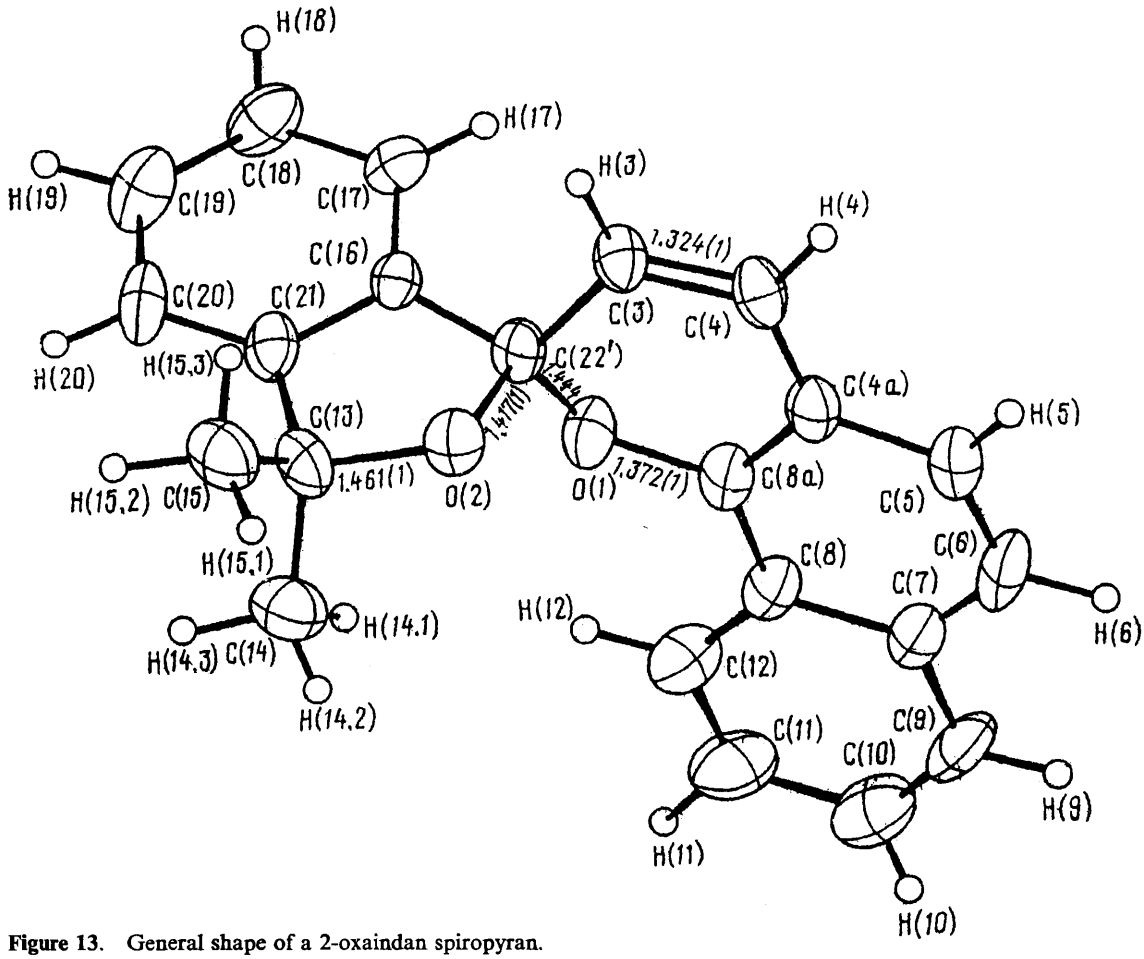
(XV): R = H, R' = H;
(XVI): R = H, R' = 10,11-benzo
(XVII): R = Br, R' = H;
(XVIII): R = NO_2, R' = H.

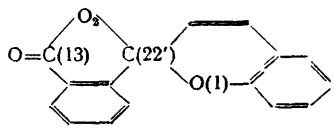
An X-ray study of SP(XV)–SP(XVIII) showed that these compounds have the same conformation. The naphtho(anthraceno)-pyran and oxaindan parts of the molecule are positioned approximately at right angles to each other. The dihedral angle between the O(1)C(2)C(3) and O(2)C(2)O(16) planes is 93–95°. In all of the SPs studied the pyran and oxaindan residues are nonplanar. The first has a folded conformation with dihedral angles along the lines of O(1)...C(3) and O(1)...C(4) of 21.4 to 28.6° and 10.2 to 13.3° respectively, while the second has the conformation of an envelope with an angle of inflection along the line of C(2)...C(13) equal to 15.5–17.3°. The structure of one of the spiropyrans studied is shown in Fig. 13 and their main structural parameters are given in Table 2.

In the same way as in the previously studied indoline SPs, the C_{spiro}–O(1) bond is elongated in SP(XV)–SP(XVIII). However, while in SP(I)–SP(XI) the lengths of these bonds are in the range 1.460(2)–1.496(4) Å, in SP(XV)–SP(XVIII) these bond lengths are in the range 1.444(1)–1.465(2) Å. At the same time in the unsubstituted SP(XV) this bond [1.444(1) Å] is the least elongated in comparison with the lengths of normal C–O bonds (1.41–1.43 Å) in six-membered heterocycles. Annelation of an additional benzene ring to SP(XVI) has virtually no effect on the length of the C(22')–O(1) bond [1.447(1) Å]. The introduction of electron-acceptor substituents into the 6-position of the naphthopyran residue—Br in SP(XVII) and particularly the NO_2 group in SP(XVIII)—results in this bond being extended to 1.455(3) Å and 1.465(2) Å respectively (Table 2). In the oxaindan residue of SP(XV)–SP(XVIII) the C(22')–O(2) bond was shortened to 1.417(1)–1.407(3) Å compared to the normal length of a C–O bond in five-membered heterocycles (1.426 Å).[85] As the C(22')–O(1) bond increases in length, the C(22')–O(2) bond has a tendency to contract, whereas the O(2)–C(13) bond in these SPs remains elongated (see Table 2).

In the spiro centre of SP(XV)–SP(XVIII) there are two heteroatoms which are both oxygen. In those systems in which two oxygen atoms are bound to an anomeric carbon atom, the efficiency of the $n-\sigma^*$ interaction will primarily depend on the geometric configuration of the UEP of the oxygen atoms and the electronic state of these atoms.

The compounds studied [SP(XV)–SP(XVIII)] have the same conformation with similar values of angles τ and Δ (see Table 2). However, the electronic states of the O(1) and O(2) atoms in them differ substantially. The O(1) atom is bound to the aromatic π-system of the naphthalene or anthracene residues, the bond lengths of O(1)–C(8*a*) [1.354(2)–1.377(1) Å] are similar to the lengths of the corresponding bonds in α-naphthol (1.37 Å)[86] and suggest that there is significant conjugation of the UEP of the O(1) atom with the neighbouring π-system. This conjugation will increase the polarity of the C(22')–O(1) bond relative to the polarity of the C(22')–O(2)





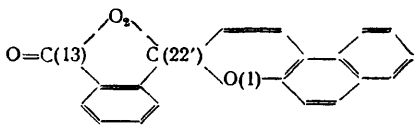


Figure 13. General shape of a 2-oxaindan spiropyran.

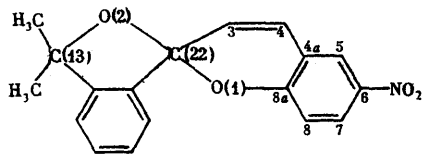
bond and decrease the activity of the UEP of the O(1) atom compared to the activity of the UEP of the O(2) atom. Therefore in these spiropyrans the $n[O(2)]-\sigma^*[C(22')-O(1)]$ interactions should be stronger than the $n[O(1)-\sigma^*[C(22')-O(2)]$ interactions and may be responsible for the elongation of the C(22')–O(1) bonds and contraction of the C(22')–O(2) bonds found in these SPs. In the same way as in SP(XIII), these interactions are weaker in SP(XV)–SP(XVIII) than in SP(I)–SP(XI), which contain different heteroatoms (O and N) in the spiro centre, and the lesser elongation of the $C_{spiro}-O(1)$ bond in SP(XV)–SP(XVIII) is related to this.

In SP(XIX) and SP(XX), which were studied previously,[87,88]

СП (XIX)



SP(XX)

the π-UEP of the O(2) atom are conjugated with the π-bond of the neighbouring carbonyl group, as is indicated by the length of the O(2)–C(13) bond (1.35–1.37 Å), therefore the $n-\sigma^*$ interactions of the O(1) and O(2) atoms in these molecules are small and the lengths of the C(22')–O(1) bonds (1.42 and 1.399 Å) are of normal magnitude.

Introduction of the electron-acceptor substituents Br and NO_2 into the 6-position of the naphthalene residue gives rise to an elongation of the C(22')–O(1) bond, which increases as the electron-acceptor properties of the substituents increase [1.455(3) Å in SP(XVII) and 1.465(2) Å in SP(XVIII)]. At the same time there is a contraction of the O(1)–C(8*a*) bond to 1.366(3) Å in SP(XVII) and 1.354(2) Å in SP(XVIII) compared to the length of this bond in SP(XV) and SP(XVI), in which it amounts to 1.372(1) and 1.377(1) Å respectively. This suggests that there is an increase in conjugation of the UEP of the O(1) atom with the π-system of the naphthalene residue on introduction of electron-acceptor substituents, so the elongation of the C(22')–O(1) bond in SP(XVII) and SP(XVIII) is related to the strengthening of the $n[O(2)]-\sigma^*[C(22')-O(1)]$ interaction in these compounds, which also results in a contraction of the C(22')–O(2) bond in SP(XVII) and SP(XVIII) to 1.413(3) and 1.407(3) Å respectively in comparison with the length of this bond in SP(XV) and SP(XVI), where it is equal to 1.417(1) Å.

It is interesting that in the analogous benzopyran SP(XXI)[89]

SP(XXI)

with an NO_2 group at the *para*-position relative to the O(1) atom, the C(22′)–O(1) bond is less elongated (1.452 Å) and the O(1)–C(8*a*) bond (average 1.366 Å) is less contracted than in SP(XVIII). These results suggest that the electron-acceptor effect of the NO_2 group on the O atom is more marked in a naphthalene residue than in a benzene residue.

In order to confirm the electronic rather than steric nature of the elongation of the C(22′)–O(1) and O(2)–C(13) bonds and contraction of the C(22′)–O(2) bond, conformational calculations on a model SP were carried out.[84] After minimisation of the energy of strain in the molecule the length of the C(22′)–O(1) bond in it proved to be of normal magnitude (1.422 Å) while the lengths of the C(22′)–O(2) (1.434 Å) and O(2)–C(13) (1.439 Å) bonds were the same and close to normal values.

2. Thermal valence isomerisation of SPs

Spiropyrans SP(XV)–SP(XVIII) have distinct thermochromic properties in solutions of polar and nonpolar solvents. From the values calculated from dynamic NMR data for the free energy of activation of thermally induced valence isomerisation of SP(XV)–SP(XVIII)[84] and certain other SPs that were studied[90] and comparing them with the lengths of the C_{spiro}–O(1) bonds in these compounds the following conclusions could be drawn:

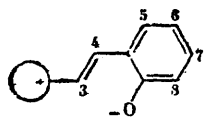
1) a variation in structure of the heterene and pyran residues of the SP molecule has no substantial effect on the free energy of activation of the SP;

2) there is no correlation between the C_{spiro}–O(1) bond length in SP(XV)–SP(XVIII) and the free energy of activation.

The lack of this correlation, which was also predicted from quantum-chemical calculations,[91] evidently arises because the C_{spiro}–O(1) bond length in the ground transition state (the region of thermochromic cleavage), as was demonstrated by Simkin et al.,[46] is almost constant (~1.95 Å) and differs considerably from the length of this bond in the initial state. Therefore the small changes in length of this bond which occur as a result of structural factors do not have any substantial effect on the energy of activation for cleavage of this bond.

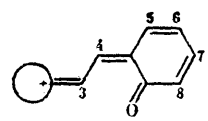
3. Photochromism of 2-oxaindan spiropyrans

The photochromic properties of SP(XV)–SP(XVIII) in liquid and solid solutions are exhibited over a wide temperature range (from 77 to 273 K). By using the technique of flash photolysis it is possible to observe reversible photocoloration even at 20 °C. In order to determine the relative photochemical activity of SP(XV)–SP(XVIII), Aldoshin et al.[84] studied the ease of photocoloration ("colorability") of these compounds. The results of a study of the "colorability" of SP(XV)–SP(XVIII) compared to the C_{spiro}–O(1) bond length are given in Table 3. It is clear from Table 3 that these values vary in a similar manner, the highest photochemical activity being exhibited by SP(XVIII) with the most elongated bond. This apparently occurs because the C_{spiro}–O(1) bond length in the excited transition state is much shorter than that in the ground transition state. Consequently, the reaction barriers of SPs in the excited states are markedly reduced. Therefore the photochemical activity for coloration of an SP proves to be sensitive to even small changes in the C_{spiro}–O(1) bond length in the ground state, which result from the influence of different structural factors in SP molecules.



Unfortunately, it was not possible to carry out an X-ray diffraction study of the resulting open coloured form of 2-oxaindan SPs, and the structure of the coloured products can only be assessed

Table 2. Main structural parameters of 2-oxaindan spiropyrans studied.



SP	Substituents		Bond lengths*1, Å				Angles, deg				
	R	R′	C(22′)–O(1)	C(22′)–O(2)	O(1)–C(8*a*)	O(2)–C(13)	α	β	γ	τ*2	Δ*3
(XV)	H	—	1.444	1.417	1.372	1.461	17.3	21.4	10.2	159.6	159.8
(XVI)	H	10,11-benzo	1.447	1.417	1.377	1.461	16.3	22.2	10.3	158.4	159.8

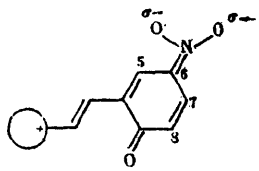
*3 Angle between the π-UEP of the O(1) atom and the C(2)–O(2) bond.



from indirect evidence. The X-ray diffraction study of the open forms of indoline SPs showed that they have the zwitterion structure (A) with an appreciable contribution from the canonical structure (C).

(A)

(B)

(C)

However, in contrast to indoline SPs, SP(XV)–SP(XVIII) and SP(XXII) reveal bathochromic shifts of the photoinduced absorption bands on increasing the polarity of the medium, regardless of the nature of the substituents.[92] These findings suggest that the quinoid structure makes a decisive contribution to the structure of the coloured form. It was suggested above (see Section III) that annelation of additional benzene rings to the phenolate residue at the 5,6- and 7,8-positions should stabilise the quinoid structure (C) while annelation at the 6,7-position would destabilise this structure. The increase in the lifetime of SPs on going from SP(XV) to SP(XVI) supports this view and is an indication of the important role of this method for stabilising an open SP form.

Table 3. "Colorability" of spiropyrans SP(XV)–SP(XVIII) and the C_{spiro}–O(1) bond length.

SP	"Colorability"*	C_{spiro}–O(1) bond length, Å
(XV)	0.22	1.444 (1)
(XVI)	0.32	1.447 (1)
(XVII)	0.36	1.455 (3)
(XVIII)	0.46	1.465 (2)

*The colorability is determined from the initial absorption A_0 of solutions of photochromic SPs under exactly the same irradiation conditions (temperature, SP concentration, length and volume of cell, irradiation intensity). Indoline SP(IV) is most frequently used as the reference compound, for which $A_0 = 1$.

The introduction of electron-acceptor substituents into the naphthopyran residue of these SPs also increases the lifetime of the open forms. The nitro group with its strong electron-acceptor properties has the greatest stabilising effect. As in indoline SPs, the stabilisation of the coloured products of SP(XVIII) with electron-acceptor substituents appears to be related to the increased contribution of the resonance form (C) to their structure.

An additional factor for stabilisation of the coloured forms of these SPs may also be the formation of different intermolecular associates, as takes place for the open merocyanine forms of indoline SPs. At the same time, the more extended the conjugated π-system of the SP, the more stable (through π–π interaction) may be the associates.

VI. Conclusion

Thus, as a result of analysing the structure of different classes of spiropyrans, the structural factors which affect their photochemical properties have been established.

It has been shown that the photochemical properties of spiropyrans in many respects is due to the fact that even in the ground state the C_{spiro}–O bond, which undergoes cleavage on photoexcitation, is weakened and elongated through specific $n-\sigma^*$ orbital interactions, which on going to excited photochemically active states are even further strengthened, thus assisting the cleavage of this bond. It has been established that the photochemical activity of spiropyrans depends on the length of the C_{spiro}–O bond in the ground state and the nature of the change in length of this bond in the excited state. At the same time the photochemical activity of spiropyrans proves to be more sensitive to the length of the C_{spiro}–O bond being cleaved than does the thermochromic activity.

A study has been made of the effect of different substituents in the benzopyran and indoline residues, the nature, electronic state, and relative orientation of the heteroatoms in the spiro centre, and the size of the heterocycles on the efficiency of $n-\sigma^*$ interactions in spiropyran molecules and on the length of the C_{spiro}–O bond in the ground state.

The structure of the photoconversion products of spiropyrans and the stereochemical factors responsible for stabilising it have been examined. For the coloured photoforms of spiropyrans in the crystalline state the formation of different strong intermolecular associates and solvates has been detected, which to a considerable degree govern the stabilisation of the complex resonance structure of spiropyrans not only in the crystalline state but also in solution, which is a more probable cause of the complex absorption spectrum of these compounds than the proposed existence of various isomers.

The structure of novel conductive dithiolate complexes

V E Shklover, S S Nagapetyan, Yu T Struchkov
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The characteristics of the molecular and crystalline structure of novel transition metal dithiolate complexes are examined and the correlation between structure and electrical conductivity of these compounds is discussed. The material reviewed is of interest both for the crystal chemistry and physical chemistry of the respective class of molecular conductors and for the structural chemistry of dithiolates.

The bibliography includes 94 references.

