$$A_{sm} = \alpha \times 55.51 M_1/\rho_1 = L \times 273.15 \times 55.51 M_1/T, \quad (3)$$

where ρ_1 is the density of the pure or mixed solvent. The formulae

relating the different ways of expressing the solubility of oxygen are as follows:

$$L = \alpha T/273.15, \ [cm_g^3/cm_s^3],$$
$$X_2 = (RT/Lp_2V_1 + 1)^{-1},$$
$$K_H = RT/LV_1 + p_2, \ [Pa],$$
$$K_c = 1/L, \ [cm_s^3/cm_g^3],$$
$$\alpha = S\rho, \ [cm_g^3/cm_s^3],$$
$$C_w = \alpha/V_2^\circ\rho, \ [mol/g],$$
$$L = C_wV_2^T\rho,$$
$$X_2(p_2 = 101.325 \text{ kPa}) = C_wM_1/(1 + c_wM_1),$$

where R is the gas constant, p_2 the gas partial pressure, V_1° the molar volume of the solvent at a temperature T (cm^3 mol^{-1}), ρ the density of the solution (g cm^{-3}), V_2° the molar volume of the gas in cm^3 at 0 °C, V_2^T the molar volume of the gas in cm^3 at the temperature of the measurements, and M_1 the molecular weight of the solvent (g mol^{-1}).

The expressions for the solubilities of gases become more complex if the solvent contains a dissolved electrolyte.[17] For example, Eqns. (2) and (3) assume the form of Eqns. (4) and (5) respectively:

$$X_2 = n_2 \Big/ \sum_{i=1}^{k} n_i = n_2 \Big/ \left(n_2 + n_1 + \sum_{j=3}^{k} n_j \right), \quad (4)$$

where n_1 and n_2 are the numbers of moles of the solvent and the gas respectively and n_j is the number of moles of the dissolved electrolyte;

$$A_{sm} = \alpha\,(55.51\,M_1 + c_{sm,s}M_3)/\rho = L\,(55.51\,M_1 + c_{sm,s}M_3)\,273.15/\rho T, \quad (5)$$

where $c_{sm,s}$ and ρ are the solvomolal concentration and the density of a solution of an electrolyte with a molecular weight M_3.

X_2 and K_H have been most frequently used in recent years because these quantities are more convenient for calculating the thermodynamic characteristics of the dissolution of oxygen.

The Kuenen(S) and Cook coefficients, which have the advantage of being expressed in terms of weight concentrations, i.e. temperature has no influence on the concentration, suffer from the disadvantage that, on replacement of one solvent by another, the ratio of the dissolved oxygen and the solvent changes, which makes it difficult to compare the results. The absorption (β), Bunsen (α), and Ostwald (L) coefficients depend on temperature and they can therefore be used in thermodynamic calculations only to a limited extent. The solvomolal concentration (c_{sm}) combines the advantages of the molal concentration and mole fractions, both of which are widely used in the thermodynamics of solutions. The solvomolal absorption coefficient (A_{sm}) has been recommended to characterise the solubility of gases in pure and mixed solvents.[14]

In reviews, monographs, and original papers, one may encounter a wide variety of expressions for the solubility of oxygen in liquids, which is inconvenient when they are used and compared by different workers. Therefore it was suggested in 1975[18] that the mole fraction of the dissolved gas X_2 at a pressure of 101.325 kPa and a temperature T, at which the solubility measurements were made, be used as the standard unit of the solubility of the gas.

In the study of the thermodynamics of the dissolution of oxygen in water and in other pure solvents, X_2, K_H, or c_{sm} are used.

III. Methods for the study of the solubility of oxygen

In the study of the solubility of oxygen in liquids, methods are employed which are divided in the literature by convention into physical, chemical, and physicochemical.[18–23] They are being continually improved and developed.

The volumetric and manometric methods belong to the class of physical procedures. Their essential feature involves the measurement of the volume (pressure) of oxygen absorbed by the degassed liquid or desorbed from the liquid.[2,22–28] Chemical methods are based on the interaction of oxygen with reductants.[19,22,29]

Among physicochemical methods, spectroscopic, electrochemical, chromatographic, kinetic, radiometric, and mass-spectrometric methods as well as methods based on the paramagnetic properties of oxygen (EPR, NMR) are employed. In certain methods, the dissolved oxygen is evolved from the liquid, freed from the gases and vapours present, and its amount is measured.[30,31] During the last five years, the electrochemical methods (using voltammetric membrane sensors) have been most vigorously developed. Their advantages are speed, continuity, automation, and the possibility of carrying out measurements in reaction systems, natural and industrial waters, and biological liquids.

The error of the physical methods varies from several per cent to hundredths per cent.[4,32] The error of the determination of the solubility of oxygen usually varies in the range 1–2%, rarely in the range 0.1–0.2%; an error smaller than 0.1% has been achieved.[33] The disadvantages of the physical methods include the need to use large volumes of samples, the need to degas the liquid, to carry out repeated calibrations, to monitor the purity of oxygen, and to devise large thermostats, prolonged and laborious analysis, and the impossibility of carrying out continuous measurements of the concentration of oxygen.

1. Chemical methods

Among chemical methods, the iodometric method, first introduced by Winkler who described it in its classical form,[34] has come to be most widely used. Winkler's method is based on the reaction between dissolved O_2 and $Mn(OH)_2$ in a highly alkaline medium.

On acidification in the presence of iodide, the oxidised manganese hydroxide is reduced back to manganese(II) and the iodine liberated, whose amount is equivalent to the concentration of dissolved oxygen, is determined by titration with sodium thiosulphate. The error of the determination of the concentration of dissolved oxygen in pure water by Winkler's method is 0.03–0.05 mg $litre^{-1}$ (0.5%).[19,35] Disadvantages of the method are the impossibility of determining dissolved oxygen in inorganic (NH_3, Cl_2, etc.) and organic solvents and of assessing the influence of various substances (oxidants, reductants, carbonates, phosphates, borates, and fluorides).[29,35]

It is difficult to measure continuously the solubility of oxygen by this method. Winkler's method has therefore been frequently improved and its improvement is being continued up to the present time.[36–39] A novel apparatus has been devised for saturating water with oxygen and for establishing an equilibrium between the dissolved and gaseous oxygen with subsequent application of Winkler's method.[40,41] Modifications of Winkler's method have been developed in order to eliminate the interfering influence of oxidants and reductants[29] (substances which react with I_2 and I^- [42]) in the presence of carbonates, phosphates, borates, and fluorides[40,41] and Ca^{2+}, Fe^{3+}, NO_2^-, and CH_3COO^- ions,[43] as the concentration of oxygen in coloured solutions is varied,[44] and in the presence of

high concentrations of dissolved oxygen (more than 15 mg litre^{-1}) and organic substances.[45,46] The optimum conditions for the occurrence of the chemical reactions and the principal sources of errors and the methods used to eliminate them in the determination of the solubility of oxygen by Winkler's method have been described.[29,36,37,39,47,48] The use of potentiometric and amperometric titration as well as a photometric method to determine the end point has increased the sensitivity and accuracy of the method.[19,49]

Chemical methods not involving the oxidation of manganese(II) have been described.[19] However, their accuracy is lower than that of Winkler's method, which has come to be widely used in the practical investigation of the solubility of oxygen in pure water, in electrolyte solutions, and in natural, waste, and industrial waters. Winkler's method has been recommended[4,7,35,50] as the standard method by means of which one can test and calibrate other methods and instruments.

2. Spectroscopic methods

These methods are based on the selective absorption of light by substances whose colour changes on chemical interaction with oxygen. Indigocarmine, Methylene Blue, safranine T, β-sulphoanthraquinone, diphenyl-3,4-dihydroxy-L-β-phenylalanine, 3,3'-dimethylnaphthidine, and others have been used as substances of this kind.[23] The photometric determinations[38,51] of manganese(III) compounds (after the addition of complex-forming agents), of I_3^- ions formed when Winkler's method is employed, of iron(II) complexes of 4,7-dihydroxy-1,10-phenanthroline[52] and iron(II) complexes formed with an alkaline solution of catechol,[13] of cobalt(II) complexes of L-histidine and a tetraazamacrocyclic ligand,[53] and of a cobalt(II) complex of bis(salicylaldehyde)ethylenediamine deposited on a polymer or metallic (aluminium) film[54] have been described.[38,51] Compounds containing the $[Co(MoS_4)_2]^{3-}$ ion which change colour from green to black on interaction with O_2, can serve as indicators for oxygen.[55]

Optical sensors with an emulsified oxygen indicator in a polymer layer have been developed.[56,57] The spectroscopic methods are sensitive to impurities and require the maintenance of a specified pH for a specified exposure time, as well as calibration. The advantages of the spectroscopic methods are high sensitivity and the possibility of determining very low oxygen concentrations. The range of the measured oxygen concentrations is 0.005–0.4 mg litre^{-1} and the error is 2–15%. The concentrations of oxygen in water, in electrolyte solutions,[12,13] in natural and waste waters,[58] and in organic solvents[59] have been determined by these methods. However, the spectroscopic methods have been most widely used in the determination of low oxygen concentrations in the deaerated water in large thermal power stations and atomic power stations.

3. Optical fibre sensors

During the last 3–4 years, a new type of photometric device has been developed — chemical sensors (optical sensors) which consist of a section of a fibrous light guide, on the end-face or lateral surface of which a special reagent has been deposited. The interaction of oxygen with the reagent alters its optical characteristics and leads to the appearance of a signal in the absorption, reflection, or fluorescence spectrum.[60–69] Optical sensors can be used in combination with electrochemical sensors and are promising for the determination of oxygen in various media in industrial undertakings, especially in contaminated zones dangerous to health and in clinical and biomedical research.

4. The laser absorption method

This method is based on the absorption of radiation by the molecules of the substance analysed when the frequency emitted coincides with the frequency of the absorption line.[70] The amount of radiation absorbed is governed by the number of O_2 molecules. The concentration of oxygen mixed with other gases can be determined continuously by this procedure. The sensitivity of the method is 0.003 mg litre^{-1} and the error is 1–3%.

5. Luminescence methods

These methods for the determination of dissolved oxygen are based on the glow of the phosphors formed as a result of the chemical reaction of oxygen with certain substances. Such compounds are luminol (3-aminophthalic acid hydrazide), lucigenin (bis-*N*-*N*'-methylacridinium nitrate), 9,10-diphenylanthracene, acriflavin on rigidly porous sorbents, and derivatives of 4-bromo-1-naphthol extracted into cyclodextrin and fixed on cellulose and other carriers.[71–78] The emitted intensity depends on the pH of the solution and on the presence of impurities, temperature, and exposure time. In the luminescence analysis, it is therefore necessary to stabilise all these factors. The range of the concentrations of dissolved oxygen in water measured by the chemiluminescence method in the presence of lucigenin is 6.5–15 mg litre^{-1} and the error is 0.6%. The prolonged afterglow of acriflavin on silica gel [in the oxygen concentration range $(0.3-0.5)\times10^{-3}$ mg litre^{-1}] and on cellulose [in the range 0.01–0.2 mg litre^{-1}] has been used[72] to determine microconcentrations of oxygen.

A luminescence method for the determination of oxygen with the aid of an optical fibre fluorimeter has been reported.[73] The advantages of the luminescence methods over other physicochemical methods for the determination of the concentration of dissolved oxygen are high accuracy, the possibility of using small volumes of water samples to be analysed, and the automation of the measuring process.

6. Kinetic method

This method of determining the concentration of oxygen in aqueous solutions is based on the measurement of the induction period of the reaction catalysed by the copper complex of tetrabenzo[*b*,*f*,*g*,*n*][1,5,9,13]tetraazacyclohexadecyne, in which ascorbic acid is oxidised by oxygen.[79] The range of oxygen concentrations which can be determined is 0.5–32 mg litre^{-1} with an error of 0.1 mg litre^{-1}. Compared with Winkler's method, the kinetic method yields low solubilities of oxygen. Combined luminescence-kinetic methods, based on the quenching of the luminescence of dyes by oxygen, are being developed.[80]

7. Electrochemical methods

Electrochemical methods include amperometric, potentiometric, voltammetric, coulometric, and conductimetric methods.[19,20,81] The theory of these methods has been described in detail.[19,20] The electrochemical methods for the determination of oxygen in liquids have advantages over the chemical methods.[82] Firstly, the apparatus used in electrochemical methods gives rise to an electrical output signal, which can be applied in automatic regulation and control systems. Secondly, with the aid of electrochemical methods it is possible to determine continuously the rate of change of the concentration of oxygen. Thirdly, the composition of the liquid analysed hardly changes after contact with the electrochemical sensor.

Amperometric methods are based on the measurement of the diffusion current, which varies in the course of titration. The titration is carried out at a constant potential corresponding to the region of the limiting diffusion current of oxygen. Two versions of the amperometric methods are used. In the first version, one electrode serves as the indicator electrode and the other is used as the reference electrode; in the second version, two indicator electrodes are employed (biamperometric titration).[83] The advantages of the method are high sensitivity and accuracy, high speed of measurement, and the possibility of determining oxygen in coloured and turbid aqueous and non-aqueous solutions.

Potentiometric methods are based on the dependence of the e.m.f. of a galvanic cell on the concentration of ions in the electrolyte and on the oxidation-reduction processes occurring at the electrodes as a result of the reduction of the dissolved oxygen.[84–86] The thallium electrode has been thoroughly investigated for such purposes.[87–89] The concentration of oxygen in the range 0.4–20 mg litre^{-1} with a 5% error can be determined with its aid. However, owing to the toxicity of thallium, such electrodes have not come to be widely used.

A potentiometric sensor, whose electrolytic cell consists of a reference electrode (air/Pt, Na_2HPO_4 or $NaHCO_3$), a proton-conducting solid electrolyte [$Sb_2O_3.4H_2O$, $Zr(HPO_4)_2.H_2O$, and a Nafion membrane], and a platinum indicator electrode, has been proposed.[84] It has been suggested that the Cu(II)–Cu(I)–NH_3–H_2O oxidation-reduction system be used to determine oxygen in organic and aqueous organic solvents.[85] The disadvantages of the method are the need to devise a cumbersome apparatus to maintain a definite pH.

Voltammetric methods are based on the measurements of limiting diffusion current for oxygen reduction at the cathode at a constant potential. There are two varieties of the voltammetric method: with a mercury dropping electrode and with solid electrodes. The latter are used both without membranes and with gas-permeable membranes separating the electrochemical cell from the medium in which the concentration of dissolved oxygen is measured.

The sensitivity of the classical polarographic method with respect to oxygen is 0.05–0.1 mg litre^{-1} and the error is 0.02 mg litre^{-1}. The principal disadvantages arising in the use of the mercury dropping electrode are the difficulties associated with the measurements *in situ* and the risk of contaminating the test system with mercury. Solid electrodes are free from these disadvantages. the oxygen reduction limiting current at the cathode (Pt, Au, etc.) is proportional to the concentration of dissolved oxygen.[19] Carbon glass, boron carbide, or carbon paste "wall-jet" electrodes have been described.[90] A disadvantage of the membrane-free electrodes is the possibility of their contamination. Furthermore, the medium in which oxygen is determined must exhibit a sufficient electrical conductivity, since otherwise the true current may be appreciably altered under the influence of interfering substances. These disadvantages are eliminated when membrane voltammetric sensors (MVS), first proposed by Clark,[91] are used. Platinum, palladium, rhodium, and gold cathodes are used. Instead of expensive materials, it has been suggested that the cathode by made from nickel or nichrome (however, these require additional activation)[92] as well as carbon sitals, carbon fibres, and graphite.[82,93,94] Porous silver indicator electrodes have been proposed.[95]

The use of membranes suffers from a number of disadvantages: membranes are subject to mechanical damage; if membranes are made thicker in order to increase their mechanical strength, the inertia of the sensor increases; owing to the non-uniform thickness of the membrane, a scatter of the results of measurements is observed, which requires careful calibration of the sensor; the temperature, stirring, and pH of the solution influence the readings of the sensor.[96,97] Polyethylene and fluorinated polymers 10–25 μm thick have been used as membranes.[19,98] Membranes made of a multilayer polytetrafluoroethylene film containing 60% of Mn_4N,[99] cellophane,[100] silicones,[101] and other materials[102] have been put forward.

In biologically active media, membranes are coated by a biological film, as a result of which the sensitivity of the MVS diminishes. Hydraulic or mechanical purification is normally employed. Novel sensors, in which the membrane is freed from biocontaminants by means of gases, have been developed.[103,104]

Novel stirring devices have been proposed.[105,106] In order to increase the sensitivity of the MVS, the electrodes are activated.[107–109] A sensor without a layer of electrolyte between the cathode and membrane has been developed to diminish the influence of the pressure and vibration on the membrane.[96,110] A "protecting" electrode having the same size as the cathode has been introduced to diminish the influence of the background current between the cathode and anode.[111] The range of concentrations of the sorbed oxygen measured with the aid of the MVS is 0–50 mg litre^{-1}, the relative error is 1–6%, and the sensitivity is 0.05 mg litre^{-1}.[19] MVS with pulsed action have been developed.[112–114]

Electrochemical oxygen sensors have been standardised[115,116] and have been developed to the greatest extent. They are distinguished by simplicity in operation and can be easily transported. The application of MVS makes it possible to monitor rapidly and continuously the concentration of oxygen *in situ* under industrial, laboratory, and field conditions.[117] By virtue of high speed of the response of the MVS, they are used in systems for the automatic monitoring and regulation of the oxygen conditions in the purification of sewage, in aeration devices, and for the investigation of processes involving the biochemical consumption of oxygen (BCO) and of the intensity of the respiration of microorganisms in fish-farming water reservoirs.[82,97,118,119]

In addition MVS are widely used in biology and medicine.[101,120–122] Microbial amperometric sensors for the determination of biological consumption of oxygen have been developed.[123] The interest in MVS has grown continuously.[124–138] KP-101,[139] KL-115 N20-IOA,[140] KAP-105,[141] AKVA-S,[142] KM-105, KM-101, KM-201, and KMV-110[143] oxygen measuring devices are being manufactured in the USSR. AKP-205 apparatus has been developed for the determination of low oxygen concentrations in the range 0–0.5 mg litre^{-1} subject to an error of 0.001 mg litre^{-1}.[144]

Coulometric methods are based on the direct proportionality between the weight of the electrochemically reduced oxygen and the amount of electricity which has passed through the solution. Dissolved oxygen can be determined both directly in a water sample[145] and after its evolution from the solution.[146] In these methods, there is no need to have standard samples with dissolved oxygen. During the last three years, oxygen measuring devices using an indirect coulometric method have been created.[147] An advantage of the coulometric sensors over the MVS is the smaller influence of temperature on the oxygen reduction current. The temperature-induced changes influence the reproducibility of the MVS readings owing to the temperature-induced hysteresis in the membrane. The disadvantages of these methods are the impossibility

of measuring the concentration of dissolved oxygen *in situ* and the contamination of electrodes (unless special measures are taken before analysis to purify the water). The range of variation of the oxygen concentrations which can be measured is 0.03–66 mg litre^{-1}, the relative error is ~1%, and the duration of analysis is 4–5 min.

Conductimetric methods are based on the measurement of the electrical conductivity of either an electrolyte solution in which oxygen is dissolved or of metal oxides on interaction with the gaseous oxygen evolved from the solution.[81,148–151] These methods are highly sensitive and are suitable for the continuous determination of oxygen. However, they cannot be employed to determine the concentration of oxygen *in situ* partly owing to the contamination of the electrodes. When high-frequency conductimetry is used, this problem can be solved.[19] The disadvantages of these methods are the need for preliminary passage of the sample through an ion exchanger as a result of which dissolved oxygen may be lost; when thallium oxygen-measuring devices are employed, the high toxicity of Tl^+ is a disadvantage. The range of the measureable oxygen concentrations is 0.002–1 mg litre^{-1}, the sensitivity is to within 10^{-3} mg litre^{-1}, the error is several per cent,[19] and the analysis time is several minutes. Conductimetric methods are suitable for the determination of dissolved oxygen in very pure waters with a low electrical conductivity. Analysis of the literature[81,82,87,120] of the most recent years shows that conductimetric methods are relatively unpromising.

A second type of the conductimetric determination of oxygen is based on the dependence of the electrical conductivity of metal oxides (CoO, ZnO, TiO_2, etc.) and solid electrolytes ($Nd_\alpha Y_\beta F_\gamma O_\delta$, where $\alpha = 4.5–7.5$, $\beta = 4.5–7.5$, $\gamma = 14–24$, and $\delta = 6–11$) on the concentration of oxygen and temperature.[150–152] Oxygen can be determined continuously with the aid of these procedures.

New electrochemical methods. During the last five years, new electrochemical methods have been proposed for the measurement of the concentration of dissolved oxygen: the adsorption-kinetic methods[153,154] based on the measurement of the rate of displacement of the electrode potential under the influence of dissolved oxygen, the anodic inversion, pulse, and cyclic voltammetric methods,[155–160] the chronocoulometric method,[161,162] the chronopotentiometric method,[163] the chronoamperometric method using platinum microelectrodes,[164–166] inversion potentiometric analysis,[167,168] and the method involving the measurement of the electrical resistance or the pressure exerted by the semiconducting oxide film formed on the electrode in contact with the medium being analysed.[169,170]

8. Chromatographic methods

These methods are based on the use of the difference between the adsorbabilities of oxygen, other gases, and solvent vapour.[171–175] They are used for the determination of the weight concentration of the dissolved oxygen (in a mixture of gases) in liquids.[176,177] The analysis requires 10 μl of the liquid.[172] Chromatographic methods require special equipment and calibration and with their aid it is difficult to perform continuous measurements *in situ*. The error of the method is usually 3–15%,[175] sometimes 0.33–0.5%,[172,178] the sensitivity is 0.005–0.01 mg litre^{-1},[179] and the duration of the analysis is 10–15 min, sometimes 3–5 min.[174]

A new method has been proposed[180,181] for the determination of the concentration of dissolved oxygen—liquid–gas partition chromatography based on the filtration of the sample of the analysed solution through a column with a hydrophobic filler (for example, porous polytetrafluoroethylene) and the flushing of the column with the carrier gas. In contrast to the other types of the chromatographic process, in which the stationary phase is a solid or a liquid, in this case the gas deposited on the surface of a solid carrier serves as the stationary phase. This method made it possible to automate readily the extraction of dissolved oxygen from the liquid and to reduce appreciably the lower limit of the concentrations which can be determined—to $(2–4) \times 10^{-3}$ mg litre^{-1}. In certain cases, the chromatographic procedure is combined with other analytical methods.[182,183]

9. Resonance methods

The paramagnetic properties of oxygen made it possible to develop a series of methods and to construct on their basis automatic analysers for the measurement of the concentration of oxygen dissolved in water.[21,184] The range of measured concentrations is 0–50 mg litre^{-1} and the error is 3%. An advantage of this method is the rapid response (in ~1 s) to a change in the oxygen concentration.

The EPR method is based on the use of the phenomenon of the resonance absorption of the energy of electromagnetic waves by paramagnetic species in a steady magnetic field and is used for the continuous determination of oxygen dissolved in water at concentrations in excess of 0.3 mg litre^{-1}. The error is several tens per cent. The concentration of oxygen in liquid mixtures can also be determined by this method.[185] The EPR method is promising, since, in contrast to other gases, oxygen is paramagnetic and can be determined in a mixture of gases.

The NMR method is based on the measurement of the proton spin–lattice relaxation time τ of the paramagnetic species in solution. The time τ is linearly related to the concentration of dissolved oxygen.[186] However, the application of the EPR and NMR methods requires a complex apparatus. The rate of consumption and diffusion of oxygen in cells has been investigated with the aid of NMR.[187]

10. Radiometric methods

These methods are based on the determination of the radioactivity of the elements or compounds formed when nucleons or radioactive elements react with dissolved oxygen. When a liquid sample is irradiated with fast neutrons, ^{16}O is converted into the unstable isotope ^{16}N with a half-life of 7.35 s.

The advantages of the method include a high sensitivity ($2 \times 10^{-4}–2 \times 10^{-2}$ ml litre^{-1}) and the disadvantages include the need for special equipment and calibration. In another radiometric method, the radioactive ^{204}Tl isotope is oxidised by dissolved oxygen.[188] The decrease in the intensity of the emission from ^{204}Tl is directly proportional to the concentration of dissolved oxygen. Salts dissolved in water, which influence the solubility of Tl^+ compounds, have an interfering effect. Furthermore, the extent of the oxidation of thallium depends on the pH and the presence of oxidants.

The indirect determination of the oxygen dissolved in water by atomic absorption spectrometry is based on the interaction of oxygen with thallium and the determination of Tl^+ ions by atomic absorption spectrometry. The sensitivity of the method is 0.019 mg litre^{-1} and the error is 0.04 mg litre^{-1}.[189]

11. The mass-spectrometric method

This method is used when it is necessary to know the isotopic composition of oxygen.[190–195] It is highly sensitive and does not require calibration. The relative error is 2%. A disadvantage of the method is the need for complex equipment.

An isotope-spectroscopic method for the measurement of oxygen concentration has been reported.[196] The method consists in the metered introduction of a rare stable oxygen isotope into the gas analysed, the attainment of a uniform distribution of isotopes in the resulting mixture, and the determination of the isotope composition of oxygen on the basis of emission spectra. The principle of the method is the direct proportionality of the intensity of the spectral lines or bands emitted by the atoms or molecules to their concentration in the discharge, the latter serving as the source of light. The advantages and disadvantages are the same as in the mass-spectrometric method.

The analytical possibilities for the quantitative determination of oxygen dissolved in liquids using a laser microprobe have been investigated.[197] The range of concentrations which can be measured is 0.4–2 g litre^{-1} and the error is 5%.

IV. Results of the experimental study of the solubility of oxygen in water and in electrolyte solutions

The solubility of oxygen in water and in certain electrolytes has been investigated in numerous studies whose results have been compiled and discussed.[1–4,7,198] The solubility of oxygen in pure water and sea water and also in aqueous solutions of acids, alkalis, and salts of alkali and alkaline earth metals has now been studied most fully.[1,4,198]

1. Solubility of oxygen in water at different temperatures

In most studies, the solubility of oxygen in water was investigated in the temperature range 273–348 K at atmospheric pressure. With increase in temperature, the vapour pressure of water increases and it is more difficult to maintain a constant degree of saturation. This entails a decrease in the accuracy of the determination of the experimental solubilities of oxygen. Therefore it has been suggested that the oxygen solubility data[4] be expressed with different errors in two temperature ranges: with an average error of 0.30% at temperatures below 348 K and with an average error of 2% above 348 K. The International Standard ISO 5814-84 lists the solubilities of oxygen in water as a function of temperature (0–40%) and salinity (0–35 g dm^{-3}).[35]

In most studies, the gas used to saturate the solution with oxygen was air and the experimental solubilities of oxygen were adjusted to p_{O_2} = 101.325 kPa taking into account the vapour pressure of water. The use of air instead of pure oxygen is a disadvantage, since, together with oxygen, nitrogen and other gases (nitrogen, carbon and sulphur oxides as well as ammonia) dissolve and interact with water, which may alter the chemical compositions of the solutions and their pH. This factor has not been taken into account in all studies and special measures to purify the air saturating the solutions have not always not been taken. Therefore the studies in which pure oxygen was used to saturate the solutions are the most reliable and accurate. Furthermore, the air or oxygen supplied to the solution must be saturated with water vapour and at elevated temperatures must be heated. Such improvements of the methods have been described.[40,41]

Battino et al.[4] treated by least squares the most reliable experimental data from 15 literature sources in the range 273–348 K and obtained the following expression:

$$\ln X_2 = -64.21517 + 8391.236/T + 23.24323 \ln(T/100). \quad (6)$$

(average error 0.30%), where X_2 is the solubility (mole fractions) of oxygen in pure water and T is the temperature (in K).

Benson et al.[193] proposed the following equation for the description of the temperature dependence of the solubility of oxygen in water in the range 273–373 K:

$$-\ln X_2 = 3.71814 + 5.59617 \cdot 10^3/T - 1.049668 \cdot 10^6/T^2, \quad (7)$$

with an average error of 0.017%.

The solubilities of oxygen in water at 273–373 K, calculated[4] from Eqns. (6) and (7) are presented in Table 1.

The differences between the solubilities of oxygen in water which we calculated by Eqns. (6) and (7) are presented in Fig. 1 as a function of temperature. At temperatures below 323 K, the relative difference of the solubilities is 0.2–0.4%, which agrees with the error (0.3%) of the calculation of the solubility of oxygen by Eqn. (6). At temperatures above 328 K, greater discrepancies between the solubilities of oxygen calculated by the two formulae are observed. This shows that the representation of the oxygen solubility data in the two temperature ranges (273–348 and 348–573 K) proposed by Battino et al.[4] is not altogether correct. It is desirable to restrict the first range to 273–328 K. In this range, the average error of the solubility of oxygen in water does not exceed 0.30%.

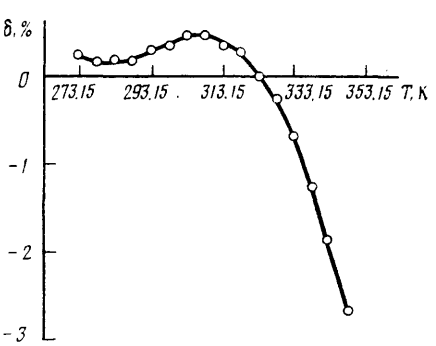

Figure 1. Temperature dependence of the relative difference δ between the solubilities of oxygen in pure water calculated by Eqns. (6) and (7).

The solubility of oxygen in water above 343 K has been studied in a number of investigations.[199–202] The following equation has been obtained[203] on the basis of experimental data:[199,204]

$$\ln X_2 = -54.0411 + 6889.61/T + 18.554 \ln(T/100). \quad (8)$$

The solubilities of oxygen in water at 348–573 K, calculated by Eqn. (8), are also listed in Table 1. The error of the determination of these quantities is 2%.

Table 1. The solubilities of oxygen ($10^5 X_2$, mole fraction) in water at 273.15–573.15 K (p_{O_2} = 101.325 kPa).[4,193,203]

T, K	From Eqn. (6)	From Eqn. (7)	T, K	From Eqn. (6)	From Eqn. (7)	T, K	From Eqn. (8)	T, K	From Eqn. (8)
273.15	3.949	3.958	313.15	1.867	1.874	353.15	1.478	453.15	2.038
278.15	3.460	3.465	318.15	1.773	1.778	358.15	1.462	473.15	2.388
283.15	3.070	3.075	323.15	1.697	1.697	363.15	1.450	493.15	2.852
288.15	2.756	2.761	328.15	1.635	1.631	368.15	1.445	513.15	3.460
293.15	2.501	2.508	333.15	1.586	1.575	373.15	1.444	533.15	4.250
298.15	2.293	2.301	338.15	1.549	1.530	393.15	1.487	553.15	5.276
303.15	2.122	1.982	343.15	1.521	1.493	413.15	1.599	573.15	6.603
308.15	1.982	1.991	348.15	1.502	1.463	433.15	1.780		

The solubility of oxygen in heavy water (D_2O) has been measured as a function of temperature[205] (p_{O_2} = 101.325 kPa):

T, K	278.15	283.15	288.15	293.15	298.15	303.15	308.15	313.15
$10^5 X_2$, mole fraction	3.729	3.332	2.950	2.673	2.459	2.263	2.101	2.000

The solubility of oxygen in D_2O is higher than in H_2O, but the difference diminishes with increase in temperature from 278 to 313 K.

The solubilities of different oxygen isotopes in pure water[193,194] and sea water[195] have been investigated. Heavy oxygen isotopes dissolve in water more readily than the light isotopes.

2. Minima in the temperature variation of the solubility of oxygen in water

Table 1 shows that, with increase in temperature, the solubility of oxygen diminishes to a minimum and then increases. The minimum solubility of oxygen in pure water is observed at 373 K (p_{O_2} = 101.325 kPa) and is independent of whether the water was saturated with air or oxygen.

The minima on the curves relating the solubility of gases in liquids to temperature were first observed in the study of the solubilities of hydrogen[206] and helium[207] in water. On the basis of the general rules governing the behaviour of binary mixtures, it has been pointed out[208] that there must be a minimum in the temperature variation of the solubilities of all gases in liquids.

The presence of a minimum in the temperature variations of the solubilities of gases and the thermodynamic interpretation of this phenomenon have been reported.[209] A minimum has been observed experimentally[210] in the temperature variation of the solubility of radon in water (at T_{min} = 366 K). However, the author himself[210] believed that the minimum in the solubility of radon is an anomalous phenomenon. It has been reported[211] that the minimum in the solubilities of the majority of gases in water occurs in the range 323–343 K. The minimum solubility of oxygen in water at T_{min} = 348 K (p_{O_2} = 10 MPa) has been established experimentally.[212,213] Later the inversion in the influence of temperature on the solubility of oxygen in water was confirmed,[199,200] but the values of T_{min} were found to be higher than those observed previously[212,213] by 37 K (at p_{O_2} = 7–35 atm and 70–140 atm). A minimum has been observed[214] in the influence of temperature on the solubility of oxygen in pure water at approximately 373 K (p_{O_2} = 20–60 atm). The latest studies[201,215] established the presence of a minimum in the solubility of oxygen in water at ~373 K regardless of pressure (in the range 1–5 MPa). An increase in pressure from 0.7 to 5 MPa hardly affects T_{min},[199,201] but a further increase in pressure from 7 to 10 MPa leads to a decrease in T_{min}.[216] The presence of a minimum in the plot of the solubility of oxygen in water against temperature is a firmly established fact. The explanation of this phenomenon is considered below.

3. Solubility of oxygen in water—a recommended standard in the measurements of the solubilities of gases in liquids

The solubility of oxygen in pure water at 298.15 K has been more often and more thoroughly measured than in other gas–liquid systems. After a critical analysis of the most reliable data, Battino and Clever[7] recommended as a standard the solubility of oxygen in pure water at 298.15 K and p_{O_2} = 101.325 kPa, which is characterised by the following parameters: α = 0.02847, L = 0.03108, $X_2 = 2.295 \times 10^{-5}$, and $c_w = 1.274 \times 10^{-6}$.[7] The average error in the calculation of this solubility from seven of the most reliable results is 0.21%.

Numerous data obtained by different workers for the solubility of oxygen in water over a wide temperature range have been analysed[4] and the solubilities in the range 273.15–348.15 K have been recommended with an average error of 0.30% (Table 1). The solubility of oxygen in water, amounting to $X_2 = 2.301 \times 10^{-5}$ (T = 298.15 K; p_{O_2} = 101.325 kPa, was determined in 1979 with an average error of 0.017%.[193] This solubility is greater by 0.35% than the value $X_2 = 2.295 \times 10^{-5}$ recommended by Battino and Clever.[7] The error in the measurement of the solubility of oxygen obtained by Benson et al.[193] is smaller by an order of magnitude than that of the value recommended by Battino and Clever.[7] Therefore the quantity $X_2 = 2.301 \times 10^{-5}$ may be regarded as the most reliable and the solubilities of oxygen obtained by new methods, with the aid of new types of apparatus, etc. should be compared with it.

4. The influence of the nature and concentration of electrolytes on the solubility of oxygen in water

The introduction of electrolytes into water leads as a rule to the salting out of oxygen.[40,198,217] The salting out coefficient, called in the literature the Sechenov coefficient $K_{c\alpha}$, has come to be regarded as a quantitative characteristic of this phenomenon:

$$K_{c\alpha} = 1/c \lg(\alpha_0/\alpha), \text{ [litre mol}^{-1}\text{]}, \quad (9)$$

where c is the molar concentration of the electrolyte and α_0 and α are the solubilities (expressed in terms of the Bunsen coefficients) of oxygen in pure water and in the electrolyte solution. Over a narrow range of electrolyte concentrations and for low values of the latter, Eqn. (9) holds rigorously. This concentration range depends on the nature of the electrolyte and the gas.[1,40,218–220] There exist numerous modifications of the Sechenov equation.[219,221,222] It has been shown[221] that for appreciable electrolyte concentrations it is useful to formulate Eqn. (9) as follows:

$$K_I = 1/I \lg(\alpha_0/\alpha), \text{ [litre mol}^{-1}\text{]}, \quad (10)$$

where the molar concentration of the electrolyte c has been replaced by the ionic strength I:

$$I = 1/2\sum c_i Z_i^2, \text{ [litre mol}^{-1}\text{]},$$

where c_i is the molar concentration of the ith ion and Z_i is its charge. Eqn. (10) holds for $I \leqslant 5.6$.[223]

It has been proposed[218,219] that the dependence of the logarithm of the solubility of oxygen on the electrolyte concentration over a wide range of the latter be described by the formula

$$\lg(\alpha_0/\alpha) = K_c^0 c/(1 + K_c' c), \quad (11)$$

where K_c^0 and K_c' are constants. For $c \to 0$, Eqn. (11) is converted into the Sechenov equation (9). The available literature values of the coefficients for the salting out of oxygen from solutions in 70 electrolytes, calculated with the aid of Eqn. (9) over a wide range of experimental conditions, have been compiled and tabulated.[220] In one of the latest studies,[13] the coefficients for the salting out of oxygen from solutions of 68 electrolytes at 310.2 K and p_{O_2} = 101.325 kPa were determined. In some communications, there is no information about the determination of the particular equilibrium concentration (solubility) of oxygen and the errors of the calculation of the salting out coefficients are not indicated. The corresponding data are not considered in this review. The oxygen salting out coefficients depend on the nature of the anions and cations, temperature and pressure, and for certain electrolytes also on their concentration.

(a) Solutions of acids

Coefficients for the salting out of oxygen from aqueous HCl, H_2SO_4, and HNO_3 solutions are presented in Table 2. The solubility of oxygen as a function of H_2SO_4 concentration is described by a curve with a maximum.[224] The oxygen salting out coefficients decrease with increase in the H_2SO_4 concentration.[224] An appreciable effect of pressure (in the range 0.5–1.5 MPa) on K_c has not been observed.[228] The coefficient for the salting out of oxygen from 1 M H_2SO_4 is 0.10 litre mol^{-1} (p = 5 MPa) at 323 K and hardly changes with increase in temperature to 523 K.[225] Extrema are observed in the dependence of the solubility of oxygen on the HNO_3 concentration and temperature. This will be described in detail below.

The dependence of the logarithm of the solubility of oxygen on the H_3PO_4 concentration (in the range 1.5–14.6 M) at 298–333 K is not linear.[229] The literature data[166,230,231] concerning the influence of the H_3PO_4 concentration (85–100 wt.%) and temperature (373–423 K) on the solubility of oxygen are contradictory.

Table 2. The coefficients of the salting out of oxygen from 1.0 M HCl, H_2SO_4, and HNO_3 solutions.

Acid	T, K	p_{O_2}, MPa	$K_{c\alpha}$, litre mol^{-1}	Refs.

RbOH	0–0.5	0.168	0–3.187	0.161
CsOH	0–0.5	0.158	0–2.325	0.153

* c is the range of concentrations of alkalis for which $K_{c\alpha}$ has been determined.

Note. The numerals in square brackets denote references (Translator).

(b) Solutions of alkalis

The coefficients for the salting out of oxygen from solutions of alkali are presented in Table 3, which shows that two different values of $K_{c\alpha}$ are observed in LiOH solutions at 298.15 K: in the region of low (up to 0.07 M) and high (0.15–1.2 M) electrolyte concentrations. A similar effect has been established in a study of the solubility of oxygen in NaOH solutions at 323–423 K and p_{O_2} = 1–5 MPa:[232] an anomalously large oxygen salting out coefficient has been observed in 0.01–0.1 M NaOH solutions (K_c =

0.65 litre mol^{-1}). An increase in temperature from 323 to 523 K (p_{O_2} = 5 MPa) hardly affects K_c in NaOH solutions.[225] At 310.2 K, the quantity $K_{c\alpha}$ is constant over the entire concentration range (0–4.059 M) of LiOH.[13] The dependence of the solubility of oxygen on the KOH concentration is described satisfactorily by the Sechenov equation (9) over a wide range of concentrations (0–16 M) and temperatures (288–373 K).[229,233–235]

The coefficient for the salting out of oxygen from NH_4OH solution is very low (k_c = 0.006 litre mol^{-1}) and hardly changes with increase in the NH_4OH concentration (0–8 M) and temperature (323–423 K).[225]

(c) Salt solutions

Salts as a rule salt out oxygen from solutions (Tables 4–6). It is seen from Tables 4–6 that the oxygen salting out coefficients as a rule increase with decrease in the atomic number and size of the ion. For salts with the F^-, BO_2^-, and $B_4O_7^{2-}$ ions, anomalously large values of K_c have been observed.[220] Salts with H^+, NH_4^+, and Li^+ cations are exceptions (Table 6).

Table 4. The coefficients K_c (litre mol^{-1}) of the salting out of oxygen from solutions of alkali metal halide salts (T = 298.15 K, p_{O_2} = 0.1 MPa).[40]

Ion	F^-	Cl^-	Br^-	I^-
Li^+	0.725 –0.385	0.112 0.070	0.252 0.084	0.163
Na^+	0.284	0.145	0.131	0.120
K^+	0.203	0.129	0.117	0.093
Rb^+	0.146	0.120	0.104	0.086
Cs^+	0.114	0.098	0.078	0.062

Note. The concentration range was 0–1.2 M for the sodium and potassium salts and LiI and 0–0.5 M for rubidium and caesium salts. For LiF, the first value of K_c was measured in the range 0–0.01 M and the second in the range 0.04–0.1 M; for LiCl and LiBr, the first value of K_c was measured in the range 0–0.07 M and the second in the range 0.15–1.2 M.

It is noteworthy that two oxygen salting out coefficients can be observed in solutions of lithium salts: in the region of low (up to 0.7 M) electrolyte concentrations and in the region of high concentrations (0.15–1.2 M).[40] In the first concentration range, the coefficients K_c are greater by a factor of 2–3 than in the second. An analogous effect has been established for $NaHCO_3$.[232] The same [constant] value of K_c has been observed only for the salts LiI, Li_2SO_4, and Li_2CO_3 at concentrations in the range 0–1.2 M). Constant values of K_c have been established[13] for the salts LiCl, $LiNO_3$, and Li_2SO_4 over a wide concentration range (Table 6). The anomalous behaviour of lithium salts in relation to oxygen persists over a wide temperature range[217,220] and has been explained by the appreciable hydration of lithium ions, as a result of which the amount of free water diminishes markedly and this leads in its turn to a corresponding decrease in the solubility of oxygen.

It is seen from Tables 2–6 that there are differences in the salting out of oxygen by acids, alkalis, and salts. The replacement of hydrogen in acids by a metal cation results in an appreciable increase in K_c. The oxygen salting out coefficients K_c are smaller for many salts than for alkalis. Alkali metal, ammonium, p metal (Mg, Ca, Ba, Al) and d metal (Mn, Fe, Co, Ni, Cu, Zn) carbonates, phosphates, and borates hydrolyse, as a result of which different forms of the salts exist in solution and it is difficult to attribute the salting out coefficient to any particular form. The coefficients for the salting out of oxygen from solutions in these salts therefore require careful checking. An example is provided by the values of $K_{c\alpha}$ for the salting out of oxygen from NH_4Cl solutions obtained in two investigations.[12,218] The solubilities of oxygen in NH_4Cl solution established by MacArthur[218] have been included in many textbooks[11] and handbooks.[10] However, measurements in recent years have shown[12,13] that $K_{c\alpha}$ for oxygen in NH_4Cl solution is appreciably smaller ($K_{c\alpha}$ = 2.76 litre mol^{-1}) than the value obtained previously[218] ($K_{c\alpha}$ = 2.79 litre mol^{-1}). In order to prevent the hydrolysis of p and d metal salts, a small amount of acid (0.01–0.04 M), which does not affect appreciably the solubility of oxygen, was added by Lang and Zander.[13] One can therefore postulate that Lang and Zander[13] determined the values of $K_{c\alpha}$ for oxygen in the presence of non-hydrolysed salts.

Table 5. The coefficients K_c (litre mol^{-1}) of the salting out of oxygen from solutions of alkali metal salts with oxygen-containing anions at 298.15 K (p_{O_2} = 0.1 MPa).[40*]

Ion	ClO_4^-	NO^-	SO_4^{2-}	CO_3^{2-}	PO_4^{3-}
Li^+	0.218 (0–0,07 M) 0.066 (0.15–1.2 M)	0.196 (0–0.07 M) –0,040 (0.15–1.2 M)	0.244 — —	0.254 — —	— — —
Na^+	0.160	0.124	0.376	0.464	0.652 (0–0.6 M)
K^+	0.150 (0–0,12 M)	0.105	0,297 (0–0,6 M)	0.379	0.507 (0–0.6 M)
Rb^+	0.138** (0–0.1 M)	0.096 (0–0,5 M)	0.290 (0–0,3 M)	—	—
Cs^+	—	0.066 (0–0,5 M)	0,255** (0–0.45 M)	—	—

*The salt concentration ranges for which the values of K_c were calculated are indicated in brackets; in the remaining cases the concentration range was 0–1.2 M.

**The values of K_c for the salting out of oxygen from $RbClO_4$ and Cs_2SO_4 solutions quoted by Battino et al.[4] are incorrect; the values from the original source[40] are quoted here.

The electron shells of s, p, and d elements have a significant influence on the values of $K_{c\alpha}$ (Fig. 2). Fig. 2 shows that $K_{c\alpha}$ for oxygen is a periodic function of the atomic number of the element in the Periodic System. The periodicity of the function is manifested by the fact that a similarity is observed between sections of the given

relation within Periods, i.e. there is a periodic variation in $K_{c\alpha}$ with increase in the atomic number of the element.

Table 6. The coefficients $K_{c\alpha}$ (litre mol^{-1}) of the salting out of oxygen from salt solutions (T = 310.2 K; p_{O_2} = 0.1 MPa).[13]

Ion	Cl^-	NO_3^-	SO_4^{2-}	HSO_4^-

Ce^{3+}	0.347 (0—2.462 M)	0.236 (0—2.952 M)	—	—
Th^{4+}	—	0.302 (0—1.385 M)	—	—

Note. The salt concentration ranges for which the values of $K_{c\alpha}$ have been calculated are indicated in brackets; the error of the calculation of $K_{c\alpha}$ is 1—4%; the values of $K_{c\alpha}$ for the salts $ZnCl_2$ and $CdCl_2$ were calculated from the slope of the lg α—c curve in the salt concentration range 0—0.5 M.

(d) The influence of pH on the solubility of oxygen

We are aware of only two studies[236,237] in which the influence of pH on the solubility of oxygen in water and electrolyte solutions was investigated. Both in pure water and in 0.1 M CH_3COONa solution, the solubility of oxygen is independent of pH in the range from 2 to 12 at 293—313 K. Only when the pH is reduced from 2 to 0 and increased from 12 to 14 does the solubility of oxygen diminish, which is due to the presence of considerable amounts of HCl and NaOH respectively. The solubility of oxygen in 0.1 M Na_2SO_4 solution does not change when the pH is reduced from 6 to 1.

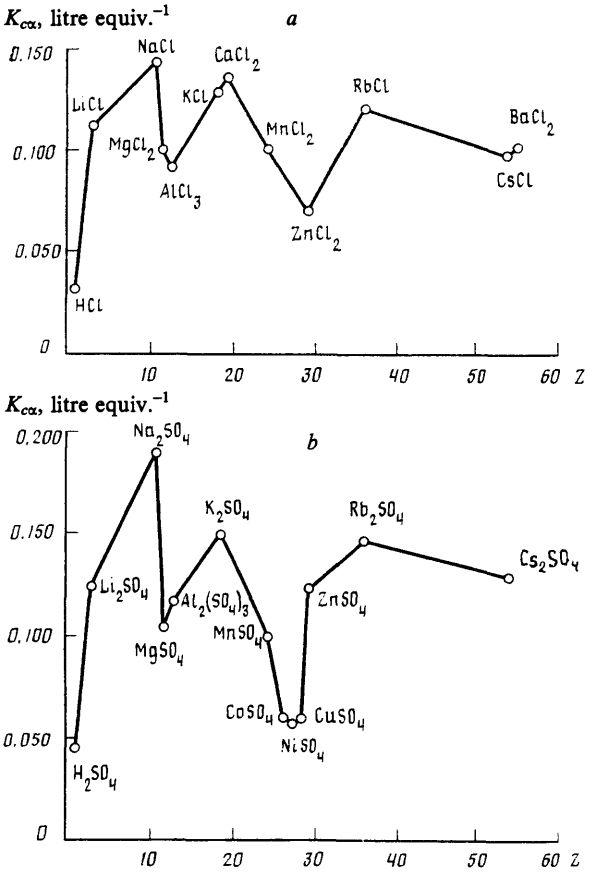

Figure 2. Dependence of the oxygen salting-out coefficient in solutions of chlorides (*a*) and sulphates (*b*) on the atomic number of the cation in the Periodic System; T = 298.15 K; p_{O_2} = 101.325 kPa (the quantities $K_{c\alpha}$ for $CoSO_4$, $NiSO_4$, and $CuSO_4$ were obtained at p_{O_2} = 5 MPa[225]).

5. The influence of temperature and pressure on the oxygen salting out coefficients

With increase in temperature, the coefficients $K_{c\alpha}$ for the salting out of oxygen from electrolyte solutions as a rule diminish.[220] The influence of temperature (in the range 298—523 K) on the values of $K_{c\alpha}$ in solutions of ammonium, copper, zinc, nickel, and cobalt sulphates and ammonium chloride is slight.[184] The temperature coefficients of the quantities $K_{c\alpha}$ depend on pressure. With increase in oxygen pressure, the coefficients for salting out from $(NH_4)_2SO_4$ solutions increase and those for salting out from NH_4OH

and $NaHCO_3$ solutions diminish.[232,238] At elevated temperatures ($T > 423$ K), the influence of pressure on the coefficients $K_{c\alpha}$ decreases. At high electrolyte concentrations (~ 0.5 M) and pressures up to 2 MPa, the coefficients $K_{c\alpha}$ diminish with increase in temperature.[232] At high temperatures ($\sim 400-428$ K) there is an inversion: with increase in temperature from 273 to 400–428 K, the coefficients $K_{c\alpha}$ diminish to a minimum and increase on subsequent increase in T (above 428 K).[202,232]

Minima in the dependence of $K_{c\alpha}$ on T are observed at temperatures exceeding by 25–50 K the temperature of the minimum solubility of oxygen in water.

6. The influence of pressure on the solubility of oxygen in electrolyte solutions

At oxygen pressures up to 3 MPa, solutions of oxygen both in water and in electrolyte solutions rigorously obey Henry's law expressed in the form applied to ideal systems.[212,229,232,239–241] The temperature and electrolyte concentration influence the behaviour of the oxygen–liquid phase systems.[201,232] At 323 K and $p_{O_2} > 3$ MPa, deviations from Henry's law are observed in dilute electrolyte solutions. With increase in electrolyte concentration, the deviations from Henry's law diminish.[232]

7. The solubility of oxygen in solutions of mixtures of electrolytes. The problem of the calculation of individual ionic oxygen salting-out coefficients

The solubility of oxygen has been investigated in solutions of mixtures of certain electrolytes.[242–248] It has been established[243–245,247] that the solubility of oxygen in solutions of mixtures of electrolytes is close to the corresponding solubility for the dominant electrolyte in the solution. However, it has been noted[248] that the salting out depends on the overall salt concentration in solution.

Solubilities of oxygen in solutions of KCl, $CaCl_2$, and $AlCl_3$ at the same equivalent concentrations and in their mixtures are the same and independent of the nature of the cation.[246] The availability of only a few and contradictory data hinders the calculation of the individual ionic oxygen salting-out coefficients and the analysis of their additivity.

We shall consider the existing literature procedures for the calculation of individual ionic oxygen salting-out coefficients. On the assumption that the salting out effect of ions and salts is additive, it has been suggested that the overall salting out effect be described with the aid of the formula:[249,250]

$$\lg (c_0/c) = \sum h_i I_i ,$$

or:[12]

$$\lg (c_0/c) = \sum K_i m_i, \qquad (12)$$

where h_i are constants referring to salts or ions, I_i are the contributions of ions of the *ith* kind to the ionic strength of the solution, K_i are individual ionic salting-out coefficients, and m_i are the molalities of the ith components (in the ionic or molecular form).

It has been suggested[251] that the salting-out coefficient be regarded as the sum of three constants characterising the behaviour of the gas (K_g), the cation (K_c) and the anion (K_a):

$$K = K_g + K_c + K_a, \qquad (13)$$

where K_g is the component of the gas salting-out coefficient independent of the nature of the electrolyte in the solution of which the gas is being dissolved and which depends solely on temperature, while K_c and K_a are the components of the salting-out coefficient referring to the cations and anions which are independent of temperature.

Van Krevelen and Hoftijzer[251] failed to give a theoretical justification of Eqn. (13) and did not indicate a method for the determination of the quantities K_g, K_c, and K_a although the values of K_c and K_a for 13 ions are quoted (Table 1). The assumption of the additivity of the salting-out coefficient underlies Eqn. (13).

The authors[251] assumed arbitrarily (without explanation) that $K_{H^+} = K_{NO_3^-} = 0$. It may be that the authors assumed that the coefficient for the salting out of oxygen from HNO_3 solutions at 298 K is lowest (Table 2). Lang and Zander[13] calculated the individual ionic oxygen salting-out coefficients on the assumption that $K_{Na^+} = 0$ (Table 7). The Na^+ ion was selected as the reference ion on the grounds that the Na_2SO_4 molecules are more effectively dissociated than H_2SO_4.

The idea of subdividing the gas salting-out coefficient into three components [see Eqn. (13)] was used by a number of workers[223,250,252] who obtained individual ionic oxygen salting-out coefficients (Table 7) from the experimental coefficients for the salting out of oxygen from electrolyte solutions by the method of least squares (i.e. by minimising the squares of the differences between the experimental K_c and the values of K_c calculated from the ionic salting-out coefficients K_i). These coefficients have been related[12] to the Sechenov constant by means of Eqn. (12), while other investigators[13,250,252] used for this purpose the equation:

$$K_{c\alpha} = 1/2 \sum_i K_i n_i Z_i^2,$$

where n_i is the number of ions of the ith kind referred to one electrolyte molecule and Z_i is the ionic charge.

For the same ions, the individual ionic salting-out coefficients, obtained by different workers, are not identical owing to the differences between the reference systems and between the methods of calculation of the ionic salting-out coefficients adopted. In order to eliminate the differences between the relative reference systems, a single reference system has been proposed.[253] It makes it possible to recalculate the ionic salting-out coefficients with the aid of the formulae

$$K_c^* = K_c - K^+, \qquad (14)$$

$$K_a^* = K_a - K^-, \qquad (15)$$

$$K_g^* = K_g + K^+ + K^-, \qquad (16)$$

and thus to compare the individual ionic oxygen salting-out coefficients obtained by different workers. In Eqns. (14)–(16), K_c and K_a, and K_g are the individual salting-out coefficients calculated by the method of least squares[223,250] or by some other procedure from the experimental values of K_c and K^+ and K^- are arbitrary constants referring to the cation and anion respectively. On adding together Eqns. (14)–(16), we obtain

$$K = K_c^* + K_a^* + K_g^*.$$

The new values of K_i^*, characterising the behaviour of the gas (K_g^*), the cation (K_c^*), and the anion (K_a^*), are evidently equivalent to the values of K_g, K_c, and K_a respectively in Eqn. (13), since the summation of the former three quantities (K_i^*) leads to the same value of K as the summation of the latter three quantities (K_i).

The NaCl solution–O_2 system, for which $K_c = K_c^*(Na^*) = 0.091$ and $K_a = K_a^*(Cl^-) = 0.021$ and which has been most thoroughly investigated, has been proposed as the reference system.[253]

However, a subsequent check[254] of the proposed method indicated considerable discrepancies between the ionic salting-out coefficients obtained by different workers.[12,250]

A satisfactory agreement has been established[12,223,250,252] between the experimental and calculated (assuming additivity) coefficients for the salting out of oxygen from aqueous and non-aqueous solutions of certain electrolytes. However, analysis of the oxygen salting-out coefficients based on additivity using individual ionic salting-out coefficients[12,223,250] with the aid of the constant differences law showed[254] that additivity is by no means observed in all cases. The best agreement between the experimental oxygen salting-out coefficients and the values calculated assuming additivity has been observed for nitrates, sulphates, chlorides, bromides, hydroxides, and perchlorates. Considerable discrepancies have been observed between K_{exp} and K_{calc} for fluorides, lithium salts, and lithium hydroxides, ammonium hydroxide, carbonates, and phosphates.[254] These discrepancies may be caused by the unreliability of the experimental coefficients for the salting out of oxygen from certain electrolyte solutions, the possibility of complex formation (lithium salts), and the hydrolysis of many salts (carbonates and phosphates).

V. Extrema in the influence of temperature and electrolyte concentration on the solubility of oxygen

In most modern textbooks of chemistry and physical chemistry and also in the Short Chemical Encyclopaedia and in certain monographs,[255,259] it has been reported that either all gases dissolve in liquids with evolution of heat and that the solubility of gases in liquids diminishes as the temperature is raised or that there are rare exceptions where the solubility of a gas at normal pressures increases with increase in temperature.

However, experimental facts have shown that the inversion of the influence of temperature and electrolyte concentration on the solubility of oxygen and other non-polar gases in water and electrolyte solutions is not all that rare a phenomenon. Experimental data are available concerning the presence of a minimum in the temperature variation of the solubility of oxygen not only in water[199,201,202] but also in organic and inorganic solvents,[260–262] in electrolyte solutions,[212,217,225,227] and in natural salt solutions.[202,215]

Measurements of the solubility of oxygen in pure water over a wide range of temperatures and pressures carried out most thoroughly during the last ten years have shown that the temperature of the minimum solubility of oxygen in pure water is 373 K (p_{O_2} = 0.1–5 MPa).[201,202] It is seen from Table 8 that in aqueous electrolyte solutions this temperature is lower and depends on the nature and concentration of the electrolyte (Figs. 3 and 4).[217,226,227] An increase in the electrolyte concentration shifts the region of the solubility minimum towards lower temperatures. The depth of the minimum also diminishes under these conditions. An increase in pressure from 1 to 5 MPa hardly affects the temperature of the minimum solubility of oxygen in the electrolyte solution but increases the depth of the minimum.[232]

Thus the presence of a minimum in the temperature variation of the solubility of oxygen in water and in electrolyte solutions should be regarded as a firmly established fact. The practical importance of this phenomenon is that it can be used in the development of rational conditions for the deoxygenation of sewage and industrial waters, i.e. for the deaeration process at the temperature of the minimum solubility of oxygen, for the selection of the conditions for the autoclave dissolution of sulphide products, in processes designed to protect power station equipment against oxygen, etc.[214,263]

Table 8. Experimental quantities characterising the minima in the temperature variations of the solubility of oxygen in water and aqueous electrolyte solutions.

1. The salting in of oxygen by aqueous electrolyte solutions

The salting out of oxygen is characteristic of many electrolytes over a wide range of experimental conditions.[220] However, in many instances salting in takes place.[40,238,264] The salting in phenomenon has been observed for a number of electrolytes both at 298 K (LiF, $NiNO_3$,[40] HNO_3,[226,227] $Na_2B_4O_7$,[165] and tetraethylammonium bromide[264]) and at higher temperatures of ~333—423 K (LiCl, $NaBO_2$, $Na_2B_4O_7$,[220] NH_4OH,[238] HNO_3,[226,239] H_3PO_4 [231]). The salting in of oxygen in the presence of salts is observed in the range of low concentrations of the latter where most of the water is not bound to the electrolyte ions. On the other hand, for acids and alkalis salting in is observed at high electrolyte concentrations.[227,231,265] The salting in of oxygen in dilute $Na_2B_4O_7$ solutions has been explained by the formation of oxygen-borate complexes.[165]

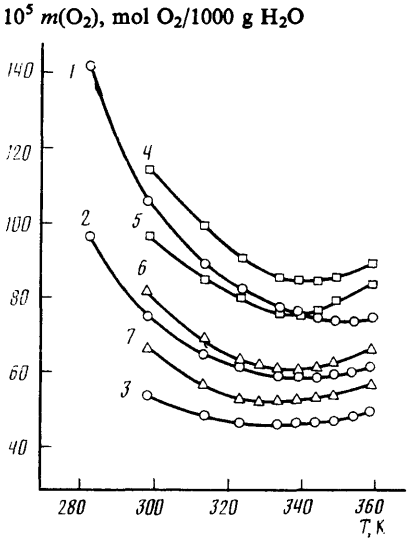

Figure 3. Temperature dependence of the solubility of oxygen in aqueous solutions of Na_2SO_4 (curves *1*—*3*), LiCl (curves *4* and *5*), and Li_2SO_4 (curves *6* and *7*) at different molalities *m*: *1* and *4*, 0.2; *2* and *6*, 0.6; *3* and *5*, 1.0; *7*, 0.95.[217]

The increase in the solubility of oxygen in HNO_3 with increase in temperature has been attributed to the decomposition of HNO_3:[266]

$$2HNO_3 \rightleftarrows N_2O_4 + H_2O + {}^1/_2O_2.$$

Apparently the inversion in the influence of the electrolyte concentration on the solubility of oxygen is associated both with the characteristics of the dissociation of electrolytes and with the formation of oxygen complexes and the structural changes occurring in solutions.

2. Theoretical justification of the inversion in the influence of temperature on the solubility of oxygen

The first explanation of the minima on the curves relating the solubilities of gases in liquids to temperature is due to Winkler.[267] On the basis of the relation between the absorption of a gas and the internal friction (viscosity) and density of the liquid, he showed that the changes in the latter two properties as a function of temperature affect the solubility of the gas in opposite ways, which leads to a minimum in the temperature variation of the solubility of the gas in the liquid.

According to Kuenen,[208] the minimum in the temperature variations of the solubilities of gases in liquids is due to the fact that, above the critical temperature of the solvent, both components mix in all proportions, i.e., as the critical point is approached, an increase in solubility should be observed. Therefore in cases where

the solubility of the gas diminishes with increase in temperature, the minimum solubility should occur at a higher temperature. Consequently the existence of a minimum is a common phenomenon and is not associated with specific properties of the solvent and the dissolved gas.

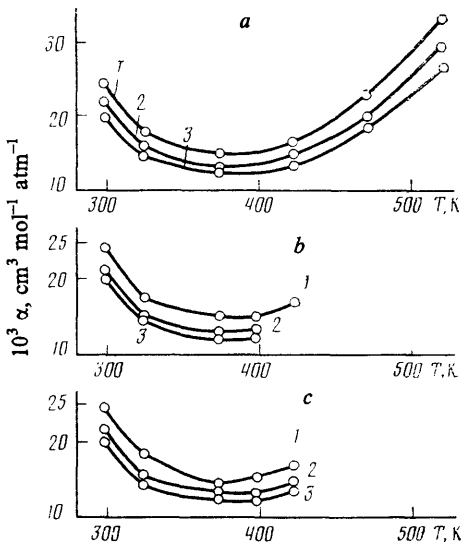

Figure 4. Temperature dependence of the solubility of oxygen in solutions of $CuSO_4$ (*a*), $CoSO_4$ (*b*), and $NiSO_4$ (*c*) at different salt concentrations (M): *1*, 0.5; *2*, 1.0; *3*, 1.5.[225]

The next attempt to explain the presence of a minimum in the curves for the temperature variation of the solubilities of gases in water was made by Tammann[211] in 1926 on the basis of the hydration theory. However, the gas solubility minima are encountered also in non-aqueous solvents.[260–262]

According to modern ideas,[268,269] there are two mechanisms of the dissolution of a gas in water and in aqueous electrolyte solutions: the filling of vacancies and the substitution of water molecules in the structural framework of water. These two mechanisms have been called vacancy and solvation mechanisms by Borina and Samoilov,[268] the insertion and insertion-substitution mechanisms by Frank and Quist,[270] and the hydrophobic and hydrophilic mechanisms by Krestov.[271] The diminution of the vacancy contribution and the increase in that of the solvation contribution with increase in temperature are responsible for the presence of a minimum in the curves for the temperature variation of the solubility of oxygen (as well as other non-polar gases in water).[268]

The phenomenon of inversion in the influence of temperature on the solubility and the salting-out coefficients of oxygen in water and in electrolyte solutions can be understood in the light of the thermodynamic theory[272–274] and with the aid of the structural model of solutions of non-polar gases in water.[272,275] The presence of a minimum in the curves for the temperature variation of the solubility of oxygen implies that the dissolution is exothermic at $T < T_{min}$ and endothermic at $T > T_{min}$. On the assumption that the ice-like framework is stabilised in the vicinity of the gas molecule, the minimum in the temperature variation of the solubility of a gas has been explained[272] with the aid of thermodynamic analysis. The partial molar enthalpy of solution of the gas was expressed in the form

$$\bar{H}_2 = \bar{H}_2^0 + \Delta\bar{H}^0\left(\frac{\partial\nu}{\partial y}\right)_p - \overline{H}_2^\circ + H_2^{st},$$

where $\overline{H}_2^\circ$ is the partial enthalpy of gas molecules in solution subject to the exclusion of the structural contribution corresponding to the redistribution of the molecules between the vacancies and the framework, $\Delta\overline{H}^\circ$ is the enthalpy of the transfer of one mole of water from the cavities in the water structure to the framework, ν is the fraction of water molecules at the lattice sites of the framework, and $y = N_2/N_1$, N_1 and N_2 being the numbers of water and gas molecules in the system. The structural component H_2^{st} diminishes with increase in temperature, because $\Delta\overline{H}^\circ$, defined by the formula

$$\left(\frac{\partial\nu}{\partial y}\right)_p = \nu(1-\nu)[\nu - 2(1-\nu)] \cdot \frac{\Delta\bar{H}^0}{RT^2},$$

decreases with increase in temperature. The structural component of the hydrophobic hydration of a gas diminishes with increase in temperature, while the exothermic component of the transfer of molecules from the vacancies in the water structure to the framework disappears, as a result of which the overall heat of solution of gases becomes positive.

A method has been proposed[276] for the determination of the temperature of the minimum solubility of a gas in a liquid. For this purpose, the relation between the standard thermodynamic characteristics calculated from the solubility (ΔH_2°) and in terms of the phase distribution constant ($\Delta H_2^\ominus$) is expressed in the form

$$\Delta H_2^\ominus = \Delta H_2^\circ - \Delta H_{cond,1}^\circ, \qquad (17)$$

where $\Delta H_{cond,1}^\circ$ is the standard enthalpy of condensation of the solvent under a pressure p_1.

In contrast to the generally adopted approach in the study of the dissolution of a gas in a liquid (G⇄S), Krestov and Kudryavtsev[276] suggested that account be taken of the composition of the vapour phase, i.e., that the dissolution should be described by G + V⇄S, where G, V, and S are respectively the symbols for the gas, the vapour, and the solvent in the solution.

Since at the temperature of the minimum solubility of the gas $\Delta H_2^\circ = 0$, Eqn. (17) becomes:

$$\Delta H_2^\ominus = -\Delta H_{cond,1}^\circ,$$

The point of intersection of the $\Delta H_2^\ominus(T)$ and $\Delta H_{cond,1}^\circ(T)$ relations defines the temperature of the minimum solubility of the gas.

The experimental data show that the temperature dependence of the oxygen salting-out coefficient is also described by a curve with a minimum.[215,232] In the literature attempts have been made[274] to establish the causes of the inversion in the influence of temperature on the coefficients for the salting-out of non-polar gases from aqueous electrolyte solutions.

The temperature dependence of the coefficient of the salting out of a gas from aqueous solutions has been found:

$$\left(\frac{\partial K_{c\alpha}}{\partial T}\right)_p = \frac{H_1 - H_1^*}{2{,}3\,mRT^2} = \frac{\partial \lg (f_1^*/f_1^0)}{\partial T}, \qquad (18)$$

where H_1 and H_1^* are the enthalpies of water molecules in water and in solution, f_1^* and f_1° are the fugacities of water over the solution and pure water, and m is the molal electrolyte concentration. The

experimental vapour pressures of water over electrolyte solutions show that the differences $H_1 - H_1^* > 0$ and increase with temperature. In conformity with Eqn. (18), the quantities $K_{c\alpha}$ should increase more rapidly with temperature at high values of the latter.[274] However, it is not stated[274] why $K_{c\alpha}$ decreases with increase in temperature at low values of the latter.

On combining the Gibbs–Helmholtz equation and the Sechenov equation, one can obtain

$$\frac{\partial K_{c\alpha}}{\partial T} = \frac{(H_2)_{H_2O} - (H_2)_{soln}}{2.3\, mRT^2} = \frac{1000}{m\rho} \frac{\partial \lg (f_2/f_2^0)}{\partial T} - K_{c\alpha} \frac{\partial \ln \rho}{\partial T},$$

where $(H_2)_{H_2O}$ and $(H_2)_{soln}$ are the enthalpies of dissolved oxygen molecules in pure water and in solution respectively, ρ is the density of the solution, and f_2^0 and f_2 are the fugacities of dissolved oxygen in pure water and in solution.

Apparenty both the appearance of a minimum on the curves relating the solubility of oxygen to temperature and the minimum in the temperature dependence of $K_{c\alpha}$ are caused by the structural changes in the solution, i.e. the quasi-clathrate (vacancy) and quasi-crystalline (solvation) structures of the oxygen solution predominate at low and high temperatures respectively. The temperature-dependent differences in the nature of the oxygen dissolution process are caused by the different relative enthalpies of dissolved oxygen in water and in the solution, which leads to a minimum on the curves for the temperature variation of the salting-out coefficient.

---o0o---

The great role of oxygen in many chemical, biochemical, electrochemical, ecological, and corrosion processes has made it necessary to know its solubility in water and in electrolyte solutions. This requires in turn the existence of precise, highly sensitive and convenient methods for the determination of the concentration of dissolved oxygen. Electrochemical methods, in particular membrane voltammetric sensors, which make it possible to measure the concentration of dissolved oxygen in various gas–liquid systems over a wide range of experimental conditions, have come to be most widely used during the last five years. However, the smallest error (less than 0.1%) can be achieved with the aid of the volumetric method.

Despite the large number of methods of expressing the solubility of oxygen, preference has been given at the present time to the Henry coefficient (K_H) and the mole fraction (X_2).

The solubility of oxygen in water is the recommended standard quantity in the measurements of the solubilities of gases in liquids.

Temperature and the nature and concentration of the electrolytes exert a significant influence on the solubility of oxygen in water. The problem of the individual ionic oxygen salting-out coefficients has been discussed for the first time.

The greatest advances have been made in the study of the influence of temperature and the nature and concentration of electrolytes on the solubility of oxygen. Such studies have led to the discovery of extrema involving a change in the sign of the temperature variation of the solubility of oxygen in water and in electrolyte solutions and also a change from salting out to salting in (or conversely) with increase in the concentrations of certain electrolytes and temperature.

Interaction of uranium oxides with dinitrogen tetroxide

L V Kobets, G N Klavsut'
Sevchenko Institute of Applied Physical Problems, Minsk

ABSTRACT. Data on the interaction of nitrogen oxides in different oxidation states with dinitrogen tetroxide in the temperature range 273–1073 K and in the pressure range 0.1–10 MPa are surveyed. The mechanisms of the interaction of the dissociating $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ system, liquid N_2O_4, and N_2O_4–organic solvent mixtures with uranium oxides are discussed as a function of the oxidation state of uranium, the specific surface and structure of the oxides, the state of aggregation of N_2O_4, the presence of impurities in the latter, and the presence of organic solvents. The behaviour of uranium oxides in relation to that of the other metal oxides is subjected to a comparative analysis.

The bibliography includes 91 references.

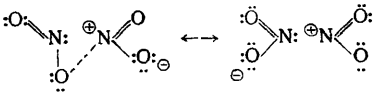
I. Introduction

The present development of chemical industry and engineering requires the use of non-traditional liquid media (non-aqueous and mixed solvents) with a wide range of varied properties. They make it possible to solve problems involving the optimisation of processes, ecological problems, the creation of waste-free technologies, etc., which are in principle impossible in aqueous solutions.

In the field concerned with the use of non-aqueous solvents, there has been in recent years the most vigorous accumulation of qualitative and quantitative data necessary for the study of the general characteristics of the behaviour of such media and for the creation of theoretical foundations for processes involving interactions in non-aqueous solvents.

Liquid dinitrogen tetroxide N_2O_4 is a typical representative of the class of non-aqueous inorganic solvents. Its physicochemical properties had been investigated previously for the purposes of preparative chemistry in the synthesis of anhydrous nitrates. A new stage in the study of the properties of N_2O_4 involved its application as an oxidant in rocket engines and later as a possible heat exchanger in atomic power stations.[1–4]

N_2O_4 is known to be a very reactive chemical substance which can exist in both liquid and gaseous states depending on the conditions. The chemical properties of N_2O_4 in different states of aggregation differ appreciably. At atmospheric pressure, N_2O_4 exists in the liquid state at temperatures in the range 261.8–294.15 K. The temperature range of the stability of liquid N_2O_4 extends to 473, 523, and 553 K and pressures of 0.5, 2.0, and 10 MPa respectively.



In the temperature range 263–283 K, N_2O_4 has a high density (1.470–1.515 g cm^{-3}), a low viscosity (0.468–0.599 cP),[4] and a low surface tension, amounting to 26.5 dyn cm^{-1} at 293 K and comparable to that of many volatile organic solvents. The electrical conductivity of N_2O_4 (10^{-12} Ω^{-1} cm^{-1}) is much lower than the corresponding values for liquid NH_3 and H_2O (10^{-11} at 239.6 K and 10^{-8} and 293 K).[5] The dielectric constant of liquid N_2O_4 is only 2.42 at 291 K [6] and its dipole moment is close to zero.[6]

The structures of the gaseous and solid tetroxide have been discussed in a number of studies.[7–9] According to revised data,[9] the r(N–N) distance in gaseous N_2O_4 is 0.1782 ± 0.0008 nm, r(NO) = 0.1190 ± 0.0001 nm, and ∠ONO = 135.4°. In the solid state, r(N–N) is reduced to 0.174 nm and the angle is reduced to 126°.[8] The structure of N_2O_4 has a number of features. While the N_2O_4 molecule is planar, its N–N bond length is unusually large (greater by 0.03 nm than in N_2H_4 and N_2F_2). The interatomic distances in the NO_2 groups are virtually the same as in the NO_2 molecule. The latter is consistent with the low dissociation constants of N_2O_4 at 293 K (3.43×10^{-4}–2.6×10^{-3}). It has been suggested,[10] within the framework of the valence bond method, that the greatest energy contribution to the stabilisation of the planar structure comes from the structure involving three-electron O···O bonds between the *cis*- and *trans*-oxygen atoms as a consequence of the resonance

$$O\cdot{:}O^- \leftrightarrow O\cdots O \leftrightarrow O^+{:}\,O^- \leftrightarrow O^-{:}\cdot\,O^+,$$

and

$$O^-{:}\cdot O \leftrightarrow O\cdot{:}O \leftrightarrow O^-{:}\cdot O^+.$$

Of the 21 types of ionic and covalent structures described in a N_2O_4 molecule, only one has the N–N bond, which explains, according to the author,[10] the greater bond length than the value corresponding to a single bond. The oxide N_2O_4 is capable of self-ionisation and dissociation in accordance with the schemes

$$N_2O_4 \rightleftharpoons NO_2^+ + NO_2^-,$$
$$N_2O_4 \rightleftharpoons NO^+ + NO_3^-. \qquad (2)$$

The ion pairs $[NO_2^+][NO_2^-]$ and $[NO^+][NO_3^-]$ are formed in the first stages of these processes. Since the formation of nitrites was not observed on treating metals and their salts with liquid N_2O_4,[4] it has been suggested that oxygen exchange takes place immediately after

dissociation in accordance with Scheme (3):

$$NO_2^+ + NO_2^- \rightleftharpoons NO^+ + NO_3^-. \quad (3)$$

It has been established[4,11,12] that liquid N_2O_4 interacts with alkali and many other metals (Ag, Zn, Cu, Hg). Pure N_2O_4 does not interact with the majority of metals. In order to achieve reaction, use is made of mixtures of N_2O_4 with organic solvents which are capable of increasing the dielectric constant and the degree of dissociation of N_2O_4 according to Schemes (1) and (2). In the reactions with metals, an electron is transferred from the metal atom to the NO^+ ion:

$$M + N_2O_4 \rightarrow MNO_3 + NO. \quad (4)$$

The products of the reactions of N_2O_4 with metals are nitrates as well as adducts of nitrates with N_2O_4.

At atmospheric pressure, N_2O_4 exists in the liquid state up to 294 K. The brown colour of the liquid is due to the presence of nitrogen dioxide formed via the reaction $N_2O_4 \rightleftarrows 2NO_2$. With increase in temperature, the liquid is converted into a gas with the subsequent dissociation $2NO_2 \rightleftarrows 2NO + O_2$. A characteristic feature of $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ system is that individual components do not exist in a pure form,[1-3] always forming an equilibrium mixture. The system behaves as an integral whole and is characterised by its physical and thermophysical properties which have been analysed in detail.[1-3]

The forward and reverse $N_2O_4 \rightleftarrows 2NO_2$ reactions take place at very high rates even at room temperature and the equilibrium between N_2O_4 and NO_2 is established almost instantaneously. N_2O_4 dissociates via the formation of an excited $N_2O_4^*$ molecule; ΔH for the reaction $N_2O_4 \rightleftarrows 2NO_2$ at 298.16 K is 57.11 kJ mol^{-1}.[13] With increase in temperature, the rate of dissociation of N_2O_4 rises and at 430–450 K the reaction equilibrium is almost wholly displaced to the right. At higher temperatures, the reaction $2NO_2 \rightleftarrows 2NO + O_2$ takes place and its equilibrium is established in 10^{-3}–10 s depending on the temperature and pressure. With increase in pressure, the equilibrium is displaced to the left in both reactions.

Oxides of the type NO_3, N_3O_6, and N_2O_2 and the radicals NO_3^- are formed as intermediates in the system. Apart from reversible processes, there is also a possibility of irreversible processes with formation of N_2O_3, O_3, N_2, N_2O, and O_2.

II. Interaction of uranium oxides with liquid dinitrogen tetroxide

We shall consider below the interaction of uranium oxides with liquid and gaseous dinitrogen tetroxide over a wide range of temperatures and pressures, because these processes have been studied most fully.

It follows from Addison's studies that metallic uranium interacts with liquid N_2O_4 only after the addition of nitrosyl chloride[14] and alkylammonium nitrates[15] or organic solvents (ethyl acetate, methyl acetate, nitromethane, etc.[16]). The processes are completed by the formation of $UO_2(NO_3)_2.N_2O_4$, $RHN_3[UO_2.(NO_3)_3]$, or $UO_2(NO_3).mL$, where L is an organic base. It follows from a number of investigations[15,17,18] that uranium oxides either do not interact at all with liquid N_2O_4 or react with it extremely slowly.

In characterising the chemical behaviour of uranium oxides, one should note that, among metal–oxygen systems, one of the most complex is the uranium–oxygen system because of the ability of uranium to form compounds in different oxidation states and also because of the existence of oxides in several polymorphic modifications and the formation of non-stoichiometric compounds. Makarov[19] put forward the hypothesis that uranium oxides obey the general homologous U_yO_{2y+2} relation; a vanishingly small change in the chemical composition of the oxides takes place in this series with increase in y and the composition tends to UO_2. Data on uranium oxides have been surveyed by Vlasov et al.[20]

UO_3 has the largest number of polymorphic forms, the existence of seven crystalline α-, β-, γ-, δ-, ε-, ξ-, and η-forms and one amorphous form of UO_3 being known.[21-25] There is a correlation between the specific surfaces of the trioxides and their reactivities in relation to oxygen.[20,26] The following crystalline modifications of U_3O_8 have been reported in the literature: α-, α′-, β-, and γ-U_3O_8.[27-29]

$(UO_3)_{am}$ has been obtained[30,31] by heating up $UO_4.2H_2O$ at temperatures in the range 623–723 K, ε- and γ-UO_3 have been prepared by the method described by Hoekstra and Siegel,[27] and "active" UO_2 has been obtained by decomposing $UO_2C_2O_4.3H_2O$.[30] The oxides UO_2, $(UO_2)_{act}$, U_3O_8, $(UO_3)_{am}$, β-UO_3, ε-UO_3, and γ-UO_3 had the following specific surfaces (m^2 g^{-1}): 2.7, 89.0, 1.5, 9.7, 7.4, 2.8, and 0.9 respectively. Uranium oxides were brought into contact with liquid N_2O_4 in sealed tubes with stirring.[31]

When $(UO_3)_{am}$ is introduced into liquid dinitrogen tetroxide, the latter boils vigorously and the liquid acquires a blue-green colour, indicating the formation of N_2O_3. The rate of interaction of $(UO_3)_{am}$ with liquid N_2O_4 depends on the initial treatment in the synthesis of the oxide $(UO_3)_{am}$ and in the first place on the conditions under which $UO_4.2H_2O$ was heated. The presence of traces of water in the oxide has a catalytic effect on the process.

The results of chemical analysis are consistent with the presence in the final product of components having the overall compositions $UO_2(NO_3)_2.2NO_2$ and $UO_2(NO_3)_2.N_2O_4$. It has been suggested[32] that the formula of the compound be written as $NO[UO_2(NO_3)_3]$. The identification of the complex as an adduct of uranyl nitrate with dinitrogen tetroxide[15] was based on the presence in its IR spectrum of low-intensity bands in the range 1730–1770 cm^{-1} corresponding to absorption by N_2O_4.[31-34] Such an identification is not unambiguous, because bands in the range 1700–1800 cm^{-1}, corresponding to the compound absorption frequencies of NO_3^- are also manifested in the IR spectra of different nitrates.[35,36]

In order to infer the structure of the compound, its vibrational spectra were compared[37] with the spectra of potassium, rubidium, caesium, and ammonium trinitratouranylates,[38,39] which were virtually identical as regards the intensity and location of the absorption bands of the nitrate groups and the uranyl ion (Table 1).

The vibrations of the nitrate groups correspond to the symmetry point group C_{2v}, which has six bands active in the IR spectra ($3A_1 + B_1 + 2B_2$). According to the ideas of Katzin[40] and Field and Hardy,[41] the splitting of the ν_4–ν_1 bands, amounting to 270 cm^{-1}, corresponds to the bidentate binding of the nitrate groups in the compound. Its IR and Raman spectra contain a narrow moderately intense band at 2294 cm^{-1}, which is absent from the spectra of complexes incorporating alkali metals. It is characteristic of the vibrations of the nitrosonium ion.[42,43] Consequently the product of the interaction of $(UO_3)_{am}$ with liquid N_2O_4 has the same structure as rubidium, caesium, potassium, and ammonium trinitratouranylates. It undergoes purely electronic transitions in the luminescence spectra close to those of the uranylates {21 235 and 21 203 cm^{-1} for $NO[UO_2(NO_3)_3]$ and $Rb[UO_2(NO_3)_3]$ [37]}.

In conformity with the formula $NO[UO_2(NO_3)_3]$, nitrogen was detected in the complex in the +3 and +5 oxidation states. It was determined by a standard method.[44]

Table 1. Vibrational frequencies of nitrosonium trinitratouranylate.[37]

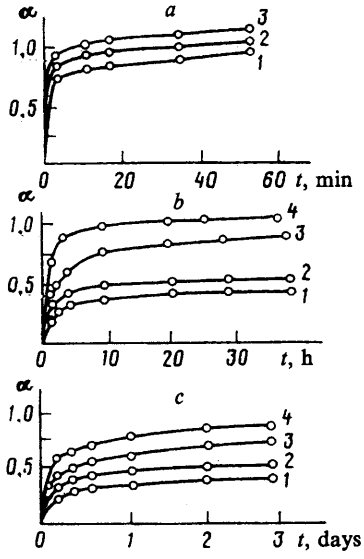

Figure 1. Dependence of the degree of conversion α of uranium trioxides $(UO_3)_{am}$ (*a*), ε-UO_3 (*b*), and γ-UO_3 (*c*) in liquid dinitrogen tetroxide on time (*t*) at different temperatures (K): *1*, 293; *2*, 323; *3*, 373; *4*, 423.

The formation of nitrosonium trinitratouranylate (NTN) on interaction of amorphous uranium trioxide with liquid N_2O_4 indicates the dissociation of the latter in accordance with Scheme (2). The reaction can be represented by the equation

$$UO_3+3N_2O_4=NO[UO_2(NO_3)_3]+N_2O_3\,. \qquad (5)$$

The product of the reactions of β-UO_3, ε-UO_3, and γ-UO_3 with liquid N_2O_4 is also NTN, but the above oxides react at a lower rate than $(UO_3)_{am}$. The properties of the oxide ε-UO_3 are closest to those of $(UO_3)_{am}$. Its degree of conversion into NTN in 1 h was 0.8 and that of ε-UO_3 was 0.25. NTN is formed from ε-UO_3 only after a month and its formation from γ-UO_3 requires more than half a year. With increase in temperature, the degrees of conversion of all the modifications of uranium trioxide in liquid N_2O_4 increase.[45] Fig. 1 illustrates the time variation of the degree of reaction of the oxides UO_3 with N_2O_4 in the temperature range 293–423 K. It is seen that the rate of reaction is especially high in the initial instant (10–30 min), after which the process gradually slows down and the time variation of α becomes almost linear. It has been observed by X-ray diffraction that the interaction is not accompanied by the formation of any intermediates.

Heterogeneous processes have been described satisfactorily by the equation $\alpha = 1 - \exp(-kt^n)$,[46] where *t* is the time and *k* and *n* are constants. (The quantity *n* indicates the region where heterogeneous reactions take place.)

Least squares treatment of the experimental data in terms of the variables $y = \lg[-\lg(1-\alpha)]$ and $x = \lg t$ yielded a slope *n* of the straight line less than 0.5 for all the modifications of uranium oxides (Table 2),[45] which corresponds to the diffusion of N_2O_4 to the surfaces of the initial uranium trioxides.

Table 2. The values of *n* and $\lg K$ for the reactions of uranium trioxides with liquid N_2O_4.

T, K	$(UO_3)_{am}$		ε-UO_3		γ-UO_3 $(UO_3)_{am}$	
	n	$\lg K$	*n*	$\lg K$	*n*	$\lg K$
293	0.46	−0.91	0.23	−5.07	0.20	−6.90
323	0.44	−0.54	0.28	−4.35	0.16	−6.23
348	0.48	−0.35	—	—	0.24	−5.13
373	0.39	−0.11	0.38	−2.73	0.19	−4.73
398	—	—	—	—	0.32	−3.80
423	—	—	0.45	−1.92	0.12	−3.68

The reaction rate constants calculated from the equation $K = nk^{1/n}$ [47] are greater by almost 5–7 orders of magnitude for $(UO_3)_{am}$ than for ε- and γ-UO_3 (Table 2).

The slopes of the $\lg K - 1/T$ relation where 0.57 ± 0.13, 3.01 ± 0.15, and 3.30 ± 0.22 for $(UO_3)_{am}$ and ε- and γ-UO_3 respectively. The empirical equations for the temperature variations of the rate constants for the reactions of the oxides with liquid N_2O_4 are as follows:[45]

$$(UO_3)_{\text{ам}}: K=10^{4.36\pm0.43}\cdot\exp-(10\,800\pm2500)/RT,$$
$$\varepsilon\text{-}UO_3: K=10^{5.20\pm0.46}\cdot\exp-(53\,300\pm2900)/RT,$$
$$\gamma\text{-}UO_3: K=10^{4.22\pm0.63}\cdot\exp-(63\,000\pm4200)/RT.$$

The lowest apparent activation energy E_A for the reaction with liquid N_2O_4 corresponded to the amorphous uranium trioxide (10.8 kJ mol^{-1}) and proved to be appreciably smaller than the energy of the dissociation of the N—N bond via the reaction $N_2O_4 \rightleftarrows 2NO_2$ (ΔH = 53.86 kJ mol^{-1} [11]). A linear relation is

observed between E_A for the formation of NTN from different uranium oxides and the specific surfaces of the latter[45] (Fig. 2). The differences between the reaction rate constants and the apparent activation energies for the reactions of the polymorphic forms of uranium trioxide with liquid N_2O_4 are probably caused by the structural features of the oxides. On passing from amorphous uranium trioxide to the crystalline modifications (β-UO_3, γ-UO_3, ε-UO_3), the quantity E_A increases by ~41.8 kJ mol^{-1}. The product of the reactions of U_3O_8 and UO_2 in the temperature range 293–423 K is also NTN. The curves for the time variation of the degrees of conversion of uranium oxides indicates the acceleration of the process with increase in temperature (Fig. 3).[45] The oxide U_3O_8 is more reactive than γ-UO_3. The conversion of U_3O_8 into NTN at 293, 323, 373, and 423 K takes place after ~180, 35, 5, and 1 days, while the corresponding times for UO_2 are 240, 100, 80, and 5 days. The rate of the process is limited by the diffusion of liquid dinitrogen tetroxide to the surface of uranium oxide. After 10–30 min, the rate of reaction falls owing to the formation of a layer of the reaction product on the surface of the oxide (n < 0.5) (Table 3).