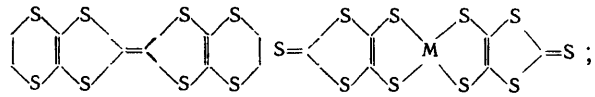
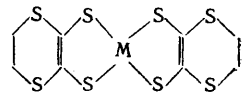
I. Introduction

Solid-state reactions are of increasing interest to research workers. This is because the limited mobility of reacting molecules in a crystal makes it possible to carry out a successive structural study of a whole chain of molecular reactions and to obtain polymers of a regular structure, large, defect-free monocrystals, etc. This is all due to the origination and development of a new branch of science—crystal engineering—which is aimed at studying the principles and laws governing the formation of those types of packing of potentially reactive molecules and crystals in which favourable conditions are created for the molecules to participate in given reactions and rearrangements.[1–21]



At the present time the concepts of crystal engineering have been developed further in studies on crystalline low-dimensional semiconductors, metals, and superconductors. Special emphasis has been given to research on the properties of this promising class of organic materials (the design of molecular "corridors" of the primary movement of electrons, the use of heteroatoms for achieving overlap of orbitals of neighbouring molecules, the elimination of spatial modulation of charge density by changing the intermolecular distances, etc.).

The structure and packing of donor and acceptor molecules in crystals of organic conductors have a number of specific features. Donor molecules should be planar and include π-residues and heteroatoms (nitrogen, oxygen, or chalcogen atoms). For acceptor molecules the shape, size, and charge are important. In the crystal the donor and acceptor molecules should be located so as to achieve the necessary electronic interaction for delocalisation of electrons and high electrical conductivity. In other words, the molecular building blocks of an organic conductor should be well suited to achieve overlap between the π-electron systems of neighbouring molecules. By changing the structure of donor and acceptor molecules and also the conditions for obtaining the organic conductor that affect its composition (the ratio of donor to acceptor), it is possible to vary the crystalline structure, and this in turn leads to a change in the degree of charge transfer and electrical conductivity of the crystal under these conditions. As examples of the "active" modification of the properties of an organic metal (or superconductor) through alteration of the molecular structure of its components, mention can be made, for example, of the change from salts of the type TTF–TCNQ to the salts $(TMTSF)_2X$ (for notation see Table 1), the structure of which exhibits more pronounced two-dimensional characteristics as a result of introducing Me groups and Se atoms into the donor molecule and replacing acceptors of the type TCNQ by monovalent anions of the type X = PF_6;[22–24] the change from salts of the type $(TMTSF)_2X$ to salts of the type $(BEDT–TTF)_2Y_3$, which have a stronger interstack interaction and a higher value of the transition temperature to a superconductive state (T_c) as a result of replacement of the donors TMTSF by BEDT–TTF;[25–27] and the further increase in T_c in $(BEDT–TTF)_2Y_3$ salts by altering the Y_3 anions ("chemical compression" effect).[28–31]

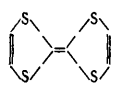


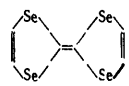
At the present time organic metals and superconductors in which BEDT–TTF acts as the donor have been studied the most actively. In contrast to conductive radical cation salts with packing in stacks (perylenium salts, for example),[32] in crystals of BEDT–TTF salts the central π-electron system of the molecule† is not involved in intermolecular interaction. On the other hand, in conductive crystals, the so-called one-dimensional transition metal complexes with organic ligands, the conductive corridors are in fact produced from the electrons of the "central" metal ions interacting with their neighbours in the stack situated above and below the central ion. The organic ligands do not participate in intermolecular electron transfer.[33] It was natural that the idea of synthesising compounds that would simultaneously combine the properties of salts of the type BEDT–TTF and those of one-dimensional metal complexes should develop (see, for example, the study of Keller et al.),[34] and this was carried out at approximately the same time by different groups of research workers. They synthesised transition metal complexes with novel sulphur-containing ligands such as $[M(dmit)_2]^n$ and

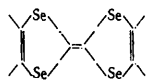
†In this and other cases (which will subsequently not be mentioned separately) we are, of course, dealing with a radical ion (in this case the radical cation $BEDT–TTF^{+\cdot}$) that is called a "molecule" in order to simplify the discussion of the crystalline structure in terms of the crystal chemistry of molecular crystals.

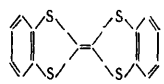
$[M(DDDT)_2]^n$. Their salts have a close structural similarity to salts of BEDT–TTF.

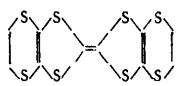
BEDT—TTF $[M(dmit)_2]^n$

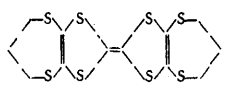


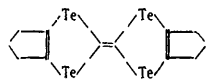


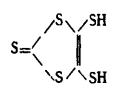


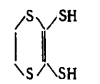


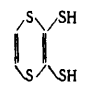


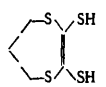












$[M(DDDT)_2]^n$

The complexes $[M(dmit)_2]^n$ and $[M(DDDT)_2]^n$ belong to a well-known class of dithiolate complexes. The structure of simpler dithiolate complexes has been discussed several times (see, for example, two studies[35,36]). Thus, their molecules or ions were observed to have an overall planar structure regardless of the nature of metal or its degree of oxidation, a capacity for reversible electron transfer reactions with the formation of stable products, considerable delocalisation of the π-type HOMO, and a high electron-acceptor capacity relative to organic donors.

Dithiolate complexes have considerable structural flexibility (geometric and electronic) with regard to replacement of the central metal atom and the substituents in the ligands and counterions.

In this review the literature data and the present authors' own results in studies on the structure of novel sulphur-containing dithiolate complexes of the type $[M(dmit)_2]^n$ and $[M(DDDT)_2]^n$ and on the search for correlations between structure and electrical conductivity are examined.

Table 1. Notation used in this review.

Name	Structural formula	Notation
Tetrathiafulvalene		TTF
Tetraselenafulvalene		TSF
Tetramethyltetraselenafulvalene		TMTSF
Dibenzotetrathiafulvalene		DBTTF
Bis(ethylenedithio)tetrathiafulvalene		BEDT—TTF
Bis(propylenedithio)tetrathiafulvalene		BPDT—TTF
Bis(trimethylene)tetratellurafulvalene		HMTTeF
Tetracyanoquinodimethane		TCNQ
4,5-Dimercapto-1,3-dithiole-2-thione		H_2dmit
5,6-Dihydro-1,4-dithiin-2,3-dithiol		H_2DDDT
1,4-Dithiin-2,3-dithiol		H_2DDT
5,6-Dihydro-1,4-dithiepin-2,3-dithiol		H_2DDTDT

II. Structure of salts of 4,5-dimercapto-2-thione-1,3-dithiolates with "closed" cations

Table 2 lists the main data on the structures and conductivity of $Cat_x[M(dmit)_2]^{x-}$ salts, formed with "closed" cations. These are cations of the type Me_4N^+, Et_4N^+, Me_3S^+, Ph_4As^+, etc., which, in contrast to cations (donors) of the type TTF, TMTSF, and BEDT–TTF, are incapable of intermolecular electron transfer. Since in all cases Cat is a single-charged cation, the value of x is equal to the formal average negative charge of the complex anion $[M(dmit)_2]^{x-}$. In the crystal of the neutral complex $Ni(dmit)_2$ (I)[37] the molecules are arranged in a displaced manner in stacks, the normal to the plane of the complex forms an angle of 48.0° with the [010] direction. There is one shortened intermolecular S...S contact (3.577 Å) within a stack and three contacts between stacks (3.580, 3.580 and 3.575 Å). In the opinion of Valade et al.,[37] the interstack contacts have a short length because they are formed by the thione S atoms and the corresponding S...S vectors are aligned at considerable angles to the plane of complex (I) (far from parallel to this plane).‡ In other words, because of the anisotropy in the relative orientation of the π-atomic orbitals of the atoms in different molecules, even close contacts can lead to small values of the electron hopping parameter.

It has been observed by Valade et al.[37] that the crystal of (I) meets the structural requirements needed for highly conductive systems (the occurrence of regular stacks and reduced intermolecular distances) but it does not satisfy the main electronic criterion—the occurrence of a fractional charge, which accounts for the low conductivity of (I) ($\sigma \sim 3.5 \times 10^{-3}$ Ω^{-1} cm^{-1}).§ Localisation of a

‡In an analysis of the crystalline structure of organic conductors, the interaction (orbital overlap) between neighbouring molecules is determined by comparing the intermolecular distances with the sum of the van der Waals radii of the atoms (see, for example, Pauling[51]). In molecular crystals at room temperature the orbital overlap is small if the intermolecular distances are greater than the sum of the van der Waals radii. At distances smaller than the sum of the van der Waals radii, the contribution of orbital overlap increases exponentially.[52] In addition to the absolute values of the intermolecular distances it is also necessary to take into account the relative orientation of the orbitals of the molecules in contact (see, for example, the study of Mori et al.[53]) in a determination of orbital overlap.

§The specific conductivity σ of insulators varies over the range $10^{-22}-10^{-15}$ Ω^{-1} cm^{-1}, for semiconductors it varies over the range $10^{-8}-10^{-2}$ Ω^{-1} cm^{-1} (increases as the temperature is increased), and for metals the variation is $10-10^4$ Ω^{-1} cm^{-1} (increases as the temperature is lowered).

Table 2. The main data on $Cat_x[M(dmit)_2]^{x-}$ compounds.

*Interplanar distance (between planes of neighbouring anions in a stack or between planes of layers) is given.
**These figures were not given in the original study.
***Insulator.

fractional charge on donor and acceptor molecules in the crystal of an organic metal assists the formation of vacancies on to which electrons can hop at sufficiently high values of the resonance parameters.

In the crystal of $(Me_4N)_{0.5}[Ni(dmit)_2]$ (II) the almost planar $[Ni(dmit)_2]^{1/2-}$ complexes are stacked along the [110] direction. The distances between the planes of the complexes in the stacks alternate between 3.53 and 3.58 Å (Fig. 1). The reduced intermolecular S...S contacts combine the stacks of anions into layers parallel to the (001) plane and alternating along the [001] direction) with layers of Me_4N^+ cations.

The electrical conductivity of the crystal of (II) in a plane parallel to the planes of the layers [parallel to the (001) plane of the crystal] is $\sim 50\ \Omega^{-1}$ cm^{-1} at room temperature, while in a plane perpendicular to the (001) plane it is $\sim 10^{-2}\ \Omega^{-1}$ cm^{-1}. At 100 K the crystal of (II) undergoes a metal–semimetal transition (concentration of conducting electrons decreases to $10^{-3}-10^{-5}$ electrons per atom) and the electrical conductivity along the planes of the layers falls to $1.4\times10^{-2}\ \Omega^{-1}$ cm^{-1}, with the resistance in the plane perpendicular to the layers remaining approximately 10^3 times higher in value.

The stacks of anions directed along [110] and [1$\bar{1}$0] alternate in the [001] direction. Significant is the absence of satellite reflections on the X-ray photographs of samples of (II) when they are cooled below 100 K, where the crystal of (II) undergoes a metal–semimetal transition. X-Ray diffraction analysis of a sample of (II) carried out at temperatures above (293 K) and below (92 K) the transition temperature did not reveal any structural differences in the crystal on changing the temperature.

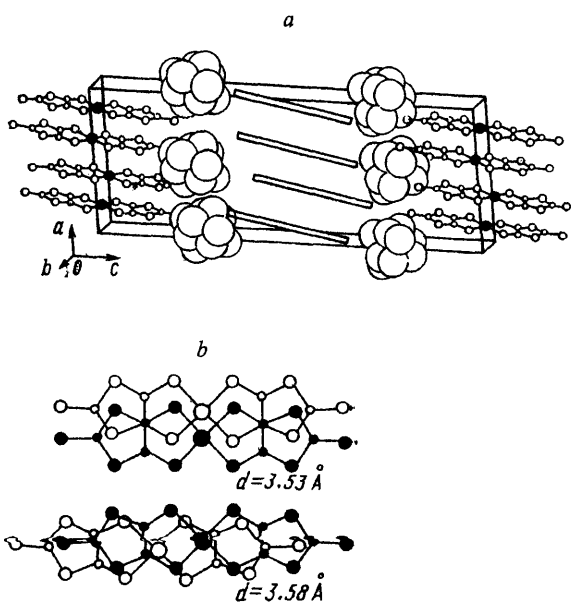

Figure 1. The structure of crystals of $(Me_4N)_{0.5}[Ni(dmit)_2]$ (II) at 95 K (*a*) and the two ways in which the $[Ni(dmit)_2]^{1/2-}$ anions are superimposed in stacks along the [110] direction[38,39] (*b*). The van der Waals spheres of the H atoms in the disordered Me_4N^+ cations are depicted as large circles. The anions perpendicular to the plane of Fig. 1 are shown as rods.

The dependence of the resistance of the crystal of (II) on pressure was studied up to a pressure of 7 kbar. On increasing the pressure the metal–semimetal transition is suppressed and above 3 kbar phenomena characteristic of a superconductive transition occur. At 7 kbar the transition temperature (T_c) was 5 K and the value of dT_c/dP for complex (II) was greater than zero. A positive value of dT_c/dP also occurs for $(TTF)_{0.5}[Ni(dmit)_2]$,[38,39] while for the salts $(TMTSF)_2X$ (X = ClO_4, PF_6, and others)[54] and β-(BEDT–TTF)$_2$X (X = I_3, IBr_2)[55] this value is less than zero.

The hysteresis from continuous heating and cooling a crystal of (II) over the range from about 90 to 300 K is attributed by Kobayashi et al.[39] to the rotational randomisation of the Me groups at room temperature, frozen out on cooling the samples to 95 K.

Compound (II) is the first molecular superconductor to consist of π-acceptor molecules and cations of a closed type.[39] Molecular superconductors consisting of π-donor molecules and closed anions [for example, Bechgaard salts $(TMTSF)_2X$] have previously been reported.[22–24]

In the crystal of α-{$(Me_2Et_2N)_{0.5}[Ni(dmit)_2]$} (III), obtained by electrochemical oxidation of the salt $(Me_2Et_2N)[Ni(dmit)_2]$, the planar $Ni(dmit)_2$ anions are arranged along the *b* axis in stacks in which two types of orbital overlap occur (Fig. 2) through intermolecular S...S contacts (3.424–3.605 Å). Overlap of type (A) occurs between a reference $Ni(dmit)_2$ molecule and two molecules that are not completely parallel to it (dihedral angle 171°), located above the reference one on the *b* axis (lapped overlap). Overlap of type (A) leads to the stacks being combined into layers. Overlap of type (B) takes place between a reference molecule and a molecule parallel to it which is located below on the *b* axis (interplanar distance *d* = 3.52 Å). In a crystal of (III) there are also very short intermolecular S...S distances (3.352 Å) between the thione S atoms of molecules in different layers along the *a* axis.

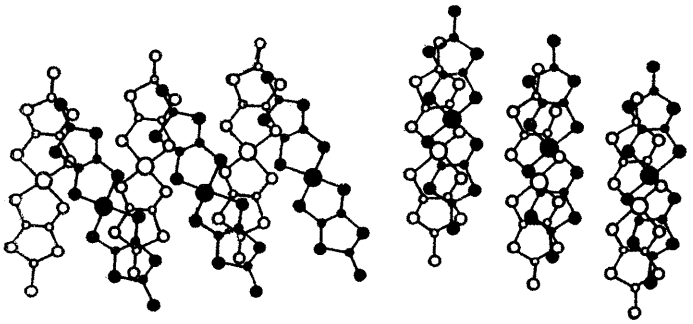

Figure 2. The two ways (*A* and *B*) in which the $[Ni(dmit)_2]^{1/2-}$ anions are superimposed in the crystal of (III).[40]

The electrical conductivity of crystals of (III) in the *bc* plane is isotropic, where σ_{293} = 20–100 Ω^{-1} cm^{-1}; this type of electrical conductivity (typical for metals) is retained down to 1.5 K and a metal–insulator transition does not occur. The electrical conductivity of crystals of (III) along the *a* axis is also quite high: σ_{293} = 1 Ω^{-1} cm^{-1}. At 1.5 K a superconductive transition occurs. Calculation of the overlap integrals of the LUMOs forming the conductivity zone using the extended Hückel (EH) method confirmed the essentially two-dimensional nature of the zone structure in crystals of (III). However, crystals of (III) differ from other $Cat_x[M(dmit)_2]^x$ salts in that for the first time a clear but small interaction was also observed in them in a "third" direction (along the *a* axis).

According to calculations[56] of the intermolecular overlap integrals of the LUMOs in crystals of a number of salts of $M(dmit)_2$ complexes it was found that the b_{2g} symmetry characteristic of these orbitals is not conducive for their overlap in the direction of the short axes of the planar molecules, which is not consistent with the formation of two-dimensional conductive motifs. However, the "lapped" overlap occurring in the crystal of (III) may be regarded as one of the ways of forming two-dimensional motifs.

In the crystal of (IV), which contains the larger Et_4N^+ cations, the $[Ni(dmit)_2]^{1/2-}$ anions are stacked along the [010] direction (Fig. 3).[41] In the stacks there are shortened intermolecular distances between molecules A and B′ but not between molecules A and B. The corresponding interplanar distances are equal to 3.437 Å (between A and B′) and 3.759 Å (between A and B), namely, the anion stacks consist of weakly bound dimers. There are a large number of shortened intermolecular S...S distances between the stacks of anions, as a result of which layers of interacting anions are formed parallel to the (100) plane in the crystal of (IV).

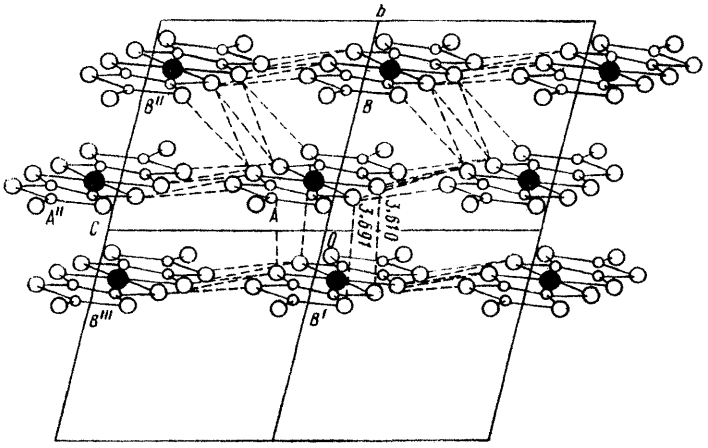

Figure 3. Projection of the crystalline structure of $(Et_4N)_{0.5}[Ni(dmit)_2]$ (IV) on to the *bc* plane (the Et_4N^+ cations are not shown).[41] Here and subsequently shortened intermolecular S...S contacts are indicated by broken lines.