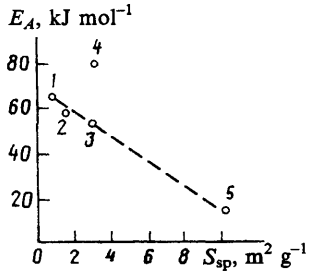

Figure 2. Dependence of the apparent activation energy E_A for the reaction of uranium oxides with liquid dinitrogen tetroxide on the specific surface of the oxide S_{sp}: *1*, γ-UO_3; *2*, U_3O_8; *3*, ε-UO_3; *4*, UO_2; *5*, $(UO)_{3am}$.

In discussing the mechanism of the interaction of uranium oxides with liquid N_2O_4, it is of interest to compare the apparent activation energies obtained from oxides having approximately the same specific surfaces but different oxidation states of uranium: ε-UO_3, U_3O_8, and UO_2 (S_{sp} = 2.8, 1.5, and 2.7 m^2 g^{-1}). On passing from the trioxide to U_3O_8 and UO_2, E_A increases and amounts to 53.3, 56.9, 75.7 kJ mol^{-1}. These data suggest that the conversion into NTN is preceded by the uranium oxidation stage. The approximate energy expenditures on the oxidation of U_3O_8 and UO_2 to the hexavalent state in liquid N_2O_4 were about 4 and 20 kJ mol^{-1} respectively. As a consequence of the oxidation of UO_2, the activation energy E_A for its interaction with N_2O_4 does not fit on the linear dependence of E_A on the specific surface of the oxide (Fig. 2).

The reactivities of the uranium oxides are probably determined not only by the state of their surfaces but also by the oxidation state of uranium in the oxide. This can be seen also in relation to amorphous UO_3 and $(UO_2)_{act}$. Although the apparent activation energy for the interaction of the oxides with N_2O_4 diminishes with increase in their specific surface, E_A for the "active" UO_2 amounted to 43.4 ± 1.88 kJ mol^{-1} compared with 10.9 kJ mol^{-1} for $(UO_3)_{am}$ despite the fact that S_{sp} for $(UO_2)_{act}$ ≃ 89.0 m^2 g^{-1} [30] is almost an order of magnitude higher than for $(UO_3)_{am}$. The value of E_A for the oxidation of "active" UO_2 to the trioxide is correlated with the values obtained for the crystalline specimens.

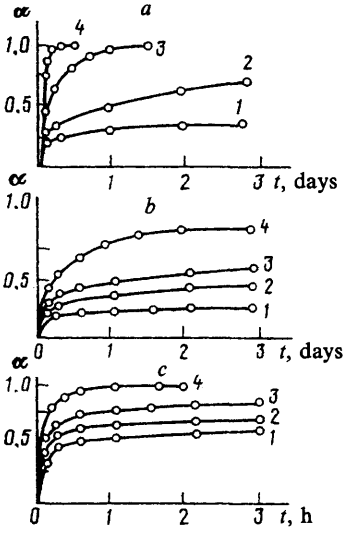

Figure 3. Time variation of the degree of conversion of the uranium oxides U_3O_8 (*a*), UO_2 (*b*), and $(UO_2)_{act}$ (*c*) in liquid dinitrogen tetroxide at different temperatures (K): *1*, 293; *2*, 323; *3*, 373; *4*, 423.

Table 3. The values of n and lg K for the reactions of the oxides U_3O_8 and UO_2 with liquid dinitrogen tetroxide and the mixture of N_2O_4 with 15% of $N_2O_3^*$ in the temperature range 293–423 K.[45]

T, K	U_3O_8				UO_2				$(UO_2)_{act}$	
	n	$-\lg K$	n^*	$-\lg K^*$	n	$-\lg K$	n^*	$-\lg K^*$	n	$-\lg K$
293	0.26	4.74	0.26	5.25	0.20	5.70	0.26	5.14	0.14	3.12
323	0.35	3.73	0.35	4.06	0.17	6.01	0.22	4.98	0.23	2.14
343	0.41	3.41	0.41	3.41	0.21	5.20	0.18	5.30	0.30	1.89
373	0.51	2.61	0.48	2.67	0.29	4.43	0.29	4.80	0.24	1.64
398	0.54	2.31	0.59	2.30	0.25	4.13	0.24	4.10	0.28	0.97
423	0.46	1.78	0.49	1.76	0.35	3.18	0.29	3.35	0.35	0.75

The conversion of "active" UO_2 into NTN is completed after 48, 36, 24, and 2 h at 293, 323, 373, and 423 K respectively. The interaction of U_3O_8 and UO_2 with liquid N_2O_4 can be represented by the following schemes:

$$U_3O_8+10N_2O_4=3NO[UO_2(NO_3)_3]+4N_2O_3, \quad (6)$$

$$UO_2+4N_2O_4=NO[UO_2(NO_3)_3]+2N_2O_3. \quad (7)$$

Since dinitrogen tetroxide contains as a rule admixtures of N_2O_3, the influence of the addition of this component on the reactions was investigated. It is also seen from Eqns. (6) and (7) that N_2O_3 is a reaction product and may accumulate in the reaction mixture. In experiments with different N_2O_3 contents, it was noted that in the temperature range 293–423 K the product of the reactions of all the uranium oxides is NTN. It follows from the data in Table 3 that the introduction of 15% of N_2O_3 does not influence significantly the process kinetics in the temperature range 323–423 K. Some differences are observed at temperatures below 323 K; here the rate of reaction in the $N_2O_4-N_2O_3$ mixtures is higher than in N_2O_4 (Table 3).[48] A similar behaviour has been shown also by metallic zinc.[49] The apparent activation energies for the interaction of UO_2 and U_3O_8 with $N_2O_4-N_2O_3$ mixtures were found to be 76.48 ± 17.6 and 52.8 ± 1.63 kJ mol^{-1} respectively.[45] They are close to the values obtained for pure N_2O_4.

The increase in the rates of reaction of uranium oxides with liquid N_2O_4 in the presence of admixtures of N_2O_3 is caused by the increase in the concentrations of the NO^+ and NO_3^- ions, since N_2O_3 shows a greater tendency towards dissociation than N_2O_4. As a consequence of the dissociation of N_2O_3, according to the schemes

$$2N_2O_3 \rightleftharpoons 2NO+2NO_2 \rightleftharpoons [NO^+][NO_3^-]+2NO, \quad (8)$$

$$N_2O_3 \rightleftharpoons NO+NO_2, \quad (9)$$

$$2NO_2 \rightleftharpoons NO^+ + NO_3^-, \quad (10)$$

the amount of the reactive ion pairs $[NO^+][NO_3^-]$ as well as NO^+ and NO_3^- ions in solution increases. With increase in temperature, the degree of dissociation of N_2O_4 itself also rises appreciably and abolishes the effect of the dissociation of the added N_2O_3 observed at lower temperatures. Presumably the addition of more than 15% of N_2O_3 would also increase the kinetic parameters of the processes investigated at temperatures above 323 K, as was observed by Addison et al.[49]

Since the processes under discussion are extremely difficult to carry out in the absence of traces of water, a study has been made[31] of the influence of added H_2O on the kinetics and the composition of the reaction products. It was noted that the introduction of water appreciably increases the degree of conversion of the oxides. Thus the reaction of amorphous UO_3 in the presence of 0.2% of water is completed after 15 min and with increase in the water content the rate of reaction increases still further. The acceleration of the process has been observed also for other modifications of UO_3 as well as U_3O_8. The degree of conversion of ε-UO_3 in the presence of a water content of about 3% is 65% (45% for anhydrous ε-UO_3) and the reaction reaches completion after 20 days.

Uranium dioxide behaves somewhat differently.[31] When the water content on the surface of the oxide is less than 1.5%, its reactivity hardly changes, whereas in the presence of larger amounts of water the process is appreciably accelerated and in the presence of 15% of water it takes place almost instantaneously. The acceleration of the process in the presence of water is probably induced by the formation of nitric acid, which activates the surface and increases the content of NO_3^- ions.

III. Interaction of uranium oxides with the gaseous dissociating $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ system

The interaction of uranium oxides with the dissociating system has been investigated under dynamic and static conditions at 293–1073 K.[50–52] In the experiments under dynamic conditions, powders of the uranium oxides were placed in a tubular furnace heated to a specified temperature. The stability of the pressure in the gas stream was achieved by maintaining liquid N_2O_4 at the boiling point (294 K) in a thermostatted cell. The contact time was 5 h in all the experiments. The interaction of uranium oxides with the gaseous dissociating system at 323–873 K and at pressures in the range 0.5–10 MPa was carried out in thick-walled glass tubes, the lower part of which was filled with liquid N_2O_4 (it was frozen with liquid nitrogen before the experiment), while uranium oxides were placed in the upper part of the tube on a special suspension. The tube was sealed off and electric furnaces were moved over its lower and upper parts. The furnace over the lower part of the tube served to ensure a constant N_2O_4 pressure during the experiment, while the necessary reaction temperature was maintained with the aid of the furnace over the upper part of the tube. (The pressure developed in the tube was calculated from the temperature dependence of the $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ vapour pressure over the liquid, as described by Nesterenko et al.[1]) At the end of the experiment, the tube was removed from the furnaces, cooled rapidly with liquid nitrogen, and then opened.

Amorphous UO_3 readily reacts in the $N_2O_4 \rightleftarrows 2NO_2$ medium at room temperature and atmospheric pressure. A 70% increase in weight is attained after 5 h under static conditions and after 3 h under dynamic conditions.[51] The changes in the rate of $(UO_3)_{am}$, the results of chemical analysis, and the results of spectroscopic studies on the product indicate that the latter is NTN. Treatment of the kinetic curves[51] yielded n close to two, which shows that the initial stages of the process take place under kinetic conditions. As the reaction product accumulates on the oxide surface, the process slows down and passes to the diffusional region (n = 0.5). With increase in temperature, the reaction also slows down. Fig. 4 illustrates the variation of the weight of the uranium trioxides with the temperature of the dissociating system for a contact time of 5 h. Curve *2* corresponding to the equilibrium process is shown for comparison. It is seen from Fig. 4 that, under equilibrium conditions, the increase in weight reaches 20–70% in the temperature range 293–423 K, after which $\Delta m/m$ falls sharply to zero. The inflections at 423 K were observed also on curves *1* and *3* and their positions are correlated with the contents of NO_2 and N_2O_4 in the gas phase. The degree of conversion of γ-UO_3 is appreciable after 5 h only close to room temperature, while at higher temperatures α did not exceed 1%.

The apparent activation energy E_A for the formation of NTN from $(UO_3)_{am}$ in the temperature range 293–423 K at atmospheric pressure, calculated by several independent equations,[53] amounted to −8.11 ± 0.83 and −7.90 ± 0.83 kJ mol^{-1}.[51] Negative values of E_A were obtained also for the reaction of sodium and potassium peroxides with the dissociating system.[54,55]

Similarly to the observation for liquid N_2O_4, the rate of reaction of gaseous N_2O_4 with $(UO_3)_{am}$ depends on the method of preparation of amorphous uranium trioxide. $(UO_3)_{am}$ specimens with specific surfaces of ~25, 10, and 5 m^2 g^{-1}, obtained by heating $UO_4.2H_2O$ at 623, 673, and 723 K, are converted into NTN after 0.5, 6, and 24 h respectively.[52]

The reactivities of other modifications of uranium trioxide in relation to the $N_2O_4 \rightleftarrows 2NO_2$ system vary in the sequence γ-UO_3 < ε-UO_3 < $(UO_3)_{am}$ and are correlated with their specific surfaces[52] (S_{sp} = 0.9, 2.8, and 9.7 $m^2\ g^{-1}$).

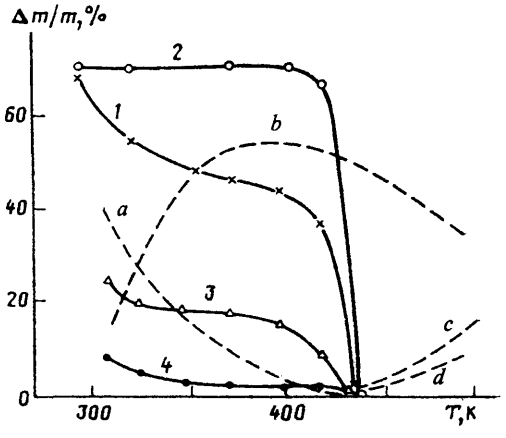

Figure 4. Weight change curves for $(UO_3)_{am}$ (curves *1* and *2*), ε-UO_3 (curve *3*), and γ-UO_3 (curve *4*) in gaseous dinitrogen tetroxide as a function of temperature at p = 0.1 MPa; contact time 5 h except for curves *1*, *3*, and *4*; *2*, specimens maintained under given conditions until the attainment of constant weight; the temperature variation of the composition of the gas phase is shown by dashed curves: *a*, N_2O_4; *b*, NO_2; *c*, NO; *d*, O_2.

The weight of uranium trioxides (Fig. 4) does not change after prolonged contact with the dissociating system at temperatures in the range 423–723 K and there is also no change in the X-ray diffraction patterns of the oxides. This constitutes the difference between the behaviour of uranium trioxides on contact with the dissociating system and that of alkali and alkaline earth metal oxides[56–61] and a series of transition and lanthanide oxides,[52,63] which form nitrides at temperatures above 423 K and the latter are stable in the range 473–673 K.

Starting from temperatures in the range 773–823 K, uranium trioxides in the $2NO_2 \rightleftarrows 2NO + O_2$ medium lose up to 0.5% of their weight and crystallise in the form of a new phase, which was identified as $UO_{2.9}$,[29,64] while in the temperature range 873–1073 K a further weight loss is observed (by 1.8%) and U_3O_8 is formed. In contrast to $(UO_3)_{am}$, ε-UO_3 and γ-UO_3 are converted into U_3O_8, bypassing the $UO_{2.9}$ formation stage.[52]

The nature of the interaction of uranium oxides with the dissociating system in the range 423–723 K is probably determined by the properties of the intermediate products of the decomposition of NTN and in the first place of anhydrous uranyl nitrate.[16–18,37,65–69]

Vibrational spectroscopic data indicate a complex structure of anhydrous $UO_2(NO_3)_2$. The vibration frequencies $\nu_3(UO_2^{2+})$ in this compound are represented by an intense band with three maxima at 990, 980, and 965 cm^{-1}. The fully symmetrical $\nu_1(UO_2^{2+})$ vibration is manifested in the Raman spectrum by doublet bands at 903 and 895 cm^{-1}, one of the components of which (at 895 cm^{-1}) is active in the IR spectrum. The absorption of the nitrate groups in the compounds is distinguished by the greatest complexity. Simultaneously with the presence of doublet bands corresponding to the symmetry point group C_{2v} (1635, 1616 and 1235, 1220 cm^{-1}), the spectrum contains vibrations characteristic of the NO_3^- ion (1381 and 1414 cm^{-1}, Table 4). It has been suggested[37] that the structure of anhydrous uranyl nitrate probably includes at least two types of non-equivalent nitrate groups, the bands at 1414, 1381, 1235, 1220, 1635, and 1616 cm^{-1} belonging to vibrations of the test compounds and not being a result of the interaction of the substance with the material of the filler and hydrate impurities, as suggested by Vdovenko et al.[70]

Table 4. Vibrational frequencies of anhydrous uranyl nitrate.[37]

IR	Raman	Assignment	IR	Raman	Assignment
1635	—		895	903

965	—				

According to structural data,[71] discontinuous ("island type") packing with a bidentate mode of addition of nitrate groups is most characteristic of uranyl nitrate complexes of the type $M[UO_2(NO_3)_3]$ and $UO_2(NO_3)_2.2L$. The coordination number of the UO_2^{2+} ion in such compounds is six. The structure of anhydrous uranyl nitrate has been represented[65,66] by a tetragonal bipyramid with equivalent NO_3^- groups and a coordination number of UO_2^{2+} equal to four. It was shown above that this structure of anhydrous uranyl nitrate is inconsistent with the observed IR absorption of UO_2^{2+} and nitrate groups and also with the results of structural analysis. Apart from bidentate binding, in the test compounds there is probably also bridge type binding of nitrate groups, which is fairly well known for other metal nitrates.[72]

Although anhydrous $UO_2(NO_3)_2$ is formed on heating NTN, the results of different workers concerning the temperature ranges and mechanisms of the decomposition of these substances are different.[16–18,67] In particular, it has been claimed[18] that $UO_2(NO_3)_2$ is formed only within the narrow temperature range 436–438 K and that it decomposes to UO_3 in a single stage, while in another study it was assumed[16] that the formation of UO_3 is preceded by a series of intermediate stages with formation of the polymeric oxonitrates $U_2O_5(NO_3)_2$, $U_3O_8(NO_3)_2$, and $U_4O_{11}(NO_3)_2$.

The thermal stability of NTN has been investigated[37] under different atmospheres: in air, in an inert gas stream, *in vacuo*, and in the $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ medium. There are three endothermic effects at 443, 543, and 833 K on the differential thermal analysis

(DTA) curve. The first effect corresponds to the removal of nitrogen dioxide and the formation of anhydrous $UO_2(NO_3)_2$:

$$NO[UO_2(NO_3)_3] \rightarrow UO_2(NO_3)_2 + 2NO_2. \quad (11)$$

Uranyl nitrate is stable within the relatively narrow temperature range 443–473 K, above which it begins to decompose to UO_3. Special experiments involving treatment with acetone of the heat-treatment products obtained at 523, 543, and 573 K [73] (to separate the soluble uranyl nitrates from UO_3) revealed that the $U:NO_3^-$ ratio in the wash solution was 1:2, while the solid residue was UO_3. Thus NTN decomposes in a single stage with formation of uranium trioxide:

$$2UO_2(NO_3)_2 \rightarrow 2UO_3 + 4NO_2 + O_2. \quad (12)$$

In the temperature range 823–873 K, the trioxide UO_3 loses 1.9% of its weight and is converted into U_3O_8.

It has been shown[73] that $NO[UO_2(NO_3)_3]$ decomposes to uranyl nitrate in the temperature range 403–453 K in the kinetic region and takes place from the surface into the bulk of the NTN particles. The process activation energy is ~104.5 kJ mol^{-1}. In contrast to NTN, anhydrous uranyl nitrate decomposes in the diffusional-kinetic region with an activation energy of ~133.9 kJ mol^{-1}. The activation energy E_A for the decomposition of anhydrous uranyl nitrate, quoted by Klavsut',[73] is higher than the value of E_A obtained by Ondrejcin and Garrett[67] and amounts to 98.3 kJ mol^{-1}.

In the gaseous dissociating dinitrogen tetroxide at a pressure of 0.1 MPa, the thermal decomposition of $NO[UO_2(NO_3)_3]$ begins at 453–463 K. With increase in the pressure of a dissociating system, the stability of NTN rises and the limits of its stability at pressures of 0.5, 2, and 10 MPa shift to 503, 523, and 573 K. It has also been observed that NTN decomposes in the dissociating system to UO_3, bypassing the stage involving the formation of anhydrous uranyl nitrate. The presence of the latter has not been detected from the Raman spectra and from the diffraction patterns of the product maintained in the dissociating system at a temperature above 573 K and a pressure in the range 2–10 MPa.[50–52]

On decomposition of NTN and of anhydrous uranyl nitrate, the formation of intermediate oxonitrates as well as uranyl nitrates was not observed. They are not formed in the above heterogeneous processes and can be synthesised only by ligand substitution reactions.[74]

When U_3O_8 and UO_2 are treated with gaseous dinitrogen tetroxide at room temperature under dynamic conditions, the change in weight after 5 h is ~15%, while under static conditions the weight increment reaches 10% only after 24 h. The process then slows down and under static conditions its completion requires approximately half a year. The interaction with UO_2 is even slower. Under dynamic conditions, the increase in weight after 24 h is only 3%. The reaction is completed after 8–10 months. The changes in the weight of U_3O_8 and UO_2 are 73 and 80% respectively, which corresponds to the formation of NTN. The kinetics of the reactions depend on the specific surfaces of the initial specimens: U_3O_8 with S_{sp} = 13.6 m^2 g^{-1} is converted into $NO[UO_2(NO_3)_3]$ after 10 and 15 days at 293 K under dynamic and static conditions, while $(UO_2)_{act}$ is converted after 2 and 3 days respectively (S_{sp} ~ 80 m^2 g^{-1}).

There are two sections on the kinetic curves for the interaction of U_3O_8 and UO_2 with the gaseous dissociating $N_2O_4 \rightleftarrows 2NO_2 \rightleftarrows 2NO + O_2$ system: the initial sharp increase in the degree of conversion and the subsequent retardation of the process (Fig. 5). The value of n along the initial sections for U_3O_8 is 1.6–2.0, which corresponds to the occurrence of the process in the kinetic region. The apparent activiation energy for the formation of NTN from U_3O_8 is -10.59 ± 1.84 kJ mol^{-1} and is close to that for UO_3. As NTN accumulates on the surface of the oxide, the reaction occurs in the diffusional region (n = 0.1–0.5).

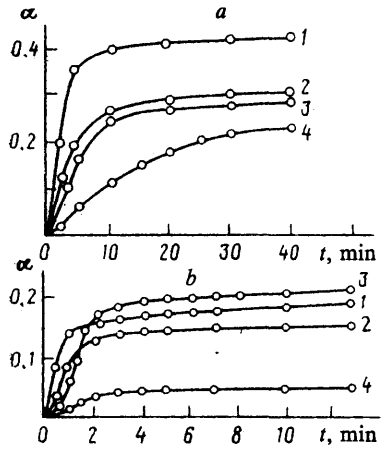

Figure 5. Variation of the degree of conversion of U_3O_8 (*a*) and UO_2 (*b*) in gaseous dinitrogen tetroxide at different temperatures (K): *1*, 293; *2*, 323; *3*, 373; *4*, 423.

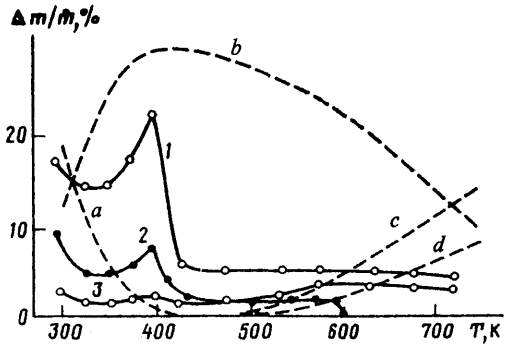

Figure 6. Weight change curves for $(UO_2)_{act}$ (curve *1*), U_3O_8 (curve *2*), and UO_2 (curve *3*) in gaseous dinitrogen tetroxide as a function of temperature at p = 0.1 MPa in the course of 5 h; the temperature variation of the composition of the gas phase is shown by dashed curves: *a*, N_2O_4; *b*, NO_2; *c*, NO; *d*, O_2.

In contrast to uranium trioxides, the temperature variation of the degrees of conversion of U_3O_8 and UO_2 is complex. When the plot of $\Delta m/m$ against T in the range 293–423 K is analysed, the presence of a very intense maximum for $(UO_2)_{act}$ and a less intense one for U_3O_8 at 393–403 K is striking (Fig. 6).[50,51] The increase in the reactivity of uranium oxides in which the oxidation state of the metal is less than 6 at 392 K is determined by the formation of

ε-UO_3 during the reaction. Its appearance has been established by X-ray diffraction. After the uranium oxides had been kept in dinitrogen tetroxide at the temperature indicated, they were treated with acetone to remove uranyl nitrates. It was found that, apart from the peaks characteristic of the initial oxides, the ε-UO_3 diffraction maxima are present on the diffraction patterns of the specimens. The presence of ε-UO_3 as an intermediate phase in the products of the reaction of U_3O_8 and UO_2 with the dissociating system shows that they react in two stages: the oxidation of U_3O_8 and UO_2 to ε-UO_3 and the subsequent formation of NTN. With increase in temperature, the rate of the first process rises and that of the second falls. The formation of the intermediate oxide ε-UO_3, which is more reactive than UO_2 and U_3O_8, accelerates the formation of NTN and induces the appearance of a maximum on the curves for the temperature variation of α. At temperatures above 423 K and a pressure of 0.1 MPa, the formation of NTN ceases as a consequence of its thermal decomposition and a sharp fall in weight is observed on the curves (Fig. 6).

In the range 453–523 K, the main product of the reaction of U_3O_8 with the dissociating system is ε-UO_3. The kinetic curves for the conversion of U_3O_8 into ε-UO_3 obtained by the present authors[51] show that the process is accelerated as the temperature rises. They are described satisfactorily by a first-order reaction equation: $\alpha = 1 - \exp(-kT)$; the activation energy is $E_A = 79.5 \pm 0.88$ kJ mol^{-1}. At temperatures above 623 K, no changes in the weight of U_3O_8 are observed although ε-UO_3 has been stated[27,75] to be stable up to 723 K. This is probably due to the phase transition from orthorhombic U_3O_8 to U_3O_8 with a hexagonal structure[76] whose properties are similar to those of hexagonal ε-UO_3.[77]

In the case of UO_2, in the range 453–523 K an increment in weight of ~1% has been observed, but the X-ray diffraction patterns of the specimens remain unchanged under these conditions.[50] This is evidence for the insertion of oxygen into the cavities of the fluorite structure of uranium dioxide with formation of the non-stoichiometric compounds UO_{2+x}, where $x = 0.20-0.34$.[78] At 623 K and above, the main phase is U_3O_8.

With increase in pressure in the system, the rate of formation of NTN increases appreciably. Thus $(UO_3)_{am}$ is fully converted into NTN after 5 h at 0.5 MPa and temperatures in the range 323–473 K and after 1 h at a pressure of 10 MPa and 473 K. The temperature range corresponding to the stability of NTN shifts at the same time to the region of higher temperatures.[52] NTN remains stable up to 503 K at a pressure of 0.5 MPa and up to 573 K at 10 MPa. The curves for the variation of the weight of U_3O_8 and UO_2 with the pressure of the dissociating system exhibit a maximum similar to that observed at atmospheric pressure.[50,51] However, the position of the maximum, corresponding to the formation of ε-UO_3, is displaced towards higher temperatures. The reactivity of uranium oxides in relation to the dissociating system follows the same sequence as at atmospheric pressure: $(UO_3)_{am} > \varepsilon\text{-}UO_3 > \gamma\text{-}UO_3 > U_3O_8 > UO_2$.[52] Consequently, with increase in the pressure of the dissociating system, the mechanisms of the reactions with uranium oxides do not change and only the rate of reaction and the thermal stability of NTN increase significantly. Above 573 K, NTN is not formed from uranium trioxides even at a pressure of 10 MPa.

In contrast to the reactions at atmospheric pressure, at $p > 0.5$ MPa in the temperature range 573–723 K the oxides $(UO_3)_{am}$ and ε-UO_3 undergo a phase transition with formation of the most stable modification γ-UO_3, which loses oxygen at a temperature above 773 K with formation of the oxide $UO_{2.9}$ and then U_3O_8.

γ-UO_3 is obtained under the same conditions as U_3O_8. The phase having the composition $UO_{2.9}$ is formed during the oxidation of U_3O_8 at temperatures in the range 623–723 K at a pressure of 0.5 MPa. In the temperature range 723–873 K and in the pressure range 0.2–10 MPa, uranium trioxides and UO_2 are converted into U_3O_8. However, at pressures above 2 MPa in the temperature range 573–673 K, the γ-UO_3 phase was detected in reaction products. It was absent at the same temperatures and atmospheric pressure.

IV. Interaction of uranium oxides with N_2O_4–organic solvent mixtures

We noted above that liquid N_2O_4 does not interact with the majority of metals. In order to achieve such reactions, mixtures of liquid N_2O_4 with organic solvents are employed. The chemical behaviour of dinitrogen tetroxide is associated with the characteristics of its electronic structure. Each atom in N_2O_4 has *p* orbitals perpendicular to the plane of the molecule and forming a system made up of six π molecular orbitals in which 12 electrons can be accommodated. N_2O_4 has only eight electrons in its molecular orbitals, as a result of which it exhibits the properties of an acceptor capable of accepting two pairs of electrons. The tetroxide N_2O_4 does not show a tendency to react with metals. On the other hand it forms readily molecular complexes with electron-donating solvents.[79] It has been noted[80] that, as the electron-donating properties of the solvent are enhanced, the absorption maximum $\lambda_{max}(N_2O_4)$ in the range 330–340 nm diminishes and the extinction coefficient of the complex formed increases. According to Solov'ev et al.,[81] in weak organic bases at high concentrations of N_2O_4 the latter exists mainly as undissociated molecules. Only at low N_2O_4 concentrations does the homolytic dissociation $N_2O_4 \rightleftarrows 2NO_2$ occur and the concentration of NO_2 becomes comparable to that of N_2O_4. The thermodynamic parameters of the homolytic dissociation reactions of N_2O_4 in CS_2, $CHCl_3$, CCl_4, $SiCl_4$, and n-hexane depend little on the nature of the solvent.[81] On the other hand, in strong organic bases the heterolytic dissociation $N_2O_4 \rightleftarrows NO^+ + NO_3^-$ takes place.[79]

The introduction of an organic solvent increases the dielectric constant of N_2O_4, promoting the formation of ion pairs. The processes can be represented by the following scheme:

$$m\,L + N_2O_4 \rightleftharpoons (L)_m \cdot N_2O_4 \rightleftharpoons [L_mNO^+]\,[NO_3^-]. \qquad (13)$$

Since the N_2O_4 molecule can accept two electron pairs in its orbitals, *m* is as a rule equal to two.

Adducts of the nitrates of the corresponding metal with N_2O_4 or with the solvent are formed in mixed solvents: $M(NO_3)_2.N_2O_4$ and $M(NO_3)_2.nL$. The former complexes are usually nitrosonium compounds in the solid phase, like nitrosonium trinitratouranylate.

In the reactions of metallic uranium and its oxides with mixtures of N_2O_4 and organic solvents, the solvent was evaporated in order to obtain the final products. As a result, NTN was formed from mixtures of N_2O_4 with nitromethane and nitrobenzene whereas adducts of uranyl nitrate with two molecules of the organic base, namely $UO_2(NO_3)_2.2L$, were obtained with solvents such as CH_3CN, $(CH_3)_2CO$, $(C_2H_5)_2O$, $(CH_3)_2NCOH$, and $(CH_3)_2SO$.[14,16,82]

We may note that the formation of uranium(IV) compounds was not observed as a result of the reaction, only uranyl complexes being detected in the reaction products. Thus, as has been observed for gaseous and liquid N_2O_4, in mixtures of N_2O_4 with organic solvents the

first stage of the reaction is the oxidation of uranium to the hexavalent state:

$$U + 2\,[NO^+]\,[NO_3^-] \rightarrow UO_2^{2+} + 2\,N_2O_3. \quad (14)$$

Since NTN is formed only in the case of nitromethane and nitrobenzene, its formation cannot be accounted for by the high dielectric constant of the solvent, which is responsible according to Addison and co-workers,[82-84] for the heterolytic dissociation of N_2O_4. Indeed, adducts formed by the addition of two molecules of the solvent to uranyl nitrate are obtained in the reactions with acetonitrile, dimethylformamide, and dimethyl sulphoxide, which have higher dielectric constants (ε = 38.0, 36.1, and 44.5) than nitromethane and nitrobenzene (35.9 and 34.8 respectively).

The formation of the adducts agrees well with the increasing electron-donating capacity of the solvent. On passing from nitromethane and nitrobenzene to stronger bases, i.e. acetone, diethyl ether, dimethylformamide, and dimethyl sulphoxide, their donor numbers increase correspondingly: 2.7, 4.4, 17.0, 19.2, 26.6, and 29.8.[85] Thus the complexes $UO_2(NO_3)_2.N_2O_4$ for solvents having a low electron-donating capacity probably exist in solutions of N_2O_4. Their composition is better reflected by the formula $UO_2(NO_3)_2.N_2O_4$ than by $UO_2(NO_3)_2.2NO_2$, because the degree of the dissociation $N_2O_4 \rightleftarrows 2NO_2$ in liquid N_2O_4 is 140–500 times smaller than in the gas phase owing to the "cage" effect of the liquid.[86] In solution, the stability of the complex is apparently achieved via the stable isomer O_2N-NO_2,[87] which behaves as a bidentate neutral ligand. As the complex passes to the solid phase, the stability of this isomer diminishes and it is converted into the $ON-NO_3$ isomer with formation of a nitrosonium compound. The equilibrium in the heterolytic dissociation of liquid N_2O_4 has been displaced[88-91] by adding alkylammonium nitrates or nitrosyl chloride.

In terms of its electron-donating properties, N_2O_4 is probably close to nitrobenzene and stronger bases can compete with N_2O_4, displacing it from the inner coordination sphere of UO_2^{2+}.

Layered compounds of alkali metals in graphite in fine organic synthesis

V V Aksënov, V M Vlasov, G N Shnitko
Novosibirsk Institute of Organic Chemistry, USSR Academy of Sciences

ABSTRACT. The review deals with the use in fine organic synthesis of layered compounds of graphite with alkali metals as catalysts and reactants. The high reactivity of these compounds in alkylation, polymerisation, reduction, and certain other reactions is demonstrated.

The bibliography includes 76 references.

I. Introduction

As enhanced interest in non-traditional compounds with unique properties is constantly manifested in chemistry. An expansion of the range of practical applications of layered compounds of graphite (LCG) with unusual physicochemical properties has been noted recently. For example, LCG, which are good electrical conductors, can be used as cathodic materials in the construction of chemical current sources and also as systems designed for the storage of thermal energy.[1] The application of LCG as additives improving the physicochemical properties of certain varieties of abrasive materials and powdered alloyed steels as well as raw materials for the preparation of new carbon materials with controllable physicochemical properties appears promising.[2] It is of interest to use LCG as catalysts and reactants in various chemical processes, for example, in the synthesis of ammonia and artificial diamonds[3,4] and also in fine organic syntheses.[3]

There exist several reviews devoted to the application of LCG with alkali metals in organic reactions.[5–8] The review of Novikov and Vol'pin[5] is devoted to the preparation of LCG with alkali metals, their structure, and their thermodynamic and physicochemical properties. It includes a brief list of the simplest reactions with participation of these compounds. Boersma's review[6] deals with a limited range of organic reactions: dimerisation, isomerisation, and polymerisation of unsaturated aliphatic compounds catalysed by alkali metals in graphite. Inclusion compounds of graphite with various substances (acids, salts, alkali metals, etc.) and their use in organic chemistry have been described in two other reviews[7,8] without a detailed consideration of the reactions occurring in the presence of LCG with alkali metals.

In view of the foregoing, it appeared useful to subject the characteristic properties of LCG with alkali metals to a comprehensive consideration, concentrating attention on the use of these unusual compounds in synthetic organic chemistry.

II. Preparation of layered compounds of graphite with alkali metals

Three main methods of preparation of LCG with alkali metals have been described. In our view, the most convenient and most widely used is the method involving the joint heating of the alkali metal and graphite,[5,9–11] which is usually carried out in a stream of an inert gas. LCG with K, Rb, and Cs can be readily obtained by this procedure at temperatures from 100 to 500 °C. The composition of the layered compounds obtained varies from C_8M to $C_{60}M$ (M = metal). For a long time, it was impossible to synthesise by this procedure the analogous compounds of graphite with lithium or sodium, but ultimately LCG having the composition C_nNa, where $n = 60-68$, and C_nLi, where $n = 4-72$, were obtained.[5] The method of preparation of LCG with potassium or lithium under pressure (2.0–8.0 GPa, 200–300 °C) made it possible to synthesise inclusion compounds with an increased metal content: $C_{2.00-2.5}Li$ and $C_{4.0-4.5}K$.[12,13]

Yet another method of synthesis of LCG with alkali metals is based on the reaction of graphite with the metals in solution.[5,11,14,15] Polar solvents of the type of ammonia, 1,2-dimethoxyethane, amines, hexamethylphosphoramide, etc. are usually employed and the reaction is carried out at temperatures from −50 to −100 °C. Together with alkali metals, the solvent is also incorporated in graphite in this instance.[5,15] The amount of incorporated solvent depends on the size of its molecules. For example, in the preparation of LCG with potassium in ammonia, we have the ratio $K:NH_3 = 1:2$, while in the case where pyridine or methylamine are used the corresponding ratio is 1:1.

The third method of preparation of the LCG considered provides for the interaction of graphite with solutions of radical-anions derived from aromatic compounds (biphenyl, naphthalene, phenanthrene, etc.)[5] in accordance with the following general scheme:

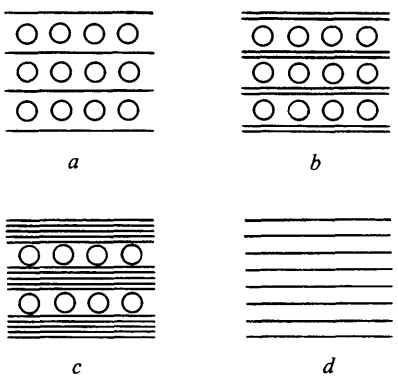
$$ArH^{-}M^{+} + \text{graphite} \rightleftarrows ArH + \text{graphite}^{-}M^{+}(Solv)(ArH). \quad (1)$$

The equilibrium amount of alkali metal incorporated in graphite is independent of the nature of the radical-anion, which does, however, influence the rate of equilibration. For example, equilibrium (1) is more rapidly established in the reaction with biphenyl than with naphthalene. This is probably associated primarily with the electrochemical potentials of aromatic compounds. Thus the reduction potential of naphthalene in relation to biphenyl is +0.9 V.[5]

The rate of incorporation of the metal in graphite varies in the course of the reaction. For example, when a solution of naphthalenepotassium is used, 80% of potassium is incorporated in the first 5 h, while the incorporation of the remaining 20% requires a further 45 h. Apart from the alkali metal, the solvent and small amounts of the aromatic compound can also be incorporated in graphite in this method of preparation.[5]

III. The structure of layered compounds of graphite with alkali metals

The carbon atoms in graphite form planar network structures with hexagonal cells of the type of benzene rings. Each carbon atom in this system has a free π-electron in the p orbital located at right angles to the molecular plane. The parallel networks of carbon atoms are linked by weak van der Waals forces, and not chemical bonds, which permits the incorporation of various compounds into the interlayer space. The graphite layers are then moved apart and LCG are formed in which there are no strong vertical bonds, i.e. bonds between the incorporated compound and the carbon atoms of graphite.



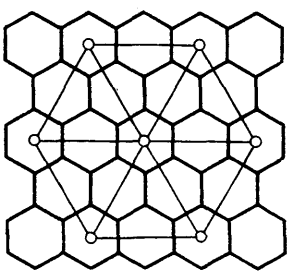


Figure 1. Disposition of the layers of graphite and alkali metal atoms in intercalation compounds: *a*, 1st stage LCG (C_8M); *b*, 2nd stage LCG ($C_{24}M$); *c*, 5th level LCG ($C_{60}M$); *d*, graphite.

In terms of their structure, LCG with alkali metals can be divided into five stages[5,10,11] (Fig. 1). In the first stage, the layers of metal and graphite alternate and the metal atoms form a monatomic layer equidistant from the nearest carbon layers. In the metallic layer, a network is created in which the distance between the atoms is 4.30 Å (Fig. 2). In the second stage ($C_{24}M$), each metal layer is followed by two graphite layers, while in fifth stage compounds ($C_{60}M$) each metal layer is followed by five graphite layers. The thickness of the filled graphite layer in LCG with the same metal is the same for compounds corresponding to any stage and depends solely on the size of the incorporated metal. The interplanar distances are 3.73, 4.50, 5.33, 5.68, and 5.94 Å for Li, Na, K, Rb, and Cs compounds respectively. On passing to higher stages, not only does the number of carbon layers per metal layer increase but there also is a change in the structure of the metal layer itself. In the compounds C_8M, the metal atoms are arranged in a triangular network (Fig. 2), while on passing to the second stage they are rearranged to a hexagonal network, i.e. the central metal atom is displaced from the plane of the lattice (Fig. 2).

○alkali metal atom

Figure 2. Disposition of alkali metal atoms in intercalation compounds in relation to the carbon matrix of graphite.

The structure of LCG containing, apart from alkali metals, also the solvent is similar to that of compounds formed in the absence of the solvent. Solvent molecules are distributed in the same layer as the metal atoms. The distance between the graphite layers (the thickness of the filled layer) in the intercalation compounds consists of the distance between the same layers in the unfilled graphite (3.35 Å) and the thickness of the layer of solvated ions. The latter quantity is 6.6 Å for ammonia, 6.9 Å for methylamine, and 8.5 Å for ethylenediamine. The thickness of the filled layer is independent of the nature of the metal and the stage of the compound but does not depend on the molecular size of the solvent.

The question of the nature of the bond with alkali metals in the LCG is very important. The model according to which the layered compounds consist of "metal-like" carbon networks of graphite and layers of M^+ metal ions appears most likely. The cations are formed as a result of the transfer of one electron from the metal atoms to the conductivity band of the neighbouring graphite layer. Consequently, the alkali metals in LCG are fully ionised and the formation of a bond between the alkali metal and the carbon network of graphite is determined by the electrostatic interaction of the positively charged metal ions with the free electrons of the conductivity band of the neighbouring graphite layers.[10,11,16,17]

IV. Chemical properties

1. Reactions with gases and proton-donating compounds

The layered compounds of graphite with alkali metals are pyrophoric and ignite in air. They are therefore usually obtained and stored under an inert atmosphere (helium, argon). Compounds of the type C_8M (M = K, Rb, Cs) can be stored under a nitrogen atmosphere (Table 1).[6] Compounds of the type $C_{24}M$ sorb virtually all the gases listed in Table 1, including argon, but excluding helium and neon,

while the compounds C_8M do not sorb any of the gases. This difference is probably due to the fact that the density of alkali metal atoms in C_8M is approximately 1.5 times greater than in $C_{24}M$. This prevents the incorporation of gas molecules into the interlayer space of compounds of the type C_8M.

LCG with alkali metals can be stored not only under an inert atmosphere but also in dry solvents (diethyl ether, pentane and others). The reactivity of the inclusion compounds is maintained for a long time under these conditions.

Table 1. The ratio of the number of gas molecules absorbed by LCG to the number of intercalated alkali metal atoms (at −67 to −190 °C).[6]

LCG	He	Ne	Ar	N_2	H_2, D_2	CH_4
$C_{24}K$	nil	nil	nil	0.70	2.10	nil
$C_{24}Rb$	nil	nil	1.20	1.00	2.05	0.90
$C_{24}Cs$	nil	nil	1.40	1.30	2.00	1.20
C_8M (M = K, Rb, Cs)	nil	nil	nil	nil	nil	nil

Table 2. The interaction of the compound C_8K with certain oxides and oxygen.[6]

Oxide	Reaction temperature, °C		Products
	start	end	
O_2	25	120	graphite + α-KO_2
N_2O	120	200	graphite + α-KO_2 + $N_2\uparrow$
NO*	25	250	graphite + Q** + ?
NO_2*	25	100	graphite + KNO_2 + Q
SO_2	25	300	graphite + K_2SO_4 + $S\downarrow$
CO_2	120	400	graphite + K_2CO_3 + $CO\uparrow$
CO	200	500	graphite + K_2CO_3

* Exothermic process.

** Q is the amount of heat evolved during the reaction.

LCG with alkali metals can react with various oxides and oxygen (Table 2).[6] These reactions, which usually begin at room temperature, proceed with evolution of heat. This normally results in the formation of two-phase systems consisting of graphite and a finely dispersed inorganic salt. Attention should be drawn to the fact that, in the interaction of C_8K with O_2 and N_2O, the α-form of KO_2 is formed. In the absence of LCG, it is usually obtained at temperatures below −75 °C. At room temperature, the β-form of this compound is stable.

The compound C_8K is capable of absorbing hydrogen even at room temperature.[18,19] On heating, the reaction is accelerated with formation of products having the composition C_8KH_x, where x depends on the reaction temperature and reaches a limiting value of 0.67. The compounds C_8Rb and C_8Cs are more stable in relation to hydrogen than C_8K. The maximum value of x in C_8RbH_x, attained at 60 °C, is 0.05; C_8Cs begins to react with hydrogen above 150 °C.

Gaseous chlorine, bromine, and iodine react very vigorously with C_8K and C_8Cs, forming finely dispersed metal halides.[20] In this case, the structure of the LCG is fully disrupted and, according to X-ray diffraction data, the final specimen consists of two phases — graphite and the metal halide.[6,20]

When LCG with alkali metals (K, Rb, Cs) are acted upon by water, the following reactions take place:[21,22]

$$C_8M + H_2O \rightarrow C_8H + MOH, \quad (2)$$

$$C_8M + H_2O \rightarrow 8C + MOH + {}^1/_2H_2. \quad (3)$$

Since 0.5 mol of hydrogen should be evolved in reaction (3) per mole of C_8M, while in the experiment where water is added to LCG with alkali metals only 0.01−0.08 mol is evolved, one may conclude that reaction (2) predominates in this process, the remaining hydrogen being consumed in the hydrogenation of graphite. Under the experimental conditions, it is difficult to separate the contributions of reactions (2) and (3). At any rate in the reactions of LCG containing alkali metals with water, the evolution of H_2 has always been detected,[5,21,22] the amount of such hydrogen depending greatly on the particle size of the graphite employed.[23] It has been suggested that, when LCG with alkali metals are acted upon by water, only the positively charged metal layer interacts with water, while the graphite layer represents an inert macroanion, which does not react with water, forming inclusion compounds with the latter.[24]

Hydrogen is also evolved when ternary compounds of the type graphite/alkali metal/solvent are treated with water. The solvents employed are tetrahydrofuran (THF)[21,25] or ammonia.[26]

The interaction of alkali metal intercalants in graphite with alcohol proceeds similarly, but in this case the corresponding alkoxides are formed in addition to hydrogen.[21]

A detailed investigation of the reaction of the potassium intercalant in graphite with various alcohols and diols[27] is important because compounds with an OH group are extremely common in synthetic organic chemistry. When the LCG with potassium is acted upon by an alcohol or diol, both the evolution of hydrogen and the formation of the corresponding alkoxide are observed.

The amount of potassium extractable from the intercalant in the form of the alkoxide depends on the structure of the alcohol (diol), the type of intercalant, and the nature of the solvent used to extract the alkoxide (Table 3). Naturally, with decrease in the content of potassium in graphite, the amount of extractable alkoxide diminishes but not in proportion to the molar content of potassium. For example, after the treatment of the LCG with 2-butanol, cyclohexane extracts from $C_{24}K$ even more potassium alkoxide than from C_8K (36 and 24% respectively). The effectiveness of the solvent used to extract alkali metals from intercalants increases in the sequence cyclohexane ≃ hexane < benzene < THF ≃ dimethoxyethane (DME).[28,29] Monohydric alcohols extract alkoxides more effectively than polyhydric alcohols. Lithium passes to the alcohol phase much less effectively than potassium (by a factor of approximately 2). The most complete extraction of potassium has been observed in THF, where the degree of extraction reaches 60−70% (Table 3). The extraction is hindered by side

reactions occurring when OH-containing compounds interact with LCG which contain alkali metals, namely reactions due to the evolved hydrogen and others.

Table 3. The amount of potassium extracted from LCG by alcohols and glycols (contact time 48 h, 23 °C).[27]

Alcohol (diol)	No. of carbon atoms (n) in C_nK	Degree of extraction of potassium, %		
		by cyclohexane	by benzene	by THF
2-Butanol	8	24	55	67
2-Butanol	24	36	47	64
t-Butyl alcohol	8	20	43	60
t-Butyl alcohol	24	18	40	58
Diphenylmethanol	24	—	20	59
Diphenylmethanol	12*	—	10	27
Decanediol	24	—	2	17
PEG (300)**	24	—	35	50
PPG (400)***	24	—	38	53

* $C_{12}Li$ was used.
** Polyethylene with a molecular weight of 300.
*** Polypropylene with a molecular weight of 400.

It is believed [21] that such reactions do not take place with amines which are less acidic than alcohols. Thus, when cyclohexylamine or pyrrolidinone was added to a suspension of C_8K in THF, hydrogen was not evolved and the colour of the solution did not change.

2. Hydrogenation and reduction reactions

The reducing properties of C_8K were first demonstrated in relation to the reaction of bis(trialkyl phosphite)nickel(2+) dichloride with an excess of trialkyl phosphite, which resulted in the formation of a zerovalent nickel complex—tetrakis(triethyl phosphite)nickel(0).[30]

Treatment with the potassium intercalant in graphite results in the hydrogenation of the double bond in α,β-unsaturated ketones and acids and the formation of a satisfactory yield of the corresponding unsaturated compounds under mild conditions:[31]

$$C_6H_5-CH=CH-CO-CH_3 \xrightarrow[2)\ H_2O,\ 10\ min,\ 25\ ^\circ C]{1)\ C_8K,\ THF,\ [(H_3C)_3Si]_2NH} C_6H_5-CH_2-CH_2-CO-CH_3,$$

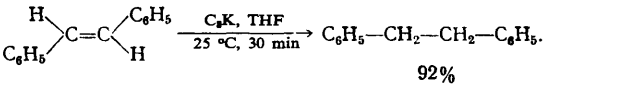
(I)

85%

$$R^1-CH=CH-COOH \xrightarrow[2)\ H^+/H_2O,\ 55\ ^\circ C,\ 60-90\ min]{1)\ C_8K,\ THF} R^1-CH_2-CH_2-COOH.$$

R^1	Yield, %
C_6H_5	86
CH_3	85
COOH	89

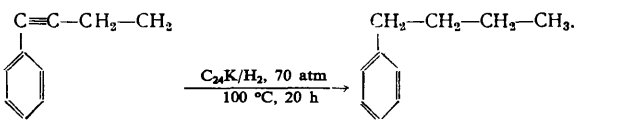
When type (I) unsaturated ketones were hydrogenated, best results were achieved using a 5:1 mixture of THF and hexamethyldisilazane as the reaction medium.



Aromatic Schiff bases are also reduced under mild conditions, affording the corresponding secondary amines:[31]

$$C_6H_5-CH=N-R^1 \xrightarrow[2)\ H_2O,\ 25\ ^\circ C]{1)\ C_8K,\ THF} C_6H_5-CH_2-NH-R^1.$$

The yield was 83% for R^1 = cyclo-C_6H_{11} and 92% for R^1 = t-C_4H_9. On the other hand, α,β-unsaturated esters, such as the ethyl esters of fumaric, geranic and 3-methylbut-2-enoic acids, give rise mainly to dimerisation products under these conditions.[31]



The hydrogenation of mixtures of alkenes, namely oct-1-ene and 1-methylcyclohexene, oct-1-ene and dodec-1-ene, and *cis*-oct-2-ene and 1-methylcyclohex-1-ene in the presence of $C_{24}K$ has been described (70 atm, 100 °C, 20–24 h).[32] The reaction took place most effectively on treating a mixture of oct-1-ene and the dodec-1-ene with the potassium intercalant, whereupon octane and dodecane were formed in equal yields (28% each).

1,2-Diphenylethane has been obtained in 92% yield (70 atm, 100 °C, 60 h) from *trans*-stilbene in benzene on treatment with H_2 and $C_{24}K$. The same yield of 1,2-diphenylethane was achieved on treating *trans*-stilbene with a fivefold excess of C_8K in THF but under milder conditions and without adding hydrogen:[31]

92%

Examples of the hydrogenation of the triple bond are also known. For example, on treatment with $C_{24}K$, 1-phenyl-1-yne is converted into n-butylbenzene in a satisfactory yield:[32]

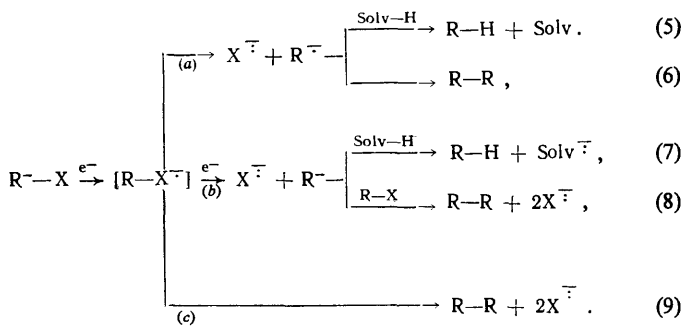
75%

The reduction of many primary halogenoalkanes on treatment with C_8K has been described:[21]

$$CH_3(CH_2)_{16}CH_2X + C_8K \xrightarrow[30\ min]{25\ ^\circ C} \underset{(II)}{C_{18}H_{38}} + \underset{(III)}{C_{36}H_{74}}. \qquad (4)$$

X	Solvent	Yield, % (II)	Yield, % (III)
Cl	C_5H_{12}	40	—
Cl	$(C_2H_5)_2O$	93	—
Br	THF	38	56
I	$(C_2H_5)_2O$	47	53
I	THF	26	73

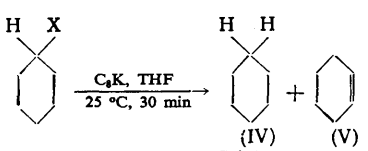
In process (4), reduction is the dominant reaction when chloro-derivatives of organic compounds are used, especially in diethyl ether. On passing to bromo- and iodo-derivatives, the Wurtz reaction begins to predominate.



Under these conditions, tosyl derivatives afford mainly alcohols and phenols:[21]

$$R-OTs \xrightarrow[25\ ^\circ C,\ 30\ min]{C_8K,\ THF} R-OH,$$

$OTs = p\text{-}CH_3C_6H_4SO_3$.

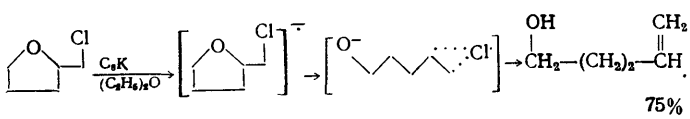


R	Yield, %
$CH_3(CH_2)_{16}CH_2$	95
C_6H_5	61

The mechanism of the reduction of halogenoalkanes by LCG with alkali metals can be represented schematically as follows:

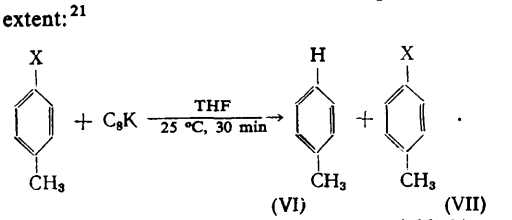
In the first stage, one-electron transfer takes place with formation of a radical-anion, which can react further via several pathways (*a*, *b*, *c*). The heterolytic dissociation of the bond in the radical-anion complex (pathway *a*) results in the formation of a free radical which "abstracts" a hydrogen atom from the solvent Solv-H [reaction (5)] or dimerises [reaction (6)]. At the same time, yet another electron can add to the radical-anion, after which fragmentation (pathway *b*) and reactions (7) and (8) take place. One cannot rule out also the direct dimerisation of the radical-anion via pathway *c* [reaction (9)].

Halogenocyclohexanes are reduced on treatment with C_8K to unsubstituted cyclohexanes or cyclohexenes:[21]



Yield, %

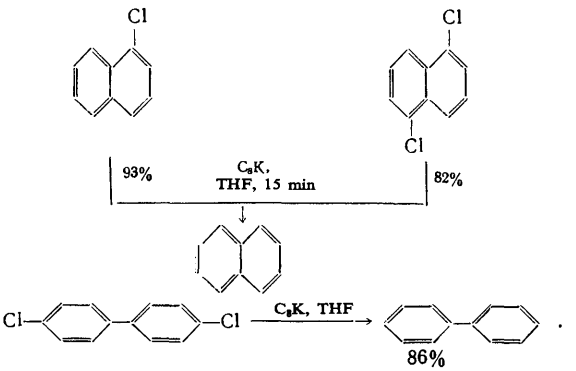
X	(IV)	(V)
Cl	84	15
Br	56	40
I	5	88



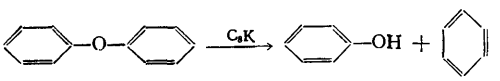
The composition of the products of this reaction is to a large extent determined by the nature of the substituent X. If X = Cl, then the main product is cyclohexane, while for X = I dehydrohalogenation with formation of cyclohexene predominates.

On treatment with LCG with potassium, tetrahydrofurfuryl chloride is converted into pent-4-en-1-ol:[21]

75%

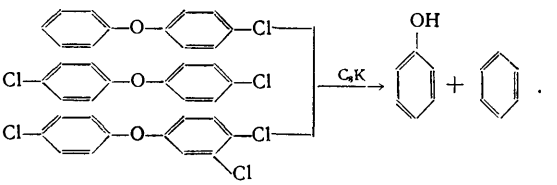


Aromatic halogeno-derivatives are more resistant to the action of LCG with alkali metals and the reduction process takes place to a lesser extent:[21]



Yield, %

X	(VI)	(VII)
Cl	50	50
Br	48	52



On the other hand, polynuclear aromatic halogeno-compounds, namely 1-chloronaphthalene, 1,8-dichloronaphthalene, or 4,4′-dichlorobiphenyl, afford the corresponding hydrocarbons in a high yield on treatment with C_8K at room temperature:[33]

Examples of the cleavage of the Ar—O—Ar linkage are also described in the same communication:[33]

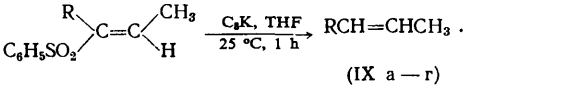
Reactions involving dehydrohalogenation and the cleavage of the Ar—O—Ar linkage can also take place simultaneously:[33]

On treatment with C_8K, 1,2-dihalogenoalkanes are readily converted into the corresponding alkenes[21] and the double bond formed is not hydrogenated, although, for example, stilbene is hydrogenated quantitatively to 1,2-diphenylmethane under these conditions after 30 min:[31]

$$C_8H_{17}CHBr—HCHBr \xrightarrow[25\ ^\circ C,\ 24\ h]{C_8K,\ THF} C_8H_{17}CH{=}CH_2.$$

94%

The reduction of such double bonds probably requires more severe conditions and the presence of excess hydrogen.[6]



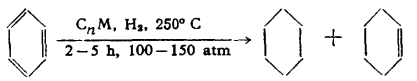
1,2-Disulphonic acid esters of type (VIII) also afford alkenes under these conditions but in a lower yield, because the elimination process is complicated by side reactions:[21]

$$C_6H_{13}\underset{\underset{OMs}{|}}{CH}—\underset{\underset{OMs}{|}}{CH_2} \xrightarrow[25\ ^\circ C,\ 24\ h]{C_8K,\ THF} C_6H_{13}CH{=}CH_2;$$

(VIII) 58%

Ms = SO_2CH_3.

A novel example of the stereoselective reduction in the presence of C_8K of α,β-unsaturated phenyl sulphones to alkenes with the preferential formation of the (*E*)-isomer has been described:[34]



(IX a — r)

R	Yield of (IX), % (*Z*:*E* ratio)
(a) n-C_4H_9	61 (30:70)
(b) n-C_8H_{17}	65 (35:65)
(c) n-$C_{16}H_{33}$	55 (35:65)
(d) $C_6H_5CH_2$	26 (40:60)

If the reduction is carried out in the presence of lithium methylamide, undec-2-ene, with the (*Z*)-isomer predominating (65%), is formed from benzene-2-sulphonylundec-2-ene in 55% yield.[34]

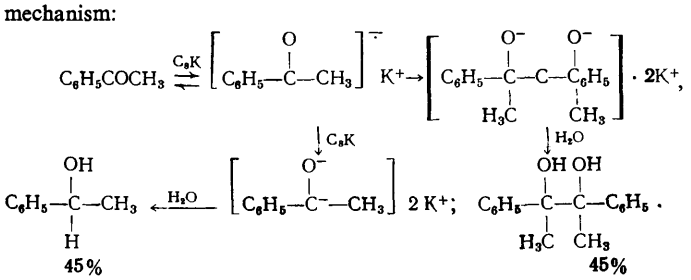
Using potassium intercalants in graphite, it has been possible to achieve the catalytic hydrogenation of benzene and alkylbenzenes under relatively mild conditions:[35]

(X) (XI) (12)

Yield, %

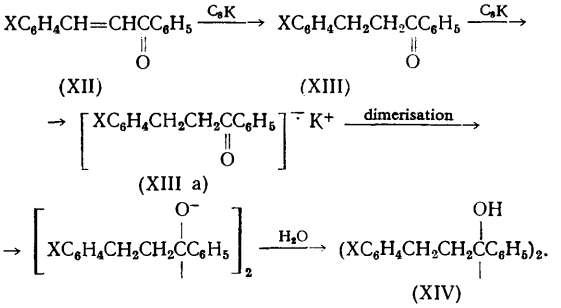
C_nM	(X)	(XI)
C_8K	79.7	—
$C_{24}K$	86.0	—
K/C	37.0	—
$C_{24}Li$	14.0	—
K	2.7	87.0

The most effective catalysts of this process are C_8K and $C_{24}K$. Metallic potassium deposited on activated charcoal with a specific surface of 890 $m^2 g^{-1}$ has an appreciably lower catalytic activity than the potassium intercalants (the specific surfaces of C_8K and $C_{24}K$ are less than 10 $m^2 g^{-1}$). LCG with lithium is even less active. In the presence of metallic potassium, the main reaction product is cyclohexene.



Toluene and propylbenzene can also be reduced under analogous conditions on treatment with $C_{24}K$, but the yield of the hydrogenated products is in this case much lower. Methylcyclohexane is formed from toluene in 8% yield and propylcyclohexane is formed from propylbenzene in 49% yield. In this case, the process is complicated by dealkylation and the reaction products contain methane, cyclohexane, and other compounds.[35]

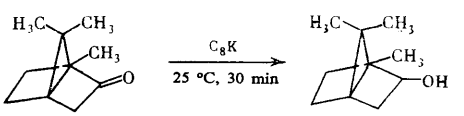
Evidence for the appreciable reducing activity of LCG with alkali metals is provided by the possibility of using them to synthesise dinuclear carbonyls from metal carbonyls:[36]



$$2M(CO)_6 + 2C_8K \xrightarrow[25\ ^\circ C,\ 30\ min]{THF} K_2[M_2(CO)_{10}] + 2CO + 16C;$$
$$M = Cr,\ Mo,\ W.$$

Iron pentacarbonyl and dicobalt octacarbonyl can also be reduced with the aid of C_8K to $K_4[Fe_2(CO)_8]$ and $K[Co(CO)_4]$ respectively. The advantages of this reduction procedure compared with methods based on the use of $NaBH_4$ [37] and sodium amalgam[38] is shorter reaction time (30 min against 18–1400 h) and a high selectivity (99%).

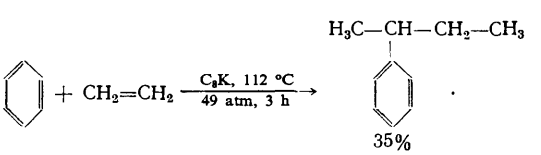
LCG with alkali metals are used to reduce a number of ketones.[39] For example, benzophenone is converted quantitatively into benzhydrol (diphenylmethanol) on treatment with C_8K in THF after 2 h at 25 °C. However, the acetophenone reduction process can proceed via two pathways, the corresponding alcohol and pinacol being formed in equal amounts after hydrolysis with water. It has been suggested that the reaction proceeds via the following mechanism:



The double bond hydrogenation process and the reduction of the carbonyl group have been described[7] as follows:

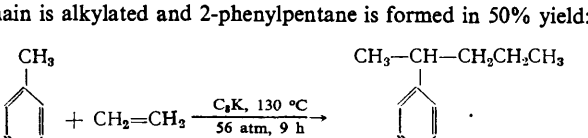
On treatment with the LCG with potassium, initially the double bond of the chalcone (XII) is hydrogenated with formation of compound (XIII), which subsequently affords the radical-anion (XIIIa). The dimerisation of the radical-anion (XIIIa) followed by protonation leads to the formation of compound (XIV). The ratio of the yields of compounds (XIII) and (XIV) depends on the nature of the substituent X: the enhancement of its electron-donating character promotes the formation of compound (XIV).

Interesting results have been obtained in the reduction of camphor in the presence of LCG with potassium, whereupon the *exo*-alcohol was detected as the main product:[39]



exo (60%)
endo (30%)

If camphor is reduced by traditional methods (using metallic potassium in alcohol or non-intercalated potassium in the presence of graphite), only the *endo*-alcohol is formed. Such regioselectivity of C_8K can be explained by the specific adsorption of the ketone on the surface of the intercalant.



3. Alkylation reactions

One of the first examples of alkylation in the presence of alkali metal intercalants has been the reaction of benzene with ethylene:[40]

The main reaction product is 2-phenylbutane, but other monoalkylbenzenes and *m*-dialkylbenzenes are formed in addition. Under more severe conditions (200 °C, 20 h, 63 atm), the yield of 2-phenylbutane falls to 23% and 19% of biphenyl is formed in addition to the products indicated.

When ethylene interacts with toluene in the presence of C_8K, the side chain is alkylated and 2-phenylpentane is formed in 50% yield:[40]

Under more severe conditions (155 °C, 68 atm, 3 h), the main reaction product becomes n-propylbenzene (48%) and the yield of

2-phenylpentane falls to 17%. It had been shown earlier that alkylation in the side chain can proceed on treatment with metallic sodium but only in the presence of promoting agents (anthracene, phenanthracene, etc.).[41] In this case, mainly n-propylbenzene is formed (57–71%) from toluene and ethylene, while the yield of 2-phenylpentane does not exceed 22%. Thus the C_8K-initiated alkylation is an effective procedure for increasing the length of the side chain in aromatic compounds.

Examples of the alkylation of a series of ketones in the presence of sodium (potassium) on graphite or on wood charcoal have been described.[42] The alkylation of cyclohexanone by methyl iodide, catalysed by sodium on charcoal, affords, together with the monoalkylation (53%) and dialkylation (18%) products, an appreciable amount of cyclohexanol (up to 11%). When sodium in graphite (with hexane as solvent) is used in this reaction, the yield of the reduction product (cyclohexanol) falls to 4% and there is also a simultaneous decrease in the yield of the monosubstitution product (to 40%), while the content of the disubstituted product rises to 27%. If THF is used as the solvent, then the alkylation is complicated still further by reduction (up to 27%) and the yield of the monoalkylated product (23%) becomes almost identical with that of the dialkylated compound (25%). Similar results have been obtained also in the reaction of 2-methylcyclohexanone or 4-t-butylcyclohexane with methyl iodide.[42]

An appreciable yield of the mono-substituted product is achieved in the alkylation of 1- and 2-tetralone with allyl bromide or methyl iodide.[42] For example, in the reaction of 1-tetralone with allyl bromide in hexane in the presence of C_8K, the yield of the monoalkylated product was 98%. A comparable yield (95%) was achieved in the presence of sodium on charcoal. However, when the process was initiated by C_8K in THF, the yield of the monosubstituted compound fell to 62% and the content of the disubstituted product rose at the same time to 38%.[42]

Compounds with an active methylene group, such as nitriles, esters, etc., are capable of being deprotonated in the presence of alkali metal intercalants, forming carbanions which are subsequently alkylated by alkyl halides or react with compounds having a multiple bond, for example with aldehydes. Even a CH acid as weak as acetonitrile is alkylated in THF at a low temperature:[43]

$$RCH_2CN \xrightarrow[4\ h,\ -60\ ^\circ C]{C_8K,\ THF} \left[\begin{matrix}RCHCN^-\\ K^+\end{matrix}\right] \xrightarrow{R^1X} \underset{R^1}{RCHCN} + \underset{R^1}{RCR^1CN}.$$

(XV) (XVI)

R	R^1X	Yield, % (XV)	(XVI)
H	$1\text{-}C_8H_{17}Br$	65	7
H	$C_6H_5CH_2Cl$	42	—
C_6H_5	CH_3I	60	6
C_6H_5	$1\text{-}C_4H_9Br$	67	3

The reaction with esters proceeds similarly:[43]

$$C_6H_5CH_2CO_2C_2H_5 \xrightarrow[4\ h,\ -60\ ^\circ C]{C_8K,\ THF} [C_6H_5CHCO_2C_2H_5]^-K^+ \xrightarrow{RX} C_6H_5CHRCO_2C_2H_5 + C_6H_5C(R)_2CO_2C_2H_5 .$$

(XVII) (XVIII)

RX	Yield, % (XVII)	(XVIII)
CH_3I	70	4
$1\text{-}C_4H_9Br$	70	5
$2\text{-}C_3H_7Br$	45	4

It is noteworthy that mainly monoalkylation occurs in the presence of C_8K, whereas in the reaction employing, for example, t-butyllithium or lithium t-butoxide the yield of the monoalkylated product was 10 and 14% respectively.[44] Thus alkylation in the presence of alkali metal intercalants is a convenient method of synthesis of monosubstituted nitriles and esters.

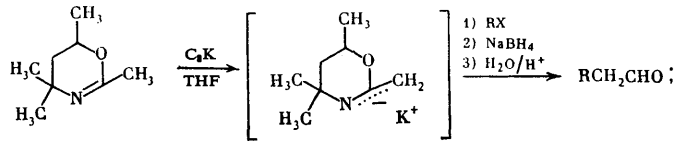
In the presence of C_8K, nitriles and esters react with aldehydes to form β-hydroxynitriles (XIXa) or β-hydroxy-esters (XIXb) as well as the α,β-unsaturated compounds (XXa) and (XXb); the overall yield of compounds (XIXa) and (XXa) is 35%:[43]

$$C_6H_5CH_2Y \xrightarrow{C_8K} [C_6H_5CHY]^-K^+ \xrightarrow[2)\ H_2O]{1)\ RCHO} \underset{OH}{\overset{Y}{C_6H_5CHCHR}} + C_6H_5CY{=}CHR,$$

(XIXa, b) (XXa, b)

(a) Y = CN; R = C_3H_7, C_6H_5;
(b) Y = $CO_2C_2H_5$; R = C_3H_7, C_6H_5.

On treatment with C_8K, various Schiff bases afford the corresponding aldehydes or ketones:[45]



$$RCH_2C{=}NR^1 \xrightarrow[25\ ^\circ C,\ 10\ h]{C_8K,\ THF} \left[\begin{matrix}K^+\\ RCH{\cdots}\overset{\cdots}{C}{\cdots}NR^1\\ R^2\end{matrix}\right] \xrightarrow[2)\ H_2O/H^+,\ 2h]{1)\ R^3X,\ THF} \underset{H}{\overset{R^3}{R-C}}-\underset{R^2}{\overset{}{C}}{=}O;$$

(XXI)

R = H, Alk, Ar; R^1 = t-C_4H_9, cyclo-C_6H_{11}; R^2 = H, Alk; R^3 = Alk; X = Cl, Br, I.

The potassium salt of the enamine anion of type (XXI) is obtained in the first stage. It interacts with alkyl halides and subsequently undergoes acid hydrolysis. The process may be complicated by the Wurtz reaction and it is therefore important to select correctly the reactant ratio in order to obtain the optimum yield of products. Best results (50–70% yield) were obtained for the reactant ratios imine : C_8K : R^3X = 1 : 2 : 2.[45]

The reactions of 2,4,4,6-tetramethyl-5,6-dihydro-1,3-oxazine with propyl iodide and benzyl bromide take place similarly and result in the formation of the corresponding aldehydes in 50 and 58% yields:[45]

R = C_3H_7I, $C_6H_5CH_2Br$.

4. Polymerisation and isomerisation reactions

Alkali metals are known to catalyse polymerisation[46] and it is therefore not surprising that one of the first examples of the use of alkali metal intercalants in organic chemistry was in reactions of this type.

Ethylene polymerises in the presence of catalytic amounts of C_8K in isooctane or n-heptane at 200 °C and 70 atm with formation after 6–20 h of a set of C_8–C_{14} *trans*-monoalkenes and small amounts of solid polyethylene having a low molecular weight and a linear structure.[47] At lower temperatures (120–150 °C) the polymerisation of ethylene does not occur in the presence of the same catalyst even after a period longer than 120 h.

When benzene, toluene, or isopropylbenzene are used as solvents, the compounds are alkylated by ethylene and the yield of polymerisation products falls sharply.[47]

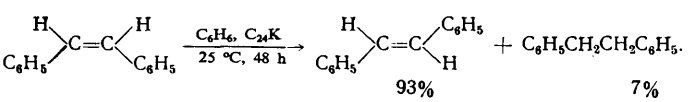
When the polymerisation reactions of ethylene in the presence of metallic potassium sputtered onto potassium chloride and sodium oxide were compared, it was shown that metallic potassium on Na_2O does not initiate this process at all, while in the presence of metallic potassium on KCl the amount of polymerisation product (C_4-C_8) formed is three times smaller than on treatment with C_8K and solid polyethylene is not formed at all. On the other hand, it is known that metallic potassium on Na_2O is an effective catalyst of the interaction of toluene and isopropylbenzene with alkyl halides.[48]

On treatment with C_8K and $C_{24}K$, polystyrene is formed from styrene after 18 h at 30 °C in 17 and 18% yields respectively,[49,50] whereas in the presence of metallic potassium the yield of the polymerisation product reaches 55%. However, in the former case the molecular weight of the polymer is approximately twice as high as in the latter. The yield of the polymer can be increased sharply by carrying out the reaction in solution. Thus the polymerisation of styrene in THF in the presence of C_8K (4 h, 23 °C) affords polystyrene in 98% yield.[51] The most suitable solvent for such polymerisation reactions is THF. The yield of polystyrene was 53% in 1,2-dimethoxyethane, 30% in benzene, and only 5% in heptane. The yield of polystyrene falls also on reducing the potassium content in graphite. Whereas, as stated above, in the presence of C_8K (THF, 4 h, 23 °C) the yield of the polymer reaches 90%, in the presence of $C_{24}K$ it is . . . [part of the Russian text appears to be missing (Ed. of Translation)] under the same conditions, while in the presence of $C_{32}K$ it is only 13%.[51] Methyl methacrylate and acrylonitrile polymerise less effectively than styrene. Thus, when $C_{16}K$ was used as the catalyst, the maximum yield of poly(methyl methacrylate) in THF was 60% and that of polyacrylonitrile was 10%.

Butadiene is polymerised most effectively on treatment with C_8K or $C_{24}K$ in the absence of solvents (30 °C, 30 min), the degree of conversion reaching 100%. In solution (in cyclohexane), the yield of the polymer is usually lower (40–80%).[49]

Isoprene is also polymerised best in the presence of C_8K and $C_{24}K$ without solvent, the yield of the polymer amounting to 100% (12 h, 75 °C, catalyst content 1%).[43] The polymer consists mainly of 3,4-adducts (56 and 44% when C_8K and $C_{24}K$ are used) and *trans*-1,4-adducts (37% in both cases). Polymerisation in cyclohexane (at 75 °C) takes place with a yield of 15–40%. The results of Parrod and Beinert,[50] according to which isoprene polymerises fully in cyclohexane after 12 h at 75 °C and in the presence of the same catalyst, conflict with these data.

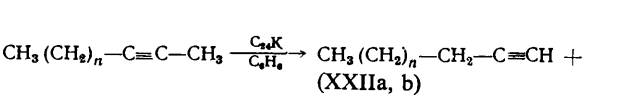
The anionic polymerisation of styrene, methyl methacrylate, butadiene, and isoprene is also initiated successfully by the lithium intercalant.[52] Styrene polymerises more effectively in toluene (34.5% after 48 h) than in dimethoxyethane (16.5% after 144 h). The higher activity of lithium fluoride compared with $C_{12}Li$ in the polymerisation of methyl methacrylate is noteworthy: in the presence of LiF in toluene or dimethoxyethane, the degree of reaction of 100%,[53,54] whereas in the presence of $C_{12}Li$ in dimethoxyethane the yield of the polymer is 80% and in toluene it is 0%. The most suitable solvent for the polymerisation of butadiene and isoprene is cyclohexane (15 °C, 42–168 h), the yields of polybutadiene and polyisoprene amounting to 51 and 80% respectively.[52]



The polymerisation of isoprene on treatment with LCG containing transition metals in potassium results in the formation of a high-molecular-weight amorphous polyisoprene, which consists predominantly of 3,4-adducts.[55] In the presence of graphite compounds containing only a transition metal, isoprene does not polymerise, while the polymer formed on treatment with LCG with potassium contains both 3,4- and 1,4-adducts. The $C_{9.5}CoK_2$ and $C_{9.5}CoK$ catalysts are most stereospecific. In their presence, the content of 3,4-units in polyisoprene reaches 95%. The stereospecificity of compounds having the general formula C_nMK_2 diminishes in the sequence Co > Mo > Fe > Ni. The increase in the potassium content above the stoichiometric value, corresponding to the formula C_nMK_2, reduces the stereospecificity of this reaction.[55]

The polymerisation of epoxyethane takes place successfully on treatment with $C_{24}K$ (THF, 20 °C). For the optimum process time (40–50 min) and catalyst concentration (0.01 M), the degree of polymerisation reaches 60–70%.[56]

The activities of a series of catalysts have been investigated in the polymerisation of β-propiolactone. They can be arranged in the following sequence based on the decrease in activity (the percentage yield of the polymer is indicated in brackets): C_8HgK (100) > $C_{24}K$ (98) > $C_{12}Li$ (94) ≃ $C_{24}K.(DME)_2$ (94) > $C_{28}K.DMSO$ (84) > C_8K (77).[57] $C_{24}K$ in xylene or THF is an effective catalyst of the polymerisation of δ-valerolactone.[58] The yield of poly(δ-valerolactone) in the presence of $C_{24}K$ is 20% smaller than in the presence of metallic potassium (91 and 70% respectively) and exceeds by a factor greater than 2 the yield (44%) attained in the presence of the homogeneous benzophenone/potassium catalyst.[58]



Organocyclosiloxanes polymerise in satisfactory yields (70–80%) in the presence of LCG with potassium or lithium.[59]

On treatment with LCG with alkali metals, unsaturated compounds can be not only hydrogenated but can also undergo the migration of the multiple bond or a change in their steric structure. For example, *cis*-stilbene isomerises wholly to the *trans*-isomer in the presence of $C_{24}K$ under mild conditions:[32]

If this mixture of *cis*- and *trans*-stilbenes is kept at 25 °C for 20 h in the presence of an excess of hydrogen (14 atm), the fraction of the *trans*-isomer rises to 96%.[32]

LCG with potassium initiates the not altogether usual triple bond isomerisation reactions.[33] Thus treatment of dec-2-yne or oct-2-yne with $C_{24}K$ results in the formation of the following products:

	Yield, % (XXII)	(XXIII)
(a) $n=4$ (80 °C, 100 h)	26	2
(b) $n=6$ (25 °C, 48 h)	20	9

These reactions are interesting because of the formation of the terminal 1,2-unsaturated bond, although usually the bond located within the hydrocarbon chain is more stable. Under more severe conditions (80 °C, 60 h), the yield of compound (XXIIb) rises to 65% and, when the reaction is carried out in cyclohexane, the yield of dec-1-yne is 86% (80 °C, 4 h).[32]

5. Condensation and cyclisation reactions

As already stated above, dimerisation processes predominate in the reduction of primary alkyl halides, especially the iodides, in the presence of LCG with alkali metals:[21]

$$C_{18}H_{37}I \xrightarrow[25\ ^\circ C,\ 1\ h]{C_8K,\ THF} C_{18}H_{37}—C_{18}H_{37}.$$

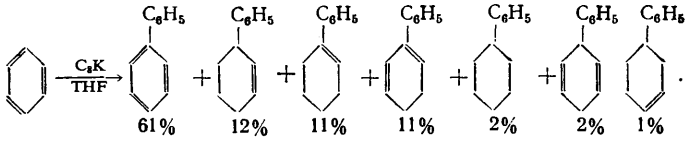
On treatment with C_8K, benzyl chloride and bromide also enter into the Wurtz reaction, affording 1,2-diphenylethane in a high yield.[60] Chlorodiphenylmethane reacts with greater difficulty under these conditions and the dimerisation takes place only to the extent of 50%:[60]

$$(C_6H_5)_2CHCl \xrightarrow{C_8K} \underset{50\%}{(C_6H_5)_2CHCH(C_6H_5)_2}.$$

The product of the reaction of β-chloroethylbenzene in the presence of LCG with potassium is mainly polystyrene (80%) and only 4% of 2,3-diphenylbutane is formed:[60]

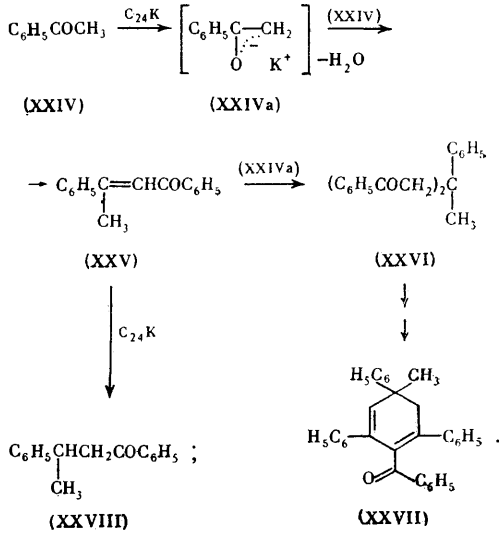
$$C_6H_5CH_2CH_2Cl \xrightarrow{-HCl} n\,C_6H_5CH{=}CH_2 \rightarrow -(CH(C_6H_5)-CH_2)_n- \ ; \quad 80\%$$

$$C_6H_5CH_2CH_2Cl \rightarrow CH_3-CH(C_6H_5)-CH(C_6H_5)-CH_3 \ . \quad 4\%$$



Certain organometallic compounds undergo similar reactions on treatment with LCG with alkali metals. For example, triphenyltin bromide gives rise mainly to hexaphenyl distannate under these conditions:[60]

$$(C_6H_5)_3SnBr \xrightarrow{K/graphite} \underset{53\%}{(C_6H_5)_3Sn—Sn(C_6H_5)_3}.$$



Trialkyl derivatives of chlorosilanes react similarly on treatment with C_8K, affording dimerisation products:[61]

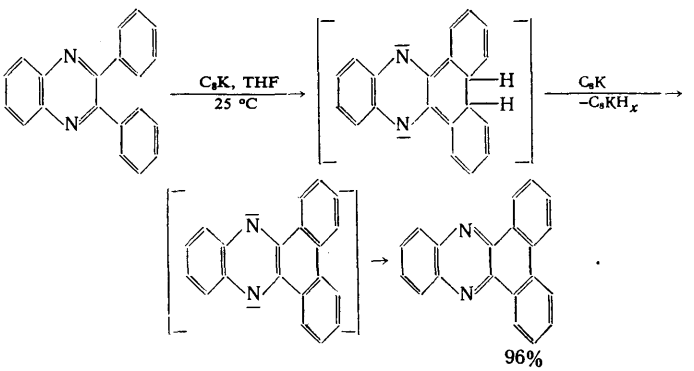
$$R_3SiCl + C_8K \xrightarrow[0^\circ C]{oxolan} R_3Si—SiR_3,$$
$$R = CH_3,\ C_6H_5,\ t\text{-}C_4H_9.$$

It had been noted earlier that benzene is predominantly hydrogenated in the presence of C_8K and H_2 with formation of cyclohexane.[32] In the absence of hydrogen, the reaction in THF proceeds differently:[62]

Under these conditions, quantitative dimerisation, accompanied by partial or complete hydrogenation of one of the rings, takes place. It is of interest to note that the products of the hydrogenation of both benzene rings were not detected. If the process is carried out without THF, no transformation of benzene takes place on treatment with C_8K after four weeks at 50 °C.[62] The condensation of acetophenone can be initiated by various alkali metals (Na and K) and also by $C_{24}K$:[7]

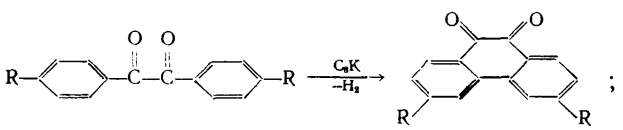
The crotonic condensation of two acetophenone molecules leads to the formation of compound (XXV), which can be hydrogenated with formation of compound (XXVIII) or can enter into the Michael reaction, affording compound (XXVI) as a result of the addition of the enolate anion (XXIVa) to the activated multiple bond. Compound (XXVI) probably also undergoes successive conversion via the Michael reaction and crotonic condensation to the product (XXVII). The ratios of the yields of compounds (XXVI)–(XXVIII) depend on the process conditions. Best results are obtained when metallic sodium is used as the catalyst, whereupon the yield of compound (XXVI) reaches 65–80%. An appreciable amount of the hydrogenated product (XXVIII) (10–15%) is then formed. The yield of the latter compound is reduced if the process is carried out in the presence of $C_{24}K$, but in this case the yield of compound (XXVI) also falls to 45–55%, since compound (XXVI) begins to cyclise to compound (XXVII). The mode of reaction depends significantly on temperature. At 40 °C, 40% of compound (XXVI) and 5% of compound (XXVII) are formed. At 95 °C, only 30% of acetophenone (XXIV) is converted into the product (XXVI), but the yield of compounds (XXV) and (XXVII) increases to 22%. In the presence of a metallic potassium film, the yield of compounds (XXV) and (XXVIII) increases still further, while that of the product (XXVI) falls to 20–40%.

In the presence of LCG with potassium, acetophenone condenses with benzaldehyde, affording a chalcone in a quantitative yield:[63]



$$C_6H_5-\overset{O}{\overset{\|}{C}}-CH_3 + C_6H_5-\overset{O}{\overset{\|}{C}}H \xrightarrow[-H_2O]{K/graphite} \underset{100\%}{C_6H_5CH{=}CH-\overset{O}{\overset{\|}{C}}-C_6H_5}.$$

Acetone gives rise to the phorone (XXIX) under similar conditions:[63]



$$3\,CH_3-\overset{O}{\overset{\|}{C}}-CH_3 \xrightarrow[-2H_2O]{K/graphite} \underset{(XXIX),\ 86\%}{(CH_3)_2C{=}CH-\overset{O}{\overset{\|}{C}}-CH{=}C(CH_3)_2}.$$

A novel procedure for the intramolecular carbocyclisation of various heterocyclic systems on treatment with C_8K has been described.[64] A series of quinoxalines, namely 2,3-diphenylquinoxaline, 2,3-diphenyldibenzo[*d*]quinoxaline, and 2,3-di-*o*-tolylquinoxaline, give rise to the corresponding phenazines in 60–96%

yields on treatment with LCG with potassium:

The attempts to carry out this reaction in the presence of dispersed potassium (instead of C_8K) lead to the decomposition of the products. DME is preferable to THF as the reaction medium.[64] This method for intramolecular carbocyclisation on treatment with C_8K is fairly general and makes it possible to obtain a wide range of polycyclic compounds. In particular, phenanthrenenequinone can be obtained in this way from benzil in the presence of C_8K:[65]

R=H, CH_3.

6. Other reactions

The sodium intercalant in graphite catalyses the reaction of carbon monoxide with hydrogen (the Fischer–Tropsch reaction),[66] which leads to the formation of a mixture of hydrocarbons ranging from C_1 to C_4:

$$CO + H_2 \xrightarrow[300\ ^\circ C,\ 20\ h]{Na/graphite} \underset{2\%}{CH_4} + \underset{74\%}{(C_2H_6 + CH_2{=}CH_2)} +$$

$$+ \underset{22\%}{(C_3H_8 + CH_2{=}CHCH_3)} + (\text{butane} + \text{but-1-ene}$$

$$+ \textit{cis}\text{-but-2-ene} + \textit{trans}\text{-but-2-ene}).$$

The yield of the products increases if the potassium intercalant in graphite is used together with transition metal chlorides ($FeCl_3$, $RuCl_3$, $OsCl_3$, $MoCl_5$, $PtCl_4$, $NiCl_2$, $PdCl_2$, WCl_6). In the presence of LCG containing only the chlorides (without metallic potassium), this reaction does not occur.