It should be noted that the shortest S...S contacts occur between the "inner" S atoms of the $[Ni(dmit)_2]^{1/2-}$ complexes (3.499 Å), whereas the distances between the "outer" S atoms are more than twice the van der Waals radius of the S atom. Thus, the inner S atoms of the $[Ni(dmit)_2]^{1/2-}$ complexes play a more important role in interstack contacts.

The $[M(dmit)_2]^{x-}$ anions (*x* = 0, ... 1) in crystals of (I)–(VIII) are virtually planar. The bond lengths in the chelate centres of dithiolene complexes of transition metals vary according to their degree of oxidation.[41] The Ni–S distance [2.147(2) Å] in (I) is at the lower limit of the range of Ni–S distances in complexes (I)–(VIII). When the negative charge of the $[Ni(dmit)_2]^{x-}$ complex

is increased, in general there is a tendency for the Ni–S distances to increase (see Table 2). In both the neutral complex (I) and the negatively charged complex (IV) (x = ½), delocalisation of electron density through the chelate residues of the type (Ni)S⋯C⋯C⋯S(Ni) is substantial; the C=C bond lengths are increased to 1.391(9) Å in a crystal of (I) and to 1.39(1) and 1.40(1) Å in (IV), and the (Ni)S–C bond is shortened to 1.699(7) Å in (I) and to 1.682–1.701(7) Å in (IV) compared to the (S=C)S–C bonds in (I) [1.731(7) Å] and in (IV) [1.725–1.732(7) Å]. In the different salts of the anionic $[M(dmit)_2]^{x-}$ complexes the degree of delocalisation through the chelate residues of dithiolene complexes is apparent to a different extent (see below).

The crystal of (IV) is a semiconductor with a low anisotropy of conductivity. The maximum value of electrical conductivity occurs in the plane of the *ac* layer along the stacks ($\sigma_b = 4.5 \times 10^{-2}$ Ω^{-1} cm^{-1}), the energy of activation of electrical conductivity along the *a*, *b*, and *c* axes is 0.15, 0.16, and 0.16 eV respectively. At 300 K $\sigma_a : \sigma_b : \sigma_c = 1 : 50 : 8$.

The intermolecular overlap integrals (S) of the LUMOs of neutral $Ni(dmit)_2$ molecules placed in the positions occupied by the corresponding anions in the crystal of (IV) have been calculated using the extended Hückel method. The values of S for the molecules within the stacks [S(A–B′) = 9.06×10^{-3}, S(A–B) = -2.06×10^{-3}] are higher than those between stacks [S(A–A″) = 1.17×10^{-3}, S(A–B″) = 0.89×10^{-3}, S(A–B‴) = 0.27×10^{-3}], which is consistent with the direction of maximum electrical conductivity.

The crystal of $(Bu_4N)_{0.29}[Ni(dmit)_2]$.MeCN (V) contains eight crystallographically independent $[Ni(dmit)_2]^{0.29-}$ anions (j = 1–8), two of which (j = 1 and 5) are located at centres of symmetry, two crystallographically independent Bu_4N^+ cations, and two MeCN solvate molecules. In all of the (Ni)S⋯C⋯C⋯S(Ni) chelate residues conjugation is clearly apparent—the C=C, (Ni)S–C, and (S=C)S–C distances are (on average) equal to 1.39(2), 1.70(2), and 1.74(2) Å respectively.

The $[Ni(dmit)_2]^{0.29-}$ anions are arranged along the [110] direction into stacks of two types (Fig. 4). In the stacks centrosymmetric triads and tetrads of complexes alternate. The axes of the triads and tetrads are parallel and form angles of ~21° with the plane of the [110] stack. The distances between the mean planes of the complexes in the stacks, which vary from 3.48 to 3.57 Å, are typical for a strong intermolecular π-interaction; for example, in the crystal of (TTF)$[Ni(dmit)_2]_2$ (XV), which has the conductivity of a metal, the interplanar distance in a regular stack is 3.55 Å.[57] According to Soos et al.,[33] an irregular stack structure [both in terms of the interplanar distances (Fig. 4) and the nature of the molecular overlap] is probably responsible for the "nonmetallic" nature of the conductivity in the crystal of (V).

The large number of shortened interstack S...S contacts (34 of the 39 interanion S...S contacts, less than 3.60 Å, relate to contacts between stacks, the shortest of these contacts being 3.442 Å) combine the stacks of $Ni(dmit)_2$ complexes in the crystal of (V) into layers parallel to the (001) plane and separated by layers of Bu_4N^+ cations and MeCN solvate molecules.

Crystals of (V) have a thermally activated (E_a = 0.02–0.1 eV) electrical conductivity σ_{300} = 1–10 Ω^{-1} cm^{-1}. The weak electroconductive anisotropy observed ($\sigma_a/\sigma_b \approx 1$) is consistent with the two-dimensional nature of the structure of (V). The low electrical conductivity in the third direction (along the *c* axis, $\sigma_{300} \approx 10^{-3}$ Ω^{-1} cm^{-1}) is due to the presence of barrier layers of Bu_4N^+ cations and MeCN molecules parallel to the (001) plane.

The Ni–S distances [2.211 and 2.221(6) Å] in the $[Ni(dmit)_2]^{2-}$ anion of the crystal of (VI)[43] are greater than the distances that occur in the $[Ni(dmit)_2]^{x-}$ anions of other complexes (see Table 2) that have a lower negative charge. Information is available[43] on this type of relationship between the Ni–S distances and charges on the anions in simpler dithiolate Ni complexes. The (Ni)S–C distances in the crystal of (VI) [1.74 and 1.76(1) Å] are greater than the

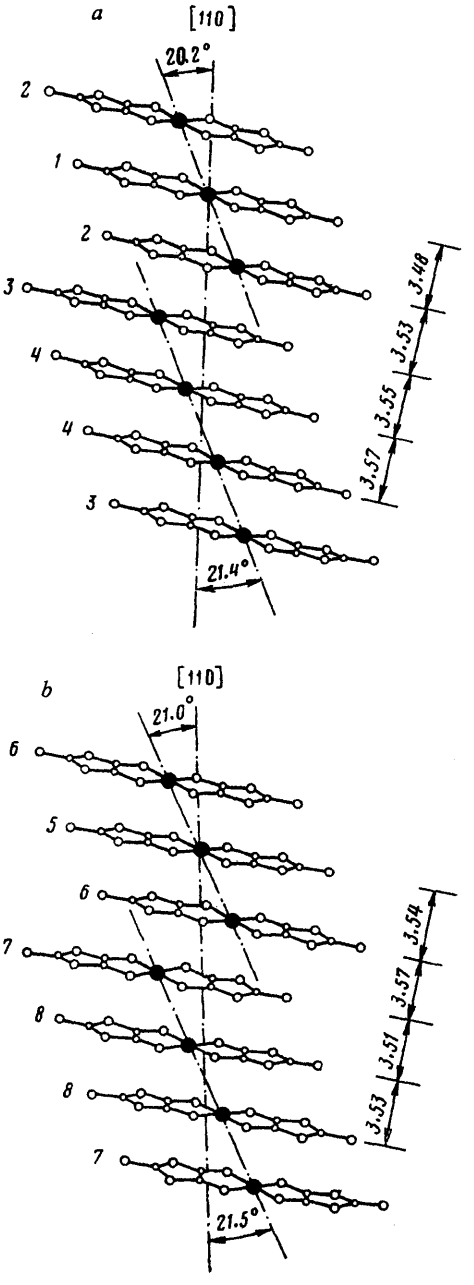

Figure 4. Packing of planar $Ni(dmit)_2$ complexes in the crystal of $(Bu_4N)_{0.29}[Ni(dmit)_2]$.MeCN (V) in stacks of two types (*a* and *b*) along the [110] direction. A projection on to the plane including the [110] vector and the long axis of the complex (the line joining the thione S atoms) is given.[37]

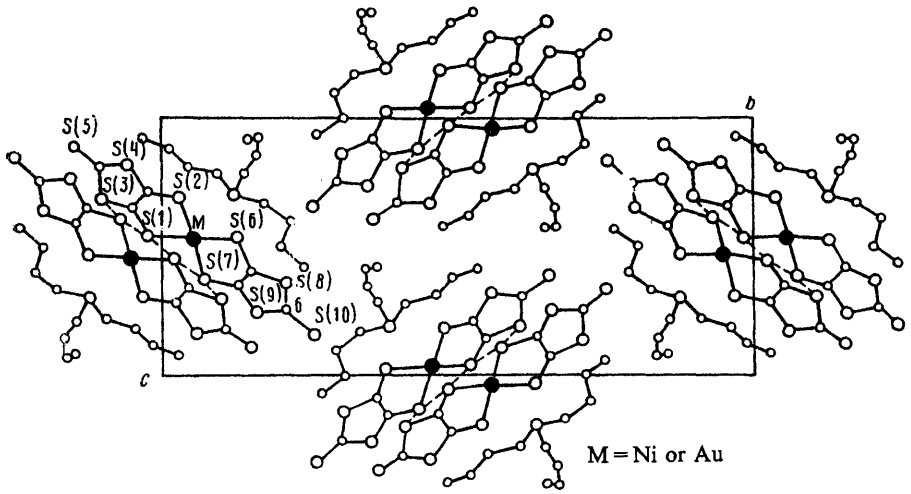

Figure 5. Projection of the isostructural crystals of $(Bu_3S)[Ni(dmit)_2]$ (VII) and $(Bu_3S)[Au(dmit)_2]$ (XIV) on to the *bc* plane.

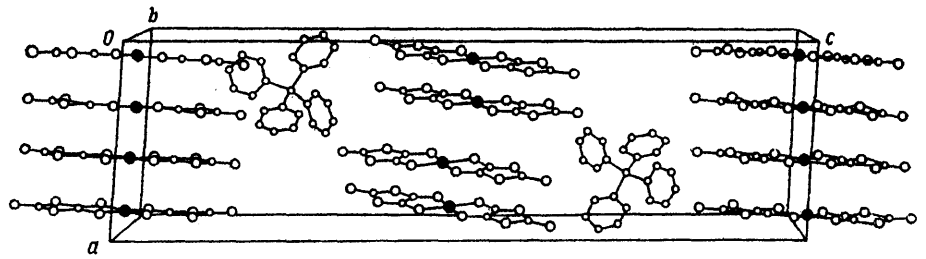

Figure 6. The crystalline structure of (VIII).[45]

(S=C)S−C distances [1.71 and 1.72(1) Å] and the C=C distance is somewhat increased [1.39(2) Å]. The anion of (VI) has an optimum planar structure and an actual optimum characteristic *mmm* symmetry. There are no characteristic structural motifs or shortened intermolecular contacts in the crystal of (VI).

Crystals of the insulator (VII) [and crystals of (XIV) which are isostructural to them] do not contain infinite structural motifs and they are composed of anions joined into dimers by (0, ½, ½) centres of symmetry (Fig. 5). In the dimers there are shortened S(1)...S(1′) contacts of 3.620(3) Å, S(1)...S(7′) contacts of 3.681(3) Å, and S(3)...S(7′) contacts of 3.605(3) Å between $[Ni(dmit)_2]^-$ anions, while in the dimers of the crystal of (XIV), where the $[Au(dmit)_2]^-$ anions are packed more closely than in the Ni analogue, these S...S contacts are 3.496, 3.491, and 3.551(3) Å. The somewhat greater degree of flattening of $[Au(dmit)_2]^-$ anions in (XIV) compared to $[Ni(dmit)_2]^-$ anions in (VII) may also be mentioned (the maximum deviation of the atoms in the anion from its mean plane is given by Δ_{max} = 0.073 and 0.102 Å respectively).

The crystal of (VIII) is composed of two independent $[Ni(dmit)_2]^{0.25-}$ anions in general positions and a Ph_4As^+ cation occupying an individual position on axis 2. The structure of the crystal of (VIII) may be described as consisting of layers of $[Ni(dmit)_2]^{0.25-}$ complexes parallel to the (001) plane, separated by layers of Ph_4As^+ cations (Fig. 6). In the anion layers stacks are formed along the $[\bar{1}10]$ direction when $z \approx 0$ and [110] direction when $z \approx ½$. The stacks consist of approximately parallel complexes grouped into tetrads (Fig. 7). The intermolecular distances in the tetrads (3.53, 3.50, and 3.53 Å) are in good agreement with the observed interplanar distance of 3.55 Å in regular stacks of the crystal of $(TTF)[Ni(dmit)_2]_2$ (XV), which is electroconductive at a low temperature.[57,58] The interplanar distance of d = 3.61 Å between the tetrads is appreciably greater than within the tetrads and is an indication of the "modulated" structure of the stacks.¶ A modulated arrangement of the planar anions in stacks also occurs in the related structures (IV) and (V)—alternation of the diads in (IV) and of the triads and tetrads in (V). Within the triads and tetrads the interplanar distances d vary from 3.48 to 3.57 Å while in the diads they are 3.44 Å. Judging by the interplanar distances, the $[Ni(dmit)_2]^{x-}$ anions interact more strongly within the diads [the crystal of (IV)] than within the triads and tetrads [crystals of (V) and (VIII)]. This is also supported by the distances between the diads, triads, and tetrads in the stacks; in (IV) the interplanar distance between diads is equal to 3.76 Å, in (V) the interplanar distance between triads is 3.53 Å and between tetrads is 3.57 Å, while in (VIII) the interplanar distance between tetrads is 3.61 Å.

¶The occurrence in the stack of two or more interplanar distances rather than one is implied.

The type of overlap of $[Ni(dmit)_2]^{0.25-}$ complexes in the tetrads of the crystal of (VIII) is shown in Fig. 8. It is clear that within the tetrads there is an appreciable relative lateral shift of the molecules, which leads to overlap of the complexes within the tetrads of the type "sulphur-over-ring" (Fig. 8*a*). Conversely, between the tetrads a longitudinal shift generally occurs, leading to overlap of the complexes of the type "metal-over-ring" (Fig. 8*b*), which may be regarded as a disturbance of the continuous structure of a stack.

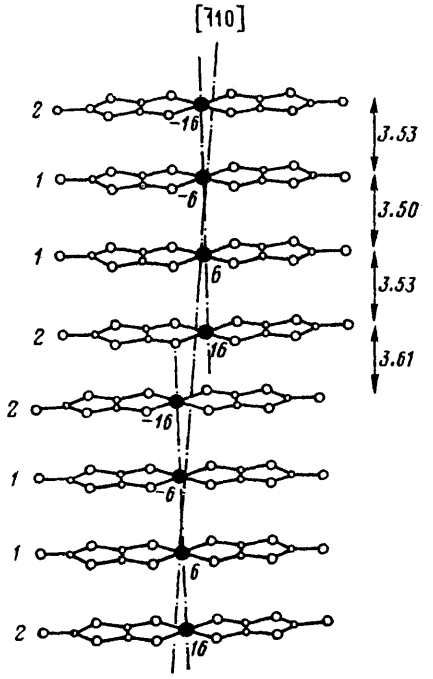

Figure 7. Projection of the anion stacks in the crystal of (VIII) on to the plane defined by the [$\bar{1}$10] vector and the long axis of the complex (the line joining the thione S atoms). The interplanar distances and magnitudes of projection of the Ni atoms from this plane ($\times 10^{-2}$ Å) are shown. The two symmetrically independent $Ni(dmit)_2$ complexes[45] are denoted by the numbers j = 1, 2.

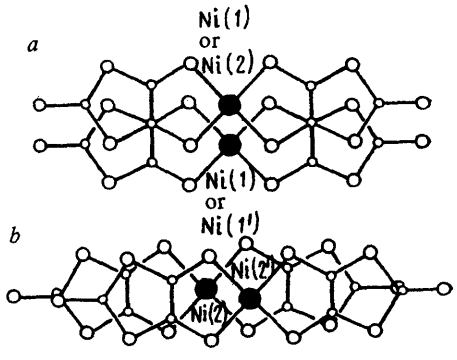

Figure 8. Intrastack overlap of $[Ni(dmit)_2]^{0.25-}$ complexes within the tetrads (*a*) and between the tetrads (*b*) of the crystal of (VIII).[45]

In the crystal of (VIII) almost all of the intermolecular S...S distances which are less than twice the van der Waals radius of the S atom (3.70 Å)[51] are contacts between stacks. If the limited disturbance to the regular stack structure (shifts of the molecules in the stacks in lateral and longitudinal directions) as mentioned above is neglected, the shortened interstack S...S contacts lead to the formation of layer motifs, parallel to the (001) plane, in the crystal of (VIII). The occurrence of these two-dimensional structural motifs governs the two-dimensional nature of the electroconductive properties of salt (VIII) [like salts (II)–(V)]. However, while the layers of Bu_4N^+ and Ph_4As^+ cations in (V), (VI), and (VIII) form "strong" barriers, virtually eliminating electrical conductivity in a "third" direction (perpendicular to the layers of $[Ni(dmit)_2]^{x-}$ anions), cations that are smaller in size, such as Et_4N^+ in (IV), also allow electrical conductivity in the third direction, resulting from the weak interaction between the terminal S atoms of neighbouring anion layers (the corresponding S...S distances are 3.90 Å). Thus, salt (IV) may be regarded as the precursor of a three-dimensional molecular metal.

It is likely that the tendency to form three-dimensional electroconductive motifs would be strengthened by replacing the Et_4N^+ cations with sulphur-containing cation-radical donor molecules.[44] In fact, in the crystal of $(TTF)_{0.5}[Ni(dmit)_2]$ the layers of $[Ni(dmit)_2]^{1/2-}$ complexes are combined with TTF molecules through S...S contacts into a quasi-three-dimensional structure.[58]

The electrical conductivity along the [010] direction of needle-shaped crystals of (VIII) is 10–15 Ω^{-1} cm^{-1}. This direction corresponds to the axis of the needles and is perpendicular to the most extensive plane of laminar crystals of (VIII). The electrical conductivity has a thermally activated nature. Low anisotropy of electrical conductivity in the (001) plane of the laminar crystal of (VIII) has been recorded ($\sigma_a : \sigma_b : \sigma_c = 1 : 1 : 10^{-5}$).

In contrast to salts (I)–(VIII), there are no anion stacks in the crystal of $(Bu_4N)[Pt(dmit)_2]$ (IX) but chains along the c axis can be distinguished, formed through interanion S...S contacts (3.55 Å). There are not enough of these contacts to form an electroconductive system; electrical conductivity along the chain is given by $\sigma_c < 10^{-8}$ Ω^{-1} cm^{-1}. The low electrical conductivity of crystals of (IX) is consistent with its IR spectrum; in the region of 400–4000 cm^{-1} there is no broad band characteristic of highly conductive molecular complexes.[46] It follows from the EPR spectra that the unpaired electrons in $[Pt(dmit)_2]^-$ anions are located on the Pt atoms.[46] Measurement of the temperature dependence of magnetic susceptibility indicates that indirect antiferromagnetic exchange through the system of these intermolecular S...S contacts occurs in the crystal of (IX).

The question of the similarity in crystal structure of the semiconductor (X) and its precursor (XI) [compound (X) is obtained by oxidation of salt (XI)], which is an insulator, is of interest. The $[Au(dmit)_2]^{x-}$ anions in crystals of (X) and (XI) retain an approximately planar structure [Δ_{max} = 0.048 Å in (X) and 0.13 Å in (XI)], the Au–S and C=C bond lengths in (X) and (XI) are similar [Au–S is 2.314–2.321(1) Å and C=C is 1.349 and 1.351(6) Å in (X) and Au–S is 2.311–2.320(2) Å and C=C is 1.345 and 1.365(9) Å in (XI)]. In (X), however, there is a difference between the (Au)S–C [1.713–1.732(4) Å] and (S=C)S–C [1.745–1.758(4) Å] distances, while in (XI) there is no such difference [1.730–1.751(7) Å and 1.725–1.747(7) Å respectively], which is a probable indication of the greater electron delocalisation in the chelate rings of complex (XI). In the crystals of both (X) and (XI) the $[Au(dmit)_2]^{x-}$ anions form stacks (with some tendency for

dimerisation to occur) along the axes a = 7.425 Å in (X) and b = 7.4186 Å in (XI) [the interplanar distances in the stacks are 3.49 and 3.79 Å in (X) and 3.57 and 3.64 Å in (XI)]. The nature of the overlap of the complexes in the stacks of crystals of (X) and (XI) varies slightly. In the crystal of (X) there is a greater relative longitudinal shift and smaller lateral shift of the anions in comparison with (XI) (Figs. 9 and 10). In (XI) there is only one slightly shortened S(5)...S(8) contact [3.681(2) Å] in the stack in contrast to the three significantly shortened S...S contacts in (X) [S(2)...S(6) at 3.489 Å, S(2)...S(8) at 3.529 Å, and S(6)...S(6) at 3.510(2) Å].

The crystal of (X) is isostructural to the crystal of (IV). As in the crystal of (IV), "dimerisation" of the anions occurs in the stacks of the crystal of (X), the interplanar distances between the planes of $[Au(dmit)_2]^{1/2-}$ anions being 3.49 and 3.79 Å. In the stacks of the crystal of (XI) each Au atom is situated at a distance of 3.620 and 3.849(2) Å from the sulphur atoms of the $[Au(dmit)_2]^-$ anions located in the same stack above and below the reference anion, and the S...Au...S vector is approximately perpendicular to the plane of the reference complex.

While the stacks of $[Au(dmit)_2]^{1/2-}$ anions in the crystal of (X) are combined into layers via a large number of shortened S...S contacts in the [100] direction (3.463–3.525 Å), the presence of twice as many Et_4N^+ cations in (XI) results in an isolated configuration of the stacks of complex anions and the structure of (XI) losing the "two-dimensional" nature that is characteristic of the crystal of (X).

The temperature dependence of the electrical conductivity of crystals of (X) has a semiconductive character. When $(Et_4N)[Au(dmit)_2]$ was oxidised, β-$\{(Et_4N)_{0.5}[Au(dmit)_2]\}$ (the β-form), which has metallic properties, was obtained in addition to the α-form.

There is definite interest in making a detailed comparison of the structures of conductive and nonconductive salts composed of uniform anions and cations but in different ratios, as in the structures of (V) and (IX) or (V) and (XII). This type of comparison is presented below for the structures of (V) and (XII), since the structural information published[46] on salt (IX) is insufficient for a detailed comparison.

On going from the electroconductive stack-layer nonstoichiometric Ni phase of (V) to the Au salt (XII), containing the same cations,

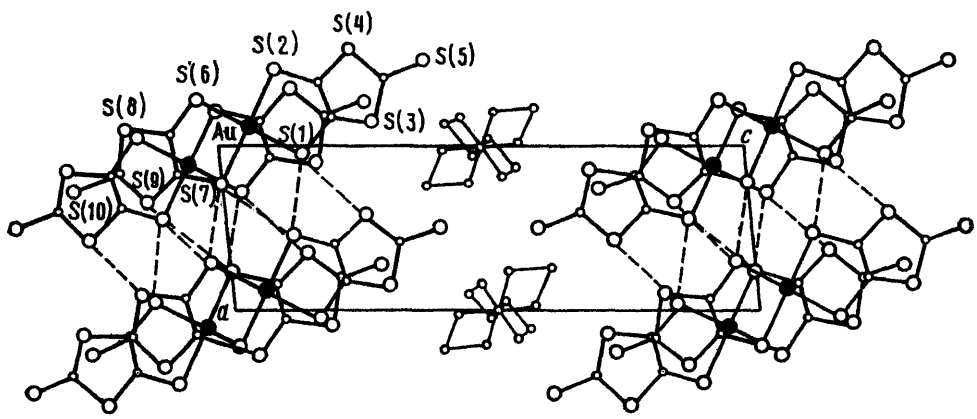

Figure 9. Projection of the crystalline structure of (X) on to the *ac* plane. The Et_4N^+ cations are randomised relative to the centres of symmetry.[47]

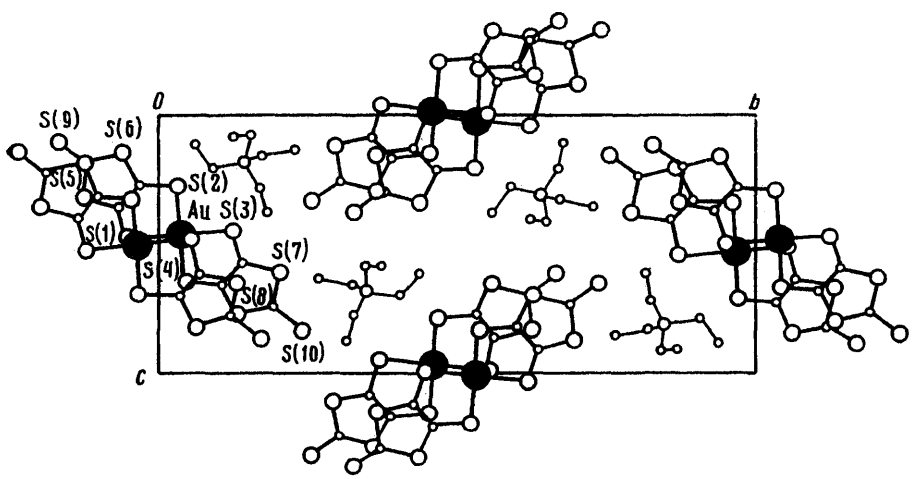

Figure 10. Projection of the crystalline structure of (XI) on to the *bc* plane.[48]

there is a more fundamental structural rearrangement than on going from (X) to (XI). A structure which is only approximately planar (in the two symmetrically independent anions Δ_{max} = 0.11 and 0.19 Å) characterises the $[Au(dmit)_2]^-$ anions of salt (XII). The Au–S distances [2.316–2.327(4) Å] in (XII) are in good agreement with those found in the two Au complexes of the type $Cat^+[Au(dmit)_2]^-$ (see Table 2). In contrast to the structure of (V), there is no conjugation in the (Au)S–C=C–S(Au) chelate residue in the crystal of (XII). The C=C, (Au)S–C, and (S=C)S–C distances in the two symmetrically independent molecules are equal to 1.29 and 1.30(2) Å, 1.73–1.76(1) Å, and 1.75–1.76(1) Å respectively.

In the crystal of (XII) the $[Au(dmit)_2]^-$ anions do not form stacks, and the symmetrically independent anions A and B which alternate along the *a* axis are not parallel, the dihedral angle between their planes being 76.2° (Fig. 11). There is only one shortened S(2)...S(8′) contact [3.565(5) Å] between the A and B anions. Between the B anions, related by (½, ½, ½) centres of symmetry, there are several shortened S(8′)...S(8″) contacts [3.495(5) Å], which form infinite chains of anions along the [011] direction. A parallel arrangement of anions A and B, in other words, the formation of stacks in the crystal of (XII), is prevented by the Bu_4N^+ cations, which are "wedged" between the anions, forming layers together with the anions parallel to the (010) plane.

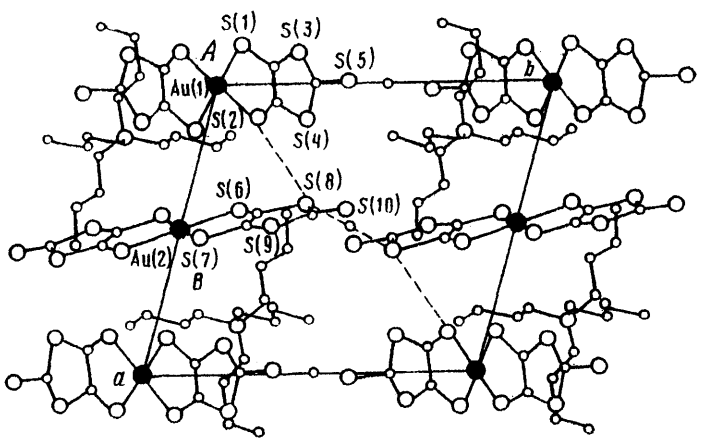

Figure 11. Projection of the crystalline structure of (XII) on to the *ab* plane.[49]

The salt $(Me_3S)[Au(dmit)_2]$ (XIII) has a structure which is quite distinct from other salts of the type $Cat_x^+[M(dmit)_2]^{x-}$ listed in Table 2. In fact, in the crystal of (XIII), which, like the crystal of (XII), is composed of two symmetrically independent anions A(1) and A(2) and cations Cat(1) and Cat(2), all anions are essentially parallel to each other (the dihedral angle between the planes of A(1) and A(2) is 1.0°) and to within about 0.1 Å occur in the same plane $(21\bar{3})$ passing through the centres of symmetry (0, ½, 0), (1, 0, ½), and (½, 1, ½) (Fig. 12). The neighbouring anion planes are separated from this plane by a distance of 3.59 Å, related to each other by the translation *a* or by centres of symmetry of the type (½, ½, ½). The Me_3S^+ cations on the edges of the layer form rows along the $[2\bar{1}1]$ direction.

At the edges of a layer in the structure of (XIII) it is possible to distinguish three types of interanion S...S contact responsible for electrical conductivity. A considerably shortened S(10)...S(10′) distance [3.128(4) Å] occurs between the A(1) anions related by a (½, 1, ½) centre of symmetry. This is the shortest intermolecular S...S distance of those found for potentially electroconductive S-containing compounds. A similar but slightly greater S...S distance (3.16 Å) occurs between stacks of planar anions in the crystal of $Li_{0.75}[Pt(C_4N_2S_2^{2-})_2].2H_2O$ ($H_2C_4N_2S_2$ is 1,2-dicyanovinylene-1,2-dithiol, σ_{293} = 30–212 Ω^{-1} cm^{-1}).[59]

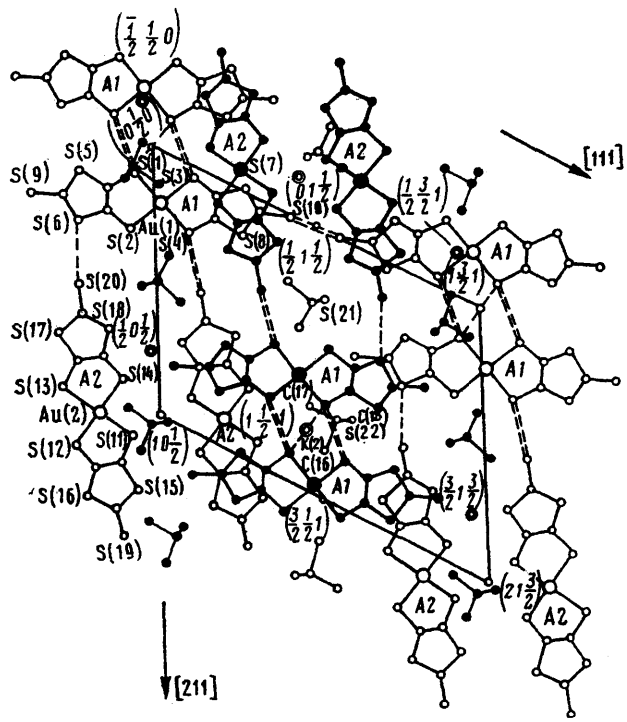

Figure 12. Projection of the crystalline structure of (XIII) on to the plane of the $[21\bar{3}]$ layer. Two layers (light and dark circles) are shown.[50]

The second group comprises shortened contacts [3.407(4) Å] between S(4)...S(19) atoms related by a (1–*x*, –*y*, 1–*z*) centre of symmetry) and S(1)...S(3) atoms [3.478(4) Å] related by a (–*x*, 1–*y*, –*z*) centre of symmetry. These contacts are appreciably less than twice the van der Waals radius of the S atom. Finally, the third group comprises contacts that are slightly less or approximately equal to twice the van der Waals radius of the S atom: S(1)...S(1), (–*x*, 1–*y*, –*z*), 3.572(4) Å; S(6)...S(20), (1 + *x*, *y*, *z*) 3.588(4) Å; and S(3)...S(5), (–*x*, 1–*y*, –*z*) 3.679(4) Å.

The layers are superimposed in such a manner that the rows of cations of each layer extending along the [211] direction occur between the rows of anions of the neighbouring layers and *vice versa* (anions between cations, Fig. 12). The shortest S...S distances between layers are nearly equal to twice the van der Waals radius of the S atom and are contacts of the type anion...cation: S(1)...S(21), (*x*, *y*, *z*), 3.654(4) Å and S(11)...S(22), (–*x*, –*y*, 1–*z*), 3.688(4) Å.

Table 3. The main data on $D[M(dmit)_2]_x$ compounds (D = donor molecule).

Compound	Chemical formula	Structural motif	M–S distance, Å	Conductivity** σ_{293}, Ω^{-1} cm^{-1}	Refs.
(XV)	$(TTF)[Ni(dmit)_2]_2$	Segregated stacks of D (d=3.65 Å) and A (d=3.55 Å)→mixed layers →quasi-three-dimensional structure	2.161–2.172 (8)	300 (metal)	[57, 58]
(XVI)	$(TSF)[Ni(dmit)_2]_3$	Stacks of A (d=3.54 and 3.63 Å)→layers of A	2.152–2.165	4 (semiconductor)	[61]

*Not in the original study.
**If the values of σ in the different crystallographic directions differ, the maximum values are given here.

The crystal of (XIII) is an insulator ($\sigma_{293} \approx 10^{-5}$ Ω^{-1} cm^{-1}). Oxidation of compound (XIII) with iodine gives a product with good conductivity ($\sigma_{293} \approx 30$ Ω^{-1} cm^{-1}), whose composition and structure have so far not been established.[50]

III. Structure of salts of 4,5-dimercapto-2-thione-1,3-dithiolates with "open" cations

A basic feature of the compounds examined in this section is the participation of both donor molecules and acceptor molecules in the formation of electroconductive corridors. We should also point out the difference between salts of "open" cations† and organic conductors of the type TTF–TCNQ[1–3] or $(TTF)[Ni(mnt)_2]$[60] (mnt = maleonitrilo-1,2-dithiolate), for example, in which the electroconductivity can in principle be related to the presence of donor stacks (in the first case) or acceptor stacks (in the second). In fact, in layers of $Cat_x^+[M(dmit)_2]^{x-}$ of the type TTF or BEDT–TTF (Table 3) both the cations of the donor and the anions of the acceptor contain a large number of sulphur atoms, which helps to increase the dimensionality of electroconductive motifs.

Crystals of $(TTF)[Ni(dmit)_2]_2$ (XV) are composed of segregated stacks of donors and acceptors extended along the [010] direction. The molecule of the donor (TTF) is completely planar while the molecule of the acceptor $Ni(dmit)_2$ is slightly bent (by 4.4°). The translation along the b axis is equal to 3.73 Å, but because both molecules—TTF and $Ni(dmit)_2$—are inclined towards the (010) plane, the intrastack interplanar distances d are less (in the donor stacks the molecules are inclined towards the (010) plane by 12° and d = 3.65 Å and in the acceptor stacks the molecules are inclined by 18° and d = 3.55 Å).

The intrastack S...S distances in the donor stacks are slightly less than in the acceptor stacks. Moreover, there are a large number of shortened intermolecular interstack S...S contacts involving molecules of both donor and acceptor in the crystal of (XV) (Fig. 13). Thus, between the $Ni(dmit)_2$ molecules of neighbouring stacks in the [001] direction there are S...S contacts (3.45 Å) which lead to the formation of a two-dimensional layer motifs of closely packed molecules of donor and acceptor located in the (100) plane. The even closer S...S contacts (3.38 Å) between the terminal S atoms of the $Ni(dmit)_2$ molecules and the TTF molecules convert the whole system of donor and acceptor molecules interacting in the crystal of (XV) into a three-dimensional arrangement. The high dimensionality of the structure assists the transition of the crystal of (XV) to a superconductive state at 1.62 K and 7 kbar.[58]

In contrast to TTF, its selenium analogue (TSF) forms a semiconductive phase of composition 1:3—$(TSF)[Ni(dmit)_2]_3$ (XVI)—with the $Ni(dmit)_2$ complex. The crystal of (XVI) is composed of two symmetrically independent $Ni(dmit)_2$ molecules (A at the centre of symmetry, B at a general position) and a TSF molecule (at the centre of symmetry). The length of the central C=C double bond in the TSF molecule is increased to 1.431 Å; this suggests that there is significant delocalisation of π-electron density in the donor molecule, which is typical for its cationic state $(TSF)^+$.[67] The lengths of the Ni–S bonds in molecules of A (2.153 and 2.165 Å) and B (2.152–2.163 Å) do not differ. In both types of anion, delocalisation of electrons occurs in the (Ni)S=C=C=S(Ni) residues; the C=C bond lengths are equal to 1.380 Å (A) and 1.380 and 1.393 Å (B), and the (Ni)S–C

†Cations of an "open" donor participate in electron transfer.

distances of 1.689 and 1.702 Å (A) and 1.688–1.708 Å (B) are appreciably less than the (S=C)S–C distances of 1.744 and 1.745 Å (A) and 1.739–1.743 Å (B).