Systems of the type graphite/$FeCl_3$/M (M = K, Na, Rb) catalyse also the synthesis of ammonia from nitrogen and hydrogen:[67]

$$N_2 + 3\,H_2 \xrightarrow[300-350\ ^\circ C,\ 20\ h]{graphite/FeCl_3/M} 2\,NH_3 .$$

M	Yield, %
K	90
Na	52
Pb	43

The catalyst containing potassium is the most active in this process, while that containing rubidium is least active. When $FeCl_3$ in the LCG with potassium is replaced by other salts ($RuCl_3$, $OsCl_3$, $MoCl_5$), the percentage conversion becomes lower and amounts respectively to 30, 60, and 1%. The use of the graphite/$OsCl_3$/K system also leads to the formation of appreciable amounts of hydrocarbons (methane, ethane, etc.).[67]

An interesting application of C_8K has been described.[68] When this intercalant is treated with magnesium iodide, compound (XXX) is obtained. It reacts with a series of alkyl and aryl halides, affording an unusual Grignard reagent (XXXI):

$$2\,C_8K + MgI_2 \xrightarrow[\text{or } C_6H_6]{(C_2H_5)_2O} \underset{\text{(XXX)}}{C_{16}Mg(KI)_2} \xrightarrow{RX}$$

$$\rightarrow \underset{\text{(XXXI)}}{C_{16}(RMgX)(KI)_2} + RMgX,$$

RX = C_2H_5Br, C_6H_5Br, C_6H_5Cl, p-$Br_2C_6H_4$, $CH_3CBr{=}CH_2$.

The reaction takes place more effectively in non-polar benzene (yield 83–98%) than in ether (40–70%). Compound (XXXI), isolated as a friable powder, can be used in classical reactions involving a Grignard reagent (Table 4). It is extremely important that the Grignard reagents obtained in this way can be stored for a long time without a significant loss of their activity.

Table 4. Reactions of $C_{16}(RMgX)(KI)_2$ with electrophiles.[68]

RMgX in $C_{16}(RMgX)(KI)_2$	Electrophile	Yield of product*, %		
		RCOOH	$R(C_6H_5)_2COH$	RH
C_6H_5MgBr	$(C_6H_5)_2CO$	—	88 (84)	—
	CO_2	87 (82)	—	—
	H_2O	—	—	96 (93)
C_2H_5MgBr	$(C_6H_5)_2CO$	—	87 (84)	—
	CO_2	93 (88)	—	—
	H_2O	—	—	95 (92)

* The yields attained using the reagent $C_{16}(RMgX)(KI)_2$ stored for 300 days are indicated in brackets.

The reactions of alkali metal intercalants in graphite with organic perfluoro-compounds (perfluorinated amines, perfluorodecalin, etc.) result in the formation of the corresponding alkali metal fluorides, incorporated in graphite,[69] which are active basic catalysts of certain organic reactions[70] and also function as effective fluorinating agents.[71]

The isotope exchange of hydrogen and deuterium in the presence of LCG with alkali metals has been studied in a number of investigations.[72–74] The activity of the intercalants in this reaction decreases in the sequence $C_{24}K > C_{36}K \gg C_8KH_{0.67} \gg C_8K \simeq 0$. The zero activity of C_8K is evidently due to the fact that neither hydrogen nor deuterium can enter the interlayer space in this inclusion compound owing to the high density of the alkali metal ions.[6] On the other hand, the hydrogen in methane can be exchanged for deuterium in the presence of both $C_{24}K$ and C_8K. The rate of exchange in the presence of $C_{24}K$ is more than twice as high as with participation of C_8K.[75]

The formation of reliably detected radical-anions has been observed[76] in the reactions of $C_{24}K$ with various organic compounds. Examples of the extraction of potassium by a series of organic compounds with formation of the corresponding radical-anions are presented in Table 5. In the case of polycyclic aromatic compounds (Table 5, Nos. 1–7), this process can be described by the following scheme:

$$C_{24}K + x\text{ArH} \xrightarrow{\text{DME}} KC_yDME_z + x[\text{ArH}]^- - K^+DME,\ y>24,\ 1<z<2.$$

The degree of extraction of potassium depends significantly on the electron affinity of the polycyclic compounds. While the degree of extraction of potassium by naphthalene (E_0 = 0.09) is only 18%, that by acenaphthene (E_0 = 1.12) increases to 76%.[76] The appearance of a double bond in the side chain of the arene probably promotes for the same reason an increase in the degree of extraction of potassium (Table 5, cf. Nos. 1 and 9 and 2 and 10).

Table 5. Extraction of potassium from $C_{24}K$ by aromatic compounds[76] (5×10^{-2} M solution in DME, contact time 48 h, 23 °C).

No.	Compound	Electron affinity* (E_0)	Degree of extraction of K, %
1	Biphenyl	0.0	15
2	Naphthalene	0.09	18
3	Phenanthrene	0.17	25
4	Pyrene	0.06	38

15	1-Cyanopyrene	—	99

* Determined potentiometrically in DME relative to the biphenyl radical-anion.

Aromatic nitriles and ketones (Table 5, Nos. 11–15) are more effective potassium extractants. The formation of radical-anions in such cases probably proceeds in accordance with the following schemes:

$$x\text{Ar}-\text{CO}-\text{Ar} + C_{24}K \xrightarrow{\text{DME}} x[\text{Ar}-\text{CO}-\text{Ar}]^- K^+.\text{DME} + KC_yDME_z,$$

$$x\text{Ar}-\text{CN} + C_{24}K \xrightarrow{\text{DME}} x[\text{Ar}-\text{CN}]^- K^+.\text{DME} + KC_yDME_z.$$

The examples presented demonstrate the high electron-donating capacity of LCG with alkali metals in relation to weak electron acceptors and confirm the hypothesis that the layers of graphite in LCG with alkali metals can be regarded as macropolyanions in which electrons are located in different energy levels.

* * *

Thus layered compounds of graphite with alkali metals are used in various fields of organic synthesis as Lewis bases and one-electron reductants. Their advantages over alkali metals consist in the fact that they ensure milder reaction conditions and easier separation of the reaction products and make it possible to regulate the selectivity and stereoselectivity of the processes by varying the nature of the alkali metal in the LCG and the type of intercalant. The high sensitivity of LCG with alkali metals to the presence of traces of oxygen and water should be included among the disadvantages of their use in organosynthesis.

Introduction of a carbon–carbon bond into electron-deficient aromatic compounds

G A Artamkina, S V Kovalenko, I P Beletskaya, O E Reutov
M V Lomonosov Moscow State University

ABSTRACT. Methods for introducing a new carbon–carbon bond into aromatic compounds containing such electron-accepting groups as NO_2, SO_2CF_3, or oxazoline and into perfluoroarenes are discussed in the review. These methods comprise S_NAr reactions, oxidation of anionic σ-complexes, isolated previously or obtained *in situ*, and vicarious nucleophilic substitution reactions.

The bibliography contains 371 references.

I. Introduction

The interest of organic chemists in nucleophilic aromatic substitution, and in anionic σ-complexes as possible intermediates in these reactions, has not weakened during almost four decades. Both the overall number of publications and the continuous appearance of new reviews and monographs indicate this.[1–20] In spite of apparent outward simplicity the nucleophilic aromatic substitution reaction is distinguished by the complexity and diversity of its mechanisms.

Reactions of the S_NAr type which lead to the formation of a new C–C bond have special significance and are consequently extremely important in organic synthesis. Such reactions occur most smoothly with perfluoroarenes. However for several halonitroarenes they proceed in a far more complex manner and frequently lead to mixtures of products. The functionalisation of nitroarenes has great importance since the compounds obtained serve as starting materials for the synthesis of various biologically active heterocycles.[21,22]

It is well known that at first a rapid and reversible formation of anionic σ-complexes occurs at an unsubstituted carbon atom in the reaction of charged nucleophiles with electron-deficient arenes. The most stable of these are complexes with carbon–carbon bonds since their rearrangement into 1,1-σ-complexes, from which substitution products are then formed, proceeds most slowly. As a result they are able to undergo various conversions such as entering into oxidation-reduction reactions with the participation of the nitro group. These complexes may also be oxidised by suitable oxidising agents so that halogens and other substituents in the benzene ring are unaffected. Thus the preparation of anionic σ-complexes and their subsequent oxidation may be an alternative method of introducing a C–C bond into an electron-deficient arene. It is probable that this very route is the most acceptable for substrates containing several electron-accepting groups such as 1,3,5-trinitrobenzene or 1,3,5-*tris*-(trifluoromethylsulphonyl)benzene which form stable σ-complexes. However good results were also obtained when oxidising unstable σ-complexes formed from mononitroarenes.

Arenes activated by an oxazoline group, besides nitro- and *tris*-(trifluoromethylsulphonyl)-aromatic compounds, are widely used at present as substrates in S_NAr type reactions. Although the activating effect of this group is weaker than that of a NO_2 group similar compounds prove to be valuable intermediates in synthesis.

Methods are discussed in the present review for introducing a C–C bond into electron-deficient arenes and include nucleophilic substitution of halogen and hydrogen. Since there are practically no data on reactions of the S_NAr type with carbanions in the known reviews[1–5] and monograph[6] they are considered in ample detail in the present review. On the other hand a whole series of reviews[7–19] and a recently published fundamental monograph[20] have been devoted to anionic σ-complexes and contain information on complexes with various types of C–Nu bonds, and on their physicochemical characteristics and stability constants. Consequently we will not list all the σ-complexes with C–C bonds obtained to date in the present review but will indicate only the main carbanions with which σ-complexes are successfully obtained. Principal attention will be paid to the conditions for obtaining σ-complexes and also to the methods for aromatising them.

Reactions for adding organometallic compounds and carbanions to mononitroarenes are segregated into a separate section. Removal of hydride ion from an intermediate unstable σ-complex occurs only under the action of an external oxidising agent or a nitroarene. The interesting vicarious nucleophilic substitution reactions are included here.

The limited size of the review does not permit inclusion of S_NAr type reactions (and the formation of σ-complexes) in neutral and cationic complexes of arenes with the transition metals, which are being widely studied at present. Reactions with carbanions in the heterocyclic series have been partially considered in reviews which have appeared comparatively recently.[23,24]

II. Nucleophilic aromatic substitution reactions

1. Substrates activated by NO_2, SO_2CF_3 and oxazoline groups

a) Substitution of halogen

As mentioned above halonitro derivatives are the most frequently used subjects of nucleophilic aromatic substitution reactions since the nitro group is one of the very strong electron-accepting substituents

Table 1. Replacement of halogen in halonitrobenzenes by carbanions of malonic, acetoacetic and cyanoacetic esters and of acetylacetone.

No.	Substrate	Carbanion from	Group replaced	Solvent	Yield, %	Refs.
1	1-Chloro-2-nitrobenzene	$NaCH(COOEt)_2$	Cl	t-BuOH	54	[32]
2	1-Bromo-2-nitrobenzene	$NaCH(COOEt)_2$	Br	Et_2O		[31]

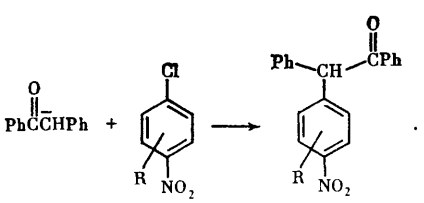
5	1-Chloro-2,4-dinitrobenzene	$NaCH(COOEt)_2$	Cl	EtOH		[30]
6	1-Bromo-2,4-dinitrobenzene	$NaCH(COOEt)_2$	Br	EtOH		[33, 35]
7	1-Chloro-2,6-dinitrobenzene	$NaCH(COOEt)_2$	Cl	Et_2O		[25]
8	1-Chloro-4-methyl-2,6-dinitrobenzene	$NaCH(COOEt)_2$	Cl	Et_2O		[27]
9	1,5-dichloro-2,4-dinitrobenzene	$NaCH(COOEt)_2$	Cl	Et_2O		[28]
10	1-Chloro-2,4,6-trinitrobenzene	$NaCH(COOEt)_2$	Cl	$EtOH+C_6H_6$		[29]
11	1-Chloro-2,4-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	75	[37]
		NaCH(COOEt)COMe	Cl	Et_2O	74	[45]
		NaCH(COOEt)COMe	Cl	EtOH		[30, 36]
12	1-Chloro-2,6-dinitrobenzene	NaCH(COOEt)COMe	Cl	EtOH	90	[26]
13	1,2-Dichloro-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	59	[41]
14	1-Bromo-2-chloro-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	88	[38]
15	1-Chloro-2-iodo-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	57,4	[40]
16	1,4-Dichloro-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	56	[42]
17	1-Bromo-4-chloro-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	98	[39]
18	1-Chloro-4-iodo-3,5-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	84	[43]
19	1,5-dichloro-2,4-dinitrobenzene	NaCH(COOEt)COMe	Cl	Et_2O	80	[30]
20	1-Chloro-2,4,6-trinitrobenzene	NaCH(COOEt)COMe	Cl	EtOH		[44]
21	1-Chloro-2-nitrobenzene	NaCH(CN)COOEt	Cl	t-BuOH	70	[43]
22	1-Chloro-4-nitrobenzene	NaCH(CN)COOEt	Cl	EtOH		[46]
23	1-Chloro-2,4-dinitrobenzene	NaCH(CN)COOEt	Cl	EtOH	90	[46]
24	2-Chloro-5-nitrobenzonitrile	NaCH(CN)COOEt	Cl	EtOH		[30]
25	1-Chloro-2,4,6-trinitrobenzene	NaCH(CN)COOEt	Cl	EtOH	53	[46]
26	1-Chloro-2,4-dinitrobenzene	$NaCH(COMe)_2$	Cl	EtOH	54	[47, 48]

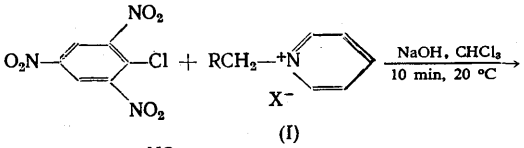


and halogen is a good leaving group. The activating influence of other electron-accepting groups (CN, CF_3, COR, etc.) for substitution of halogen in ArX usually proves to be insufficient.

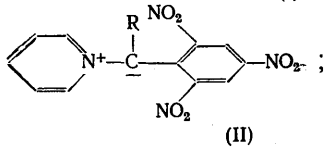
The substitution of halogen under the action of anions of malonic,[25–33] acetoacetic[26,30,34–35] and cyanoacetic[30,43,46] esters and acetylacetone[47,48] in ether and alcohol has been studied recently. In these solvents carbanions display fairly low reactivity, they react successfully with strongly activated di- and trinitrohalobenzenes where yields are satisfactorily high (Table 1).

For example the sodium salts of malonic and acetoacetic esters do not react in alcohol with 2-chloro-5-nitrobenzonitrile† or with 2-chloro-5-nitrobenzoic acid.[30] However in t-butanol the potassium salts of cyanoacetic and malonic esters react successfully with *o*-chloronitrobenzene and give low yields of substitution products in ether and ethanol.[32] Generally speaking these studies are fairly complex to analyse since product yields are often not given. It is interesting to mention that the structures of the α-picryl and 2,4-dinitrophenyl derivatives of acetoacetic ester, obtained at the end of the past century,[44] were established only comparatively recently. It was shown that they were enols not only in solution[45,49,50] but also in the solid state.[51] α-Picrylacetylacetone is completely enolised in solution.[52]

The new stage in the study of nucleophilic aromatic substitution is linked with the use of dipolar aprotic solvents of the type of dimethylsulphoxide (DMSO), hexamethylphosphoramide (HMPA) or pyridine (Py) which usually smooth the course of the reaction. Thus the sodium salts of malonic ester and acetylacetone react with *o*-chloronitrobenzene, *p*-chloronitrobenzene, and 1,4-dichloro-2-nitrobenzene in dimethylformamide (DMF), DMSO and HMPA at 100 °C in 1 to 5 h, the yields of arylation products being from 20 to 65%.[53] Arylation of phenylacetonitrile with *p*-chloronitrobenzene was carried out successfully in pyridine in the presence of KOH.[54]



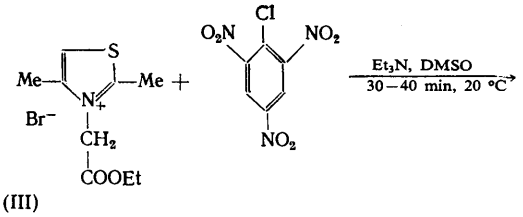
Arylation of the carbanion of desoxybenzoin by various halonitrobenzenes was carried out in DMSO and DMF, *p*-halonitrobenzenes gave products in ~60% yield but *ortho* isomers reacted non-selectively and yields of substitution products were low.[55]



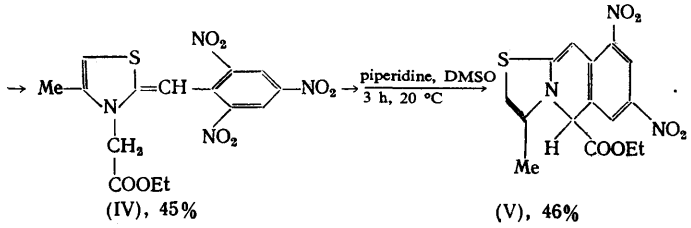
In aromatic nitrotoluenes the methyl group located in the *para* position to the nitro group may be deprotonated under the action of base. It was shown that 2,4,6-trinitrotoluene reacts in the presence of MeONa with picryl chloride, 1-chloro-2,4-dinitrobenzene, 1-fluoro-2,4-dinitrobenzene and 1,3-dibromo-2,4,6-trinitrobenzene with the formation of polynitrodiphenylmethanes.[56] Highest yields of products were achieved on carrying out the reaction in a tetrahydrofuran (THF)–DMSO mixture however even under these conditions 2,4,6-trinitrotoluene did not react with mononitro- and 1-halo-3,5-dinitro- and 1-halo-2,6-dinitrobenzenes.[56]

†A report on the isolation of a product from the reaction of sodiomalonic ester with 4-bromo-3-nitrobenzonitrile is seemingly erroneous.[32,30]

Among the other reactions of halonitrobenzenes with carbanions it is necessary to mention the preparation of ylids (II) by reacting picryl chloride with quaternary salts of pyridine (I) in the presence of alkali.[57]



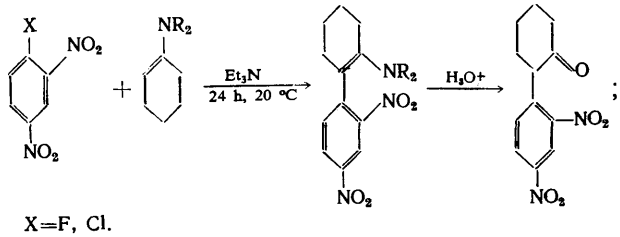
(I)



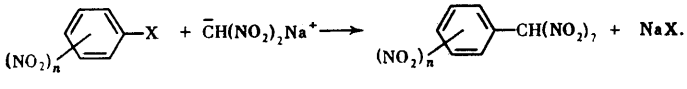
(II)

R = PhCO, MeCO etc.

Reactions of picryl chloride with salts of type (III) in DMSO in the presence of base lead to the formation either of ylid (IV) or the product of intramolecular substitution (V) of a nitro group by the carbanion of ylid (IV).[58]

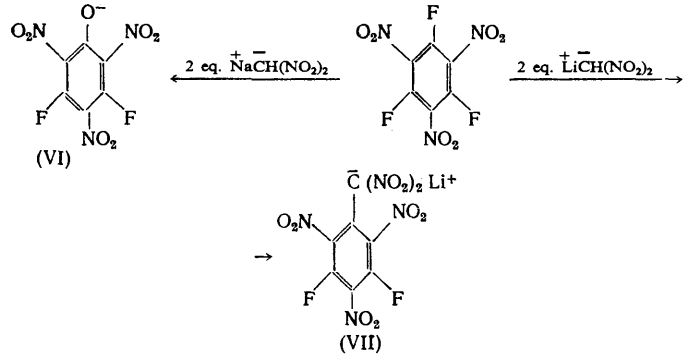


(III)



(IV), 45% (V), 46%

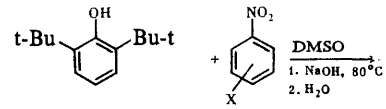
Products of substitution of the halogen atom in 1-chloro-2,4-dinitrobenzene or 1-fluoro-2,4-dinitrobenzene by enamines were obtained in 80–90% yield in the presence of an equimolar quantity of triethylamine.[59] It was noted that in the absence of Et_3N yields were sharply reduced (to 6–30%).



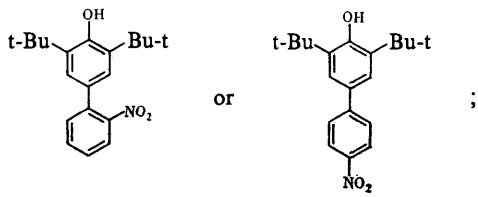
X=F, Cl.

Reactions of the sodium salt of dinitromethane with various halonitrobenzenes in DMF have been investigated.[60]

1-Halo-2,4-dinitrobenzenes displayed the greatest reactivity in this reaction. The reaction of 1,2-dichloro-4-nitrobenzene and 1,4-dichloro-3-nitrobenzene with $\bar{C}H(NO_2)_2Na^+$ was not complete even after a year (20 to 25 °C); *o*- and *p*-chloronitrobenzenes and 2,3,5,6-tetrachloro-3-nitrobenzene generally did not react.



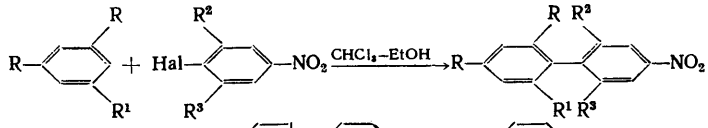
2,4-Dinitrophenoxide and picrate were isolated on attempting to react the sodium salts of bromodinitromethane and trinitromethane with 1-chloro-2,4-dinitro- and 1-chloro-2,4,6-trinitrobenzenes respectively.[60] The picrate (VI) was isolated from the reaction of 1,3,5-trifluorotrinitrobenzene with the Na salt of dinitromethane. However use of the Li salt made it possible to obtain the *C*-arylated product (VII) in 43% yield[61] (see also p. 755). Regrettably no opinion was expressed on possible routes of forming phenoxides and picrates.[60]



(VI)

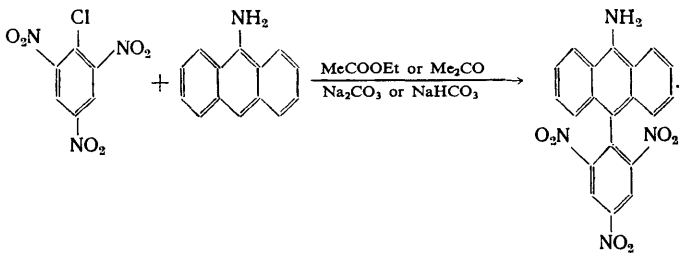
(VII)

Phenoxide ions and aromatic amines occasionally emerge as *C*-nucleophiles in S_NAr type reactions[62–66] (see also p. 761). Usually 2,6-dialkylphenols react with *p*-chloronitrobenzene in DMSO in the presence of KOH giving diphenyl ethers.[62] However 2,6-di-(t-butyl)phenol forms *C*-arylation products under these conditions[62,63] (cf. p. 761).



64–97%

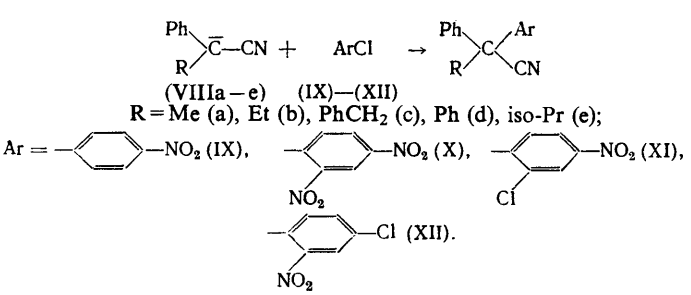
X = 2-F, Cl, Br, I, NO_2, SO_2Ph, 4-NO_2.



Diaryls formed by reaction of aminobenzenes with activated aryl halides are intensely coloured and are intramolecular charge-transfer complexes.[65,66]

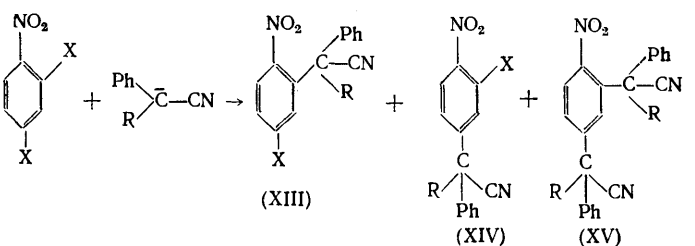
R, R^1 = N⟨ , N⟨ , NMe_2, N⟨ O;

Hal = F, Cl; R^2, R^3 = NO_2, H, CN, CO_2Me.



The reactivity of ArHal and arylamines in these reactions varies within wide limits. Thus the interaction of picryl chloride, the most reactive of all the aryl chlorides, with all triaminobenzenes proceeds readily, with dipyrrolidino- and dipiperidinobenzenes more extended heating is required and with mono(dialkylamino)benzenes generally does not occur.[65] Products of *C*-arylation were also obtained in the reaction of 9-aminoanthracene and 2-amino-*N*-methylindole with picryl chloride.[66]

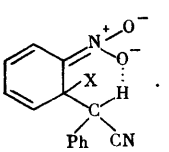
It was noted that the remaining primary amines investigated (derivatives of benzene, diphenyl, naphthalene, pyridine, quinoline, carbazole, etc.) were arylated at nitrogen.[66]



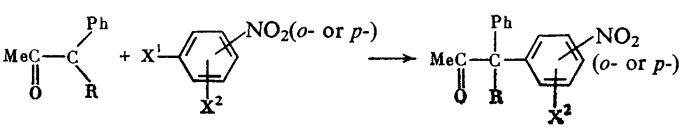
The application of dipolar aprotic solvents has therefore extended significantly the scope of the nucleophilic aromatic substitution reaction, however the high cost of these solvents and mainly the difficulties of separating the reaction products from them significantly limit their use. The application of phase-transfer catalysis (PTC) is more promising.[67–69] Good results were obtained on using PTC to prepare polynitrodiphenylmethanes from 2,4,6-trinitrotoluene and picryl chloride or 1-chloro-2,4-dinitrobenzene. Reaction was effected in methylene chloride in the presence of aqueous alkali solution and a phase transfer agent (18-crown-6 ether, $PhCH_2\overset{+}{N}Et_3Cl^-$), yields of products were ~90%.[70]

The PTC method has been successfully applied for the arylation of alkyl- and phenylacetonitriles with various chloronitrobenzenes in a system of 50% aqueous NaOH in the presence of triethylbenzylammonium chloride. Yields of products were 80–90%.[54,71–75]

Regrettably not all reactions proceed readily under these conditions. For example, in the case of carbanions (VIIId) and (VIIIe) the results varied with the nature of ArCl and the reaction conditions. Both carbanions form normal substitution products with chlorodinitrobenzene (X) however nitroarylation occurs only in the presence of DMSO with 1,2-dichloro-3-nitrobenzene (XI). In the absence of DMSO (VIIId) and (XI) react to form 1,1-dicyanotetraphenylethane and reduction products of the nitro group but 4-chloro-2-nitrophenol is formed from (VIIIe) and (XII) in the presence of DMSO.[54]



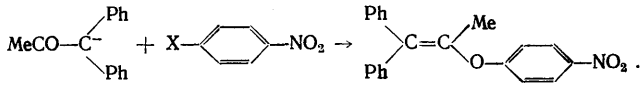
It was also noted that anions of active methylene compounds (phenylacetonitrile, desoxybenzoin, ethyl cyanoacetate, malonic ester) do not form arylation products under PTC conditions in good yield.[55,74,75] These reactions are successfully effected in aprotic dipolar solvents.[53–55] It is interesting that such carbanions replace the halogen in the *ortho* position of 2,4-dihalonitrobenzenes although the yield of product (XIII) was fairly low.[75] These reactions always give a complex mixture of products and are accompanied by resinification to a significant extent (see also pp. 768 and 769). However carbanions of phenylalkylacetonitriles and also ethyl malonate replace halogen predominantly at the *para* position.[75]



X = Cl, Br; R = Me, $PhCH_2$, Et, Ph, H.

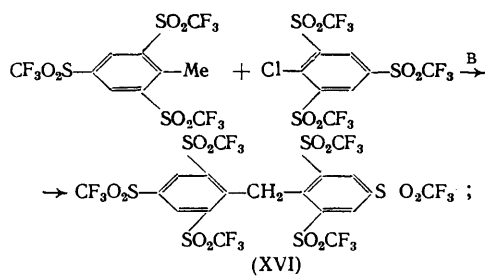
The yield of product (XIV) was 70–90%, compounds (XIII) and (XV) if formed were in minimal amounts (2–4%). Compounds (XIII) and (XV) were obtained in somewhat larger yield from benzylphenylacetonitrile (15.6% and 10.7% respectively).

The observed phenomenon of the preferential replacement of the *ortho* halogen in 2,4-dihalonitrobenzenes is explained by the *ortho* effect of the nitro group which is also known for reactions with other nucleophiles. In the reaction of 1,3-dihalo-4-nitrobenzenes with tertiary amines and anionic reagents, the halogen atom in the *para* position is the more reactive while with primary and secondary amines the *ortho* halogen is more reactive.[3] It was suggested that the presence of hydrogen atoms in the anion enables the formation of an intramolecular hydrogen bond with the *ortho*-nitro group in the σ-anionic complex which leads to its further stabilisation and increases the rate of nucleophilic substitution of the halogen atom in the *ortho* position (see also Chapter IV, section 2).



Nitroarylation of ketone enolates has been carried out in aprotic dipolar solvents and in a two-phase catalytic system.[76]

R=H, Et, Pr, Bu; X^1=F, Cl; X^2=H, Cl, NO_2.

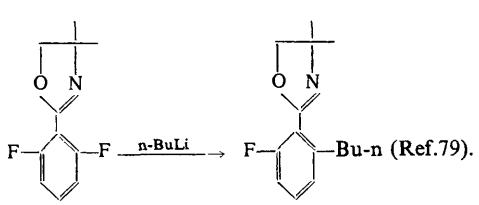


The reaction of benzylmethylacetone with halonitrobenzenes has been carried out in DMSO or DMF using NaOH or NaH. 1-Alkyl-1-phenylacetones are arylated better in a two-phase system, the reaction being accelerated by small additions of DMSO. Yields

were higher for *o*- and *p*-fluoronitrobenzenes than for the chloro derivatives. It was noted that only the product of *O*-arylation was isolated on arylation of 1,1-diphenylacetone under these conditions.[76]

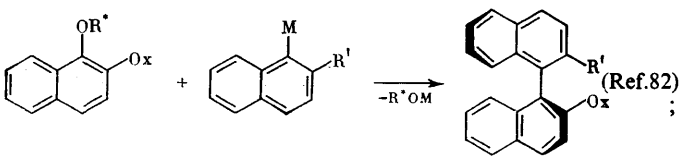
It is evident from the material stated above that carrying out a nucleophilic substitution reaction under PTC conditions is promising. Regrettably it was impossible to react the most reactive nitroaromatic compounds of the picryl halide type with insufficiently stable carbanions under these conditions.

It is known that the SO_2CF_3 group displays an even stronger electron-accepting effect than the nitro group. Like 2,4,6-trinitrotoluene 1-methyl-2,4,6-*tris*-(trifluoromethylsulphonyl)benzene reacts readily in the presence of various bases (B) with 1-chloro-2,4,6-*tris*-(trifluoromethylsulphonyl)benzene with the formation of the corresponding diphenylmethane (XVI).[77]



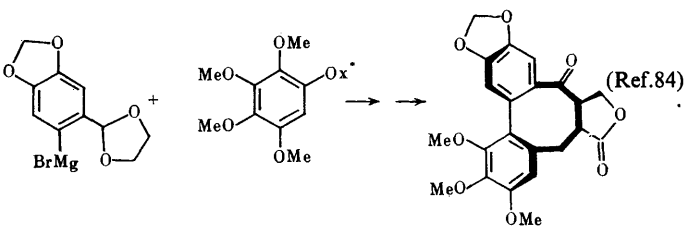
(XVI)

B = MeMgI (yield 16–57%), NaH (17%), KOH (47%), KF (79%).



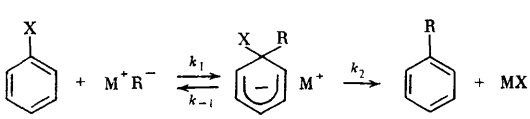
In this case KF proved to be the most effective base.

Several papers have appeared very recently in which the activating influence of the oxazoline group in nucleophilic aromatic substitution reactions has been reported.[78–86] This group is valuable because nucleophilic substitution reactions of various organomagnesium and organolithium compounds occur readily in its presence and the oxazoline group itself may be converted into carboxyl, ester or amide.[78] A fluoride or methoxyl group in the *ortho* position to the oxazoline ring may emerge as leaving group.[78]



The introduction of the oxazoline group to activate the aromatic nucleus has enabled the development of methods of obtaining chiral biaryls. Good results were obtained both on using a chiral leaving group OR* and a chiral oxazoline fragment OX*.[81–84] However it is necessary to note that the activating influence of the oxazoline group frequently proved to be insufficient to effect a nucleophilic substitution with stabilised carbanions.

Several studies on the kinetics of the reaction of halonitrobenzenes with carbanions are known.[52,87–96] In all cases the nucleophilic substitution reaction is considered as a two-step process where the rate-determining step is the formation of a 1,1-σ-complex and the removal of halide ion occurs in the subsequent rapid step‡. This is the most common situation for an S_NAr mechanism.[52,87–90]

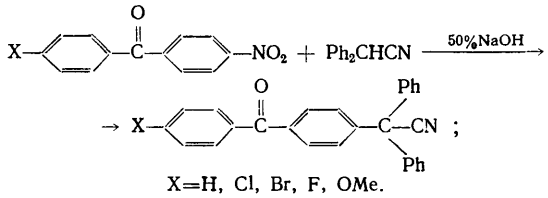


(Ref.82);

(Ref.84).

It should be noted that on the basis of purely kinetic data is is probably impossible in these cases to establish the rate-determining step although indirect data indicate that such a mechanism is correct.[52,87,89] From general considerations it is also evident that the halide removal step (k_2) must not be slower than breakdown of the carbanion (k_{-1}).

This was confirmed by data on the influence of the nature of the leaving group on the rate of halogen replacement in the reactions of *p*-halonitrobenzenes with fluorenyl anions.[91] It was shown that the reaction rate increases in the series F > Cl > Br > I. Results on a study of competing substitution of halogen atom in dihalonitro compounds under the action of anions of malonic and acetoacetic esters are in agreement with this conclusion (see also Table 1).[38–40,43] Similarly for chloropentafluorobenzene reacting with 9-carbomethoxyfluorenyl anion where preferential replacement of the fluoride ion in the *para* position to chlorine was observed.[92,93] Essentially the formation of a 1,1,-σ-complex has not been established in any of the work in which the kinetics of halogen replacement have been studied. It is known that picryl chloride and even 1-halo-2,4-dinitrobenzene form stable 1,3-σ-complexes in reactions with nucleophiles, including carbanions, and these complexes have been isolated and characterised by PMR spectroscopy.[97–99] These complexes are sometimes very stable, as for example in the case of R = CH_2COMe which gave no further substitution product or this conversion occurs very slowly. The 1,3-σ-complexes formed on interacting picryl chloride with anions of malonic and cyanoacetic esters[52,88,89] or malondinitrile[90] are seemingly less stable (lower pK_a values for the CH-acid) and subsequently rearrange into 1,1-σ-complexes (not recorded) which also give substitution products.



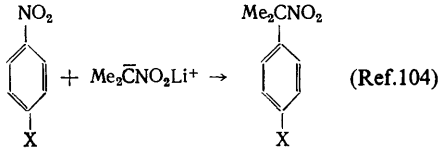
‡The rate-determining removal of halide ion has been proposed.[95,96] However the conclusions were incorrect since these authors proceeded from the false premise of assuming the 1,1-σ-complex to be more stable than the 1,3-σ-complex.

When the group being replaced is MeO^- the second step may remain slow. Such a situation was observed in the reaction of 2,4,6-trinitroanisole with anions of malonic and cyanoacetic esters.[100,101]

It was noted above that high yields of halogen substitution products were successfully achieved on carrying out the reaction in DMSO or under PTC conditions, i.e. in systems where carbanions are in the form of free ions or solvent-separated ion pairs. On the other hand in systems of NaH (or $NaNH_2$)–ether (or THF, benzene) yields of products were, as a rule, low.[54] In these solvents carbanions usually form contact ion pairs or associates. Similar rules for the influence of the medium or of the counter-ion were confirmed by results on the study of the kinetics of arylation of the Na salts of cyanoacetamides and of the K salts of 9-carbomethoxyfluorene by halonitrobenzenes. Here the free ions react at a greater rate than the ion pairs.[92,93,102] The exception was the arylation reaction of the Na salt of *N,N*-dimethylcyanoacetamide by *o*-chloronitrobenzene where the ion pair proved to be more reactive than the free ion. The authors linked this with stabilisation of the σ-anionic complex formed by coordination of the counter ion with oxygen of the nitro group.[102]

b) Replacement of other groups

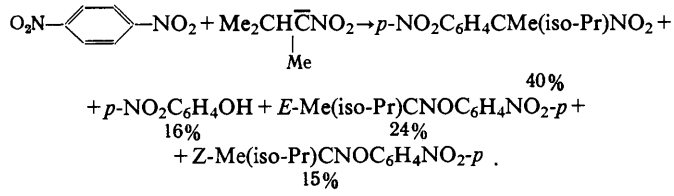
It is known in principle that the nitro group is a fairly good leaving group under conditions when it is activated by another electron-accepting substituent.[4] Examples of such substitution under the action of carbanions are sparse as yet. The substitution of a nitro group in nitrobenzophenones occurs readily under PTC conditions.[54]



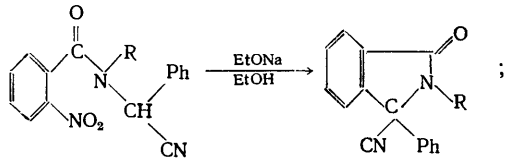
X=H, Cl, Br, F, OMe.

Replacement of a nitro group also takes place in the reaction of perfluoronitrobenzene with perfluoro-t-butyl anion.[103]

$$C_6F_5NO_2 + (CF_3)_3C^- \rightarrow C_6F_5C(CF_3)_3.$$



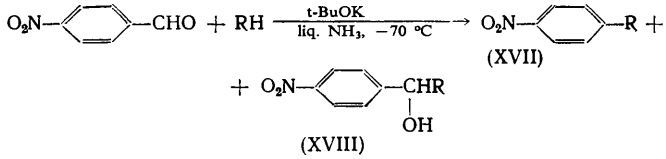
Anions of nitroalkanes (Li salts of 2-nitropropane, 2-nitrobutane[104] and 2-R-5-nitro-1,3-dioxan[105,106]) were used in the majority of studies on nitro group substitutions.



X = NO_2, CN, SO_2Ph, COOMe, COPh.

It was noted that tetrabutylammonium salts of nitroalkanes are more reactive than Li salts.[107,108] For example the reaction of *p*-dinitrobenzene (*p*-DNB) with tetrabutylammonium salts in DMSO, benzene and acetone was complete in less than 5 min while with Li salts only after 3 to 30 h.[107]

The reaction of *p*-DNB with 1,2-dimethyl-1-nitropropane anion in benzene and in DMSO occurs in a more complex manner. In addition to the normal substitution product *p*-nitrophenol and *p*-nitrophenyl ethers of methylisopropylketoxime were formed.[107,108]



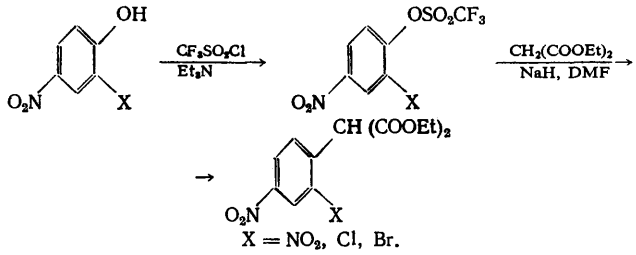
R = Me, $PhCH_2$.

The reacting carbanions may be obtained *in situ* from the corresponding CH-acids in the presence of t-BuOK as was shown for the reaction of *p*-DNB with various RH in liquid NH_3.[110]

R = CH_2COMe, CH(Me)COEt, CH_2COOEt, CH_2CN, CH(Ph)CN etc.

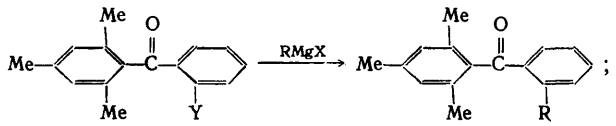
In the case of *p*-nitrobenzaldehyde an unusual substitution was observed under these conditions when fission of a carbon-carbon bond occurred.[111]

(XVII)



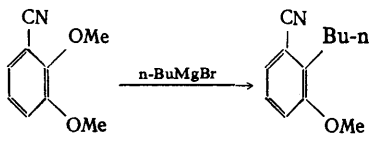
(XVIII)

R = CH_2COOMe, CH_2COBu-t, CH_2COOEt, CH(CN)Ph etc.



The reaction of *p*-nitrobenzaldehyde with t-BuCOMe was carried out in the presence of various bases. It turned out that systems of t-BuOK/liq.NH_3 and KNH_2/liq.NH_3 were the most effective, yields of substitution products (XVII) were 64% and 71% respectively. The use of other systems, and particularly t-BuOK/t-$BuNH_2$, t-BuOK/THF, t-BuOK/ether, t-BuOK/DMF, $NaNH_2$/liq.NH_3 led to a lower yield of product (XVII). On using the n-BuLi/THF system only alcohol (XVIII), R = CH_2CO-t-Bu was obtained in 76% yield. The reaction mechanism is unknown. Strictly speaking the mechanism has not been established and it is possible, for the nitro group substitution reactions enumerated above, that an $S_{RN}1$ mechanism is effected in some of them.

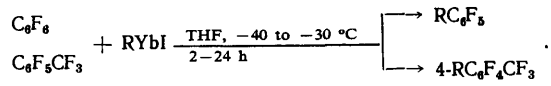
One of the best leaving groups in reactions of the S_NAr type is the triflate group which is replaced more readily than a nitro group. The example given below illustrates the possibility of applying the



reaction to the synthesis of nitroarylmalonic esters (and nitroarylacetic acids and oxindoles in general) from the corresponding phenols.[112]

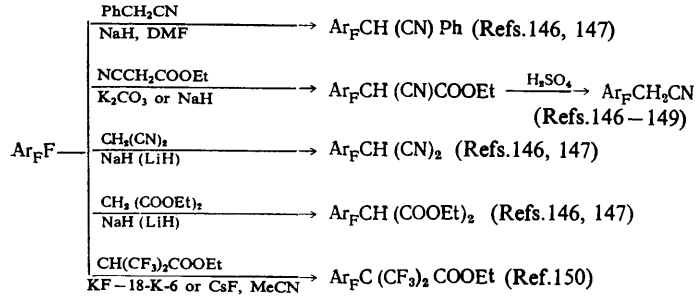
There is also information on other groups. For example methylphenylketones, having a leaving group Y in the *ortho* position, react with RMgX with the formation of products of the aromatic substitution of Y.[113–115]

Replacement of the OR group under the action of a Grignard reagent has been shown.[116–118]



The majority of the carbanions considered in S_NAr reactions are ambident which raises the question of possible arylation at two centres. It is noted that the nature of the leaving group is one of the principal factors controlling the direction of *C*- and *O*-arylation of alkali metal salts of carbonyl compounds. For example the quantity of *C*-isomer falls along the series OPh < Hal < OMe < OAc < OSO_2Me in the reaction of picryl chloride with enolates of β-dicarbonyl compounds with an increase in the hardness of the leaving group. The structure of the enolate, the nature of the alkali metal and the solvent also influence the course of the reaction in a substantial manner. Other conditions being equal the use of softer enolate ions, cations of a lower radius and less polar aprotic solvents aid the preference for *C*-isomer formation.[119–122]

2. Nucleophilic substitution reactions in perfluoroarenes

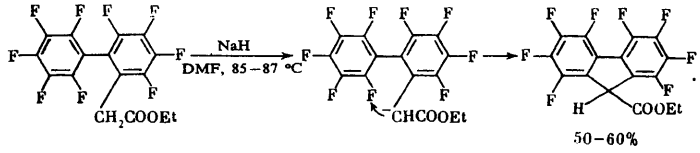


As already mentioned in the Introduction perfluoroarenes react fairly readily by the S_NAr type reaction both with organolithium and with organomagnesium compounds and with carbanions. Aryl (Ph, 3,5-dibromopyridyl, thienyl) and alkyl (Me, Bu) groups have been introduced into the perfluoroaromatic ring by the action of RMgX or RLi.[123–141] Yields of substitution products were fairly high (up to 70%) in several cases, however the reactivity of organomagnesium compounds occasionally proved to be inadequate and the more reactive lithium derivatives led to the formation of disubstitution byproducts. Even in the case of the less reactive propenyl and acetylenyl lithium derivatives a mixture of mono- and disubstituted products was formed as a rule.[138–141]

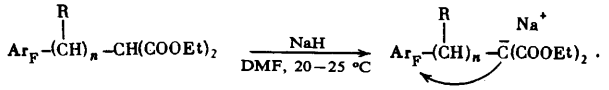
It was shown comparatively recently that organoytterbium compounds are excellent nucleophilic reagents in substitution reactions at vinyl and aromatic carbon atoms.

A comparative study of nucleophilic substitution reactions of perfluoroarenes under the action of RYbI, RLi and RMgX (R = Ph, Bu, PhC≡C) showed that RYbI (R = Ph, Bu) surpassed RLi in selectivity of substitution and the more preferred RMgX in the yield of desired products. However of the phenylacetylenyl derivatives only PhC≡CLi was capable of replacing fluoride ion in reactions with C_6F_6 or $C_6F_5CF_3$.[144] It is noted that iodine in pentafluoroiodobenzene is replaced by the action of copper phenylacetylide.[145]

Various carbanions, generated *in situ* from CH-acids using NaH, LiH, K_2CO_3 (usually in DMF), KF or CsF as bases, are involved in nucleophilic substitution reactions with perfluoroaromatic compounds.[146–150]

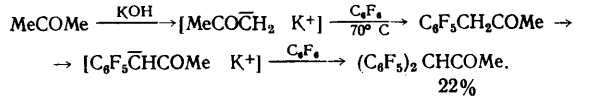


Fairly forcing conditions (100–135 °C) are required to carry out such reactions and then yields of substitution products are moderate (20–60%). However reactions proceeded as a rule at room temperature when using perfluoroarenes with electron-accepting substituents of the type of CN, CF_3 or $C(CF_3)_3$ but yields of products were significantly increased (70–85%).

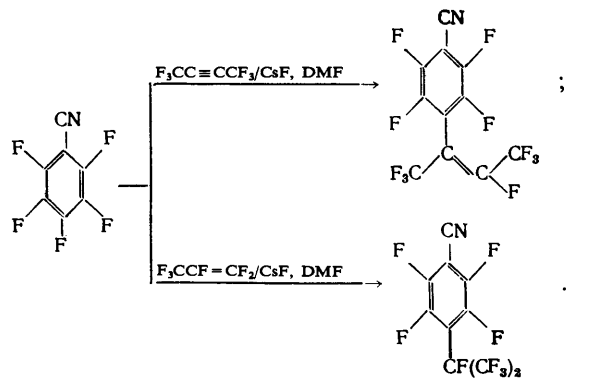


The polyfluoroarene-containing compounds obtained in this way were strong CH-acids. The carbanions corresponding to them, possessing a poorly screened reaction centre, are fairly active reactants in S_NAr type reactions and are used for example for the synthesis of perfluorinated benzhydryl derivatives.[149]

The anion of ethyl polyfluorinated diphenylacetate has been suggested for the synthesis of fluorinated fluorene.[151,152]

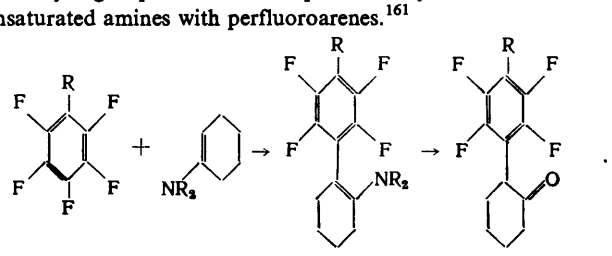


This example may be considered as a particular case of a general method of obtaining polyfluorinated carbocyclic compounds by the intramolecular nucleophilic substitution of a fluorine atom by aralkyl substituted malonic or cyanoacetic esters.[147]



Derivatives of indane (n = 2), acenaphthene (n = 2) and 9,10-dihydrophenanthrene (n = 1, Ar = $C_6H_5C_6F_4$-2) were obtained in this way.[153,154]

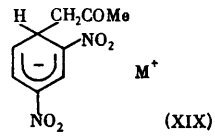
Ambident anions may react with perfluoroarenes at both reaction centres. Thus anions of acetoacetic ester[155,156] and acetophenone[157] react with hexafluorobenzene and perfluorotoluene at a carbon atom with subsequent intramolecular cyclisation at oxygen with the formation of 4,5,6,7-tetrafluorobenzofurans (80–140 °C). At lower temperatures the reaction was successfully stopped at the *C*-arylation stage.[157,158]



However depending on the nature of the substrate, solvent and enolate ion a mixture of *O*- and *C*-isomers or even predominantly the *O*-isomer may be formed. Thus replacement of fluoride ion by acetate or mesylate in octafluorotoluene leads preferentially to *O*-arylation of the potassium derivative of acetoacetic ester (DME, dimethylacetamide, EtOH).[122] On interacting the anion of pentafluoroacetophenone with $C_6F_5CF_3$ a mixture of *O*- and *C*-arylation products is formed the ratio of which depends on the nature of the solvent.[158]

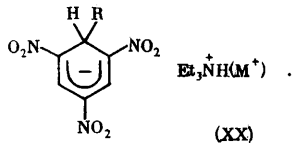
The reaction of perfluoroaromatic compounds with perfluoroalkenes or alkynes in the presence of fluoride ion is of particular interest since it is a nucleophilic variant of the Friedel–Craft reaction.[103,159,160]

It is possible to obtain ketones, esters and amides containing a perfluoroaryl group in the α position by condensation of α,β-unsaturated amines with perfluoroarenes.[161]



III. Preparation of anionic σ-complexes with C–C bonds

One further route to introduce a C–C bond into electron-deficient arenes comprises the preparation and oxidation of anionic σ-complexes, including 1,3-σ-complexes, containing good leaving groups of the halogen type in the aromatic ring.



1. Reaction of aromatic compounds with carbanions and heteroorganic compounds

The simplest method of obtaining anionic σ-complexes of aromatic compounds containing electron-accepting groups (NO_2, CN, SO_2CF_3, etc.) with carbanions is the interaction of an aromatic substrate with a CH-acid in the presence of base. The possibility of forming stable complexes of such type was shown for the first time by Janovsky[162,163] in 1886 in the reaction of *m*-dinitrobenzene (*m*-DNB) with alkaline aqueous acetone. However only in 1963 was this σ-complex successfully isolated in the solid state[164] and its structure demonstrated.[165]

(XIX)

Historically most work is linked with the study of σ-complexes of nitroaromatic compounds with the acetonyl anion. Potassium carbonate,[166] alkali metal hydroxides and alkoxides[164,167–169] and amines[170,171] were used as bases for their preparation. The σ-complex of 1,3,5-trinitrobenzene (TNB) with acetonyl anion was obtained on carrying out the reaction in an acetone medium (~20–30 fold excess) in the presence of a twofold excess of KOH (spectro-photometric check). The yield of (XX) for R = CH_2COMe was 73%.[164]

(XX)

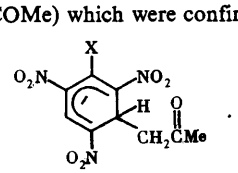
It was shown by PMR spectroscopy that in the presence of triethyl- or diethylamine TNB forms a σ-complex (XX) with various ketones which simultaneously serve as solvents [R = CH_2COMe, CH(Me)COEt, CH(Ph)$COCH_2Ph$, $CH(CH_2)_4CO$, $CH(CH_2)_3CO$,[170,171] $CH(CH_2)_5CO$, CH_2COPh], yield was 78%.[172]

These complexes may readily be isolated by precipitation with ether. With unsymmetrical ketones such as methylethylketone a mixture is formed of the isomeric complexes (XX) [R = CH_2COEt or CH(Me)COMe].[171] The exception was methylisopropylketone, in this case only one complex is formed of type (XX) (R = CH_2COPr-iso).[170]

To obtain complexes of TNB with anions of *para* substituted acetophenones XC_6H_4COMe (X = NO_2, OMe, CN) the reaction was carried out in dioxan in the presence of a large (~20 fold) excess of Et_3N.[172] In this case a twofold quantity of the CH-acid

was used (yields of complexes were not indicated). Complexes of TNB with anions of α-haloketones were obtained on carrying out the reaction in MeCN in the presence of Et_3N.[173]

The formation of adducts (XX) with anions of nitroaliphatic compounds [R = CH_2NO_2, $CH(Me)NO_2$, $CH(Et)NO_2$, $C(Me)_2NO_2$],[174] acetonitrile,[175] propionaldehyde[176] and phenylacetonitrile[170] was demonstrated by PMR spectroscopy. In all cases the reaction was carried out in the presence of a large excess of CH acid. The complex of TNB with nitromethane anion was isolated using NaH as base (yield was 35%).[177] An equimolar amount of CH-acid was applied to obtain the complex of TNB with the anion of acetylcyclopentadienylmanganese tricarbonyl which is formed in the presence of NEt_3 in a medium of MeCN (50% yield).[178]

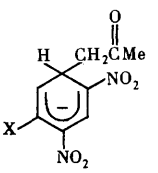


The alkali metal methoxides are effective bases for obtaining anionic σ-complexes.[168,169] Complexes of TNB with anions of acetone, cyclobutanone, cyclopentanone and cyclohexanone were isolated in quantitative yield on carrying out the reaction in a medium of the ketone.[169] To obtain complexes of TNB with cyanoacetic and malonic esters the same authors used an equimolar and double amount of the corresponding CH-acid, reaction was carried out in MeOH and yields of complexes were quantitative.[179] The σ-complexes of TNB with CCl_3 and CBr_3 anions were isolated in yields of 80 and 63%.[180] Reaction in these cases was carried out in DMSO with an excess (10 fold) of chloroform or bromoform in the presence of MeONa. The complex of TNB with the trichloromethyl anion was also formed from trichloroacetic acid and TNB in DMSO. The corresponding substitution product was isolated on oxidation of this complex with bromine in pyridine.[181]

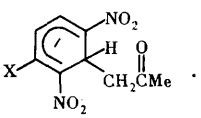
It is known that acetoacetic ester reacts with TNB in the presence of various bases (KOH, Et_3N, MeONa) with the formation of a bicyclic complex (see Chapter III, section 3). However on interacting TNB with potassium-acetoacetic ester a complex of type (XX) [R = CH(COMe)COOEt] was also obtained in 33% yield.[182]

Finally σ-complexes of TNB with the anions of DMF, dimethylacetamide and DMSO were synthesised in the presence of KOH or Bu_4NOH in a dioxan medium. In each case the CH-acid was introduced in excess (yields of complexes were 40, 75 and 80% respectively).[183] The σ-complex of TNB with indole was obtained in 60–90% yield in the two-phase system $CH_2Cl_2-H_2O-NaOH$ in the presence of *N*-methylquinolinium, *N*-methylisoquinolinium or tetramethylammonium salts.[184]

As already mentioned a methyl group located in the *para* position to a nitro group in polynitro aromatic compounds may be deprotonated by the action of base in polar solvents (DMSO). The resulting carbanion reacts with TNB giving anionic σ-complexes.[185,186] On using equimolar amounts of CH-acid and KOH or MeONa as base complexes of TNB were isolated (yield ~50%) and characterised with anions of 2,4,6-trinitrotoluene,[185,186] 2,4-dinitrotoluene, 4,6-dinitro-*m*-xylene and 2,4,6-trinitro-*m*-xylene.[186] Addition of two molecules of TNB is possible (in an excess of base) for the latter.



In the presence of Et_3N, MeONa or KOH 1-X-2,4,6-trinitrobenzene (X = OEt, OMe, OPh, Me, Cl, NMe_2, COOH, COOMe, SMe) reacts with acetone forming 1,3-σ-complexes (XXI) (R = CH_2COMe) which were confirmed by PMR spectroscopy.[98,187–189]

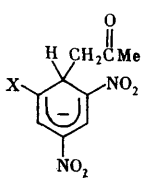


(XXI)

In contrast to ketones which form stable 1,3-σ-complexes with 1-X-2,4,6-trinitrobenzene, the stronger CH-acids such as acetoacetic, malonic, and cyanoacetic esters, and malondinitrile react with 1-X-2,4,6-trinitrobenzene (X = OMe, OCOMe, Cl, OAr) in the presence of MeONa giving 1,3-σ-complexes which rearrange into 1,1-σ-complexes with the subsequent formation of a substitution product.[52,88–90,100,101]

It is known that anionic complexes of *m*-dinitrobenzene (DNB) derivatives are far less stable than complexes of TNB. For example, the equilibrium constant of the complex of TNB with methoxide ion is 17 lit.mol^{-1} and for the complex of *m*-DNB with methoxide ion the equilibrium constant is only 1×10^{-6} lit.mol^{-1}.[190] As mentioned above the σ-complex of TNB with acetonyl ion was obtained in 73% yield on using KOH as base. Under the same conditions *m*-DNB gave a σ-complex in only 34% yield.[164] Similarly 1-X-2,4-dinitrobenzenes react in alkaline medium with acetone with the formation of the isomeric complexes (XXII) and (XXIII).

(XXII)



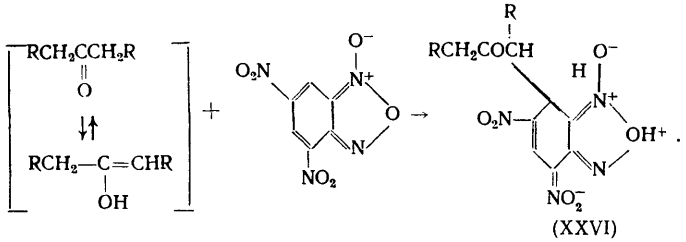
(XXIII)

A σ-complex (XXII) is mainly formed when X = H, OMe, COOMe, Cl, Br, I, Me, n-Pr, n-Bu, or SO_2Ph[99,164,191–193] but when X = F, SEt, SCN, or SPh a σ-complex of type (XXIII) predominates.[164,192,193] On carrying out the reaction in an acetone medium and using KOH as base the yield of complexes was 10–35% overall.[99,164,191–193,195] However on using alkali metal (Na, K, Rb, Cs) methoxides the yields of σ-complexes became almost quantitative.[167]

The σ-complexes of 2,4-dinitronaphthalene, 2,4,5,7-tetranitronaphthalene and 9-nitroanthracene with acetonyl and nitromethyl anions have been obtained and characterised.[174,187]

1-X-3,5-Dinitrobenzenes react in alkaline medium with acetone giving two isomeric products (XXIV) and (XXV). When X = OMe or Me only complexes (XXIV) were obtained in 7.5 and 18% yield in the presence of KOH.[194] A mixture of σ-complexes (XXIV) and (XXV) was formed when X = COOEt,[194,195] CF_3,[194–196] CN,[196] COOMe and COO^-,[197] $CONH_2$ and $CONMe_2$.[198]

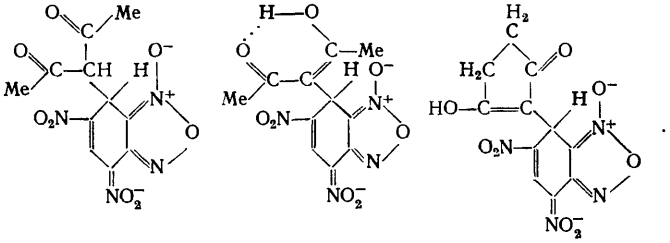
(XXIV)



(XXV)

Isomerisation constants were measured for σ-complex (XXIV) going to (XXV), which had been obtained from the enolates of cyclohexanone and 1-X-3,5-dinitrobenzene [X = $CON(CH_2)_5$, COOMe, CN].[199]

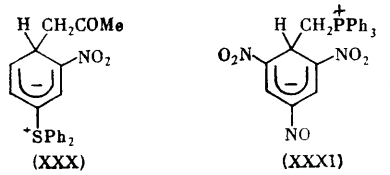
Complexes obtained from 1,3,5-*tris*-(trifluoromethylsulphonyl)-benzene (TFMSB) proved to be several orders of magnitude more stable than complexes of TNB. The complex of TFMSB with



acetonyl anion using KOH in acetone as base was isolated in 24% yield[200] but on using EtOH the yield was 97%.[177] The complex of TFMSB with nitromethane anion was isolated (67% yield) using NaH.[177] Complexes of TFMSB with the anions of diethyl malonate and propionaldehyde were not isolated but were oxidised to the corresponding substitution products.[201]

4,6-Dinitrobenzofuroxan (DNBFX) and 4,6-dinitrobenzofurazan (DNBFZ) are even stronger electron-accepting substrates capable of forming anionic σ-complexes even in the absence of base. DNBFX reacts with water and methanol in the absence of base forming hydroxyl and methoxyl complexes and also with ketones. The formation of σ-complexes (XXVI) with anions of acetone, cyclopentanone, cycloheptanone, pentane-2,4-dione and 3-methylpentane-2,4-dione has been demonstrated.[202] It was proposed that reaction was effected with the enolic form of the ketone or with the enolate ion formed as a result of its partial ionisation.[202]

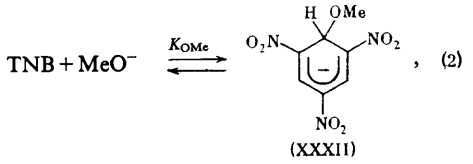
(XXVI)



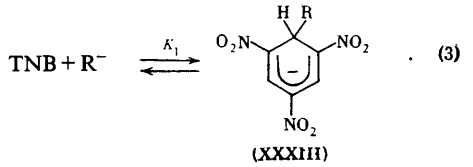
β-Dicarbonyl compounds like pentane-2,4-dione or cyclopentane-1,3-dione give adducts which may exist both in the ketonic (XXVII) and in the enolic forms (XXVIII) and (XXIX).[202]

(XXVII) (XXVIII) (XXIX)

Compounds DNBFX and DNBFZ form complexes even with such weak bases as 1,3,5-trimethoxybenzene (see also p. 765).[203]



Zwitterionic σ-complexes (XXX) and (XXXI) were obtained by the reaction of an alcoholic solution of KOH with an acetone solution of *m*-nitrophenyldiphenylsulphonium fluoroborate[204] and methylenetriphenylphosphorane with TNB.[205]



(XXX) (XXXI)

The kinetics of formation and stability constants of σ-complexes of TNB with appropriate carbanions have been studied for a series of CH-acids in the presence of MeONa.[179,90] The following scheme has been proposed for the formation of a σ-complex with a C–C bond where the limiting step is the addition reaction of carbanion to TNB [reaction (3)].

$$RH + MeO^- \overset{K}{\rightleftarrows} R^- + MeOH, \quad (1)$$

(XXXII)

(XXXIII)

Rate constants are given in Table 2 for the formation and dissociation (k_1 and k_{-1}) of σ-complexes of TNB and also the equilibrium constant (K_1). It is seen from the data given in Table 2 that the stability of σ-complexes falls as the strength of the CH-acid increases. It was reported[179] that TNB complexes with a C–C bond possess a higher stability than complexes with *O*-nucleophiles. The complex with acetone is more than 10 orders of magnitude more stable than the complex with methoxide. The anions of methyl acetate, methyl cyanoacetate, dimethyl malonate and malondinitrile are less basic than MeO^- but their complexes with TNB proved to be more stable than methoxyl [the equilibrium constant for the formation of complex (XXXII) K_{OMe} = 17 lit.mol^{-1} is comparable only with the equilibrium constant for the formation of the least stable complex of TNB with methyl acetoacetate]. The high stability of complexes with enolate ions is confirmed also by the low values for the decomposition rate constants of σ-complexes (in certain cases values of k_{-1} are so low as to be difficult to measure).[172]

Table 2. Kinetic and equilibrium parameters for the reaction of TNB with carbanions in methanol.[179]

Carbonyl compounds	K, lit. mol^{-1}	k_1, lit. mol^{-1}.sec	k_{-1}, sec^{-1}	K_1, lit.mol^{-1}
MeCOMe	10^{-6}	$3.30\cdot10^{6}$	$8.2\cdot10^{-6}$	$4\cdot10^{11}$
	10^{-4}	$1.62\cdot10^{5}$	$1.76\cdot10^{-4}$	$9.2\cdot10^{8}$
$CH_2(COOMe)_2$	0.5	$2.5\cdot10^{5}$	20.5	$1.22\cdot10^{4}$

*Literature data.[90]

In the majority of the reactions described above the CH-acid which is a source of carbanion is taken in excess and frequently serves as solvent. The excess of CH-acid may be avoided if the

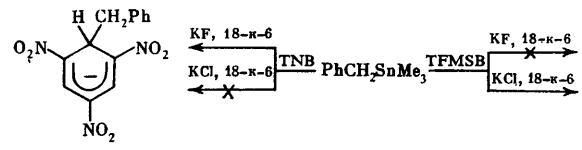
reaction is carried out in a two-phase system of solid base–solvent. At the same time the use of such a system makes it possible to extend significantly the limits of the pK_a of the CH-acids entering into the reaction. Thus in the system THF–solid base (KF, K_2CO_3, KOH)–18-crown-6 ether the σ-complexes of TNB with such radicals R as CH(Ph)COOEt(Me), CH(Ph)CN, C_6F_5 or fluorenyl were successfully obtained.[206] These complexes contain 1 mole 18-crown-6 ether in their composition. The complexes had been obtained previously by reactions with organomercury and organotin compounds.[207–210] The weakest CH-acid which reacts with TNB under these conditions (KOH as base, KF and K_2CO_3 proved to be ineffective) was pentafluorobenzene. Phenylacetylene (pK_a 29.4 in DMSO[211]) did not react with TNB even in the presence of KOH. It should be mentioned that the final result of the reaction depends not only on the base strength and on the CH-acid but also on the stability of the σ-complex (XXXII) of aromatic substrate with base, the formation of which often precedes the formation of a σ-complex (XXXIII) with the carbanion. For this reason KF proved to be a more effective base than K_2CO_3. The stability of the σ-complex formed with base may explain the fact that TFMSB, which significantly surpasses TNB in electrophilicity, reacts under PTC conditions only with fairly strong CH-acids, such as diethyl malonate, when, as for TNB, a σ-complex was obtained with anions of weaker acids such as phenylacetonitrile, ethyl phenylacetate, pentafluorobenzene or fluorene.[206]

Not only CH-acids but also organometallic compounds have been used to obtain σ-complexes. It was shown by PMR spectroscopy that organomercury compounds R_2Hg (or RHgX), where R = CH_2COMe, CH(Ph)COOEt, CCl_3, C_6F_5, $CH(CF_3)_2$ or *o*-carboranyl, react with TNB forming σ-complexes (XX) under conditions of nucleophilic catalysis with iodide ion.[207,208] Some organotin compounds $RSnMe_3$, where R is acetonyl, fluorenyl, indenyl or cyclopentadienyl also successfully react with TNB. In this case the solvent DMSO played the role of nucleophilic catalyst.[209,210]

It has been shown possible to use organocopper and organotin compounds for the synthesis of σ-complexes with TNB. Reactions of TNB with phenyl- and 2,6-dimethoxyphenylcopper,[212] 2,6-dimethoxy- and 2,4,6-trimethoxyphenylsilver,[213] copper and silver phenylacetylides,[214] hexenylcopper,[214] 2-furyl- and 2-thienylcopper,[215] acetylcyclopentadienylmanganese tricarbonylsilver,[216] cyclopentadienyl- and indenylsilver[217,218] occur at room or lower temperatures in pyridine or quinoline. Organocopper compounds proved to be somewhat more reactive than silver derivatives. The σ-complexes were isolated in some cases[212,213,215–218] and were oxidised to the corresponding substitution products (see chapter III, section 5). The interesting σ-complex (XXXIV) was obtained from TNB and t-BuNC in the presence of copper or Cu_2O.[219] Complex (XXXIV) was unstable and reacted with CH-acids with the formation of σ-complexes with CCl_3, indenyl, and cyclopentadienyl anions.

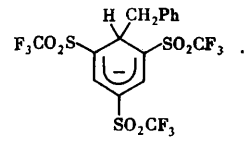
(XXXIV)

Organosilicon compounds $RSiMe_3$ also react with TNB with fluoride ion catalysis. These were of various types, benzyl and allyl derivatives, silylated ketones, ethers and acylsilanes (pK_a of the corresponding RH was 20–35) and form ionic σ-complexes in good and occasionally quantitative yield.[220,221]



$$TNB + RSiMe_3 \xrightarrow[THF]{KF,\ 18\text{-}K\text{-}6} [TNB.R']K^+.(18\text{-}K\text{-}6),$$

$$R = \bigcirc\!\!-O-,\quad R' = \bigcirc\!\!=O,$$

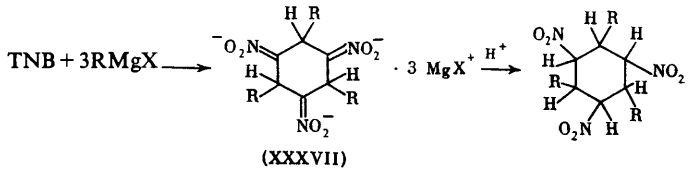


R = R′=CH_2COOMe, CH_2COOEt, CH_2COEt, COPh, COMe, CH_2Ph, All, C≡CPh.

It should be mentioned that organosilicon reagents have proved to be useful in the synthesis of various σ-complexes which are difficult to obtain by other routes, such as σ-complexes with alkyl (CH_2Ph, $CH_2CH=CH_2$) and acyl (COMe, COPh) groups. The application of organosilicon compounds has enabled the selective introduction of the trinitrophenyl group into unsymmetrical ketones while the reaction of TNB with these ketones in the presence of base gives a mixture of isomers. In certain cases, for example when obtaining complexes $[TNB.C{\equiv}CR]^-$ and $[TNB.\overline{CH-(CH_2)_4-CO}]^-$, the use of $RSiMe_3$ is more convenient than CH-acids or organo-silver or copper compounds and gives better yields.

TFMSB, in contrast to TNB, reacts under conditions of catalysis by fluoride ion only with the most reactive of the $RSiMe_3$ studied, viz. the trimethylsilyl ether of cyclohexanone enol. In all the remaining cases the reaction stops at the stage of forming an anionic σ-complex with fluoride ion. It was mentioned above that the same result was observed in reactions of TFMSB with CH-acids. In the presence of fluoride ion TFMSB does not form a σ-complex with a C–C bond even with $PhCH_2SnMe_3$, while TNB reacts readily, giving complex (XXXV). However to obtain the σ-complex of TFMSB with a $PhCH_2$ group (XXXVI) it was sufficient to replace fluoride ion by chloride ion which also forms a complex with TFMSB but is undoubtedly less stable than the complex with fluoride. It has been reported that complex (XXXV) was not formed in the reaction of TNB with $PhCH_2SnMe_3$ in the presence of KCl.[211]

(XXXV)



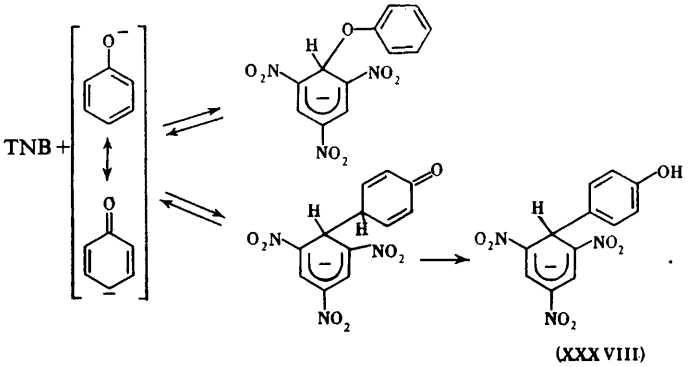
(XXXVI)

Organosilicon compounds have also been proposed for introducing C–C bonds into 1-X-2,4-dinitrobenzenes. However the complexes formed were less stable than complexes of TNB and their oxidation was carried out without isolation (see p. 763–764).[222]

Organolithium and organomagnesium compounds are used as a carbanion source for CH-acids with pK_a 30–33. However TNB adds three molecules of RMgX on carrying out the reaction in ether

or THF giving 1,3,5-trialkyl-2,4,6-trinitrocyclohexanes [the intermediate (XXXVII) was not identified] on acidification of the reaction mixture.[223,224]

(XXXVII)

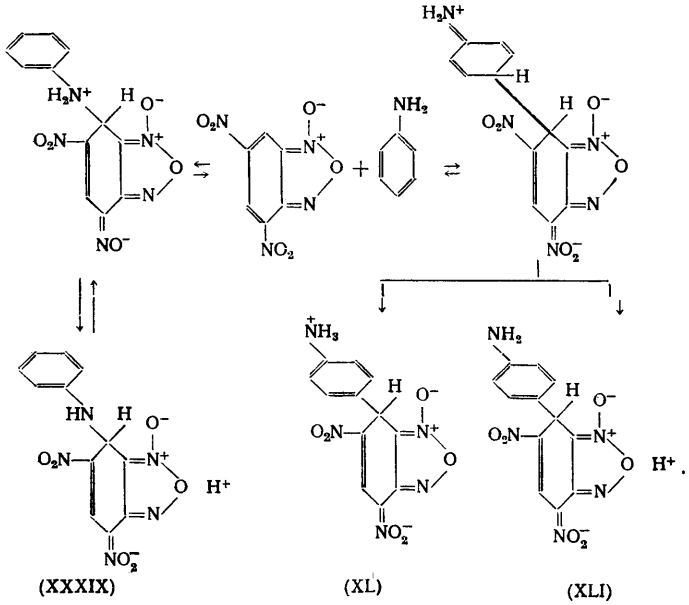


R = Me, Et, n-Pr, n-Bu, iso-Bu.

The reaction of RMgX with *m*-DNB, 1-chloro-2,4-dinitrobenzene and 2,4-dinitroanisole proceeds in a similar manner.[225] However in the majority of cases the reaction of organolithium and organomagnesium compounds with polynitroaromatic compounds gives a mixture of products of oxidation-reduction reactions and addition reactions at the nitro group. Consequently it is a fairly complex problem to obtain anionic σ-complexes from weak CH-acids (pK_a > 30–33). Taylor has succeeded in obtaining σ-complexes of TNB with methyl and n-butyl groups using the appropriate tetraalkylboron salts $Alk_4B^-Me_4N^+$ (or Ph_4As^+).[226]

σ-Complexes with Me_3ECH_2-groups, where E = Si, Sn or Ge, were obtained in a similar manner.[227] On using tetraalkylammonium salts $(CH_2EMe_3)_4B^-Me_4N^+$ σ-complexes of TNB with Me_3ECH_2-groups were successfully obtained while the use of lithium salts, such as Me_3SiCH_2Li or $(Me_3SiCH_2)_4BLi$, led to a mixture of unidentified products.[227]

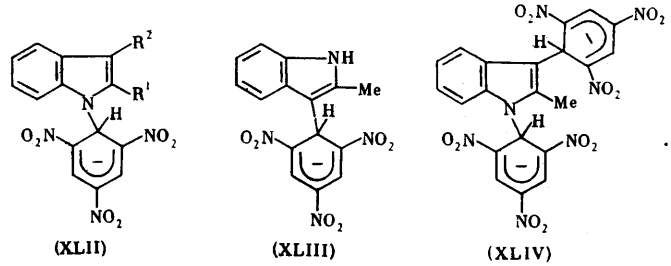
2. Reaction with phenoxide ions and nitrogen bases



The ability of phenols and aromatic amines to act as *C*-nucleophiles in reactions of the S_NAr type in the presence of base was recorded in Chapter II. Phenoxide ions, anions of nitrogen heterocycles and anilines, in the presence of NEt_3 or 1,4-diazabicyclooctane, also form σ-complexes with C–C bonds in several cases,[228–234] and therefore may be used to introduce homo- or heterocyclic radicals containing strongly electron-donating substituents into electron-deficient aromatic substrates. In the reactions of phenols σ-complexes with C–O bonds are usually the reaction products under kinetic control and then rearrange into complexes with C–C bonds, the reaction products under thermodynamic control.[234]

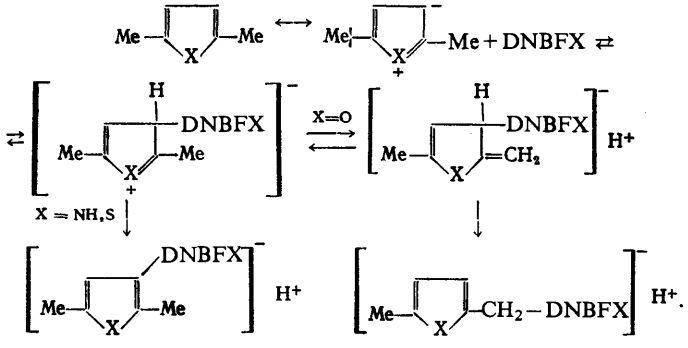
(XXXVIII)

Adduct (XXXVIII) was obtained by the reaction of TNB with PhOH in DMSO or in DMSO–MeOH in the presence of MeONa (80% yield).[231] A small quantity of the corresponding *ortho* isomer was formed in addition to the *para* isomer (XXXVIII) and was detected by PMR spectroscopy.[231] A bond was formed in the *ortho* position in the complex of TNB with the anion of α-naphthol.[232]



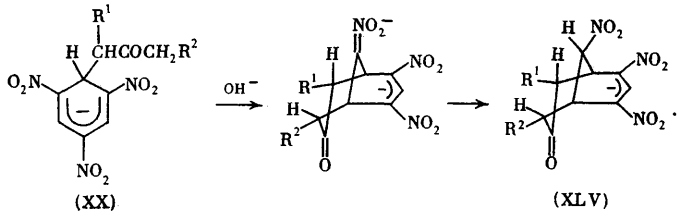
In contrast to phenoxide ion, aniline gives only a complex with a C–N bond with TNB in the presence of Et_3N or 1,4-diazabicyclooctane.[235,236] However with a more strongly electron-deficient substrate like DNBFX, depending on the experimental conditions, it is possible to obtain both a complex with a C–N bond (XXXIX) and a σ-complex with a C–C bond (XL) or (XLI).[237–240] Only complex (XLI) is formed when using equimolar amounts of aniline and DNBFX. The application of a two fold excess of $PhNH_2$ leads to a mixture of products (XXXIX) and (XLI) but on adding Et_3N only complex (XXXIX) was isolated and was established by PMR spectroscopy.[238]

(XXXIX) (XL) (XLI)



1,8-*bis*-(Dimethylamino)naphthalene reacts with DNBFX or 4,6-DNBFZ giving an adduct of the type of (XLI) in quantitative yield.[241,242]

TNB reacts with nitrogen heterocycles in the presence of base forming a mixture of complexes with C–N and C–C bonds the stability of which is determined by the nature of the heterocycle.[231–234,243–246] Thus 3-methyl- and 2,3-dimethylindoles in DMSO in the presence of MeONa give only complexes with a C–N bond (XLII), while with TNB 2-methylindole forms a mixture of complexes (XLII)–(XLIV) with a predominance of complex (XLIII) which, after some time, becomes the sole product.[243]

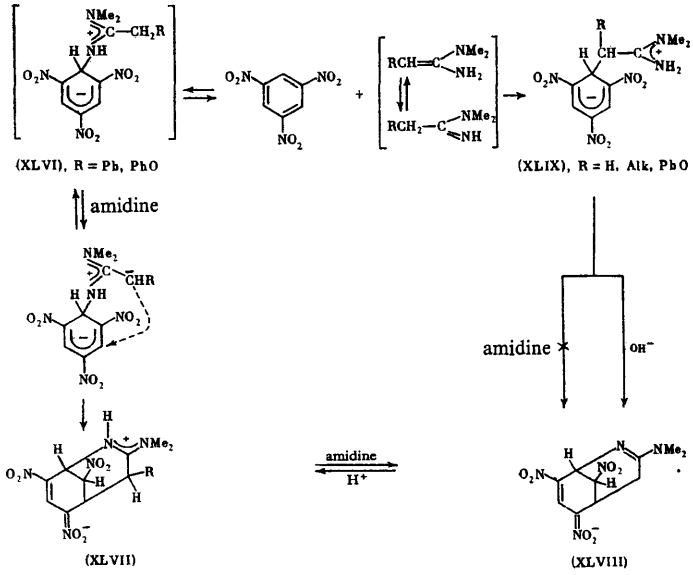


(XLII) (XLIII) (XLIV)

Compounds DNBFX and DNBFZ are also capable of reacting with nitrogen heterocycles in the absence of base.[247–249] Only complexes with C–N bonds are formed with imidazole or with *N*-alkylimidazole and only complexes with C–C bonds are formed with pyrrole, indole, thiophen and their *N*-alkyl substituted derivatives. However a methyl group proved to be more reactive in 2,5-dimethylfuran.[249]

3. Formation of bi- and tricyclic complexes

As mentioned above, the σ-complexes of TNB with anions of ketones are fairly stable. However, in the presence of strong bases such as KOH or NaOH they may be subject to further conversion generally forming bicyclic adducts (XLV).[250]



(XX) (XLV)

The reaction stopped at the stage of forming σ-complex (XX) o using Et_3N as base.[170,171] It is interesting that bicyclic adducts wer formed on interacting TNB with ketones in the presence c diethylamine (Et_2NH) although the basicities of Et_3N and Et_2NH are close.[251] It was considered that the corresponding enamines added to TNB in this case.[252] A tricyclic complex was obtained from cyclohexanone in the presence of Et_2NH while cyclopentanone gave the usual σ-complex (XX) with R = $\overline{CH-(CH_2)_3-CO}$.[253]

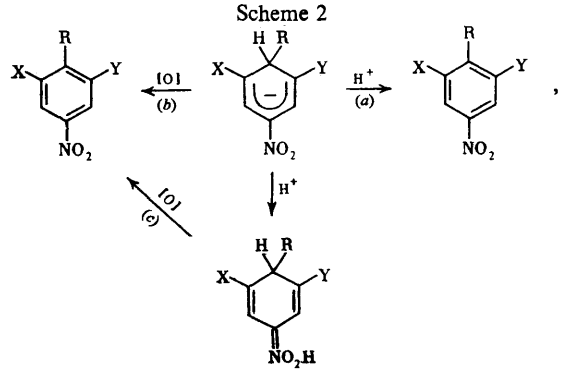
The only result of interacting TNB with β-dicarbonyl compounds in the presence of Et_3N were bicyclic adducts of the (XLV) type. Complexes of type (XX) were not isolated.[15,254–258] 1-Cyano-3,5-dinitrobenzene, methyl 3,5-dinitrobenzoate, methyl 2,4,6-trinitrobenzoate, picryl amide and picric acid react with β-dicarbonyl compounds (acetoacetic ester, 1,3-dicarbomethoxyacetone) in a similar manner.[254,255,259] Bicyclic products were also formed on interacting 1,3-dicarbomethoxyacetone with dinitro- and tetranitronaphthalenes.[255]

Recently the reaction of nitro aromatic compounds with amidines has been studied intensively.[260–264] The products of these reactions may be of considerable interest to pharmacologists.[260] Generally it is possible to form several complexes (XLVI)–(XLIX) by reacting TNB with amidine (Scheme 1).

Scheme 1

(XLVI), R = Ph, PhO (XLIX), R = H, Alk, PhO

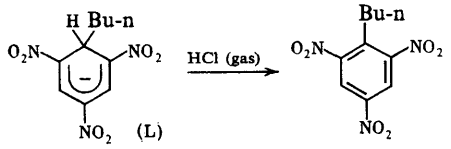
(XLVII) (XLVIII)



Although the formation of adduct (XLVI) was not confirmed by PMR spectroscopy it was proposed that this particular σ-complex was a precursor in the formation of bicyclic adduct (XLVIII). This conclusion was drawn on the basis that the alternative σ-complex (XLIX), which may occasionally be isolated together with bicyclic product (XLVII), is not converted into (XLVIII) by the action of amidine.[260,262] Complex (XLIX) may be converted into a bicyclic adduct, however it was necessary to apply a stronger base, such as KOH, to carry out the conversion.[261]

Adducts analogous to (XLVIII) were also formed from 1,3-dinitro- and 1,3,6,8-tetranitronaphthalene.[262] With a less strongly electron-deficient substrate, viz. 1-cyano-3,5-dinitrobenzene, no bicyclic adduct was formed.[263] It should be mentioned that products of intramolecular attack by the oxygen atom with the formation of bicyclic adducts were not detected.[253]

4. Oxidation of anionic σ-complexes

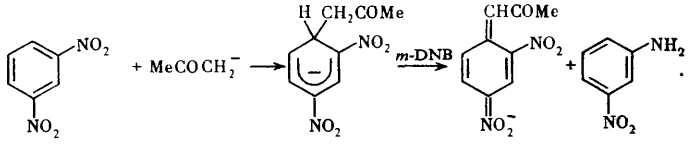


Products of substitution of hydride ion may be obtained from anionic σ-complexes by one of the methods given in Scheme 2:

Scheme 2

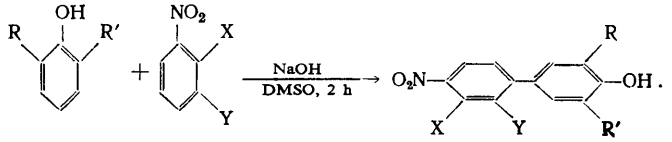
(a) action of acid on the σ-complex, (b) oxidation of the σ-complex, (c) protonation of the σ-complex to a nitronic acid with its subsequent oxidation.

It was shown by PMR spectroscopy that 1-n-butyl-2,4,6-trinitrobenzene was formed quantitatively on passing gaseous HCl into a solution of σ-complex (L) in CD_3CN.[226]



2,4-Dinitrophenylacetone (24%) was isolated on acidifying the Janovsky σ-complex (XIX)§.[265]

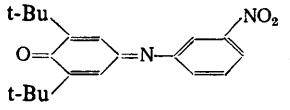
On acidification of solutions of anionic σ-complexes there usually occurs either decomposition into starting materials or the formation of nitronic acids which may then be converted into substitution products by the action of a suitable oxidising agent [route (c)]. Substitution products from σ-complexes of TNB with indenyl, cyclopentadienyl,[217,218] 1,3-dimethoxyphenyl,[213] thienyl and furyl[215] groups have been obtained in the same way.



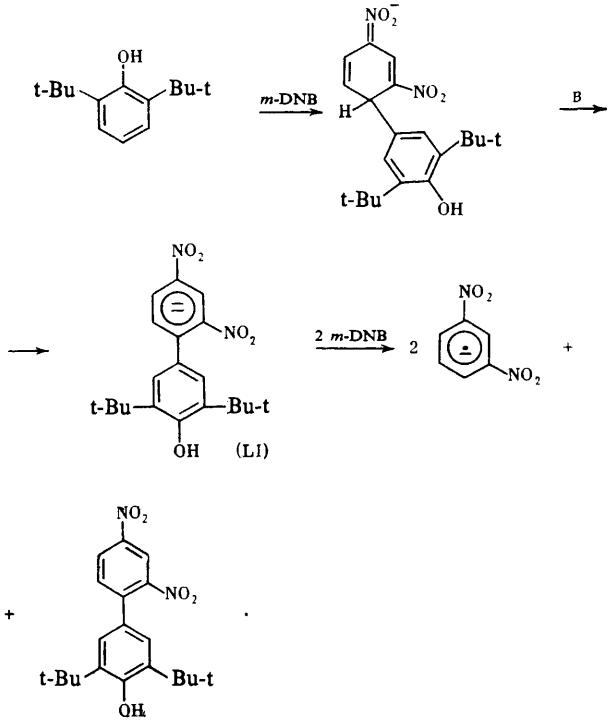
Most frequently σ-complexes are oxidised directly [route (b)]. It has been shown[218] that product yields on oxidation of σ-complexes of TNB (R is indenyl, cyclopentadienyl) with 1,4-benzoquinone or H_2O_2 were somewhat lower than on using method (c) [2,4,6-trinitrophenylcyclopentadiene was obtained in 80% yield by method (c) and in 52% yield by method (b)].