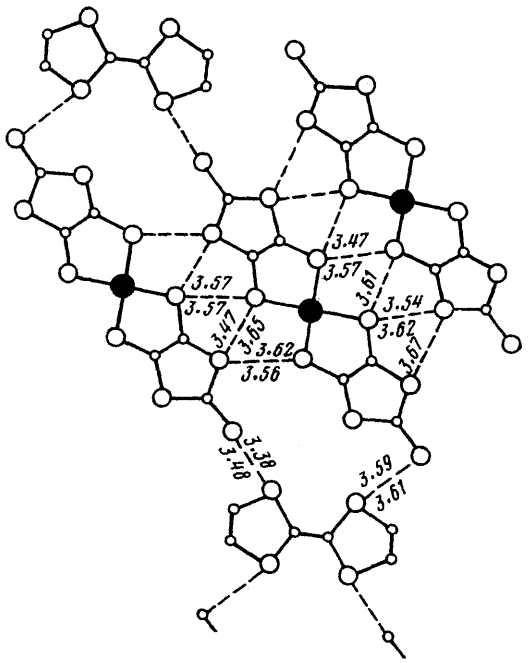

Figure 13. Part of the crystalline structure of (TTF)[Ni(dmit)$_2$]$_2$ (XV) (projection on to the *ac* plane).[57,58]

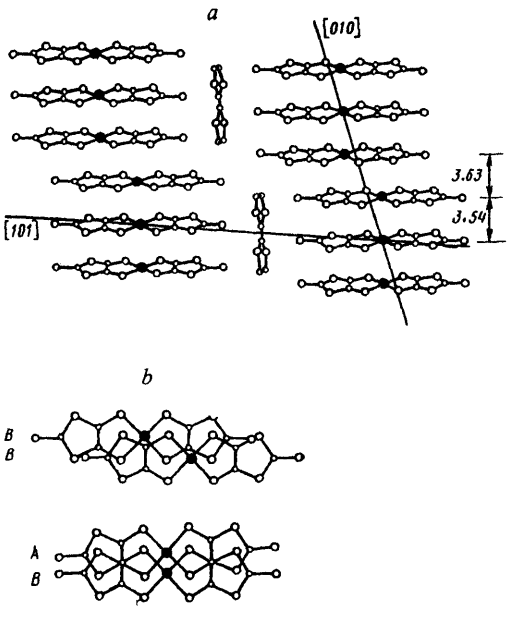

Figure 14. Crystalline structure of (TSF)[Ni(dmit)$_2$]$_3$ (XVI): *a*) relative configuration of the molecules of donor (TSF) and acceptor Ni(dmit)$_2$ (the interplanar distances in the centrosymmetric triads formed in the acceptor stacks are given); *b*) the two types of overlap of Ni(dmit)$_2$ molecules—A...B (within triads) and B...B (between triads).[61]

The Ni(dmit)$_2$ acceptor molecules are located parallel to each other with a slight shift and form BAB triads stacked along the *b* axis, with the interplanar distances within the triads equal to 3.54 Å (3.63 Å between the triads) (Fig. 14). The normal to the plane of the Ni(dmit)$_2$ complex forms an angle of 26° with the *b* axis of the crystal of (XVI). The stacks of acceptor molecules form via S...S contacts (3.503–3.646 Å) layers that are perpendicular to the [101] direction, between which are located TSF molecules not forming stacks. There are a number of shortened S...Se contacts (3.417–3.587 Å) between the terminal S atoms of the Ni(dmit)$_2$ complexes and Se atoms of the TSF molecules (sum of the van der Waals radii of S and Se atoms is 3.85 Å).[51]

When the temperature is lowered to 65 K in crystals of (XVI) a phase transition occurs, which is accompanied by a doubling of the spacing *a* and which appears to have a one-dimensional character of spin-Peierls type.[61] The shortest S...S distances occur along the *a* axis in the crystal of (XVI)—the anion stacks interact to form layers. Thus, this phase transition is probably related to dimerisation in the layers of acceptor molecules. It has been noted[61] that the spins of Ni(dmit)$_2$ complexes make a very small contribution to the total magnetic moment of the crystal of (XVI) and the total magnetic susceptibility of (XVI) is determined by TSF molecules, which have an unpaired electron that behaves as a virtually free spin, being related to the almost perpendicular relative configuration of Ni(dmit)$_2$ and TSF molecules and the large distance between TSF molecules [there are no short Se...Se contacts in the crystal of (XVI)]. On lowering the temperature (below 65 K) the spins of the TSF molecules start to line up.

A model has been proposed[56] to account for the magnetic behaviour of (XVI)—at temperatures >150 K the magnetic moment is independent of temperature and constitutes 2.1 B.M. On lowering the temperature to ~100 K the magnetic moment starts to decrease. The curve of magnetic susceptibility (χ) reaches a maximum at ~20 K, below this temperature χ decreases rapidly.

The conductive properties of crystals of (XVI) are mainly determined by the two-dimensional system of Ni(dmit)$_2$ molecules. The resistance of crystals of (XVI) along the *a* axis is very small (0.25 Ω cm) and increases monotonically on lowering the temperature.

A previous X-ray diffraction study of (TMTSF)[Ni(dmit)$_2$] (XVII) showed that the lattice of (XVII) is modulated sinusoidally. With a spacing of 9*b* on the X-ray photograph, there are satellite reflections which indicate that a ninefold superlattice occurs. The parameters of the unit cell of the superlattice are: a=15.227(4) Å, b=34.559(5) Å, c = 25.455(6) Å, β = 105.70(2)°, V = 12895(5) Å^3, Z = 18, space group $P2_1/n$. The vectors of the units cell of the fundamental lattice are given by $\mathbf{a}_0 = \mathbf{a}$, $\mathbf{b}_0 = \mathbf{b}/9$, $\mathbf{c}_0 = \mathbf{c}$. The wave amplitude of the periodic distortion of the lattice (PDL) was determined from the variation in intensities of the main and satellite reflections.

The fundamental structure of (XVII) is shown in Fig. 15. Molecules of TMTSF and Ni(dmit)$_2$ forms segregated stacks along the axis $b_0 = b/9 = 3.840$ Å. In the stacks the molecules of TMTSF donor are almost completely superimposed on each other, the interplanar distance d being equal to 3.75 Å. On the other hand, in the stacks of acceptor molecules overlap is small. The TMTSF and Ni(dmit)$_2$ molecules form a dihedral angle of 27°.

An important role in determining the direction of electron transfer is played by the anisotropy of the intermolecular overlap integrals (S) of the HOMOs of donor molecules and/or LUMOs of acceptor molecules. The transfer integral (t) is approximately proportional to S ($t \approx -ES$, where E is a constant). In accordance with the close

contacts and precise overlap of the molecules in the stacks of TMTSF, the width of the corresponding energy zone in (XVII) is twice as great as in stacks of salts of the type $(TMTSF)_2X$.[68] In the $Ni(dmit)_2$ stacks the overlap integral is very small. It has been noted[57] that the Fermi surface of the crystal of (XVII) has a flattened profile and is perpendicular to the *b* axis (the direction of the stacks). In contrast to the holes in the TMTSF stacks, the electrons in the $Ni(dmit)_2$ stacks have low mobility, which may be related to the small values of the overlap integrals along the stacks.

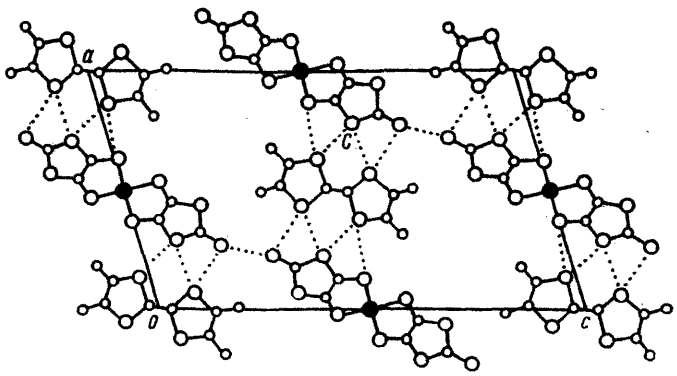

Figure 15. Projection of the main structure of (XVII) along the $\bar{b}_0$ direction. Interstack S...S contacts are shown as dotted lines.[62]

It has been noted by Kobayashi et al.[62] that when there is a planar form of the Fermi surface, if the structure is not modulated the system must be a one-dimensional metal. The observed semiconductive nature of the crystal of (XVII) is evidently due to the occurrence of PDL. It is known that a Peierls distortion with a period of $2k_F$ or PDL with a frequency of $2k_0$ can destabilise the metallic state. The existing experimental data suggest that in this case the semiconductive nature of (XVII) is due to the existence of PDL with a period of $2k_0$. Thus, in contrast to single-chain systems in which the main mechanism for disruption of stability is a Peierls distortion, destabilisation in double-chain systems with intersecting energy zones [an example of which is the crystal of (XVII)] may be caused by transverse PDL waves. The relatively large interchain interaction and large amplitude of the PDL wave are responsible for the behaviour of crystals of (XVII) as a narrow-zone semiconductor.

The structure of (XVIII) is similar to the structure of (XVII); DBTTF and $Ni(dmit)_2$ molecules form segregated stacks directed along the short axis b = 3.830(5) Å. The normals to the planes of the donor and acceptor molecules deviate in different directions from the line of the *b* axis and form angles of 23° and 22° respectively with it, namely, the cation planes are not parallel to the anion planes and intersect them at an angle of 135° (Fig. 16). The superimposition of molecules in both types of stacks occurs with a small (~1–1.5 Å) relative shift of the molecules in directions perpendicular to their long axes. In contrast to the structure of (XVII), the interplanar distances in the donor and acceptor stacks in the structure of (XVIII) are similar (3.53 and 3.55 Å), and there are no shortened intermolecular distances in the stacks of either type. Shortened contacts occur between DBTTF and $Ni(dmit)_2$ molecules that belong to neighbouring stacks along the *a* axis, which leads to a two-dimensional type of structure for (XVIII) (layers parallel to the *ab* plane). The *B*1 and *B*2 overlap integrals in the stacks (and, hence, the width of the forbidden zone) are comparable to those calculated for the system TTF–TCNQ.[69] However, in (XVIII) the ratio σ_b (within stacks): σ_a (between stacks) ≈10, i.e., less than in TTF–TCNQ, where it is ~10^2 and close to that found in $(TMTSF)_2X$ salts.[68] The overlap integrals along the *c* axis of the crystal of (XVIII) also have an appreciable value, which can suggest that there is also a significant electronic interaction in a third direction (perpendicular to the layers). For a double-chain donor-acceptor system when the interaction between frontier orbitals from different stacks is neglected, zone structures of two types are possible: with two intersecting mutually inverted dispersion curves and with "parallel" overlapping but not intersecting dispersion curves.[63] In the first case the overlap integral between the corresponding frontier orbitals of molecules in one of the stacks (S_1) has a sign opposite to that of the corresponding overlap integral (S_2) in the other stack. In the second case the signs of S_1 and S_2 are the same. Examples of systems of the first type are TTF–TCNQ[69] or (TMTSF)[Ni(dmit)$_2$] (XVII).[62] In these systems the position of the

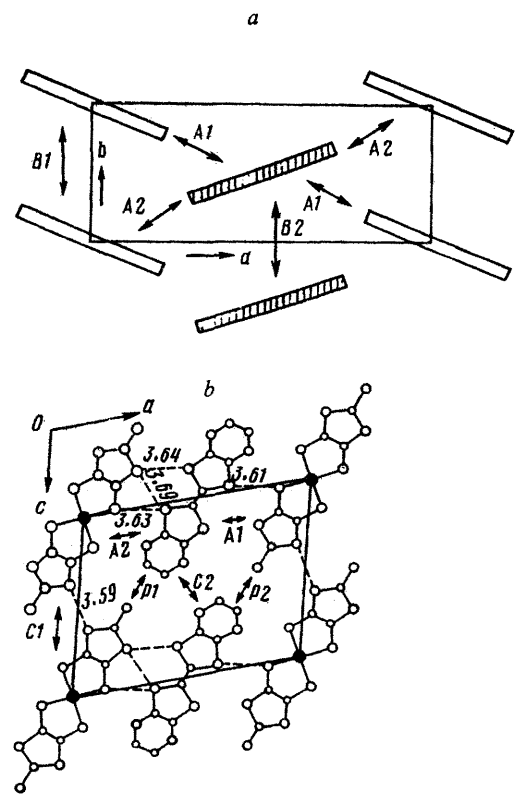

Figure 16. Crystalline structure of (DBTTF)[Ni(dmit)$_2$] (XVIII). *a*) Relative inclination of donor molecules and acceptor molecules (hatched); *b*) shortened intermolecular S...S contacts combining the donor and acceptor molecules into layers parallel to the *ab* plane. The main types of paired intermolecular interactions for which the overlap integrals of the HOMOs of the donor and LUMOs of the acceptor have been calculated are shown ($\times 10^3$): *B*1–12.72 (donor stack), *B*2–9.46 (acceptor stack), *A*1 0.875, *A*2 0.731, *C*1–0.208, *C*2 0.358, *P*1–0.307, and *P*2–0.119 (between stacks).[63]

Fermi level corresponds to the point of intersection of the dispersion curves. When the (donor–acceptor) stacks interact, the metallic state becomes unstable. The energy level that corresponds to the Fermi energy is split and a zone structure characteristic of semiconductors with a zero width of the forbidden zone is possible.[70]

In the case of the crystal of (XVIII) the overlap integrals S_1 and S_2 for the stacks of DBTTF and Ni(dmit)$_2$ respectively have the same sign. In this case the dispersion curves are "parallel". Therefore the metallic state proves stable in relation to interstack interaction. This phenomenon is responsible for the special interest in the low-temperature electrical properties of (XVIII). According to initial measurements, the electrical conductivity of (XVIII) is very high (σ_{293}, $b \approx 300\ \Omega^{-1}\ cm^{-1}$), and on lowering the temperature the value of σ_b shows very little change.

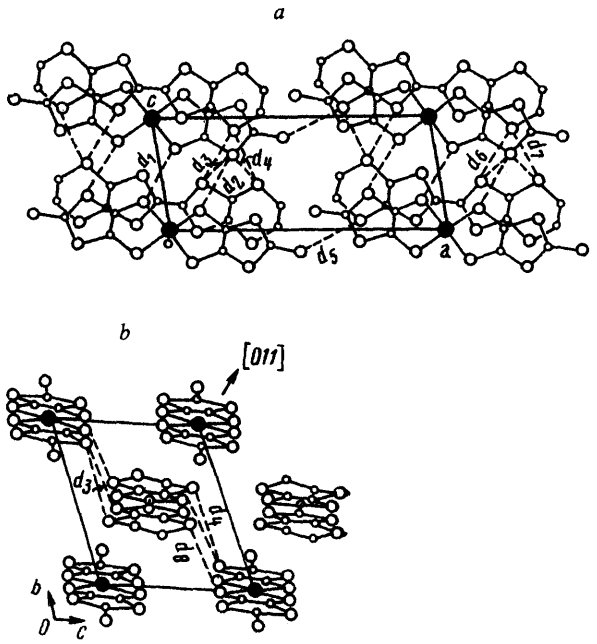

Figure 17. Crystalline structure of (BEDT–TTF)[Ni(dmit)$_2$] (XIX): *a*) projection on to the *ac* plane parallel to the plane of Ni(dmit)$_2$; *b*) projection on to the *bc* plane. The [011] direction of mixed stacks of donor and acceptor is shown. Broken lines represent the shortened interstack S...S contacts with distances d_1 = 3.53, d_2 = 3.65, d_3 = 3.65, d_4 = 3.63, d_5 = 3.58, d_6 = 3.52, d_7 = 3.41, d_8 = 3.68 Å.[64]

In contrast to the salts (XV)–(XVIII) examined above, whose structures are composed of segregated donor and acceptor stacks, in the crystal of (BEDT–TTF)[Ni(dmit)$_2$] (XIX) there are mixed stacks along the [011] direction (Fig. 17). Despite the clear overlap of cations and anions in the stacks, there are no shortened S...S contacts within the stacks probably because of the presence of the terminal ethylene spacers in the BEDT–TTF molecules. At the same time, there are quite a number of shortened S...S contacts along the [001] direction, in other words, there is a tendency which is characteristic of BEDT–TTF and M(dmit)$_2$ molecules to undergo "face" interactions.

The electrical conductivity of the crystal of (XIX) in the [001] direction at 300 K is $\sigma^{\parallel}_{300} = 0.02\ \Omega^{-1}\ cm^{-1}$ (the ratio $\sigma^{\parallel}/\sigma^{\perp} \approx 0.66$); on lowering the temperature the conductivity decreases. The energies of activation of electrical conductivity $\sigma^{\parallel}$ and $\sigma^{\perp}$ are almost equal (0.28 eV). As was noted by Kobayashi et al.,[64] all of the previously studied charge-transfer complexes (CTC) with mixed stacks were insulators, therefore the relatively high conductivity of the crystal of (XIX) caused considerable interest. Kobayashi et al.[62] have made a detailed review of physical models used to account for this phenomenon.

For a linear chain (stack) of alternating donor (D) and acceptor (A) molecules extending along the *c* axis (Fig. 18*a*) with a simple approximation of a strong bond, one-dimensional energy zones are formed by the frontier orbitals (HOMOs of the donor and LUMOs of the acceptor). It can be shown that the energy gap of such a system ($E_A - E_D$) (E_A and E_D are the energies of the LUMOs and HOMOs) is not decreased by an intermolecular interaction, and CTCs with mixed stacks are insulators. If the interaction between stacks is significantly greater than along them, molecules of D and A form segregated zones in a lateral direction (Fig. 18*b*).

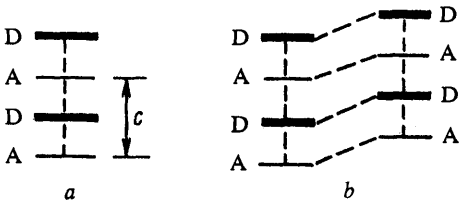

Figure 18. Two ways of arranging the molecules of donor (D) and acceptor (A) in the crystal of a CTC with mixed stacks. The direction of the main interaction between molecules of D and A is shown as a broken line.[64]

Taking into account the anisotropy of the π-orbitals, it could be assumed that the lateral intermolecular interactions in organic conductors must be small. However, calculations of the zone structure show that for molecules of the type BEDT–TTF, lateral (and/or tangential) interactions may be considerable. Calculation of the overlap integrals (*S*) of the frontier orbitals of BEDT–TTF (D) and Ni(dmit)$_2$ (A) in the crystal of (XIX) using the EH method gave the following values:[64] for contact D(x, y, z)...D(x, y, z + 1) the value of $S \times 10^3$ is 2.26, for D(x, y, z)...A(x, y, z + 1) it is 1.14, for D(x, y, z)...A(x, y, z) it is 0.75, for A(x, y, z)...A(x, y, z + 1) it is 0.28, and for D(x, y, z)...A(x + 1, y + 1, z) it is 0.11. It was noted by Kobayashi et al.[64] that since the symmetry of the HOMOs (BEDT–TTF) and LUMOs [Ni(dmit)$_2$] are different, the overlap integrals of D...A along the [011] direction in the crystal of (XIX) can be neglected. The integral of lateral overlap D(x, y, z)...D(x, y, z + 1) has the highest value, in other words, it is possible to consider segregated motifs formed by BEDT–TTF in a lateral direction relative to the stacks in the crystal of (XIX) (see also the study of Mori et al.).[71]

Kobayashi et al.[64] regard salt (XIX), which is characterised by partial D→A charge transfer and a fairly strong lateral interaction between BEDT–TTF molecules, as a novel type of organic metal, although the overlap integral (*S*) of the frontier orbitals of

BEDT–TTF molecules in (XIX) is not very large. It is known that the overlap integral of BEDT–TTF molecules is determined by the "configurational" parameters R and φ, which are governed by the relative‡ orientation of neighbouring molecules.[71] The relative orientation of BEDT–TTF molecules in the crystal of (XIX) is such that the value of S proves to be 5–10 times less than in the superconductor β-(BEDT–TTF)$_2$I$_3$.[72]

The crystal of the salt α-{(BPDT–TTF)[Ni(dmit)$_2$]$_2$} (XX), which differs from the crystal of (XIX) in its ratio of donor to acceptor and the even less planar structure of the donor molecule [because of the presence of an additional methylene group in the side rings of the molecule of (XX)], is composed of segregated stacks of donor and acceptor molecules, the acceptor stacks forming paired chains.[65] At room temperature (300 K) the electrical conductivity of (XX) is 5–10 Ω^{-1} cm^{-1} and progressively decreases as the temperature is lowered to 120 K. Below 120 K (XX) undergoes a transition to a nonconductive state. An X-ray diffraction study was carried out on salt (XX) at 293 and 96 K and no substantial differences in the structure of crystals of (XX) were detected at the different temperatures. Nevertheless, the overlap integrals of the frontier molecular orbitals, calculated for salt (XX) at 293 and 96 K, are somewhat different, which suggests that there is a strengthening of the lateral S...S interaction between the paired stacks of Ni(dmit)$_2$ in the crystal recorded at 96 K. Kobayashi et al.[65] have proposed a mechanism for the transition of (XX) to a nonconductive state, requiring only a small change in the degree of charge transfer and hence not producing significant changes in the crystalline structure of (XX) on going from 293 to 96 K.

The salt (TTF)[Pt(dmit)$_2$]$_3$ (XXI) has the same ratio of donor to acceptor as salt (XVI) (1 : 3 in both cases) and has similar parameters of its unit cell. However, it has an unusual feature which does not occur in any of the M(dmit)$_2$ salts; one of the crystallographically independent complexes Pt(dmit)$_2$ complexes forms a centrosymmetric dimer via a direct Pt–Pt bond of length 2.935 Å. Despite the formation of the Pt–Pt bond, the increase in basal Pt–S distances in the [Pt(dmit)$_2$]$_2$ dimers is small. In the dimer the Pt–S bond lengths are 2.30–2.32(1) Å, and in the monomer they are 2.29–2.30(1) Å. In the sterically less strained neutral dimer [Pt(S$_2$C$_2$H$_2$)$_2$]$_2$ the Pt–Pt distance is somewhat less (2.748 Å).[73] As in the [Pt(S$_2$C$_2$H$_2$)$_2$]$_2$ complex, the planarity of both parts of the dimer in [Pt(dmit)$_2$]$_2$ is considerably distorted, the dihedral angle between the two Pt(dmit) residues in each half of the dimer being 11.2°. The second crystallographically independent Pt(dmit)$_2$ anion remains in the crystal of (XXI) in monomer form and occupies a particular position at the centre of symmetry like the TTF molecule.

The structural motif of the crystal of (XXI) resembles that of (XVI)—layers of monomers and Pt(dmit)$_2$ dimers are parallel to the (001) plane and alternate with layers of TTF molecules. In the acceptor layers, stacks are distinguishable along the [1$\bar{1}$0] direction in which monomers and dimers alternate. The normal to the average plane of the Pt(dmit)$_2$ monomer and also the Pt–Pt bond in the dimer form similar angles (~23°) with the [1$\bar{1}$0] direction (stack axis).

‡For two molecules of BEDT–TTF which are parallel but displaced, the value of R is the relative displacement of the molecules along their long axes, and φ is the angle between the vector joining the long axes of the molecules (and that perpendicular to them) and the plane of the molecule (see, for example, Mori et al).[71]

In contrast to the crystal of (XVI), in which shortened intermolecular distances (of the type S...Se) occur only between molecules of acceptor (superimposed in stacks) and donor (located between stacks), in the crystal of (XXI) there are a considerable number of shortened S...S contacts: in the stacks within the dimers (four contacts of length 3.23–3.66 Å, inducing intramolecular contacts), in the stacks between the monomers and dimers (four contacts of length 3.63–3.66 Å), and between the Pt(dmit)$_2$ residues of monomers or dimers of neighbouring stacks (17 contacts of length 3.47–3.65 Å). On the whole the shortened S...S contacts between the acceptor molecules result in the formation in the crystal of (XXI) of the above-mentioned acceptor layers, parallel to the (001) plane. The donor molecules only participate in a single shortened intermolecular contact with the Pt(dmit)$_2$ monomer (a distance of 3.45 Å) and there are no shortened contacts of the type TTF...TTF in the crystal of (XXI).

The crystal of (XXI) is a semiconductor in the temperature range 300–100 K. The observed thermally activated electrical conductivity is probably due to the alternation of monomer and dimer molecules in the Pt(dmit)$_2$ stacks, resulting in the formation of a gap in the zone structure in the region of the Fermi level. Nevertheless, the electrical conductivity of the crystal of (XXI) at room temperature is unexpectedly high (20 Ω^{-1} cm^{-1}), which Bousseau et al.[58] thought could be due to significant interstack interaction.

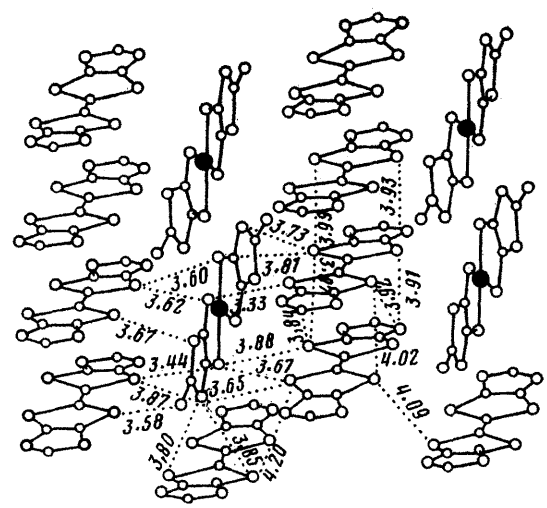

Figure 19. Short intermolecular contacts involving chalcogenide atoms in the crystal of (HMTTeF)[Pt(dmit)$_2$]$_{0.5}$ (XXII).[66]

For the crystal of (HMTTeF)[Pt(dmit)$_2$]$_{0.5}$ (XXII), the electrical conductivity at room temperature (20 Ω^{-1} cm^{-1}) and semiconductive nature of the temperature dependence of conductivity are found to be the same as for (XXI). The HMTTeF molecules are packed in the crystal of (XXII) (Fig. 19) into centrosymmetric stacks (tetrads), each with four molecules (two of them are crystallographically independent).

The interplanar distances in the tetrads are 3.62 and 3.70 Å. One of the crystallographically independent HMTTeF molecules is planar, the second is slightly bent along the line of Te...Te of one of

the heterocycles (by 9°). The tetrad stacks are combined into a two-dimensional system through short Te...Te contacts. The $Pt(dmit)_2$ complexes are located between the tetrad systems of HMTTeF molecules, the planes of the anions being approximately perpendicular to the planes of the HMTTeF molecules.

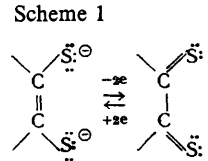
In the crystal of $(HMTTeF)_4(PF_6)_2$, the first CTC based on HMTTeF to be studied using X-ray diffraction, the HMTTeF molecules are arranged in stacks possessing a triad structure; the fourth (neutral) HMTTeF molecule is located between the stacks, with its plane parallel to the stack axis.[74] A similar structural motif also occurs in the monoclinic phase of β-$(HMTTeF)_2(PF_6)$.[66] It was noted by Kato et al.[75] that this type of packing is typical for salts with well-defined two-dimensional motifs.

The overlap integrals (S) of the HOMOs of HMTTeF molecules in the tetrads of (XXII) (-65.58×10^{-3} and 60.28×10^{-3}) are considerably higher than in other chalcogenfulvalene derivatives (for example, $S = 5\times10^{-3}$ in the TTF stacks of the salt TTF.TCNQ[69] and $S = 40\times10^{-3}$ in the TMTSF stacks of the salt (TMTSF)[Ni(dmit)$_2$] (XVII)[62]). The overlap integrals of the frontier orbitals of HMTTeF molecules of nieghbouring tetrads constitute about one third of the corresponding overlap integrals within the tetrads. The zone structure of (XXII) was calculated with a simple approximation of a strong bond.

It is difficult to determine experimentally the degree of charge transfer in salt (XXII) (from bond lengths, for example) because of the absence of accurate structural data on salts of the donor HMTTeF occurring in difference valence states.[66] If the formal charge x of the $[Pt(dmit)_2]^x$ complex is assumed to be equal to -1.0, as in the initial salt $(Bu_4N)[Pt(dmit)_2]$, the energy zone of (XXII) is 3/4 full. It follows from a calculation of the zone structure that compound (XXII) is not a metal. It is interesting that the hypothetical compound with the same composition as (XXII) but with a diad stack structure is characterised by the same form of Fermi surface as that calculated for the superconductor β-$(BEDT-TTF)_2I_3$,[76] but with a considerably wider conductivity zone than in known molecular metals,[66] which is an indication of the potentiality of the donor HMTTeF in the molecular design of low-dimensional metals.

Molecular donor-acceptor π-complexes of the type (TTF)[M(dmit)$_2$]$_x$ have all the required properties for high electrical conductivity: planarity of the donor and acceptor components, sufficiently compact and segregated stacks, substantial systems of conjugation and effective intermolecular π-overlap, and similar values of the redox potentials of donor and acceptor. Complexes of the type (TTF)[M(dmit)$_2$]$_x$ have a tendency to form two-dimensional systems, which removes the problem of Peierls distortions in one-dimensional metallic systems. This is shown particularly clearly for the compound (TTF)[Ni(dmit)$_2$]$_2$ (XV), whose high conductivity is retained down to 4 K, and at 1.6 K it undergoes a transition to a superconductive state.[76] It has been noted[56] that such behaviour of (TTF)[Pt(dmit)$_2$]$_2$ is unique for molecular donor-acceptor π-complexes that have a maximum electrical conductivity at temperatures well above 4 K (see, for example, two studies[77,78]) and is due to the presence of an extended three-dimensional network of shortened intermolecular S...S contacts in the crystal of (XV).

It was mentioned above that a distinctive feature of molecular π-complexes of the type D[M(dmit)$_2$]$_x$ (as opposed to Cat$_x$[M(dmit)$_2$] salts) is the possibility of both donor and acceptor molecules participating in the formation of electroconductive channels. In principle, by varying the molecules of donor and acceptor in the two-stack system (in which each type of stack forms its own electroconductive channel), and hence by varying the type of interaction between the stacks in layers, it is possible to obtain conductors with different properties. However, in some cases the strong interstack interaction may lead to the formation of an energy gap. In order to identify the causes of this effect, which is unfavourable for conductivity, a quantum-chemical calculation of the molecules of donor and acceptor, a study of the way in which stacks are formed and combined, and a study of the effect of the cation/anion ratio on the structure of the molecular complex are required.



Finally, we should mention once again that D[M(dmit)$_2$]$_x$ salts (D is an open donor) have the highest conductivity among molecular solids in general and among transition metal complexes in particular. Thus, for example, the electrical conductivity of needle-shaped monocrystals of (XV) along the [010] direction (needle axis is direction of segregated stacks of donor and acceptor) is $\sigma_{293} = 300\ \Omega^{-1}\ cm^{-1}$; over the range 300–4 K the temperature dependence of electrical conductivity is of a type characteristic of metals.

IV. Crystalline structures of 5,6-dihydro-1,4-dithiin-2,3-dithiolate complexes and their salts

There is clearly a close similarity between the molecular structure of 5,6-dihydro-1,4-dithiin-2,3-dithiolates of transition metals Cat$_x$[M(DDDT)$_2$]^x (XXIII)–(XXIX) (Table 4) and BEDT–TTF (one of the most promising donors in organic conductors). The close similarity between the molecular packing in crystals of BEDT–TTF and Au(DDDT)$_2$ has also been noted.[81]

Crystals of the neutral complexes Ni(DDDT)$_2$ (XXIII) and Au(DDDT)$_2$ (XXVIII) are not isostructural. The crystal of (XXIII) is composed of two symmetrically independent centrosymmetric molecules. In both molecules the lengths of the formally double C=C bonds [1.389 and 1.388(4) Å] are considerably greater than the length of a normal C=C double bond (in cyclopentene, for example, r(C=C) = 1.323 Å),[85] approaching the length of a C⩬C aromatic bond (1.380 Å).[85] Electron delocalisation in the chelate residues (Ni)S⩬C⩬C⩬S(Ni), in the same way as in M(dmit)$_2$ complexes, may be assumed to occur in this case. It may also be assumed[36,79] that there is an approximately equal contribution of both canonical forms of the ligands (Scheme 1) to the valence state of DDDT. The average charge of each ligand is equal to -1, and the electronic configuration of the Ni atom (occurring in a formal oxidation state of 2+) is d^8.

Scheme 1

Complex (XXIII) has an essentially planar structure, the maximum deviation (Δ_{max}) of the atoms (without taking into account the peripheral C atoms of the ligands) from the plane of the central NiS_4 residue does not exceed 0.03(1) Å. Amongst the M(DDDT)$_2$ complexes in (XXIII)–(XXIX) the greatest deviation from planarity occurs in the neutral complex (XXVIII) [Δ_{max} = 0.77(1) Å]. On the whole M(DDDT)$_2$ complexes are less rigid and more likely to undergo distortion of the planar structure than M(dmit)$_2$ complexes.

In the crystal of (XXIII) two independent $Ni(DDDT)_2$ molecules are arranged in separate stacks along the short *b* translation. The angles formed by the normals to the coordination planes of the Ni atoms in the molecules of (XXIII, A) and (XXIII, B) with the *b* axis are similar (36.1 and 36.7°). The interplanar distances in the stacks of molecules (XXIII, A) and (XXIII, B) are equal to 3.78 and 3.75 Å. There are no shortened S...S contacts within the stacks. On the other hand, shortened S...S contacts occur between the stacks [3.594(3) and 3.483(3) Å].

The Ni–S distances in the $[Ni(DDDT)_2]^-$ anions of salts (XXIV) [2.146 and 2.149(2) Å] and (XXV) [2.130–2.145(9) Å] are slightly greater than in the neutral $Ni(DDDT)_2$ complex (XXIII) [2.129–2.135(1) Å]. A similar trend was noted above for complexes of the type $[M(dmit)_2]^x$. In the crystal of (XXIV) anions form layers and cations are arranged between these layers. The S...S distances in the crystal of (XXIV) are not reduced. In the crystal of (XXV) there are two types of symmetrically independent anion—(XXV, A) and (XXV, B). Anions (XXV, A) form stacks (with partial overlap of the orbitals of the anions) along the *a* axis, anions (XXV, B) are arranged roughly perpendicular to anions (XXV, A) and do not form stacks (Fig. 20). As in (XXIV), there are no shortened intermolecular S...S contacts in the structure of (XXV).

Crystals of the salt $(Bu_4N)[Ni(DDT)_2]$ (XXVI), which differs from (XXV) in that unsaturated ethylene residues occur in the DDT ligands instead of saturated residues in the DDDT ligands, are composed, in the same way as crystals of (XXV), of two symmetrically independent centrosymmetric anions (XXVI, A) and (XXVI, B). All of the atoms in the anions lie in the same plane, with the exception of the terminal C atoms of the peripheral rings. Thus, the 1,4-dithiin rings are bent along the line of S...S by 28.2° [anion (XXVI, A)] and 38.8° [anion (XXVI, B)]. Anions (XXVI, B), overlapping in a displaced manner, form stacks along the *b* axis with an interplanar distance of $d = 4.03$ Å. Anions (XXVI, A) do not form stacks, but, alternating with cations, are aligned into layers, parallel to *bc*.