Occasionally the role of oxidising agent may be fulfilled by the initial nitroaromatic compound. Such a situation is brought about in, for instance, the known Zimmerman reaction.

The presence of *m*-nitroaniline among the reaction products supports this scheme.[266,267] A similar case has been described.[63]

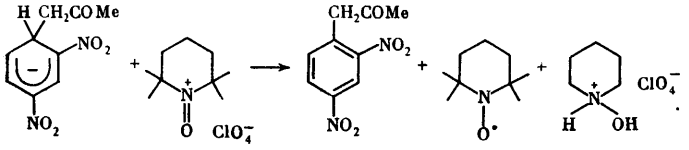


The reaction of *m*-DNB and of *m*- and *o*-cyanonitrobenzenes with 1,6-dialkylphenols (Alk = t-Bu or Me) in alkaline medium leads to a diaryl (28–69% yield). In the case of an unsubstituted phenol the yield of products fell to 17%. Mononitro compounds (nitrobenzene, 2-nitroacetophenone, 9-nitroanthracene) react differently with phenols but TNB forms only a σ-complex.[63]



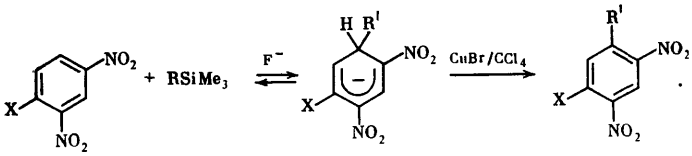
R, R′=Alk; X=H: Y=NO_2, CN; X=CN: Y=H.

§The formation of substitution products has also been recorded in other cases. However their yields did not exceed 10–15%.[188,214]

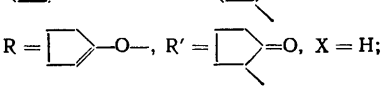


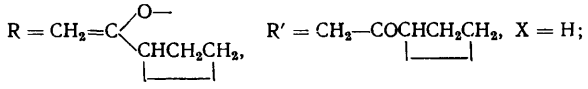
It is possible that the reaction mechanism comprises formation of a σ-complex and subsequent oxidation of it by nitroarene to the diaryl.[63,268] The imine

was detected among the products of reaction with *m*-DNB, i.e. reduction of the nitro compound occurred during the course of the reaction.[63]



The oxidation[269] of the Janovsky complex to 2,4-dinitrobenzylmethylketone by manganese(III) acetate (yield not stated) and by *N*-oxopiperidinium perchlorate (80%) has been effected.[270]



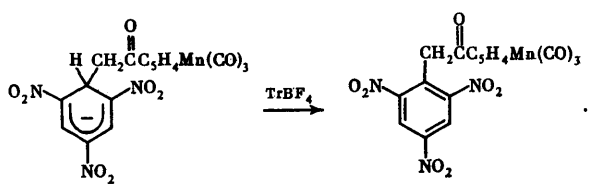


Using as example the σ-complex of *m*-DNB with cyclohexanone anion it was shown that it was possible to apply other oxidising agents such as 2,3-dichloro-5,6-dicyanobenzoquinone (DDBQ), $(NH_4)_2Ce(NO_3)_6$, Br_2 in hexane or $CuBr_2$ in DMF, to the oxidation of complexes of DNB. Systems containing a catalytic amount of CuBr (or $CuBr_2$)/CCl_4 in MeCN also proved to be no less effective. These systems have been used for the oxidation of σ-complexes of

1-X-2,4-DNB obtained *in situ* from organosilicon compounds in the presence of fluoride ion.[222]

R =  , X = H, Cl, I, Me;

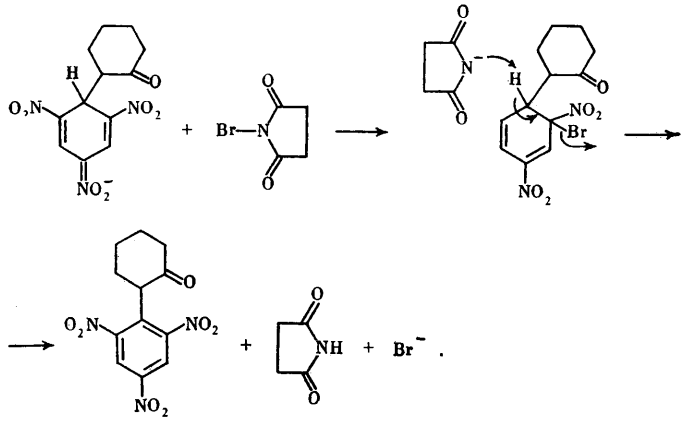
$R = R' = CH_2COOEt$, X = H;



$R = R' = CH_2Ph$, X = H;

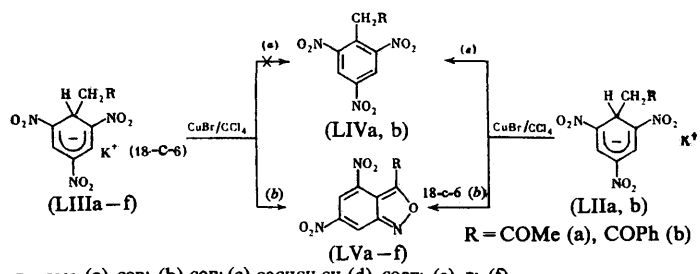
$R = R' = CH_2CH{=}CH_2$, X = H.

The effectiveness of the $CuBr/CCl_4$ system was confirmed by an experiment on the oxidation of the isolated and characterised Janovsky complex. The yield of 2,4-dinitrobenzylmethylketone was 80%,[222] i.e. the same as on oxidation with *N*-oxopiperidinium perchlorate.[270]



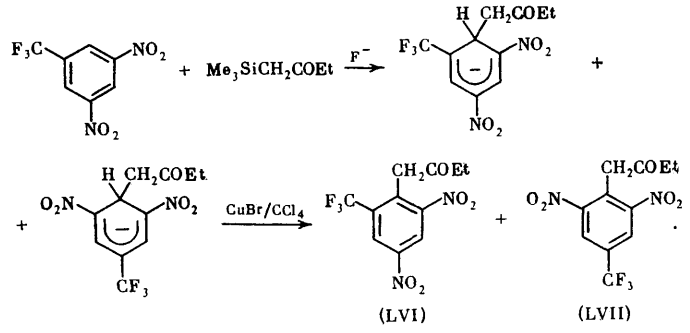
The oxidation of σ-complexes of TNB has been most widely studied. Various organic and inorganic compounds have been proposed as oxidising agents, the use of the latter is convenient and economical due to their availability. In addition the use of inorganic reagents simplifies, as a rule, the isolation of reaction products. The indisputable advantage of organic oxidising agents is their effectiveness. Chloranil, 2,3-dichloro-5,6-dicyanobenzoquinone, tropylium fluoroborate, *N*-oxopiperidinium perchlorate, and *N*-bromosuccinimide (NBS) are used most successfully in the oxidation of σ-complexes.[269–272] $FeCl_3$, $AgNO_3$, $(NH_4)_2Ce(NO_3)_6$, H_2O_2, $Pb(OAc)_4$, and solutions of halogens in water or organic solvents (Py, t-BuOH) are the inorganic reagents applied to the oxidation of σ-complexes.[180,181,271] It should be mentioned that the oxidation of the σ-complex $[TNB.CH_2COMe]^-K^+$ is the only one that has been widely studied. This complex is oxidised in an excellent manner by practically any oxidising agent. In the majority of cases it is seemingly impossible to predict which oxidising agent will prove to be most effective.[221]

It is known that the σ-complex of TNB with acetylcyclopentadienylmanganese tricarbonyl anion is oxidised by tropylium fluoroborate forming the substitution product in 80% yield, however on oxidation with trityl (Tr) fluoroborate a TNB derivative is formed.[178]



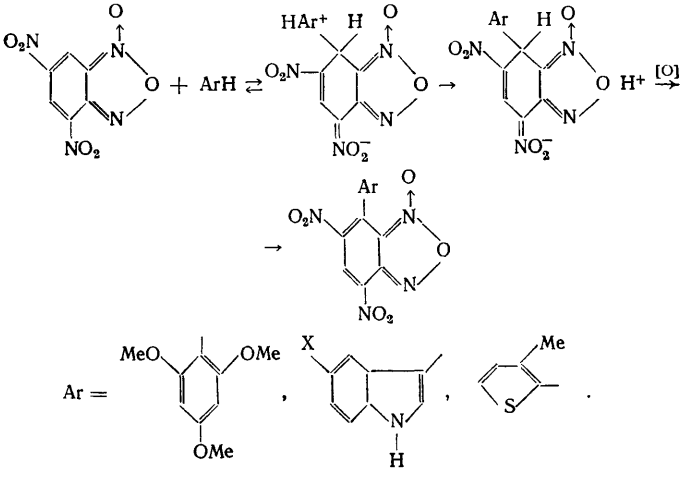
The complexes $[THB.CHal_3]^-$ (Hal = Cl, Br)[128,129] and complexes of TFMSB with $R = CH_2COMe$, $CH(COOEt)_2$, CH_2NO_2, $CH_2C(O)H$[201] were oxidised by solutions of bromine or chlorine in pyridine or t-BuOH.

NBS has been used successfully as oxidising agent for complexes of TNB with anions of ketones.[221,272] The reaction probably occurs in the following manner.



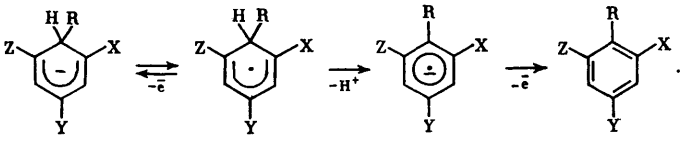
This mechanism was proposed on the basis of data obtained on the oxidation of the σ-complex of TNB with amidine.[20,264] Isoxazoline *N*-oxides are formed on oxidation of bicyclic complexes of TNB and β-dicarbonyl compounds with an excess of NBS.[273] *N*-Bromosuccinimide proved to be an effective oxidising agent for several other σ-complexes such as $[TNB.R]^-K^+$.18-crown-6 ether, where R = $CH(CH_2)_4CO$, COMe, COPh, or CH_2Ph.[221] A two fold excess of NBS was required for the oxidation of the σ-complex of TNB (XX) with R = CH_2COOMe when the methyl ester of (2,4,6-trinitrophenyl)bromoacetic acid was formed in 60% yield.[221] To obtain trinitrophenylacetic acid ester $(NH_4)_2Ce(NO_3)_6$ was used as oxidising agent. This reagent also proved to be effective for the oxidation of σ-complexes of TNB with R = C_6F_5, CH_2COEt. When R = All and C≡CPh the use of Cl_2O in CCl_4 has been proposed since the oxidising agents listed above proved to be ineffective.[221]

An unexpected result was obtained on oxidising σ-complexes with the system $CuBr/CCl_4$.[274] On oxidising σ-complexes (LII) where R = CH_2COMe and CH_2COPh substitution products (LIV) were formed. However if the oxidation was carried out in the presence of 18-crown-6 ether (18-c-6) then in place of the expected products (LIV) derivatives of 4,6-dinitrobenzisoxazole (4,6-dinitroanthranil) (LVa–f) were formed (30–70% yield). The result did not depend on whether the reaction was carried out with σ-complexes (LVa–f), whether the content of 18-c-6 was known, or the crown ether was introduced into the reaction mixture simultaneously with $CuBr/CCl_4$ and with complexes (LIIa,b). A necessary condition for such a conversion was the presence of a CH_2R group at the geminal point of the σ-complex.



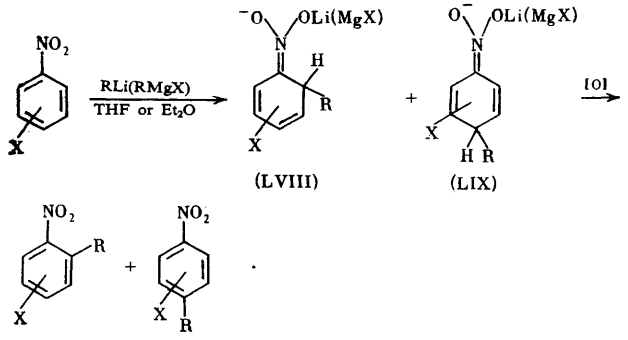
R = COMe (a), COPh (b)

Finally there is one further requirement, viz. the presence of three nitro groups in the aromatic nucleus, for anthranil formation. On oxidation of the σ-complex of 3,5-dinitrobenzotrifluoride only substitution products (LVI) and (LVII) were isolated (1 : 1).



It is interesting that complexes of DNBFX and DNBFZ containing proton as counter ion were capable of spontaneous oxidation in DMSO. This ability is lost on replacement of H^+ by the cation of a metal such as Ag^+.[203]

This observation is all the more astonishing since such complexes are oxidised only by fairly strong oxidising agents such as $KMnO_4$.[203]



The electrochemical oxidation of acetone complexes of *m*-DNB, TNB and TFMSB and also the complexes of TNB and TFMSB with nitromethane anion has been studied.[177,269,275] It was shown that electrochemical oxidation of σ-complexes proceeds in one irreversible two-electron step and the oxidation potentials of the σ-complexes of TNB (0.82 – 0.92 V) were significantly greater than that of the complex of *m*-DNB (0.33 V) and lower than the oxidation potentials of σ-complexes of TFMSB (1.37 – 1.60 V). The oxidation potentials of σ-complexes increased in the same order as their thermodynamic stabilities. The following scheme was proposed for the oxidation of anionic σ-complexes.

IV. Alkylation of mononitro aromatic compounds

1. Reactions with organometallic compounds and with carbanions

The action of strongly basic organolithium and organomagnesium compounds on nitroarenes usually forms a complex mixture of products of oxidation-reduction reactions and of addition at the nitro group.[5,276–285] It was shown only comparatively recently that this reaction may be successfully applied to the synthesis of various alkyl nitro aromatic compounds if it is carried out at low temperature (–30 to 0 °C) and the reaction mixture is treated with suitable oxidising agents, reducing agents or acids literally a few minutes after mixing the reagents.[286–304] It is evident that unstable σ-complexes like (LVIII) and (LIX) (products of 1,4- and 1,6-conjugated addition) are formed in the reaction of RLi or RMgX with a nitroarene.[289]

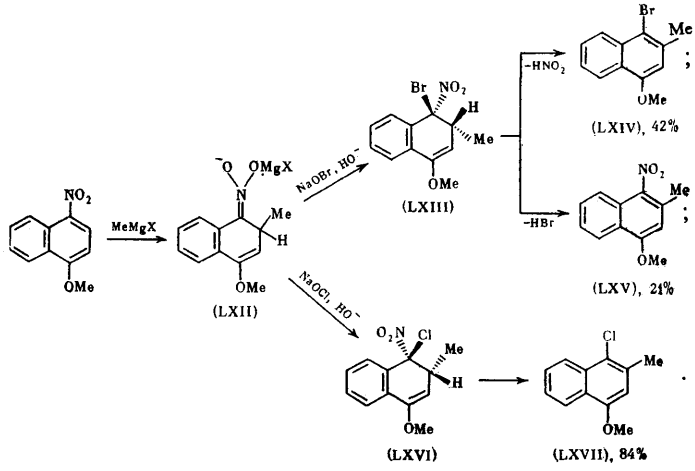
The process is reversible if an equimolar ratio of reactants is used, a significant amount of nitro compound is recovered unchanged after the reaction. Best results were obtained using a two fold excess of RMgX. The reversibility of the reaction was also confirmed by the fact that the ratio of adducts (LVIII) and (LIX) changed with time. In the reaction of *o*-nitrotoluene with AlkLi the ratio of products (LVIII) : (LIX) = 1 : 4 after 1 h and 3 : 4 after 5 h.[289,298]

Adducts (LVIII) and (LIX) must be oxidised to obtain nitro alkylaromatic compounds. DDBQ, Br_2, O_2, $Na_2[Fe(CN)_6]$, $KMnO_4$, and $Pb(OAc)_4$ have been used as oxidising agents.[287,289–292] DDBQ is probably the most effective of them, but because of its high cost and poor availability its use is expedient in exceptional cases when a chemoselective oxidising agent not affecting other groups is required.[290,291]

In many cases good results were achieved using $KMnO_4$ in alkaline aqueous acetone.[289] The alkylated derivatives of nitrobenzene, naphthalene and several heterocycles were obtained in this way. $Pb(OAc)_4$ proved to be more effective for the oxidation of adducts of RMgX with polycyclic nitro compounds.[292] It should be mentioned that high yields of oxidation products (70 – 71%) were successfully achieved only for bi- and tricyclic compounds,[287,289,292] i.e. when adducts of type (LVIII) and (LIX) are fairly stable. In the case of nitrobenzene yields did not exceed 50%.[287,289] This is odd, extremely low yields were obtained on alkylating *m*-DNB (5%) and 2,4-dinitrotoluene (12%) (see however pp. 763 – 764).[287]

A comparison has been carried out of the effectiveness of various oxidising agents in relation to the adduct of 2-methyl-1-nitronaphthalene with BuLi (LX) (Table 3).[287] As is evident from the data in Table 3 DDBQ and Br_2 proved to be comparable in effectiveness for this system.

It is interesting that the nitro group is replaced by halogen on oxidation of adducts of type (LVIII) and (LIX) by hypohalites in alkaline medium.[293,294] Thus on treatment of adduct (LXII) with an alkaline solution of hypobromite the dihydro-isomer (LXIII), with bromine and the methyl group in *trans* configuration, is formed in high yield.



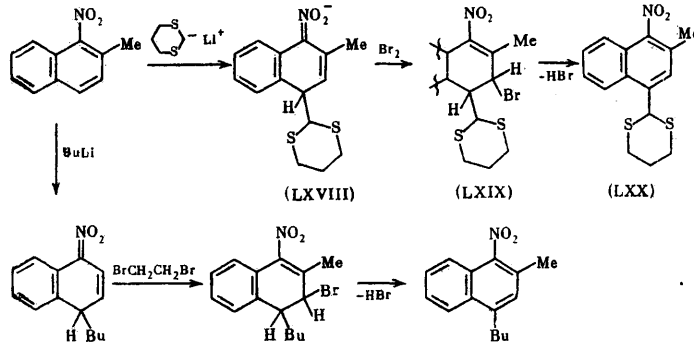


Table 3. Yields of 1-butyl-2-methyl-4-nitronaphthalene (LXI) obtained by the oxidation of adduct (LX) by various oxidising agents.

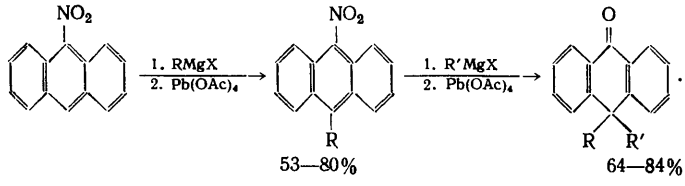
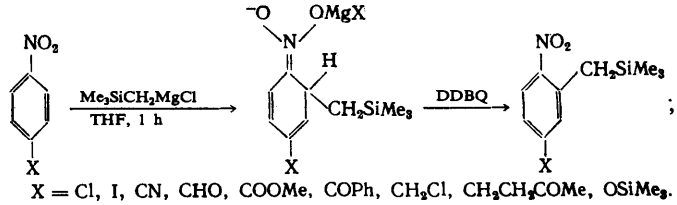
Oxidant	Solvent	Yield (LXI), %	Oxidant	Solvent	Yield (LXI), %
DDBQ	Ether	75	$Na_3[Fe(CN)_6]$	Ether	40
Br_2	Ether	70	$BrCH_2CH_2Br$	Hexane	26
O_2	Hexane	30			



The adduct (LXIII) eliminates HNO_2 in alkaline medium (E_2 type process). The *trans* elimination occurs more readily than *cis* elimination (HBr) which also determines the predominant formation of product (LXIV) [ratio (LXIV):(LXV) = 2:1].[288,294] On replacing bromine by the poorer leaving group chlorine, i.e. on oxidising compound (LXII) with hypochlorite, the chloro derivative (LXVII) was formed exclusively.[293,294] The latter reaction was used for the synthesis of several chloro alkylarenes.[293]

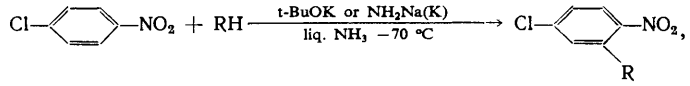
It has been proposed that bromination of the nucleus occurs, albeit partially, on oxidation of adducts of type (LVIII) and (LIX) with bromine or dibromoethane. Subsequently aromatisation of the intermediate compound takes place by elimination of HBr.[287] In reality compound (LXIX) was isolated in 50% yield on oxidation of adduct (LXVIII) with bromine. On treatment with Et_3N, HBr was eliminated and (LXIX) was converted into the oxidation product (LXX).



Other valuable compounds may be obtained from adducts (LVIII) and (LIX), such as nitroso alkylarenes (by treatment with BF_3 or concentrated HCl),[290,295–297] amines and hydroxylamines [by the action of an excess of RMgX and catalytic amounts of CuI or phosphorus(III) compounds].[298,299] A good method of obtaining arylamines is the reduction of adducts (LVIII) and (LIX) with hydrides ($LiAlH_4$ or $NaBH_4$) in the presence of catalytic amounts of Pd/C (–30 °C, ~20 min, 30–75% yield).[300]

It should be mentioned that the reaction of RM with nitroarenes is extremely regioselective. When a substituent such as OMe, OAr, SMe, SPh, Cl or F is present in the *ortho* or *para* position of a nitroarene an alkyl group R will enter almost exclusively at the unsubstituted position.[288,290] However when alkyl substituents are present a mixture of 1,4- and 1,6-addition products are formed in the ratio 2:1.[288,297] This special feature may be used for alkylating 1-R-2-naphthalenes at the C-1 atom[301] or for the two step synthesis of 10-R-10-R'-anthrones from 9-nitroanthracene.[292]

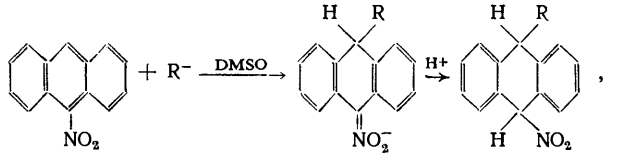
The reaction of nitroarenes with Me_3SiCH_2MgCl has been proposed for the synthesis of organosilicon compounds of the benzyl type.[302,303] The high regio- and chemoselectivity of this reaction enables the preparation of benzyl compounds of silicon containing such substituents as halogens, carbonyl and cyano groups.[303] Yields of products were 53–80%.



X = Cl, I, CN, CHO, COOMe, COPh, CH_2Cl, CH_2CH_2COMe, $OSiMe_3$.

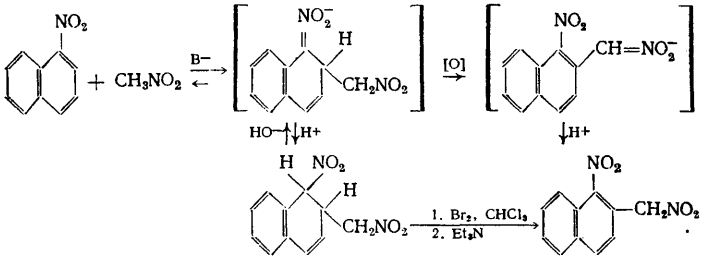
Reaction in this case was carried out with a stoichiometric amount of RMgX and, as a rule, at low temperature (–70 to 0 °C). DDBQ proved to be the best oxidising agent, however oxidation has been carried out with $KMnO_4$.[302] The same high yields of organosilicon compounds were obtained in the reaction of Me_3SiCH_2MgCl with homo- and heterocyclic nitroaromatic compounds of naphthalene, quinoline, indole and anthracene.[303]

In contrast to alkyl magnesium chloride, allyl magnesium chloride gives adducts with 1,2-addition at the nitro group with $ArNO_2$, treatment of which *in situ* with $LiAlH_4$ in the presence of catalytic amounts of Pd/C leads to *N*-allyl-*N*-arylhydroxylamines or *N*-allylanilines.[304]



As already mentioned the reaction of mononitroarenes is reversible even with RLi or RMgX which is all the more remarkable since nitroarenes react with fairly stable carbanions (pK_a 20–12 for the corresponding CH-acid) in liquid NH_3.[305-306]

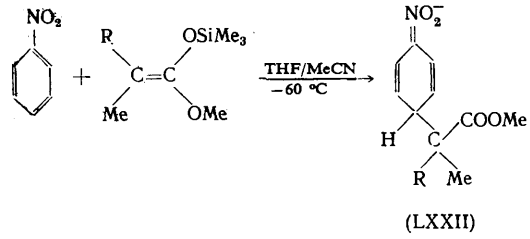
R = CH_2COMe, CH_2COBu-t, CH_2COPh, CH_2CN, CH_2COOBu-t.



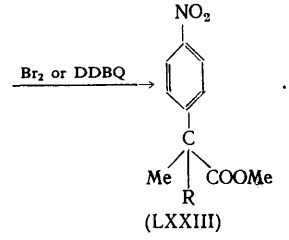
The oxidising agent is evidently partially *n*-$NO_2C_6H_4Cl$ itself and partially O_2 since the yields of substitution products (22–62%) were reduced on carrying out the reaction in an inert atmosphere.

It is possible to isolate the corresponding dihydro derivatives in good yield in the case of 1-nitronaphthalene and 9-nitroanthracene.[307]

R=CH $(COOEt)_2$, C (Me) $(COOEt)_2$, CH $(CN)_2$, Me_2CNO_2.



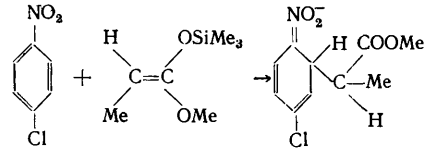
Nitromethane reacts with 1-nitronaphthalene in DMSO in the presence of NaOH forming an anionic σ-complex which may be oxidised directly or through the step of obtaining the dihydro derivative.



Monocyclic arenes do not react under these conditions.[308]

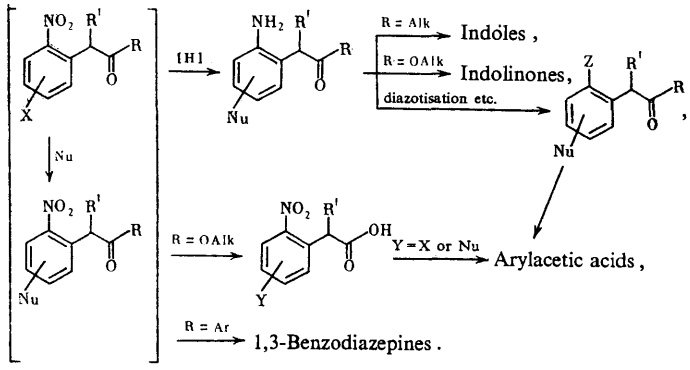
Such reactive organosilicon compounds as silylenol ethers and silyl ketene acetals and also *C*-silylated methyl acetate react successfully with mononitroarenes in the presence of F ion.[309,310] The salt *tris*-(dimethylamino)sulphonium difluorotrimethylsiliconate $(Et_2N)_3S^+Me_3SiF_2^-$, which is soluble in organic solvents, served as the source of F ion. The yields of products were reduced on using Bu_4NF.[310]

Adducts of 1,4- and 1,6-addition of $RSiMe_3$ were established in the reaction by PMR spectroscopy at –60 °C. Thus ketenacetal (LXXI) gives adduct (LXXII) with nitrobenzene.[310]



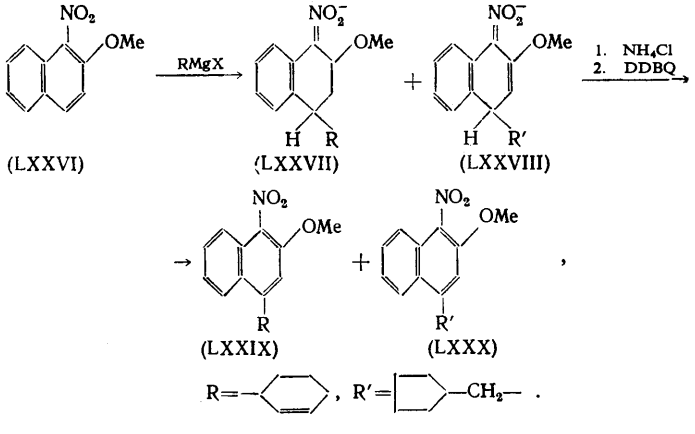
(LXXII)

(LXXIII)



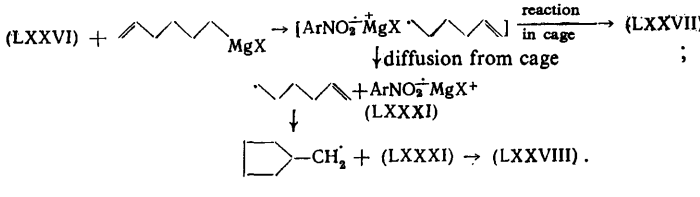
Adduct (LXXV) was established in the reaction of ketenacetal (LXXIV) with 4-chloronitrobenzene.[310]

(LXXIV) (LXXV)



It was noted that alkali metal enolates did not add to nitroarenes under these conditions.[310]

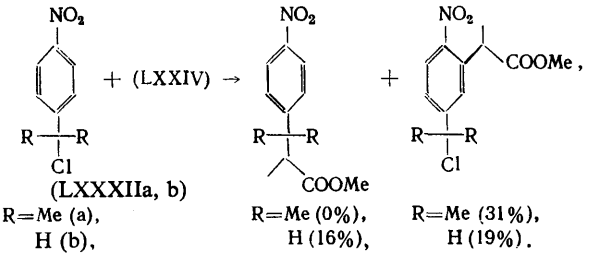
The use of silyl ketene acetals, silylenol ethers and trimethylsilylacetic ester enables synthesis of α-nitroarylated ketones and ethers which are proposed for use in the synthesis of indoles, indolinones and arylacetic acids with various substituents.[311]



The principles discovered when studying the reaction of nitroarenes with Grignard reagents[288] and $RSiMe_3$ [309,310] are extremely complex. The regiochemistry of the addition is controlled by the size of the organosilicon compound. For example compound (LXXIII) is a single isomer in the reaction shown above. With less sterically hindered silyl ketene acetals such as Me_3SiCH_3COOMe the *ortho*-isomer is formed predominantly. In reactions of nitroarenes with $RSiMe_3$, as in reactions with RMgX, the halogen atom in the nucleus is not affected.[288,310] In the case of arenes with bi- and tricyclic nuclei it is possible to isolate the corresponding dihydro derivatives by treatment of the reaction mixture with acid. On oxidising the adducts with bromine dihydro compounds like (LXIX), which have a bromine atom in the nucleus, were detected.[310]

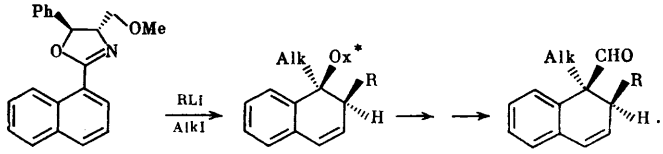
It is well known that the formation of anion radicals (AR) is repeatedly observed in reactions of nitroarenes with $RMgX$[284] or carbanions.[312] Furthermore, certain carbanions such as diphenylacetonitrile,[54] diphenylallyl,[313] fluorenyl[314,315] and others are oxidised by nitrobenzene to dimers, i.e. under definite conditions the reaction of $ArNO_2$ with RM may proceed by a single-electron-transfer (*SET*) mechanism. The problem then arises as to whether adducts (LVIII) and (LIX) are formed by the usual heterolytic route or by *SET*. The reaction of 2-methoxy-1-nitronaphthalene with hexen-5-ylmagnesium bromide was selected as a test for the existence of the *SET* mechanism.[288,291] [It is known that the hexen-5-yl radical rapidly cyclises at room temperature into the cyclopentylmethyl radical ($K \sim 10^5$ sec^{-1})[316]]. After adding DDBQ to the reaction mixture two alkylnitro compounds (LXXIX) and (LXXX) were isolated in the ratio 64:36 (overall yield 78%).

This result afforded the conclusion[288,291] that the reaction proceeded according to the radical route by at least 36%, but it is quite probable that the whole process is radical.



The order of reactivities of various RMgX [in reactions with nitroarene (LXXVI)] also supports the radical mechanism.

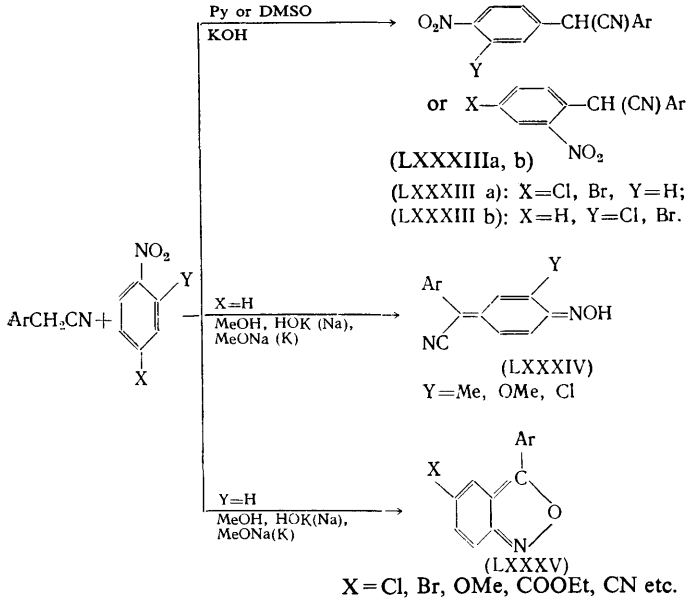
$$\text{iso-PrMgBr} > PhCH_2MgBr \simeq EtMgBr > MeMgBr.$$



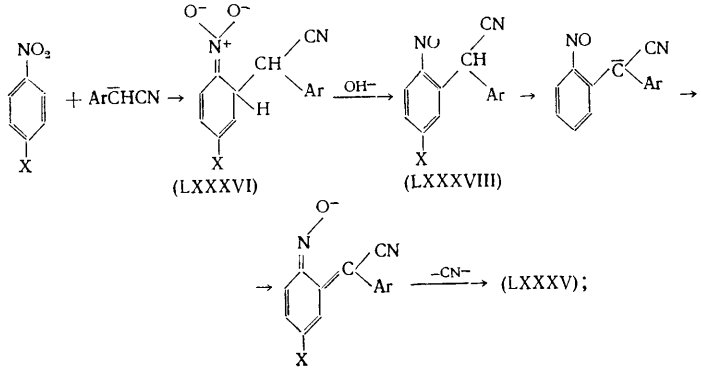
The order is determined by the ease of oxidation.[291,317]

Certain authors[310] considered the reaction of NO_2Ar with organosilicon compounds to be a heterolytic process. Their reasoning was as follows. Firstly, halogen on the nucleus is not affected in these reactions, if AR are formed then elimination of halogen must be observed. Secondly, in the reaction of (LXXIV) with 4-nitrocumyl chloride (LXXXIIa) replacement of chlorine did not occur and dicumyl or the dimer of the enolate were not detected.

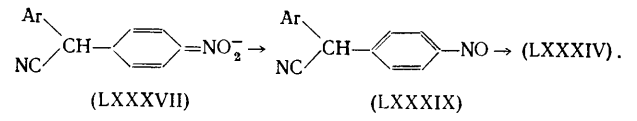
However, replacement of chlorine takes place in the case of the unhindered *n*-$NO_2C_6H_4CH_2Cl$ (LXXXIIb). In addition 1-cyclopropyl-4-nitrobenzene reacts with (LXXIV) without fission of the cyclopropane ring. Finally, as already mentioned above, the formation of adducts (LXXII) and (LXXV) was detected by PMR spectroscopy and at –60 °C the signals in the PMR spectra were not broadened.[310]



Usually the alkylation reactions described above are possible only for nitroarenes, the presence of such substituents as CF_3, CN or COR proved to be insufficient to activate the arene. However it was found comparatively recently that similar reactions (with RLi or RMgX) also occur on activation of the arene nucleus with an oxazoline group (see also p. 754). Products of *trans*-addition were formed in high yield on treating the adducts obtained with various electrophiles.[318–321]

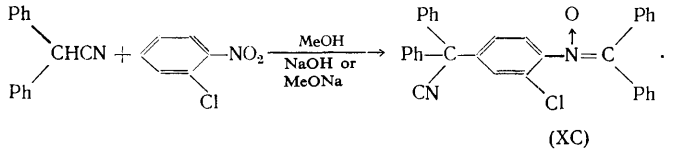


Such 'tandem addition' of RLi, RMgX and carbon-containing electrophiles has been described for (1-naphthyl)- and (2-naphthyl)-oxazolines.[318,319] Various proton sources were also used as electrophiles.[319–321]

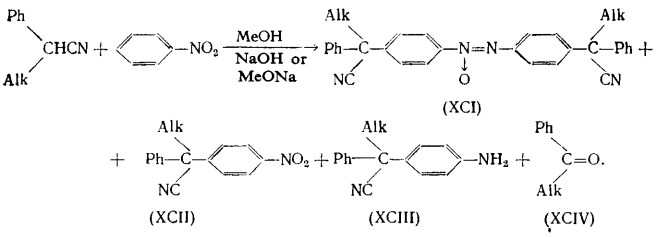


Adducts formed by addition of carbanions to nitro compounds (LVIII) and (LIX) are capable in certain cases of further spontaneous conversion which may be considered as oxidation-reduction processes with the participation of the NO_2 group. Thus over many years the steady attention of investigators has been attracted by the reaction of phenylacetonitrile and its substituted derivatives with nitroarenes which occasionally leads to the formation of unusual products.[54,322–333] The interaction of $ArCH_2CN$ with halonitrobenzenes may proceed according to three

different routes depending on the nature of the nitrocompound and the solvent.[54,322–333]



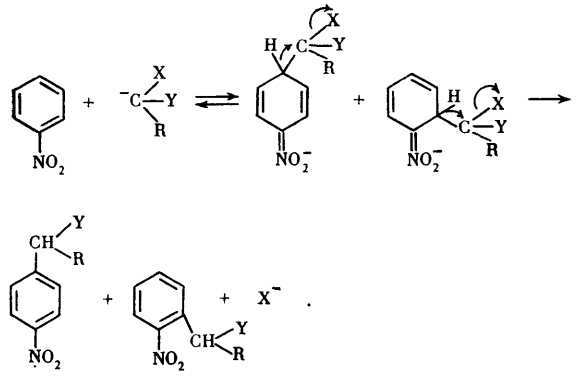
As already mentioned, replacement of halogen was observed in aprotic dipolar solvents like DMSO or Py.[54,322,323] However the situation changes sharply on replacing an aprotic solvent by methanol. In this case derivatives of quinonoxime (LXXXIV) (the oxime of 4-α-cyanoarylidene-2,5-cyclohexadien-1-one) are formed if the *para* position in the nitroarene is free.[324–328] This reaction route is effected with the selfsame variety of acetonitrile derivatives (Ar is homo- or heteroaryl) and various nitroarenes, including bicyclic and heterocyclic. When the *para* position is blocked and the *ortho* position free 3-arylanthranils (LXXXV) are formed which are used for the synthesis of 9-acridinone, acridine, benzophenones and 1,4-benzodiazepines.[323,329–331,334] The formation of both compounds (LXXXIV) and (LXXXV) may be explained within the framework of one or the other mechanism, comprising attack of the carbanion at the *ortho* or *para* position of the benzene ring [formation of adducts (LXXXVI) and (LXXXVII)], elimination of hydroxyl ion which leads to nitroso compounds (LXXXVIII) and (LXXXIX), intramolecular cyclisation of *o*-nitro compound (LXXXVIII) to anthranil (LXXXV) or isomerisation of the *p*-nitro compound (LXXXIX) to quinonoxime (LXXXIV).[54,323,325]



Regrettably it is still unclear in what way the conversion of (LXXXVI) →(LXXXVIII) or (LXXXVII)→(LXXXIX) occurs. The strong influence of solvent on the route of reaction is also not understood.

Phenylacetonitriles substituted in the α-position are evidently unable to give products like (LXXXIV) and (LXXXV). Diphenylacetonitrile forms nitrone (XC) in high yield on reaction with a nitroarene with a free *para* position in the benzene ring.[54,323,332–334]

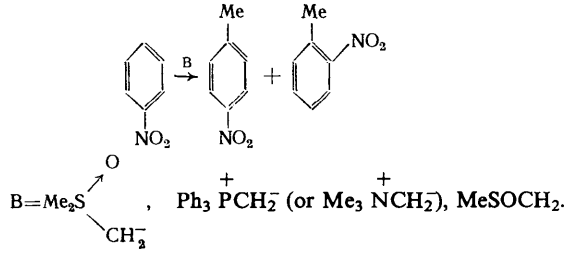
Under these conditions α-alkylphenylacetonitriles gives a complex mixture of compounds (XCI)–(XCIV) with $PhNO_2$ among which is the product of replacement of hydride ion.[54,332]



The presence of amine (XCIII) in the reaction mixture probably indicates that 1 mole of nitro compound behaves as an oxidising agent in relation to an adduct like (LXXXVII). The formation of all the remaining products is readily explained by subsequent conversions of nitroso compounds.[54,332,333] It is noted that in weakly polar solvents like benzene the anion of diphenylacetonitrile is oxidised by nitroarenes to the dimer.[54,332]

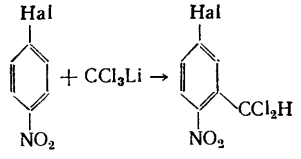
2. Vicarious nucleophilic substitution of hydrogen

The alkylation of nitroaromatic compounds by carbanions has been described above. In these reactions removal of hydride ion from the intermediate complex is effected by an oxidising agent. The oxidising agent is introduced into the reaction mixture specially or the initial nitroarene fulfils this role, in this way an intra- or intermolecular oxidation of the σ-complex occurs.



Another route for converting adducts (LVIII) and (LIX) into alkylnitroarenes has emerged using carbanions containing 'good' leaving groups. The essence of the reaction is that under the action of the carbanion a hydrogen atom in the position *ortho* or *para* to the nitro group of the nitroarene is replaced. The substituent X acts as a 'vicarious' leaving group and Makosza and collaborators

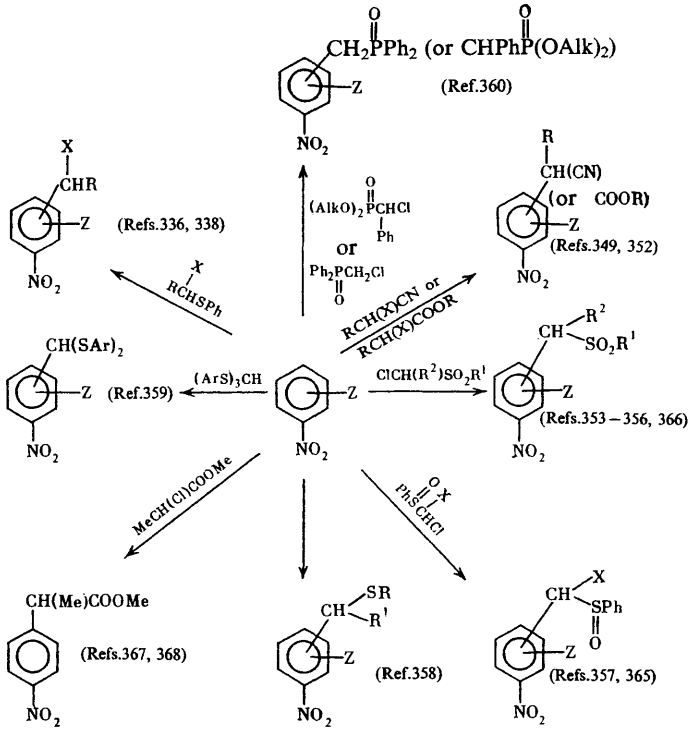
have proposed the general name of vicarious nucleophilic substitution (VNS) for the whole process.[335–339]



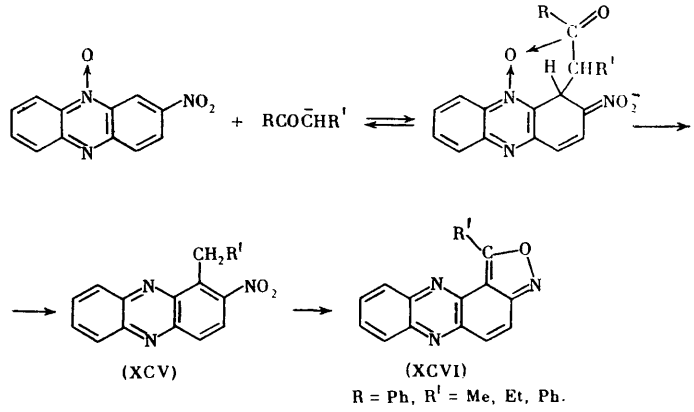
X is a leaving group: Cl, Br, PhS, PhO, $R_2NC(S)S$, etc.; Y is a group stabilising the carbanion: SO_2Ar, SO_2NR_2, SO_2OR, SOAr, CN, COOR, $CONR_2$, $P(O)Ph_2$, $P(O)(OEt)_2$, etc.; R = H, Alk, Ar. In spite of the fact that individual examples of similar reactions were known previously,[340–346] only the systematic work of Makosza and collaborators has attracted general attention to like reactions and the study of them has proceeded independently.

It is known that methylation of nitrobenzene and certain of its substituted derivatives occurs under the action of methylids of sulphur, phosphorus or of dimethylsulphinyl carbanion.[340,341]

The reaction of halonitrobenzenes with CCl_3Li, which may serve as a method of dichloromethylating and formylating nitroarenes, should also be considered as a VNS.[342,347]



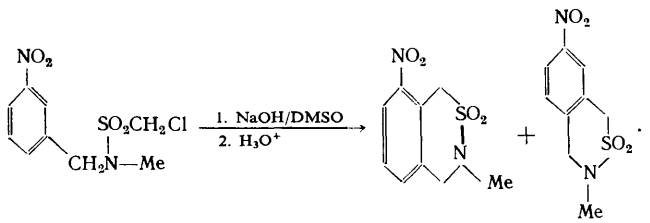
The possibility of nucleophilic substitution of hydrogen in nitroheteroarenes has been shown.[343–346]



In the general case, as shown by Makosza and collaborators,[336–339] for the successful achievement of the VNS reaction, it is necessary that the carbanions are sufficiently stable and do not react with the CH-acids from which they were formed. This is attained by an appropriate combination of groups X and Y. However when X = Hal not many CH-acids satisfy this requirement consequently CH-acids are used which contain poorer leaving groups such as PhS, PhO, $R_2NC(S)S$, etc.[336–339]

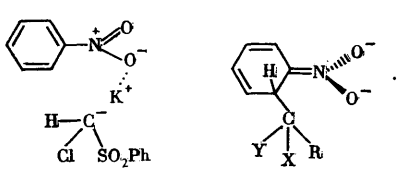
The choice of base and solvent is another important requirement. Such systems as NaOH(KOH)/DMSO or NH_3, NaOH/DMF, R_4NOH/PhH(PhCl) proved to be most suitable. This means that solvent-separated ion pairs or free ions possess the greatest reactivity. Under such conditions the VNS reaction enables the introduction of various α-functionalised alkyl groups into the *ortho* and *para* positions of nitro aromatic compounds.[335–368] It should be mentioned that the products of VNS contain at least one acid hydrogen atom in the α-position, consequently they may react with other electrophiles such as RHal, RCHO, etc. (Scheme 3).[347]

Scheme 3



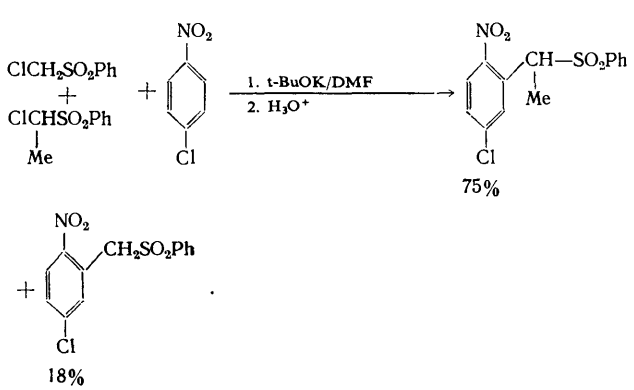
A more complex case of the VNS reaction has been described[346] in which the leaving group is carboxylate ($RCOO^-$). Various products are obtained depending on the nature of the ketone which reacts with 2-nitrophenazine-10-*N*-oxide. These include the normal products of substitution of hydride ion (XCV), anthranils (XCVI) and other more complex compounds (see previous section).[346]

(XCV) (XCVI)



R = Ph, R' = Me, Et, Ph.

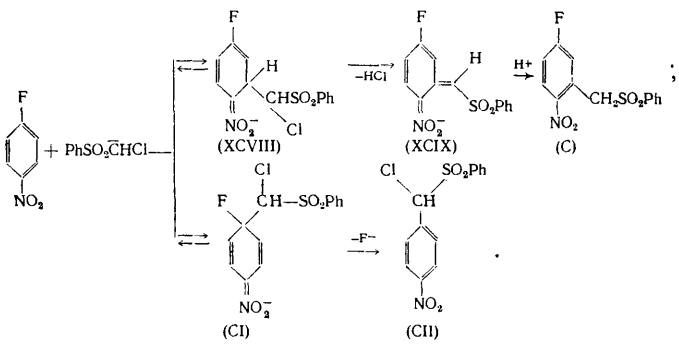
The intramolecular VNS process may serve as a source of various isocyclic and heterocyclic compounds.[369]



The intramolecular VNS reaction is used for the synthesis of tetracycline derivatives.[370]

The VNS reaction is distinguished by several special features. Tertiary carbanions usually replace a hydrogen atom in the *para* position of the nitroarene,[337,338,357] although there are several exceptions.[349,357] A mixture of *ortho* and *para* isomers, the ratio of which depends on the size of groups X and Y, is formed from secondary carbanions when using DMSO, DMF or liquid NH_3 as solvent.[349,350] On the other hand, the application of the THF/t-BuOK system enables selective replacement of hydrogen in the *ortho* position to the nitro group.[351,352,356] This is explained by the fact that the carbanions are mainly in the form of contact ion pairs or aggregates with the potassium ion in THF in difference to DMSO. The potassium cation, forming a bond with negatively charged oxygen in the NO_2 group, directs the associated carbanion to the *ortho* position.[352,356]

However under definite conditions (DMF, t-BuOK, –40 to –30 °C)¶ tertiary carbanions like α-chloroalkylphenylsulphone also readily substitute hydrogen in the *ortho* position of a nitroarene. Furthermore in competing reactions of tertiary and secondary carbanions the former react at the higher rate.[366]



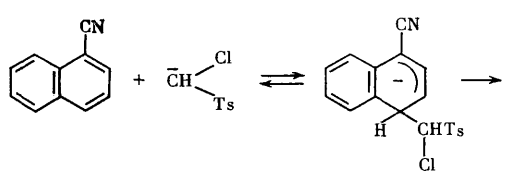
¶Tertiary carbanions and *o*-nitrobenzyl carbanions of the corresponding products are unstable at higher temperatures.[367]

Of the two possible *ortho* isomers the most hindered (1,2,3 isomer) is formed for the majority of 3-substituted nitrobenzenes.[353,356] This same special feature of the reaction was also observed in the methylation of nitroarenes by ylids.[342] Thus by changing the solvent and by varying groups R, X and Y in the carbanion it is possible to change the regioselectivity of the VNS reaction in an effective manner.

The VNS reaction is distinguished by its special features for naphthalenes.[365] 1-Nitronaphthalene gives a mixture of 2- and 4-substituted products [in reactions with $ClCH(R^2)SO_2R^1$ the ratio of 2-isomer : 4-isomer = 10 : 1]. The preference for attack by the carbanion at position 2 is comprehensible on considering the mesomeric structures of the appropriate σ-adducts. Reaction of 2-nitronaphthalene with secondary carbanions occurs exclusively at position 1. This tendency was so large that no VNS reaction occurred on blocking position 1 with a MeO group but a nucleophilic aromatic substitution of the MeO group took place. No reaction occurred with tertiary carbanions (such as α-chloropropyl-p-tolylsulphone).[365]

Donor groups (NMe_2, Me, OR) and even negatively charged groups of the COO^- type proved to have no significant influence on the VNS reaction.[355,361] Mononitrophenoxides did not undergo a VNS reaction, however this reaction is possible for di- and trinitrophenoxides.[362] In this case it probably occurs as a nucleophilic addition to the cyclohexadienenitronate system.[362] We also note that VNS reactions are known for DNB and TNB in which it is possible to substitute two and three hydrogen atoms respectively.[362]

Like the reactions with RLi, RMgX or $RSiMe_3$ vicarious nucleophilic substitution may be used for alkylating halogen-substituted nitrobenzenes since the rate of substituting hydrogen is far greater than that for Cl, Br or I. Replacement of both hydrogen and fluorine or nitro group depending on the conditions was observed in *o*- and *p*-fluoronitrobenzenes and *p*-dinitrobenzene.[336–339,363,368] An interesting dependence of reaction route on base concentration has been discovered.[363] On interacting *p*-fluoronitrobenzene with chloromethylphenylsulphone (XCVII) at a ratio (XCVII)/t-BuOK = 2 the formation of both possible products (C) and (CII) was observed but with a four fold excess of t-BuOK the product of VNS (C) was obtained exclusively.



This dependence is displayed even more clearly in the competing reaction of phenoxyphenylacetonitrile (CV) with a mixture of NO_2Ph and n-$FC_6H_4NO_2$. At a ratio (CV)/t-BuOK equal to 2 approximately identical amounts of the VNS product and that from fluoride

ion substitution were obtained. At a ratio (CV)/t-BuOK = 4 practically only the product of hydrogen substitution was obtained. From this it follows that addition of carbanion to an unsubstituted carbon atom [adduct (XCVIII)] occurs more rapidly than formation of an adduct containing a fluorine atom at the geminal node (CI).[339,363]

It is certain that the VNS reaction includes the reversible formation of an intermediate σ-complex. It is assumed that its conversion into the reaction product may occur either by removal of the leaving group X from the carbanion with a simultaneous 1,2-hydride shift or by base catalysed elimination of HX.[336–339,363] The observed dependence of the reaction route on base concentration and also isotope effects K_H/K_D found in several cases,[339,363,368] indicate that the second mechanism is true. The mechanism of VNS therefore includes a rapid, reversible σ-complex formation and subsequent slow elimination of HX. The rate of elimination must, nonetheless, be more than the rate of addition of carbanion to the carbon bonded to halogen.[339]

Regarding the mechanism of formation of the σ-complex, the authors regard this reaction to be ionic.[339] The clearly expressed influence of solvation of the cation on the route of addition of carbanion to NO_2Ar indicates this. In addition cyclisation products were not detected in the reaction of 1-chloro-5-hexenylphenylsulphone with nitroarenes[339] (cf. addition reactions of RMgX to NO_2Ar[285]).

In conclusion we note that the VNS reaction, like the alkylation reaction described in Chapter IV, Section 1, is only possible for nitroaromatic compounds. Arenes with less strongly electron-accepting substituents in the nucleus, as a rule, do not take part in this reaction. The reaction of 1-cyanonaphthalene with chloromethyl-4-tolylsulphone leading to *bis*-cyclopropane derivative (CIV) proved to be even more unexpected.[364]

(CIII) (CIV)

This result is probably explained by addition of carbanion at the C-4 atom with subsequent intramolecular nucleophilic substitution which leads to the monoannulated product (CIII). The latter, being an active Michael acceptor, adds a second molecule of carbanion finally forming (CIV).[364]

We note that vicarious nucleophilic substitution has been illuminated in more detail in a review.[371]

Thermal reactions of thiyl radicals

M G Voronkov, E N Deryagina
Irkutsk Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences

ABSTRACT. The review presents data on the methods of generation and properties of thiyl radicals. The results of studies on the reactivities of thiyl radicals in thermal processes, permitting the synthesis of a wide variety of organic sulphur compounds and compounds of other types, are surveyed.

The bibliography includes 167 references.

I. Introduction

Thiyl (sulphur-centred) free radicals are short-lived reactive sulphur-containing intermediates RS$^{\cdot}$ (R = H or an organic group) whose sulphur atom has an unpaired electron. They participate in many chemical reactions, including various industrial and natural processes and are therefore of practical and theoretical interest.

The stability of free radicals is determined by the degree of delocalisation of the unpaired electron.[1] This can be estimated quantitatively from electronic, spectroscopic, and EPR data. According to Walter's classification, free radicals can be divided into two groups:[2]

1. The radical centre possesses an unshared electron pair together with the unpaired electron. The delocalisation of the electron is promoted by electron-donating substituents at the radical centre.

2. The paramagnetic centre has only the unpaired electron whose delocalisation is promoted by both electron-donating and electron-accepting substituents.

The energy characteristics of the level occupied by the unpaired electron have also been used recently for the classification of free radicals. According to this classification, the radicals can be divided into three groups:[3]

1. Electrophilic radicals containing the unpaired electron in the highest bonding orbital. Such radicals tend to be converted into the energetically more favourable ionic state by capturing an electron.

2. Nucleophilic radicals containing the unpaired electron in the lowest antibonding orbital and exhibiting a tendency to give it up.

3. Amphoteric radicals containing the unpaired electron in a non-bonding orbital.

Thiyl radicals having an unshared electron pair at the radical centre are electrophiles judging from their reactivity. The energies of the highest molecular orbitals occupied by one electron may serve as a characteristic of the relative stability of thiyl radicals.[3]

This review deals for the first time with thermal methods for the generation of thiyl radicals from very simple sources such as hydrogen sulphide and its organic derivatives† as well as the methods for high-temperature organic synthesis using thiyl radicals. The description of these data (mainly obtained by the present authors) is preceded by an account of the general information about the method of generation and detection and the properties of thiyl radicals secured earlier in the study of the photochemical and other types of reactions and frequently quoted in certain reviews and monographs.

II. Generation, detection, structure, and properties of thiyl radicals

1. Generation

Thiyl radicals usually arise in the photolysis, radiolysis, and thermolysis of hydrogen sulphide and its organic derivatives (thiols, sulphides, thionitrites, etc.). They can also be generated on treatment of the above compounds by initiators such as peroxides, diazo-compounds, etc.[6,7] Overall, the dissociation energies of the S–H, S–C, and S–S bonds are fairly high (87, 69, and 63 kcal mol^{-1} respectively) compared with the dissociation energies of other bonds (N–N, O–O, Si–Si, Ge–Ge, Sn–Sn, As–H, Sn–H, Sn–C, etc.) (Table 1).

The strength of the E–H, and E–C bonds involving elements of a given Group of the Periodic System decreases with increase in the atomic number of the element E (Table 1). Accordingly the S–H, and S–C bonds are weaker than the O–H and O–C bonds but are more stable than the Se–H and Se–C bonds respectively. The S–H bonds in alkanethiols are stronger than the CH_2–H bonds in propylene and toluene but weaker than the O–H bond in alkanols.[8]

The strength of the bonds between two identical non-metal atoms or two atoms of an amphoteric non-transition metal (E–E) in Group IV decreases with increase in the atomic number of the element E. On the other hand, the energy of the E–E bonds

†As regards the role of thiyl radicals in reactions of organic compounds with participation of elemental sulphur, see Voronkov, et al.[4,5]

involving Group V–VII elements in the Third Period (P–P, S–S, and Cl–Cl) proves to be a maximum in the given Group, which can apparently be accounted for by the $p-\pi$, $d-\pi$ interaction, as a result of which the effect of the repulsion of the unshared electron pairs loses its importance. By virtue of this, the S–S bond in organic disulphides is much stronger than the O–O, Se–Se, and Te–Te bonds in the isostructural peroxides, diselenides, and ditellurides (Table 1).

Table 1. The average enthalpies of the E–H, E–C, and E–E bonds involving non-metallic elements.

Element E	ΔH°_{298}, kcal mol^{-1}*		
	E–H	E–C	E–E

Note. The data were taken from handbooks: V I Vedeneev, L V Gurvich, V N Kondriat'ev, et al. *Energii Razryva Khimicheskikh Svoiazei* (Chemical Bond Dissociation Energies), Izd. Akad. Nauk SSSR, Moscow, 1962, 215 pp; A J Gordon, R A Ford *A Chemist's Companion* (Translated into Russian), Izd. Mir, Moscow, 1976, p. 134

*The values determined by other methods are given in brackets.

The structure of the alkyl groups linked to the sulphur atom in alkanethiols, alkyl sulphides, and alkyl disulphides has little influence on the strength of the S–H, S–C, and S–S bonds. On the other hand, the presence of a π-electron system at the sulphur atom reduces the strength of these bonds[9,10] (Table 2).

The difference between the dissociation energies of the C=S and C–S bonds (45 kcal mol^{-1}) is much smaller than the difference between the dissociation energies of the C=O and C–O bonds (73 kcal mol^{-1}). The conversion of thiyl radicals into thiocarbonyl compounds is usually not observed, while the analogous reactions involving oxyl radicals, readily affording carbonyl compounds, do take place.

The steric hindrance in the reactions involving thiyl radicals is less significant than in the reactions involving oxyl radicals, since the C–S bond length (1.81 Å) is greater by almost 30% than the C–O interatomic distance (1.42 Å).[1]

The electron affinity of thiyl radicals is greater than that of oxyl radicals, which is apparently due to the presence of unoccupied *d* orbitals in the sulphur atom. The stabilisation of thiyl radicals at low temperatures is difficult, since, in contrast to oxyl radicals, they readily recombine (cf. the S–S and O–O bond energies listed in Table 1).

Table 2. The dissociation energies (E_D) of the S–H, C–S, and S–S bonds in certain organic sulphur compounds.[9,10,11]

The enthalpy of formation of the sulphydryl radical HS$^{\cdot}$ varies in the range 31.9–35.0 kcal mol^{-1} according to different data.[9,12–14] The dipole moments, obtained by the EPR method, are contradictory (0.62 D [15] or 1.47 D [16]). The ν(SH) and ν(SD) frequencies in the IR spectra of HS$^{\cdot}$ and DS$^{\cdot}$ radicals matrix-isolated in argon are respectively 2450.8 and 1847.8 cm^{-1}.[12] The ionisation potential of HS$^{\cdot}$ is 10.5 eV [12] and its electron affinity varies in the range from 53.1 kcal mol^{-1} at −273 °C to 58.8 kcal mol^{-1} at 1527 °C.[17]

The enthalpy of formation of alkanethiyl radicals decreases with increasing length and degree of branching of the alkane chain from 31 for $CH_3S^{\cdot}$ to 15 for n-$C_4H_9S^{\cdot}$ and 11 kcal mol^{-1} for t-$C_4H_9S^{\cdot}$.[4] The entropy and heat generating capacity increase in the same sequence.[18]

The simplest arenethiyl radical $C_6H_5S^{\cdot}$ is distinguished by a high enthalpy of formation (ΔH°_{298} = 56.8 ± 2.0 kcal mol^{-1}).[14] Its stabilisation energy (9.6 kcal mol^{-1}) is close to the stabilisation energy of the benzyl radical (13.5 kcal mol^{-1}), but is appreciably lower than that of the phenoxyl radical (17.5 kcal mol^{-1}).[14]

The molecular and electronic structures of the $CH_3S^{\cdot}$ and $C_2H_5S^{\cdot}$ radicals, which have the C_s symmetry, were calculated by the MNDO method. The molecular orbital is localised predominantly on the sulphur atom, is located at right angles to the C–S bond, and has the A' symmetry.[19] This agrees with experimental data characterising the Mo of thiyl radicals as π orbitals. The heats of the rearrangement reaction involving the migration of a hydrogen

atom in the $CH_3S^{\cdot}$ and $C_2H_5S^{\cdot}$ radicals have been calculated:

$$CH_3S^{\cdot} \rightarrow \dot{C}H_2SH \ (0.6 \text{ kJ mol}^{-1}),$$

$$CH_3CH_2S^{\cdot} \rightarrow CH_3\dot{C}HSH \ (26.4 \text{ kJ mol}^{-1}).$$

The values obtained indicate the exothermic character of these reactions.

The rearranged radicals $\dot{C}H_2SH$ and $CH_3\dot{C}HSH$ have the C_s symmetry, while the molecular orbital is located at right angles to the CSH plane and has the A'' symmetry.

2. Detection

In contrast to the alkoxyl radicals $RO^{\cdot}$, the alkanethiyl radicals $RS^{\cdot}$ cannot be detected in the liquid phase by the EPR method since their $p-\pi$ orbitals are degenerate and the spin–orbital interaction constants for the sulphur atom are large.[20,21] The EPR spectra of alkanethiyl radicals in the solid state have a fairly anisotropic g-tensor,[22–24] whose components can differ appreciably depending on the structure of the radical.[25] In the thiyl radicals where the sulphur atom is linked to a π-electron system ($CH_2=CH$, C_6H_5, etc.), the degeneracy of the π levels is removed as a result of the delocalisation of the unpaired electron over the multiple bond. Their EPR spectra can be recorded in certain cases even in liquid media. The photochemically generated 2,4,6-tri-(t-butyl)benzenethiyl radical gives in its EPR spectrum a singlet ($\Delta\beta$ = 2.89) with g = 2.0103 and an unresolved hyperfine structure due to the hydrogen atoms.[26] This radical is in equilibrium with the dimer below 313 K (ΔH = –23.3 kcal mol^{-1}). After prolonged photolysis of thiophenols, a very complex effect of the chemically induced dynamic electronic polarisation (CIDEP), which promotes a marked decrease of the signal, was observed. In many cases, after the removal of the source of irradiation, the height of the lines in the EPR spectra of thiyl radicals increases suddenly and then slowly diminishes.[27]

A strong signal with a typically anisotropic g-factor was detected in the EPR spectrum of diphenyl disulphide irradiated with UV light at –200 °C.[28] The g-tensor is almost axially symmetrical and has the extremum values g = 2.006 and 2.012. The marked anisotropy of the g-factor is caused by the localisation of the unpaired electron on the sulphur atom of the $C_6H_5S^{\cdot}$ radical.[28,29] The absorption spectrum of $C_6H_5S^{\cdot}$ contains bands of 355 and 380 nm, while the luminescence spectrum has bands at 374 and 240 nm.[30] The colour of the 4-dimethylaminobenzenethiyl and 4-diphenylaminobenzenethiyl radicals is appreciable even at –73 °C.[29]

Thiyl radicals have also been identified by EPR spectroscopy in the form of their spin-adducts with different trapping agents. The spin-adducts of thiyl radicals with nitroso-compounds are unstable and are therefore detected only when they are generated directly in the resonator of the spectrometer.[31,32]

Thiyl radicals have been detected as spin-adducts with 2-nitrosopropane, 2-methyl-2-nitrosopropane, nitrosobenzene, pentamethylnitrosobenzene, nitrosodurene, 2, 4, 6-tri-(t-butyl)nitrosobenzene, and 5,5-dimethyl-Δ^1-pyrroline N-oxide.[33–37]

Thiyl radicals react at a high rate with stable radicals. The rate constants for the reactions between *para*-substituted benzenethiyl radicals and free radicals such as di(t-butyl)nitroxyl (DBNO$^{\cdot}$) and galvinoxyl (Q$^{\cdot}$) have been determined.[37] In the case of Q$^{\cdot}$ (ρ^+ = +0.25), the reaction is controlled solely by the stability of the thiyl radical, while for DBNO$^{\cdot}$ the polarity of the transition state (ρ^+ = +0.75) is also important.

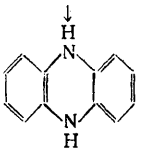
The radical $C_6H_5S^{\cdot}$ reacts at a higher rate with pentamethylnitrosobenzene than with 2-methyl-2-nitrosopropane or nitrosodurene.[38]

The EPR spectra of the spin-adducts of the thiyl radicals with 2-methyl-2-nitrosopropane consist of a triplet with similar values of the g-factor and a_N constants in the range 16.5–18.5 G, whose values are characteristic solely of thiyl radicals.[20,21,39–42]

A specific feature of these spin-adducts is the rapid disappearance of the signal when irradiation ceases.[43] The g-factor of thiylalkyl(thiylaryl)nitroxyls is greater than the g-factor for the free electron.[40] The temperature and the solvent do not affect the parameters of the EPR spectra of thiylnitroxyls.

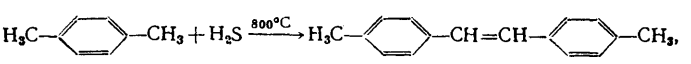
3. Chemical properties

The characteristic reactions of thiyl radicals involve addition to multiple bonds and the abstraction of a hydrogen atom from organic molecules. The rates of these processes depend on polar effects as a consequence of the high electron affinity of thiyl radicals and the strength of the S–H bond arising when they are generated. In reactions involving the abstraction of a hydrogen atom from hydrocarbons, thiyl radicals are more selective than the bromine atom or the trichloromethyl radical.[44]



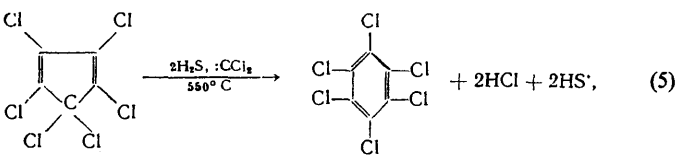
Thiyl radicals function as agents transferring hydrogen atoms from molecules to radicals.:[45]

$$RS^{\cdot} + HR' \rightleftarrows RSH + {}^{\cdot}R'. \quad (1)$$

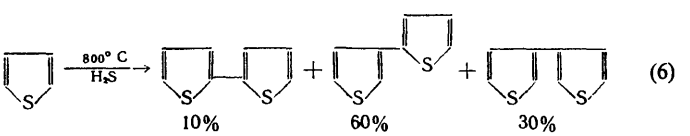


Reaction (1) is sensitive to steric hindrance in molecules and radicals. As a result of the transfer of a hydrogen atom, thiyl radicals accelerate the pyrolysis of hydrocarbons or even alter its direction[8,46–52] and they catalyse the decarbonylation of aldehydes[53] and the conversion of a series of alcohols into ketones.[54] At temperatures above 450 °C in hydrogen sulphide, the thermal conversions of aniline into 5,10-dihydrophenazine,[55] of benzaldehyde into stilbene,[56] of *p*-xylene into 4,4′-dimethylstilbene,[57] and of hexachlorocyclopentadiene into hexachlorobenzene[58] are initiated.

Hydrogen sulphide accelerates with thermal dehydrodimerisation of thiophen into isomeric bithienyls[59] [reaction (6)]:



$$C_6H_5NH_2 + HS^{\cdot} \xrightarrow{750^\circ C} C_6H_5\dot{N}H + H_2S, \quad (2)$$



$$2C_6H_5CHO + 2H_2S \xrightarrow{500^\circ C} C_6H_5CH{=}CHC_6H_5 + 2H_2O + 2S, \quad (3)$$

(4)

(5)

(6)

In a hydrogen sulphide atmosphere, ethyl vinyl ether is transformed, with a high degree of conversion, preferentially into s-butyl vinyl ether. The interaction with hydrogen sulphide over iron sulphide leads to the almost complete conversion of ethyl vinyl ether into acetaldehyde diethylacetal:[60]

$$CH_2{=}CHOCH_2CH_3 \xrightarrow{Z} \underset{(A)}{CH_3CH(OC_2H_5)_2} + \underset{(B)}{CH_2{=}CHOCH(CH_3)C_2H_5}.$$

Reagent Z	N_2	H_2S	H_2S over FeS
Yield of (A), %	8.5	7.0	90
Yield of (B), %	8.5	64.0	—

In the hydrogen sulphide–iodine system, the decomposition of alkyl vinyl ethers at 250 °C leads to trithioacetaldehyde and ethanol.[61] The catalytic effect of iodine apparently consists in the initiation of the formation of thiyl radicals[62] [reaction (7)] which subsequently substitute the RO group in the ether via reaction (8):

$$I_2 \rightleftarrows 2I^{\cdot}; \quad I^{\cdot} + H_2S \rightleftarrows HI + HS^{\cdot}, \tag{7}$$

$$CH_2{=}CHOR + HS^{\cdot} \rightarrow CH_2{=}CHSH + {}^{\cdot}OR,$$

$$CH_2{=}CHSH \rightarrow CH_3CHS \rightarrow {}^1/_3(CH_3CHS)_3,$$

$$RO^{\cdot} + H_2S \rightarrow ROH + HS^{\cdot},$$

$$R = C_2H_5, \quad n\text{-}C_4H_9. \tag{8}$$

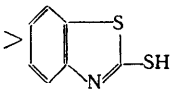
The chemical properties of thiyl radicals are reflected most clearly by their reactions with unsaturated compounds. The free-radical addition of hydrogen sulphide and thiols to multiple bonds (the thiylation reaction) is usually initiated by peroxides, azo-compounds, and also by radiation and UV irradiation.[7, 63–78] These reactions confirm the electrophilic nature of thiyl radicals, since they attack the reaction centre with the highest electron density. The mechanism of the thiylation reaction is described by the following general scheme:

$$RSH \rightarrow RS^{\cdot} + H^{\cdot}, \tag{9}$$

$$RS^{\cdot} + \rangle C{=}C\langle \rightleftarrows RS{-}\overset{|}{C}{-}\overset{|}{\underset{\cdot}{C}}\langle, \tag{10}$$

$$RS{-}\overset{|}{C}{-}\overset{|}{\underset{\cdot}{C}}\langle + HSR \rightleftarrows RS{-}\overset{|}{C}{-}\overset{|}{C}{-}H + RS^{\cdot}. \tag{11}$$

Reactions (9)–(11) cannot be achieved with thermal initiation apparently because of the low thermal stability of the sulphides formed, which promotes the reversibility of the process.[79] Reactions (10) and (11) are appreciably exothermic, which leads to rapid chain propagation.



The stability of the radicals RS$^{\cdot}$ exerts the greatest influence on the rate of homolytic thiylation. The radicals are stabilised by electron-donating substituents and are destabilised by electron-accepting ones.[80] The rate of abstraction of the hydrogen atom from the HS group in alkanethiols diminishes approximately by a factor of 20 in the following sequence based on different alkyl groups:[45,81–83]

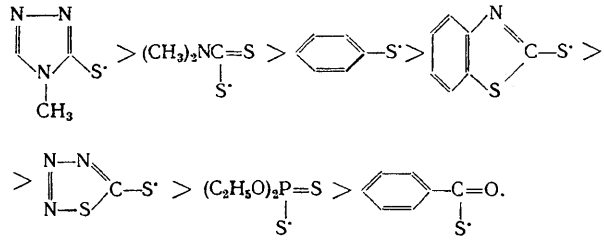
$$C_5H_{11} > C_4H_9 > (CH_3)_2CHCH_2 > (CH_3)_3C.$$

The sulphydryl hydrogen atom is abstracted from thiophenol several hundred times more readily than from butanethiol.[84]

The ability of thiols to generate thiyl radicals has been estimated quantitatively from the rate of their oxidation, which decreases in the following sequence:[85,86]

$$ArSH > C_6H_5CH_2SH > HOCOCH_2SH > RCH_2SH >$$

$$> RR'CHSH > RR'R''CSH > \text{  }$$



In reactions involving addition to a double bond, the reactivity of the radicals RS$^{\cdot}$ diminishes in the following sequence of substituents R:[84]

$$Cl_3CCO > Cl_2CHCO > ClCH_2CO > CH_3CO > C_6H_5 > HCOCH_2.$$

The rate of addition of arenethiyl radicals 4-$XC_6H_5S^{\cdot}$ to vinyl monomers is inversely proportional to the electron-donating properties of the *para*-substituents X.[87,88] The latter stabilise benzenethiyl radicals in the following sequence:[88]

$$Cl < H < CH_3 < CH_3O.$$

The stability series of thiyl radicals has also been established by their combined elimination in reactions of ketodithials with tributylstannane:[89]

Thiyl radicals substitute fairly readily different groups linked to polyvalent heteroatoms in organoelement compounds.[90]

III. High-temperature reactions of thiyl radicals

During the last one and a half decades, extensive studies have been carried out on the high-temperature reactions of thiyl radicals with organic compounds.[91–94] They have shown, in particular, that hydrogen sulphide is the most readily available and promising source of thiyl radicals, which subsequently initiate a wide variety of thermal and organic reactions.

1. Thermolysis of hydrogen sulphide

As early as 1852, Cluzel[95] established that hydrogen sulphide decomposes on heating into its constituent elements—hydrogen and sulphur. This process begins at 350–400 °C [96] and becomes appreciable at 1300–1600 °C.[97] The degree of decomposition of hydrogen sulphide is 0.003% at 700 °C,[98] 15–20% at 930 °C,[99] and 83% at 1700 °C.[98] Equilibrium is established after 10 s at 430 °C and after 0.4 s at 930 °C.[99] The thermolysis of hydrogen sulphide is characterised by a small exothermic effect:[100]

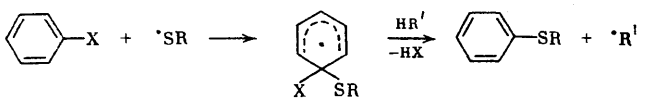
$$H_2S \rightarrow H_2 + 0.25S_4, \quad \Delta H^0_{298} = 13 \text{ kcal mol}^{-1}.$$

The energy of the dissociation of hydrogen sulphide into atoms is 173 kcal mol^{-1}.[101] The study of the thermal degradation of hydrogen sulphide in shock waves when it is present at low concentrations in argon revealed the most energy consuming stage:

the dissociation into free radicals with participation of argon molecules:[102,103]

$$H_2S + Ar \xrightarrow{2400-3500\,^{\circ}C} HS^{\cdot} + H^{\cdot} + Ar. \quad (12)$$

The activation energy for reaction (12) is 92 kcal mol^{-1} according to Nagashima[98] or 74 kcal mol^{-1} according to Bowman and Dodge[103] and is close to the dissociation energy of the S–H bond in the hydrogen sulphide molecule: 98.3,[104] 95.0,[105] 81.2,[106] and 92.0 kcal mol^{-1}.[9] The inhibition of the thermolysis of hydrogen sulphide by nitrogen oxide[102] and the initiation of this process by atomic hydrogen[102–107] indicate its radical mechanism. The exothermic reaction of hydrogen sulphide with atomic hydrogen, occurring at a high rate, plays a significant role in the homolytic decomposition of hydrogen sulphide. It also initiates the decomposition of hydrogen sulphide into the elements via the stage involving the generation of sulphydryl radicals:[107]



$$H_2S + H^{\cdot} \rightarrow HS^{\cdot} + H_2;$$

$$2HS^{\cdot} \rightarrow H_2S + S; \quad HS^{\cdot} + S \rightarrow H^{\cdot} + S_2. \quad (13)$$

Reaction (13) ensures a low activation energy (37 kcal mol^{-1}) for the thermolysis of undiluted hydrogen sulphide[108] at 400–1000 °C. Under these conditions, hydrogen sulphide does not decompose into the elements via a molecular mechanism in view of the reversibility of the synthesis of H_2S from sulphur and hydrogen.[109]

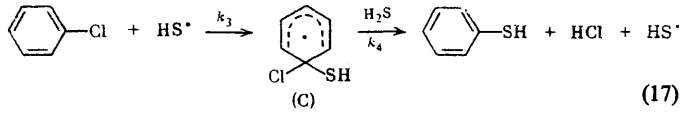
2. Gas-phase reactions of hydrogen sulphide with aromatic halogeno-compounds and hetero-compounds

The thermal reactions of hydrogen sulphide with aromatic and unsaturated chloro- and bromo-substituted hydrocarbons and their derivatives have been studied in greatest detail. These readily available organic compounds have a high thermal stability[110] and a low reactivity in nucleophilic thiylation.[111] On the other hand, the thermal reactions involving the *ipso*-substitution of a halogen atom in the aromatic ring by sulphydryl and arene- or ethylene-thiyl radicals are promoted by the electrophilic nature of thiyl radicals, the enhanced electron density in the C_{sp^2}–X (X = Cl, Br) bond, the possibility of the formation of an intermediate radical-adduct stabilised with participation of the π-system of the aromatic ring, and also the removal of the halogen atom in the form of a thermally stable hydrogen halide.[112]

X = Cl, Br; R = H, CH_2=CH, Ar

Such reactions were carried out in standard flow systems (empty quartz tube), which model, in terms of their size, the conditions in an ideal displacement reactor.

The gas-phase reaction of hydrogen sulphide with chlorobenzene begins at 550 °C, takes place effectively at 600–700 °C (the degree of conversion of chlorobenzene is 40–90%) with formation of thiophenol, diphenyl sulphide, and benzene. Their ratios are to a large extent determined by the reaction temperature. The yield of thiophenol and diphenyl sulphide reaches a maximum in the narrow temperature range 600–620 °C, above which the formation of benzene increases significantly. In the same temperature range, diphenyl sulphide cyclises partially to dibenzothiophen.[113,114] The excess hydrogen sulphide promotes an increase in the yields of thiophenol, while the excess chlorobenzene increases the yield of diphenyl sulphide.[115–117] The kinetic curves characterise the reaction of chlorobenzene with hydrogen sulphide as a complex process consisting of consecutive-parallel irreversible reactions. Chlorobenzene is converted in succession, via the intermediate formation of thiophenol, into diphenyl sulphide and is at the same time reduced to benzene:[116]



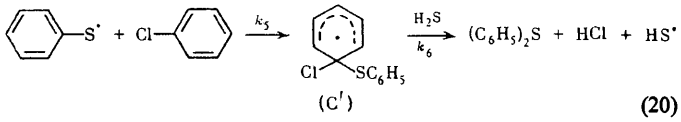
$$C_6H_5Cl + H_2S \xrightarrow{k_1} C_6H_5SH + HCl, \quad (14)$$

$$C_6H_5Cl + C_6H_5SH \xrightarrow{k_2} C_6H_5SC_6H_5 + HCl, \quad (15)$$

$$C_6H_5Cl + H_2S \rightarrow C_6H_6 + HCl + S. \quad (16)$$

The reaction conditions leading to the maximum yield of thiophenol have been optimised by mathematical experimental design.[115] The yield of C_6H_5SH reaches 30% relative to the initial chlorobenzene and 90% relative to the reacted chlorobenzene at 600–620 °C for the molar ratio H_2S:C_6H_5Cl = 3:1 and a contact time of 38–48 s.

Since the thermolysis of chlorobenzene with dissociation of the C–Cl bond does not yet begin at 600 °C while the dissociation of hydrogen sulphide with formation of thiyl radicals does already occur, on the basis of the kinetic data the mechanism of the formation of thiophenol and diphenyl sulphide can be represented by the following scheme:[118]



(C) (17)

(18)

(19)

(C′) (20)

According to this scheme, the *ipso*-substitution of the chlorine atom in the aromatic ring by thiyl radicals takes place via a bimolecular chain mechanism. Thiyl radicals are generated preferentially in the chain transfer stages. Radical-adduct formation stages (17) and (20) are slowest. Stage (20) is evidently rate-limiting, since the concentration of benzenethiyl radicals is always lower than that of sulphydryl radicals. This scheme is confirmed by the fact that alkyl chlorides are not thiylated by hydrogen sulphide in the gas phase and are merely reduced. Benzene also does not react with hydrogen sulphide under the conditions investigated.

The Arrhenius expressions for the rate constants for the formation of thiophenol (k_1) and diphenyl sulphide (k_2) via reactions (14) and (15) and as a result of the direct reaction of thiophenol with chlorobenzene (k_2') assume the following form:[118]

$$k_1 = 10^{5.15\pm0.9}\exp[(-27.7\pm0.37)/RT],\ s^{-1},$$

$$k_2 = 10^{8.30\pm0.14}\exp[(-29.0\pm0.6)/RT),\ \text{litre mol}^{-1}\ s^{-1},$$

$$k_2' = 10^{10.17\pm0.63}\exp[(-33.6\pm3.0)/RT],\ \text{litre mol}^{-1}\ s^{-1}.$$

The activation energies for reactions (14) and (15) are similar, which shows that the change in the hybridisation of the carbon atom of the C–Cl bond in chlorobenzene on formation by the latter of the

activated complex (C) or (C′) with a thiyl radical makes the decisive contribution to the activation energy in all cases. The low entropies of activation indicate bimolecular mechanisms of the formation of thiophenol and diphenyl sulphide. The rate constant for the formation of diphenyl sulphide in the chlorobenzene–thiophenol system (k_2') is approximately five times greater than the analogous constant obtained in the chlorobenzene–hydrogen sulphide system.

Eqn. (21) for the constant k_2, obtained by comparing the functional identities of the differential equations describing the real chlorobenzene thiylation process [reactions (14) and (15)] and its mechanism [reactions (17)–(20)], shows that this constant includes also the rate constant for the rate-limiting stage [the formation of the activated complex (C′)] and depends on the ratio of the concentrations of the benzenethiyl radical and thiophenol:

$$k_2 = k_5[C_6H_5S^{\cdot}]/[C_6H_5SH]. \quad (21)$$

The constant k_2 increases on direct interaction of chlorobenzene with thiophenol in the absence of hydrogen sulphide. The excess of the latter promotes the occurrence of reaction (19), as a result of which there is an increase in the concentration of thiophenol [the denominator in Eqn. (21)] and the rate constant for the formation of diphenyl sulphide (k_2) diminishes. This entails an increase in the selectivity of the synthesis of thiophenol by reaction (14).

The initiators and inhibitors of free-radical reactions respectively influence the rate and direction of the reaction of hydrogen sulphide with chlorobenzene. Phenol and cyclohexene retard this reaction, lowering the degree of conversion of chlorobenzene by a factor of 2.[116] Chloromethanes, generating on thermolysis free radicals and carbenes,[119] accelerate the thiophenol formation stage apparently as a result of the additional initiation of the chain decomposition of hydrogen sulphide.[120] An increase in the surface area of the reaction zone lowers the degree of conversion of chlorobenzene without altering the kinetics of its reaction with hydrogen sulphide, which shows that the latter occurs in the bulk phase.

The walls of the reactor promote the generation and destruction of thiyl radicals[116] and the material of the reactor therefore influences significantly the rates of reactions (14) and (15). For the same contact time, the degree of conversion of chlorobenzene in a steel reactor is approximately 30% greater than in a quartz reactor. In this case, the ratio of the reaction products changes in favour of thiophenol and benzene.[121] Evidently the walls of the steel reactor participate in the formation of the radicals $HS^{\cdot}$ and $C_6H_5^{\cdot}$ as a result of the catalysis of the thermolysis of hydrogen sulphide and chlorobenzene by nickel and chromium sulphides and polysulphides,[122] formed on passivation of the reaction surface by hydrogen sulphide. In a copper reactor, hydrogen sulphide does not react with chlorobenzene. The *para*-substituted derivatives of chlorobenzene 4-XC_6H_4Cl react with hydrogen sulphide in the gas phase similarly to chlorobenzene itself. The formation under these conditions of the corresponding thiol 4-XC_6H_4SH and the sulphide $(4\text{-}XC_6H_4)_2S$ indicates the *ipso*-substitution of the chlorine atom by thiyl radicals and confirms the mechanism described by reactions (17)–(20).[123] The following reactions then take place:

$$4\text{-}XC_6H_4Cl + H_2S \rightarrow 4\text{-}XC_6H_4SH + HCl, \quad (22)$$

$$4\text{-}XC_6H_4Cl + 4\text{-}XC_6H_4SH \rightarrow (4\text{-}XC_6H_4)_2S + HCl, \quad (23)$$

$$4\text{-}XC_6H_4Cl + H_2S \rightarrow 4\text{-}XC_6H_5 + HCl + S,$$

$$X = H,\ Cl,\ OH,\ CH_3,\ CF_3. \quad (24)$$

Chloropentafluorobenzene reacts similarly with hydrogen sulphide, affording C_6F_5SH and $(C_6F_5)_2S$. The optimum temperature for the formation of the thiol and the sulphide is determined by the nature of the substituent X (in the case of chlorobenzene) and also by the nature of the benzene ring (in the case of C_6F_5Cl). It decreases with increase in the capacity of the C–Cl bond for homolytic dissociation.

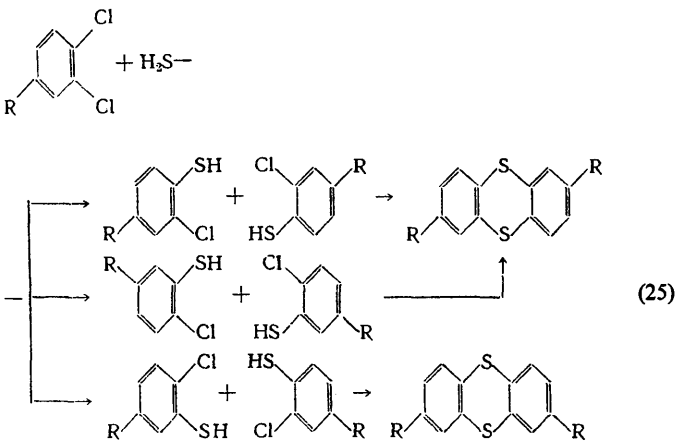
The sequence in which the degree of conversion of the chloro-derivatives increases is identical with the sequence based on the increase in electron density at the chlorine atom. Accordingly, the degree of conversion of 4-XC_6H_4Cl in the reaction with H_2S and also the physicochemical parameters of the C–Cl bond vary in the following sequence of substituents X:

	OH	< Cl	< CF_3	< H	< CH_3
Charge Q (Cl), eV	−0.16	—	0.15	−0.17	−0.17
$\nu(^{35}Cl$ NQR), cm^{-1}	34.9	34.8	34.7	34.65	34.5
$\delta[^{13}C(C^1)]$ relative to X = H, p.p.m.	−8.74	−1.71	3.88	0.00	−3.21
Charge on C^1 (π) atom, eV	−0.04	—	3.03	0.00	−0.02

The ratio of the thiylation products (thiol/sulphide) depends significantly on the reactivity of the intermediate thiol. It is correlated with parameters of the electronic structure of the compounds 4-XC_6H_4SH and their reactivity, increasing in the following sequence of substituents X:

$$Cl < CH_3 < H < CF_3 < OH.$$

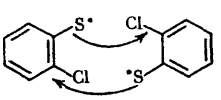
$C_5F_5Cl[\nu(^{35}Cl$ NQR) = 39.4 $cm^{-1}]$ reacts most slowly with hydrogen sulphide among all the *para*-substituted chlorobenzenes. The thiol/sulphide ratio in the thiylation products is highest in this instance.



The reactivity of these thiols is largely determined by the degree of localisation of the HOMO on the sulphur atom, since the other parameters of the electronic structure (the ionisation potential and the charge on the sulphur atom) depend little on the nature of the substituent X or the benzene ring.

The degree of localisation of the HOMO on the sulphur atom is correlated only with the resonance component of the substituent X, increasing with decrease in its electron-donating capacity. The thiol/sulphide ratio is correlated directly with the degree of localisation of the HOMO on the sulphur atom of the thiol, diminishing with enhancement of the π-electron-donating properties of the substituent X. Thus the π-electron-accepting substituents X in the thiol 4-XC_6H_4SH decrease the reactivity of the thiol in its interaction with the initial chloro-derivative [scheme (23)], while π-electron-donating substituents increase it. From the standpoint of the free-radical mechanism of reactions (22) and (23), the formation of the arenethiyl radical, which then participates in the second stage of scheme (20) under the conditions of the competing interaction with H_2S [see scheme (19)], determines the capacity of this radical for stabilisation.

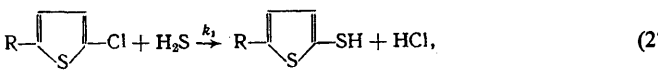
It has been suggested that the distribution of the unpaired electron in 4-$XC_6H_4S^{\cdot}$ is analogous to the distribution of the HOMO in 4-XC_6H_4SH, so that π-electron-donating substituents X stabilise the arenethiyl radicals, whilst π-electron-accepting substituents destabilise them, as a result of which in the latter case the radicals are formed at a lower rate and subsequently react preferentially with hydrogen sulphide in accordance with scheme (19) and not with the initial chloro-derivatives in accordance with scheme (20). 4-Hydroxythiophenol is an exception, which is evidently associated with the autoinhibition of the free-radical process in this case. By increasing the dehydrating activity of the 4-$XC_6H_4S^{\cdot}$



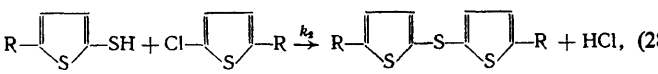
radical, π-electron-accepting substituents X promote the formation of the thiol 4-XC_6H_4SH via scheme (22) with a high selectivity (for a low degree of conversion of the initial chloride). C_6F_5SH is formed with the highest selectivity. *ortho*-Substituted chlorobenzenes react with hydrogen sulphide in the gas phase via pathways different from those for the *para*-substituted derivatives. The main product of the thiylation of 2-chlorotoluene or chloromesitylene is the corresponding thiol [scheme (14)], since the steric effect of the *ortho*-ethyl group hinders the interaction of the 2-methylbenzenethiyl or mesitylenethiyl radical in the sulphide formation stage via scheme (20).[124]

The interaction of 1,2-dichloro- or 1,2,4-trichloro-benzenes with hydrogen sulphide results in the formation of a thianthrene or dichlorothianthrenes respectively according to scheme (25):[125]

(25)



Their formation is apparently determined by the intermolecular cyclisation of *ortho*-chloro-substituted benzenethiyl radicals proceeding via scheme (26) at a high rate:



(26)

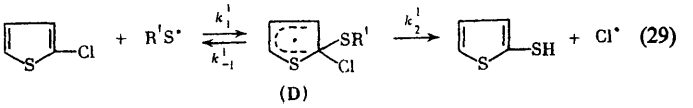
In contrast to *p*-chlorophenol, *o*-chlorophenol reacts with hydrogen sulphide more effectively and with a more selective formation of 2-hydroxythiophenol in accordance with scheme (22).[126]

The reaction of hydrogen sulphide with 2-chlorothiophen, leading to thiophen-2-thiol and di(2-thienyl)sulphide takes place at lower temperatures (500–540 °C) than in the case of chlorobenzene:[127]

(27)

(28)

R=H, Cl, C_2H_5.



Reaction (28), leading to the sulphides, then proceeds at a higher rate than in the case of chlorobenzene [scheme (14)].

Arrhenius expressions have been obtained for the rate constants k_1 and k_2 for the formation of thiophen-2-thiol and di(2-thienyl)-sulphide [schemes (27)–(28)]:

$$k_1 = 10^{14.2\pm0.4}\exp[(-52.0\pm3.4)\times10^3/RT],\ s^{-1},$$

$$k_2 = 10^{13.8\pm0.2}\exp[(-55.7\pm2.9)\times10^3/RT],\ mol^{-1}\ s^{-1}.$$

The high activation energies for both reaction stages and the high pre-exponential factors indicate a unimolecular mechanism of the reaction. This can be due to the faster attack by the thiyl radicals HS˙ and RS˙ on the polarised double bonds of the thiophen ring and the greater stability of the activated complex (D), which decomposes slowly in the rate-limiting stage in accordance with scheme (29):[128]

(29)

(D)

R^1 = H, R.

5-Ethylthiophen-2-thiol is formed from 2-chloro-5-ethylthiophen via schemes (27) and (28) in a higher yield and 5-chlorothiophen-2-thiol is formed from 2,5-dichlorothiophen in a lower yield than that of thiophen-2-thiol formed from 2-chlorothiophen. In the absence of hydrogen sulphide, 2,5-dichlorothiophen dehydrodimerises at 560–570 °C to tetrachloro-3,3′-bithienyl.[129]

The reaction of hydrogen sulphide with bromobenzene begins at 500 °C, i.e. at a temperature lower by 50 K than the reaction of H_2S with chlorobenzene. At all the temperatures investigated, the degree of conversion of bromobenzene is higher than that of chlorobenzene, while the products of the reaction with hydrogen sulphide are similar. However, their ratios and yields differ.[130] The reactions of hydrogen sulphide with bromobenzene and its substituted derivatives lead mainly to the corresponding sulphides [via schemes analogous to schemes (22) and (23)].

The bromo-derivatives of condensed aromatic hydrocarbons (naphthalene, anthracene, phenanthrene) react with hydrogen sulphide even in the liquid phase at 150–250 °C,[131] forming only the corresponding sulphides.

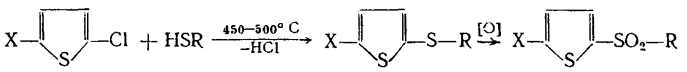
Iodobenzene reacts with hydrogen sulphide already at 480 to 500 °C, being converted preferentially into diphenyl sulphide and benzene. Thiophenol and diphenyl disulphide are formed in small amounts in addition to the above compounds. In the interaction of halogenobenzenes with hydrogen sulphide, the optimum temperature for the formation of thiophenol and diphenyl sulphide decreases with increase in the atomic number of the halogen:

Cl (600—620° C) > Br (550—580° C) > I (480—500° C).

The degree of conversion of the halogeno-derivative increases and the thiol/sulphide ratio decreases in the same sequence. The sequence in the variation of the mobility of the halogen corresponds to the variation of the C–X bond strength in halogenobenzenes (Table 1) and is characteristic of radical reactions.[132] Fluorobenzene does not react with hydrogen sulphide even at 700 °C. Above this temperature, it is partly converted into a mixture of isomeric mono- and di-fluorobiphenyls.

3. Gas-phase reactions of thiophenol with aromatic and heteroaromatic halogeno compounds

Thiophenol interacts with aromatic halogeno-derivatives at 400–600 °C primarily with formation of asymmetric aromatic sulphides in accordance with the general mechanism[133]

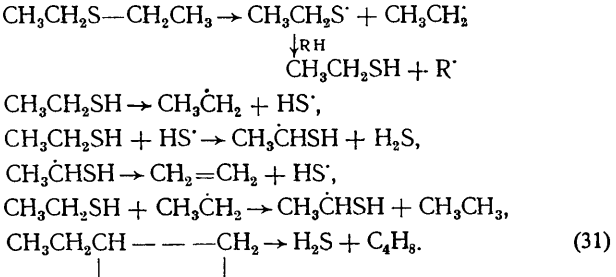


$$C_6H_5SH + RX \rightarrow C_6H_5SR + HX, \quad (30)$$

R = aryl, thienyl, naphthyl; X = Cl, Br.

Reaction (30) is favoured by an excess of the halogeno-derivatives and the lowest possible temperature. With increase in temperature and in the concentration of thiophenol, processes involving the reduction of the halogeno-derivative, exchange reactions, and

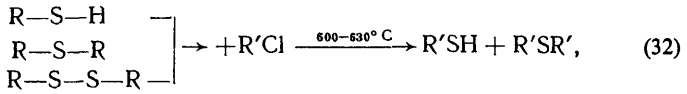
cyclisation reactions of diaryl sulphides and thiyl radicals are accelerated. The reactions of thiophenol with *ortho*-substituted halogenobenzenes are accompanied by the formation of sulphur-containing heterocyclic compounds: thus the interaction of thiophenol with 2-chlorotoluene led to the isolation of thioxanthrene,[134] the interaction with *o*-dihalogenobenzene afforded thianthrene,[125] and the interaction with *o*-chlorobenzene gave rise to 4-hydroxydibenzothiophen.[135]



Many asymmetric aryl thienyl sulphides were obtained for the first time by the reaction of aromatic thiols with 2-chlorothiophen and its 5-substituted derivatives[136] (yield 44–76%):

$X = H,\ C_2H_5,\ Cl;$
$R = C_6H_5,\ 4\text{-}H_3CC_6H_4,\ 1\text{-}C_{10}H_7.$

4. Gas-phase reactions of alkanethiols, dialkyl sulphides, and dialkyl polysulphides with aromatic halogeno-compounds



The readily available alkanethiols, dialkyl sulphides and polysulphides, or their mixtures can be used as sources of thiyl radicals for the interaction of the latter with aromatic halogeno-compounds. The thiols and sulphides decompose in the gas phase with formation of hydrogen sulphide and alkenes via a free-radical mechanism with the immediate generation of thiyl radicals,[137] for example:

(31)

$D_{C_2H_5SH}(C-S) = 63.5$ kcal mol^{-1};
$D_{H_2S}(S-H) = \sim 90$ kcal mol^{-1}.

The high-temperature reactions of alkanethiols, dialkyl sulphides, and dialkyl disulphides with chloro-derivatives of benzene, thiophen, and naphthalene lead to the same thiylation products as in the case where hydrogen sulphide is used.[138–140] This indicates a unique mechanism of reactions involving the participation of thiyl radicals according to schemes (17)–(20):

(32)

$R = Alk;\ R' = C_6H_5,\ 4\text{-}CH_3C_6H_4,\ 4\text{-}ClC_6H_4,\ 2\text{-}ClC_6H_4,$
$4\text{-}CF_3C_6H_4,\ C_6F_5,\ 3,4\text{-}Cl_2C_6H_3,\ C_{10}H_7,\ C_4H_3S.$

The reactions of alkanethiols with aryl halides differ by the increased selectivity in the formation of the thiol R'SH [scheme (32)]. The alkenes formed via scheme (31) probably inhibit the rate-limiting stage in the formation of the sulphide R'SR'.

IV. Liquid-phase thermal reactions of thiyl radicals

Thiyl radicals can be generated in the liquid phase from diaryl disulphides, arenethiols, and the sulphur–hydrogen sulphide system even at moderately high temperatures (100–250 °C).

Heating of diphenyl disulphide with bromoarenes at 125–230 °C in hydrogen sulphide at atmospheric pressure leads to the corresponding aryl phenyl sulphides:[141]

$Ar = C_6H_5,\ 2\text{-}HOC_6H_4,\ 4\text{-}HOC_6H_4,\ 4\text{-}C_2H_5OC_6H_4,$
$C_{10}H_7,\ 2\text{-}HOC_{10}H_6.$

Aromatic chloro-compounds and 2-chlorothiophen hardly enter into reaction (33), which is apparently due to the high strength of the C–Cl bond, the boiling points of the initial reactants being inadequate for the homolysis of the latter. The temperature of the thiylation of bromoarenes in accordance with scheme (33) diminishes after the introduction of a π-electron-donating substituent into the benzene ring. Above this temperature, the reactions leading to the reduction of the halogeno-derivative to the corresponding aromatic hydrocarbon are accelerated. Thiophenol and diphenyl sulphides are formed simultaneously in a low yield from diphenyl disulphide as a result of thermolysis and hydrothiolysis.

Reaction (33) is initiated by the free radicals formed in the thermolysis of the initial compounds:

(33)

(34)

(35)

(36)

(37)

(38)

Reactions (34)–(36) of free radicals with H_2S lead to the formation of thiophenol and the products of the reduction of Br$^{\cdot}$ and Ar$^{\cdot}$. In the reactions of the latter with thiophenol, which is a stronger H-donor than hydrogen sulphide, benzenethiyl radicals are generated. They are responsible for the chain thiylation of ArBr via scheme (20).

The radicals $C_6H_5S^{\cdot}$ play the role of agents transferring hydrogen atoms from hydrogen sulphide to the radicals Br$^{\cdot}$ and Ar$^{\cdot}$ in reaction (33).

When thiophenol is heated with aryl bromides, the corresponding aryl phenol sulphides are also formed [see schemes (37), (38), and (20)].[142] However, a more limited amount of bromide enters into the reaction with thiophenol, which is due to the inadequately high boiling point of the reaction mixture (the boiling point of thiophenol is 180 °C).

Fairly simple methods of synthesis of aryl phenyl sulphides have been developed on the basis of the reactions of Ph_2S (in H_2S or thiophenol) and ArBr.

Thiophen-2-thiol and 1-thionaphthol do not react with aryl bromides in the liquid phase to form the corresponding sulphides. The initial bromides are merely reduced to the corresponding aromatic hydrocarbons, while the thiols are then converted into symmetrical sulphides. This shows that the thiophen-2-thiyl and naphthalene-1-thiyl radicals are weaker hydrogen atom transferring agents than the benzenethiyl radical. Overall, this disturbs the process and leads to the termination of the chain transfer stage.

The sulphydryl radicals HS$^{\cdot}$ can be generated on interaction of elemental sulphur with hydrogen sulphide even at 110–230 °C. Thus 1-chloronaphthalene, 1-bromo-4-chlorobenzene, and 4-bromotoluene react in accordance with scheme (39) with the sulphur–hydrogen sulphide system at 180–230 °C, forming the corresponding diaryl sulphide in 8–88% yield:[43]

$$ArX \xrightarrow[180-230^{\circ}C]{H_2S+S} Ar_2S + HX. \quad (39)$$

The reaction of 4-bromophenol with the S + H_2S system takes place already at 110–125 °C, being completed after 2 h by the formation of di(hydroxyphenyl) sulphides and phenol.

At 200 °C, 4-chlorophenol reacts with hydrogen sulphide and sulphur via the same pathway, but the reaction is completed after 45 h. 2-Bromophenol reacts with the S + H_2S system more slowly than does 4-bromophenol and at a higher temperature (200 °C):[144]

$$H_2S + S \rightleftarrows 2HS^{\cdot},$$

$$4\text{-}BrC_6H_4OH + HS^{\cdot} \xrightarrow[110-125^{\circ}C]{H_2S} 4\text{-}HOC_6H_4SH + HBr + HS^{\cdot}, \quad (40)$$

$$4\text{-}BrC_6H_4OH + 4\text{-}HOC_6H_4SH \rightarrow (4\text{-}HOC_6H_4)_2S + HBr + HS^{\cdot},$$

$$4\text{-}HOC_6H_4Br \rightarrow 4\text{-}HOC_6H_4^{\cdot} + Br^{\cdot},$$

$$4\text{-}HOC_6H_4^{\cdot} + H_2S \rightarrow C_6H_5OH + HS^{\cdot}. \quad (41)$$

The nature of the halogen atom in the molecules of aryl halide influences the rate and direction of the liquid-phase reaction of aryl halides with the S–H_2S system in the same way as it affects the rate of their reaction with gaseous hydrogen sulphide. This confirms that HS$^{\cdot}$ radicals are generated from hydrogen sulphide in the presence of sulphur and react with halogenoarenes via schemes (40) and (41) under mild conditions.

V. Reactions of hydrogen sulphide, thiols, and dialkyl sulphides and polysulphides with halogenoalkenes

At 400–550 °C, hydrogen sulphide condenses with halogenoalkenes. The simplest of these (vinyl chloride) reacts with hydrogen sulphide at 530–560 °C to form ethylenethiol and thiophen. In the presence of an excess of hydrogen sulphide ethylenethiol is the main reaction product (yield 60%), while in the presence of an excess of vinyl chloride mainly thiophen is formed (yield 60–80%):[145]

$$CH_2{=}CHCl + H_2S \rightarrow CH_2{=}CHSH + HCl, \quad (42)$$

$$CH_2{=}CHCl + HSCH{=}CH_2 \xrightarrow{-HCl} \xrightarrow{-H_2} . \quad (43)$$

At the outlet for the gas phase, ethylenethiol is stabilised by being cooled to −70 °C after which it is warmed rapidly and analysed.[146] It trimerises rapidly at room temperature.

Reactions (42) and (43) proceed with participation of thiyl radicals which add to the carbon atom of the double bond of the halogenoalkene linked to the halogen atom. This leads to the *ipso*-substitution of the latter via the following scheme:

$$CH_2{=}CHCl + HS^{\cdot} \rightarrow {}^{\cdot}CH_2{-}CH(Cl)SH \xrightarrow{H_2S} CH_2{=}CHSH + HCl + HS^{\cdot}$$

$$\xrightarrow[-HCl]{} CH_2{=}CHS^{\cdot} \xrightarrow{CH_2=CHCl} \rightarrow \left[\text{Cl-thiophenyl}\right] \xrightarrow[-HCl,\ -H^{\cdot}]{H_2S} \text{thiophen} \quad (44)$$

(A)

(A) $\xrightarrow[-HCl,\ -HS^{\cdot}]{H_2S}$ thiophen $\xrightarrow{-H_2}$ thiophen

The ethylenethiyl radical is generated thermally from the primary product of reaction (44)—ethylenethiol. The radical then initiates the chain thiylation of vinyl chloride. Thiophen can be the product of the cyclisation of the radical-adduct (A) or of divinyl sulphide. Scheme (44) is confirmed by the fact that neither ethylene nor acetylene react with hydrogen sulphide under analogous conditions. This is also confirmed by the pathway followed in the reactions of dichloroethylenes with hydrogen sulphide and its organic derivatives (see below).

In contrast to vinyl chloride, vinyl bromide reacts with hydrogen sulphide at 450–500 °C to form only ethylenethiol (regardless of the reaction conditions[147]) in accordance with scheme (42). This may be due to the inhibiting effect of the hydrogen bromide evolved during the reaction. Being a stronger hydrogen donor than hydrogen sulphide, it reacts rapidly with the ethylenethiyl radical, as a result of which the latter does not participate in the stages of reaction (44) leading to thiophen.

The reactions of dichloroethylene with hydrogen sulphide take place mainly in accordance with schemes (42)–(44). However, under these conditions a mixture of organosulphur compounds is formed, which is due to the secondary reactions of labile intermediates. The interaction of 1,2-dichloroethylene with hydrogen sulphide is illustrated by scheme (45), which explains the formation of all the reaction products detected:[148]

$$ClCH{=}CHCl + H_2S \rightarrow ClCH{=}CHSH + HCl,$$

$$ClCH{=}CHSH + ClCH{=}CHCl \rightarrow ClCH{=}CHSCH{=}CHCl + HCl,$$

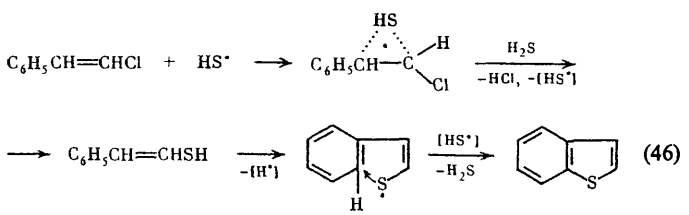
$$2ClCH{=}CHSCH{=}CHCl \rightarrow \text{Cl-thiophenyl} + \text{Cl-thiophenyl} + 2HCl,$$

Cl-thiophenyl + H_2S → SH-thiophenyl + HCl,

SH-thiophenyl + ClCH=CHCl → SCH=CHCl-thiophenyl $\xrightarrow{-HCl}$

→ thiophen + thiophen (45)

An excess of 1,2-dichloroethylene promotes the preferential formation of 2- and 3-chlorothiophens, whose yield reaches 30–35%.

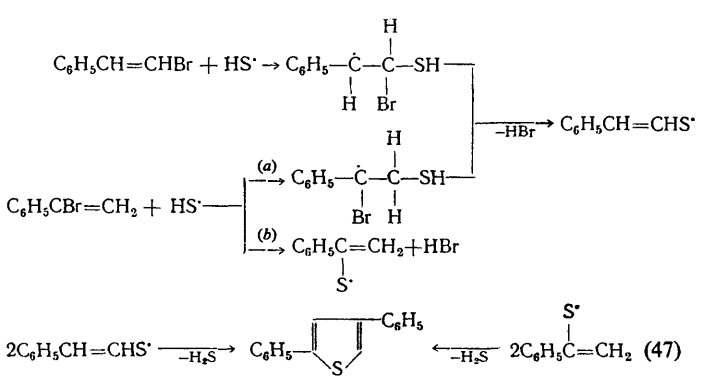


A mixture of 2- and 3-chlorothiophens, thiophen, thiophen-2-thiol, thiophen-3-thiol, thienothiophens, and vinyl sulphides is formed from 1,1-dichloroethylene and hydrogen sulphide at 470–550 °C via schemes analogous to scheme (45).[149] However, the sulphides obtained under these conditions contain a chlorine atom not in the β-position but in the α-position relative to the sulphur atom. This shows that the primary product of the reaction of 1,1-dichloroethylene with hydrogen sulphide is α-chloroethylenethiol, from which the α-chloroethylenethiyl radical, responsible for the formation of all the subsequent reaction products, is generated:

$$CH_2{=}CCl_2 + HS^{\cdot} \rightarrow {}^{\cdot}CH_2CCl(SH)_2 \xrightarrow[-HCl,\ -[HS^{\cdot}]]{H_2S} \xrightarrow{-HCl} CH_2{=}CClSH \rightarrow CH_2{=}CClS^{\cdot}$$

The regiospecificity of the thermal addition of thiyl radicals to halogenoalkenes, namely to the carbon atom linked to the halogen atom, is unambiguously demonstrated in this case.

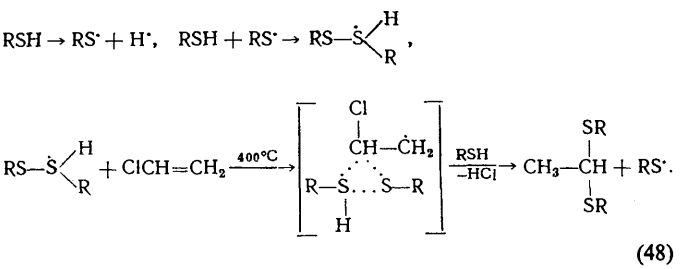
The reaction of trichloroethylene with hydrogen sulphide in the gas phase does not lead to sulphur-containing compounds.[150] The reaction of tetrachloroethylene with hydrogen sulphide at 450 °C leads to tetrachlorothiophen (yield 75%) but it is slower than in the case of other chloroalkenes having polarised double bonds.[151]



Virtually the only product of the reaction of β-chlorostyrene with hydrogen sulphide at 600 °C is benzo[*b*]thiophen (yield 85%). The 2-phenylethylenethiol formed initially readily generates the 2-phenylethylenethiyl radical (stabilised as a result of the π,π-conjugation of the ring and the double bond), which undergoes intramolecular condensation to benzothiophen at a high rate:[152,153]

(46)

Instead of β-chlorostyrene, its gas-phase precursor (αβ-dichloroethylbenzene) can be introduced into reaction (46), and instead of hydrogen sulphide lower alkanethiols can be introduced.



In the liquid phase, boiling β-chlorostyrene does not react with hydrogen sulphide, whereas α- and β-bromostyrenes interact with hydrogen sulphide in the liquid phase even at 150–170 °C, affording mainly 2,4-diphenylthiophen (yield 37%). Apparently in the liquid phase phenylethylenethiyl radicals undergo merely intermolecular condensation, leading to the same product of reaction (47)—2,4-diphenylthiophen[154] (the cage effect and the fairly high concentration of radicals at the instant of formation exert an influence):

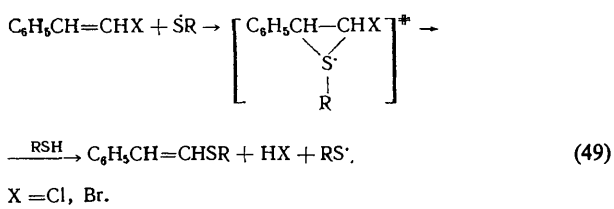
(47)

Benzothiophen is formed in the gas phase in 76% yield from β-bromostyrene and hydrogen sulphide and in 9% yield from α-bromostyrene and hydrogen sulphide. In the latter case, the β-phenylethylenethiyl radicals are formed to some extent, but this direction of attack by the thiyl radical HS˙ on the halogenoalkene molecule takes place to an insignificant degree [scheme (47), pathway (*b*) is preferred to pathway (*a*)] even when a radical-adduct of the benzyl type is formed.

Organic derivatives of hydrogen sulphide (thiols, dialkyl sulphides, and dialkyl disulphides) react with halogenoalkenes both in the gas phase and in the liquid phase. The products of their reactions with vinyl chloride at 400 °C are 1,1-di(alkylthio)ethanes (yield 10–33%), formed as a result of the preliminary thermal condensation of alkanethiyl radicals with the initial sulphide reagent via scheme (48):[155]

(48)

Alkyl vinyl sulphides are not intermediates in the formation of dithioacetals under these conditions, since the thermal addition of alkanethiols to them under analogous conditions leads to the usual anti-Markovnikov adducts. On the other hand, the conversion of 1,2-di(alkylthio)ethanes to the isomeric dithioacetals is also not observed under these conditions:



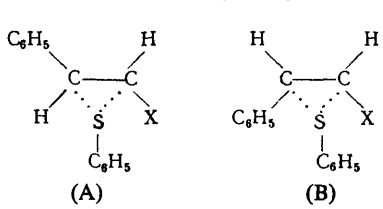
$$RSH + CH_2{=}CHSR \rightarrow RSCH_2{-}CH_2SR.$$

The gas-phase reactions of vinyl chloride with aromatic thiols and thiophen-2-thiol lead to the corresponding aryl vinyl sulphides or 2-thienyl vinyl sulphide respectively. The selective occurrence of this reaction is promoted by a large excess of the chloro-derivative:[156]

$$RSH + ClCH{=}CH_2 \xrightarrow{350\text{–}450\,^\circ C} \underset{60\text{–}90\%}{RS{-}CH{=}CH_2} + HCl,$$

$R = C_6H_5$, 4-$CH_3C_6H_4$, 3-$CH_3C_6H_4$, 1-$C_{10}H_7$, 2-C_4H_3S.

Aromatic thiols and thiophen-2-thiol react with β-chloro- and β-bromostyrenes in the liquid phase even at 80–160 °C with formation of 1-phenyl-2-arylthio- or 1-phenyl-2-thienylthio-ethylenes respectively (yield 70–95%):[157]

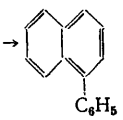


(49)

X = Cl, Br.

Reaction (49) begins already at 80 °C and proceeds efficiently at 140–160 °C.

At 80–100°, only the *trans*-isomer of the β-halogenostyrene enters into reaction (49), whilst at 140–160 °C both isomers react. The process takes place rigorously stereospecifically, which is apparently due to the stabilisation of the radical-adduct with participation of the β-phenylthio-group. The transition state (A), which is sterically less strained than the state (B), is then formed from the *trans*-isomer of the β-halogenostyrene:



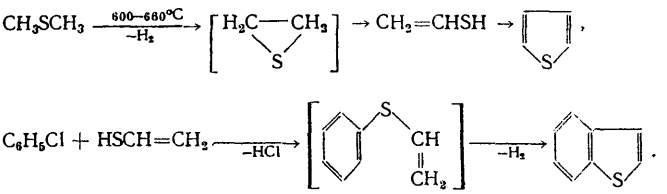
(50)

Thiophenthiol reacts with β-bromostyrene more slowly than with β-chlorostyrene owing to the inhibiting effect of hydrogen bromide, which functions as a trapping agent for thiyl radicals and initiates

the decomposition via scheme (51) of the sulphide formed:

$$C_6H_5S^{\cdot} + HBr \rightleftarrows C_6H_5SH + Br^{\cdot},$$

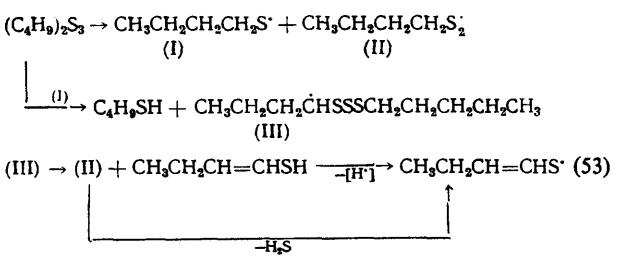
$$2C_6H_5CH{=}CHSC_6H_5 + 2Br^{\cdot} \rightarrow \left[2C_6H_5\dot{C}H{-}\underset{\displaystyle Br}{\underset{|}{C}}HSC_6H_5\right] \rightarrow$$



$$+2C_6H_5SH + 2HBr. \qquad (51)$$

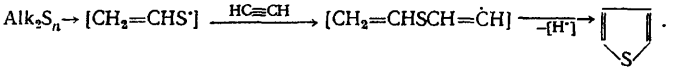
In particular, 1-phenyl-2-naphthylthioethylene and 1-phenyl-2-thienylthioethylene have been obtained via scheme (51).

VI. Thermal synthesis of thiophen and its derivatives and analogues



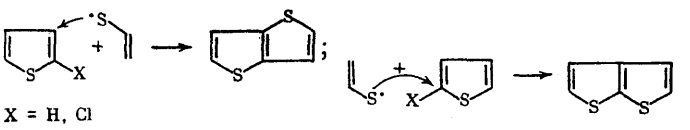
The study of the thermal reactions of thiyl radicals generated from different types of organic sulphur compounds has made it possible to develop a wide variety of methods of synthesis of thiophen, benzothiophen, dibenzothiophen, thianthrene, thioxanthene, and other sulphur-containing heterocycles. They are all based on thermal cyclisations and condensations of different types of αβ-unsaturated thiyl radicals.[158] Some of these methods have already been mentioned (see Section III above).

Thiophens are the products of the thermolysis of dialkyl sulphides, which decompose in accordance with a unique mechanism which includes a stage involving the generation of ethylenethiol. The ethylenethiyl radical formed from the latter undergoes intermolecular condensation to a thiophen, for example, in accordance with the following scheme:[159,160]



(52)

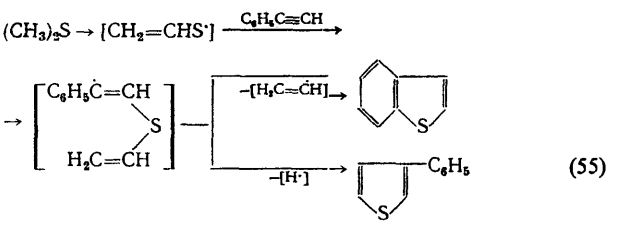
Thiophen is also formed in the pyrolysis of vinyl sulphides and dialkyl polysulphides.[161,162] The dibutyl polysulphides $(C_5H_9)_2S_n$ are thermolysed to thiophen most selectively under these conditions:[162]



For n = 3, the maximum yield of thiophen reaches 43% at 500–520 °C. According to scheme (53), the trisulphide molecule is in fact the richest source of butenethiyl radicals, which subsequently cyclise to thiophen.[161]

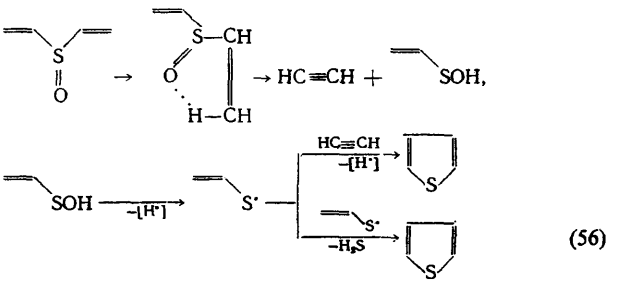
Acetylene is an effective trapping agent for ethylenethiyl radicals. Its cothermolysis with low-molecular-weight dialkyl polysulphides at 470–520 °C leads to thiophen (yield up to 62%):[169]

Two isomeric thienothiophens are then formed together with thiophen, apparently as a result of the interaction of the ethylenethiyl radical with the thiophen ring (in proportions of 1 : 1):



X = H, Cl

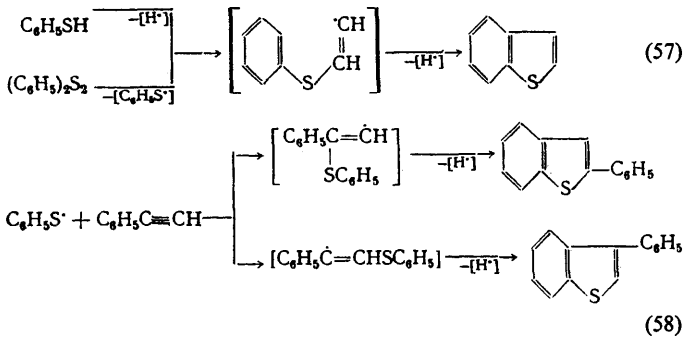
(54)



The cothermolysis of 2-chlorothiophen with a mixture of diethyl polysulphides also results in the formation, in accordance with scheme (54), of isomeric thienothiophens, but the [2,3-*b*]-isomer predominates in it.[164] This confirms the preferential attack by the thiyl radical on the sp^2-hybridised carbon atom linked to the halogen atom.

The cothermolysis of phenylacetylene with dimethyl sulphide at 450–500 °C leads to 3-phenylthiophen and benzo[*b*]thiophen in accordance with the following scheme:[165]

(55)



The main product of the gas-phase thermolysis of divinyl sulphoxide is thiophen, whose maximum yield (60%) is attained at 400 °C.[166] The mechanism of reaction (56) includes a stage in which ethylenethiyl radicals are generated:

(56)

Thiophenol reacts with acetylene at 550–590 °C, while diphenyl disulphide reacts at 500 °C with selective formation of benzo[*b*]thiophen. The products of the reaction of phenylacetylene with diphenyl disulphide are 2- and 3-phenylbenzo[*b*]thiophen (in proportions of 1 : 1.5). The mechanisms of reactions (57) and (58) include stages in which benzenethiyl radicals are generated and

add to multiple bonds:[167]

(57)

(58)

VII. Conclusion

The study of the thermal generation and reactivity of thiyl radicals established the following features:

1. The radicals HS$^{\cdot}$, $CH_2{=}CHS^{\cdot}$, and ArS$^{\cdot}$, generated from hydrogen sulphide and its organic derivatives, readily enter into reactions involving the *ipso*-substitution of the halogen atom linked to the sp^2-hybridised carbon atom.

2. Alkanethiyl radicals are incapable of such reactions. However, they undergo thermal condensation with alkanethiols, dialkyl sulphides, and dialkyl disulphides with formation of the corresponding sulphuranyl radicals $R\dot{S}_nR_2$. The latter are trapped in the gas phase by halogenoalkanes with formation dithioacetals.

3. Ethylenethiyl radicals undergo intramolecular or intermolecular cyclisation in the gas phase to heterocyclic compounds of the thiophen and benzothiophen series.

4. Acetylene and phenylacetylene are effective trapping agents for thiyl radicals. The sulphydryl radicals HS$^{\cdot}$ do not react with alkynes, alkenes, and arenes in the gas phase, but readily add to the multiple bonds of halogenoalkenes and halogenoarenes.

The observed features of the thermal reactions of thiyl radicals with organic compounds are important for the elucidation of the mechanism of the formation of sulphur-containing components of petroleums, coal, shale, and natural gas and also the products of their heat treatment.

Numerous methods for the synthesis of a wide variety of organic sulphur compounds have been developed on the basis of the reactions of thiyl radicals investigated. Many of them can be achieved on an industrial scale using readily available intermediates and sulphur-containing waste of the petrochemical, coal-chemical, chemical gas, and cellulose-paper industries.

Polymer photostabilisers. Photophysical properties and stabilising efficiency

V G Plotnikov, A A Efimov
Branch of Karpov Physicochemical Institute, Obninsk
"Khimpolimer" Research Institute, Tambov

ABSTRACT. The photophysical characteristics and luminescence-spectroscopic properties of molecules with a high photostabilising efficiency are examined. It is shown theoretically that the short lifetime and (or) low population of the triplet state of the molecule are essential (but not sufficient) conditions for its use as a photostabiliser. Both these conditions or one of them are fulfilled when systems in which non-radiative conversion processes, initiated by adiabatic reversible photochemical processes or systems with heavy atoms, are used. Experimental data confirming these postulates are presented.

The bibliography includes 218 references.

I. Introduction

The problem of increasing the photostability of polymeric materials has not lost its interest over a long period of time despite the advances achieved both in the understanding of the scientific principles of the problem and in the practical application of the results.[1–4] The reason for this is the expansion of the range of polymeric materials and their applications together with increasing requirements for their photostability, including photostability under extreme conditions.

One of the most common and promising ways of solving the problem involves the use of special additives which are introduced into polymers and polymer compositions to increase their photostability. In terms of the mechanism of their protecting action, the additives can be divided (albeit not entirely unambiguously) into two types: compounds whose action has a chemical mechanism and systems whose stabilising effect is manifested already in the initial, physical stage of the polymer phototransformation process.

The role of compounds with a chemical stabilisation mechanism involves chemical reactions of their molecules with the products of the photolysis of polymers (usually radicals) and convert the latter into an inactive state, interrupting the chain of transformations. Such compounds can be used to protect not only against the action of light but also against other factors which induce the appearance of radical polymer degradation processes (oxidation, the action of heat, mechanical stress, ionising radiation, etc.). Compounds of this type include antioxidants and thermostabilisers.

Compounds with the physical photostabilisation mechanism prevent the occurrence of the primary stage of the photolysis of polymer or impurity molecules. These compounds are intrinsic photostabilisers and in employing this term below we shall have only them in mind.

The significant advances achieved during the last decades in the creation of antioxidants and associated to a large extent with the development and introduction of a new class of stabilisers — sterically hindered amines (SHA)[3,4]—have not reduced the interest in the study and practical employment of photostabilisers. This has arisen for a number of reasons.

Photostabilisers include compounds of different classes with a broad range of protecting properties and which absorb the energy of the light radiation in different spectral regions. In contrast to the sterically hindered amines, photostabilisers have more universal applications: they can be used both for carbochain and for different kinds of heterochain polymers which undergo a short chain of photochemical transformations — in filled, dyed, and incombustible polymers. Sterically hindered amines and other compounds with a chemical stabilisation mechanism have a limited period of activity, because they are consumed after a time. The mechanism of the action of photostabilisers in the absence of side processes does not involve their consumption and can ensure a long operating life of the polymer. Photostabilisers are able to manifest a synergistic effect in mixtures with stabilisers whose action has a chemical mechanism, which makes it possible to increase the lifetime of polymeric materials and to reduce the concentration of additives.

It is noteworthy that the requirements imposed on the molecular and electronic structures of effective photostabilisers are the same or are similar to the requirements which must be satisfied by intrinsically photostable polymers (see Section IV). The development of ideas about the mechanism of the action and causes of the high efficiency of photostabilisers has thus promoted the elucidation of ways of creating photostable polymer molecules. The study of the physical stages in the stabilisation process is important also for antioxidant molecules, because on formation of complexes with electronically excited molecules (for example, with the O_2 molecule[5,6]) many of them induce their quenching. All the foregoing discussion demonstrates the current interest of the study of the mechanism of the action of photostabilisers and of the principles of their selection.

Two physical processes underlie the action of photostabilisers: the process involving the absorption of light by the stabiliser which shields the polymer molecule against the action of incident photons and the transfer of energy from the electronically excited polymer molecules to the stabiliser molecules with their subsequent deactivation. Systems in which the former process occurs preferentially are called absorbers (UV absorbers), while systems of the latter type are called quenching agents. The determination of the leading mechanism of the stabilisation process is important for the selection of the stabiliser. UV absorber photostabilisers should evidently absorb the light which photolyses the polymer molecules. The essential condition for the effective action of quenching agent molecules is the overlap of the luminescence spectrum of the polymer and of the absorption spectrum of the stabiliser.[1,2,7–12]

However, by no means all molecules satisfying these requirements can be effective photostabilisers. Furthermore, these conditions can be satisfied also by molecules of photosensitisers of the decomposition of polymers. The molecule of the effective photostabiliser should possess also a definite set of photophysical properties. Theoretical analysis of this problem is the subject of the present review. Clearly, with this formulation of the problem one can elucidate only the necessary but not sufficient conditions for the application of a molecule as a stabiliser, because the latter conditions include also a large number of parameters (compatibility with the polymer, molecular mobility, etc.).[1,2]

II. Photophysical processes in polyatomic molecules

The transformations of electronically excited molecular systems can occur with emission of photons (radiative transitions) or via a non-radiative pathway. The non-radiative routes to the decomposition of electronic states include non-radiative conversion processes in which the electronic excitation energy is converted into the vibration energy of the system without chemical transformations of the latter, autoionisation processes, electronic energy transfer and migration processes. All the processes enumerated are in the nature of physical processes involving the transformation of the electronic excitation energy and are referred to as photophysical. Apart from the photophysical routes to the transformation of molecular systems, there is also a possibility of photochemical routes, which lead to the formation of new chemical products. Photochemical processes are non-radiative.

The subdivision of the non-radiative pathways in the transformation of the electronically excited molecules into photophysical and photochemical is not always possible. In particular, it fails in molecules of many effective photostabilisers. Nevertheless, such subdivision must be used as the initial step in these cases too.

Very many studies[13–15] have been made on the characteristic features of photophysical processes in photostable molecules and on the development of their theory. Here we shall discuss briefly only the results which will be useful in the subsequent exposition.

Electronically excited molecular states can be classified[16] in terms of their multiplicity and orbital nature. The majority of molecules have a singlet ground state (S_0). In aromatic and heteroaromatic molecules the lowest excited singlet state is the $S_{\pi\pi^*}$ or $S_{n\pi^*}$ state. Triplet (T) states can also be of the $\pi\pi^*$ or $n\pi^*$ type. The lowest excited state of the molecules is a T state. There is a possibility of five types of relative dispositions of the singlet and triplet $\pi\pi^*$ and $n\pi^*$ states.[15,17]

The characteristic value of the rate constant for the radiative decomposition of $S_{\pi\pi^*}$ states (k_r^S) is $\sim 10^8-10^9$ s^{-1}, while that for the decomposition of the $S_{n\pi^*}$ state is $\sim 10^5-10^6$ s^{-1}. Since the $T-S$ transitions are forbidden as regards multiplicity, the rate constants k_r^T for the radiative decomposition of the T state are much smaller. In molecules without heavy atoms, k_r^T is $10^{-1}-10^2$ s^{-1} for $T_{\pi\pi^*}$ states and 10^3-10^4 s^{-1} for $T_{n\pi^*}$ states. The introduction of heavy atoms into the molecule leads to a significant (by several orders of magnitude) diminution of the lifetime of the T states. The above features are determined by the characteristics of the spin–orbital interaction in the molecule.[15,18–22]

There are three types of non-radiative conversion processes: internal conversion processes, which take place between states with the same multiplicity ($S-S$ or $T-T$), singlet–triplet ($S-T$) conversion processes, and triplet–singlet ($T-S$) conversion processes. We shall examine the characteristic rate constants for these processes.

The rate constants for internal conversion (k_{ic}) processes between excited states are very large ($\gtrsim 10^{11}$ s^{-1}). As a result of this, polyatomic molecules are seen to emit a luminescence with a high yield only from the lowest excited state of the given multiplicity (Kasha's rule[23]). On the other hand, it has been established for a large number of molecules that internal conversion S_1-S_0 processes make a small contribution to the decomposition of the lowest excited state,[24] i.e. that the constant k_{ic} for the S_1-S_0 conversion process is smaller than the constant k_r^S for the radiative decomposition of the S_1 states and the rate constant for the $S-T$ conversion (k_{ST}).

Theoretical study showed[25] that the above features of the internal conversion process are a consequence of the marked dependence of k_{ic} on the transition energy E_{if}. The dependence of k_{ic} on E_{if} is described approximately by the exponential law $\exp(-\alpha E_{if})$ with the parameter $\alpha \simeq 4-5$ eV^{-1}. For low values of $E_{if} \lesssim 1$ eV, the constant k_{ic} is $\gtrsim 10^{11}$ s^{-1} and exceeds the values of k_r^S and k_{ST}. Such values of E_{if} are characteristic of transitions between electronically excited states. For $E_{if} \gtrsim 2.5$ eV, the constant k_{ic} becomes smaller than k_r^S and k_{ST}. For a large number of polyatomic molecules, the energy difference between the S_1 and S_0 states satisfies this requirement and the internal conversion process is therefore unimportant in the degradation of the S_1 state. If the energy of the lowest excited state lies in the range 1.5–2.5 eV, the quantity k_{ic} is comparable to k_r^S and k_{ST} and in such molecules the S_1-S_0 internal conversion process may make an appreciable contribution. Experimental data confirming the foregoing can be found in a number of publications.[14,15,25–27]

The rate constant for the $S-T$ conversion between states of different nature ($\pi\pi^*$ and $n\pi^*$) reaches $\sim 10^{10}-10^{11}$ s^{-1} and the $S-T$ conversion process suppresses the fluorescence process.[15,21,22] The constant k_{ST} for the conversion between states of the same orbital nature is significantly lower and amounts to 10^6-10^9 s^{-1}. The $S-T$ conversion and fluorescence processes can compete in this instance.

The five types of relative positions of states of different orbital nature and with different multiplicities, mentioned above, and the characteristic features of the spin–orbital interaction and $S-T$ conversion processes serve as the basis of the luminescence-spectroscopic systematic treatment of molecules.[15,17]

Numerous studies have been devoted to the characteristics of $T-S$ conversion processes.[28–32] Of the general results, we shall mention here the energy gap law, in conformity with which the constants k_{TS} and k_{ic} diminish approximately exponentially with increase in the energy of the T state; here too the quantity α

amounts to approximately $4-5$ eV^{-1}. For many molecules in solid solutions, the constant k_{TS} is comparable to the rate constant for the radiative decomposition of the corresponding triplet state. (In liquid solutions this is not the case because different bimolecular processes involving the quenching of T states assume a significant role and the lifetime of such states falls sharply[33]).

In concluding this Section, it is important for our purpose to emphasise that the non-radiative degradation of the electronic excitation energy in the majority of photostable molecules takes place with a significant population of the triplet states, whose lifetimes are relatively long.

III. Initiation of non-radiative conversion processes by adiabatic photochemical reactions

Photochemical reactions are known to be capable of occurring via non-adiabatic or adiabatic mechanisms. The non-adiabatic reactions are similar to non-radiative conversion processes and reduce to a non-adiabatic transition between electronic states, one of which (the final state) is the state of the reaction products (for example, a predissociative state). In this case, the duration of the transition between the states is appreciably smaller than the reciprocal of the transition rate constant (i.e. the transition expectation time). The evolution of the system is therefore described with the aid of the usual kinetic scheme consisting of a series of independent competing processes, each of which is characterised by the corresponding rate constant.

Adiabatic photochemical reactions proceed without change in the electronic state of the system. They are usually described by the equation for the motion of the system on one potential surface from the minimum (region) for the initial system to the minimum (region) for the reaction products. The duration of the transition is in this case comparable to the reciprocal of the photoreaction rate constant. When an adiabatic photochemical reaction takes place, the probabilities of all the photophysical processes begin to depend on the reaction coordinate (x) and the usual kinetic treatment of the evolution of the system becomes inapplicable†. The dependence of the rate constants for the conversion processes on x becomes particularly significant.

We shall consider the possible cases where this dependence can be manifested most strongly. To make the system concrete, we shall have in mind initially S_1-S_0 internal conversion processes.[34]

The possibility of the occurrence of a photochemical reaction in the S_1 state during a period shorter than $\sim 10^{-8}$ s implies that the potential surface for this state either has no maximum, separating the initial state from the state of the reaction products, or that the maximum is small. In contrast to the S_1 state, in the S_0 state, the system is stable and the $U_0(x)$ potential surface has a deep minimum for certain equilibrium values of x. This minimum is separated by a high ($\gtrsim 1$ eV) potential barrier from the state of the reaction products in the electronic ground state. The form of the potential curves is illustrated schematically in Fig. 1*a* (continuous curves).

It is possible to distinguish another type of potential surface (Fig. 1*b*). If the reaction is impossible in the S_0 state, then that surface corresponds to repulsion. The possibility of the occurrence of the reaction in the excited state implies that the function $U_1(x)$ has a minimum corresponding to the reaction product. Isomerisation reactions (especially *cis–trans* isomerisation reactions), reactions), proton or hydrogen atom transfer reactions, etc. belong to the first type, while reactions involving the formation of excimers (an excited complex of two identical molecules) or exciplexes (an excited complex of different molecules) belong to the second type.

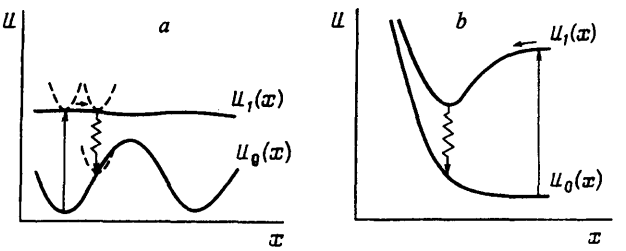

Figure 1. Schematic illustration of the potential surfaces for the isomerisation (*a*) and complex formation (*b*) reactions; the horizontal arrows indicate the movement of the system along the reaction coordinate.[34]

In the case of a condensed phase, subject to the condition that the vibrational relaxation rate constant exceeds the rate constants for all the remaining processes, the movement of the system along the reaction coordinate can be represented by a series of successive transitions through a series of quasi-equilibrium states. Their quasi-equilibrium is determined by the effect of the solvent on the molecular system—the finite orientational and translational relaxation time of the solvent (Fig. 1*a*, dashed curves). According to the theory of the condensed state put forward by Frenkel',[35] the lifetime of the system in each quasi-equilibrium state (the period between the jumps executed by solvent molecules from one state to another) exceeds $\sim 10^{-11}$ s and is much greater than the vibration period of the atoms in the system. The conversion process should therefore be regarded as one occurring between states of the system corresponding to the potential curves shown by dashed lines in Fig. 1*a*. This constitutes the difference between the mechanism of the conversion process occurring in the course of an adiabatic reaction and the mechanism of conversion in photostable systems, where the process takes place between two potential surfaces. The rate of the adiabatic photoreaction and its influence on photophysical processes and hence on the luminescence properties of the system depend on the characteristics of the medium (viscosity, intermolecular interaction, etc.).[36]

The significant decrease in the energy gap between the $U_0(x)$ and $U_1(x)$ potential curves leads to an increase in k_{ic}, which is greater the smaller the minimum difference $U_1(x)-U_0(x)$. Specific estimates can be made for certain reactions.

One of the widely occurring photoreactions with an adiabatic stage is the *cis–trans* isomerisation reaction, which can occur in the S_1 state of molecules having isolated or conjugated double bonds

† It is useful to note the analogy between this situation and the energy transfer process between diffusing molecules where the transfer rate constant depends on the distance between the moving molecules.

(stilbene and its derivatives, carbocyanine dyes, etc.).[36,37] In this case, the angle of rotation of the fragment about the double bond serves as the reaction coordinate. The activation energy $U°$ for this reaction in the S_0 state is 1–2 eV.[37] Neglecting the difference between the *cis*- and *trans*-isomers (1–3 kcal), the potential surface of the ground state can be described by the equation:

$$U_0(x) = \frac{U^0}{2}(1 - \cos 2x). \quad (1)$$

The $U_1(x)$ relation is known only for certain systems.[38] For our purposes, it is important to know only that the function $U_1(x)$ varies within narrow limits (~0.2 eV) and that the variation of the S_1-S_0 transition energy can be described satisfactorily by the expression:

$$E_{if} = E_{if}^0 - \frac{U^0}{2}(1 - \cos 2x), \quad (2)$$

where E_{if}^0 is the transition energy at $x = 0$. Using Eqn. (1) and (2) and the expressions for the rate constants k_{ic},[25] the $k_{ic}(x)$ relation has been calculated. The results are presented in Fig. 2. It follows from the data in this figure that k_{ic} increases with x to a greater extent the greater the parameter $U°$. The increase in k_{ic} becomes appreciable (by about two orders of magnitude) already in the initial stage of the reaction, where the angle of rotation of the fragment is ~45°. At $x = \pi/2$, k_{ic} reaches a maximum and diminishes on further increase in x.

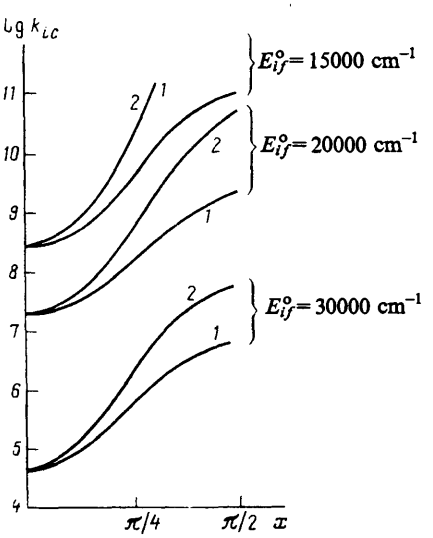

Figure 2. Dependence of k_{ic} on x for *cis–trans* isomerisation reactions with $U° = 8000$ cm^{-1} (curves *1*) and $U° = 12000$ cm^{-1} (curves *2*).[34]

If k_{ic} at $x = 0$ amounts to 10^6 s^{-1} ($E_{if}^0 \simeq 25000$ cm^{-1}), whereupon it is possible to neglect the contribution of the S_1-S_0 internal conversion process under conditions ruling out a photoreaction, then when a photoreaction occurs there is a possibility of the quenching of the fluorescence and the suppression of the $S-T$ conversion process. This effect is even more important for smaller values of E_{if}^0, whereupon the constant k_{ic} becomes $10^{10}-10^{11}$ s^{-1} during the photoreaction, which can lead to the suppression not only of the fluorescence and the $S-T$ conversion but also of the photoreaction itself. This conclusion has been confirmed experimentally[39,40] (see below).

As can be seen from Fig. 1*b*, in the case of complex formation reactions the maximum value of k_{ic} is attained at the minimum on the $U_1(x)$ curve. When excimers are formed, the decrease in the transition energy at this point reaches 5000–6000 cm^{-1}.[33] This change in the transition energy leads to a significant suppression of the fluorescence if E_{if}^0 for the isolated molecule does not exceed ~25000 cm^{-1}. It has been noted[34] that the mechanism of the initiation of the internal conversion process by the excimer formation reaction is the cause of the phenomenon of the concentration-induced quenching of the luminescence.

The initiation of the internal conversion process has been observed for proton transfer reactions.[40] For these reactions (as for any processes with a redistribution of the charge), processes involving the reorganisation (repolarisation) of the medium play a significant role. For such systems, we therefore find that, firstly, the influence of the polarity of the medium on the probability of the process is significant and, secondly, that there are difficulties in an unambiguous determination of the reaction coordinate. However, the general claim that the potential surfaces of the ground and excited states must approach one another for the initiation of the conversion process remains in force. This conclusion is consistent with experimental data, because the quenching of the S_1 states is most effective in systems where the proton acceptor is a weak base in the S_0 state, i.e. when the activation energy for the H^+ transfer process in this state is high.[40]

All that has been said above about the initiation of the internal conversion processes by adiabatic photoreactions refers directly also to the $S-T$ and $T-S$ conversion processes,[41,42] because the rate constants for the latter also increase with decrease in the energy gap. Furthermore, the change in the spin–orbital interaction (β_{s0}) as x varies is also significant for these processes. The increase in β_{s0} can be observed during reactions where fragments of the system are displaced from the plane[15] and on formation of complexes with a non-planar structure or complexes with molecules containing heavy atoms.[16] There is yet another cause of the initiation of the $S-T$ conversion process by a photoreaction: the change in the relative positions of the $\pi\pi^*$ and $n\pi^*$ states of different multiplicity during photoreactions.[41] Since the terms of the S and T states are usually of a similar form, the initiation of the $S-T$ conversion as a consequence of the change in the energy gap alone is relatively weak. In the case of the $T-S$ conversion, the occurrence of the latter is significantly reflected in the phosphorescence yield, because $k_r^T \simeq k_{TS}$ even in photostable systems.

The equation for the probability of finding the system at time t in the initial electronic state at the point x on the reaction coordinate is fairly simple and at the same time makes it possible to analyse the behaviour of the system. It assumes the form:[42,43]

$$\frac{\partial W_S}{\partial t} = D\frac{\partial^2 W_S}{\partial x^2} - v\frac{\partial W_S}{\partial x} - [k_r^S + k_{ic}(x)]\,W_S. \quad (3)$$

This follows from the more general Focker–Planck equation. Eqn. (3) has been formulated for the initiation of the S_1-S_0 internal conversion process. The parameter D characterises the diffusional movement of the system along the S_1 surface and v is the velocity of the system along the reaction coordinate under the influence of the force determined by the dependence of the S_1 term value on x, which

is assumed in this instance to be linear. It has been suggested that the rate constant for the radiative decomposition of the S_1 state is independent of x and $S-T$ conversion processes may be neglected. [For an unchanged value of k_{ST}, Eqn. (3) retains its form, but k_r^S should be understood as the sum of the rate constants for the radiative decomposition of the S_1 state and for decomposition as a consequence of the $S-T$ conversion.]

We shall consider certain special cases. Suppose that $D = 0$ and that the system is in the initial instant at the point $x = 0$ [$W_S(x, 0) = \delta(x)$] and begins to move in the positive direction of the x axis along the sloping term of the S_1 state. After the attainment of the point $x = L$, the photoreaction is assumed to be completed (at this point the potential energy increases sharply). The rate of movement of the system along the S_1 term is linked to the reaction time by the relation $\tau_R = Lv^{-1} = k_R^{-1}$. The population of the S_1 state

$$W_S(t) = \int_0^L W_S(x, t)\,dx \quad \text{at} \quad t \leqslant \tau_R ,$$

is given by the expression:

$$W_S(t) = \exp[-k_r^S t - v^{-1}k_{ic}(vt)],$$

where

$$k_{ic}(x) = \int_0^x k_{ic}(x')\,dx'.$$

The law governing the decomposition of the S_1 state is not exponential. For $t > \tau_R$, the system is in the S_1 state of the photoproduct and its further evolution is described by the usual law: $Q_R^S exp\text{-}\{[k_{ic}(L) + k_r^S]t\}$, where Q_R^S is the yield of the photoproduct in the S_1 state and $k_{ic}(L)$ is the constant for the internal conversion of this state. If during the movement along the S_1 term the energy diminishes by an amount ΔE, then the dependence of k_{ic} on x can be represented in the form $k_{ic}(x) = k_{ic}^\circ \exp(\alpha \Delta E x L^{-1})$, where k_{ic}° is the conversion constant in the initial system (for $x = 0$) and α is a coefficient in the exponential dependence of k_{ic} on the transition energy (see Section II).

The quantum yields of the fluorescence (Q_r), internal conversion (Q_{ic}), and the photoproduct (Q_R^S) are given by the expressions

$$Q_r = e^a b^b [\Gamma(-b, a) - \Gamma(-b, ae^A)],$$
$$Q_{ic} = e^a a^b [\Gamma(1-b, a) - \Gamma(1-b, ae^A)],$$
$$Q_R^S = 1 - Q_r - Q_{ic}, \qquad (4)$$

where $a = k_{ic}^\circ Z^{-1}$, $b = k_r^S Z^{-1}$, $Z = Ak_R$, $A = \alpha\Delta E$, and $\Gamma(x,y)$ is an incomplete gamma-function. The radiation and photoproduct conversion quantum yields are calculated from the usual expressions with $k_{ic} = k_{ic}^\circ \exp(\alpha \Delta E)$.

Fig. 3 presents the dependence of Q_r, Q_{ic}, and Q_R^S on the parameter A. Evidently in the range of values of A where $k_{ic}(x)$ exceeds k_r^S and k_R (for $A \geqslant 5$ or $\Delta E \gtrsim 1$ eV), the internal conversion suppresses not only the fluorescence process but also the very photoreaction which has accelerated the internal conversion.

Fig. 4 presents the dependence of Q_{ic} on D for the case where the energy of the S term is independent of x, $v = 0$, and the movement of the system along the term is diffusional in character. The initial condition has the same form as above, while $k_{ic}(x)$ is given by the expression $k_{ic}(x) = k_{ic}\exp(c \sin^2 x)$, which corresponds to Eqn. (1) for the energy of the S_0 term. The boundary condition $(\partial W_S/\partial x)_{x=\pm\pi/2} = 0$ models the situation where the photochemical reaction cannot be completed as a consquence of steric hindrance [the function $U_1(x)$ at these points becomes infinite]. The boundary condition $[W_S(x,t)]_{x=\pm\pi/2} = 0$ describes the situation where the system undergoes instantaneous photochemical decomposition after the attainment of the boundaries. (One can then introduce the reaction rate constant $k_R \simeq D$.[42]) The value of the parameter $c = \ln 10^3$ employed corresponds to the value of U° in Eqn. (2), which is $\sim$1.5 eV. Evidently even when the reaction can occur under conditions such that it cannot reach completion, the internal conversion process is rapidly accelerated, which can lead to the suppression of both fluorescence and the photoreaction itself.

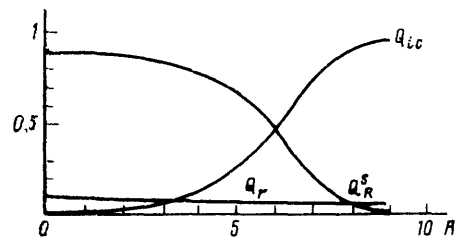

Figure 3. Dependence of Q_r, Q_{ic}, and Q_R^S on the parameter $A = \alpha\Delta E$; $k_r^S = 1$, $k_{ic}^\circ = 1$, $k_R = 10$.

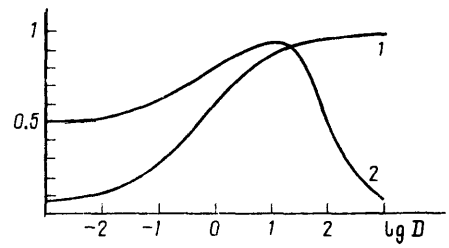

Figure 4. Dependence of Q_{ic} on D for a system with a *cis–trans* isomerisation reaction: *1*, boundary condition $(\partial W_S/\partial x)_{x=\pm\pi/2} = 0$, $k_r^S = 1$, $k_{ic}^\circ = 0.1$; *2*, boundary condition $[W_S(x,t)]_{x=\pm\pi/2} = 0$, $k_r^S = 1$, $k_{ic}^\circ = 1$.

Two main conclusions follow from the foregoing. (1) A significant initiation of the internal conversion process is observed when the minimum energy gap between the S_1 and S_0 terms does not exceed 2–2.5 eV. (2) Provided that $k_{ic}(x) \gg k_R$, $k_{ic}(x) \gg k_R^s$ for $0 < x < L$, and $k_r^S \simeq k_R$, when the first condition is fulfilled the internal conversion process leads not only to the quenching of the fluorescence but also to the suppression of the photoreaction. In the range of values $k_R \gg k_r^S$ and $k_{ic}(x) \ll k_R$, the evolution of the excited state is determined by the ratio of the quantities k_r^S and k_{ic} for the photoproduct. The latter conclusion holds also for other types of conversion.[42]

It was suggested above that the rate constant for the vibrational relaxation significantly exceeds the rate constants for other processes involved in the evolution of the system and that the movement of

the system along the reaction coordinate is limited by the relaxation of the solvent. In certain cases, this condition may break down. Thus, in the concluding stage of the reaction involving the formation of excimers or exciplexes, where there are no solvent molecules between the reacting molecules, the mutual approach of the reactants is not limited by the relaxation of the solvent. In this situation, there is a possibility of the formation of the reaction product in a highly excited vibrational state, as happens in the gas phase. A similar situation can occur also for other reactions.

This case has been analysed in detail.[44] It has been shown that the internal conversion process can compete with the vibrational relaxation process, provided that the terms of the ground and S_1 states intersect in the region of the energies of the vibrational states of the reaction product. The conversion process can occur with an appreciable probability even from states of the continuous spectrum of the collision complex, provided that the point of intersection of the surfaces is located in the classically accessible region or in its vicinity. For H atom and H^+ transfer reactions, the probability of the conversion process is high also in the sub-barrier region.

The position of the point of intersection of the terms for the excimer formation processes is determined by the oscillator strength f of the S_1-S_0 transition. It has been shown[44] that the quenching of the excimers from vibrationally excited states is possible if $f \gtrsim 0.5$, which is characteristic of many dye molecules which undergo concentration-induced quenching of their luminescence. For exciplexes with a significant charge transfer contribution, such a situation is more probable the higher the electron affinity of one of the reactants and the lower the ionisation potential of the other. The latter makes it possible to understand the characteristic features of the quenching of singlet oxygen by electron donors, in particular the observed increase in the quenching constant with decrease in the ionisation potential of the quenching agent.[5,6]

In concluding this Section, we may note that, in the case of systems with sensitised conversion processes, on the one hand, there is a significant decrease in the lifetime of the excited states and, on the other, the pathway leading to the degradation of the energy changes: as a consequence of the acceleration of the internal conversion process, the degradation of the excitation energy takes place without the triplet states being populated or with a significant decrease in their population.

IV. Photophysical properties of effective photostabilisers

Using the results described above, here we shall discuss the question which photophysical properties effective photostabilisers should possess in addition to the requirements specified in the Introduction.[1,2,7–12] It is not difficult to satisfy the requirements set out above using π-electron and especially aromatic (heteroaromatic) molecules. However, this is not sufficient.[45]

Indeed the photostabiliser molecule in an excited state can itself undergo irreversible phototransformations. It would appear that, in order to eliminate this undesirable effect, it should be sufficient to employ molecules exhibiting photostability in the lowest S and T states, which has been observed for a large number of π-electron molecules. However, it is important to take into account the following factor. The molecule in the lowest relatively long-lived T state can absorb a second light quantum and undergo a transition to highly excited T states.[46] In these states, all molecules without exception are reactive,[46,47] decomposing into fragments or ionising (auto-ionising). Although the probability of two-quantum $T-T$ excitation is low, the efficiency of the action of photostabilisers depends significantly on the contribution of these excitations, because one is dealing with the long term behaviour of this system.

The number of molecules excited to the highest triplet states increases with increase in the quantum yield of the lowest triplet states and their lifetime. An additional requirement which must be met by the properties of effective photostabilisers is therefore that the populations and lifetime of the lowest T states of the molecules should be as small as possible. We shall discuss different cases from this standpoint.

We shall consider initially molecules which are photostable in the lowest electronically excited state. In the absence of intermolecular $T-T$ energy transfer processes, the population of the lowest T state is determined by the relation between the constants for the radiative decomposition of the S_1 state and the value of k_{ST}, because in most cases S_1-S_0 conversion processes will not play a significant role. If the rate of the $S-T$ conversion process is determined by the transitions between the $S_{\pi\pi^*}$ and $T_{n\pi^*}$ or between the $S_{n\pi^*}$ and $T_{\pi\pi^*}$ states (molecules belonging to luminescence spectroscopic types II–IV [15,17]) or if the molecule contains heavy atoms, then $k_{ST} \gg k_r^S$ [16] and the quantum yield of the T state is almost unity. For molecules belonging to luminescence spectroscopic types I and V, the $S-T$ conversion process takes place between states of the same orbital nature and $k_r^S \simeq k_{ST}$.[15] Only for isolated dye molecules and effective phosphors is the relation $k_r^S \gg k_{ST}$ observed. It arises from the characteristic features of the disposition of the excited $T_{\pi\pi^*}$ states relative to the $S_{\pi\pi^*}$ state and the spin–orbital interaction selection rules.[16,48] Such molecules have a high fluorescence quantum yield and their photostabilising efficiency is frequently also high, but they cannot always be used. On the other hand, for most photostable molecules the yield of the T states cannot be very low, especially since the latter can arise also via the $T-T$ energy transfer route.

The lifetime of the $T_{\pi\pi^*}$ states of molecules without heavy atoms in solid solutions (and not only at low temperatures)[49] is very long. Photostable molecules with the lowest $T_{\pi\pi^*}$ state are therefore not very effective photostabilisers and can in fact function as photosensitisers. The $T_{n\pi^*}$ states are short-lived and the $T-T$ absorption processes are relatively unlikely for such states.[46] However, the majority of molecules with the lowest $T_{n\pi^*}$ state are reactive. In particular, they participate in photodehydrogenation reactions.[36]

The lifetime of the $T_{\pi\pi^*}$ states may be sharply reduced (by 3–4 orders of magnitude) after the introduction of heavy atoms into the molecule. It changes in inverse proportion to the fourth power of the effective charge on the heavy atom. Many organometallic compounds are therefore good photostabilisers.[1,2] (Unfortunately, some of them behave as catalysts of oxidation reactions.[50])

As is already clear from the foregoing, there exists yet another possibility of reducing the lifetime of the T states with the simultaneous decrease in their population, which is associated with the initiation of S_1-S_0 and $T-S$ conversion processes by reversible adiabatic photoreactions.

We shall consider the behaviour of a system with potential surfaces ensuring the occurrence of a reversible photoreaction in S and T states (Fig. 5). Neglecting diffusion, the population of the S_1 state $W_S(x,t)$ is specified by an equation which is analogous to Eqn. (3) for $D = 0$:

$$\frac{\partial W_S}{\partial t} = -v\frac{\partial W_S}{\partial x} - [k_r^S + k_{ST} + k_{ic}(x)]\,W_S. \qquad (5)$$

We shall assume that the constants k_r^S and k_{ST} are independent of x, that $k_{ic}(x)$ increases exponentially with increase in x, and that the initial condition is $W_S(x,0) = \delta(x)$. Using the above results, one can write the following expression for the quantum yield of the T state:

$$Q_T = k_{ST} I_1 + Q_R^S k_{ST} [k_r^S + k_{ST} + k_{ic}(L)]^{-1}, \quad (6)$$

where Q_R^S is the quantum yield of the photoproduct in the S_1 state, amounting to $1-(k_r^S + k_{ST})I_1 - I_2$, I_1 and I_2 being defined by the same expressions as Q_r and Q_{ic} respectively in Eqn. (4). The quantity $b = (k_{ST} + k_r^S)Z^{-1}$ is overdetermined.

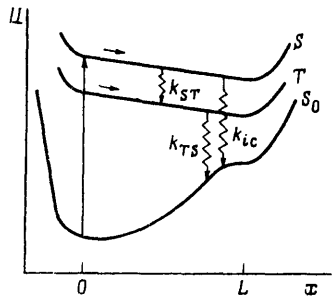

Figure 5. Schematic illustration of the terms for a molecular system with a reversible photochemical reaction; the horizontal arrows indicate the movement of the system along the reaction coordinate.[45]

Table 1. Dependence of the quantum yield of T states on the parameters $A = \alpha\Delta E$ and $k_R = v/L$ [$k_{ic}^0 = 0.1$, $k_{ic}(x) = k_{ic}^0 \exp(AxL^{-1})$, $k_{ST} = 0.5$, $k_r^S = 0.4$].

A	k_R					
	0	10^{-1}	1	10	10^2	10^3
4	0.5	0.435	0.269	0.107	0.08	0.077
6	0.5	0.424	0.220	0.049	0.016	0.012
8	0.5	0.412	0.188	0.037	0.006	0.002

Table 1 presents the quantum yields of the triplet state for different values of the parameters A and k_R. It is seen from these data that the yield of the T state diminishes sharply with increase in k_R and tends to the limiting value $k_{ST}[k_{ST} + k_r^S + k_{ic}(L)]^{-1}$ at $k_R \to \infty$, which is equal to the yield of the triplets in the photoproduct. The decrease in Q_T is more notable the higher the value of the parameter A, i.e. the greater the difference between the energies of the S_1-S_0 transition at the points $x = 0$ and $x = L$.

We shall now consider the influence of the initiation of $T-S$ conversion processes on the probability of secondary reactions. The population of the lowest T state is given by the equation:

$$\frac{\partial W_T}{\partial t} = -v\frac{\partial W_T}{\partial x} - [k_r^T + k + k_{TS}(x)]\, W_T, \quad (7)$$

where k is the rate of a secondary reaction [for example, the rate of $T-T$ absorption or transfer of energy to reactive molecules (in particular O_2)]. Subject to the initial condition $W_T(x,0) = \delta(x)$ and the exponential dependence of k_{TS} on x: $k_{TS} = K_{TS}^0 \exp(AxL^{-1})$, and for $k \ll k_r^T + k_{TS}^0$, one can find the following expression for the relation for the yield of the secondary reactions to its yield corresponding to $A = 0$:

$$\overline{Q} = (k_r^T + k_{TS}^0) I_1 + \frac{k_r^T + k_{TS}^0}{k_r^T + k_{TS}^0 e^A} Q_R^T . \quad (8)$$

The quantum yields of the photoproducts in the T state, Q_R^T and I_1, are calculated from formulae similar to those presented above. The dependence of $\overline{Q}$ on the rate of an adiabatic photoreaction is illustrated in Fig. 6. Evidently, for realistic values of the parameter $A = 4-8$ ($\Delta E = 1-2$ eV), we have $\overline{Q} < 10^{-1}$, provided that k_R exceeds the sum $k_r^T + k_{TS}^0$. A significant decrease in $\overline{Q}$ is observed even when Q_R^T is very low. $\overline{Q}$ diminishes to an even greater extent when account is taken of the effect of the occurrence of the S_1-S_0 internal conversion both as a result of the decrease in the yield of the T state and because the point from which the system begins to move along the T state surface may be one with a coordinate $x > 0$ where k_{TS} is greater than k_{TS}^0. The initiation of S_1-S_0 conversion processes suppresses the unlikely but possible two-quantum reactions in S states.

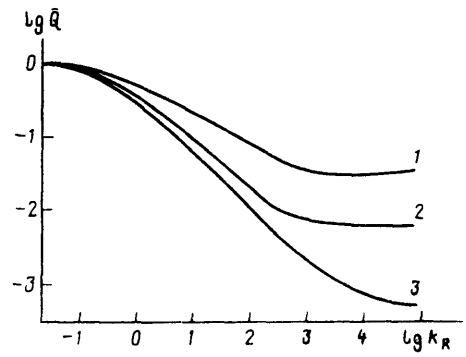

Figure 6. Dependence of $\overline{Q}$ on k_R for $k_r^T = k_{TS}^0 = 1$: *1*, $A = 4$; *2*, $A = 6$; *3*, $A = 8$.[45]

Similar results have been obtained also for more complex models of potential surfaces, in particular for the *cis–trans* isomerisation reaction for which the maximum values of $k_{ic}(x)$ and $k_{TS}(x)$ correspond not to the reaction product but to an intermediate region and movement along the term of the excited state is diffusional.

Thus in the case of the most effective photostabilisers the population of the T states and (or) their lifetime should be the smallest possible. The fulfilment of one of the conditions specified may be sufficient. The compositions formulated supplement the generally known requirements[1,2] imposed on photostabilisers. When molecules with a fluorescence quantum yield equal or close to unity are used, the first condition holds, for molecules with heavy atoms the second condition holds, while both conditions can be fulfilled in the case of molecules for which the S_1-S_0 and $T-S_0$ conversion processes are initiated by reversible photochemical reactions. Clearly the most

characteristic feature of systems of the latter type is the absence of an appreciable luminescence yield.

We emphasise that the initiation of the conversion processes by an adiabatic photoreaction is important and not the actual occurrence of the photoreaction itself.

The occurrence in the molecular system of luminescence with a large Stokes shift, which may be a consequence (although not always; see, for example, Frank-Kamenetskii and Lukashin[51]) of an adiabatic photochemical reaction, is not a sufficient condition for using the system as an effective photostabiliser.

The above requirements and the ways in which they are met hold also for intrinsically photostable polymers, since the inclusion in the polymer chain of fragments with the photophysical properties listed above increases its photostability.

The experimental data for the photostabilising efficiency of molecular systems will be considered below on the basis of the ideas described above.

V. Principal structural types of photostabiliser molecules

The agreement between the ideas set out above and the available experimental data will be demonstrated in this Section in relation to the most typical examples of systems possessing photostabilising properties. The systematic treatment of these data is based on the photophysical characteristics of photostabiliser molecules and, in particular, on the type of adiabatic photoreaction accelerating the non-radiative conversion.

1. Systems with an intramolecular hydrogen bond (IAHB)

Until recently, photostabilisers of this type have found the greatest practical application in thermoplastic, thermoelastoplastic, and reactoplastic materials[52] and they are being manufactured on a large scale by a number of undertakings in the USSR and abroad.[53–55] It is of interest to trace the development in the course of time of ideas about the mechanism of the action of photostabilisers with an intramolecular hydrogen bond.

A high capacity to absorb UV light in the range 300–400 nm is characteristic of aromatic derivatives with an intramolecular hydrogen bond. In the first publications devoted to the study of such stabilisers (derivatives of benzophenone, benzotriazole, and salicylic acid), their stabilising effect was attributed[56] to their ability to absorb UV light (shielding effect). From the middle 1940's until the beginning of the 1960's, this was the only explanation of the photostabilising capacity of such substances. However, it had long been noted that the proposed mechanism is unable to account fully for the observed protecting effect. For example, a decrease in the molar extinction coefficient ε of phenyl salicylate derivatives leads to an increase in the photoprotecting effect.[57] It was also not understood why certain structurally similar substances with an intermolecular hydrogen bond and with a high extinction coefficient ε (for example, 2-hydroxyphenyl-1,2,4-triazole) do not exhibit a photostabilising effect.[58]

Later the view was expressed in a number of studies[59–62] that, together with the absorption of UV light, UV absorbers can quench excited polymer centres or impurities which are always present in real industrial polymers. The absorption of light in the range 280–400 nm in polymers such as polyolefins (PO), poly(vinyl chloride) (PVC), and polystyrene (PS) is associated with the presence in these substances of oxidation products, variable-valence metallic impurities (for example, catalyst residues), and polycyclic hydrocarbons adsorbed from the atmosphere.[63,64] Furthermore, in the presence of oxygen in polymers [polyethylene (PE), polypropylene (PP), etc.], complexes are formed whose absorption spectra have undergone a bathochromic shift compared with the spectrum of the [pure] polymer owing to the appearance of a charge-transfer band.[65–67] The oxygen molecule is an effective quenching agent for excited states[58] but it does not exhibit photostabilising effects in polymers. On the contrary, it accelerates the photodecomposition of many polymeric materials.[68]

In 1966–1968, Pivovarov and Lukovnikov and co-workers[7–10] and later George[69,70] published a series of studies which significantly altered the ideas about the mechanism of the action of UV absorbers with an intramolecular hydrogen bond. It was shown convincingly in relation to polypropylene that typical UV absorbers such as *p*-(*t*-butyl)phenyl salicylate, 2-(2-hydroxy-5-methylphenyl)benzotriazole, and 2-hydroxy-4-octyloxybenzophenone effectively quenched the luminescence of the polymer with energy transfer to the stabiliser. Depending on the polymer irradiation conditions, the cross-section of the specimens, the exposure time, and the type of stabiliser, the contributions of the shielding and quenching effects may vary and quenching can predominate.[8] Furthermore, after prolonged exposure of the polymer specimens, the quenching of the photochemical oxidation products (carbonyl groups) may become important.[70]

The rules specified above, according to which the stabiliser must absorb light energy to the maximum extent in the region where the polymer absorbs and in the region of its luminescence, were formulated in these studies.[9] In polymers which luminesce in their initial state (before irradiation), the greatest protecting efficiency may be achieved by using mixtures of stabilisers one of which ensures the protection of the polymer molecules and the other must deactivate the oxidative degradation products.[70,71] The validity of these conclusions was confirmed in subsequent investigations.[72–74]

Until recently there was no unanimous view in the literature concerning the role of the intramolecular hydrogen bond in the appearance of the photostabilising effect. The stabilising properties of UV absorbers have been attributed[75–77] to the presence in their structure of a quasi-aromatic ring with a strong hydrogen bond in the ground state of the molecule. However, the estimate of the efficiency of these compounds based on the strength of the intramolecular hydrogen bond[78,79] reflects only the shielding capacity of the stabiliser (the intensity of the absorption band in the range 310–370 nm increases with increase in the energy of the intramolecular hydrogen bond) and does not indicate the practical possibility of using the compound as a photostabiliser. On the other hand, if account is taken of the fact that the energy of the intramolecular hydrogen bond changes when the molecule passes to an excited state and the bond frequently breaks,[80] the possibility of correlation between the strength of the intramolecular hydrogen bond and the stabilising efficiency looks problematical.

It is essential to note yet another approach to the explanation of the mechanism of the deactivation of energy by UV absorbers with intramolecular hydrogen bonds. It has been suggested[81,82] that the most effective stabilisers should be aromatic compounds with an intramolecular hydrogen bond which fluoresce with an anomalously large Stokes shift (derivatives of 2-hydroxyphenylbenzotriazole and 2-hydroxyphenylbenzoxazole) but no experimental data confirming the high efficiency of these compounds are quoted. On the other hand, it is known from literature data[58] that 2-hydroxyphenylbenzoxazole is not efficient as a photostabiliser. Furthermore, in

highly dilute solutions in hydrocarbons, 2-hydroxy-derivatives of benzotriazole exhibit a weak fluorescence with a normal Stokes shift[83] and λ_{max} = 25 000 cm^{-1}, while the glow of this compound observed by Betin[82] is due to the crystalline phase (λ_{max} = 15 000 cm^{-1}). The glow of the crystalline phase at λ_{max} = 22 000 cm^{-1}, erroneously attributed to fluorescence with an anomalously large Stokes shift, has been observed[84] for 2-hydroxyphenylbenzoxazole whose crystals fluoresce with λ_{max} = 21 500 cm^{-1}.[85]

A significant step towards the understanding of the problem under discussion was made in a number of studies[83,86–89] carried out in 1979–1986 using luminescence-spectroscopic methods. The authors analysed the results of investigations of the photostabilising efficiencies of compounds with an intramolecular hydrogen bond on the basis of modern ideas concerning the nature of non-radiative conversion processes in polyatomic molecules, in particular, taking into account the effect of the initiation of these processes by adiabatic photoreactions.[89,90] *It was concluded that molecules with an intramolecular hydrogen bond, for which the lifetime and population of the triplet state are low, exhibit a high photostabilising efficiency as a consequence of the initiation of the S_1-S_0 and $T-S$ conversion processes by reversible intramolecular proton transfer reactions.* This effect leads to the suppression of secondary reactions of T states and ensures a high photostabilising efficiency of systems of this kind.

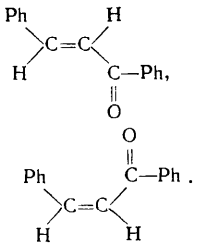
In conclusion of this Section, we may note that during the last ten years no information has appeared in the literature concerning new types of photostabilisers with an intramolecular hydrogen bond. Benzotriazole[91–96] and benzophenone[97–101] derivatives, modified by different substituents in order to diminish their migration from the polymer and to improve their toxicological properties, are still being patented and recommended for use. A fairly complete survey of the methods of synthesis and applications of different derivatives of 2-hydroxyphenylbenzotriazole has been published.[102]

2. Molecules in which there is a possibility of the *cis–trans* isomerisation reaction

The *cis–trans* isomerisation photoreaction is possible in molecules of azo-compounds, azomethines, stilbenes, chalcones, etc. The rotation of the molecular fragments in the electronically excited state is about the –N=N–, –N=C–, and –C=C– bonds. The reaction can take place both in the liquid phase and in solid polymer matrices.[103] Data on the mechanism of the *cis–trans* isomerisation reaction can be found in a number of communications.[104–107]

A characteristic feature of the majority of arylazo-compounds is the absence of luminescence in liquid and solid solutions and in polymer matrices (alkylamino- and dialkylamino-azobenzenes luminesce weakly in solid matrices at 77 K[108]). Very intense fluorescence has been observed only in *o*-hydroxyarylazo-compounds which tend to undergo the azo-hydrazone tautomerism. The fluorescence has been attributed to the hydrazo-form,[109] which is incapable of *cis–trans* isomerisation.

Among azo-compounds there are dyes of virtually every colour ranging from yellow to black. Depending on the nature of the substituent in the aromatic ring, the photostability and photochemical activity of azo-compounds can vary significantly—from the sensitisation of photochemical reactions to the pronounced photostabilisation effect. It has been observed experimentally that, as a rule, the fluorescent azo-dyes are sensitisers of the photodegradation of polymeric materials.[1] On the other hand, in the majority of photostable dyes, which are capable of increasing the photostability of the polymer (polyamide fabrics), there is no luminescence or it is observed to occur with a very low quantum yield.[110,111] The results of studies on the use of arylazo-compounds as photostabilisers of block-copolymers of isoprene with styrene (IST-30) have been published.[112–114] It has been shown that many azo-compounds, particularly those with amino- or hydroxy-groups in the *para*-position in the benzene ring, as well as nitro- or phenylazo-groups in the 4-position relative to the azo-group are more effective photostabilisers of polydienes than the photostabiliser Tinuvin P used in industry. On the other hand, compounds containing a hydroxy-group in the *ortho*-position relative to the azo-group are relatively ineffective as photostabilisers. The reason for the low efficiency of *ortho*-substituted derivatives and the high efficiency of the *para*-substituted derivatives is that in the series of derivatives of azo-benzene, *para*-derivatives do not luminesce as a consequence of the effective non-radiative deactivation initiated by the *cis–trans* isomerisation reaction, while *ortho*-hydroxy-derivatives do exhibit a luminescence with a high quantum yield[115] and therefore their excited states have a relatively long lifetime.