Kim et al.[86] have discussed the results of an EH calculation of the coefficients of the real part of the expression for the LUMOs of the $[Ni(DDT)_2]^-$ anion, which have the same symmetry as the LUMOs of the $[Ni(dmit)_2]^-$ and $[Ni(DDDT)_2]^-$ anions.[86] In the case of the $[Ni(dmit)_2]^-$ anion, the contribution of the LUMOs localised on the "outer" $S(a_0)$ atoms constitutes about 1/5 of the contribution (a_i) of the "inner" S atoms (bonded to the Ni atom), therefore the interaction between the "terminal" molecules in crystals of $Ni(dmit)_2$ complexes is small.[87] In the $[Ni(DDDT)_2]^-$ anion there is the relationship $a_0/a_i \approx 1/2$, which must favour the formation of two-dimensional electroconductive motifs. In the $[Ni(DDT)_2]^-$ anion the relationship $a_0/a_i \approx 3/5$ is even more favourable for the formation of two-dimensional motifs; however, as has been noted,[81] in the synthesis of organic metals an important factor is the

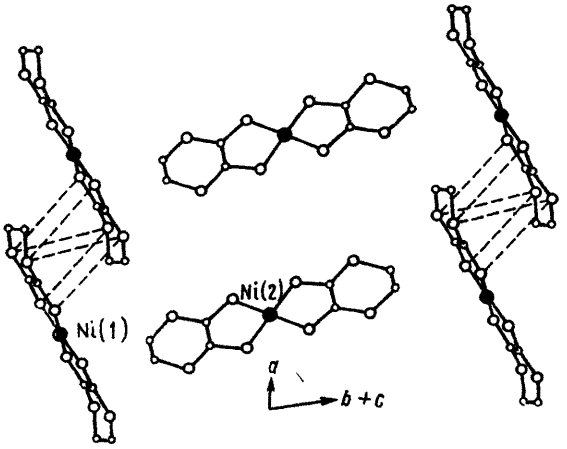


Figure 20. Packing of $[Ni(DDDT)_2]^-$ anions in the crystal of (XXV). The (XXV, A) anions [Ni(1) atom] form stacks (with partial overlap of the anions along the *a* axis). The S...S contacts in the stacks (depicted by broken lines) are not shortened. The (XXV, B) anions [Ni(2) atom] are arranged roughly perpendicular to the (XXV, A) stacks.[82]

Table 4. The main data on $[M(DDDT)_2]^x$ and $[M(DDT)_2]^x$ compounds.

Compound	Chemical formula	*x*	M–S distance, Å	Main structural motif	Conductivity σ_{293}, Ω^{-1} cm^{-1}	Refs.
(XXIII)	$Ni(DDDT)_2$	0	2.129–2.135(1)	Stacks (d = 3.75 and 3.78 Å)	10^{-5}–10^{-6}	[79, 80]
(XXIV)	$(Et_4N)[Ni(DDDT)_2]$	−1	2.146; 2.149(2)	Layers	see*	[81]

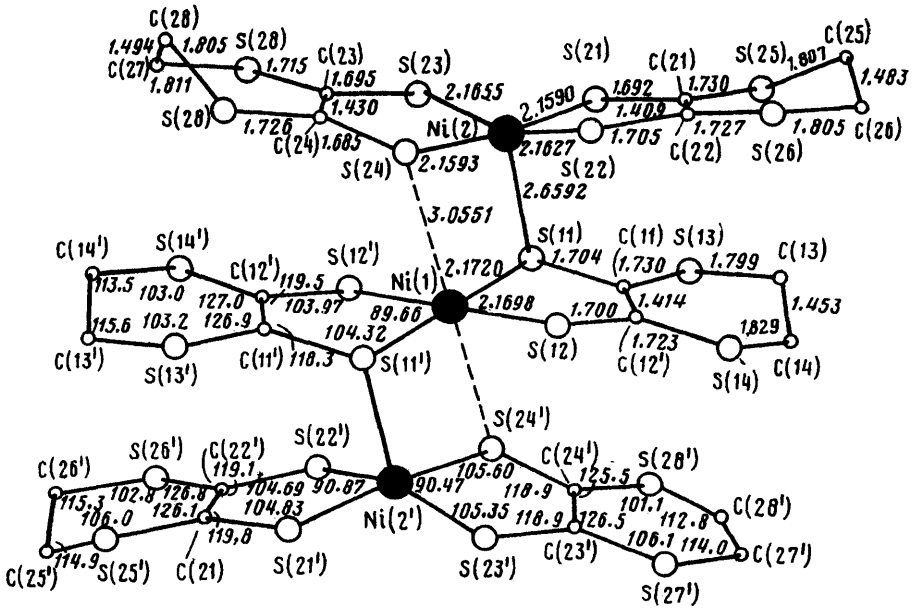

Figure 21. Structure of the trimeric $[Ni(DDDT)_2]_3^{2+}$ cation in the crystal of (XXVII).[80,84]

electrochemical properties of the components,§ namely, the magnitude of $\Delta E = E_1 - E_2$, which for the $[Ni(DDT)_2]^-$ anion has a value intermediate between ΔE for the $[Ni(dmit)_2]^-$ and $[Ni(DDDT)_2]^-$ anions.

The formal degrees of oxidation of the Ni atom and DDDT ligand in the $[Ni(DDDT)_2]^-$ complex can be represented as $[Ni^{3+}(d^7)(DDDT)_2^{2-}]^-$ or $[Ni^{2+}(d^8)(DDDT)_2^{3-}]^-$. For d^7 and d^8 configurations of the Ni atom the unpaired electron is situated on the metal atom or DDDT ligand respectively. The d^8 configuration is more consistent with a square planar coordination of the metal atom. Calculations of the population of the atomic orbitals of the Ni atom in the $[Ni(DDDT)_2]^-$ atom as well as magnetic measurements confirm a d^8 configuration of the Ni atom in this salt and that the unpaired electron is mainly located on the DDDT ligands.[82]

Salt (XXV) is paramagnetic over the whole temperature range of magnetic susceptibility measurements (from 300 to 4.2 K) in contrast to salt (XXIV), which is characterised by ferromagnetic exchange below 15 K. This difference between salts (XXIV) and (XXV) is probably due to the larger size of the cations in (XXV), which leads to an increase in intermolecular S...S distances, resulting in a weakening of magnetic exchange.[82] In fact, the shortest intermolecular S...S distances in the crystal of (XXIV) (3.98 Å within layers and 4.49 Å between layers) is appreciably less than in the crystal of (XXV) (4.75 Å within the stacks).

Electrochemical oxidation of complex (XXIII) gives salt (XXVII), the crystal of which is composed of the centrosymmetric trimeric cations $[Ni(DDDT)_2]_3^{2+}$ and two symmetrically independent ClO_4^- anions occurring in general positions. This cationic structure of the $[Ni(DDDT)_2]_3^{2+}$ complex is quite surprising. In the other crystals of (XXIII)–(XXIX) (Table 4) the $[M(DDDT)_2]^x$ complexes occur either in anionic or neutral forms. Amongst related $[M(dmit)_2]^x$ complexes that have been sufficiently well studied (in relation to the structure and electrical conductivity), again only anionic and neutral complexes are known.

The structures of the inner and outer residues of the trimeric cation of (XXVII) are considerably different. The central Ni(1) atom has a square planar coordination, increased to a [4+2]-type of pseudo-octahedral coordination through Ni(1)...S(24) and Ni(1)...S(24') interactions [3.0551(6) Å] (Fig. 21). The Ni(1)...S(24) vector forms an angle of 86.5° with the S(11)S(12)S(11')S(12') equatorial coordination plane of the Ni(1) atom. The Ni(2) atom [and symmetrically equivalent Ni(2') atom] has a fivefold tetragonal pyramidal coordination and deviates by 0.291 Å from the basal S(21)S(22)S(23)S(24) plane towards the apical S(11) atom of the inner cation residue. The basal Ni(2)–S distance [2.1590–2.1655(6) Å] is somewhat less than the equatorial Ni(1)–S distances [2.1698 and 2.1720(6) Å] and is appreciably less than the apical Ni(2)–S(11) distance [2.6592(7) Å]. All of the basal Ni–S distances in the cation of (XXVII) are clearly greater than in the neutral complex (XXIII) and anions of (XXIV) and (XXV).

The considerable similarity between the lengths of the corresponding S–C and C–C bonds in the inner and outer DDDT ligands of complex (XXVII) should be noted (Fig. 21). On the whole the lengths of the C–C bonds (average 1.418 Å) and S–C (average 1.697 Å) suggest that, as in complex (XXIII), there is appreciable delocalisation of electron density in the chelate rings and that there is an approximately equal contribution of the two canonical forms (*a*) and (*b*) (Scheme 1) to the state of the ligands of DDDT. The cation of (XXVII) can be represented as $\{[Ni^{2+}(d^8)(DDDT^-)_2][Ni^{3+}(d^7)(DDDT^-)_2]_2\}$.[80,84]

The association of dithiolene complexes through M...S interactions is well-known.[36] However, only dimeric dithiolate complexes with a coordination of the M atom of the type [4+1]

§ E_1 and E_2 are the values of the redox potentials for the reactions $[ML_2]^2 \overset{E_1}{\rightleftarrows} [ML_2]^- \overset{E_2}{\rightleftarrows} [ML_2]^0$, where ML_2 is the 1,4-dithiolene complex of the metal.[88]

were previously studied structurally.[36] Thus, the Fe atoms in the centrosymmetric dimer $\{Fe_2[S_2C_2(COOMe)_2]_4\}^{2-}$ formed through Fe...S interactions [Fe–S_{bas} distances equal to 2.230–2.256(2) Å, Fe–S_{apic} distance is 2.446(2) Å, projection of the Fe atoms from the basal planes $\Delta(Fe_{bas})$ = 0.434(1) Å, Fe...Fe is 3.120 Å] have [4+1] coordination similar to the Ni(2) atom.[89] Polymeric dithiolene complexes with a [4+2]-type of coordination of the Ni atoms (Fig. 22), like the Ni(1) atom in (XXVII), have also been theoretically predicted.[36] However, such structures have so far not been detected experimentally.

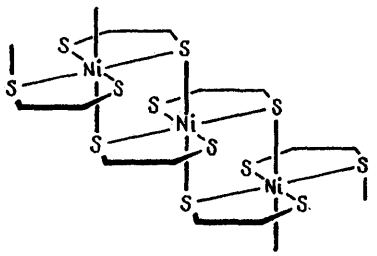

Figure 22. Hypothetical polymer chain of $Ni(edt)_2$ complexes (edt = ethylenedithiolate) combined through Ni...S interactions with [4+2] coordination of the Ni atoms.[36]

Despite the eclipsed relative configuration of the central and outer residues (Figs. 21 and 23), there is no substantial steric strain in the cation of (XXVII). The intercation contacts between the inner and outer residues [S(11)...S(23) 3.676(3) Å, S(11)...S(24′) 3.694(3) Å, S(12)...S(24′) 3.652(3) Å] are only slightly less than twice the van der Waals radius of the S atom (3.70 Å).[80] The Ni(1)...Ni(2) distance is 3.3310(4) Å, i.e., it does not correspond to a metal–metal interaction.

The cations in the crystal of (XXVII) are arranged in stacks along the axis c = 12.148 Å (Fig. 23). The S...S contacts in the stacks between the trimers are not shortened. Shortened contacts occur between stacks: $S(11)...S(25)_A$ 3.667(3) Å, $S(12)...S(21)_D$ 3.606(3) Å, $S(12)...S(26)_B$ 3.657(3) Å, $S(13)...S(25)_A$ 3.366(3) Å, $S(21)...S(24)_E$, 3.609(3) Å, $S(22)...S(23)_D$ 3.547(3) Å, $S(23)...S(26)_E$ 3.463(3) Å, $S(26)...S(27)_D$ 3.514(3) Å [atom S_A is projected from the S atom by the transformation $(x, \frac{1}{2}-y, \frac{1}{2}+z)$, S_B by $(x, 3/2-y, \frac{1}{2}+z)$, S_E by $(-x, -\frac{1}{2}+y, \frac{1}{2}-z)$, and S_D by $(-x, \frac{1}{2}+y, \frac{1}{2}-z)$]. These shortened contacts combine the stacks of cations into layers, parallel to the *bc* plane of the crystal of (XXVII).

The molecular metal $(BEDT-TTF)_3(ClO_4)_2$ has a structure very similar to (XXVII); there are stacks along the [011] direction, in which triads of BEDT–TTF radical cations are separated with a period of 12.172 Å, short S...S contacts occurring only between stacks.[90] The low electrical conductivity of (XXVII) is probably due to the high localisation of charges in the cation trimers.

$Au(DDDT)_2$ complexes (XXVIII) are packed in the crystal with the same structural motif (centrosymmetric dimers) as for neutral BEDT–TTF molecules (Fig. 24). The similarity of structural motifs with comparable parameters of the unit cells [(XXVIII): a = 6.496(1) Å, b = 13.267(4) Å, c = 16.775(3) Å, β = 94.87(2)°, V = 1440.5(5) Å^3, Z = 4, space group $P2_1/n$; BEDT–TTF (transformed cell):[82] a = 6.614 Å, b = 13.985 Å, c = 15.721 Å,

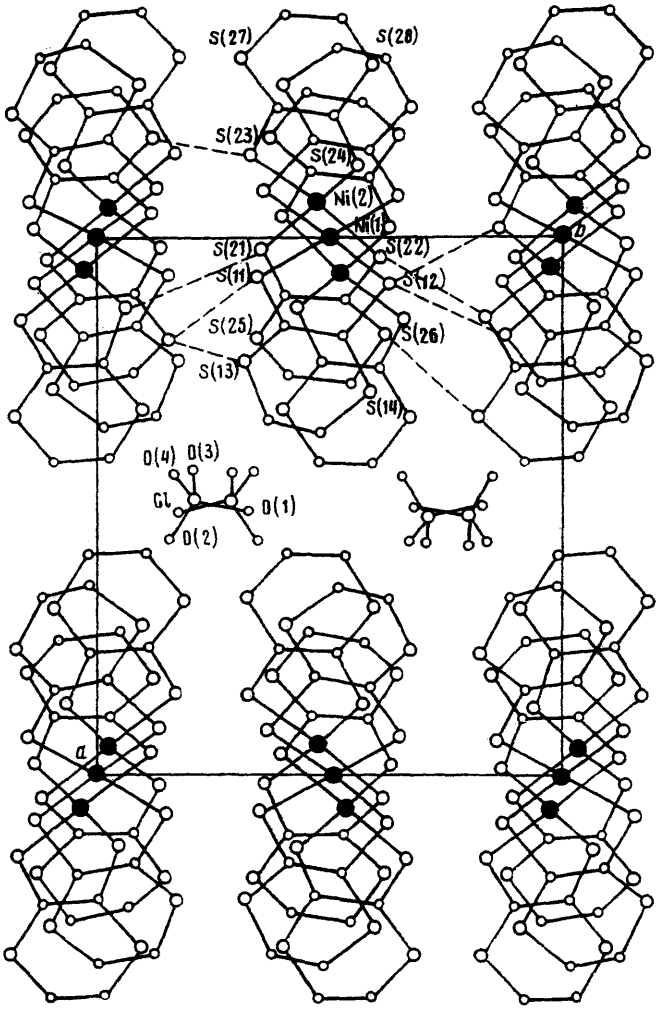

Figure 23. Projection of the crystalline structure of (XXVII) on to the *ab* plane. Shortened intercation S...S contacts are indicated by broken lines.[80,84]

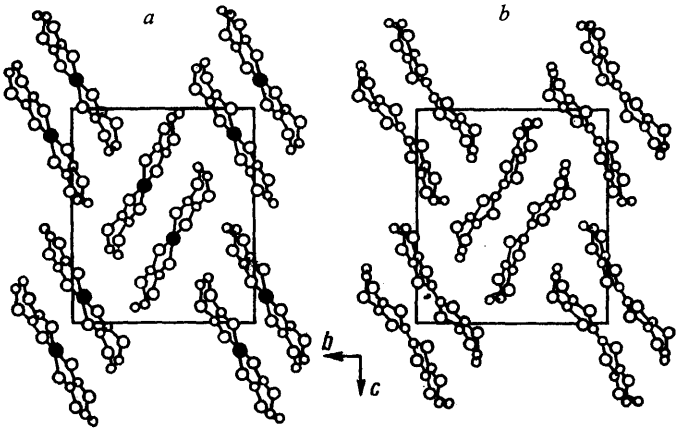

Figure 24. Projections of the crystalline structures of (XXVIII) (*a*) and BEDT–TTF (*b*) on to the *bc* plane. The diagram is taken from the study of Schultz et al.[82] and converted to the modified coordinates given by Kobayashi et al.[91]

$\beta = 93.81°$, $V = 1451$ Å^3, $Z = 4$, space group $P2_1/n$] is consistent with the structural similarity of the (XXVIII) and BEDT–TTF molecules. Shortened intermolecular S...S contacts (<3.70 Å) in both crystals only occur between dimers and combine the molecules into a three-dimensional system, and judging by the values of these contacts [the two crystals each have five shortened contacts: 3.59–3.67 Å in (XXVIII) and 3.48–3.69 Å in BEDT–TTF], the packing of the BEDT–TTF molecules is denser.

The Au–S distance in the $[Au(DDDT)_2]^-$ anion in the crystal of (XXIX) [2.310 and 2.312(3) Å (average 2.311 Å)] is slightly greater than in the neutral $Au(DDDT)_2$ complex (XXVIII) [2.280–2.317(9) Å (average 2.304 Å)] and is in good agreement with those found in $[Au(dmit)_2]^{n-}$ anionic complexes (see Table 2). It is not possible to make any definite conclusions as to whether there is electron delocalisation because of the insufficient accuracy of the X-ray diffraction study of compound (XXIX). Significant structural motifs in terms of electrical conductivity (stacks, layers) are absent and there are no shortened interanion S...S contacts.