Although the wide-scale practical application of arylazo-compounds as photostabilisers of polymeric materials is limited because of their intrinsic colour (they are unsuitable for the manufacture of white or colourless articles from polymers), they have been recommended for use in polyolefins and in PVC,[116,117] in vulcanised butyl rubbers dyed to give light colour shades,[118] in linear polyesters,[119] and in styrene and rubber block-copolymers.[120] They exhibit a high stabilising effect in polyamides.[121]

Compounds with C=N bonds, namely benazine,[122] furfurylazine,[123] salicylazine,[124] and tetrazine,[125] have already been known for many years as photostabilisers of polymers of different types. There is a high probability of deactivation processes involving the non-rigid molecules of these compounds, which are capable of *cis–trans* isomerisation. Thus benazine (dibenzylideneazine) Ph–CH=N–N=CH–Ph does not luminesce either as a crystal or in solution (at room temperature and at 77 K).[85] Benzylideneaniline and many similar azomethines having different substituents in the benzene ring behave similarly. The effective non-radiative conversion in these systems is associated with the change in the steric structure in the excited state.[126,127] Molecules with a rigid structure, where the C=N group is incorporated in a ring (for example, phenylbenzimidazole) or having rings with intramolecular hydrogen bonds (salicylideneanilines, *o*-tosylaminobenzaldehydes), become luminescent.[128–130] In this case the *cis–trans* isomerisation reaction is impossible or is greatly hindered and the photostabilising properties of the molecules are impaired.

Diarylethylenes (stilbenes) are typical representatives of systems in which *cis–trans* isomerisation takes place. There exists an extensive literature on studies of the luminescence-spectroscopic properties of these compounds and of the isomerisation reaction mechanism.[85,131–138] As a rule, molecules in the *trans*-form fluoresce, while the *cis*-isomers hardly fluoresce. Apparently the difference in the behaviour of the *cis*- and *trans*-forms limits the applicability of stilbenes as stabilisers.

The molecules of indigoid and thioindigoid dyes having a central C=C bond also undergo *cis–trans* isomerisation. A high photostability and ability to increase the resistance to light-induced ageing of dyed materials are characteristic of these compounds.[139,140] It has been shown[141] that only the *trans*-isomers fluoresce, while the *cis*-isomers do not fluoresce and do not phosphoresce. The luminescence-spectroscopic properties of indigoid dyes have been surveyed.[115,142]

The *cis—trans* isomerisation reaction is characteristic also of α,β-unsaturated ketones with aromatic rings (chalcones). The isomerism of these compounds is determined by the relative positions of the substituents in relation to the C=C bond of the vinylene group:

These compounds do not luminesce, like other compounds with a non-rigid structure,[142] because the conversion processes occurring in them are accelerated by *cis—trans* isomerisation reactions. They have been recommended as effective photostabilisers.[143,144]

Thus many systems in which conversion processes are initiated by the *cis—trans* isomerisation reaction are effective photostabilisers.

3. Systems in which there is a possibility of the formation of excimers and exciplexes

As stated in Section IV, the non-radiative conversion processes can be accelerated on formation of excimers and exciplexes. Some data on the properties of these systems can be found in a number of communications.[31,145,146] Apart from intermolecular excimers and exciplexes, it has become usual to refer also to intramolecular ones. The formation of the latter is attributed to a rearrangement of the structure of the molecule in the excited state such that the different fragments undergo a significant change in their positions in space and the distance between them diminishes. Examples of the formation of intramolecular excimers have been published.[147–149]

Among systems used as photostabilisers in which there is a possibility of the formation of excimers (exciplexes), mention should be made of derivatives of acrylic acid,[150–152] benzylidenemalonates,[56] phenyl benzoates and carboxylic acid amides,[153] and aromatic derivatives of phosphoric acid.[154] The mechanism of the photoprotecting action of these compounds was not understood until attention was turned to the relation between the stabilising properties of molecules and the initiation of non-radiative conversion by reversible photoreactions.[45]

A detailed analysis of the mechanism of conversion for aromatic derivatives of phosphoric acid has been carried out[155] on the basis of quantum-chemical calculations by the CNDO/2 method.[156] Compounds having the structure Ph—X—PO(Y—Ph)—X—Ph, where X = Y = O, X = Y = NH, and X = O, Y = NH, were investigated. It was established that, in the equilibrium configuration of the excited S_1 state, these molecules have a sandwich structure with an almost parallel disposition of benzene rings, as in the excimers of benzene[157] and polystyrene.[158] This entails a decrease in the difference between the energies of the S_1 and S_0 states, the acceleration of the internal conversion process, and a decrease in the population of the T states. Furthermore, the non-planar structure of these systems and the presence of the central heavy P atoms ensure a high rate of $T—S$ conversion processes. Accordingly, aromatic derivatives of phosphoric acid do not luminesce in solutions either at room temperature or at 77 K and exhibit very pronounced photostabilising properties.[154]

A similar conversion mechanism operates in other known photostabilisers which do not contain an intramolecular hydrogen bond in their structure (oxanilides, benzamides, benzoates, and acrylate esters). Their steric rearrangement in the excited state is sufficiently rapid (over a period $\lesssim 10^{-11}$ s[159]) to ensure conditions for the initiation of conversion processes.

The unusual behaviour of phenyl benzoates in polymers has for a long time attracted attention.[2] The stabilising capacity of these systems has been traditionally attributed to the Fries photorearrange-ment,[160] which results in the formation of 2-hydroxybenzophenones which protect the polymer as molecules with an intramolecular hydrogen bond. However, this explanation proved to be over-simplified because it has been shown[57] and then confirmed[161] that phenyl benzoates are themselves photostabilisers. An even more direct proof of this postulate was obtained in a study[162] where it was shown that chloro-substituted phenyl benzoates, in which the Fries rearrangement is impossible, exhibit a stronger photoprotecting effect than compounds in which such rearrangement is possible.[125] The mechanism of such conversion in phenyl benzoate has been examined in an investigation[163] where it was shown that the absence of luminescence and the high photostabilising efficiency of this compound are associated with the initiation of conversion processes as a consequence of a conformational rearrangement of the type involving the formation of an intramolecular excimer.

Aromatic derivatives of acrylic acid, investigated by luminescence spectroscopic methods,[164] also have a low luminescence yield as a consequence of sensitised conversion processes. Since in addition they do not undergo irreversible photoreactions,[165] their photostabilising efficiency is high.

Diaryloxamides,[166–171] having the general formula $R^1—Ph—NH—CO—CO—NH—Ph—R^2$ and exhibiting a high stabilising efficiency in polymer-containing coatings, varnishes, and polycarbonates, have similar properties. The conversion mechanism under discussion operates also in the recommended derivatives of benzoic and benzacrylic acids[170–174] and in benzoylmethane[175–177] (stabilisers of butadiene rubber and cosmetic preparations).

There are fairly numerous literature data on the quenching of the excited states of polymers by electron-donating complex-forming agents. Thus it is well known that the formation of complexes between amines and the carbonyl groups of polymeric molecules entails the initiation of conversion processes and the quenching of excited states in exciplexes.[145] Other compounds having a relatively low ionisation potential behave similarly.[145]

The question of the deactivation of singlet oxygen molecules occupies an important place in the problem of the photostabilisation of polymers. They arise as a result of energy transfer from different sensitiser molecules (aromatic hydrocarbons, dyes, pigments, carbonyl compounds)[1,2,104,178] and participate in reactions involving the formation of hydroperoxides, the oxidation of C=C bonds, addition to diene systems, etc.[179–182] Tertiary amines, substituted phenols, chelate complexes, and β-carotene are used to suppress polymer photochemical oxidation processes.[179–182] Singlet oxygen is then quenched in exciplexes and in the case of β-carotene this is accompanied also by the *cis—trans* isomerisation reaction.

Thus many systems in which there is a possibility of the formation of intermolecular or intramolecular exciplexes, which initiate conversion processes, exhibit effective photostabilising properties.

4. Compounds containing a metal atom

As mentioned in Section II, a molecular system with a heavy atom usually has a short lifetime of the T state and can therefore be an effective photostabiliser. An example of systems of this type is provided by organometallic compounds (for example, ferrocenes) and metal chelates.[1,2] These compounds can be both UV radiation absorbers and quenching agents for excited states of the polymer or impurity molecules. We shall consider this question briefly.

Apparently the first experimental indication of the possibility of energy transfer from the polymer to the molecules of phenylferrocene and *o*-hydroxybenzoylferrocene, used to photostabilise melamine-alkyd coatings, was obtained by Schmitt and Hirt.[184] Ferrocene derivatives also protect other polymers against the action of light.[1]

Chelate complexes of heavy metal ions (Ni, Cr, Eu, etc.) with thiobisphenols quench the triplet state of the carbonyl group[185] and other chromophores.[1] For this reason alone, they exhibit photostabilising properties. However, it is known that not all metal chelates are quenching agents for the excited states of carbonyl groups.[2] Thus nickel thiophenoxide does not quench the T states of ketones but nevertheless exhibits photostabilising properties, which have been attributed to the involvement of this chelate in processes leading to the quenching of singlet oxygen molecules.[186,187] In terms of the efficiency of the quenching of singlet oxygen, metal chelates can be arranged in the following sequence depending on the nature of the metal: $Mn^{2+} \simeq Cu^{2+} < Co^{2+} < Ni^{2+} \simeq Fe^{3+}$. As already mentioned above, singlet oxygen may be quenched by the formation of complexes. In the case of metal chelates, the spin–orbit interaction, which is determined by the charge on the metal nucleus, is important for this quenching mechanism. This problem has not yet been considered theoretically.

If the quenching of excited states in polymers is associated with energy transfer to the photostabiliser molecule, it is subject to the same rules as in other molecular systems:[14] energy transfer takes place only when the energy at the lowest excited state of the acceptor is lower than the energy of the donor; triplet–triplet transfer occurs via an exchange-resonance mechanism while singlet–singlet transfer involves an inductive-resonance mechanism; the efficiency of the transfer increases with increase in the overlap integral for the emission spectrum of the donor and the absorption spectrum of the acceptor. When the photophysical properties of the photostabilising molecule are known, this permits conclusions about the mechanism of its action and a description of the dependence of the transfer constants on the type of photostabiliser molecule and the type of polymer.[188,189]

It is essential to note that the photostabilising effect of metal chelates does not reduce to the physical mechanism of their action, because they function also as activators of the non-radical decomposition of hydroperoxides and their efficiency depends also on the type of ligand.[190–192] Detailed studies have been made on the mechanism of the action and efficiency of the complexes most widely used to stabilise polydienes.[193] Similar results were also obtained in another investigation.[194]

New metal chelate stabilisers for butadiene rubber, polystyrene, and polyolefins have been proposed in recent years.[195–198] As a rule, their action does not reduce to a single mechanism but involves shielding processes, the quenching of excited states, and chemical inhibition of photoreactions.

VI. Synergistic mixtures of photostabilisers

Under the real conditions of industrial processing and use of articles made of polymer materials, the polymer is acted upon by different ageing factors (heat, light, oxidants, mechanical stresses, etc.), and different ones can predominate. In order to impart to polymer articles an increased useful lifetime, in practice one usually employs not individual stabilisers but their mixtures, which frequently exhibit a synergistic effect. Such synergistic mixtures can comprise UV absorbers and quenching agents, antioxidants (including PZA) and UV absorbers, quenching agents, and antioxidants of various types, etc. Ternary mixtures of stabilisers are sometimes used.

Thus a mixture of the 2-hydroxy-4-octyloxybenzophenone photostabiliser and PZA (Tinuvin 770) in proportions of 9:1 imparts a significantly greater photostability to polypropylene than when each stabiliser is used separately.[199] It has been shown[200] that the employment of PZA in a mixture with physical mechanism stabilisers makes it possible to increase the photostability of polypropylene and high- and low-pressure polyethylenes by a factor of 6–8. It has been reported that sheeting for agricultural purposes with a useful lifetime of 3–4 years has been developed in Hungary using mixtures of this type. A synergistic effect has been observed[201,202] when a mixture of Tinuvin 770 with the Tsissorb [Cis-sorb?] 531 photostabiliser (2-hydroxybenzophenone) was used.

The causes of the synergism between PZA and photostabilisers have been investigated.[203–205] It was shown for the first time in these studies that the synergistic effect depends on the cross-section of the polymer article: a significant effect is observed in articles with a cross-section greater than 1 mm. A diffusion mechanism of the synergistic effect has been put forward to account for this finding. The diffusion of photostabiliser molecules to the PZA from the bulk of the polymer and from its surface ensures the protection of the surface layer undergoing further chemical oxidation (the "depot" effect).

Similar ideas have been put forward in another study,[206] where the photostabilisation of polypropylene, polystyrene, high pressure polyethylene, and ABC resins was investigated using synergistic mixtures of PZA and UV absorbers. According to these ideas, in the case of thin-profile articles the synergistic effect is either small or is altogether absent. Apparently this was observed in a study[207] where mixtures of Tinuvin 770 with the Tsissorb 531 photostabiliser, Tinuvin 327, and the UV-1084, Negopex B, and Irgastab 2002 nickel chelates failed to give a synergistic effect when films up to 200 μm thick were used.

Interesting results for the stabilisation of polyurethane systems have been obtained.[208] The authors investigated the protection of these systems against photooxidative ageing using PZA, photostabilisers, and phenolic antioxidants as well as their mixtures. It was established that in the case of polymers containing aromatic fragments the use of synergistic mixtures of these three types of stabilisers is the most effective.

The most complete survey and theoretical consideration of numerous experimental data on the synergism between various types of stabilisers and auxiliary substances were carried out by Ivanov and Shlyapintokh.[209] They considered the nature of the synergistic effect in the photostabilisation of polymers and they assumed that the effect is based on the following mechanisms: (1) diffusional transfer of the antioxidant to the photoreaction zone generated by the UV absorber; (2) protection of the photostabiliser by the antioxidant; (3) the action of the main stabiliser during use and of

the additional stabiliser during the processing of the polymer; (4) the increase in the efficiency of the UV absorber in the presence of an antioxidant as a consequence of the change in the mechanism of chain termination; (5) protection of the polymer by auxiliary additives during the activation of the main stabiliser in the initial stage of the ageing process; (6) the effect of one stabiliser as a radical acceptor and of another as a compound decomposing hydroperoxides; (7) quenching of the excited states of the antioxidant by the photostabiliser; (8) the use of special additives to improve the distribution of stabilisers in the polymer; (9) the formation of effective stabilisers on reaction of stabilising additives; (10) regeneration of the effective stabiliser. The authors estimated the maximum synergistic effects based on these mechanisms and the optimum component ratios. They analysed the probable changes in the effects as the thickness of the polymer specimens, the light intensity, and temperature were varied. Mechanisms 1–5 and 7–9 were studied experimentally.

Synergistic mixtures containing photostabilisers have been proposed recently for the stabilisation of polyethylene,[210,211] automobile enamels,[212] enamels for polyurethane coatings,[213] and other polymer systems.[214–218]

It is important to emphasise that all the photostabilisers used in synergistic mixtures are systems in which the T states are either not populated or have a short lifetime.

---o0o---

Thus analysis of theoretical and experimental data makes it possible to formulate requirements, in addition to those already well known, which must be satisfied by the photophysical properties of molecular systems with a high photostabilising efficiency. The possibilities in the search for new types of photostabilisers have been by no means exhausted since only a small number of systems with a limited set of the simplest reversible adiabatic photoreactions, initiating non-radiative conversion processes, have been used hitherto. The ideas described determine to a large extent the pathways followed in such search.

β-Aminophosphonates and β-aminophosphinates, synthesis, and properties

E S Gubnitskaya, L P Peresypkina, L I Samarai
Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. **Methods of obtaining β-aminophosphonates and β-aminophosphinates, their physical and chemical properties and also the practical application of these substances are reviewed.**

The bibliography contains 98 references.

IV.	Applications	815

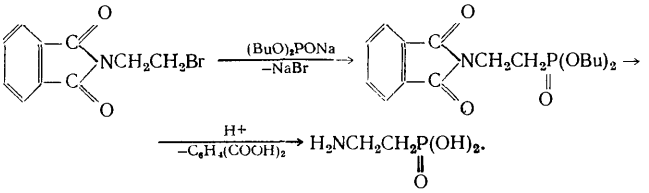
I. Introduction

β-Aminoethylphosphonic acid (AEP) was isolated for the first time in 1959 from a living organism (molluscs) by Horiguchi and Kondatsu[1] who named it ciliatine. Other authors later isolated AEP and derivatives of it from other natural sources.[2–4] AEP is a component of cell membranes and protects them from degradation of cellular structure. There is currently a hypothesis that AEP is a vitamin or equates to one.[5] It has been established that AEP and its derivatives possess high biological activity.[6,7]

The chemistry of aminophosphonates and aminophosphinates has been discussed in several reviews but these are mainly devoted to α-aminomethylphosphonates[6–10] or the biochemistry of these substances.[11,12]

Preparative methods, chemical and physical properties, and the practical use of β-aminophosphonates and β-aminophosphinates are considered in the present review.

II. Methods of preparation



1. The Michaelis–Becker reaction

The method consists of the reaction of β-substituted ethyl halides with the sodium or potassium salt of a dialkyl phosphorous acid (Michaelis–Becker reagent).[13–22] The reaction is carried out in acid or other inert solvent.

AEP was synthesised for the first time by the Michaelis–Becker reaction in 1946.[13] On reacting the Michaelis–Becker reagent with the ethyl ester of β-bromopropionic acid a phosphonocarboxylic acid triester is formed. It was converted into the amide then AEP was obtained by a Hofmann rearrangement.

$$BrCH_2CH_2COOEt \xrightarrow[-NaBr]{(EtO)_2PONa} (EtO)_2P(O)CH_2CH_2COOEt \xrightarrow{NH_3} (EtO)_2P(O)CH_2CH_2CONH_2 \xrightarrow[2)\ H^+]{1)\ NaOBr} (HO)_2P(O)CH_2CH_2NH_2.$$

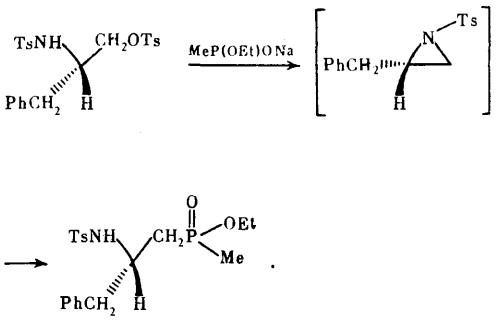
Soon afterwards AEP was synthesised by the reaction of sodium dibutyl phosphite with bromoethylphthalimide and subsequent hydrolysis with hydrobromic acid.[14]

When using β-bromoethylamine hydrobromide in place of the phthalimide the yield of AEP fell sharply probably as a result of the poor solubility of the initial hydrobromide in inert solvent.[15]

The Michaelis–Becker method is useful for introducing a phosphono group into a molecule of a compound in which there is a chlorine atom in the β position to an amino group.[16–19]

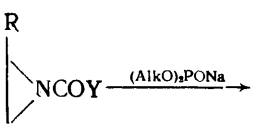
M I Kabachnik and collaborators[16] synthesised the dibutyl ester of a β-piperidino substituted phosphonate. This same compound was formed on oxidation of β-piperidinoethylphosphinic acid diester with manganese dioxide.

$$C_5H_{10}NCH_2CH_2Cl \xrightarrow{(BuO)_2PONa} C_5H_{10}NCH_2CH_2P(O)(OBu)_2 \xleftarrow{MnO_2} C_5H_{10}NCH_2CH_2P(OBu)_2$$

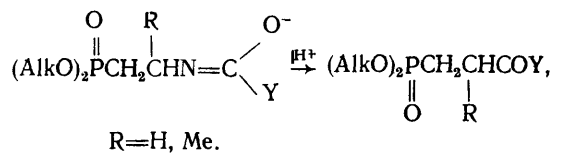


N-Alkyl- and *N*-silylaminophosphonates were obtained by the reaction of the corresponding *N*-substituted β-chloroethylamines with a Michaelis–Becker reagent.[17,19]

$$R'R''NCH_2CH_2Cl \xrightarrow{(EtO)_2PONa} R'R''NCH_2CH_2P(O)(OEt)_2.$$

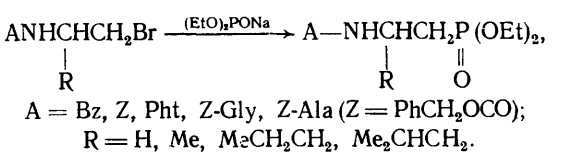


Maier has synthesised 'tris-AEP'.[18]

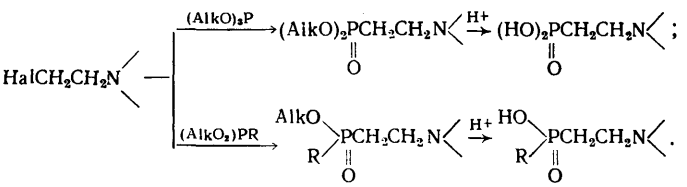


$$N(CH_2CH_2Cl)_3 \xrightarrow{(EtO)_2POK} N[CH_2CH_2P(O)(OEt)_2]_3 \xrightarrow{H^+} N[CH_2CH_2P(O)(OH)_2]_3.$$

A method[21] has been developed for obtaining optically active *N*-substituted β-aminoethylphosphonic acid and -phosphinic acids. An ester is formed by reacting an *N*-tosylaminotosylate with an excess of Michaelis–Becker reagent in tetrahydrofuran solution at room temperature and is converted into the acid by hydrolysis with 48% HBr.

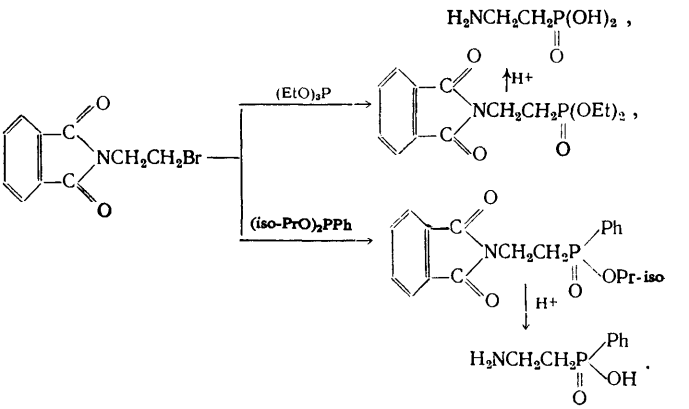


The reaction proceeds through an *N*-tosylaziridine intermediate. Aminophosphonates were obtained with high diastereoselectivity in relation to the chiral centre at phosphorus. *N*-Acyl substituted diesters of aminophosphonic acid were synthesised from *N*-acyl- or *N*-sulphonylaziridines and a Michaelis–Becker reagent.[22]



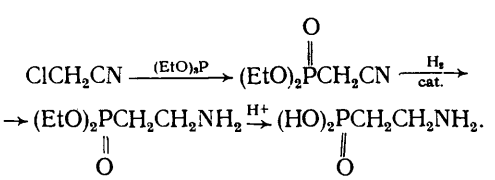
The Michaelis–Becker reaction is used for obtaining phosphonate analogues of aminoacids and peptides.[23]

Phthaloylglycine, benzoylglycine, carbobenzoxydipeptides, carbobenzoxyaminoacids, etc. were used as starting materials. The method has great importance since it affords the preparation of various phosphonic analogues of biologically active aminoacids containing functional groups and asymmetric centres and also of polyphosphonopeptides.[23]

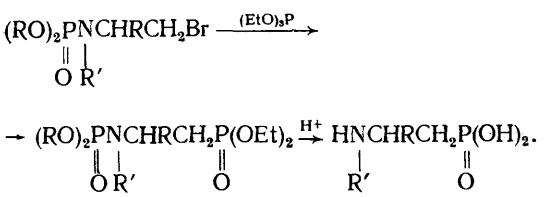


2. The Arbuzov reaction

The method comprises the introduction of an alkylphosphonic group with the aid of a trialkyl phosphite or dialkylaryl phosphonite into a molecule of *N*-substituted amine with the formation of a phosphorus–carbon bond and subsequent hydrolysis of the ester groups.[24–29]

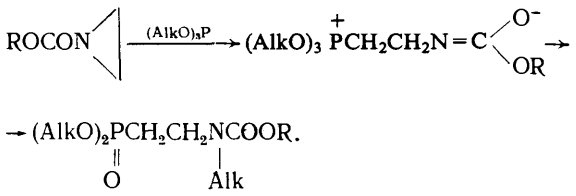


β-Aminoethylphosphonic acid was obtained by the Arbuzov reaction by heating β-bromoethylphthalimide with triethyl phosphite at 160 °C and subsequent hydrolysis of the ester groups.[25]

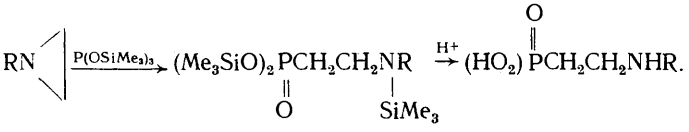


The reaction with *O,O*-diisopropyl phenylphosphonite proceeds in a similar manner, whereby β-aminoethylphenylphosphinic acid is obtained in good yield.[26]

An aminophosphonate is formed by reacting chloroacetonitrile with triethyl phosphite and subsequent reduction of the nitrile group. This compound is converted into AEP by hydrolysis of the ester group.[11]



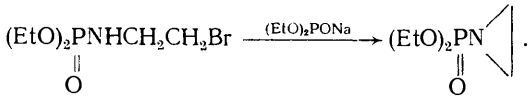
N-Substituted aminophosphonates containing substituents at the α- and β-carbon atoms have been obtained by the Arbuzov reaction.[27,28] *N*-Phosphorylated diesters are formed by reacting the β-bromoethylamide of a dialkyl phosphate with triethyl phosphite at 150–160 °C. Subsequent hydrolysis with hydrochloric acid leads to fission of the ester groups and the nitrogen–phosphorus bond forming β-aminoethylphosphonic acids.



A non-classical variant of the Arbuzov reaction has been used to obtain *N*-acylated aminophosphonates.[24] *N*-Acylaziridines in place of alkyl halides were reacted with esters of trivalent phosphorus

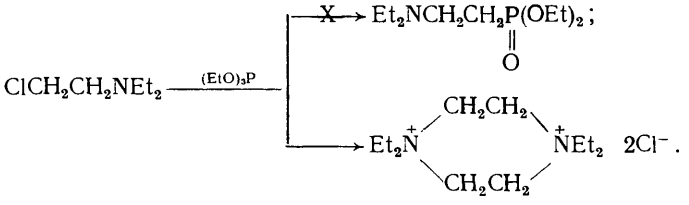
acids. It was suggested that the reaction proceeds through a zwitterionic intermediate.

The hydrobromide of aminoethylphosphonic acid was isolated after further hydrolysis with hydrobromic acid.



N-Acylaziridines react with *tris*-(trimethylsilyl) phosphite in a similar manner.[30]

Drawbacks of the method of obtaining aminophosphonates by the Arbuzov reaction are the time taken for the process and the forcing conditions of carrying out the reaction.

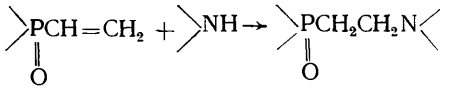


It should be mentioned that in certain cases it is possible to obtain an aminophosphonate (-phosphinate) only by the Arbuzov or Michaelis–Becker reactions.

An *N*-phosphorylated aziridine is formed by interacting the β-bromoethylamide of a diethyl phosphate with a Michaelis–Becker reagent.[28]

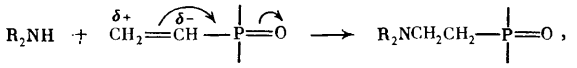
In this case the Arbuzov reaction is used to obtain the β-aminophosphonate.

The dimer of the initial amine is obtained on reacting β-chloroethyldiethylamine with triethyl phosphite.[17]



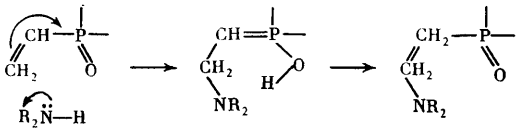
The reaction with *tris*-(β-chloroethyl)amine proceeds in a similar manner.[18]

The Michaelis–Becker and Arbuzov reactions do not have broad scope and are strictly specific methods for obtaining particular aminophosphonates and -phosphinates.



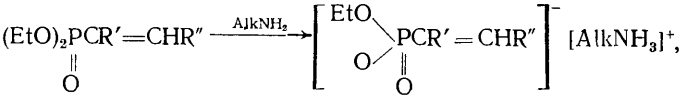
3. Addition to an unsaturated system

a) Addition of amines to a multiple carbon–carbon bond in phosphonates



Addition of amines at a multiple carbon–carbon bond in phosphonates has been studied in fair detail.[16,31–48] In all cases addition occurs according to the inverse Markovnikov rule, i.e. the amino group is added to the β-carbon atom of the vinyl group.[32]

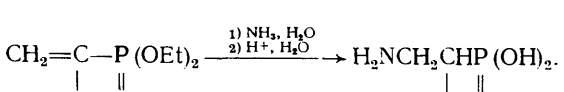
Kabachnik and collaborators[16,32] have interpreted the addition to the β-position by a shift of electrons under the influence of the electron-accepting group:



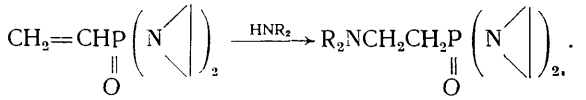
or by the formation of a transition complex.

The addition of amines to a diethyl vinylphosphonate has been studied.[35,36] The reaction proceeds most readily with secondary amines and with more difficulty with primary amines and ammonia.[35,36,38] Dimethylamine adds to diethyl vinylphosphonate without a catalyst at 20 °C.[13] Piperidine reacts similarly.[16,32,35] The reaction of vinylphosphonates with secondary amines usually proceeds with an equimolar ratio of reactants without a solvent or with a 10–15% excess of amine or in aqueous solution.[31,35,39]

Primary amines react only in the presence of a catalyst, such as an alkali metal alkoxide, in an excess of amine on heating.[19,35,38,40]

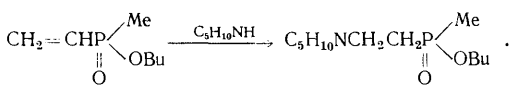


It should be mentioned that the action of alkylamines on a vinylphosphonate containing substituents at the α- or β-carbon atom leads to dealkylation of the initial phosphonate and the formation of an alkylammonium salt of the ethyl vinylphosphonate.[19]

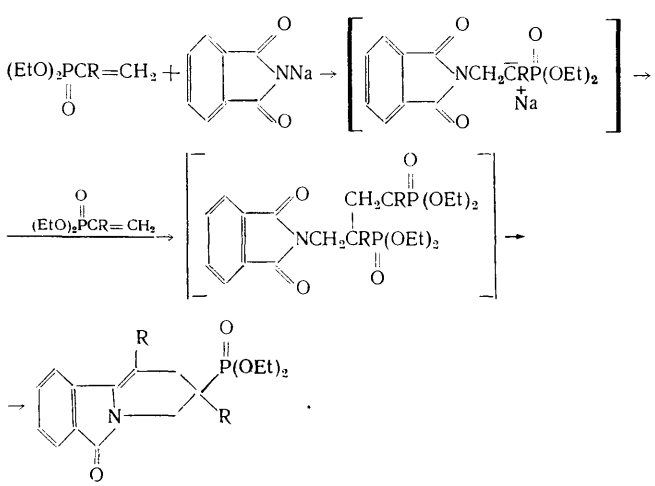


R′, R″ = Me, Ph.

The more basic aliphatic amines react more readily and give aminophosphonates in high yield. Diethyl vinylphosphonate reacts with butylamine in the presence of catalytic amounts of sodium ethoxide at 80–90 °C.[19,40] Diethyl vinylphosphonate reacts with aniline on heating on a water bath. The yield of diethyl *N*-phenylaminophosphonate was low due to the formation of a larger quantity of byproducts.[35,36] Sterically hindered amines [Me_3CNH_2, $(Me_3Si)_2NH$] did not add to vinylphosphonate in the presence of catalytic amounts of sodium ethoxide even on extended boiling (15–20 h) because of the spatial obstacles.[19]

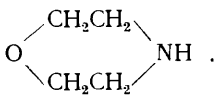


An aminoethylphosphonate with a free amino group was obtained in high yield by reacting a vinylphosphonate with ammonia in alcoholic solution in the presence of catalytic amounts of sodium methoxide.[35,36] α-Bromovinylphosphonate reacts with a concentrated aqueous solution of ammonia on heating for 10 min at 50–60 °C and subsequent hydrolysis of the ester groups with hydrochloric acid.[41,42]



The rate of addition depends not only on the nature of the amine but also on the nature of the substituent at the phosphorus atom. An increase in electron-donating properties for the substituent at phosphorus significantly reduces the reaction rate.[43] This is caused by the different polarity of the multiple bond in imides and esters of vinylphosphonic acid. Vinylphosphonic acid diamides react with ethylenimine, diethylamine, piperidine and morpholine at 20 °C for 1.5–2 d or at 40–50 °C for 4–5 h. Allylamine and dibenzylamine add in the presence of catalytic amounts of sodium ethoxide.

Reaction of the butyl ester of methylvinylphosphonic acid with piperidine continued for 4 days at 20 °C and led to an almost quantitative yield of *N*-substituted phosphonate.[32]

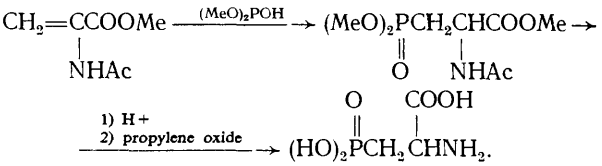


α-Substituted vinylphosphonates are synthons for preparing AEP and its derivatives.[49]

Various heterocyclic compounds were obtained by this method by treating vinylphosphonates with such imides as maleimide, succinimide and glutarimide.[49]

Reactions of vinylenediphosphonic acid with primary and secondary aliphatic and cyclic amines have been investigated. These were carried out in water or other highly polar media (H_2O–EtOH, AcOH) at 100–120 °C.[44–46]

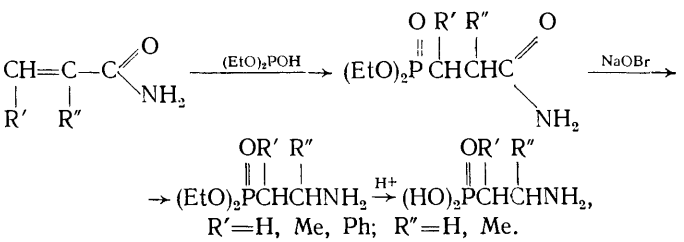
$CH_2{=}C(PO_3H_2)_2 \xrightarrow{R'R''NH} R'R''NCH_2CH(PO_3H_2)_2$,
$R'R''NH$ = $MeNH_2$, $EtNH_2$, $(HOCH_2)_3CNH_2$, $HOCH_2CH_2NH_2$, $C_5H_{11}NH_2$, $C_7H_{15}NH_2$, $C_9H_{19}NH_2$, Et_2NH, $(HOCH_2CH_2)_2NH$, $(CH_2)_5NH$,



Usually a 2–6 fold molar excess of amine was used especially in the case of primary amines to suppress further reaction of products with the initial acid.

Investigation by TLC of the dependence of reaction rate on the pH of the medium showed the existence of an optimum region of pH values which was 7–9 for ethylamine, diethylamine and piperidine. At lower and higher pH values the reaction rate was sharply reduced. It was assumed that the optimum pH value must be lower than the pK_a of the nucleophile.[44–46] As was to be expected the sterically hindered *tris*-hydroxymethylaminomethane proved to be the least active. In difference to the indicated amines morpholine added at a high rate to the acid in the pH range 2–8.

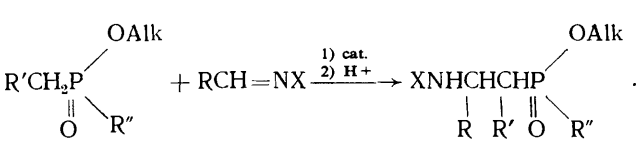
b) Addition of dialkyl phosphites to unsaturated nitrogen-containing compounds



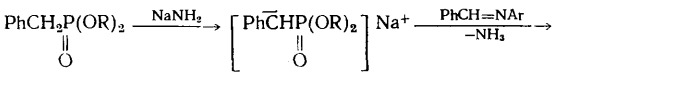
The addition of dialkyl phosphites to unsaturated compounds containing a carboxyl or carbonyl group has been described. The products were converted into amino compounds (by Hofmann, Curtius or Beckmann reactions).[11,50–52]

The ability of dimethyl phosphite to add to an activated carbon–carbon double bond has been demonstrated.[50] The phosphonic analogue of aspartic acid, where the β-carboxyl group is replaced by a phosphonate group, was obtained by the interaction of the methyl ester of *N*-acyl-α-aminoacrylic acid with dimethyl phosphite and subsequent hydrolysis.

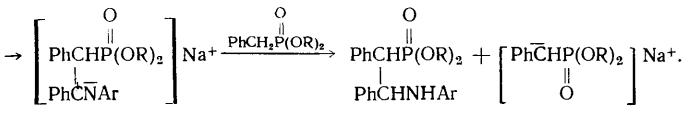
Soroka and collaborators[53] improved this method by using esters of methyl- or ethylphosphonic acids in place of dimethyl phosphite. As a result the corresponding phosphinic analogues of aspartic acid were formed.



Carbamoyl phosphonates were formed on reacting amides of unsaturated acids with diethyl phosphite in the presence of catalytic amounts of EtONa. AEP or its analogues were obtained after several conversions and hydrolysis.[51,52]

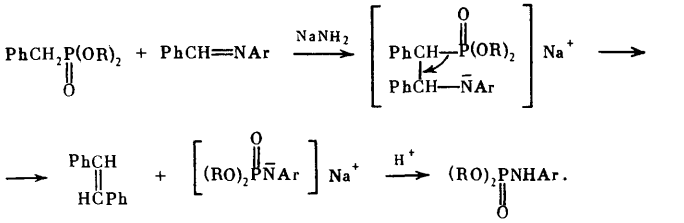


This reaction enabled AEP analogues to be obtained with various substituents on the α- and β-carbon atoms.[51]



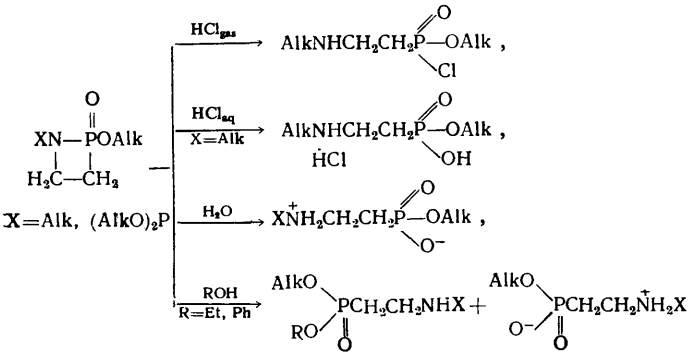
c) Addition of phosphonates at multiple carbon–nitrogen bonds

Aminophosphonates were obtained from Schiff's bases and phosphonates with an active methylene group in the presence of acidic or basic catalysts.[54–59]



The reactions were investigated in the presence or absence of catalysts ($AlCl_3$, $NaNH_2$, $LiNH_2$) in ether and liquid ammonia at various temperatures. The influence was studied of the position of the substituent in the phenyl nucleus located on the nitrogen atom of the Schiff's base on the rate and route of the reaction. Optimum conditions were established for forming aminophosphonates. The following reaction mechanism was proposed.

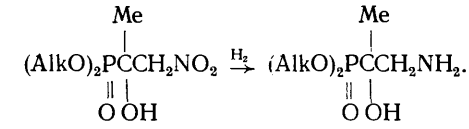
The reaction did not proceed without a catalyst. In the presence of an excess of catalyst breakdown of the intermediate probably occurs and olefins are formed.



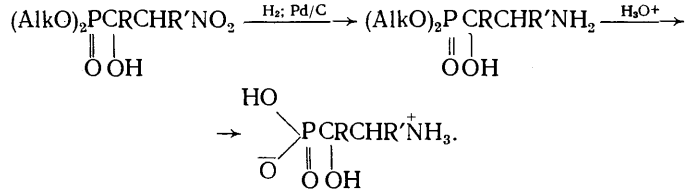
Chlorine in the *meta*-position of a benzene ring on the nitrogen atom increases the yield of aminophosphonate by 5–10%. The influence of electron-donating substituents varies depending on the position in the benzene ring. A methyl substituent in the *ortho*-position increases the yield of aminophosphonate, in the *para*- and *meta*-positions it aids dephosphorylation and the formation of olefins. The aminophosphonate is formed in 52–88% yield on reacting equimolar quantities of phosphonate and azomethine in the presence of catalytic amounts of sodium amide at 10–15 °C in ether.[54]

This method is very important since it affords the possibility of obtaining 1,2-substituted *N*-aryl-, *N*-carboxyl- and *N*-acylamino-phosphonates which are difficult to obtain by other routes.

4. Decomposition of 1,2-azaphosphetidines

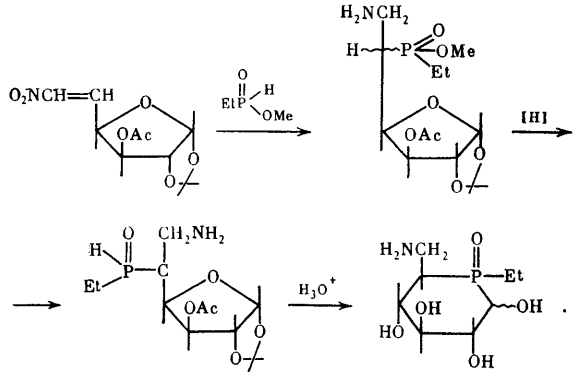


Monoesters of *N*-substituted aminoethylphosphonates are readily formed in almost quantitative yield by the action of hydrogen chloride, water or hydrochloric acid on 1,2-azaphosphetidines.[60–63] Diesters of aminophosphonates, together with the monoester, are formed on reaction with alcohol or phenol. Yields of mono- and diesters were not high because of the formation of reaction byproducts.



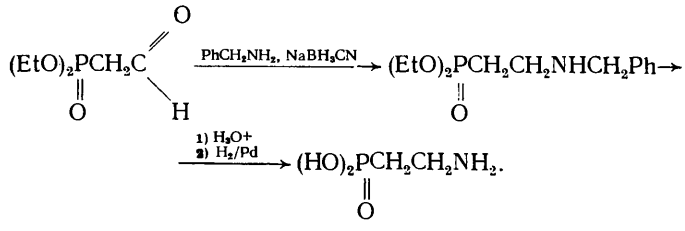
5. Reductive amination

a) Reduction of nitro compounds

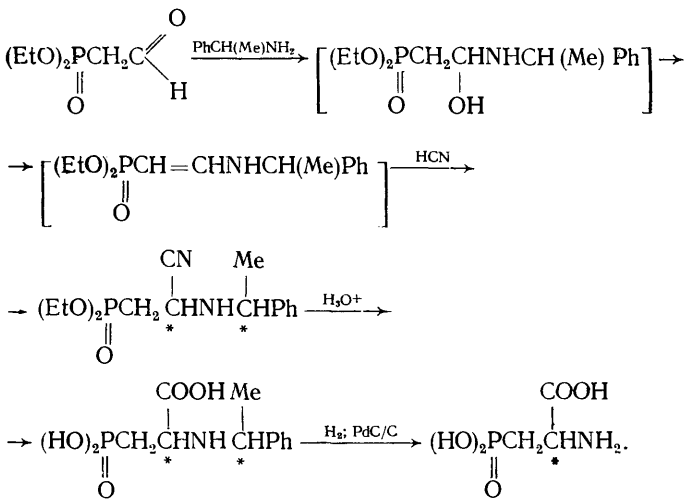


Aminophosphonates have been obtained by the reduction of nitro groups in phosphonates in the presence of Raney nickel catalyst.[64–67]

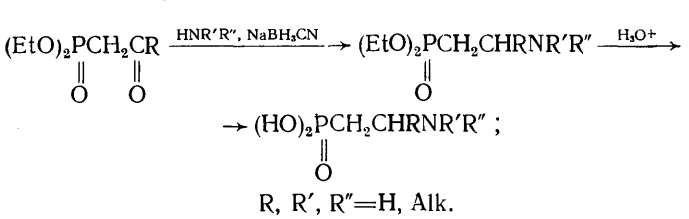
The hydrogenation of α-hydroxy-β-nitroalkylphosphonates over a neutral 5% palladium on carbon catalyst proved to be more successful. Aminophosphonates were obtained in high yield. They gave AEP analogues on hydrolysis with hydrochloric acid (1 : 1).[64–66,68,69]



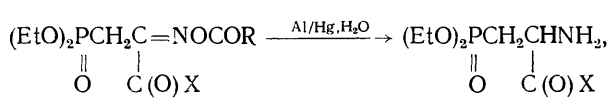
Japanese authors[70] have carried out hydrophosphorylation of a carbohydrate nitrovinyl derivative with the methyl ester of ethylphosphonic acid then reduction of the nitro and phosphono groups in the adduct obtained with the aim of taking off protecting groups. An original cyclisation reaction occurred.



b) Reduction of azomethines

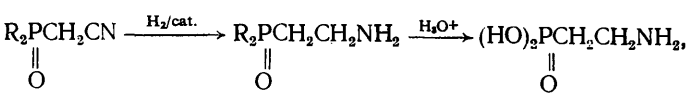


N-Benzylaminophosphonates are formed on condensing phosphonaldehydes with benzylamine in the presence of sodium cyanoborohydride.[71] Hydrogenolysis in the presence of palladium catalyst was used to remove the protecting *N*-benzyl and obtain a free amino group.



Phosphonaldehydes react with $S(-)$α-methylbenzylamine in the presence of HCN with the formation of optically active *N*-substituted aminophosphonates with an enantiomeric excess of 50%. Removal of the α-methylbenzylamino group by hydrogenolysis in the presence of a 10% palladium on carbon catalyst, followed by hydrolysis of the ester groups at the P atom with hydrochloric acid to obtain β-phosphonylalanine, occurred without epimerisation.[72]

Ketophosphonates,[73,74] like phosphonoaldehydes[71] also condense readily with amines in the presence of sodium cyanoborohydride. The reaction takes place in methanol at 20 °C and aminophosphonates are formed in high yield. β-Aminoethylphosphonic acids, either mono-*N*-substituted or containing a free amino group were obtained by hydrolysis of the ester groups at the P atom.[73]

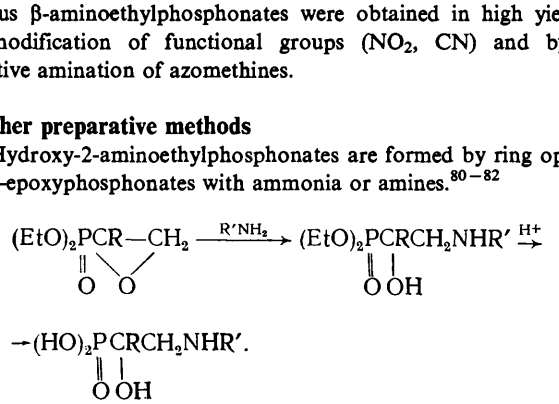


An interesting method of obtaining β-phosphonylalanine by reduction of *O*-acylated oximes with aluminium amalgam has been proposed.[75]

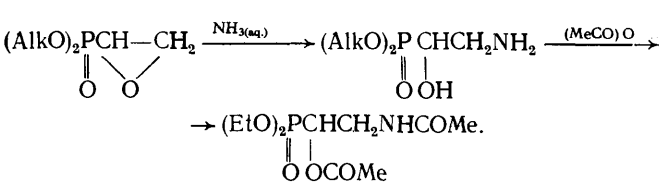
This method is convenient for the synthesis of various β-phosphorylated derivatives of α-aminopropionic acid.[75]

c) Reduction of the nitrile group

Aminoethylphosphonates are formed on reducing phosphonacetonitriles.[76–79]



Hydrogenation was carried out in alcoholic ammonia solution in the presence of Rh/Al_2O_3 catalyst[76] and other additives preventing polymerisation at the increased pressure of 3–4 atm.[78] Dimethyl amido- and diethyl cyanomethylphosphonates were readily hydrogenated in the presence of Raney nickel catalyst and on hydrolysis gave AEP.[77–79] Palladium (10%) on carbon was also used as catalyst for the reduction of the CN group in diethyl cyanomethylphosphonate.[79]

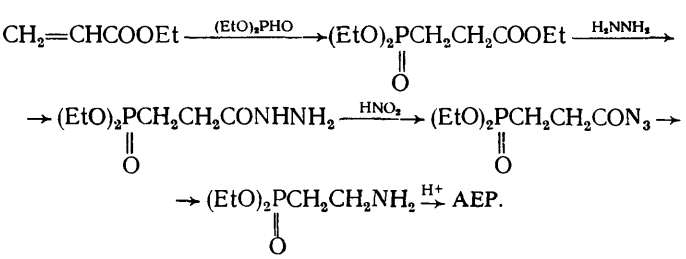


Thus β-aminoethylphosphonates were obtained in high yield by the modification of functional groups (NO_2, CN) and by the reductive amination of azomethines.

6. Other preparative methods

1-Hydroxy-2-aminoethylphosphonates are formed by ring opening of 1,2-epoxyphosphonates with ammonia or amines.[80–82]

The interaction of dialkyl 1,2-epoxyethylphosphonates with ammonia and with aniline has been investigated.[81] It was established that the reaction proceeded more readily with ammonia. With an excess of aqueous ammonia at 20 °C a distillable substance was obtained which was identified by conversion into the acetyl derivative.



With aniline reaction occurred at 120–125 °C and took 24 h.

A method has been patented for obtaining *N*-substituted aminodiphosphonates by the action of ammonia, arylamines and dialkylamines on 2,2-diphosphonyloxirane.[82]

A method has been proposed for obtaining AEP by a scheme comprising addition of diethyl phosphite to an unsaturated compound, several transformations and subsequent hydrolysis of the resulting diethyl β-aminoethylphosphonate.[11]

Aminophosphonates are formed in high yield on reacting diethyl β-bromoethylphosphonate with diethylamine or dibutylamine.

The reaction was effected by boiling with an excess of amine in aqueous solution.[83]

$$(EtO)_2PCH_2CH_2Br \xrightarrow[H_2O]{Et_2NH} (EtO)_2PCH_2CH_2NEt_2.$$

Reaction with aziridine was carried out in a similar manner in aqueous solution in the presence of triethylamine.[84]

$$(EtO)_2PCH_2CH_2Br \xrightarrow[Et_3N]{HN} (EtO)_2PCH_2CH_2N$$

Synthesis of a carbamate of β-aminophosphonic acid has been effected starting from the diester of β-phosphonocarboxylic acid. This was converted into the azide which was then subjected to a Curtius rearrangement to give the carbamate.[85]

$$(EtO)_2PCH_2CH_2COOH \xrightarrow[PhCH_2OH,\ Et_3N]{(PhO)_2PON_3} \rightarrow (EtO)_2PCH_2CH_2NHC(O)OCH_2Ph.$$

This reaction has been used to obtain *N*-substituted urethanes and ureas.[86]

$$(AlkO)_2PCH_2CH_2NCO \xrightarrow{Alk'OH} (AlkO)_2PCH_2CH_2NHCOOAlk',$$
$$(AlkO)_2PCH_2CH_2NCO \xrightarrow{ArNH_2} (AlkO)_2PCH_2CH_2NHCONHAr.$$

This phosphonic and phosphinic analogues of aspartic acid have been obtained using the Strecker reaction.[87,88]

$$R(EtO)P(O)CH_2CHO \xrightarrow[2)\ H_3O^+]{1)\ NaCN,\ RNH_2\cdot HCl} R(HO)P(O)CH_2CHNHR\cdot COOH.$$

β-Aminoethylphenylphosphinic acid was formed on oxidation of a phosphine with hydrogen peroxide.[89]

$$PhP(H)CH_2CH_2NH_2 \xrightarrow{2H_2O_2} PhP(O)(OH)CH_2CH_2NH_2.$$

Diesters of 2-benzylimidazolylmethylphosphonic acid were synthesised by reacting *C*-phosphorylated imidates with *o*-phenylenediamine.[90]

$$(RO)_2PCH_2C(=NH\cdot HCl)OR' \xrightarrow[-R'OH,\ -NH_4Cl]{-NH_2,\ -NH_2} \text{benzimidazole-}CH_2P(O)(OR)_2.$$

A method has been suggested for obtaining optically active β-aminophosphonates and -phosphinates.[21,91]

III. Properties

1. Physical properties

β-Aminoethylphosphonic and -phosphinic acids are colourless, high melting, crystalline substances, soluble in water, less well in ethanol, nitromethanol and other polar solvents. The potentiometric titration curve for the amino acids has three discontinuities corresponding to the three ionisation constants of these compounds.[12] As for other aminophosphonic acids, they have a zwitterionic structure.[8] Polymorphism is a characteristic of AEP, two crystalline forms of it are known, an α form of rhombic plates and a β of needles, which is more stable.[11,12,79] The melting point is near 280 °C, however depending on the form the melting point may vary up to 20 °C.[12]

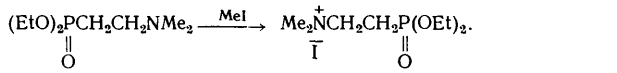
The diesters of *N*-alkylaminoethylphosphonic acids are colourless liquids, distillable in vacuum. The diesters of 1-hydroxy-2-aminoethyl phosphonic acids are thick viscous liquids, decomposing on distillation in vacuum.

There are broad absorption bands in the infra-red spectra of 1-hydroxy-2-aminoethylphosphonic acids in the 2700–3400 cm^{-1} region characteristic of the zwitterionic $PO^-\ldots NH_3^+$ with strong hydrogen bonds.[66] The zwitterionic structure is also confirmed by the presence of bands at 1620–1660 and 1520 cm^{-1} characteristic of NH and NH_3^+ deformation vibrations. The absorption frequency of the phosphoryl group is lowered to 1120–1150 cm^{-1}. An absorption band in the region of 3260 cm^{-1} is characteristic of OH group vibrations.

A significant low frequency shift was observed in the IR spectra of the mono ester of aminophosphonic acid[61] for the stretching vibrations of the N–H group in the 2750–2400 cm^{-1} region in comparison with the IR spectrum of the diester [ν(NH) 3280 cm^{-1}], where it was overlapped by the bands of C–H stretching vibrations,[61] which is characteristic for quaternary ammonium bases. The splitting of P=O group stretching vibrations in the 1230–1190 cm^{-1} region indicates the formation of associates.

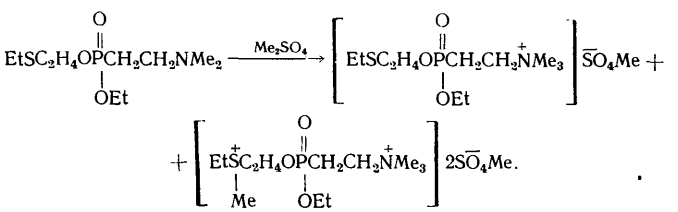
A specific absorption for the amino group of AEP esters was detected in the 3500–3300 cm^{-1} region.[75]

The ^1H and ^{31}P NMR spectra have been studied in detail.[19,21–24,28,41,49,61,62,67,71–75,77,80,81,85,87,88,91,92]



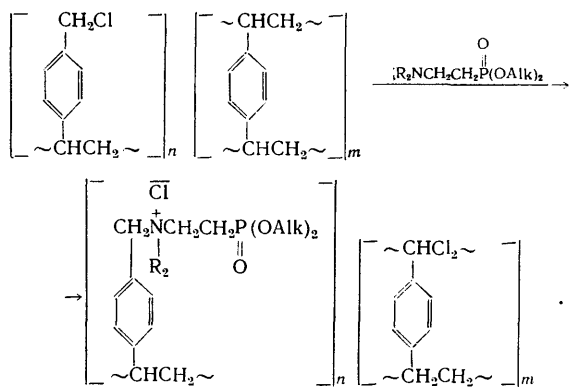
2. Chemical properties

a) Interaction with electrophilic reagents



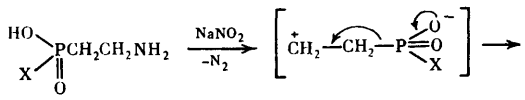
The diesters of *N*-monosubstituted aminophosphonates display the properties of proton-containing nucleophiles. They are readily phosphorylated by dialkyl chlorophosphites in the presence of triethylamine, are alkylated by alkyl halides, and add to isocyanates and *N*-oxides.[19,28,61,75]

$$(EtO)_2PCH_2CH_2NHR \xrightarrow[Et_3N]{(AlkO)_2PCl} (AlkO)_2PN(R)CH_2CH_2P(O)(OEt)_2,$$
$$(EtO)_2PCH_2CH_2NHR \xrightarrow[Et_3N]{(AlkO)_2POCl} (AlkO)_2PN(R)CH_2CH_2P(O)(OEt)_2,$$
$$(EtO)_2PCH_2CH_2NHR \xrightarrow[R=H,\ Alk]{R'NCO} R'NHCON(R)CH_2CH_2P(O)(OEt)_2,$$
$$(EtO)_2PCH_2CH_2NHR \xrightarrow{ArC\equiv N\rightarrow O} ArCN(R)CH_2CH_2P(O)(OEt)_2,$$
$$(EtO)_2PCH_2CH_2NHR \xrightarrow[R=P(O)(OAlk)_2]{AlkHal} RN(Alk)CH_2CH_2P(O)(OEt)_2.$$



N-Disubstituted aminophosphonates are also readily alkylated by methyl iodide or dimethyl sulphate with the formation of salts, viz. the iodides or methosulphates of the corresponding aminophosphonates.[31,33,93]

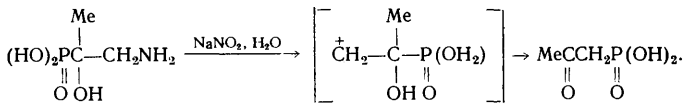
On reacting *O*-ethyl-*O*-(β-ethylmercaptoethyl)-β-dimethylaminophosphonate with dimethyl sulphate the *N*-methyl methosulphate and *N*,*S*-dimethyl dimethosulphate were formed in the ratio 1 : 2.[33]



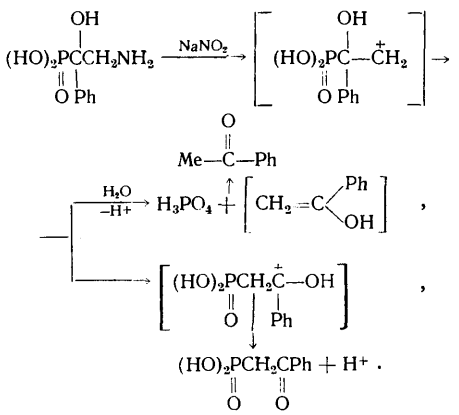
N-Disubstituted aminophosphonates react with the chloromethylated copolymer of styrene with divinylbenzene in a similar manner.[94] The reaction is usually carried out in a medium of the aminophosphonate at 90 °C in a nitrogen atmosphere.

b) Diazotisation

The diazotisation of aminophosphonates and -phosphinates has been studied.[26,69,95] It was established that the reaction proceeded through a carbocation intermediate and, depending on the structure, may go by two routes: rearrangement with migration of the phosphono group to a carbon atom with reduced electron density[95] or decomposition (fragmentation) with the formation of unsaturated compounds and inorganic phosphate.[26,69]



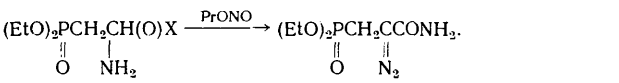
Diazotisation of aminophosphonates and -phosphinates containing an OH-group on the phosphorus atom is usually accompanied by fragmentation with the formation of olefins (in 70–80% yield), inorganic phosphate, vinylphosphonic acids and other contaminants.[26] The reaction was carried out with sodium nitrite in aqueous solution at 100 °C.



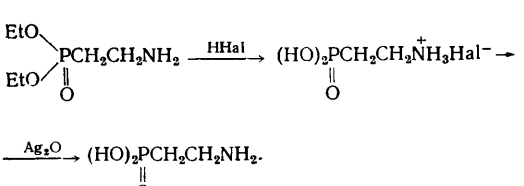
→ $CH_2=CH_2$ + inorganic phosphate,

X = OH, Ph.

When two substituents (methyl and OH-group) are present on the α-carbon atom a rearrangement occurs with migration of the phosphonic fragment and formation of 2-ketopropanephosphonic acid.[80]

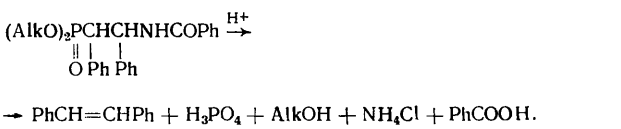


If the substituents on the α-carbon atom are OH and Ph then mainly (80%) rearrangement and only insignificant (7%) fragmentation occurs.[69]

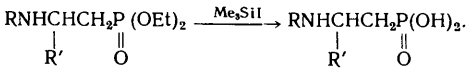


The reaction takes place at room temperature.

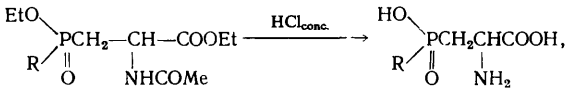
A diazo compound is formed on diazotising aminophosphonate with propyl nitrite in the presence of catalytic amounts of acetic acid.[75]



c) Hydrolysis

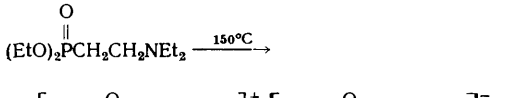


Conversion of esters of β-aminoethylphosphonic acids into the free acids is usually effected by hydrolysis in acid medium. Hal^- is removed using silver oxide,[26] propylene oxide, butylene oxide,[23,40,50] sodium hydroxide,[61] or aniline[66,68] or an aqueous solution of the aminophosphonate hydrochloride is passed through a column of Dowex 50W-X2 (H-form) ion exchange resin.[41,53,75]

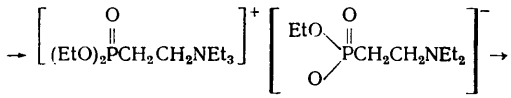


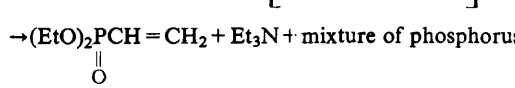
Exceptions are diesters of 1,2-diphenyl-substituted aminophosphonates which are decomposed on boiling in 20% HCl with the formation of olefin.[58]

Esters of aminophosphonic acids are converted into acids by the action of trimethylsilyl iodide[23] or trimethylsilyl bromide.[92]



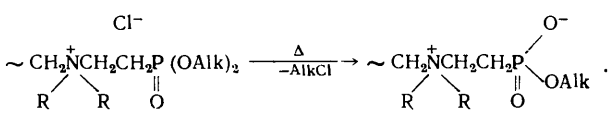
An *N*-acetyl group on an aminophosphonate may be converted into a free amino group by boiling with an excess of HCl for 10–12 h.[53]



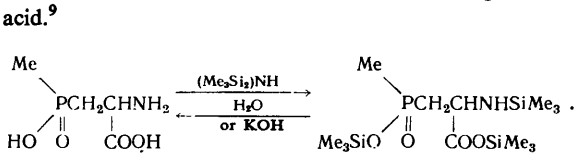


R = Me, Et, EtO.

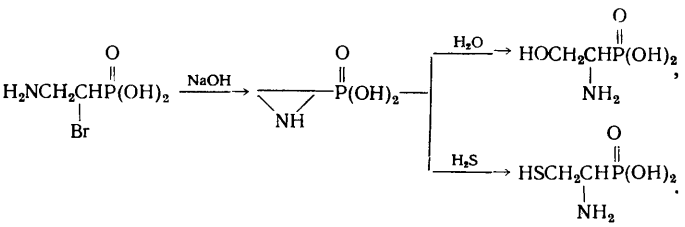
d) Stability



Diesters of 1-hydroxy-2-aminoethylphosphonic acid have low stability,[66,68] are decomposed on distillation[81] and were isolated as picrates which are then used for their purification and identification.[66,68] In contrast the diesters of β-aminoethylphosphonic acid are stable under normal conditions. On heating at 150 °C for 34 h they are decomposed with the formation of diethyl vinylphosphonate, triethylamine and a mixture of oxyacids of phosphorus.[17] It was proposed that an intermolecular reaction occurred with the formation of an intermediate salt which decomposed and gave diethyl vinylphosphonate. The presence of triethylamine was explained by an intramolecular alkylation.



On heating the diester of an *N*-polymer-containing β-aminoethylphosphonic acid at 130 °C an intramolecular ionic rearrangement occurs with the formation of the monoester.[94]



e) Other reactions

On reacting an aminoethylmethylphosphinic acid with an excess of hexamethyldisilazane an *N*-silylated derivative is formed which on treatment with water or alcohol is converted once again into the initial acid.[9]

This method has been proposed for purifying such compounds.[9]

α-Bromo-β-aminoethylphosphonic acid is cyclised in an alkaline medium to aziridinephosphonic acid.[41,42] Fission of the aziridine ring by the action of water or hydrogen sulphide leads to the formation of the phosphonic analogues of serine and cysteine respectively.

It is possible in this way to go from β-aminophosphonic to α-aminophosphonic acids.

IV. Applications

Diesters of aminophosphonic acid possess bactericidal, fungicidal and also antipyretic action.[76,96]

β-Amino-substituted phosphonates and -phosphinates display high extraction properties.[6,7,48,91,94,98] Their important advantage is the combination of good selectivity with high extractive ability.

N-Substituted phosphonic acids have been proposed as extractants and for imparting fire-resistant properties to cellulose material.[82] They possess complexing ability, immunotropic activity and may find application as chelating complexants for multicharged ions, flotation agents, and pharmaceutical preparations.[44,46]

β-Phosphonylalanine displays antiblastic action.[88] The introduction of a CH_3 group in place of an OH at phosphorus sharply reduces the cytostatic activity.[88]

The synthesis of medicinal preparations based on β-aminophosphonic acids is promising.[5,23]

The material presented shows the promise of these compounds. It is possible to be confidant that these compounds will find wide application not only in laboratory practice, but also in medicine, agriculture and other branches of the national economy.

IV. Reactions of sulphilimines 824

I. Introduction

The chemistry of sulphilimines or ~~sulphimides~~[1] originated in 1917 after the discovery[2] of the oxidative imination of sulphides, which resulted in a solution to the problem of contamination by mustard gas. Starting from this period the chemistry of sulphilimines has evolved quite rapidly and at the present time is a relatively well-developed branch of organoelemental chemistry.

Convenient preparative methods for obtaining sulphilimines have been developed, their properties have been studied thoroughly, and areas of their practical application have been found.

The interest shown in the chemistry of sulphilimines by many research workers is mainly due to the synthetic importance of these compounds. The lability of the S(IV)=N bond, its ability to be cleaved by both nucleophilic and electrophilic reagents, and also the two active reaction sites (sulphur and nitrogen) provide sulphilimines with the properties of valuable reagents for organic synthesis.

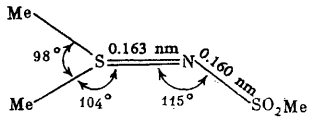
On the other hand, some examples of this class of compounds have the properties of antioxidants of polyolefins[3] and herbicidal, bactericidal, and pharmacological reagents, which also stimulates a particular interest. The chemistry of sulphilimines up to 1976 is covered by several review articles,[1,4,5] one of which[1] is exhaustive. However, since the time of publication of these articles a considerable amount of new information that requires correlating has accumulated, and this has provided the contents of the present review.

II. Nature of the S(V)=N bond and structure of sulphilimines

There is no common view about the nature of the S(IV)=N bond in sulphilimines and in other imino compounds of sulphur, although much attention has been given to this question in the literature.[6–22] This is because the S(IV)=N bond is different from a normal double bond since for elements of the third and subsequent periods of the Periodic Table of chemical elements the overlap of *p*-atomic orbitals (*p*-AOs) is energetically unfavourable. At the same time the structural features positively indicate the multiple nature of this bond but with a low π-order and with a length greater than the corresponding sum of the covalent radii and a high polarity and low potential barrier of internal rotation which does not allow diastereomeric compounds to occur as a result of hindered rotation about the S(IV)=N bond. The lability of the S(IV)=N bond varies over a wide range according to the nature of the substituents on the sulphur and nitrogen atoms. An analysis of these factors and also an analysis of information about the nature of the E=N bond of other organoelemental compounds provided a basis for the assumption that the *d* orbitals of the sulphur atom participate in the formation of the S(IV)=N bond in sulphilimines. This assumption incorporates three basic theories developed during recent years about the nature of the S(IV)=N bond in sulphilimines.

1. The S(IV)=N bond is a normal double bond in which a second bond is formed as a result of overlap between the *p* orbitals of the nitrogen atoms and *d* orbitals of the sulphur atom that have the corresponding symmetry.

2. The S(IV)=N bond is a semipolar bond in which a σ-bond is formed from AOs of *p* type from the sulphur and nitrogen atoms and the second bond is ionic, stabilised through the formation of a charge transfer complex from the electron-rich nitrogen atom (=NR groups) to the sulphur atom with a positively charged R_2S skeleton.



3. The S(IV)=N bond is a double bond in which the π-bond is stabilised through the interaction of the p_π (or *n*) orbitals of the nitrogen atom with the d_π orbitals of the sulphur atom or by a hyperconjugation effect which occurs as a result of the interaction between the unshared electron pair of nitrogen with the electrons of the antibonding σ orbitals of the neighbouring S–C bond ($n_N-\sigma_S^*$ interaction).

A detailed analysis of these three theories about the nature of the S(IV)=N bond, including quantum-mechanical calculations, structural and spectroscopic data, did not lead Egorov[21] to any definite conclusion about the nature of the S(IV)=N bond in sulphilimines. It was stated[21] that sulphilimine molecules $R_2S=NY$ and compounds isoelectronic to them are characterised by a mobile π-electron system, including as an important factor 3*d* orbitals, the population of which increases with an increase in the effective electronegativity of the substituents on the S atom and decreases in the presence of π-electron-acceptor groups on the nitrogen atom. The stabilisation energy of the S(IV)=N bond through $d_\pi-p_\pi$ conjugation is generally small and varies according to the same sequence of change in properties of substituents R and Y. Stabilisation is achieved to a greater extent through the electrostatic interaction between sites with opposite charges—the $R_2\overset{+}{S}$ and $N\overline{Y}$ groups.

On this basis Egorov[21] has proposed that the electronic structure of the S=N bond can be represented as three main resonance structures:

$$S{=}\ddot{N}{-}Y \leftrightarrow \overset{+}{S}{-}\overset{-}{\ddot{N}}{-}Y \leftrightarrow \overset{+}{S}{-}\ddot{N}{-}\overline{Y}.$$

The crystalline and molecular structures of *S*, *S*-dimethyl-*N*-methanesulphenylsulphilimine and certain *N*-arenesulphonylsulphilimines, derived using X-ray diffraction analysis, have been reported in the literature.[6,7,13,15,21] A characteristic feature of these structures is that the tetracovalent sulphur atom together with its surrounding valence bonds forms a trigonal pyramid which is quite stable towards pyramidal inversion, and this is also confirmed by the fact that sulphilimines with suitable substituents can exist in enantiomeric forms caused by the chirality of the sulphur atom. Characteristic bond lengths and bond angles are given below for a typical example of a sulphilimine—*S*,*S*-dimethyl-*N*-methansulphonylsulphilimine

The two C–S(IV) bonds in the molecule of this sulphilimine have different lengths (0.180 nm and 0.178 nm) in the crystalline state, while in solution or the liquid state these bonds are almost equal, which is due to the relatively low rotational barrier of the S(IV)=N bond, the magnitude of which can be assessed from the results of calculations on the hypothetical molecule of $H_2S{=}NH$ (9.60 kcal mol^{-1}).[23] The average length of the S(IV)–C bond is less than the sum of the respective covalent radii (0.183 nm), which is attributed to the possible hyperconjugative type of interaction between the Me groups and the sulphur atom. The bond lengths and bond angles in the molecules of other sulphilimines have very similar values (Table 1). A comparison of the physical parameters of the E=N bond (E = S, Se, Te) of sulphilimines, selenimines,[23] and tellurimines[24] revealed an increase in the length of this bond on going from sulphur to tellurium, which is consistent with the increase in covalent radii of the respective elements.

The frequencies of the stretching vibrations of the S(IV)=N bond (symmetrical and antisymmetrical), according to the literature data,[4,17–19,21] occur over a broad spectroscopic region from 750 to 1400 cm^{-1}, which leads to the assumption that the π-system of the S(IV)=N bond is highly polarisable. It is natural that the high polarisability of the bond is responsible for the considerable dependence of the position of the absorption bands on the nature of the groups on the sulphur and nitrogen atoms, having also a considerable effect on the polarity of the S(IV)=N bond, which varies over a wide range from 1.56 to 10.1 D.[25]

III. Methods for the synthesis of sulphilimines

All methods known at the present time for the synthesis of sulphilimines are based on the use of sulphides and sulphoxides and other tetracovalent sulphur compounds as the initial reactants.

1. Synthesis of sulphilimines from sulphides

a) Oxidative imination of sulphides with *N*-halo compounds

The reactions which are accompanied by the oxidation of an element and formation of an imino group are usually known as oxidative imination.[26] The oxidative imination of sulphides was first discovered by Raper,[2] who showed that mustard gas (β,β′-dichlorodiethyl sulphide) reacts with sodium *N*-chloro-*p*-toluenesulphonamide to form a physiologically inactive compound. It was reported by Nicolet and Willard[27] in 1921 that the product of the reaction between diethyl disulphide and sodium *N*-chloro-*p*-toluenesulphonamide was a colourless crystalline compound. Nicolet and Willard[27] were not able to establish the structure of this compound, and it was only in 1922 that Mann et al.[28] showed that the reaction between disulphides and sodium *N*-chlorosulphonamides results in the formation of sulphilimines.

$$R{-}S{-}R + ArSO_2NNaCl \rightarrow RRS{=}NSO_2Ar + NaCl,$$

R = Et, $ClCH_2CH_2$; Ar-*p*-MeC_6H_4.

However, not all sulphides are capable of reacting with sodium *N*-chlorosulphonamides to form sulphilimines. It was reported as early as 1922 by Mann and Pope[28,29] that an increase in the number of chlorine atoms in the alkyl groups of the sulphides reduces the capacity of the latter to undergo imination with sodium *N*-chlorosulphonamides. Leandri and Spinelli[30] showed for the reaction between sodium *N*-chloro-*p*-toluenesulphonamide with the bis-sulphides RS–X–Sr (X = Ph, –CH=CH–, $-CH_2-$, $-CH_2-CH_2-$, and others) that both terminal and internal electron-acceptor groups inhibit the process of imination and the *p*-toluenesulphonylimino group introduced as a result of imination of the first sulphur atom inhibits imination of the second sulphur atom. Therefore bis-sulphilimines were only obtained in the case of bis-sulphides in which the sulphur atoms were separated by three or more methylene groups.

Table 1. S(IV)=N bond lengths and angles in sulphilimines $RR^1S{=}NR^2$.

Et	Et	$CHCl_2CO$	0.1633	103.8 (99.2)	99.3	[21]

*The second C–S(IV)–N angle is given in brackets.

The effect of the groups on the sulphur atom on the ability of sulphides to undergo imination with sodium *N*-chlorosulphonamides was studied in greater detail by Kucsman et al.[31–34] They established that in the case of the reaction between sulphides and

sodium *N*-chlorosulphonamides in aqueous media that the corresponding sulphoxides are formed together with *N*-arenesulphonylsulphilimines

$$R_2S + ArSO_2NNaCl \xrightarrow{H_2O} \begin{cases} \rightarrow R_2S=NSO_2Ar + NaCl \\ \rightarrow R_2S=O + ArSO_2NH_2 + NaCl \end{cases}$$

In this case the ratio of sulphilimines to sulphoxides depends on the nature of the groups on the sulphur atoms in the initial sulphide, the pH of the reaction medium, and the type of solvent used. In the opinion of Kucsman et al.,[31,32] the ability of sulphides to undergo imination with sodium *N*-chlorosulphonamides is determined by the degree of electron density on the sulphur atom, which should be sufficiently high for the sulphur atom to be able to displace the chloride anion on the nitrogen atom of the *N*-chloroamide, in other words, Kucsman et al. considered that imination of sulphides occurred by nucleophilic substitution and that the formation of sulphoxides was due to the hydrolysis of sulphilimines. They subsequently concluded[35,36] that the imination of sulphides with sodium *N*-chlorosulphonamides was more complex. In their opinion, the sodium *N*-chlorosulphonamide undergoes conversion in an aqueous alcoholic medium as a result of an equilibrium reaction to *N*-chlorosulphonamide (rapidly) and to *N,N*-dichlorosulphonamide (slowly), which are quite reactive electrophilic reagents

$$2ArSO_2NNaCl \overset{H_2O}{\rightleftarrows} 2ArSO_2NHCl + NaOH,$$

$$ArSO_2NHCl \rightleftarrows ArSO_2\bar{N}Cl + H^+,$$

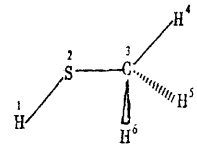
$$ArSO_2NHCl + ArSO_2\bar{N}Cl \rightarrow ArSO_2NCl_2 + ArSO_2\bar{N}H.$$

The formation of *N*-chlorosulphonamides and *N,N*-dichlorosulphonamides was also reported in other studies,[37–39] and the participation of *N,N*-dichlorosulphonamides in this process is supported by their use as iminating agents on reacting with sulphides,[40–43] which, however, is frequently accompanied by other side reactions.

On reacting with *N*-chlorosulphonamides or *N,N*-dichlorosulphonamides, sulphides form a chlorosulphonium cation $R_2\overset{+}{S}Cl$, which reacts with a sulphonamide anion $ArSO_2\bar{N}X$ (X = H, Cl) to form a sulphilimine, while hydrolysis of the chlorosulphonium cation gives a sulphoxide[35,44,45]

$$R_2S + ArSO_2NClX \rightarrow R_2\overset{+}{S}Cl + ArSO_2\bar{N}X,$$

$$R_2\overset{+}{S}Cl \begin{cases} \xrightarrow{ArSO_2\bar{N}X} R_2S{=}NSO_2Ar + XCl \\ \xrightarrow{\bar{O}H} R_2S{=}O + HCl \end{cases}$$



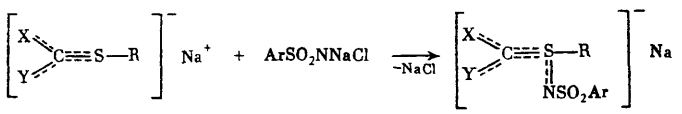
This interpretation of the mechanism for oxidative imination of sulphides with sodium *N*-chlorosulphonamides is consistent with the effect on this process of different factors, namely, the pH of the medium, the type of solvent used, and the nature of the groups on the sulphur atom in the initial sulphide. A low pH of the medium assists the conversion of sodium *N*-chlorosulphonamide to the more active *N*-chloro- and *N,N*-dichloro-sulphonamides but reduces the probability of the existence of the sulphonamide anion. According to the results of Tsujihara et al.[45] in the case of the imination of dialkyl and alkyl aryl sulphides with sodium *N*-chloro-*p*-toluenesulphonamide, a pH of 6 is the most favourable. As solutions of sodium *N*-chlorosulphonamides are alkaline, the addition of a small quantity of acetic acid to the reaction medium increases the yield of sulphilimines.[46–48] Because of the low solubility of sodium *N*-chlorosulphonamides in organic solvents, aqueous solutions of methanol, acetone, dioxan are used as the reaction medium for imination of sulphides as are two-phase media such as water–methylene dichloride, which naturally reduces the yield of sulphilimines and assists the formation of sulphoxides. Yamamoto et al.[49] showed that the use of anhydrous organic solvents such as methylene dichloride as the reaction medium and *N*-chloro-*N*-(dialkylamino)arylsulphonamides, which are readily soluble in these solvents, instead of sodium *N*-chlorosulphonamides, results in the sole formation of sulphilimines in quantitative yield

$$R_2S + R^1(R^2)NN(Cl)SO_2Ar \rightarrow R_2S{=}NSO_2Ar + R^1R^2NCl.$$

When two-phase reaction media are used, phase-transfer catalysts also help to increase the yield of sulphilimines.[50,51]

The susceptibility of the sulphur atom in a sulphide to electrophilic attack by a chlorine cation depends directly on the magnitude of its electron density, which is determined by the nature of the groups on the sulphur atom. Electron-acceptor groups on the sulphur atom in the sulphide hinder imination or make it impossible. Hence, the search for and development of methods for increasing the electron density on the sulphur atom in sulphides is important in terms of theory and synthesis. An analysis of the effective charges on the sulphur atom in the methanethiol molecule and its carbanion, obtained by quantum-mechanical calculations using the CNDO/2 method (Tables 2 and 3) shows[52] that one such method is to form an α-carbanion site in the sulphide molecule.

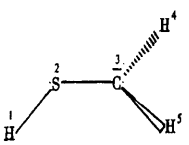
Table 2. Order of σ bond (*P*) and effective atomic charges (*q*) in the methanethiol molecule.[52]



Atom No.	*q*	Bond	*P*
1	−0.011	1–2	0.685
2	−0.043	2–3	0.773
3	−0.059	3–4	0.664
4	0.043	3–5	0.665
5	0.035	3–6	0.665
6	0.035	—	—

A reduction in electron density on the sulphur atom from the effect of electron-acceptor groups in the molecule of the initial sulphide should be balanced in a carbanion by the displacement of charge from the carbanion site.

Koval' et al.[53] demonstrated the basic possibility that arylsulphonylimination of diacylmethyl aryl sulphides containing a mobile α-H atom together with electron-acceptor groups can occur, but the sulphilimines resulting in this case undergo further conversions as a result of imino–ylide tautomerism. The use of their sodium salts instead of these sulphides assists the



arylsulphonylimination of these compounds in anionic form, as well as the stabilisation of the anion of the resulting *N*-arylsulphonylsulphilimines.[52,54–56]

$R = 2\text{-}NO_2C_6H_4$, $4\text{-}NO_2C_6H_4$, $2,4\text{-}(NO_2)_2C_6H_3$; X = Y = PhCO, X = Y = MeCO, X = Y = CN, X = Y = EtOCO;

X = MeCO, Y = EtOCO.

Table 3. Order of σ bond (*P*) and effective atomic charges (*q*) in the methanethiol carbanion.[52]

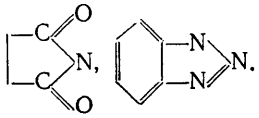
Other *N*-chloro compounds such as chloramines,[57] *N*-chlorocarboxamides,[58] *N*-chlorourethane,[59] *N*-chloroamidines,[60] *N*-chloroguanidines,[61] and *N*-chlorourea and its derivatives[62,63] react with dialkyl and alkyl aryl sulphides to form aminosulphonium salts, which are converted by bases to the corresponding sulphilimines.



$$R_2S + XNHZ \rightarrow R_2\overset{+}{S}NHZX^- \xrightarrow[-HX]{HB} R_2S{=}NZ,$$

HB – base; X = Cl, Br; Z = H, Alk, Ar, Hetar, AlkCO,

ArCO, EtOCO, R—C(=NR)—, NH_2—N=CH—, NH_2CO.

Sources of chlorine cations are also provided by chlorine,[64] t-butyl hypochlorite,[65–69] sulphuryl chloride,[70] *N*-chlorosuccinimide,[64,71,72] and other heterocyclic *N*-chloro compounds,[64] which react with sulphides at low temperatures to form chlorosulphonium intermediates that are converted by *N*-nucleophiles to sulphilimines.

$$R_2S + Cl{-}Z \rightarrow [R_2\overset{+}{S}{-}Z]\overline{Cl} \xrightarrow{R'NH_2} R_2\overset{+}{S}NHR'\overline{Cl} \xrightarrow[-HCl]{HB} R_2S{=}NR',$$

Z = Cl, t-BuO, SO_2Cl, 

Aliphatic, aromatic, and heterocyclic amines, *N*-aminophthalimide, cyanamide, and sodium sulphonamides and carboxamides are used as *N*-nucleophiles.

b) Oxidative imination of sulphides with hydroxylamine derivatives

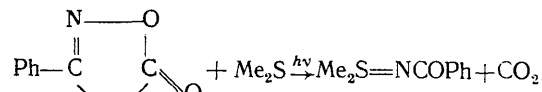
The oxidative imination of sulphides with hydroxylaminosulphuric acid, first described by Appel and Buchner,[73,74] is a specific case of the general imination of sulphides with hydroxylamine derivatives and particularly with *N*-arylsulphonyl-*O*-*p*-nitrophenylsulphonylhydroxylamine,[75] *N*-ethoxycarbonyl-*O*-*p*-nitrophenylsulphonylhydroxylamine,[75] and *O*-mesitylsulphonylhydroxylamine.[76,77]

$$R_2S + XNHOY \rightarrow R_2\overset{+}{S}NH(X)\overline{O}Y \xrightarrow[-YOH]{HB} R_2S{=}NX,$$

X = H, $ArSO_2$, EtOCO;

Y = HSO_3, $2,4,6\text{-}(Me)_3C_6H_2SO_2$, $4\text{-}NO_2C_6H_4SO_2$.

The mechanism of this reaction has not been studied, but it is possible from literature data[26] on the oxidative imination of tertiary phosphines with hydroxylaminosulphuric acid to suggest that there are two mechanisms, one involving the generation of an imene ṄH and the other, more probable, mechanism involving nucleophilic attack by sulphide on the electron-deficient nitrogen atom.

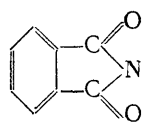


c) Reaction of sulphides with nitrenes

Sulphilimines are formed in good or moderate yield by reaction of sulphides with nitrene generated by photochemical, thermal, and chemical methods. A method involving the photolysis of different organic azides in the presence of an excess of disulphide is the most widely used.

$$XN_3 \xrightarrow{h\nu} NX: \xrightarrow{R_2S} R_2S{=}NX,$$

X = $ArSO_2$, PhCO, EtOCO, R_2PO and others.

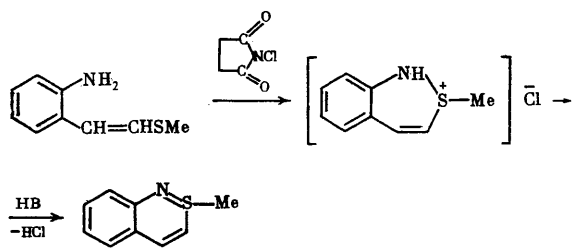


The reaction has been studied in a series of arenesulphonyl,[78] acyl,[79] alkoxycarbonyl,[79] diphenylphosphonyl and dialkylphosphonyl[80] azides. It has been proposed[81] that sulphides react more rapidly with singlet than with triplet nitrenes since the presence in the reaction mixture of products that give rise to the formation of triplet nitrenes inhibits the formation of sulphilimines. The low yields of sulphilimines may be due to their photochemical instability. At the same time during photolysis the sulphilimines themselves are sources of nitrenes, as has been noted[79] in the case of the photolysis of *S,S*-dimethyl-*N*-ethoxycarbonylsulphilimine. Sources of nitrenes are also provided by certain unstable heterocyclic compounds, photolysis of which in the presence of sulphides results in the formation of sulphilimines[82]

The main disadvantage of the method for synthesising sulphilimines by reaction between sulphides and thermally generated nitrenes is the thermal instability of the resulting sulphilimines, which has been observed in the case of the thermolysis of acyl azides,[83] alkoxycarbonyl azides,[83,84] and arylsulphonyl azides[83,85] in the presence of sulphides. It has been shown[86] that in the presence of copper the thermolysis of azides, and hence the reaction between nitrenes and sulphides, occurs at a lower temperature, which helps to increase the yield of sulphilimines.

Chemical generation of nitrenes in order to obtain sulphilimines has been used less often. In the literature there have been reports on only a few sulphilimines by reaction between sulphides and arenesulphonamides[87,88] and *N*-aminophthalimide[1] in the presence of lead tetraacetate

$$R_2S + NH_2X \xrightarrow{Pb(OAc)_4} R_2S{=}NX,$$



$X = ArSO_2$, 

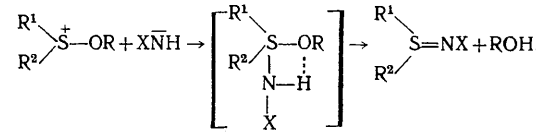
It cannot be excluded that the formation of sulphilimines in the reaction between sulphides and compounds with an E=N bond (E = S, I), as reported in the literature,[89,90] also occurs via a stage involving generation of nitrenes

$$R_2S + X{=}NTs \rightarrow R_2S{=}NTs,$$
$$X = TsN{=}S,\ ArI$$

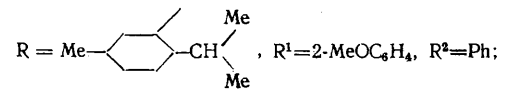
d) Oxidative cyclisation of aminosulphides

On treatment with *N*-chlorosuccinimide, aromatic amines containing alkylthio groups at the *ortho*-position form cyclic aminosulphonium salts, which in the presence of bases are converted to cyclic sulphilimines[91,92]

2. Synthesis of sulphilimines from sulphoxides



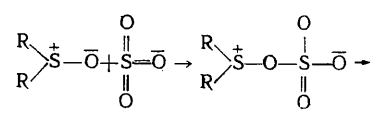
a) Condensation of sulphoxides with amides and amines in the presence of activating electrophilic reagents



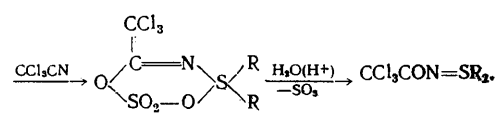
This method involves the generation of active sulphonium salts by the attack of an electrophile on the oxygen atom of a sulphoxide, which is converted to an effective leaving group

$$R_2S{=}O \xrightarrow{E^+} R_2\overset{+}{S}OE \xrightarrow[-HOE,\ -H^+]{R^1NH_2} R_2S{=}NR^1,$$
E – electrophile.

Phosphorus pentoxide,[93] trifluoroacetic anhydride,[93,94] sulphur trioxide, sulphuric acid, and boron trifluoride[95] have been used as activating electrophiles. Amides of sulphonic and carboxylic acids and certain amines have been used as *N*-nucleophiles. A number of sulphilimines have been obtained by the reaction of sodium sulphonamides and carboxamides with alkoxysulphonium salts.[68,96]

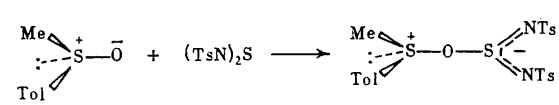


The reaction is stereospecific and occurs with retention of configuration at the sulphur atom, which in the opinion of research workers is due to the formation of an intermediate four-membered cyclic compound which is stabilised by an intramolecular hydrogen bond.



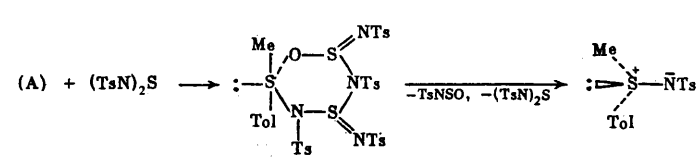
X=$ArSO_2$, CH_2ClCO, $CHCl_2CO$, CCl_3CO, CF_3CO.

The sulphonium salts formed by reaction of sulphoxides with sulphur trioxide react with nitriles to form sulphinylimines.[97] The proposed mechanism of this reaction involves attack by the electron-deficient carbon atom of the nitrile group on one of oxygen atoms of the sulphonium salt, which only takes place for nitriles containing strong electron-acceptor groups:



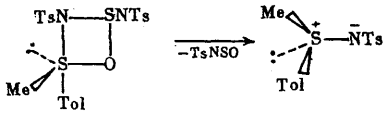
b) Condensation of sulphoxides with *N*-substituted amides

With certain *N*-substituted amides containing groups with polar double bonds as substituents, condensation of sulphoxides takes place in the absence of activating electrophilic reagents.[98–101]



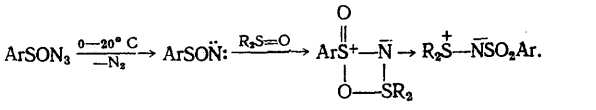
$$R_2S{=}O + YN{=}X \rightarrow R_2S{=}NY + XO,$$
$$X = SO,\ CO,\ S{=}NSO_2Ar,\ SCl_2;\ Y = ArSO_2,\ RCO,\ EtOCO,\ Ar.$$

The condensation mechanism has been studied in detail in the case of the reaction between methyl *p*-tolyl sulphoxide and *N,N'*-bis(*p*-toluenesulphonyl)sulphurdiimide.[102] It involves attack by the electron-deficient atom of the polar group on to the oxygen of the sulphoxide to form the sulphonium salt (A), whose subsequent conversion is determined by the nature of the solvent.



(A)

In pyridine, reaction of the sulphonium salt with a second molecule of sulphurdiimide results in the formation of a six-membered transition state, whose conversion to a sulphilimine is accompanied by inversion of configuration at the chiral sulphur atom.



In benzene the reaction takes place via a four-membered transition state with retention of configuration at the sulphur atom.

c) Reaction of sulphoxides with arylsulphinyl azides

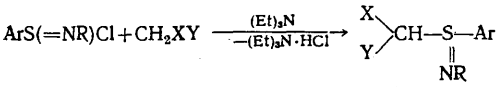
In contrast to arylsulphonyl azides, which form *N*-arylsulphonylsulphoximides with sulphoxides,[103] arylsulphinyl azides react with sulphoxides to form *N*-arylsulphonylsulphilimines.[104] It is thought that intermediate arylsulphinylnitrenes react with sulphoxides to form unstable four-membered cyclic compounds that are converted to a sulphilimine:

3. The use of other tetracovalent sulphur compounds in the synthesis of sulphilimines

a) Nucleophilic substitution on a tetracovalent sulphur atom

Nucleophilic substitution of different atoms and groups on a tetracovalent sulphur atom in order to obtain sulphilimines is utilised in two methods. The first of these involves nucleophilic substitution of halogen atoms[105,106] or alkoxy groups[105,107] in order to produce a S(IV)=N bond

$$R_2SX_2 + 3NH_3 \rightarrow R_2S{=}NH + 2NH_4X,$$

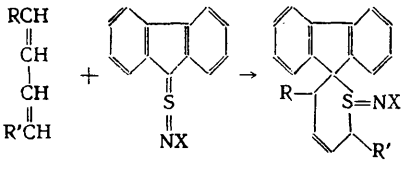


R = Ar, CF_3, X = Cl, F;

$$Ph_2S[OC(CF_3)_2Ph]_2 + RNH_2 \rightarrow Ph_2S{=}NR + 2PhC(CF_3)_2OH,$$

R = H, Alk, Ar, $ArSO_2$.

The second method involves nucleophilic substitution of halogen atoms on the tetracovalent sulphur atom in order to produce an S(IV)–C bond.[108,109]



$$F_2SNPh + 2PhLi \rightarrow Ph_2S{=}NPh + 2LiF,$$

R = $(Me)_3C$, $(Me)_2C(CN)$, $ArSO_2$; X = CN, MeCO; Y = CN, MeCO, EtOCO.

b) Reaction between thione-*S*-imines and diene hydrocarbons

It has been shown[110] that *N*-substituted thione-*S*-imines containing arylsulphonyl groups as substituents can perform as active dienophiles in [4 + 2] cycloaddition reactions with conjugated diene hydrocarbons to form sulphilimines containing a sulphur atom in the ring.

R = H, Me; R′ = Me, H; X = *p*-$MeC_6H_4SO_2$.

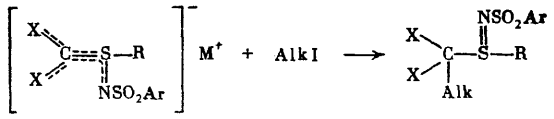
IV. Reactions of sulphilimines

All of the reactions involving sulphilimines can be divided into three groups, according to the type of change to the S(IV)=N bond: a) reactions that take place without change to the S(IV)=N bond; b) reactions that take place with conversion of the S(IV)=N bond to an S(II)–N or S(IV)–N bond; c) reactions that take place with cleavage of the S(IV)=N bond.

1. Reactions of sulphilimines that take place without change to the S(IV)=N bond

a) Modification of substituents on the sulphur and nitrogen atoms

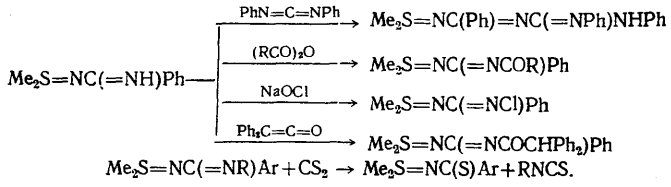
The directed chemical modification of different substituents on the sulphur and nitrogen atoms in sulphilimines is widely used in the synthesis of new types of these compounds. Particularly convenient in this respect are *S*-haloalkylsulphilimines, which as a result of nucleophilic substitution of the halogen atoms[111] or dehydrohalogenation[112] can readily be converted to new types of sulphilimines.



$$ArSO_2N{=}S(Me)CH_2X + RNa \xrightarrow[-NaX]{} ArSO_2N{=}S(Me)CH_2R,$$

X = Cl, Br; R = AlkO, ArO, PhS, NCS;

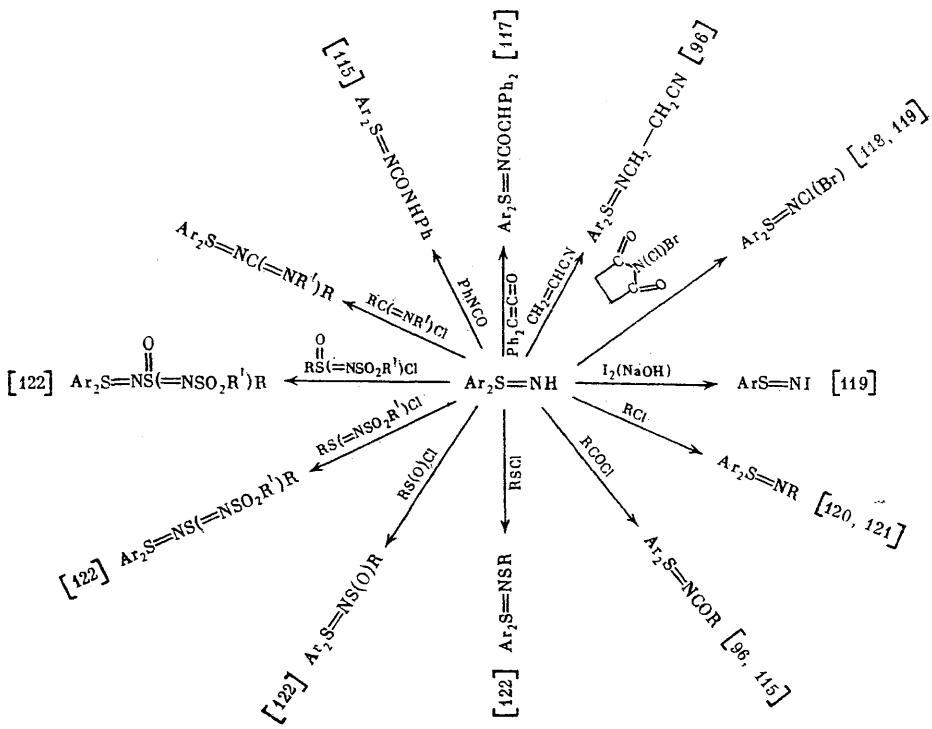
$$ArSO_2N{=}S(R)CH_2CH_2X \xrightarrow[-HX]{HB} ArSO_2N{=}S(R)CH{=}CH_2,$$



X = Cl, Br; R = Ph, 4-MeC_6H_4.

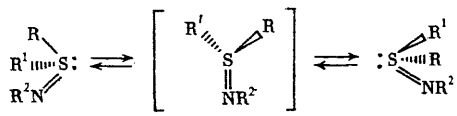
Replacement of the metal in metal salts of *N*-arylsulphonylsulphilimines by alkyl groups also gives new types of sulphilimines[52,55,56]

X = CN, MeCO, EtOCO; M = Na, Ag; R = 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$.



Examples of the modification of groups on the nitrogen atom of *N*-substituted sulphilimines are shown by the reactions of these groups with various reagents, as described in three studies[60,113,114]

$$Me_2S{=}NC(=NR)Ar + CS_2 \rightarrow Me_2S{=}NC(S)Ar + RNCS.$$



For the synthesis of new types of *N*-substituted sulphilimines, very frequent use is made of sulphilimines that are unsubstituted on the nitrogen atom and which are formed as a result of acid cleavage of

the S(IV)–N bond in *N*-arylsulphonylsulphilimines when they are reacted with 90% sulphuric acid.[115–119]

b) Thermal racemisation of sulphilimines

Sulphilimines with different substituents on the sulphur atom can exist in enantiomeric forms because of the chirality of the sulphur atom. When the temperature is increased interconversion of enantiomers occurs by a pyramidal inversion mechanism via a planar transition state.

Kinetic studies on the thermal racemisation of optically active sulphilimines 2-$MeOC_6H_4S(=NR)Ph$ (R = $PhSO_2$, 4-$MeC_6H_4SO_2$, 4-$MeOC_6H_4SO_2$, MeCO, PhCO, CF_3CO, etc.) which occurs at 75 °C in chloroform showed[123] that together with the known factors for affecting the rate of thermal racemisation (type of solvent, steric factors, etc.) an important part is played by the nature of the groups on the nitrogen atom. Strong electron-acceptor groups on the nitrogen atom reduce the rate of thermal racemisation.

Thus, for example, the rate of thermal racemisation of *N*-tosylsulphilimines is 15 times slower than the rate of thermal racemisation of *N*-trifluoroacetylsulphilimines. In the opinion of Moriyama et al.,[123] this occurs because strong electron-acceptor groups inhibit the $2p-3d$ changes in formation of the S(IV)=N bond in the transition state and also lower the repulsion between the free electron pairs, since they substantially reduce the electron density on the nitrogen atom in the pyramidal geometry of sulphilimines. Therefore, *N*-substituted sulphilimines that contain weak electron-acceptor groups as substituents adopt a configuration that is almost planar. The rate of pyramidal inversion decreases as the absorption frequency of the stretching vibrations due to the S(IV)=N bond decreases in the IR spectra, which is an indication that an increase in the bipolar nature of the S(IV)=N bond increases the barrier of pyramidal inversion.

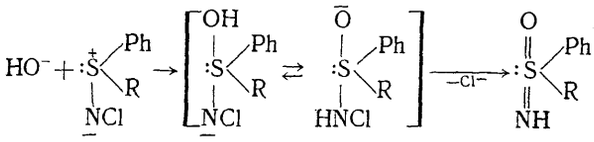
c) Oxidation of sulphilimines

Sulphilimines are as a rule stable towards oxidation, and they are only oxidised in the presence of strong oxidising agents to form sulphoximides

$$R_2S{=}NR' \xrightarrow{\text{oxidation}} R_2S(=O){=}NR'.$$

R = Alk, Ar; R′ = H, Ar, $ArSO_2$, RCO, ROCO.

The oxidising agents most frequently used are potassium permanganate,[96] hydroperoxides of aromatic carboxylic acids,[115,122] ruthenium tetroxide,[124] hydrogen peroxide in an alkaline medium,[125] and sodium hypochlorite.[126,127] During oxidation in two-phase media, phase-transfer catalysts—Bu_4NX (X = Cl, Br, ClO_4, HSO_4), $PhCH_2N(Et)_3Cl$, $C_{12}H_{15}N(Me)_3Cl$, and others—have been used.[126,127]

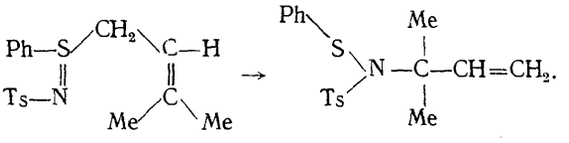


d) Alkaline hydrolysis of sulphilimines

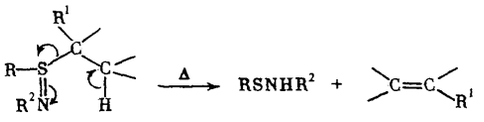
Hydrolytic cleavage of sulphilimines in the presence of mineral acids has been known for a long time and is well studied. As a rule it leads to the corresponding sulphoxides and initial *N*-nucleophiles whatever the structure of the initial sulphilimine. Hydrolysis of sulphilimines in the presence of bases has been insufficiently studied up to now. The composition and structure of the products of this

hydrolysis are frequently determined by different factors and primarily by the structure of the initial sulphilimine. It was reported,[128] for example, that the alkaline hydrolysis of 1-(*N*-*p*-toluenesulphonyl)tetrahydrothiophenesulphilimine in an alcoholic medium results in the formation of 2-alkoxytetrahydrothiophene and *p*-toluenesulphonamide. Alkaline hydrolysis of *N*-chlorosulphilimines in an aqueous medium results in the formation of sulphoximides with an unsubstituted nitrogen atom.[118]

$$R_2S{=}NCl \xrightarrow[-HCl]{H_2O(OH^-)} R_2S(=O){=}NH$$



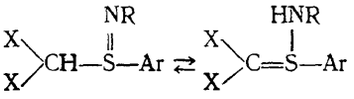
The reaction is stereospecific and in the case of optically active *N*-chlorosulphilimines takes place with 98% retention of configuration at the sulphur atom. The hydrolysis mechanism involves nucleophilic attack by an OH^- group on the sulphur atom to form a transition state which is stabilised through cleavage of a chloride anion.



2. Reactions that take place with conversion of the S(IV)=N bond to S(II)–N or S(IV)–N bonds

a) Rearrangement of sulphilimines to sulphenamides

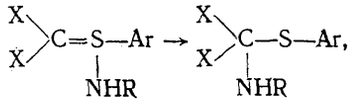
N-Substituted sulphilimines containing an allyl group on the sulphur atom readily undergo various sigmatropic rearrangements, so in many cases they cannot be isolated. One of such types of rearrangement is a [2,3] sigmatropic shift that involves migration of the allyl group from the sulphur atom to the nitrogen atom to form *N*-substituted sulphenamides.[129]



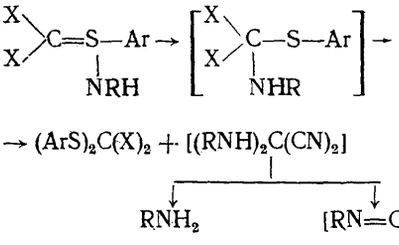
S-Alkylsulphilimines that contain a β-H atom undergo a Pummerer rearrangement on heating, to form sulphenamides and alkenes.[69]

R^1 = H, Me; R^2 = Ar, MeCO.

b) Formation of *S*-aminosulphonium ylides



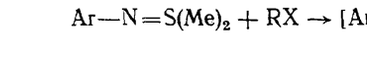
N-Substituted sulphilimines that contain an active α-H atom can undergo a [1,3] sigmatropic rearrangement to form *S*-aminosulphonium ylides



Essentially the rearrangement consists of a prototropic shift in the triad C–S–N, namely an imino–ylide tautomerism, and the possible existence of a given form is determined by the nature of the groups X and R.

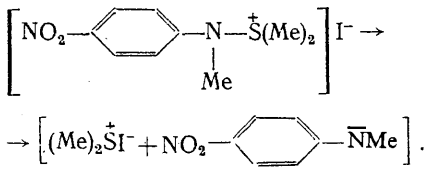
In accordance with the principles of an acid-base prototropic equilibrium,[130] a tautomeric equilibrium occurs in those cases where the dissociation constants of both forms differ by a factor of not more than 10^1-10^3. If the difference between the dissociation constants is large, the equilibrium is almost completely displaced towards the form whose dissociation constant is smaller. If we consider with this criterion the C–S–N triad of imino–ylide tautomerism which occurs in a number of *N*-substituted sulphilimines with an active α-H atom, it becomes clear that conversion of the imine form to the ylide form only occurs when the acidity of the CH-form (imine) is comparable to or greater than the acidity of the NH-form (ylide). For the acidity of the CH-form to become equal or greater than the acidity of the NH-form, a strong electron-acceptor effect from groups X is necessary. Therefore, formation of *S*-aminosulphonium ylides was observed[52,53,55,56,109] when strong electron-acceptor groups such as PhCO, MeCO, CN, EtOCO, etc. were introduced as X. In the event that X are weak electron-acceptor groups such as Ph,[131] the prototropic tautomeric equilibrium is completely shifted towards the weakly acidic imine form, namely, a [1,3] sigmatropic rearrangement does not occur.

The stability of *S*-aminosulphonium ylides which are formed as a result of a [1,3] sigmatropic rearrangement of sulphilimines is dependent to a large extent on the nature of groups R on the nitrogen atom. The relatively high stability of *S*-aryl-*S*-(t-butylamino)- and *S*-aryl-*S*-(α-cyanoisopropylamino)sulphonium methylylides has been noted,[109] while *S*-aryl-*S*-(arylsulphonylamino)-sulphonium methylylides[52,53,109] are unstable and undergo further reactions as a result of the migration of the arylsulphonamide group to the carbon atom.



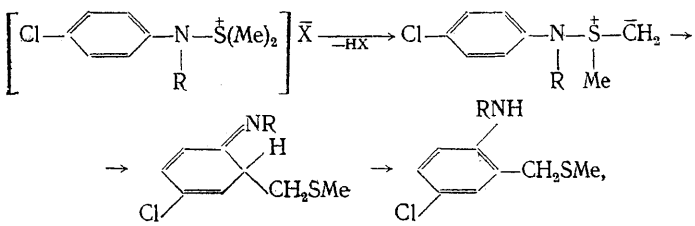
X = PhCO, MeCO; Ar = 4-ClC_6H_4, 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$;
R = $PhSO_2$, 4-$MeC_6H_4SO_2$;

X = CN, EtOCO; Ar = 4-ClC_6H_4, 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$;
R = $PhSO_2$, 4-$MeC_6H_4SO_2$.



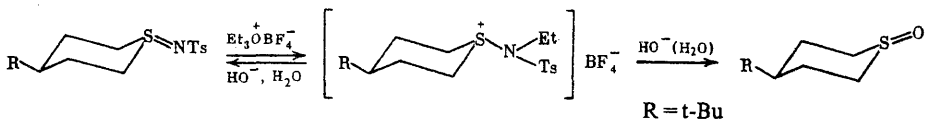
c) Formation of aminosulphonium salts

N-Arylsulphilimines form unstable aminosulphonium salts by reaction with alkylating or acylating agents.[132]

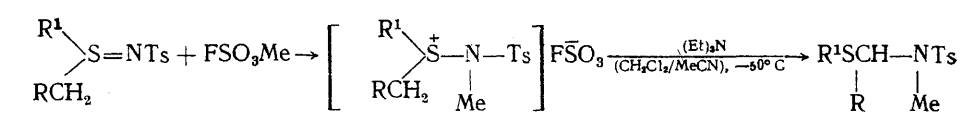


R = Me, X = I; R = EtOCO, X = Cl; R = MeCO, X = $MeCOO^-$;
Ar = *p*-$NO_2C_6H_4$, *p*-ClC_6H_4.

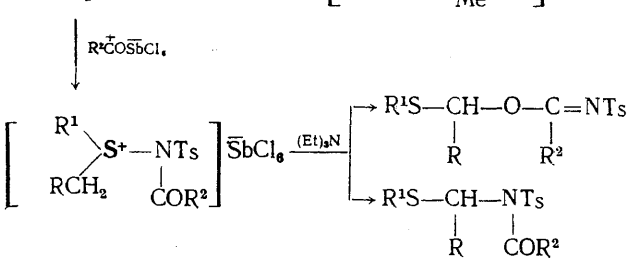
Subsequent conversion of these salts is dependent on the nature of the substituents in the benzene ring of the aryl group and the basicity of X^-. In the case of strong electron-acceptor substituents (such as NO_2) and highly basic X^-, attack by X^- on the positively charged sulphur atom takes place followed by cleavage of the S–N bond



In the case of weak electron-acceptor or electron-donor substituents anion X^- extracts a proton from a MeS group to form an intermediate ylide, which subsequently undergoes an intramolecular sigmatropic rearrangement to give unstable cyclohexadiene derivatives that are converted to more stable benzene derivatives



R = Me, X = I; R = MeCO, X = MeCOO; R = EtOCO, X = Cl.



When one of the methyl groups on the sulphur atom is replaced by an ethyl or propyl group, extraction of a proton only occurs from the MeS group, and when it is replaced by a benzyl group the proton is only extracted from the benzyl group, which is correlated with the decrease in acidity in the series $PhCH_2S$ > MeS > $AlkCH_2S$.

N-Arylsulphonylsulphilimines only form aminosulphonium salts in a reaction with highly active acylating and alkylating agents such as oxonium salts ($Et_3\overset{+}{O}BF_4^-$, for example),[129] methyl fluorosulphonate,[133] and complexes of carboxylic acid chlorides with $SbCl_5$.[133] The aminosulphonium salts formed in this case are relatively stable and undergo further reactions only on treatment with mineral or organic bases

R = t-Bu

R = H, $R^1 = R^2$ = Me; R = H, R^1 = Me, R^2 = Et; R = Ph, R^1 = Et, R^2 = Me;
R = H, R^1 = Me, R^2 = Ph; R = H; R^1 = Et, R^2 = Me.

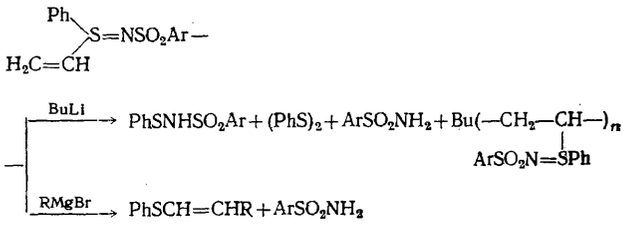
3. Reactions that take place with complete cleavage of the S(IV)=N bond

a) Thermolysis and photolysis of sulphilimines

The composition and nature of the products of thermal decomposition of sulphilimines are determined as a rule by their structure and the conditions of thermolysis. At the same time the thermal destruction processes are often accompanied by various rearrangements, which also contributes to the variety of thermolysis products. This, for example, thermolysis of *N*-acyl-*S*,*S*-diphenylsulphilimines[134] is accompanied by a Curtius rearrangement with the formation of sulphides and isocyanates

$$Ph_2SNCOR \xrightarrow{200\ ^\circ C,\ 2\ h} RNCO + Ph_2S,$$
$$R = PhCH_2,\ PhCH_2CH_2,\ 2,4,6\text{-}(Me)_3C_6H_2,\ Ph.$$

Thermolysis of *N*-*p*-toluenesulphonyl-*S*,*S*-dimethyl- and -diphenylsulphilimines[135] at 300 °C in a current of nitrogen is accompanied by reduction reactions to form mixtures of products, from which Me_2S, $(MeS-)_2$, $(MeS-)_2CH_2$, $4\text{-}MeC_6H_4SO_2NH_2$, PhMe, $(4\text{-}MeC_6H_4S-)_2$, and $4\text{-}MeC_6H_4SSMe$ are isolated. Thermolysis of heterocyclic sulphilimines is often accompanied by ring expansion.[136] The primary products of the photolysis of sulphilimines[137,138] as a rule are the initial sulphides and nitrenes, which, depending on their structure and the type of reaction medium, form various secondary products.

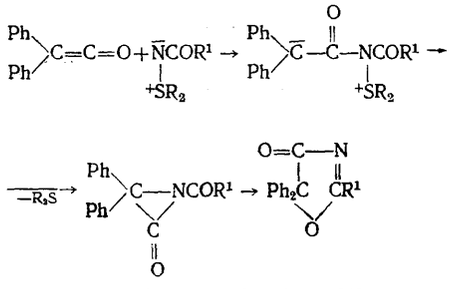


b) Reduction of sulphilimines

Sulphilimines are readily reduced by various reducing agents to give the initial sulphides

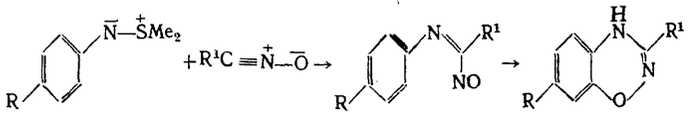
$$RR^1S{=}NR^2 \xrightarrow{\text{(reduction)}} RSR^1 + R^2NH_2,$$
$$R = R^1 = Alk,\ Ar;\ R^2 = H,\ Ar,\ AlkSO_2,\ ArSO_2.$$

Phosphorus pentasulphide,[117] titanium tetrachloride with metallic zinc,[121] cysteine,[139] sodium iodide,[140] lithium aluminium hydride,[141] and others have been used as reducing agents. The reaction of *N*-arylsulphonyl-*S*-aryl-*S*-vinylsulphilimines with organolithium and



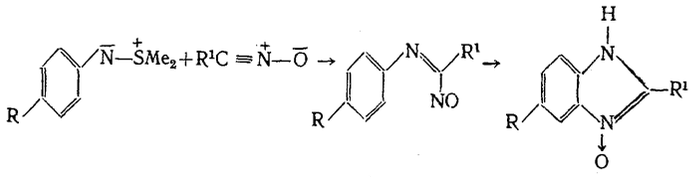
organomagnesium compounds is accompanied by reduction of these sulphilimines[142]

c) Cycloaddition reactions



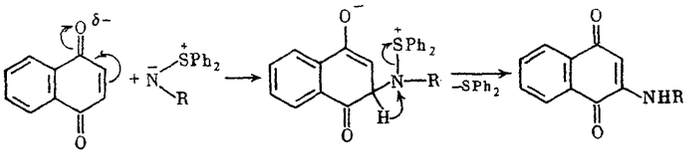
Because of the ylide nature of the S(IV)N=N bond in sulphilimines, they can be used in cycloaddition reactions with compounds containing active double or triple bonds and also systems of cumulated and conjugated double bonds. Meth-Cohn et al.[143] have studied the [4 + 2] cycloaddition of *N*-substituted sulphilimines with compounds containing active C=C bonds. The resulting adducts undergo cleavage to form the highly reactive sulphenylamines R–N=S (R = PhCO, EtOCO, $ArSO_2$). Adducts of the [2 + 2] cycloaddition of sulphilimines to carbon disulphide[114,132] are cleaved to form isothiocyanates, sulphides, and sulphur. Certain cycloaddition reactions only involve the nitrogen atom and groups bonded to it. These reactions are used in the synthesis of heterocyclic compounds. One such reaction is the interaction of *N*-acylsulphilimines with diphenylketene.[144]

The first step in this reaction is nucleophilic attack by the nitrogen atom of the sulphilimine on the electron-deficient carbon atom of the C=O group in diphenylketene followed by cyclisation of the intermediate bipolar compound to form an unstable ethylenimine derivative, which is converted to a more stable 1,3-oxazolin-4-one derivative.

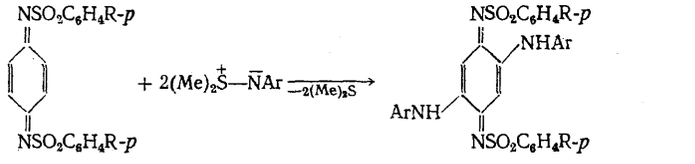


R = Me, Ph; R^1 = Me, CF_3, Ph, $PhCH_2$.

Gilchrist et al.[145] reported that the reactions products from cycloaddition of *N*-arylsulphilimines with nitrile oxides are 1,2,4-benzoxadiazines

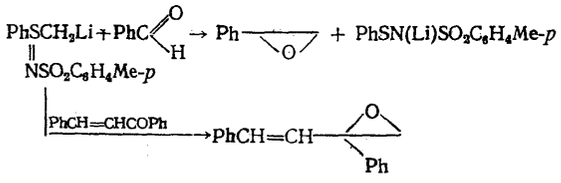


However, according to the results of Shinsaku et al.,[146] cycloaddition does not involve the oxygen atom but the nitrogen atom of the oxynitrile to form benzimidazole *N*-oxides



d) Addition to quinoid systems

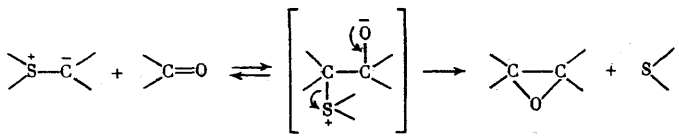
The high nucleophilicity of nitrogen in *N*-arylsulphilimines can be utilised in their nucleophilic addition reactions to the carbon atoms of a polar system of conjugated bonds of quinones[147] and quinonimines.[148] The proposed mechanism for addition involves nucleophilic attack by the nitrogen atom of the sulphilimine on the terminal carbon atom of the conjugated system of bonds to give an unstable betaine, which is converted as a result of displacement of the sulphonium group by a proton to more stable quinone and quinonimine derivatives.



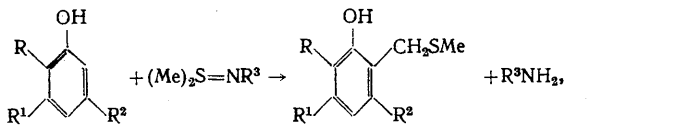
R = $PhCH_2$

R = H, Me; Ar = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$.

e) Transfer of alkylidene groups of *N*-arylsulphonylsulphilimines



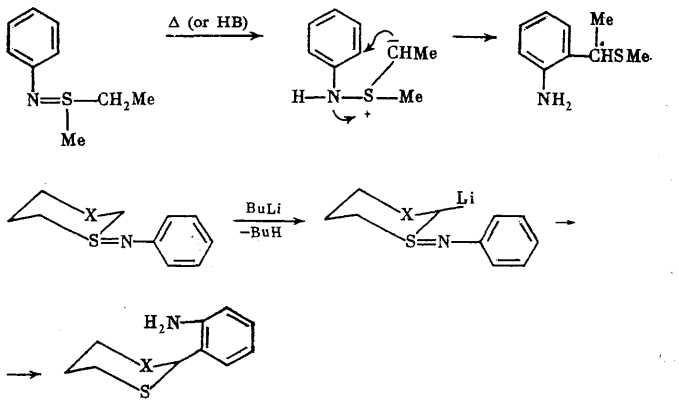
The strong electron-acceptor effect of the arylsulphonylimino group increases the acidity of the α-H atoms of the *S*-alkyl groups, which assists their replacement by an alkali metal atom. Organometallic compounds of this type are used as nucleophilic reagents that transfer alkylidene groups to an electrophilic double bond (such as C=O), forming a three-membered ring.[149] The leaving group whose separation results in the formation of the three-membered ring is a stable *N*-arylsulphonylsulphenamide anion, which also assists this process



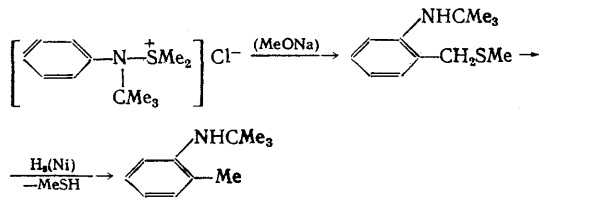
This reaction is characterised by its high stereoselectivity and when other *S*-alkylsulphilimines are used, the resulting 1,2-disubstituted oxiranes mainly have a *trans* structure.[150]

By analogy with the mechanism for transfer of the alkylidene group of sulphur ylides to an electrophilic double bond,[139] the mechanism of this reaction involves the formation of an intermediate

betaine followed by cyclisation through direct substitution at the carbon atom.



The use of *S,S*-dimethylsulphilimines for the introduction of a methylthiomethylene group into the aromatic ring of phenols has been reported in the literature.[151]



R = Me, OMe; R^1 = H, Me; R^2 = H, Me; R^3 = $ArSO_2$; 2,4-$(NO_2)_2C_6H_3$.

On heating[152] and also by treatment with bases[153] or organolithium compounds,[154] certain *N*-arylsulphilimines undergo a type of Sommelet reaction

X = CH_2S.

Gassman et al.[155] utilised a similar rearrangement of aminosulphonium salts for the *ortho*-alkylation of arylamines.

Sulphenamides and their derivatives

K A Petrov, G V Rudnev, V D Sorokin

ABSTRACT. Information has been presented systematically on the synthesis of sulphenamides and related compounds by reaction of sulphenyl chlorides and sulphur chlorides with amines and carboxylic acid amides; by reaction of chloramines with mercaptans; by transamination of *N*-acylsulphenamides; and by reaction of disulphides with amines. The following chemical reactions of sulphenamides have been examined: reaction with hydrogen halides; with acids and derivatives possessing coordinatively unsaturated atoms; and the addition of sulphenamides to the double bond of carbon disulphide, isocyanates, isothiocyanates and olefins. Data are given on the physical state of sulphenamides and on the region characteristic of the S–N bond vibrations.

The bibliography includes 190 references.

I. Introduction

Sulphenamides are important sulphenic acid derivatives which possess a S–N group. The following types of sulphenamide are known: alkyl- and aryl-sulphenamides, *S*-acyl- and *N*-acyl-sulphenamides, sulphenamides derived from the hypothetical sulphoxylic acid, $S(OH)_2$, and thiosulphoxylic acid, $S_2(OH)_2$; and aminosulphenyl chlorides which possess both a S–N bond characteristic of sulphenamides and a S–Cl bond characteristic of sulphenyl chlorides. As the S–N bond is readily cleaved with various reagents, sulphenamides are used in synthetic chemistry for introducing both sulphur and nitrogen functions, affording a variety of sulphides,[1,2] disulphides,[3,4] trisulphides,[5,6] sulphenic acid esters,[7] and other compounds.

Sulphenamides and derivatives are widely used as accelerators in the vulcanisation of rubber,[8–20] in agriculture as pesticides and fungicides,[21–29] for treating the after-effects of radiation sickness, as radio-protecting agents,[30] as polymerisation initiators,[31] and even in rocket technology as spontaneously igniting fuels.[32]

At the present time there is a large volume of data on this subject in foreign publications;[33–37] there is nothing of a review nature with the exception of one article[38] which in part summarises known information.

II. Methods of preparation

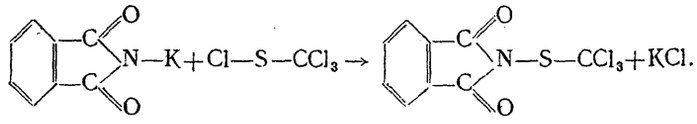
Sulphenamides and related compounds are prepared by amination of sulphenyl halides, sulphenic acid esters, and sulphur chlorides with alkyl- and aryl-amines and with amides; they are also obtained by treatment of mercaptans with chloramines, disulphides with amines, from thiosulphonates and alkylsulphenyl thiocyanates with amines, and by other methods.

1. Amination of sulphenyl halides

Zinke was first to prepare sulphenamides in high yield by treatment of sulphenyl chlorides with an excess of secondary amine in chloroform or carbon tetrachloride at low temperature.[33,36,39]

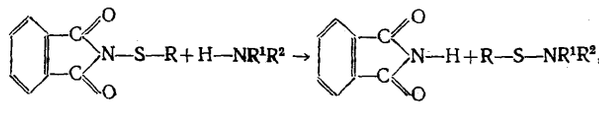
$$R{-}S{-}X + 2HNR^1_2 \rightarrow R{-}S{-}NR^1_2 + HNR^1_2 \cdot HX,$$

$R = Ph,\ O_2N{-}C_6H_4;\ R^1 = Me,\ Et;\ X = Cl,\ Br.$



Subsequently, triethylamine[40–42] was used as HCl acceptor in order to economise in the use of the secondary amine. This reaction does not always proceed smoothly with the formation of desired product in high yield. Thus, by treatment of methylsulphenyl chloride with excess of dialkylamine at 60 °C, *gem*-diamines as well as methyldi- and tri-sulphides were obtained together with the desired sulphenamides.[43]

$$Me{-}S{-}Cl + R{-}NH_2 \rightarrow Me{-}S{-}NR_2 + CH_2(NR_2)_2 + Me{-}S_2{-}Me + Me{-}S_3{-}Me,$$



R = Me, Et, *iso*-Pr.

By an analogous route, *N*-methylalkanesulphenanilides were obtained by reaction of the corresponding sulphenyl chlorides with *N*-methylaniline, the only difference being the choice of aqueous base as medium. The desired products were isolated in yields up to 70–80% by extraction and distillation.[44]

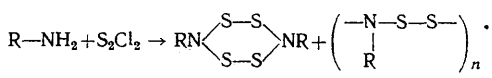
This method is recommended for low-molecular weight sulphenyl chlorides, i.e. those with small alkyl (R) groups.[45–47] By such means, *N*-acylsulphenamides are obtained in high yield by reaction of *N*-potassiophthalimide with sulphenyl chlorides.

N-Acylsulphenamides are converted to deacylated sulphenamides by transamination.[48–50]

R = Me, Et, Ph, C_6H_4; R^1 = Me, Et; R^2 = Et, *iso*-Pr.

Isolation of the desired products is facilitated by the use of non-polar solvents in which phthalimide has low solubility.

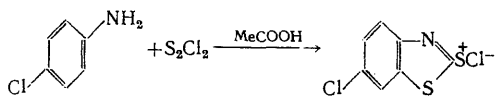
Those sulphenamides derived from the hypothetical sulphoxylic and thiosulphoxylic acids, referred to usually as thiobisamines and dithiobisamines or diaminosulphides, are obtained in around 90% yield by interaction of sulphur dichloride with secondary aliphatic, cyclic, and *N*-alkylaryl amines in chlorinated hydrocarbon solvents at low temperature or in aqueous basic medium.[51–60]



$$4R_2NH \xrightarrow{SCl_2} R_2N{-}S{-}NR_2 + R_2NH\cdot HCl$$
$$4R_2NH \xrightarrow{S_2Cl_2} R_2N{-}S_2{-}NR_2 + R_2NH\cdot HCl$$

R = Me, Et, Pr, Bu, $(CH_2)_5CH$; $R_2 = (CH_2)_2O(CH_2)_2$, $(CH_2)_5$.

Thiobisamines with a HN–S group are obtained by reaction of primary aliphatic and aromatic amines, in particular *tert*-butylamine and *p*-nitroaniline, with sulphur dichloride in ether.[61,62]

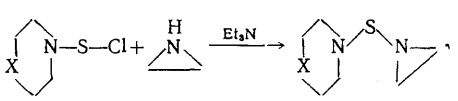


$$R{-}NH_2 + SCl_2 \xrightarrow{ether} RHN{-}S{-}NHR,$$
$$R = p\text{-}NO_2C_6H_4,\ tert\text{-}Bu.$$

It is also reported that primary aliphatic amines with sulphur monochloride produce tetrathiodiamines or polymeric disulphides in 40–60% yield.[63,64]

R = Et, Ph–CH_2, Ph–CH_2CH_2, $C_{12}H_{25}$; n=5–9.

As a rule primary aromatic amines react with sulphur monochloride to give a mixture of products, of which compounds with a C–S bond predominate.[65,66] Thus, by heating *p*-chloroaniline with sulphur monochloride in acetic acid during 3 h, yellow crystals of 6-chloro-1,2-dithiazinium chloride were obtained in 93% yield.[67]



Thiobisamines are obtained in high yield by treatment of metallated secondary amines with sulphur dichloride.[68]

$$R^1R^2NLi + SCl_2 \xrightarrow{-78^\circ C} R^1R^2N{-}S{-}NR^1R^2 + LiCl,$$
$$R^1 = SiMe_3;\ R^2 = Bu,\ iso\text{-}Pr,\ tert\text{-}Bu,\ (CH_2)_5CH.$$

Extremely reactive aminosulphenyl chlorides possessing both sulphenamide and sulphenyl chloride groups are obtained by cleavage of dithiobisamines with chlorine or sulphuryl chloride, as well as by treating thiobisamines with hydrogen chloride.[69,70]

$$R_2N{-}S{-}NR_2 + HCl \rightarrow R_2NSCl + R_2NH\cdot HCl,$$
$$R_2N{-}S_2{-}NR_2 + SO_2Cl_2 \rightarrow 2R_2N{-}S{-}Cl + SO_2,$$
$$R = Me,\ Et,\ iso\text{-}Pr,\ tert\text{-}Bu,\ (CH_2)_5CH;$$
$$R_2 = (CH_2)_2O(CH_2)_2.$$

Aminosulphenyl chlorides are used to prepare thiobisamines with a variety of amino groups. For example, unsymmetrical thiobisamines are obtained by treatment of aminosulphenyl chlorides with ethyleneimine in carbon tetrachloride in the presence of tertiary amine at room temperature.[71]

X = O, S, CH_2.

At the same time it has been reported that on treatment of diethylaminosulphenyl chloride with dimethylamine, and of dibutylaminosulphenyl chloride with dicyclohexylamine, only symmetrical thiobisamines, namely bis(dimethylamino) sulphide and bis(dicyclohexylamino) sulphide, were isolated in 80% yield. It is thought that this reaction proceeds as a result of disproportionation of an initially formed unsymmetrical thiobisamine under the action of hydrogen chloride.[72]

$$R_2NH \xrightarrow[-HCl]{R_2^1NSCl} R_2N{-}S{-}NR_2^1 \xrightarrow[-HNR_2^1]{HCl}$$
$$\rightarrow R_2NSCl \xrightarrow[-HCl]{HNR_2} R_2N{-}S{-}NR_2,$$
$$R = Me,\ (CH_2)_5CH;\ R^1 = Et,\ Bu.$$

Suphenamides phosphorylated on the sulphur atom are obtained by interaction of aminosulphenyl chlorides with dialkyl or trialkyl phosphites in high yield.[73]

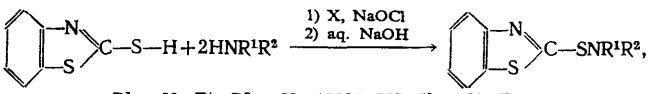
$$R_2N{-}S{-}Cl + (R^1O)_3P \rightarrow (RO)_2\overset{\overset{O}{\|}}{P}{-}SNR_2 + R^1{-}Cl,$$
$$R = Et;\ R^1 = Et,\ Pr,\ Bu.$$

The isolation of *S*-dialkylamino dialkyl thiophosphates presents no difficulty because the only side-product of the reaction is a volatile alkyl chloride.

An unstable acetylsulphenamide, which decomposes into sulphur and diethylacetamide, was obtained by reaction of acetylsulphenyl chloride with diethylamine.[74]

$$CH_3\overset{\overset{O}{\|}}{C}{-}S{-}Cl + 2(C_2H_5)_2NH \rightarrow$$
$$\rightarrow CH_3\overset{\overset{O}{\|}}{C}{-}S{-}N(C_2H_5)_2 + (C_2H_5)_2NH\cdot HCl.$$
$$\downarrow$$
$$CH_3C(O)N(C_2H_5)_2 + S$$

A similar result was obtained with piperidine. The oily sulphenamide synthesised from aniline at 3–5 °C decomposed by 50% during 24 h and completely during the course of 3 days.



2. Amination of mercaptans with chloramines

Sulphenamides with a free amino group ($-NH_2$) are obtained in yield up to 50% by reaction of mercaptides with chloramine.[75]

$$R{-}S{-}Na \xrightarrow[2)\ aq.\ NaOH]{1)\ NH_2Cl/H_2O} R{-}S{-}NH_2 + NaCl,$$
$$R = pyridyl,\ pyrimidinyl,\ 1,2\text{-}Cl_2C_6H_3,\ O_2N{-}C_6H_4.$$

The reaction was conducted in aqueous basic solution. The sulphenamides were recrystallised from a mixture of petroleum ether and isopropanol. However, if diethyl ether is used as solvent, the corresponding disulphide is formed.

Sulphenamides can also be prepared by the reaction of aromatic mercaptans, notably 2-mercaptobenzothiazoles, with ammonia, or with primary and secondary amines in the presence of hypochlorites, halogens or potassium ferricyanide in aqueous solution.[76–81]

R^1 = H, Et; R^2 = H, $(CH_2)_5CH$; X = Cl, Br, I.

This method is related to the chloramine route since mercaptans and amines react with chlorine or hypochlorite with formation of sulphenyl chlorides and chloramines, following which the former will interact with the amines and the latter with the mercaptides.

N-Acylsulphenamides are also obtained in up to 70% yield by reaction of *N*-chlorosuccinimide and *N*-chlorophthalimide with mercaptans.[82]

$$R^1R^2NCl + HS{-}R^3 \xrightarrow{OH^-} R^1R^2NSR^3,$$

R^1R^2N = succinimido, phthalimido; R^3 = Et, *iso*-Pr, Ph.

3. Amination of disulphides

One of the methods of preparing sulphenamides is based on the interaction of alkyl or aryl disulphides with primary or secondary amines in the presence of silver acetate, silver nitrate or mercuric chloride. The yield of the sulphenamides is 60–80% by this route.[83]

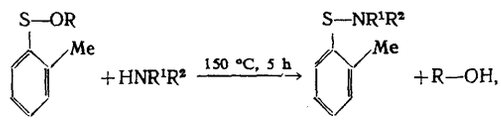
$$R{-}S_2{-}R + 2R^1_2NH + MX \xrightarrow{NaOH} \rightarrow R{-}S{-}NR^1_2 + R{-}S{-}M + R^1_2NH\cdot HX,$$

R = Me, Et, *iso*-Pr, Bu, Ph; R^1 = Me, Et, *iso*-Pr, Bu, Ph;

$MX = AgNO_3$, AgOAc, $HgCl_2$.

It is thought that, initially, a disulphide complex is formed as a result of electrophilic attack of the metal ion; the complex is then decomposed with the formation of sulphenamide as a result of nucleophilic attack by the amine. Reaction is carried out in the following way: equimolar amounts of the disulphide and metal salt in methanol or ethyl acetate are treated with an excess of the amine, the precipitated mercaptide is separated by filtration, and the sulphenamide is isolated from the filtrate by the usual means. Reaction is easiest by using aromatic, as opposed to aliphatic, disulphides, and the yield of the desired sulphenamides is highest. This method is also suitable for preparing sulphenamides with a free NH_2 group if the nucleophile which attacks the sulphur atom is more electron-accepting than 4-chlorophenyl; if the reverse obtains, bis(arylsulphenyl)amines are isolated as the main products.[83]

This method possesses a number of distinct advantages by comparison with the route based on sulphenyl chlorides. Firstly, disulphides are more stable than sulphenyl halides, and secondly the method permits the synthesis of sulphenamides which contain reactive functional groups, such as hydroxyl or a double bond, which are reactive towards sulphenyl chlorides.[45,46]



Sulphenamides phosphorylated on the sulphur atom are obtained in high yield by treatment of dithiophosphates with primary and secondary amines.[84]

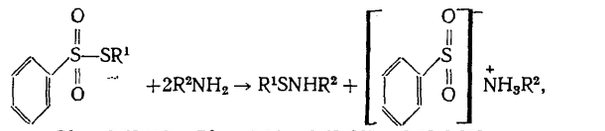
$$(RO)_2\overset{O}{\overset{\|}{P}}{-}S_2{-}\overset{O}{\overset{\|}{P}}(OR)_2 + 2HNR^1_2 \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}{-}S{-}NHR^1 + (RO)_2\overset{O}{\overset{\|}{P}}SH + H_2NR^1,$$

R = Et, *iso*-Pr; R^1 = Me, Et, *iso*-Pr.

4. Amination of arenesulphenates, alkylsulphenyl thiocyanates and thiosulphonates

Sulphenamides are obtained in high yield by amination of arenesulphenates with primary or secondary amines.[85]

R = Me; R^1 = H, Pr, Ph; R^2 = Me, Et, Pr, Bu, Ph.



This method is more advantageous than the above-described sulphenyl halide route since sulphenic acid esters are more stable than the corresponding sulphenyl chlorides.

Certain dialkylsulphenamides are obtained by interaction of alkylsulphenyl thiocyanates with a two-fold excess of secondary amine in ether.[86,87]

$$R{-}S{-}S{-}CN + 2R^1_2NH \rightarrow R{-}S{-}NR^1_2 + R^1_2NH\cdot HS{-}CN,$$

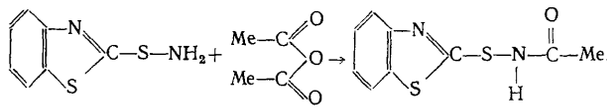
R = Et, Pr, Bu; R^1 = Et, Pr, *tert*-Bu.

The possibility of aminating thiosulphonates with amines is exemplified by the amination of 2-nitrophenyl benzenethiosulphonate with aromatic amines. In this case, the corresponding *N*-aryl-2-nitrobenzenesulphenamides are isolated in high yield.[88]

$R^1 = C_6H_4NO_2$; $R^2 = C_6H_5$; $C_6H_4CH_2$, $C_6H_4OCH_2$.

In other cases it is not possible to isolate sulphenamides from a mixture of the corresponding thiosulphonate and aromatic amine.

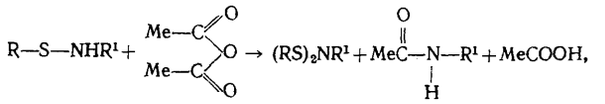
5. Other methods of synthesising sulphenamides



One of these is based on the amination of mercaptides with azides. By this means, treatment of *tert*-butyl or benzyl mercaptan with butyl azidoacetate or azidoformate in the presence of cuprous oxide or cuprous chloride affords the corresponding sulphenamides in 50% yield.[89]

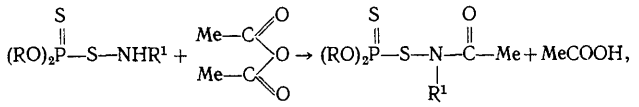
$$R{-}S{-}H \xrightarrow{Cu(I)} Cu{-}S{-}R \xrightarrow[-N_2]{N_3R^1} R^1NHSR + R{-}S_2{-}R + R^1NH_2,$$

R = tert-Bu, $C_6H_4CH_2$; $R^1 = CH_2CO_2Bu$, CO_2Bu.



It is proposed[89] that the mechanism of the reaction involves coordination of an intermediate nitrene with the copper atom, followed by insertion of the amino group into the Cu–S bond with formation of sulphenamide, amine and disulphide.

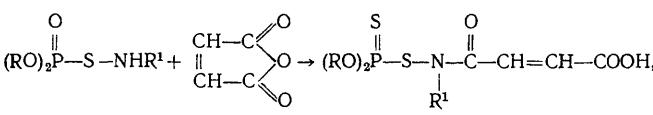
The following method, based on the acylation of sulphenamides with free amino groups, is used for the preparation of acylated 2-benzothiazolylsulphenamides.[90]



Reaction is conducted in the presence of sodium acetate. In this way, disulphide is formed in addition to acylated product. The desired product was recrystallised from ether. The yield was 30%.

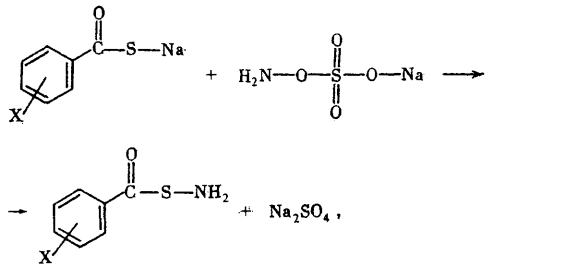
It is known that on acetylation of sulphenamides, the latter are cleaved with the formation of bis-sulphenylamines and the corresponding amide of acetic acid.[91,92]

R = Alk, R^1 = Me.



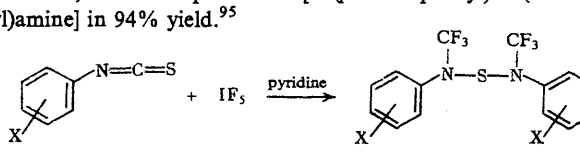
At the same time phosphorylated sulphenamides readily react with acetic anhydride with formation of the corresponding *N*-acetyl derivatives in 72–95% yield.

R = Alk, Ph; R^1 = Me.



Reaction proceeds at room temperature in the absence of solvent during 30 min, or by vigorous heating of the starting materials up to 100 °C during 2–3 min.

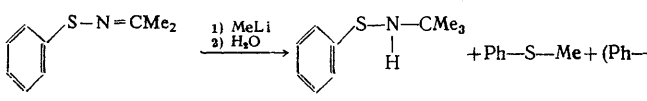
In addition to this, sulphenamides are acylated with maleic anhydride under the same conditions.[93]



R = Me, Et, *iso*-Pr; R^1 = Me.

One of the methods of preparing *S*-acylsulphenamides is by amination of salts of aromatic thioacids with hydroxylamine-*O*-sulphonates. Reaction is conducted by mixing an aqueous solution of sodium hydroxylamine-*O*-sulphonate with the sodium salt of an aromatic thioacid, followed by filtration of the product and recrystallisation from ether, methylene chloride, chloroform or carbon tetrachloride. The yield was around 90%.[94]

X = Cl, NO_2, Me, H_2NSCO.



There is a certain interest in the reaction of iodine pentafluoride with phenyl thiocyanates in methylene chloride, leading to the formation of, for example thiobis[*N*-(*p*-chlorophenyl)-*N*-(trifluoromethyl)amine] in 94% yield.[95]

X = Me, Cl, Br, I.

The thiobisamine was isolated from the reaction mixture by column chromatography (eluent: 1 : 1 pentane/methylene chloride).

Sulphenamides can also be obtained by the addition of organometallic compounds to *N*-alkylidenearenesulphenamides, followed by decomposition of the formed products with water. An *S*-phenylsulphenamide was obtained by this route. *N*-Isopropylidenebenzenesulphenamide and methyllithium were used as starting materials.[96]

Reaction was conducted in ether at a temperature around 0 °C; the yield of the sulphenamide was 78%.

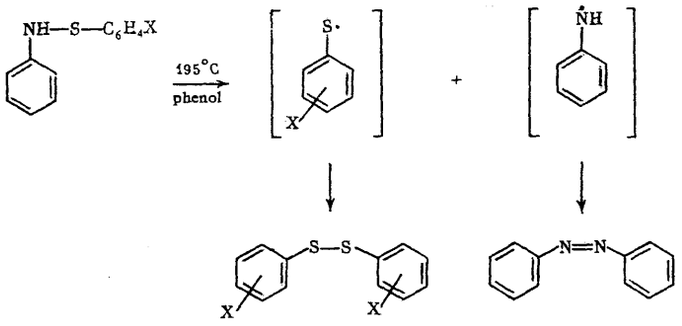
III. Physical properties

Sulphenamides and their derivatives exist as liquids or crystalline compounds with clearly defined melting points. The vast majority are colourless, but some are yellow because of impurities. They have an unpleasant smell and are readily soluble in non-polar solvents (benzene, chloroform, methylene chloride, or hexane).[33–38,69,97–100] The S–N bond order in simple methylated mono- and disulphenamides is significantly greater than one. For example, the bond orders for methylthiodimethylamine, Me_2NSMe, and bis(methylthio)methylamine, $MeN(SMe)_2$, and 1.2 and 1.5, respectively.[101] The S–N bond length in unsaturated aliphatic sulphenamides is around 160 pm; for arylsulphenamides it is around 155 pm, and for dithiobisamines the S–S bond length is approximately 195–205 pm. The C–N–S bond angle, around 100°, depends on the nature of the neighbouring atoms and groups.[102–104]

Based on a study of the temperature dependence of the PMR spectra of a series of cyclic and acyclic sulphenamides, it is assumed that inversion at the nitrogen atom is the rate-determining step only for aziridine derivatives.[105,106]

The rotation barrier around the S–N bond in compounds of the type $ArSN(SO_2Ph)Pr$-*iso* is 55–58 kJ mol^{-1}, being dependent on the lone pair interaction, the S–N bond order, and the steric effect of the substituents.[107]

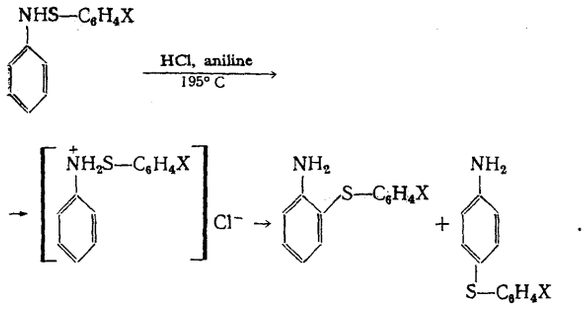
From an X-ray structural analysis, it has been established that the bonds to nitrogen lie almost in the same plane as a result of $p_\pi - d_\pi$ interaction between the sp^2-hybridised nitrogen atom and the electron-donating sulphur atom.[108–110] In the IR spectrum the S–N bond absorbs in the region 640–670 cm^{-1} and 800–900 cm^{-1}.[55,111]



IV. Chemical properties

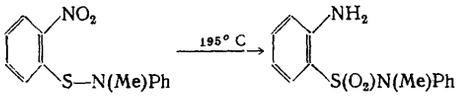
Sulphenamides and related compounds with a S–N bond are chemically reactive. Characteristically, their reactions proceed by an ionic mechanism, associated with heterolytic cleavage of the S–N bond. The vast majority of these reactions involve nucleophilic substitution or electrophilic addition to a double bond. Reactions of sulphenamides do not normally follow a radical pathway with heterolytic cleavage of the S–N bond. However, such radical reactions do take place in the vulcanisation of rubber, for which sulphenamides serve as accelerators. These reactions have been studied only in rare instances.

1. Thermal decomposition of sulphenamides

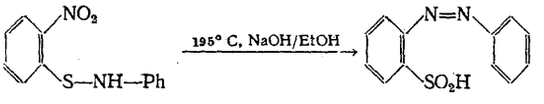


In spite of the widespread use of sulphenamides as accelerators for the vulcanisation of rubber, thermal decomposition of this class of compound has only been studied in the main with arenesulphenamides.[112–114] Thus, on heating sulphenamides to 195 °C, homolysis of the S–N bond takes place with formation of sulphenyl and aminyl radicals, which afford a mixture of disulphide and hydrazobenzene as a result of dimerisation; the hydrazobenzene

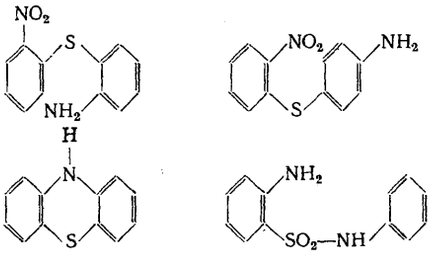
then disproportionates to the corresponding azobenzene.[112]



X = Cl, Br, NO_2.



In the presence of acid, a mixture of 2- and 4-aminophenyl aryl sulphide is formed as a result of intramolecular rearrangement of the protonated form of the corresponding sulphenamide.



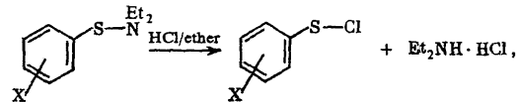
The nature of the solvent has a significant effect on the course of the reaction.[113] Thus, *N*-(2-aminobenzenesulphonyl)-*N*-methylaniline is formed on heating *N*-(2-nitrophenylsulphenyl)-*N*-methylaniline.[115,116]

In ethanolic NaOH, *N*-(2-nitrobenzenesulphenyl)aniline rearranges into an azosulphinic acid.[117]

A mixture of 2- and 4-aminophenyl 2-nitrophenyl sulphide, phenothiazine, and *N*-(2-aminobenzenesulphonyl)aniline was obtained by heating *N*-(2-nitrobenzenesulphenyl)aniline to 195 °C for 15 h in aniline.[118]

Alkylsulphenamides are more unstable than arylsulphenamides. The thermal stability decreases where a neighbouring group exerts an anchimeric effect on S–N bond cleavage (for example, in the presence of an acyl group), and as the basicity of the sulphenamide increases.[38]

2. Hydrolysis



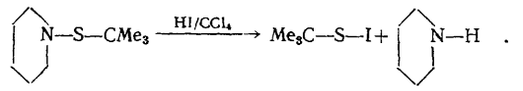
There are no data on the hydrolysis of sulphenamides. Evidently, this is explained by the fact that hydrolysis leads to sulphenic acids which in the large majority of cases are unstable.[33,119] However, a study of the hydrolysis of thiobisamines and dithiobisamines with dilute HCl has been made. Thus it has been shown that hydrolysis of these derivatives affords a mixture of sulphur dioxide, sulphur, hydrogen sulphide and the corresponding amine.[120]

$$RN_2—S_x—NR_2 \xrightarrow{H_2O+HCl} SO_2+H_2S+S+R_2NH,$$
$$R = Me, Et, iso\text{-}Pr;\ x = 1, 2.$$

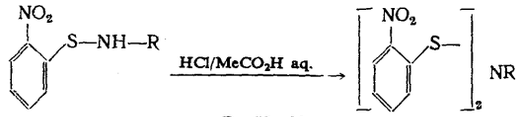
It is considered that reaction proceeds via sulphur chlorides which then undergo hydrolysis. Sulphenamides and related compounds are comparatively stable in cold aqueous and aqueous basic media, so that they can be prepared in the latter medium by reaction of sulphenyl chlorides with amines or from chloramines and mercaptides; sulphenamides may also be isolated from complexes by treatment with aqueous base.[37,121]

3. Reaction with hydrogen halides

Sulphenamides are readily cleaved with hydrogen halides with formation of sulphenyl halides in high yield.[122–133] The best results are achieved if HCl gas is passed through an ethereal solution of the sulphenamide.[122–130]



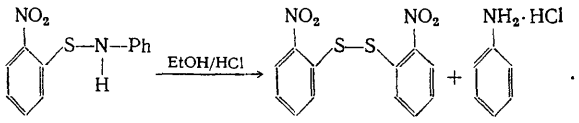
X = H, NO_2.



In this way, *o*-nitrobenzenesulphenyl chloride was obtained by using *o*-nitrobenzenesulphenamide. The yields of sulphenyl halide are lower if the sulphenamides are treated with HBr or HI.[127,131] For example, sulphenyl bromides were obtained by treating the corresponding sulphenamides with ethereal HBr at *ca.* 0 °C;[127]

$$R—S—NHR^1 \xrightarrow{HBr/ether} R—S—Br+HNRR^1,$$
$$R = tert\text{-}Bu,\ NO_2C_6H_4;\ R^1 = Me, Et, iso\text{-}Pr,$$

and *tert*-butylsulphenyl iodide and piperidine were obtained by treatment of a solution of *N*-*tert*-butylthiopiperidine with aqueous HI in carbon tetrachloride.[131]



The yields of sulphenyl chlorides are lower if the sulphenamides are cleaved with concentrated hydrochloric acid.[40,134–136] It is also reported that if the derived sulphenyl chlorides are unstable, the corresponding disulphide is obtained; and by heating sulphenamides with dilute hydrochloric or acetic acid, sulphenimides are formed.[136]

R=H, Me.

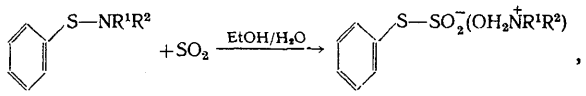
Only disulphide and aniline hydrochloride are formed on heating the corresponding sulphenanilide in ethanol or in dilute hydrochloric acid.[134,137–139]

Thio- and dithio-bisamines are cleaved at the S–N bond in the same way as sulphenamides by action of anhydrous HCl with the formation of sulphur chlorides and amine salts.[70,120]

$$R_2N{-}S_n{-}NR_2 + 4HCl \xrightarrow{\text{ether, 0 °C}} S_nCl_2 + 2R_2NH\cdot HCl,$$
$$R = Me, Et, Bu;\ n = 1, 2.$$

The reactions of sulphenamides with anhydrous HF have also been studied with a view to preparing sulphenyl fluorides, RSF, as a new class of compound.[140] However, on treatment of trichloromethylsulphenyldiethylamine with HF, the following were isolated from the reaction mixture: dichlorofluoromethylsulphenyl chloride, $CFCl_2SCl$, difluorochloromethylsulphenyl chloride, CF_2ClSCl, and products derived by cleavage of the S–C bond, namely trichlorofluoromethane and trichloromethylsulphenyl chloride.

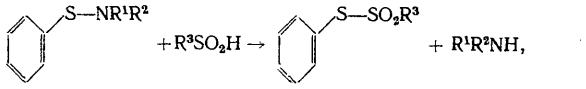
$$Cl_3CSNEt_2 \xrightarrow{\text{HF, } -78°\text{C}} CFCl_2SCl + CF_2ClSCl + CCl_3F + CCl_3CSCl.$$



The formation of sulphenyl chlorides in this reaction is evidently a consequence of an initial replacement of chlorine at the carbon atom; the resulting hydrogen chloride then cleaves the S–N bond of the sulphenamide leading to formation of the sulphenyl chloride. Trifluoromethylsulphenyldiethylamine has been used as substrate to prevent this complication. In this case, only cleavage of the S–N bond was noted on heating to 90 °C.

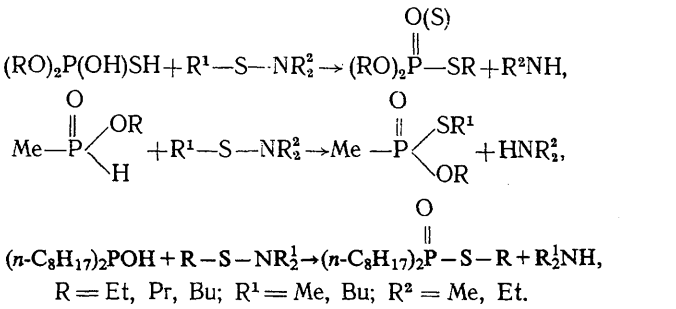
On analysing the mass spectrum of the mixture, an ion of mass 158, corresponding to CF_3SF_3, was detected. Thus, in no case is there formation of sulphenyl fluoride on treatment of the corresponding sulphenamide with anhydrous HF.

The ready cleavage of sulphenamides at the S–N bond on treatment with hydrogen halides has been applied both to the removal of *N*-sulphenyl protective groups from amino-acids in peptide synthesis,[128,129,141–143] and to the preparation of certain sulphenyl halides.[122,126,127,130]



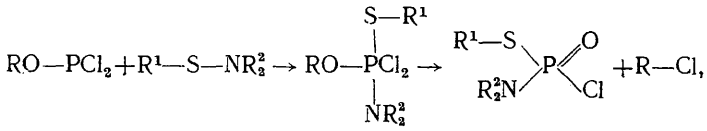
4. Reactions with sulphurous acid, sulphinic acids, dialkyl phosphites and monoalkyl phosphinites

Sulphenamides readily react with sulphur dioxide in an aqueous ethanolic medium during 1 h at 60 °C with the formation of Bunte salts in high yield up to 70%.[144]



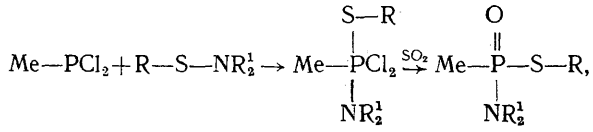
R^1 = Me, Et, *iso*-Pr; R^2 = Me, Et.

Sulphenamides react in a similar manner with sulphinic acids under the same conditions. In this case thiosulphonic acid esters are obtained.[29,145]



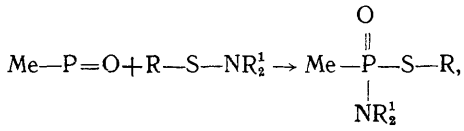
R^1, R^2 = Alk; R^3 = Alk, Ar.

Sulphenamides react with dialkyl phosphites, thiophosphites, phosphinous acid monoesters and dialkylphosphine oxides with the formation of thiolphosphates, thiolphosphonates and thiolphosphinates in 75–95% yield.[146]



R = Et, Pr, Bu; R^1 = Me, Bu; R^2 = Me, Et.

Sulphenamides react similarly with phosphonous and phosphorous acid chlorides and with phosphonous anhydrides. For example, *S*-alkyl thiophosphoramidochloridates are obtained by interaction of alkyl phosphorodichloridates with sulphenamides.



R = Me; R^1 = Bu, *tert*-Bu; R^2 = Me, Et.

Sulphenamides react with methyldichlorophosphine to afford intermediate phosphoranes which are converted to the corresponding *S*-alkyl thiophosphonamidates on treatment with sulphur dioxide.

R = Bu, *tert*-Bu; R^1 = Me, Et.

Methylphosphonous anhydride, like the corresponding dichlorophosphine, also yields *S*-alkyl thiophosphonamidates.

R = Bu, *tert*-Bu; R^1 = Me, Et.

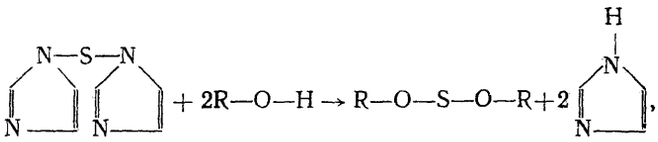
5. Reactions with hydrogen sulphide and mercaptans

Thio- and dithio-bisamines react comparatively smoothly with hydrogen sulphide to give trisulphides from the former, and polysulphides from the latter.[122]

$$RN_2{-}S_n{-}NR_2 + H_2S \rightarrow H{-}S{-}S_n{-}SH + R_2^2N^+H_2HS_4^-,$$
$$R = Me, Et, iso\text{-}Pr, tert\text{-}Bu;\ n = 1-4.$$

Aryl- and alkyl-sulphenamides react easily with mercaptans to yield the corresponding disulphide and amine, but the same reaction with *N*-acylsulphenamides is less facile. Thus, at room temperature or on cooling, arylsulphenamides are cleaved by mercaptans in dimethylformamide, hexane, or pyridine, thereby providing

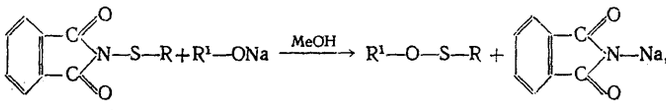
disulphides and amines in high yield.[129]



$$R{-}S{-}NR^1R^2 + H{-}S{-}R^3 \xrightarrow{DMF} R{-}S{-}S{-}R^3 + HNR^1R^2,$$

R = Me, Et, Ph, $O_2NC_6H_4$; R^1 = Me, Et, Ac; R^2 = H, Me, Et; R^3 = Et, Pr, Ph.

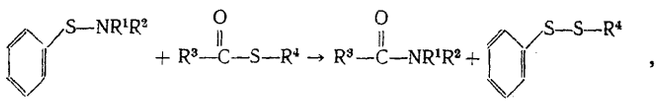
This procedure is also followed for the removal of sulphenamide protecting groups in peptide synthesis.



6. Reactions with alcohols

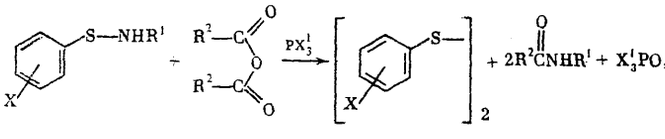
Thiobisamines react with alcohols in pentane at low temperature with the formation of sulphoxylic acid esters, as exemplified by the converison of bis(1-imidazolyl) sulphide.[147,148]

R = Et, Bu, *tert*-Bu, *iso*-Pr.



N-Acylsulphenamides interact with alkoxides in methanol at 40–50 °C to give the corresponding sulphenic acid esters in 50–70% yield.[149]

R = Bu; R^1 = Me, Et, *iso*-Pr, *tert*-Bu.

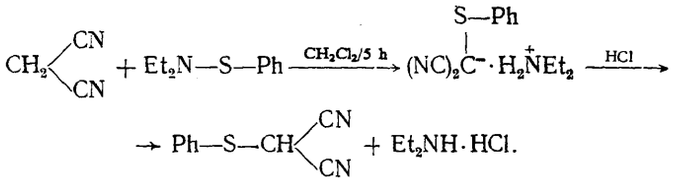


7. Reactions with carboxylic acids and their derivatives

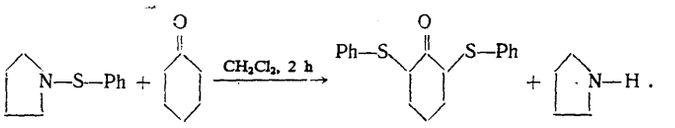
Sulphenamides are efficient reagents for the conversion of thiolcarboxylic acid esters, carboxylic acid anhydrides and acyl chlorides to the corresponding amides. Reaction proceeds under mild conditions in the presence of phosphorus(III) compounds, the amide yield sometimes reaching 95%.[150–153]

R^1 = Me, Et, Bu, Pr; R^2 = Me, Et, Bu, *iso*-Pr; R^3 = Me, Et, Bu, Ph; R^4 = Ph, $O_2NC_6H_4$.

In the case of carboxylic acid anhydrides, amination of both acyl groups takes place, the phosphorous(III) reagent serving as catalyst and, at the same time, functioning as acceptor of oxygen.[153]



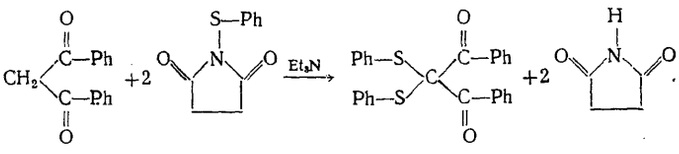
R^1 = Ph; R^2 = Me, Et, Ph; X = H, NO_2; X^1 = Ph, OEt.



The activating effect of the catalyst is explained by an initial attack on the sulphur atom of the sulphenamide, which ultimately produces an active phosphonium salt. Thus, the catalyst serves to polarise the S–N bond, and consequently effects its cleavage.[152]

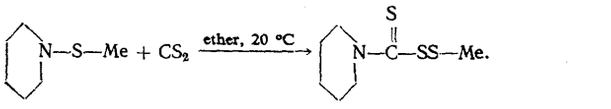
8. Reactions with CH-acids

Certain sulphenamides have proved effective for the sulphenylation of compounds possessing active methylene groups.[2,154–157] Thus, the diethylammonium salt of phenylthiomalononitrile was isolated in 85% yield by stirring equimolecular amounts of *N,N*-diethylphenylsulphenamide and malononitrile in methylene chloride during 5 h at room temperature.[2] Phenylthiomalononitrile was obtained by treatment of the salt with hydrogen chloride.



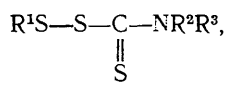
2,6-Bis(phenylthio)cyclohexanone was obtained in high yield by interaction of 2 moles of *N*-phenylthiopyrrolidine with 1 mole of cyclohexanone in methylene chloride at room temperature during 2 h.[2]

It should be pointed out that not every sulphenamide is suitable for sulphenylation. Referring to the above reaction, it is not possible to sulphenylate cyclohexanone by using *N,N*-diethylphenylsulphenamide.



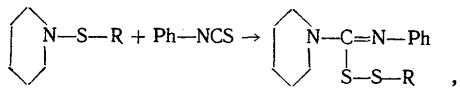
For bis-sulphenylation of methylene groups with *N*-acylsulphenamides, it is recommended that the reaction be conducted in the presence of basic reagents. Thus, bis(phenylthio)dibenzoylmethane was obtained in 50% yield by treatment of 1 mole of dibenzoylmethane with 2 moles of *N*-phenylthiosuccinimide in the presence of 2 moles of triethylamine in methylene chloride at room temperature.[154]

In this case, a succinimide-amine complex is formed together with the triethylammonium salt of the monosulphenylated derivative, which reacts with the sulphenamide to produce bis(phenylthio)-dibenzoylmethane.



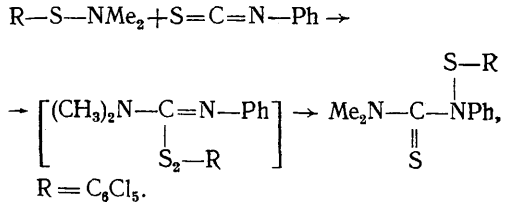
9. Addition of sulphenamides to multiple bonds

The reaction of a sulphenamide with carbon disulphide is typical of a sulphenamide addition across a multiple bond, wherein two hetero-functions are incorporated as a result of the familiar S–N bond cleavage. Thus, methyl *N*-cyclopentamethylenetrithiocarbamate was obtained in more than 80% yield by interaction of an ethereal solution of *N*-methylthiopiperidine with carbon disulphide at room temperature over 5 min.[158,159]



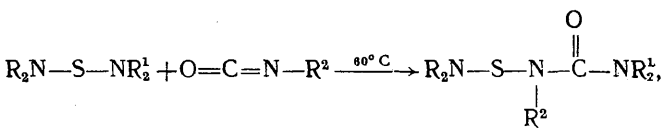
It is suggested that reaction is facilitated by coordination of carbon disulphide to the lone pair on nitrogen, with subsequent insertion into the S–N bond to provide the trithiocarbamate.

However, if the substituent on the sulphur atom of the sulphenamide is strongly electron-accepting, reaction with carbon disulphide does not take place. The following trithiocarbamates have been obtained by this method:



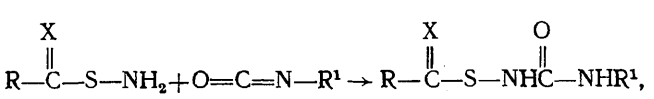
R^1 = Me, Et, *tert*-Bu, allyl;
R^2 = Me, Et, $(CH_2)_5CH$; $R^1R^2 = (CH_2)_4O$.

Sulphenamides react in the same way with isothiocyanates.[40,160,161] It was found that *S*-alkylthio-*N*-cyclopentamethylene-*N'*-phenylisothioureas are formed by interaction of *N*-*tert*-butylthio- or *N*-ethyl-thio-piperidine with phenyl isothiocyanate as a result of addition across the C=S bond, as takes place with carbon disulphide.



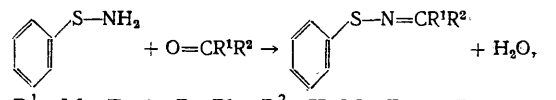
R = Et, *tert*-Bu.

The reaction of sulphenamides with isothiocyanates sometimes leads to the formation of thiourea derivatives rather than *S*-(alkylthio)isothioureas.[160] It would appear that in this case it is the C=N bond of the isothiocyanate which is cleaved, not the C=S bond as in the above case. However, mechanistically this is not true. In fact, in the initial stage of the reaction, the sulphenamide adds across the C=S bond with the formation of the corresponding *S*-(organothio)isothiourea, which subsequently isomerises to the thiourea derivative.



R = C_6Cl_5.

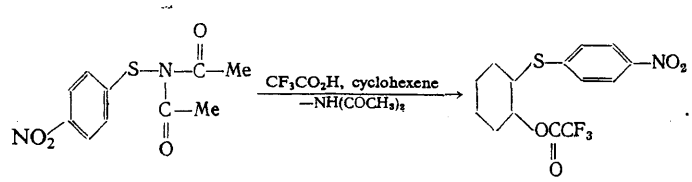
Thiobisamines add to isocyanates by cleavage of the C=N bond with the formation of *N*-substituted ureas in 80–90% yield.[160]



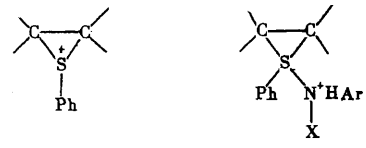
R = Et; $R^1_2 = (CH_2)_5$, $(CH_2)_4O$; R^2 = Me, Ph.

S-Acylsulphenamides react with isocyanates by addition to the N=C bond, as in the above case. For example, urea derivatives are obtained in 70–80% yield by allowing the reaction mixture to stand in acetone for 20 h.[160]

R = Ph, 3,4-$Cl_2C_6H_3$; R^1 = Me, Ph, ClC_6H_4; X = O, S.



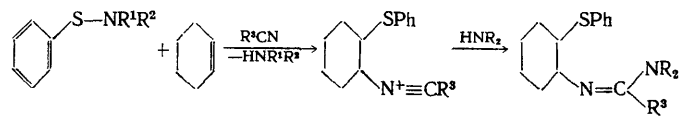
Sulphenamides with a free amino group react with aldehydes and ketones in the same manner as primary amines, affording the corresponding aldimines and ketimines.[162,163]



R^1 = Me, Et, *iso*-Pr, Ph; R^2 = H, Me, Et, *iso*-Pr.

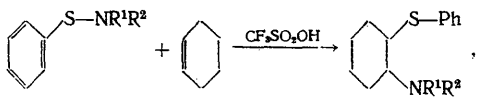
Sulphenamides with a tertiary amino group (NR_2) do not react with aldehydes and ketones.

The possibility of adding sulphenamides to a double bond with the participation of an external nucleophile was shown for the first time in 1981, for example, in the reaction of *N*,*N*-diacetyl-*p*-nitrophenylsulphenamide with cyclohexene in the presence of trifluoroacetic acid.[164]



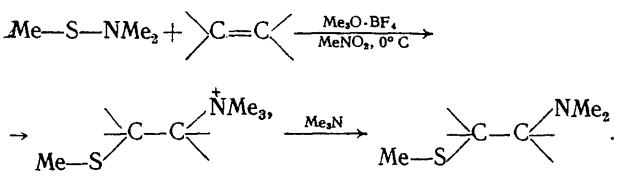
A sulphenium ion is formed as a consequence of two factors: the presence of two electron-accepting acyl groups in the sulphenamide, and the presence of a strong acid in the medium. The ion thus formed adds to the olefin producing an episulphonium complex which is cleaved by the trifluoroacetate ion to provide a *trans*-adduct: *p*-nitrophenyl *trans*-2-(trifluoroacetoxy)cyclohexyl sulphide in the above example. Thus, a sulphenium cation, or an ammonium ion in which the S–N bond is significantly polarised (a partial positive charge developing on the sulphur atom), interacts with the olefin to form either an episulphonium ion (I) or a covalently bonded sulphurane (II), which is subsequently cleaved with the nucleophile.

(I) (II)



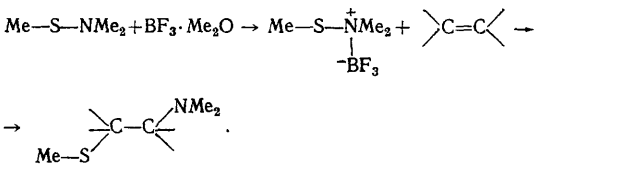
The formation of an episulphonium ion is considered more likely. With a nitrile as the external nucleophile, addition across the multiple bond takes place on activation of the sulphenamides with trifluoromethanesulphonic acid.[165–169] In this way, amidines are obtained in high yield.[165]

R=Me, Et; R^1, R^2=$(CH_2)_5CH$, $(CH_2)_2O(CH_2)_2$; R^1=H; R^2=Bu; R^3=Ph.

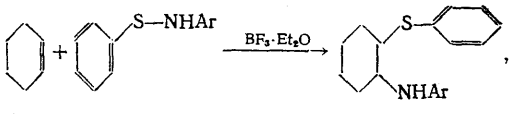


If the reaction of a phenylsulphenamide with cyclohexene in methylene chloride is allowed to proceed in the presence of an external nucleophile as well as trifluoromethanesulphonic acid as

activating agent, then aminosulphides are obtained in high yield.[170–172]

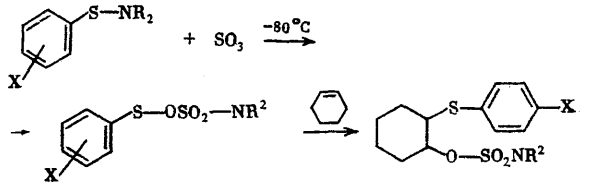


R^1, $R^2=(CH_2)_5$, $(CH_2)_2O(CH_2)_2$; $R^1=H$; $R^2=$ *tert*-Bu.

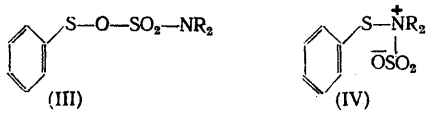


Trimethyloxonium fluoroborate or boron fluoride etherate may also serve as activator. In the presence of the former, sulphenamides interact with olefins in nitromethane to give a β-(methylthio)alkyltrimethylammonium salt which is converted into an amine on treatment with trimethylamine.[173]

In the presence of boron fluoride etherate, reaction of a sulphenamide with an olefin yields a trifluoroboratoammonium salt from which an aminoalkyl sulphide is liberated on treatment with base.



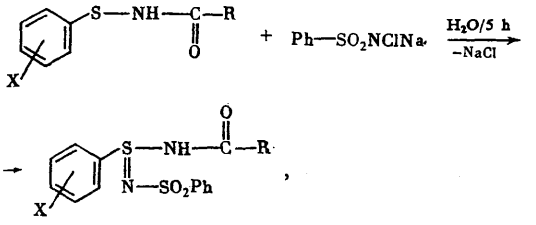
The addition of phenylsulphenamides to cyclohexene in benzene containing a 50% excess of boron fluoride at room temperature leads, stereospecifically, to the corresponding *trans*-adduct in 50 to 90% yield.[174]



Ar=4-$NO_2C_6H_4$, 4-ClC_6H_4, 4-MeC_6H_4, 4$MeOC_6H_4$, 3$MeOC_6H_4$.

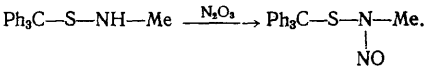
It has been shown that *N,N*-diethylphenyl- or *N,N*-diethyl-*p*-nitrophenylsulphenamide in the presence of sulphur trioxide also add stereospecifically to cyclohexene, affording *trans*-1,2-disubstituted cyclohexanes in high yield.[175–178]

R = Et; X = H, NO_2.



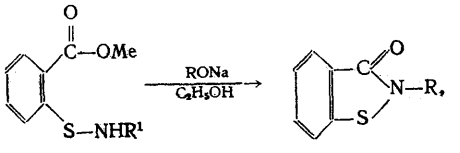
It is proposed that, initially, the sulphenamide and sulphur trioxide form an intermediate, (III) or (IV), from which the electrophilic moiety is derived.[175]

(III) (IV)



10. Other reactions

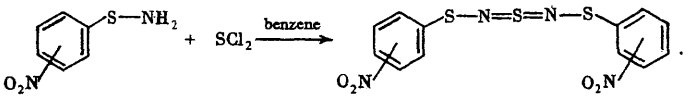
It has been reported that *N*-acylarylsulphenamides undergo sulphonylimination with sodium *N*-chlorobenzenesulphonamide (Chloramine B). Thus, as with thioethers, Chloramine B interacts with *N*-acylarylsulphenamides in aqueous medium to give the corresponding *N*-acylaryl(sulphonylimido)sulphinamides in 40–80% yield.[179–181]



R = Me, Ph; X = H, NO_2.

N-Monoalkylsulphenamides react with nitrogen oxides (N_2O_3) in the same manner as secondary amines to provide nitrososulphenamides in 50–55% yield.[137]

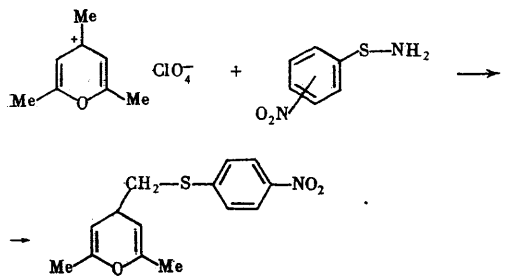
N-Monoalkylphenylsulphenamides which possess an *o*-carbalkoxy group cyclise by intramolecular acylation to 1,2-benzoisothiazol-3-ones.[182]



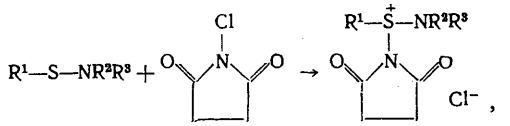
R=Alk; R^1=$PhCH_2$, Pr, CH_2CH_2OH, Ph, MeOPh.

Sulphenamides with a free amino group react with thionyl fluoride, sulphur dichloride and triphenylphosphine dichloride. Thus, in the first case, trifluoromethylthionylimine is obtained by interaction of trifluoromethylsulphenamide with thionyl fluoride in the presence of sodium fluoride at 20 °C.[183]

In the second case, *N,N'*-bis(*p*-nitrobenzenesulphenyl)sulphur diimide is formed in 70% yield by treatment of *p*-nitrobenzenesulphenamide with sulphur dichloride in benzene at room temperature.[184]



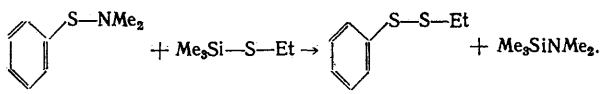
In the third case, boiling a solution of arylsulphenamide and triphenylphosphine dichloride in carbon tetrachloride for 30 min in the presence of tertiary amine affords the corresponding phosphazo compound in 50–90% yield.[185]



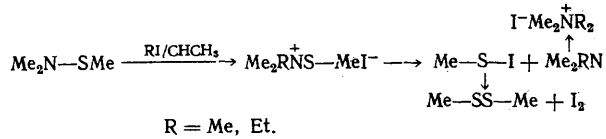
Ar=$Cl_3C_6H_2$, Cl_5C_6, $NO_2C_6H_4$.

It has been shown that a thioether is formed in 80% yield by interaction of *p*-nitrobenzenesulphenamide with a 2,4,6-trimethyl-

pyrylium salt which possesses an active methyl group at the 4 position.[185]

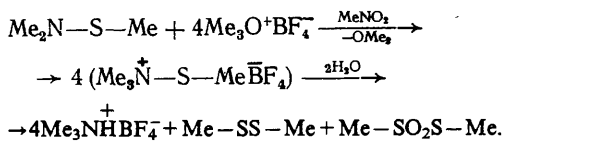


Succinimidosulphonium salts are obtained in 80–90% yield by reaction of sulphenamides with *N*-chlorosuccinimide in methylene chloride at 0 °C.[186]



R^1 = Me, Et, Ph; R^2 = Me, $PhCH_2$; R^3 = Me, $PhCH_2$.

It has been reported that unsymmetrical disulphides are obtained by reaction of sulphenamides with alkyl- or aryl-thiosilanes. Thus, ethyl phenyl disulphide was isolated in 47% yield from the reaction of *N,N*-dimethylphenylsulphenamide with ethylthiotrimethylsilane in hexane at 0 °C.[4]



Sulphenamides are alkylated with alkyl iodides with the formation of unstable salts.[4,187–190] Thus, dimethyl disulphide and a tetraalkylammonium iodide were isolated in almost quantitative yield by treatment of *N,N*-dimethylmethanesulphenamide with a solution of methyl or ethyl iodide in chloroform. The reaction proceeds via an unstable alkylthioammonium salt which disproportionates into the disulphide, iodine and the tetraalkylammonium salt.

R = Me, Et.

Furthermore, methylation of sulphenamides with trimethyloxonium fluoroborate in nitromethane also leads to the formation of an alkylthioammonium salt which is very sensitive to moisture and decomposes into the corresponding disulphide, thiosulphonate and trialkylammonium fluoroborate.[190]

A similar reaction takes place on treatment of a thiosulphonium fluoroborate with a tertiary amine in nitromethane.

Deoxygenation of coordinated and free sulphoxides

V Yu Kukushkin
Leningrad State University

ABSTRACT. The deoxygenation reactions of coordinated R_2SO molecules (R = Alk, Ar) that occur with the formation of dialkyl and diaryl sulphide complexes are examined. Reduction reactions of free sulphoxides involving metal complexes and ions have been classified. It is shown using specific examples which synthetic problems can be solved with the use of different deoxygenating agents and reagent systems.

I. Conclusion

The considerable interest in sulphoxides is in many respects governed by the role which they have played and still play in the development of theoretical concepts in chemistry and also in resolving a number of practical problems. One of the most important properties of R_2SO molecules is their ability to undergo deoxygenation to give sulphides R_2S. The number of publications on this topic is quite considerable.[1–9] The majority of these studies are devoted to the deoxygenation of free sulphoxide molecules, whereas the reduction reactions of coordinated R_2SO molecules have been examined only briefly[7–9] or not considered at all. On taking into account the fact that deoxygenation of coordinated sulphoxides is of theoretical interest in relation to studies on the reactions of coordinated ligands and also that reduction reactions of inner-sphere R_2SO molecules can be of significance for the preparation of complexes that incorporate sulphides R_2S, we decided to compensate for this omission especially since a considerable amount of factual data on the reduction reactions of R_2SO molecules in metal complexes has appeared during the last 8–10 years.

II. Reactions involving hydrohalic acids

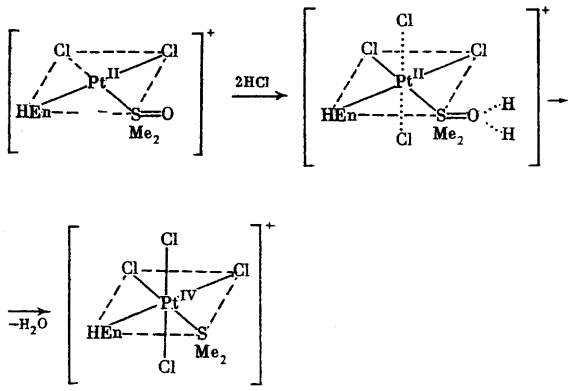
The first studies on the deoxygenation of free sulphoxides using HX (X = Cl, Br, I) were carried out at the beginning of the 20th century.[10–13] It was noted in a review article[5] that in general the reduction reactions of this type may be represented by the following equation:

$$R{-}S(O){-}R' + 2HX \rightarrow R{-}S{-}R' + X_2 + H_2O.$$

It was established also that the intermediate in this process is the halosulphonium salt $[R{-}\overset{+}{S}(X){-}R']X^-$, which, depending on X and also the nature of R and R', is either readily reduced to the corresponding sulphide RSR' or decomposes to form a mixture of products, amongst which RCl and RSH in particular have been identified.

Deoxygenation of dimethyl sulphoxide (DMSO) in a metal complex was carried out for the first time in 1968 [14] in a study of the reaction between $[Pt(DMSO)_2Cl_2]$ and hydrochloric acid. From IR spectroscopic data and elemental analysis, the reaction product was identified as $[Pt(DMS)_2Cl_4]$, where DMS = dimethyl sulphide. It was proposed[14] that the process takes place according to the following overall equation:

$$[Pt(DMSO)_2Cl_2] + 4HCl \rightarrow [Pt(DMS)_2Cl_4] + Cl_2 + 2H_2O.$$



It was noted, however, that this reaction is accompanied by two side reactions and the final Pt(IV) complex is contaminated with unidentified products.

In the same year an article was published[15] in which there was a specific description of the reaction between $PdCl_2$ and tetramethylenesulphoxide (TMSO) in acetone saturated with anhydrous HCl. It was noted that the reaction of $PdCl_2$ with TMSO takes place quite rapidly and gives the complex $[Pd(C_4H_8S)_2Cl_2]$ with coordinated tetramethylenesulphide molecules. Unfortunately, Meek et al.[15] did not study or discuss the mechanism of this reaction.

In the 1970s the chemistry of sulphoxide complexes started to undergo rapid development.[7,16–19] However, only two reports appeared in the literature on the deoxygenation of R_2SO molecules in complexes. Thus, it is noted by Braddock et al.[20] that compounds of the type $[Pt(Am)_2(DMSO)Cl]Cl$ (Am = amine) in aqueous perchloric acid ($[HClO_4] > 1.0$ mol^{-1} litre^{-1}) are converted to DMS derivatives of Pt(IV), but these products were not identified or determined. In a study by Boucher and Bosnich[21] a method is given for the preparation of the complex *cis*-$[Pt(DMSO)(C_2H_4)Cl_2]$ from $K[Pt(DMSO)Cl_3]$ and ethylene in aqueous HCl. It was noted in this case that an excess of acid leads to the reduction of DMSO catalysed

by platinum. However, in this article[21] as well, no details are given on the experiment.

Studies on the deoxygenation of inner-sphere sulphoxides have only recently started to be actively pursued. It was shown[22] that on dissolving the complex [Pt(II)(En)(DMSO)Cl]Cl (En = ethylenediamine) in a minimum solution for 2 days at 20 °C, deoxygenation of the sulphoxide ligand occurs and Pt(II) is oxidised to Pt(IV). The complex *cis*-[Pt(HEn)(DMSO)Cl_4]Cl is formed as a result. Fanizzi et al.[22] assumed that after opening of the ethylenediamine chelate ring and formation of $[Pt(HEn)(DMSO)Cl_2]^+$, the reaction takes place via a mechanism involving protonation of the inner-sphere DMSO molecule and a concerted redox conversion:

It has been established[23] that when the complex $H_2[Pt(DMSO)(\mu\text{-}O)Cl]_2$ (A) reacts with HCl in water with a molar ratio of (A) to HCl of 1:5, complex (A) is cleaved to form H[Pt(DMSO)Cl_3] and $[Pt(DMSO)(\mu\text{-}Cl)Cl]_2$. When the concentration of HCl is increased, these products are formed together with the sulphide complex *trans*-[Pt$(DMS)_2Cl_4$] (in 10–15% yield), the structure of which was established by X-ray diffraction analysis. Thus in this case also, a Pt(II) sulphoxide complex when treated with concentrated HCl is converted to a dimethyl sulphide derivatives of Pt(IV).

It was shown by Kukushkin et al.[24] that the deoxygenation of inner-sphere R_2SO molecules in platinum(II) complexes can have preparative importance. It transpired that the reaction between $(Et_4N)[Pt(II)(R_2SO)Cl_3]$ [R = Me, CH_2Ph(Bz), Ph] and HCl on heating the reaction mixture for several minutes in acetonitrile or nitromethane leads to the formation of the corresponding $(Et_4N)[Pt(IV)(R_2S)Cl_5]$ complexes, which were isolated in 80–90% yield. If HBr is used instead of HCl, the reduction of the sulphoxide and oxidation of Pt(II) is accompanied by replacement of the chloride ions in the complex by bromide ions. As a result of all these reactions, the compounds $(Et_4N)[Pt(R_2S)Br_5]$ were isolated.

It is important to note that the reaction of coordinated dibenzyl sulphoxide {in the complex $(Et_4N)[Pt(II)(Bz_2SO)Cl_3]$} with HCl takes place almost completely in favour of the deoxygenated ligand whereas reaction of free Bz_2SO with HCl is accompanied by rapid decomposition of the sulphoxide to form a mixture of products, amongst which PhCHO, BzCl, Bz_2S_2, Bz_2S, and $Bz_2S_2O_2$ have been detected.[10] Hence it follows that the reactivity of coordinated and free Bz_2SO towards HCl is substantially different. This result, so far the only one, suggests that the reduction of sulphoxides in complexes using HCl is promoted by the Pt(II) ion.

III. Conversion reactions of DMSO in systems of the type M–DMSO–RX

It was shown in a number of studies[25–35] that the reaction between the components of systems of the type M–DMSO–RX (R = H, Alk, X = Cl, Br, I) results in the deoxygenation of DMSO with the formation of DMS or secondary conversion products of DMS. The mechanism of these processes is quite complex (as is shown, for example, in four studies[31–34]). Nevertheless, it was found that an oxidisable metal promotes reaction between the components of the redox system. It may also be assumed that in the case of the reaction between metals and DMSO and HX, the resulting intermediate $Me_2\overset{+}{S}X$ is reduced by metals or metal ions formed at an intermediate stage of the process and which are oxidised and form complexes. Some of these complexes have been isolated and identified (Table 1).

IV. Reaction between inner-sphere DMSO in Pt(II) complexes and $SOCl_2$

The ability of thionyl chloride to deoxygenate free molecules of alkyl and aryl sulphoxides has been reported in the literature.[36–41] Usually these reactions take place with the formation of chloroalkyl or chloroaryl sulphides. In particular, it was established[36] that DMSO reacts with thionyl chloride at a molar ratio of 1:2 in dichloromethane to form $MeSCH_2Cl$, which was isolated in 92% yield. When diphenyl sulphoxide is reacted with $SOCl_2$, a mixture of diaryl sulphides — Ph_2S, $(p\text{-}ClC_6H_4)SPh$, and $(p\text{-}ClC_6H_4)_2S$ — is formed in the ratio 0.36:0.59:0.05 respectively.[38]

It was found[39] that coordinated DMSO reacts with $SOCl_2$ in a different way to when it is free. It transpired that the reaction of the complexes $(Et_4N)[Pt(DMSO)Cl_3]$ and *cis*-[Pt(DMSO)$(DMS)Cl_2$] with $SOCl_2$ at 20 °C in acetonitrile takes place for several minutes and gives DMS derivatives of Pt(IV) — $(Et_4N)[Pt(DMS)Cl_5]$ and *cis*-[Pt$(DMS)_2Cl_4$]. The reaction between the bis-sulphoxide complex *cis*-[Pt$(DMSO)_2Cl_2$] and $SOCl_2$ is interesting:

$$cis\text{-}[Pt(DMSO)_2Cl_2] + SOCl_2 \rightarrow cis\text{-}[Pt(DMS)(DMSO)Cl_4] + SO_2.$$

In this process only one coordinated DMSO molecule is reduced.

Thus the reaction of Pt(II) DMSO complexes with $SOCl_2$ results in the deoxygenation of DMSO and the oxidation of Pt(II) to Pt(IV); the formation of $MeSCH_2Cl$ during the reactions has not been observed. These reactions of coordinated sulphoxides have parallels in preparative organic chemistry. In particular, it was shown in three studies[39–41] that the formation of chlorinated disulphides can be avoided if the deoxygenation of R_2SO with thionyl chloride is carried out in the presence of cyclohexene[39] or sodium iodide.[41] Both of these compounds combine with chlorine. For example, the overall reaction of R_2SO with $SOCl_2$ in the presence of cyclohexene is represented by the equation

$$Ar_2SO + SOCl_2 + C_6H_{10} \rightarrow Ar_2S + SO_2 + C_6H_{10}Cl_2.$$

It may be assumed that in the reaction of Pt(II) sulphoxide complexes with $SOCl_2$, platinum(II) also acts as a chlorine-binding site. In this case Pt(IV) DMS complexes are formed.

The fact that in the reaction of the bis-sulphoxide complexes *cis*- and *trans*-[Pt$(DMSO)_2Cl_2$] with excess $SOCl_2$ only one of the DMSO ligands is reduced suggests that the processes involving reduction of DMSO and oxidation of Pt(II) are concerted.

Table 1. Initial reactants and conversion products in systems of the type metal–DMSO–RX.

Initial reactants	Products	Notes	Refs.
Pd–DMSO–n-$C_6H_{13}Br$	*trans*-[$Pd(DMS)_2Br_2$]		[25]
Rh–DMSO–n-$C_6H_{13}Br$	Rhodium(III) dimethyl sulphide complex	No information given on the structure of the rhodium and platinum complexes	[25]
Pt–DMSO–n-$C_6H_{13}Br$	Platinum(IV) dimethyl sulphide complex		
Au–DMSO–HBr	[(DMS)AuBr] and [$(DMS)AuBr_3$]	Both complexes were characterised by means of X-ray diffraction analysis	[26, 27]
M–DMSO–HX (M = Pd, Pt; X = Cl, Br)	*trans*-[$Pd(DMS)_2Cl_2$], [$Pt(DMS)_2Br_4$]	"	[28]
Noble metal–HX (X = Cl, Br)	Oxidation product of noble metal	No information given on the deoxygenation process	[29]
Ag–DMSO–HX (X = Br, I)	AgX, $(Me_3S)[AgX_2]$, $(Me_3S)[Ag_2X_3]$	$(Me_3S)[AgBr_2]$ complex was characterised by means of X-ray diffraction analysis	[30]
M–DMSO–CCl_4 (M = Fe, Co, Ni, Cu)	Metal oxidation products, DMS, CO_2, $COCl_2$, C_2Cl_6	Process takes place via the formation of dichlorocarbene	[31–34]

In concluding this section we should mention that the deoxygenation reactions of inner-sphere sulphoxides using $SOCl_2$ have parallels not only in organic but also organometallic chemistry. In particular, it has been shown[42–44] that acyl complexes can be deoxygenated with thionyl chloride or other acid halides to alkylidyne complexes

$$[M]—\overset{\overset{O}{\|}}{C}—R \rightarrow [M]\equiv C—R.$$

In these reactions also there is at least a formal reduction of the ligand and oxidation of the metal ion by the action of the acid chloride.

V. Deoxygenation of sulphoxides coordinated to Pt(II) with the reagent system PCl_5–ROH

It is known that in the reaction of phosphorus(V) pentachloride with different types of platinum(II) complexes, oxidative chlorination of the complexes occurs, giving platinum(IV) derivatives.[45–49] Fully in accordance with this are the reactions of the complexes K[$Pt(DMSO)Cl_3$] and [$Pt(R_2SO)LCl_2$] (R = Me, Et, $^1/_2C_2H_4OC_2H_4$, L = R_2SO; R = Me, L = DMS, NH_3, piperidine, pyridine, 2- and 4-methylpyridine) with PCl_5 in acetonitrile or nitromethane, resulting in the formation of the corresponding Pt(IV) compounds.[50,51]

In particular, by reacting the complex K[Pt(II)$(DMSO)Cl_3$] with PCl_5 in MeCN followed by decomposition of the excess PCl_5 with water or ethanol and addition of tetraethylammonium chloride to the mixture, (Et_4N)[Pt(IV)$(DMSO)Cl_5$] was obtained. The structure of this compound was confirmed by X-ray diffraction.[51] The reaction occurs differently if 2-propanol is used instead of water or ethanol. In this case as a result of all of the stages of the reaction, there is the formation of the DMS derivative (Et_4N)[Pt(IV)$(DMS)Cl_5$], whose structure has also been confirmed by X-ray diffraction analysis.

Similar reactions are typical for other Pt(II) sulphoxide derivatives, such as complexes of the type [Pt(II)$(R_2SO)LCl_2$]. The latter react with PCl_5 and with the reagent system PCl_5–ROH in different ways:

$$[Pt^{II}(R_2SO)LCl_2]—\begin{cases}\xrightarrow{PCl_5} [Pt^{IV}(R_2SO)LCl_4]\\ \xrightarrow{PCl_5/ROH} [Pt^{IV}(R_2S)LCl_4]\end{cases}$$

It should be mentioned in particular that on addition of EtOH or 2-PrOH to a mixture of [Pt(II)$(R_2SO)LCl_2$] and PCl_5, the dialkyl sulphide derivatives [Pt(IV)$(R_2S)LCl_4$] are formed in all cases. A mixture of K[$Pt(DMSO)Cl_3$] and PCl_5 reacts with alcohols in a different way. Thus, introduction of 2-propanol leads to the formation of the complex $[Pt(DMS)Cl_5]^-$, while introduction of ethanol gives a $[Pt(DMSO)Cl_5]^-$ complex. It follows from a comparison of the results obtained that in at least one case (in the reaction with K[$Pt(DMSO)Cl_3$] or with Pt[$R_2SO)LCl_2$], an inner-sphere rather than free molecule of R_2SO is deoxygenated.

It may be assumed that in the reaction of the complexes K[$Pt(DMSO)Cl_3$] and [$Pt(R_2SO)LCl_2$] with PCl_5, oxidation of the Pt(II) ion to Pt(IV) occurs and the intermediate (A) is formed:

$$\left[\begin{array}{c}O^+PCl_4\\ \|\\ Pt^{IV}—SMe_2\end{array}\right]$$
(A)

The subsequent addition of water leads to the hydrolysis of the sulphur-containing ligand with the formation of a Pt(IV) dialkyl sulphoxide complex, while when 2-propanol is introduced it is reduced and a Pt(IV) dialkyl sulphide derivative is formed.

It is known from the literature that the deoxygenation reactions of free R_2SO molecules using PCl_5 occur quite readily. However, there are significant differences in the form of reduction of inner-sphere and uncoordinated dialkyl sulphides. Thus, the reaction between free DMSO in PCl_5 occurs rapidly and leads to the formation of $MeSCH_2Cl$.[52,53] However, no complexes with such a

ligand were detected amongst the products from the reaction of coordinated DMSO with PCl_5.[50,51]

In the literature there are also examples of the conversion of R_2SO molecules to R_2S using PCl_5–reducing agent systems (where NaI [41] or 1-morpholino-1-cyclohexene [54] act as the reducing agent) as well as acid halide–alcohol–amine systems [where the acid halide is $SOCl_2$ and Cl(O)C–C(O)Cl].[6] In the latter case reaction of DMSO with the acid halide results in the formation of the salt $[Me\overset{+}{S}Cl]Cl^-$, which then reacts with an alcohol in the presence of NR_3 according to the scheme:[6]

$$[Me_2\overset{+}{S}Cl]\,Cl^- \xrightarrow[-NR_3\cdot HCl]{MeCH(OH)Me,\ NR_3} \rightarrow [Me_2\overset{+}{S}{-}OCHMe_2]Cl^- \xrightarrow[-NR_3\cdot HCl]{NR_3} Me_2S + Me_2CO.$$

In contrast to the reactions of free DMSO, the introduction of NR_3 is not required for the deoxygenation of inner-sphere DMSO.[39,50,51] This difference in the nature of the processes is likely to be due to the change in reactivity of the DMSO molecule as a result of coordination.

VI. Conversion of sulphoxides on treatment with metal ions in lower oxidation states

It is indicated in a review article[55] that Ti^{3+} compounds are mild and quite specific reducing agents as a result of titanium having a high affinity for oxygen. It is this factor that determines the reactivity of Ti^{3+} in reduction processes. Thus, $TiCl_3$ is an excellent reducing agent for nitro and nitroso compounds, aromatic and aliphatic *N*-oxides, and also azoxy compounds and oximes.[55] The ability of Ti^{3+} to extract an oxygen atom has also been extended to deoxygenation reactions of sulphoxides.[56,57]

It was shown[58] that the reaction of R_2SO with $TiCl_3$ can be used for the synthesis of R_2S. Different aryl and alkyl sulphides were obtained by this method. Reduction takes place for 2–4 h on boiling the reactants in a methanol–dichloromethane solvent mixture. The respective sulphides were isolated in 70–90% yield. Ho and Wong[58] assumed that the reaction takes place according to the following scheme:

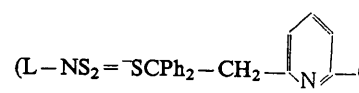
$$R_2S{=}O + Ti^{3+} \longrightarrow R_2\overset{+}{S}{-}O{-}Ti^{\cdot\cdot\cdot}\ (Cl^-) \longrightarrow R_2S + Ti{=}O^{2+}.$$

The proposed synthetic method[58] was subsequently adapted for the deoxygenation of other sulphoxides.[59,60]

The reducing power of Ti^{2+} is known to be greater than that of Ti^{3+}.[55] It has also been established that Ti^{2+} salts do not exist in aqueous solution as they are oxidised by water. However, Ti^{2+} compounds can be successfully generated in non-aqueous media, for example, by the reduction of titanium(IV) tetrachloride with zinc dust. Ti^{2+} derivatives obtained by this method were used[61] for the reduction of R_2SO (R = Alk, Bz, Ph) to R_2S. The process was carried out in an ether–dichloromethane solvent mixture at 20 °C and was complete after not more than 1 min. In another study[62] when $TiCl_4$ was reacted with LiH in THF (with a 1 : 4 molar ratio of reactants), "low-valent titanium complexes" were obtained. On boiling alkyl or aryl sulphides with these compounds in THF for 10 h, the corresponding sulphides are formed. The prolonged time and relatively high temperature of the synthesis should be noted here.

The possibility of reducing sulphoxides with tin(II) chloride in the presence of HCl was first demonstrated in 1947.[64] This method was subsequently improved.[64] The reaction is carried out by boiling a solution of dialkyl sulphoxide and $SnCl_2.H_2O$ in methanol with added HCl for 2–3 h.

Tin(II) chloride has been used[65–67] for the reduction of coordinated DMSO. It was shown that the reaction of the complex *cis*-$[Pt(II)(DMSO)_2Cl_2]$ or a mixture of $K_2[Pt(II)Cl_4]$ and DMSO in hydrochloric acid with $SnCl_2.H_2O$ for 5–7 min with heating (70–90 °C) gives *cis*- and *trans*-$[Pt(IV)(DMS)_2Cl_4]$ respectively. Pt(IV) complexes with diethyl and dipropyl sulphide ligands were obtained in a similar manner. Kukushkin et al.[65–67] assume that the reactions for formation of $[Pt(R_2S)Cl_4]$ complexes can occur in both the inner and outer sphere of the coordination compounds.



In concluding this section we should note that deoxygenation of sulphoxides can also be achieved using chromium,[68] vanadium,[69] molybdenum,[69,70] and tungsten[70,71] compounds in lower oxidation states.

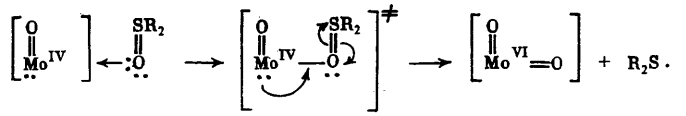
VII. Reactions of sulphoxides with Mo(IV) complexes

The enzyme molybdenum oxotransferase is known to catalyse the two-electron oxidation or reduction of substrates of the type X/XO in a process which can formally be represented by the equation:

$$X + H_2O \rightleftarrows XO + 2H^+ + 2e.$$

It was demonstrated in a number of studies by Hold et al.[72–78] that $MoO(L{-}NS_2)(DMF)$ and $MoO_2(L{-}NS_2)$ complexes

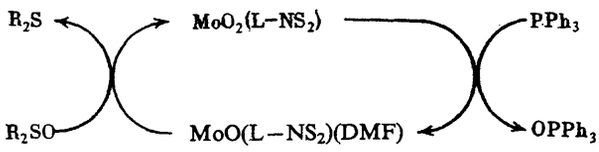
($L{-}NS_2 = {}^-SCPh_2{-}CH_2{-}$ pyridine $-CH_2{-}CPh_2S^-$) are convenient



model compounds for the study of biological oxygen transfer processes. In particular, it was shown[74] that the compound $MoO(L{-}NS_2)(DMF)$ can effectively deoxygenate different alkyl and aryl sulphoxides. The process occurs in two stages. At the first stage the inner-sphere DMF is replaced by an R_2SO molecule:†

$$MoO(L{-}NS_2)(DMF) + R_2SO \rightleftarrows MoO(L{-}NS_2)(O\text{-}R_2SO) + DMF,$$

and deoxygenation takes place at the second stage:



$$MoO\,(L{-}NS_2)\,(O\text{-}R_2SO) \rightarrow MoO_2\,(L{-}NS_2) + R_2S.$$

On the basis of the studies carried out,[74–78] the following reaction scheme was put forward:

† Inner-sphere *O*-coordinated sulphoxides will here and subsequently be denoted as *O*-R_2SO, while *S*-coordinated sulphoxides will be indicated as *S*-R_2SO.

It was shown in one of these studies[74] that the dioxomolybdenum complex $MoO_2(L-NS_2)$ oxidises triphenylphosphine to triphenylphosphine oxide. The following catalytic cycle was also established

It was shown in a number of studies[79–88] that certain other Mo(IV) complexes can effectively deoxygenate dialkyl sulphoxide molecules to give the corresponding sulphides. However, these processes have not been studied in detail.

VIII. Processes involving metal ion–reducing agent systems

In the previous section we considered deoxygenation reactions of sulphoxides using metal ions in low oxidation states that act simultaneously as electrophilic activators and reducing agents. However, metal ions in relatively high oxidation states can be used to deoxygenate R_2SO, but in this case chlorinated products are formed. Thus, in a study of the reactions of DMSO with $NbQX_4$ compounds (Q = X = Cl; Q = X = Br; Q = Me, X = Cl), XCH_2SMe products were obtained in all cases.[89–92] The authors of all four studies conclude that the process consists of two stages. At the first stage oxygen is transferred to give an oxocomplex and sulphonium salt:

$$NbQX_4 + 3Me_2SO \rightarrow NbOQX_2 \cdot 2Me_2SO + [Me_2\overset{+}{S}X]\,X^-,$$

At the second stage the sulphonium salt is converted to a haloalkyl sulphide:

$$[Me_2\overset{+}{S}X]\,X^- \rightarrow XCH_2SMe + HX.$$

The formation of XCH_2SMe can be avoided if the deoxygenation process is carried out using systems of the metal ion–reducing agent type. Complex hydrides of boron and aluminium are most frequently used as reducing agents.[93] This type of reduction of sulphoxides was first carried out in 1971.[94] In accordance with the recommended procedure stated in two studies,[94,95] the reduction was carried out by adding $NaBH_4$ slowly to a solution of R_2SO and $CoCl_2.6H_2O$ in 95% ethanol. Water was then added, heating was applied briefly, and the sulphides were extracted with ether. After removal of the ether the corresponding sulphides R_2S were isolated in good yield. The reduction of sulphoxides was also carried out using mixtures of $TiCl_4-NaBH_4$,[96,97] $TiCl_4-LiAl_4$,[98] $FeCl_3-NaBH_4$,[99] and Fe(III)LCl–$NaBH_4$ (L = tetraphenylporphyrinate).[100] The authors of all these studies[94–100] naturally assume that the process includes a stage involving *O*-coordination of R_2SO with the metal ion, resulting in electrophilic activation of the sulphoxide ligand and the sulphur atom becomes more sensitive to nucleophilic attack by hydride. It is important to note that the proposed mechanism has parallels in organic chemistry. In particular, reductions of alkoxysulphonium salts with complex boron hydrides have been reported.[101,102] An experiment carried out by Johnson and Phillips[102] demonstrated that the following conversion route occurs:

$$Ph-\overset{+}{S}(OMe)-Me \xrightarrow{[BH_4]^-} Ph-\overset{+}{S}(H)-Me \xrightarrow{-H^+} Ph-S-Me.$$

The reduction of sulphoxides with the reagent systems $BF_3.OEt_2-NaI$,[103] BF_3-NaI,[104] and $B(OPh)_3-NaBH_4$ [105] takes place via the same route.

In concluding this section we should report the results of one study[106] in which the conversions of dibutyl, dibenzyl, and diphenyl sulphoxides to the sulphides using aluminium(III) iodide in acetonitrile are recorded. It would appear that in these reactions the aluminium ion functions as the electrophilic activator and the I^- ions reduce the coordinated sulphoxides.

IX. Reduction of sulphoxides with carbonyl or carbene ligands in complexes

It is well known that the reactivity of carbon monoxide changes significantly when it is coordinated.[19] In a number of cases nucleophilic oxidation processes are made possible as a result of the electrophilic activation of CO molecules. According to studies that have been conducted, the mechanism of these types of reactions can be represented by the following scheme:

$$[M-CO] + \overline{O}-\overset{+}{A} \rightarrow \left\{M-C(=O)-O-\overset{+}{A}\right\} \xrightarrow{-CO_2} [MA].$$

Amine oxides, nitro- and nitroso-arenes, and iodosobenzene[107–109] have been widely used as oxygen donors in order to carry out these processes. It has been reported in a review article[108] that dialkyl sulphoxides can also act as this type of organic donor.

The reduction of sulphoxides by carbonyl complexes was first reported by Alper and Keung.[110] It was established that the reaction of various sulphoxides with $Fe(CO)_5$ at 130–135 °C in diglyme or di-n-butyl ether leads to the deoxygenation of R_2SO with the formation of the corresponding R_2S compounds and oxidation of an inner-sphere molecule of CO to CO_2. The nucleophilic oxygenation of the carbonyl ligand in the complex $[CpFe(CO)_3](PF_6)$ by DMSO and trimethylamine oxide has been studied.[111] Unfortunately, no information was given about the reduction products of dimethyl sulphoxide.[111]

It has been shown[112,113] that molybdenum hexacarbonyl is quite an effective agent for the deoxygenation of alkyl and aryl sulphoxides. The complex $Mo(CO)_6$ reduces sulphoxides on heating in solutions of dimethoxyethane[112] or acetic acid.[113]

Judging by the frequencies of the ν(CO) stretching vibrations in platinum(II) complexes, a CO ligand has high electrophilic activity.[107,108] The synthesis of the complex *cis*-$[Pt(DMSO)(CO)Cl_2]$ [ν(CO) = 2138 cm^{-1}] has been reported.[114] It has also been shown that heating this compound gives a mixture of products, amongst which CO_2 and CH_3Cl were identified. In the IR spectra of the solid products of thermolysis, the absorption bands characteristic of inner-sphere DMSO had disappeared. Pakhomova et al.[114] regard these results as an indication of the redox nature of the interaction between the coordination DMSO and CO ligands.

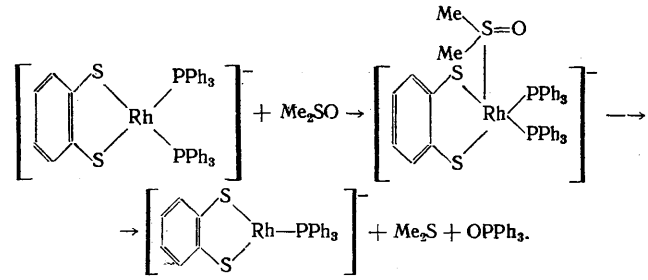
Deoxygenation of R_2SO molecules also occurs in processes involving another platinum(II) carbonyl compound—the complex $(Ph_3PBz)[Pt(CO)Cl_3]$ [ν(CO) = 2081 cm^{-1}]. Thus it was shown[115] that reaction of this complex with sulphoxides R_2SO (R = Me, Et,

n-Pr, Bz) in a nitromethane–acetic acid solvent mixture for several hours leads to the formation of $(Ph_3PBz)[Pt(R_2SO)Cl_3]$. On maintaining the complex $(Ph_3PBz)[Pt(CO)Cl_3]$ and the respective sulphoxide in an atmosphere of CO (1 atm, 20 °C, 5–7 days) in $MeNO_2$–$MeCO_2H$, deoxygenation of R_2SO molecules occurs and sulphides R_2S are formed. The reduction of sulphoxides by carbon monoxide does not occur in the absence of $(Ph_3PBz)[Pt(CO)Cl_3]$.

It was also shown in the same study[115] that reaction of $(Ph_3PBz)[Pt(R_2SO)Cl_3]$ complexes with CO under the conditions described above gives R_2S and $(Ph_3PBz)[Pt(CO)Cl_3]$ as the main products of synthesis. The reaction of $(Ph_3PBz)[Pt(Ph_2SO)Cl_3]$ with CO gives Ph_2S and a mixture of unidentified platinum-containing products. Preliminary results[115] suggest that the deoxygenation of R_2SO using CO in the presence of $(Ph_3PBz)[Pt(CO)Cl_3]$ is catalytic in nature.

The carbon atom that is bound to the central atom in carbene complexes is known to be activated as an electrophile. In the same way as for metal carbonyls, nucleophilic oxygenation reactions are typical for such compounds. Fairly recently Fisher et al.[116] obtained results indicating that DMSO can be deoxygenated by $(OC)_5W[C(R)Ph]$ complexes (R = H, Ph, OMe]. As a result of a redox reaction, the tungsten DMS complex $(OC)_5W(SMe_2)$ and O=C(R)Ph are formed.

X. Processes that occur in sulphoxide phosphine complexes



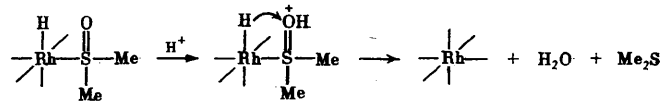
Bryan et al.[117] have reported the deoxygenation of DMSO that occurs to the following equation

$$[ReO(PPh_3)_2Cl_3] + 2Me_2SO \xrightarrow[C_6H_6]{HCl} \rightarrow [ReO(Me_2S)(OPPh_3)Cl_3] + Me_2S + OPPh_3.$$

The synthesis of $[ReO(Me_2S)(OPPh_3)Cl_3]$ takes place in the presence of hydrogen chloride, which is itself a reagent capable of deoxygenating DMSO. However, the process can also occur in the absence of HCl, but in this case the yield of DMS complex is reduced slightly (75% instead of 95%). It was also noted that $[ReO(Me_2S)(OPPh_3)Cl_3]$ is not formed when $[ReO(PPh_3)_2Cl_3]$ is treated with DMS or $OPPh_3$. It is thought[117] that the reaction mechanism includes a stage involving *O*-coordination of the DMSO molecule. The metal ion in this case functions as an electrophile activator, increasing the partial positive charge on sulphur and weakening the S–O bond. Subsequently there is a reaction with triphenylphosphine, which deoxygenates the DMSO molecule. It should be mentioned in connection with this study[117] that a process similar to that described in it had previously been reported.[118] It was established[117,118] that HCl catalyses the deoxygenation of DMSO by triphenylphosphine. This process also includes a stage involving electrophilic activation of DMSO by protonation of sulphinic oxygen.

On keeping $[M(Dppe)(O\text{-}DMSO)Cl]ClO_4$ complexes [M = Pt, Pd; Dppe = 1,2-bis(diphenylphosphino)ethane] in a mixture of dichloromethane and DMSO for a month (M = Pt) or 3 h (M = Pd), DMSO is deoxygenated to give the DMS derivatives $[M(Dppe)(DMS)Cl]ClO_4$. The latter are unstable and dimerise, giving $[\{M(Dppe)Cl\}_2](ClO_4)_2$ and DMS.[119] Unfortunately, Davies et al.[119] give no information about the oxidation product or about the presence of phosphine oxide in the mixture after completion of the reaction.

The rhodium(I) complex—$(Me_4N)[Rh(PPh_3)_2(S_2C_6H_4)]$—reacts with DMSO in DMF-d_6 and catalyses the transfer of oxygen from DMSO to triphenylphosphine.[120] Sellman et al.[120] propose that the reaction scheme includes a stage involving coordination of DMSO with the rhodium(I) ion, activation of the ligand, and formation of DMS, triphenylphosphine oxide and a tricoordinate Rh complex stabilised by the solvent:



It should be noted that the conclusion, unsupported by experimental evidence, about *S*-coordination of the sulphoxide to the Rh(I) ion bound to other "mild" ligands raises certain doubts. As a rule in this situation DMSO is coordinated by its oxygen atom rather than by sulphur.[16–19] If our assumption is subsequently proved right, it may be possible to indicate more definitely that there is a similarity between the processes described in the three studies.[117,119,120]

XI. Other deoxygenation reactions of sulphoxides

The reduction of inner-sphere DMSO can occur when thermolysis of complex compounds in the solid state is carried out. Thus, it has been reported[121] that heating of the complexes $[Os(S\text{-}DMSO)_4Cl_2]$ and $[Os(S\text{-}DMSO)_3(O\text{-}DMSO)Cl_2]$ at 150 °C causes the disproportionation of dimethyl sulphoxide to give dimethyl sulphone and the complexes $[Os_2(\mu\text{-}SMe)_2(Me_2S)_2Cl_4]$ and $[Os(\mu\text{-}SMe)_2(Me_2S)(O\text{-}Me_2SO)Cl_4]$ respectively. The thermolysis of zirconium and hafnium compounds of the type $MCl_4.9DMSO$ has been described.[122] It was shown that heating these compounds in the solid state results in the formation of the hydroxo complexes $[M(OH)_2Cl_2(DMSO)_2]$ at an initial stage through a reaction with atmospheric moisture. When the temperature is increased further, conversion of the DMSO molecules occurs. Me_2S, HCl, and $Me_3S^+Cl^-$ were identified amongst the reaction products. Arsenin et al.[122] believe that the formation of DMS occurs in the inner sphere with the participation of HCl.

The deoxygenation of dialkyl sulphoxides using rhodium complexes was reported as early as 1969.[123] Thus it was shown that DMSO in the presence of $RhCl_3.3H_2O$ or *cis*-$[Rh(Et_2S)_3Cl_3]$ can be reduced with H_2 under mild conditions. By studying the kinetics of these reactions, it was possible to deduce that reaction of the initial compounds, DMSO and H_2 leads to the formation of sulphoxide hydride derivatives:

The subsequent reaction route involves protonation of the sulphinyl oxygen atom of the ligand followed by elimination of water molecules and DMS from the inner sphere of the complex.

XII. Conclusion

It is well known that sulphoxides exhibit weak oxidising properties. For example, in water (pH 7) the redox potential of the Me_2SO/Me_2S pair is only 0.16 V [124]

$$Me_2SO + 2H^+ + 2e \rightleftarrows Me_2S + H_2O.$$

However, the reactivity of R_2SO molecules when coordinated changes significantly.

An analysis of data on the deoxygenation of sulphoxides with complexes and metal ions shows that in the vast majority of cases the first stage of the reaction consists of *O*-coordination of R_2SO molecules with an M^+ ion:

$$R_2SO + M^+ \rightarrow [R_2S{=}OM^+ \longleftrightarrow R_2\overset{+}{S}{-}OM].$$

Here the metal ion functions as an electrophilic activator which increases the partial positive charge on sulphur and makes the ligand more sensitive towards reaction with a reducing agent. In fact, analysis of a number of X-ray diffraction studies (for example, those of Cotton[125] and Elding[126]) demonstrates that there is a significant elongation of the S—O bond in complexes with *O*-coordinated R_2SO molecules in comparison with free molecules. This in turn suggests that there is a significant contribution of the structure $R_2\overset{+}{S}-OM$ in the mesomeric hybrid of the molecule. It should be noted here that electron-acceptor substituents R on the sulphur atom also assist this type of electrophilic activation.

When *S*-coordination of R_2SO molecules occurs, the contribution of a bipolar structure to the mesomeric hybrid of the molecule decreases.

$$\begin{array}{ccc} :\ddot{O}:^- & & :O: \\ | & & \| \\ Me_2S^+ : \rightarrow [M] & \longleftrightarrow & Me_2\ddot{S} : \rightarrow [M]. \end{array}$$

This is suggested by the X-ray diffraction data on S—O bond lengths for free and *S*-bonded R_2SO molecules (see, for example, the study of Davies).[7] This all signifies that the susceptibility of the oxygen atom of the inner-sphere R_2SO molecule to electrophilic attack will decrease. However, if acylation nevertheless occurs (particularly when active reagents such as PCl_5 or $SOCl_2$ are used), the coordinated sulphoxide becomes "doubly activated"—by the acyl residue on the oxygen atom and the metal ion on the sulphur atom. This type of species should evidently have a higher oxidising potential than an R_2SO molecule that is merely *O*-bonded. This may possibly account for the ease of the deoxygenation reaction of *S*-coordinated sulphoxides on treatment with hydrogen halides.

Activation of the C–H bond by metal complexes

A E Shilov, G B Shul'pin
Semenov Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. Reactions involving the cleavage of C–H bonds by metal complexes in saturated and aromatic hydrocarbons and also in other compounds are examined. Some of these processes occur with formation of a carbon–metal bond, whilst in others the interaction of the complexes with the hydrocarbon takes place without direct contact between the metal atom and the C–H bonds. Metal compounds are widely used as initiators of the liquid-phase oxidation of hydrocarbons at relatively low temperatures. There is a prospect of creating new technologies for the chemical processing of petroleum and gas hydrocarbons, whereby they can be converted into valuable products, for example, into alcohols, ketones, and carboxylic acids, on the basis of processes involving metal complexes. The study of the metal complex activation of the C–H bond also makes it possible to understand and model the metalloenzyme-catalysed hydrocarbon oxidation reactions in the living cell.

The bibliography includes 340 references.

I. Introduction

The catalytic reactions occuring with cleavage of the C–H bond in hydrocarbons and other compounds on treatment with metal complexes[1] constitute an extensive and important field of metal complex catalysis.[2] The problem of the activation of the C–H bond in fully saturated hydrocarbons (alkanes) which contain no π- or *n*-electrons and are therefore inert to many reagents which are usual in organic chemistry, is of special interest. Many fundamentally new stoichiometric reactions of alkanes (and arenes) with metal complexes (usually in a low oxidation state) were discovered in recent years, but to this day there is an acute need to seek procedures for the metal-complex catalysed introduction of functional groups into these hydrocarbons, i.e. for replacing hydrogen atoms by hydroxy-, carbonyl-, amino-, and other groups and also for obtaining alkenes and halogeno-derivatives from alkanes.

Bearing in mind the process mechanism, all the C–H bond activation reactions can be subdivided into three groups. Processes where organometallic derivatives, i. e. compounds containing an M–C σ-bond (M = transition metal), are formed as an intermediate or as the final product can be conveniently assigned to the *first group*.[3] The σ-ligand in the resulting compound is an organyl group (alkyl, aryl, vinyl, ethynyl, acyl, etc.). Subsequently the M–C σ-bond may be ruptured; naturally, in catalytic processes the dissociation of this bond is obligatory. The cleavage of the C–H bond with direct participation of a transition metal ion proceeds via the oxidative addition (OA) mechanism:

$$RH + M \rightarrow R—M—H$$

or an electrophilic substitution:

$$RH + M^{(n+)} \rightarrow R—M^{(n+)} + H^+.$$

In the case of electrophilic metallation of the aromatic nucleus, the reaction proceeds in two stages, the electrophilic species adding to the arene in the first stage with formation of a Wheland intermediate. The intermediate formed in the interaction of a saturated hydrocarbon with an electrophile is much less stable. It is therefore not surprising that the reactivities of alkanes and arenes in electrophilic substitution reactions are not the same (the reactivity of the latter is much higher). At the same time, the mechanism of the interaction of both saturated and aromatic hydrocarbons with complexes of metals in a low oxidation state is in principle the same (oxidative addition). The reactivities of arenes and alkanes in oxidative addition reactions with respect to metal complexes therefore usually differ insignificantly. Furthermore, the C–H bond in alkenes is cleaved via the same mechanism. Thus the first group includes reactions involving "true" metal complex activation of the C–H bond if such activation is understood as a process as a result or in the course of which the activated molecule is cleaved at the C–H bond and enters in the form of an organyl σ-ligand into the coordination sphere of the metal complex. The formation of weak inner- or outer-sphere adducts of alkanes with metal complexes or of π-complexes of aromatic and other unsaturated molecules with metal-containing fragments need not by any means necessarily lead to the subsequent cleavage of the C–H bond; such coordination may be referred to as preactivation of the C–H bond of the compound.

In the *second group*, it is useful to include reactions in which the C–H bond is cleaved on treatment with a metal complex but the C–M σ-bond is not generated directly at any stage. The function of the metal complex usually consists under these conditions in abstracting an electron or an H atom from the RH molecule. The radical-ions RH^+ or radicals $R^\cdot$ formed then interact with other

species present in solution, for example, with molecular oxygen. One of the ligands of the metal complex can also serve as a species of this kind. An example is provided by the hydroxylation of an alkane by an oxo-complex of a high-valence metal:

$$RH + O{=}M^{(n+)} \rightarrow R^{\cdot} + HO{-}M^{((n-1)+)} \rightarrow ROH + M^{((n-2)+)}.$$

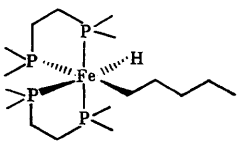
Here the oxo-complex is an oxidant of the type CrO_4^{2-} or MNO_4^- and also, for example, one of the states of the cytochrome P-450 enzyme (an oxoferryl species containing the $P^+.Fe^V = O$ species). It is noteworthy that the reaction with the intermediate participation of radicals can result in the formation of alkyl σ-complexes {for example, via the mechanism $RH + M^{(n+)} \rightarrow R^{\cdot} + M^{((n-1)+)} + H^+ \rightarrow R{-}M^{(n+)} + H^+$} and the reaction should then be assigned to the first group. Since the alkyl σ-derivative is frequently unstable, it is occasionally difficult to demonstrate its intermediate formation. The mediated (i.e. without contact with the metal ion) activation of RH by a complex can apparently be effected also via a molecular mechanism where RH is in direct contact only with a ligand of the complex. Finally the metal complex is capable of activating not only a hydrocarbon but also other reactants. Thus the active centre of cytochrome P-450 initially causes the transition of the oxygen molecule to a reactive state (one of the two atoms of dioxygen is coordinated to the iron ion, forming an oxo-ligand), after which it activates the hydrocarbon molecule.

Whereas the reactions included in the second group require direct contact between a molecule of the C–H compound and the metal complex (albeit via the ligand), in the processes belonging to the *third group* the complex activates initially not the hydrocarbon but the other reactant, for example, O_2 and H_2O_2, and the reactive species formed (a radical or carbene) rarely attacks the hydrocarbon molecule. In the H_2O_2–Fe(II) system, such a species is $HO^{\cdot}$. Sometimes the reaction initiated via this mechanism can lead to the formation of an organyl σ-derivative of the metal and the entire process then belongs to the first group. For example, the photochemical metallation of a C–H compound by a metal chloride can proceed in accordance with this scheme:

$$RH + [M{-}Cl]^* \rightarrow R^{\cdot} + M + H^+ + Cl^- \rightarrow \sigma\text{-}R{-}M + H^+ + Cl^-.$$

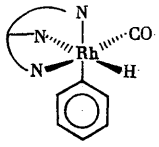
Evidently the unambiguous assignment of a process to a particular group requires a detailed knowledge of the reaction mechanism. However, at the present time the mechanisms of many processes have not been elucidated even in broad outline. We may note that the mechanisms of reactions included in the last two groups are in general not the same for paraffins, on the one hand, and aromatic hydrocarbons, on the other, although the products of these reactions can be frequently of the same type (for example, alcohols and phenols). Hence follows the possibility that arenes and alkanes may exhibit different reactivities in each specific reaction.

Although the H_2O_2–Fe(II) system, capable of hydroxylating aromatic compounds, was discovered as early as the past century,[4] the 1930s should apparently be regarded as the start of investigations into the activation of C–H compounds with participation of transition metal complexes. During this period, the reaction involving the electrophilic auration of arenes was discovered,[5] the radical chain autoxidation of hydrocarbons initiated by metal derivatives was developed,[6,7] and a method was proposed for the oxidation of alkenes and arenes by hydrogen peroxide in the presence of oxo-complexes.[8] The second spurt in the pioneering research into this field occurred in the 1960s. Reactions involving the cyclometallation (i.e. the cleavage of the C–H bond in a ligand linked to the metal via an atom of nitrogen, phosphorus, or another element) of the aromatic nucleus[9] and of an sp^3-hybridised carbon atom[10] were discovered. It was found that palladium(II) derivatives induce the oxidative coupling of arenes[11] and the arylation of alkenes,[12] while platinum(II) salts catalyse the H–D exchange with D_2O in benzene[13] and also in methane and other alkanes (a cobalt complex can also catalyse such processes).[14] It has now become evident that organometallic derivatives are formed as intermediates in all these instances. It was shown in the 1970s that alkanes are oxidised by platinum(IV),[15] palladium(II),[16] and ruthenium(IV)[17] compounds, that iridium(III)[18] and titanium(II)[19] complexes catalyse the H–D exchange, that Ziegler–Natta catalysts induce the hydrometallation of ethylene by methane with formation of propane,[20] and that the $PtCl_6^{2-}$ ion effects the electrophilic metallation of arenes.[21] The next decade was marked by a vigorous development of studies on the activation of alkanes (and arenes) by low-valence metal complexes via the oxidative addition mechanism with formation of alkyl σ-derivatives or alkenes.[22–27]



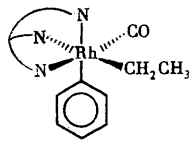
The number of known examples of the activation of the C–H bond by complexes of metals in a high oxidation state with formation of organometallic compounds is so far very small. Thus $PtCl_6^{2-}$ photochemically dehydrogenates alkanes and platinates arenes,[28] while the methyllutetium σ-complex enters into an exchange reaction with $^{13}CH_4$.[29] At the end of the 1980s, the intensity of investigations of the activation of the C–H bond by low-valence metal complexes began to diminish somewhat and interest gradually shifted to the field involving the oxidation of hydrocarbons by high-valence metal oxo-compounds and oxygen. Attention is being especially concentrated nowadays on biological oxidation and its chemical models. Studies on the modelling of cytochrome P-450 were stimulated by the use of iodosobenzene as the donor of an oxygen atom in catalytic oxidation reactions and of metalloporphyrin as a model of the active centre of the enzyme.[30] The Gif system, used for the selective oxidation of alkanes and consisting of O_2, an iron complex, a reductant, a carboxylic acid, and pyridine,[31] is of interest.

Studies on the activation of the C–H bond published up to 1987 were described in our previous review.[32] Therefore mainly publications during 1987–1990 will be discussed here. During this period, several books and reviews, wholly or partly devoted to the metal complex activation of C–H compounds, appeared.[2,33–51] We may also note that abstracts of the reports of the IInd All-Union Symposium on Homogeneous Catalysis "New Pathways in the Reactions of Saturated Hydrocarbons" have been published (Donetsk, 1988). All the papers in the special edition of the journal *Nouv. J. Chim.*, 1989, **13**, Nos. 10–11, are concerned with the activation of alkanes. The biological oxidation of hydrocarbons and the oxidation of hydrocarbons modelling the biological process (biomimetic oxidation) as well as the activation of oxygen have been described in abstracts published in a special issue of the journal *J. Inorg. Biochem.*, 1989, **36**, Nos. 3 and 4.



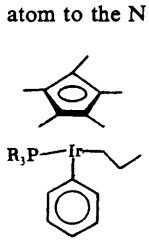
II. Activation of hydrocarbons via the oxidative addition mechanism

1. The formation of organyl σ-derivatives of metals

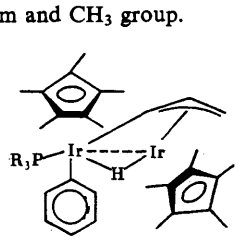


Numerous reactions involving the oxidative addition of the components of the C–H bond to metal complexes, in accordance with the scheme RH + $ML_n \rightarrow R-ML_n-H$ were discovered and investigated in detail in recent years. Alkanes, arenes, alkenes, and monosubstituted acetylenes enter into such reactions. The reaction frequently occurs in solution at room temperature, but sometimes heating is required. Certain reactions are stimulated by irradiation. An increased temperature or light are essential for the abstraction of several ligands from the initial complex and the formation of a coordinatively unsaturated species capable of effecting the oxidative addition of the C–H compound to itself. Thus irradiation at −90 °C of the phosphine complex $(PP)_2Fe(H)_2$, where PP = 1,2-bis-(dimethylphosphino)ethane, leads to the abstraction of a hydrogen molecule and the formation of the $Fe(PP)_2$ species. n-Pentane undergoes oxidative addition to this species with formation of the alkyl metal hydride complex (I).[52]

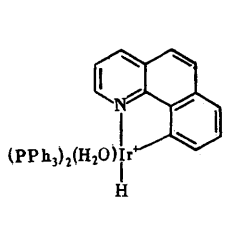
(I)



(II)

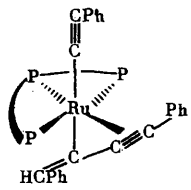


(III)

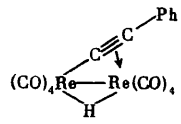


Sometimes thermal and photochemical activation can result in the formation of different products. For example, whereas heating of the solution of the ethylenerhodium carbonyl complex $[RhHBPz^*_3(CO)(C_2H_4)]$, where Pz* = 3,5-dimethylpyrazole, in benzene entails the elimination of the ethylene π-ligand and the formation of phenylrhodium hydride (II),[53] on irradiation of this solution, the hydride ligand adds not to the metal atom but to the ethylene molecule, which results in the appearance of an ethyl σ-group in the complex (III).[54] The hydrogen atom can add also to the allyl π-ligand: thermolysis of the complex $Cp^*Ir(H)(\eta^3\text{-}C_3H_5)$, where Cp* = pentamethylcyclopentadienyl, in benzene in the presence of phosphine leads to the formation of the propyl σ-derivative (IV).[55] It was of interest that at high concentrations of the initial complex the dimer (V) is obtained. It follows from the examples quoted that alkanes and arenes interact with metal complexes via the oxidative addition mechanism in a similar manner. However, differences are also sometimes observed. For example, the cyclometallation of 7,8-benzoquinoline by the complex $[LIr(PPh_3)_2]SbF_6$, where L = cycloocta-1,5-diene, in moist CH_2Cl_2 affords compound (VI),[56] whereas the analogous reaction with 8-methylquinoline does not entail the cleavage of the C–H bond in the methyl group and leads merely to the coordination of the Ir atom to the N atom and CH_3 group.

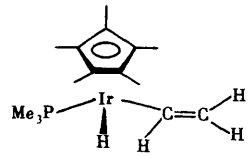
(IV)



(V)



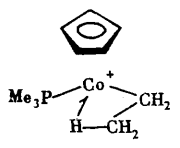
(VI)



Complexes readily cleave the C–H bond in acetylenes and acetylene molecules frequently also enter into other reactions. Thus the interaction of $RuH_4(Cyttp)$, where Cyttyp = $PhP[(CH_2)_3P(C_6H_{11})_2]_2$, with an excess of phenylacetylene gives rise to compound (VII).[57] Irradiation of a solution of phenylacetylene and $Re_2(CO)_{10}$ in ether leads to the dinuclear rhenium hydride derivative (VIII).[58]

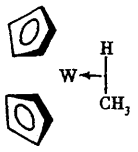
(VII)

(VIII)



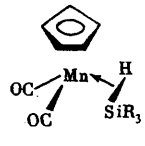
(IX)

Relatively few examples of the oxidative addition of ethylenes to the C–H bond are known. The thermolysis of the cyclohexyliridium hydride complex $Cp^*Ir(PMe_3)(H)(C_6H_{11})$ in solution in cyclohexane in the presence of ethylene results in the formation of the products of insertion in the C–H bond (IX) and of the ethylene π-complex $Cp^*Ir(PMe_3)(C_2H_4)$.[59] Finally, the components of the C–H bond in the allyl position are also capable of the oxidative addition to metal complexes: irradiation of a solution of the propene π-derivative $Cp^*Re(CO)(CH_2CHCH_3)$ affords the η^3-allylrhenium hydride complex $Cp^*Re(CO)(H).(\eta^3\text{-}CH_2CHCH_2)$.[60]



2. The reaction mechanism

The cleavage of the C–H bond can be preceded by the coordination of the saturated compound or fragment to the metal complex. Numerous complexes with hydrogen molecules have become known in recent years[61–64] and intramolecular coordination of the hydrogen atom of the C–H bond to the metal atom of the complex has been observed (the agostic C–H→M bond).[61,65] Such a bond occurs, for example, in complex (X).[66] The study of the kinetics of the reductive elimination of the CH_4 molecule from the complexes $Cp^*_2W(CH_3)H$ [67] or $Cp_2W(CH_3)H$ [68] led to the discovery of the intermediate formation of the methane "σ-complex" (XI). The existence of an analogous intermediate has been postulated in the reaction involving the elimination of CH_4 from the methylrhenium hydride derivative.[69] Presumably the alkane σ-complexes arise in the oxidative addition reaction, which leads to the formation of alkylmetal hydrides. In the photochemical reaction involving the cleavage of the Si–H bond by the $CpMn(CO)_3$ complex, which models such a process, the first stage may be the displacement of one of the CO ligands by the R_3Si-H ligand with formation of the structure (XII).[70] The adducts of alkanes with metal complexes formed at a low temperature can be detected by IR spectroscopy.[71] It has been established[72] that methane inhibits the reaction of butyllithium with butyl iodide. It has been suggested that this effect is due to the coordination of methane to the lithium alkyl in the reaction or prereaction complex. The interaction of the C–H bond with the metal complex can occur with mediation by the ligand. Thus the C–H...O=Re interaction in the oxorhenium complex has been demonstrated by X-ray diffraction.[73] The



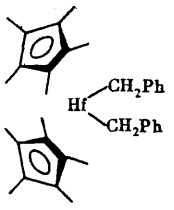
application of the NMR method led to the detection of the short-lived adducts of bis[hydrotris(pyrazolyl)borato]cobalt with alkanes in solution.[74] Outer-sphere interaction between the components takes place in this case.

(X)

(XI)

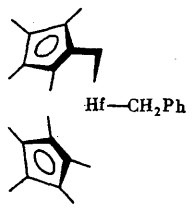
(XII)

The previous section presented examples of reactions which undoubtedly occur via the oxidative addition mechanism and in which the metal complex functions as a nucleophile. The kinetics and thermodynamics of such processes have now been investigated in fair detail[32,39,40,75,76] and quantum-chemical calculations have been carried out.[77,78] At the same time several reactions are known where attempts to describe their mechanisms as oxidative addition have encountered certain contradictions. In the first place, this applies to the activation, known for a long time, of alkanes by platinum(II) salts, which exhibit both nucleophilic and electrophilic properties. The activation of an alkane by a platinum(II) complex apparently begins as the oxidative addition of the C–H bond but the H atom acquires acid properties and is abstracted by a base (for example, the water forming part of the composition of the complex[79]):



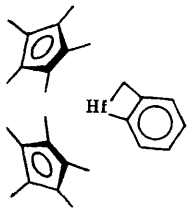
$$L_4Pt + RH \rightleftarrows [L_4Pt(H)R] \rightleftarrows L_3PtR + H^+ + L^-.$$

The rotation of the alkyl group R in the coordination sphere entails an appreciable intensification of the nucleophilic properties of the carbon atom, which should facilitate the electrophilic attack on the latter by the deuterium cation D^+:



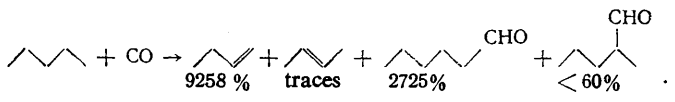
$$L_3PtCH_2R + D^+ \rightleftarrows L_3PtCHDR + H^+.$$

The alkyl group rotates synchronously with the approach of D^+ and the C–H→Pt agostic bond is formed. Since it is evident that several H atoms can be substituted by D in the alkyl group R before it is split off from Pt, the proposed mechanism explains satisfactorily the multiplicity of different types of H–D exchange in the presence of platinum(II) complexes.[79] It is believed[79] that such "alkyl" mechanisms agree better with certain features of the exchange reaction than the carbene and alkane–alkyl mechanisms proposed previously.[1,32,80]



The intermolecular activation of the C–D bond in benzene-d_6 by the complex $(PMe_3)_2Pt(CH_2CMe_3)(SO_3CF_3)$ apparently begins with the formation of the coordinatively unsaturated species $[(PMe_3)_2Pt(CH_2CMe_3)]^+$, which gives rise to an arylplatinum hydride complex with C_6D_6 as a result of oxidative addition.[81] The product $(PMe_3)_2Pt(C_6D_5)(SO_3CF_3)$ is formed after the elimination of CH_2DCMe_3. However, Brainard et al.[81] do not rule out the possibility that the positively charged species carries out an electrophilic attack on the benzene ring. Thermolysis of complex (XIII) in benzene-d_6 leads to the appearance of the intramolecular metallation product (XV).[82] The reaction takes place in several stages and the intermediate complex (XIV) has been isolated. The introduction of several substituents into the benzene ring has virtually no effect on the rate of metallation, which enabled the authors[82] to regard the transformation (XIV)→(XV) not as typical electrophilic metallation by the Hf(IV) ion but as a process which proceeds via a four-membered transition state.

(XIII)



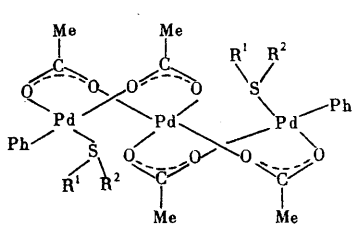
(XIV)

(XV)

3. Catalytic Processes

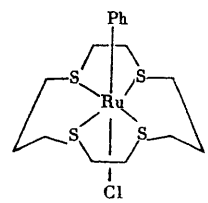
Metal complexes induce a whole series of reactions involving the substitution of hydrogen atoms in hydrocarbons by the atoms of other elements—processes involving the introduction of a functional group into the C–H bond. The complex very often catalyses such reactions. A considerable proportion of the processes proceed via the oxidative addition mechanism. Thus the complex $Li_2Pd_2Cl_6$ catalyses the H–D exchange in the allylic position in alkenes with CD_3COOD.[83] It has been suggested that the exchange proceeds with the reversible intermediate formation of an alkene π-complex of palladium(II) and its conversion into allylpalladium(IV) hydride π-derivative. The H–D exchange involving alkylsilanes catalysed by an osmium complex has been described.[84] Metal complexes dehydrogenate alkanes to alkenes. In a dark reaction, cyclohexene is formed from cyclohexane in the presence of $[PtCl_2(SnCl_3)_2]^{2-}$,[85] the complexes $[Ir(H)_2(\eta^2\text{-}O_2CCF_3)(PR_3)_2]$ dehydrogenate alkanes in the presence of 3,3-dimethylbutene, both on heating and on irradiation.[86] $RhCl(CO)(PMe_3)_2$ proved to be an effective photocatalyst of the dehydrogenation of alkanes.[87] Under the same conditions, arenes enter into an oxidative coupling reaction with alkenes, which results in the formation of substituted styrenes.[88] Finally, the above catalyst has been used for the photochemical introduction of functional groups into alkanes and arenes. Thus a complex mixture of products has been obtained from pentane and CO (the yields of the product relative to the catalyst are given below):[89]

It is of interest that the composition of the products depends on the wavelength. On irradiation of decane with light at a wavelength in the range $420 > \lambda > 295$ nm, the principal products are non-1-ene and undecanal. At $\lambda > 325$ nm, mainly isomeric C_{11} aldehydes are formed, while non-1-ene is not detected at all.[90] Irradiation with light of a solution of $RhCl(CO)(PBu_3)_2$ in pentane in the presence of cyclohexyl isocyanide leads to the formation of imines in low yields.[91] Finally, under the same conditions it is possible to silylate arenes with triethylsilane or hexamethyldisilane.[92] It is noteworthy that, on photosensitisation with mercury, dicyclohexane, cyclohexylmethanol, and ethylene glycol are formed from cyclohexane and methanol.[93]



The kinetics of the hydromethylation of acetylene by methane have been investigated in the presence of organonickel catalysts.[94] The use of $^{13}CH_4$ in an analogous system made it possible to show that propene is formed via at least two pathways and that the contribution of the pathway involving methane is only about 20%.[95] At the same time, a detailed study of the hydromethylation of acetylene by methane in the presence of $Pt(bipy)Cl_2$ in dimethylformamide showed that the products of the reaction of a mixture of $^{13}CH_4$ and C_2H_2 do not contain ^{13}C and do not differ as regards composition and quantitative yield from the products of the reaction of pure C_2H_2.[95]

III. Reactions of hydrocarbons with compounds of high valence metals



Whereas the interaction of C–H compounds with complexes of metals in a low oxidation state usually proceeds as oxidative addition, the reactions of arenes or alkanes with the derivatives of metals in high oxidation states are usually processes involving direct electrophilic substitution leading to the formation (final or intermediate) of an organometallic compound or are electron transfer or hydrogen atom abstraction processes, which are followed by the reactions of the resulting radical-cation or radical.

1. Direct electrophilic metallation of the C–H bond

In recent years electrophilic substitution by metal complexes of a hydrogen atom in aromatic compounds has been studied in detail in relation to cyclometallation reactions and in particular *ortho*-palladation (see, for example, Refs. 96–101). The reaction involving the intramolecular and intermolecular exchange of a cyclopalladated ligand in complexes has been discovered.[99–101] Previously such transfer of an aryl σ-ligand between complexes of the same metal had been observed for platinum(IV) derivatives[102] and also thallium(III) and mercury(II) derivatives. Palladocyclic compounds can be used to introduce functional groups into arenes.[103] It is well known that arylpalladium(II) σ-complexes, not stabilised by chelating ligands, are unstable and readily decompose with formation of biaryls (see, for example, Ignatenko et al.[104]). However, it has been recently possible to isolate the first phenylpalladium(II) σ-derivative, obtained directly by palladating benzene. When palladium(II) acetate was heated in benzene in the presence of dialkyl sulphides, complexes (XVI) were obtained.[105] A similar reaction has been discovered for ruthenium(II): the chloride complex with a thio-crown-ether in the presence of $Al_2(CH_3)_6$ gives rise to the phenyl derivative (XVII) on heating in benzene.[106]

(XVI)

(XVII)

The complexes formed by metallating arenes with the $PtCl_6^{2-}$ ion are sufficiently stable to be able to isolate them in a crystalline state (they can be stored for several months at room temperature), but prolonged heating of a solution of an arene and $PtCl_6^{2-}$ in $CF_3COOH-H_2O$ or CH_3COOH leads to the formation of biaryls and platinum(II) derivatives.[107] Metallation of arenes by heating with the $PtCl_6^{2-}$ ions can be achieved only in an acid medium. At the same time the rate of the light-induced reaction, occurring in acetic acid in the case of anisole with a quantum yield of 0.08 (λ = 365 nm), is independent of the acidity of the medium; the reaction can be carried out also in CH_2Cl_2.[108] Intermediate platinum(III) complexes apparently arise in the reaction.[109] The unstable arylplatinum(IV) σ-complexes, formed in the thermal reaction of arenes with $PtBr_6^{2-}$ in a $CF_3COOH-H_2O$ mixture, were not isolated, but biaryls were detected in the products.[110]

All the reactions described above, in which the formation of aryl σ-derivatives of metals was demonstrated, proceed as typical electrophilic substitution processes.[111] Nevertheless, their first stage can consist in electron transfer from the arene to the metal and the formation of an arene radical-cation, after which a Wheland intermediate is formed. However, the radical-cation may not recombine with the reduced metal ion, undergoing instead further reactions with participation of other species, for example, nucleophiles.[112–114] In this case, the arene or alkylarene is activated by the metal complex without the intermediate formation of an organometallic compound.

Metal complexes with strong electrophilic properties are capable of reacting with alkanes.[115–117] Thus, on heating a solution of CH_4 and $Pd(OOCMe)_2$ in CF_3COOH, metallic palladium and CH_3OOCCF_3 are formed in a yield greater than 60% relative to palladium(II).[116,117] It has been suggested that the product is formed when a solvent molecule attacks the methylpalladium(II) σ-complex arising as a result of electrophilic substitution. Under these conditions, arenes are activated much more readily: the trifluoroacetate group substitutes a hydrogen atom in the *p*-xylene ring more than 50 times faster than in the methyl group. It has been suggested[118] that the oxidation of alkanes by oxygen in aqueous solutions of mercury(II) salts under UV irradiation involves the intermediate formation [as a result of the electrophilic attack by Hg(II)* on RH] of alkylmercury compounds, but proof of this requires additional studies. The intermediate formation of alkylplatinum(IV) σ-complexes on photochemical dehydrogenation of n-hexane to the hexeneplatinum(II) π-complex has not been demonstrated either.[32] The possibility of the occurrence of such a process, with participation of a stage involving the β-elimination of hydrogen from the alkyl chain, has been confirmed in a study[119] where it was shown that the β-elimination from the ethylplatinum(IV) complex is the principal route to its decomposition.

2. Functionalisation on treatment with oxygen-containing complexes

Oxo-compounds of transition metals (in the first place chromium and manganese) are effective oxidants for C–H compounds.[120] Such derivatives are used in organic synthesis; for example, the $KMnO_4-NEt_3$ system oxidises the benzyl group to the ketone group with a satisfactory yield.[121] There exist also other oxo-complexes capable of oxygenating hydrocarbons: $[Ru^{VI}L_2(O)_2]^{2+}$ (L = 6,6′-dichlorobipyridyl) [122] and $[Os^{VI}(CN)_4(O)_2]^{2-}$.[123] The second complex activates the C–H bond on irradiation.

The oxidation of alkanes and of aromatic alkyl-substituted compounds by oxo-derivatives of chromium(VI) has been investigated on irradiation with light.[124–127] CH_3COOH, CH_3CN, and CH_2Cl_2 have been used as solvents; the products are alcohol

and carbonyl compounds. The reaction apparently begins with the abstraction of a hydrogen atom from the C–H bond of the oxo-complex by an excited species. On irradiation with light, the oxidation of alkanes and arenes by vanadium(5+) oxo-complexes in organic acids is greatly accelerated.

Transition metal,[128] for example palladium[129] and chromium,[130] peroxide compounds are capable of effecting the stoichiometric oxygenation of alkanes. Various chromium,[131–134] ruthenium,[135] and vanadium[136,137] complexes catalyse the oxidation of alkanes by peroxides. In many reactions of this kind, either metal peroxides are formed or the substrate is oxygenated by the oxo-compound, which is regenerated on interaction with ROOH. An alternative mechanism may be the formation of $HO^{\cdot}$ radicals when ROOH is acted upon by the complex. The hydroxylation of benzene by the H_2O_2–Fe(II) system takes place in this way.[138] Cyclohexane has been oxidised to cyclohexanol by molecular oxygen at room temperature in solution in aqueous dioxane.[139] The reaction was catalysed by the ruthenium(III) complex of ethylenediaminetetraacetic acid (EDTA). It has been suggested that a μ-peroxo-complex or an oxo-complex is formed in the first stage and then hydroxylates the alkane:

$$LRu^{III} + O_2 \rightleftarrows LRu^{IV}\,O \ldots O \ldots Ru^{IV}\,L \leftrightarrow 2LRu^{V} = O.$$

On irradiation under anaerobic conditions, alkanes dissolved in CH_3CN are converted by treatment with heteropolyacids into alkenes, dimers, *N*-alkylacetamides, alkylmethyl ketones, and also H_2.[140,141] The reaction begins with electron or H atom transfer from RH to a photoexcited polyoxometallate species. The resulting $R^{\cdot}$ radical is converted into an alkene or interacts with a solvent molecule. The reduced species derived from the oxo-compound is reoxidised by Pt(O), evolving H_2. The use of the ROOH–CCl_4 (or CBr_4) system in dark reactions catalysed by heteropolyacids induces the halogenation of the alkane, while in the interaction of alkanes with the ROOH–$C(NO_2)_4$ system nitroalkanes are formed.[142]

IV. Oxidation of saturated and aromatic alkyl-substituted hydrocarbons by oxygen

1. Initiation of the oxygenation process by metal complexes

It is well known that variable-valence metal compounds are capable of initiating in solution radical chain hydrocarbon oxidation processes.[1] Chain initiation occurs, for example in accordance with the scheme $M^{3+} + RH \rightarrow M^{2+} + R^{\cdot} + H^{+}$, after which $R^{\cdot}$ interacts rapidly with oxygen: $R^{\cdot} + O_2 \rightarrow ROO^{\cdot}$. Chain propagation takes place via the reaction $ROO^{\cdot} + RH \rightarrow ROOH + R^{\cdot}$. Complexes are usually active in the decomposition of the hydroperoxides formed (see, for example, Lauterbach et al.[143]). The participation of a metal ion in a low oxidation state in the reaction leads to chain branching. Thus, in the cobalt bromide catalysis of the oxidation of hydrocarbons,[144,145] which is of practical importance, the interaction of one $ROO^{\cdot}$ radical with Co(II) leads to the formation of three new radicals (Scheme 1):

Scheme 1

$$ROO^{\cdot} + Co\,(II) + H^{+} \rightarrow ROOH + Co\,(III)$$
$$\downarrow Co(II) \qquad Br^{-}\downarrow RH$$
$$RO^{\cdot} + Co\,(III) \quad R^{\cdot}$$
$$Br^{-}\downarrow RH \qquad \downarrow O_2$$
$$2ROO^{\cdot} \xleftarrow{O_2} 2R^{\cdot} \qquad ROO^{\cdot}$$

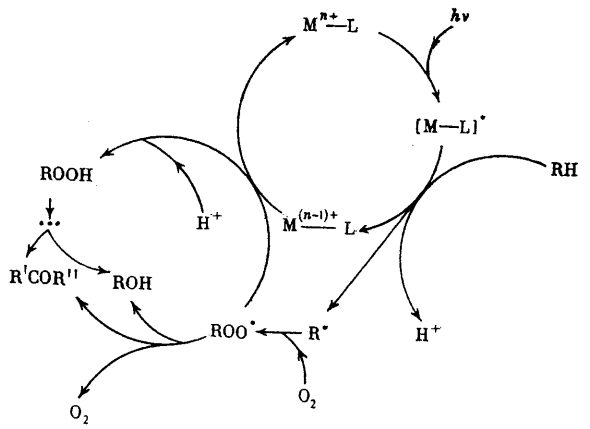
In this process, bromide ions catalyse the oxidation of RH by a cobalt(III) derivative via the reaction

$$Co\,(III) + Br^{-} \rightarrow Co\,(II) + Br^{\cdot};\quad Br^{\cdot} + RH \rightarrow Br^{-} + H^{+} + R^{\cdot}.$$

The oxidation process may not have a chain mechanism in relation to the $ROO^{\cdot}$ radicals, as shown for the oxidation of *p*-ethylnitrobenzene at 140 °C in the presence of $Mn(OOCCH_3)_2$.[146]

In the reactions mentioned above, the role of the metal complex (and also the role of the ligand, as in cobalt bromide catalysis) consists in chain initiation and propagation. However, the complex can only generate reactive species which subsequently enter into a non-chain process, which proceeds with dissociation of C–H bonds. Thus, on interaction with copper(I) and H^{+} ions, molecular oxygen gives rise to the $HO^{\cdot}$ radicals ($2Cu^{+} + O_2 + 2H^{+} \rightarrow 2Cu^{2+} + H_2O_2$; $Cu^{+} + H_2O_2 + H^{+} \rightarrow Cu^{2+} + HO^{\cdot} + H_2O$), which then hydroxylate benzene to hydroquinone. The resulting copper(II) may be reduced electrochemically.[147] The interaction of O_2 with the copper(I) complex $Py_4Cu_4Cl_4$ leads to the formation of the copper(II) oxo-complex $Py_3Cu_4Cl_4O_4$, which is capable of catalysing the oxidative coupling of 2,6-dimethylphenol.[148]

2. Photocatalytic liquid-phase oxygenation



The metal complex-catalysed photochemical oxidation of hydrocarbons by air in solutions at room temperature is of great practical interest because it can serve as a basis for new processes for the conversion of hydrocarbon raw material using sunlight as the source of energy. We shall differentiate two principal groups of metal compounds capable of effectively catalysing the photooxygenation of alkanes: the halide complexes (usually chlorometallates) and the oxo-complexes (usually polyoxometallates).

The following systems for the photochemical oxidation of hydrocarbons have been discovered and(or) studied in detail in recent years: $FeCl_3$ in CH_3COOH [149,150] and in CH_3CN;[151,152] $CuCl_2$ in CH_3CN;[151,153] $AuCl_4^{-}$ in CH_3CN [154] and CH_3COOH;[155] $Cr_2O_7^{2-}$ and $Cr_4O_{13}^{2-}$ in CH_2Cl_2;[156,157] iso- and hetero-polyacids in H_2O,[158,159] CH_3CN,[160] CH_3COOH or CH_3OH,[161] and CH_2Cl_2;[162] vanadates in CH_2Cl_2;[162] UO_2^{2+} in CH_3COOH or CH_3CN.[163] The complexes $PtCl_6^{2-}$, $PtCl_4^{2-}$, $RuCl_3$, $RhCl_3$, $IrCl_6^{2-}$, and $OsCl_6^{2-}$ can also serve as photooxygenation catalysts in acetonitrile. Cyclohexane, isobutane, toluene, ethylbenzene, and other hydrocarbons are used as substrates. The methane oxidation reactions in the presence of polyoxotungstate in H_2O [158,189] or of $HAuCl_4^{-}$ [154] and UO_2Cl_2 [163] in CH_3CN afford formaldehyde (as well as methanol and formic acid). Irradiation of a solution of an alkane (adamantane, cyclohexane) in CH_3CN in the presence of cerium ammonium nitrate gives rise to alcohols and ketones.[164]

The proposed mechanism of the photochemical oxidation processes described, including the formation on treatment with the photoexcited metal complex species of the $R^{\cdot}$ radical (in the case of

oxo-complexes, an H atom from RH apparently adds to the oxygen ligand), is presented in Scheme 2.

Scheme 2

However, in fact the mechanism is apparently more complex, at least when halides are used. Thus the photooxygenation of alkanes catalysed by the complex $AuCl_4^-$ takes place with an induction period (which proved to be particularly long in the case of the bromides $CuBr_2$, $FeBr_3$, and $PtBr_6^{2-}$). The induction period becomes shorter after the introduction of an inductant into the solution. Presumably, the oxidation proceeds also via a second pathway in which the catalyst is a low-valence metal complex obtained from the initial complex during the initial period of the reaction. Thus the complex combines with an oxygen molecule and the metal peroxide derivative formed subsequently oxidises the hydrocarbon (one cannot rule out the possibility that this process takes place under the influence of light). Furthermore, the peroxide derivative can be converted into an oxo-complex of the metal in a higher oxidation state, which subsequently reacts with the alkane.

3. Coupled oxidation

A whole series of systems containing complexes are capable of effecting the oxidation of alkanes and arenes by oxygen only in the presence of a reductant. In this case, coupled oxidation takes place.[165] Detailed study of the oxidation of cyclohexane by atmospheric oxygen in the presence of hydrazobenzene (a reductant), benzoic acid, and the complex Py_4FeCl_2 (catalyst) in acetone led to the hypothesis that the reaction proceeds with the intermediate formation of an iron hydroperoxide derivative, which hydroxylates alkanes.[165] Hence it was concluded that, despite the participation of the iron complex, molecular oxygen, and the reductant in the process, the system cannot be regarded as a model of cytochrome P-450. At the same time the oxenoid species $Fe^V = O$, which is inserted in a C—H bond (X = OH, $OCOCH_3$), plays an active role in the oxidation of alkanes by the Gif system:

$$X_2Fe^{II} + {}^{\cdot}O_2H \rightarrow X_2Fe^{III}—O—O—H \xrightarrow{H^+,\ X^-} X_3Fe^V{=}O + H_2O.$$

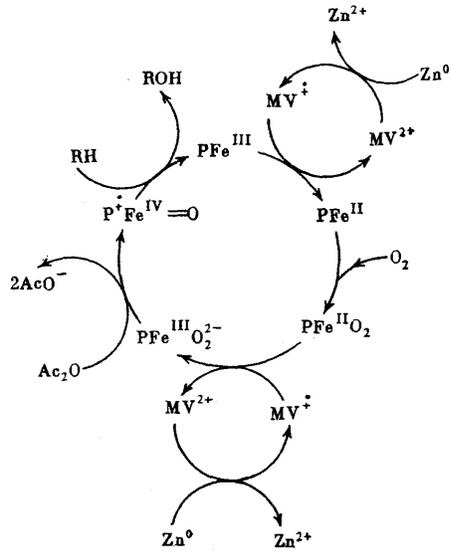
Thus the authors of the study[167] in which evidence for the formation of such a species was secured believed that the Gif system can be regarded as a model of cytochrome P-450. However, there exists also an alternative idea about the nature of the Gif system,[168,169] according to which the active centre is a solvated oxygen cation PyO^+ formed via the reaction $HO_2^{\cdot} + PyH^+ \rightleftarrows PyO^+ + H_2O$. This radical-cation, capable of oxidising hydrocarbons, was generated electrochemically[168] and by the photochemical oxidation of pyridine *N*-oxide.[169]

V. Biological oxidation and its chemical models

Alkanes or arenes are surprisingly easily oxidised by atmospheric oxygen in cells of organisms at room temperature and the usual pressure. For example, various fungi hydroxylate camphor derivatives,[170] testosterone and other steroids,[171] and the side chain in alkylbenzenes.[172] Under the influence of the *Pseudomonas putida* bacteria, benzene has been converted into *cis*-1,2-dihydroxycyclohexa-3,5-diene.[173] The cells of higher animals and man are also capable of oxidising compounds containing C—H bonds, hydroxylation occurring with the invariable participation of a reductant, whereupon one of the two atoms in the O_2 molecule is inserted into the C—H bond, while the other is reduced to H_2O. This is referred to as the monoxygenase mechanism (the catalysis is effected by monoxygenase enzymes). In all the biological oxidation reactions, hydroxylation is preceded by the activation of oxygen by the metalloenzyme.[174] The creation of chemical models of the enzymic oxidation of alkanes and arenes makes it possible not only to understand better its mechanism but also to develop what are likely to be fundamentally new processes for the conversion of the hydrocarbon raw material.[175]

1. Cytochrome P-450

Cytochrome P-450 is a widely distributed enzyme in living nature; it belongs to the group of monoxygenases and is capable, in particular, of oxidising alkanes, arenes, and their derivatives (for example, prostaglandins and aliphatic acids).[176—178] The active centre of the enzyme incorporates haem iron (whose ion forms a complex with the porphyrin). On treatment with O_2 and a reductant, the $