Let us consider one more ligand system containing a tetrathioethylene unit, namely, 5,6-dihydro-1,4-dithiepin-2,3-dithiolate (DDTDT). Metal complexes obtained from it are structurally similar to the BEDT–TTF molecule. The presence of the "extra" methylene unit in this ligand (compared to the DDDT ligand) results in an even greater deviation from planarity in DDTDT ligands, namely, in a further weakening of the intrastack interaction in crystals of $[M(DDTDT)_2]^x$ complexes relative to the interstack interaction. The main data on the structure of $[M(DDTDT)_2]^x$ complexes are given in Table 5.

Table 5. The main data on the structure of $[M(DDTDT)_2]^x$ complexes.[92]

Compound	Chemical formula	x	M–S distance, Å	Main structural motif	Conductivity σ_{293}, Ω^{-1} cm^{-1}
(XXX)	$Ni(DDTDT)_2$	0	2.121, 2.138 (1)	Stacks	10^{-6}
(XXXI)	$(Et_4N)[Ni(DDTDT)_2]$	−1	2.139–2.151 (1)	Chains	10^{-5}
(XXXII)	$(Et_4N)[Cu(DDTDT)_2]$	−1	2.179–2.190 (1)	"	10^{-5}

In the crystal of (XXX) the neutral $Ni(DDTDT)_2$ complexes occupy specific positions on the 2 axes, forming stacks along the z axis ($c = 7.553$ Å). The Ni...Ni distance (3.777 Å) in a stack is too long for a metal–metal bond to be formed; there are no shortened S...S contacts in the crystal of (XXX). The central residue of complex (XXX) (excluding the C atoms of the trimethylene groups) is virtually planar ($\Delta_{max} = 0.083$ Å).

The $[Ni(DDTDT)_2]^-$ and $[Cu(DDTDT)_2]^-$ anions in the isostructural salts (XXXI) and (XXXII) have the same, almost planar structure [$\Delta_{max} = 0.088$ and 0.053 Å in the two symmetrically independent centrosymmetric anions in the crystal of (XXXI) and 0.068 and 0.072 Å in the crystal of (XXXII)]. The Ni–S distances in the $[Ni(DDTDT)_2]$ anion [2.139–2.151(1) Å] are slightly greater than in the neutral $Ni(DDTDT)_2$ complex [2.121 and 2.138(1) Å]. The anions in the crystals of (XXXI) and (XXXII) are combined into short chains along the [101] direction through short S...S contacts between the outer S atoms of the ligands [3.505 Å in (XXXI) and 3.519 Å in (XXXII)]. A stack structure does not occur in the crystals of (XXXI) and (XXXII).

V. Conclusion

By studying the structure of complexes of the type $[M(dmit)_2]^x$ and $[M(DDDT)_2]^x$ it was possible to obtain new information about the composition of low-dimensional molecular conductors. It was found at the same time that while the crystalline structure of salts of the type $(Me_4N)_{0.5}[Ni(dmit)_2]$ [(II), $\sigma = 50$ Ω^{-1} cm^{-1}] with organic cations of small size is very much like the structure of the previously known alkali metal dithiolates of the type $Li_{0.82}\{Pt[S_2C_2(CN)_2]\}\cdot 2H_2O$ with relatively good conductivity ($\sigma = 10^2$ Ω^{-1} cm^{-1},[59] fairly dense, regular, or slightly dimerised stacks of anions combined into layers), the structural motifs of crystals of $(Bu_4N)_{0.29}[Ni(dmit)_2]$ [(V), $\sigma = 1-10$ Ω^{-1} cm^{-1}, alternation of triads and tetrads in stacks of anions] and $(Ph_4As)_{0.25}[Ni(dmit)_2]$ [(VIII), $\sigma = 10-15$ Ω^{-1} cm^{-1}, tetrads in anion stacks] are very unusual. The structure of the crystal of $(Me_3S)[Au(dmit)_2]$ [(XIII), $\sigma = 10^{-5}$ Ω^{-1} cm^{-1}], which has a well-defined layer structure, the layers being formed by both anions and cations, is also unusual. It should also be noted that the structure of the anion stacks characteristic of the salts $(Me_4N)_{0.5}[Ni(dmit)_2]$ (II), $(Et_4N)_{0.5}[Ni(dmit)_2]$ (III), and α-$\{(Et_4N)_{0.5}[Au(dmit)_2]\}$ (X), which have relatively good conductivity, also occurs in their nonconductive precursors, such as in $(Et_4N)[Au(dmit)_2]$ (XI). It is true that in the latter case the stacks are not combined into layers.

Segregated stacks of donors and acceptors constitute the predominant structural motif in the highly conductive salts $D[M(dmit)_2]_x$ (D = open donor), such as $(TTF)[Ni(dmit)_2]_2$ [(XV), $\sigma = 300$ Ω^{-1} cm^{-1}], which was found previously in salts of dithiolate complexes with organic donors, such as $(C_{20}H_{12})_2\{Pt[S_2C_2(CN)_2]_2\}$, where $C_{20}H_{12}$ = perylene ($\sigma = 400$ Ω^{-1} cm^{-1})[93] and would appear to be the most conducive to a high electrical conductivity.

The structure of $(HMTTeF)[Pt(dmit)_2]_{0.5}$ [(XXII), $\sigma = 20$ Ω^{-1} cm^{-1}] is unusual. The crystal of (XXII) comprises layers of tetrads of donor molecules, the acceptor molecules being perpendicular to these layers. Quite unexpected was the comparatively high electrical conductivity of the salt (BEDT–TTF)[Ni(dmit)$_2$] [(XIX), $\sigma = 0.02$ Ω^{-1} cm^{-1}]. The crystal of (XIX) is composed of stacks with a different structure. A quantum-chemical calculation of the zone structure showed that the electrical conductivity of this salt is caused by "lateral" donor–donor (primarily) and acceptor–acceptor interactions.

Amongst these structures are to be found two forms of association of dithiolate complexes, discussed in detail by Alvarez et al.[36] In the crystal of $(TTF)[Pt(dmit)_2]_3$ [(XXI), $\sigma = 20$ Ω^{-1} cm^{-1}], one of the symmetrically independent anions participates in the formation of dimers through a direct Pt–Pt bond, whereas the second anion remains in monomer form, the acceptor stacks (combined into electroconductive layers) are composed of alternating dimers.

The second possible form of association of dithiolene complexes occurs in the crystal of $[Ni(DDDT)_2]_3(ClO_4)_2$, (XXVII), in whose trimeric dication the Ni atoms have different types of coordination. The outer atoms have a square pyramidal coordination (through a direct Ni–S bond with the inner residue), the inner atom has a pseudo-octahedral [4+2] coordination (through additional Ni...S interactions with the outer residues).

The sixfold coordination¶ of the inner Ni atom is an indication of the possible formation of infinite one-dimensional motifs of $[M(DDDT)_2]$ complexes. A further feature of the crystal of $[Ni(DDDT)_2]_3(ClO_4)_2$ is that it is essentially isostructural with the $(BEDT-TTF)_3(ClO_4)_2$ crystal, in which triads of BEDT–TTF radical cations (also arranged in stacks) act as a structural analogue of the trimeric cations (arranged in stacks). It is known that $(BEDT-TTF)_3(ClO_4)_2$ exhibits superconductive properties at very low temperatures.

Of the dithiolates discussed in this review, only crystals of $(Me_4N)_{0.5}[Ni(dmit)_2]$ (II) and $(TTF)[Ni(dmit)_2]_2$ (XV) undergo a transition to a superconductive state. Although the complex $[Ni(DDDT)_2]_3(ClO_4)_2$ (XXVII) has low electrical conductivity and is a semiconductor, its close structural similarity to $(BEDT-TTF)_3(ClO_4)_2$ gives grounds for the hope that replacement of ClO_4^- by other anions (differing from ClO_4^- in size, shape, and charge) and of Ni by another complex-forming metal (Pt, Pd, Cu) may lead to the formation of highly conductive compounds based on monomeric or polymeric $[M(DDDT)_2]^x$ complexes as donors.

On the whole, dithiolate complexes of transition metals now form an important independent class of molecular conductors (although this has much in common with purely organic conductors). There are many opportunities for modifying the structure and properties of the dithiolates. There is greatest interest in the transition from isolated monomeric dithiolates to one-dimensional and particularly two-dimensional structural motifs, namely, approaching the structures and essentially two-dimensional properties such as those of high-temperature inorganic superconductors.

Solubility of oxygen in electrolyte solutions

A Sh Groisman, N E Khomutov (deceased)
Mendeleev Moscow Institute of Chemical Engineering

ABSTRACT. The latest advances in the study of the solubility of oxygen in water and in electrolyte solutions and of the influence of temperature and pressure on the solubility of oxygen are presented and surveyed. Advances in the development of experimental methods for the study of the solubility of oxygen are examined. The experimental results from studies of the influence of temperature and electrolyte concentration on the solubility of oxygen and their thermodynamic and molecular-statistical interpretation are described.

The bibliography includes 276 references.

V. Extrema in the influence of temperature and electrolyte concentration on the solubility of oxygen 719

I. Introduction

The reviews of Konnik[1] in this journal and of Wilhelm et al.[2] in a foreign journal were published in 1977. Konnik's review[1] was devoted to the application of salting out-salting using the theories most thoroughly developed at the time (the hydration, electrostatic, and "internal pressure" theories) in relation to oxygen at 298 K. The review of Wilhelm et al.[2] contains information about the solubilities of 57 gases, including oxygen, in pure water at a pressure of 101.325 kPa and at temperatures up to 350 K. A handbook, covering the experimental data on the solubility of oxygen in water and electrolyte solutions available in the literature up to 1978, was published in 1981.[3]

A critical review,[4] containing published data on the solubility of oxygen in water (at 273–573 K) and in electrolyte solutions at 298.15 K up to the end of 1980, appeared in 1983. A bibliographic index,[5] appeared in 1984, covering 108 literature sources (published up to the end of 1983) devoted to the study of the solubility of oxygen in water and in electrolyte solutions.

During the last decade, there has been a growth of interest in the solubility of oxygen, as shown by the number of publications (more than 200) during the last ten years (1979–1988) compared with the number of publications in 1969–1978 (about 80).

The Ist International Symposium on the Problems of the Solubility of Gases was held in 1984 in Canada. It was organised by the IUPAC Commission on Solubility.[6]

The existing reviews[1,2,4] did not deal with questions concerning methods for the study of the solubility of oxygen in liquids and also questions concerning the influence of the nature and concentration of electrolytes on the solubility of oxygen over a wide range of temperatures and pressures, as well as the problem of calculating the ionic coefficients of the salting out of oxygen from aqueous solutions.

The reviews as a rule considered the range of low temperatures and pressures. Since then, considerable advances have been achieved in solving the problem of the solubility of oxygen in water and in electrolyte solutions, namely in the development of experimental methods for the determination of the solubility of oxygen and in the study of the influence of the nature and concentration of electrolytes as well as temperature on the solubility of oxygen in electrolyte solutions. These thorough studies have led to the discovery of extrema, which are manifested particularly strikingly in electrolyte solutions. The extrema involve a change in the sign of the temperature dependence of the solubility of oxygen in water and in electrolyte solutions and the corresponding change from an exothermic to an endothermic heat of solution and also a change from salting out to salting in (or conversely) with increase in the concentration of certain electrolytes. Recently, the attention of investigators has been drawn to the explanation of these phenomena on the basis of molecular-statistical and thermodynamic theories of solutions.

The extrema are of interest for many branches of engineering and chemical and biochemical technology; their discovery should give rise to new approaches to the development of rational conditions for the passivation with oxygen of steel structures in aqueous media at high temperatures and to the deoxygenation of aqueous solutions (waste, industrial, and other solutions) in order to reduce their corrosive nature and also of conditions for the electrochemical synthesis of a number of substances and other processes.

The oxygen–water system is the recommended standard system in the study of the solubility of gases in water with which one can compare the solubilities of other gases. Such comparisons are essential in the adoption of new methods, the introduction of new gas analysers.[4,7,8] The degree of saturation of water with oxygen and the chemical and biochemical consumption of oxygen are important indices of the quality of different types of water.[9]

The existing reference literature,[10] reviews,[1,2] and textbooks,[11] which are widely used in various branches of science and chemical engineering, contain erroneous data on the solubility of oxygen. This was discovered in latest careful studies.[12] In particular, this can be seen in relation to the solubility of oxygen in NH_4Cl solution.[12,13]

The aim of the present review is to give an account of advances in the study of the solubility of oxygen in aqueous solutions of pure electrolytes and their mixtures, advances in the development of experimental methods for the study of the solubility of oxygen, and

in the analysis of experimental data on the solubility of oxygen in aqueous electrolyte systems and the influence of temperature, pressure, and the nature and concentration of electrolytes on the solubility of oxygen.

Particular attention has been devoted to the extrema observed in the study of the effect of temperature and electrolyte concentration on the solubility of oxygen and to the interpretation of the results on the basis of thermodynamic and molecular-statistical theories of solutions.

II. Methods of expressing the solubility of oxygen

More than ten methods of expressing the solubility of oxygen in liquids are known:[7,14,15] the Bunsen coefficient (α), the Ostwald coefficient (L), the Kuenen coefficient (S), the absorption coefficient (β), the Cook mass absorption coefficient (C_w), the mole fraction (X_2), the constants of Henry's law (K_H, K_2, and K_c) corresponding to the three forms of its mathematical formulation, the solvomolal concentration (c_{sm}), and the solvomolal absorption coefficient (A_{sm}). In addition, the volume and weight fractions and the molar and molal concentrations are sometimes used.

The Bunsen coefficient (α) is defined as the volume V_2 (adjusted to the normal conditions T = 273.15 K and p = 101.325 kPa) of the pure gas absorbed by a unit volume V_1 of the pure solvent and measured at a temperature T and a total pressure $p_{tot} = p_1 + p_2$:

$$\alpha = (V_2/V_1)(273.15/T), \ [cm_g^3/cm_s^3],$$

where p_1 and p_2 are the partial pressures of the solvent vapour and the gas at the temperature T. The subscripts g and s referred to the gas and the solvent.

The Ostwald coefficient (L) is defined as the ratio of the absorbed volume of gas V_2, measured at the pressure p_{tot} and the experimental temperature T, to the volume of the solvent under the same conditions:

$$L = V_2/V_1, \ [cm_g^3/cm_s^3].$$

There are four ways of expressing the Ostwald coefficient:[15]

$$L_V^\circ = (V_2/V_1^\circ)_{eq},$$

where V_2 is the volume of gas absorbed by a volume V_1° of the pure liquid at p_{tot} and T;

$$L_V = (V_2/V_1)_{eq},$$

where V_2 is the volume of gas absorbed by a volume V_1 of a saturated solution at p_{tot} and T: for dilute solutions and within an error of approximately 1%, the quantities L_v° and L_V differ insignificantly;

$$L_c = (c_2^L/c_2^V)_{eq}, \quad (1)$$

where c_2^L and c_2^V are the molar concentrations of the gas in the liquid and gas phases respectively (at p_{tot} and T). This way of expressing the Ostwald coefficient was used by Ben-Naim as the most suitable for discussion of hydrophobic interaction and the thermodynamic characteristics of the transfer of gases in solutions;[16]

$$L_c^\infty = \lim_{c_2^L \to 0} (c_2^L/c_2^V)_{eq},$$

this expression is a rigorous thermodynamic definition of the coefficient L_c [see Eqn. (1)]. The formula for the relations between the four different ways of expressing the Ostwald coefficient has been published.[15]

The Kuenen coefficient (S) is defined as the volume (cm^3) of gas at a partial pressure of 101.325 kPa (adjusted to 273.15 K and 101.325 kPa) dissolved in a solution containing 1 g of the solvent:

$$S = (V_2/m)(273.15/T), \ [cm_g^3/g_s],$$

where m is the weight of the solution.

The absorption coefficient (β) is defined as the volume of gas (measured at p_{tot} = 101.325 kPa and adjusted to 273.15 K and 101.325 kPa) dissolved in a unit volume of the solvent:

$$\beta = (V_2/V_1)(273.15/T)(p_2/101.325), \ [cm_g^3/cm_s^3].$$

The Cook mass absorption coefficient (C_w) is defined as the number of moles of gas (at p_2 = 101.325 kPa) dissolved in 1 g of the solvent:

$$C_w = (V_2/m_1 V_2^\circ)(273.15/T), \ [mol/g],$$

where m_1 is the weight of the solvent and V_2° the molar volume of the gas under normal conditions.

The mole fraciton (X_2) is defined as the ratio of the number of molecules of the dissolved gas (n_2) to the sum of the numbers of molecules of the dissolved gas and the solvent (n_1):

$$X_2 = \frac{n_2}{n_2 + n_1}. \quad (2)$$

The constants of Henry's law are described by the expression

$$K_H = \lim_{X_2 \to 0} (f_2/X_2) \cong \lim_{X_2 \to 0} (p_2/X_2), \ [Pa],$$

where f_2 is the fugacity of the gas. If the gas pressure does not differ very greatly from atmospheric, we have

$$K_H = \frac{p_2}{X_2(p_2)} = \frac{1}{X_2(p_2 = 1 \text{ atm})} \ [atm].$$

The two other ways of expressing Henry's law are as follows:

$$K_2 = p_2/c_2^s,$$

$$K_c = c_2^g/c_2^s = 1/L, \ [cm_s^3/cm_g^3],$$

where c_2^g and c_2^s are the concentrations of the gas in the gas phase at a pressure p_2 and in solution respectively.

The solvomolal concentration (c_{sm}) is defined as the ratio of the number of moles of the dissolved gas to 55.51 moles of the solvent:[14]

$$c_{sm} = \alpha \cdot 55.51 \, M_1/V_2^0\rho_1 = c_m M_1 \cdot 55.51/1000 = \\ = c_M M_1 \cdot 55.51/(1000\,\rho - c_M M_2) = X_2 \cdot 55.51/(1 - X_2),$$

where α is the gas concentration (ml under normal conditions per ml of the solvent), M_1 and M_2 are the molecular weights of the solvent and the gas (g mol^{-1}), ρ_1 and ρ are the densities of the solvent and the solution (g ml^{-1}), and c_M and c_m are the molar and molal concentrations of the gas in the liquid.

The solvomolal absorption coefficient (A_{sm}) is defined as the volume of the pure gas (V_2) (at a partial gas pressure p_2 = 101.325 kPa under normal conditions) absorbed in an amount of the pure or mixed solvent such that it contains 55.51 moles of the solvent:[14]
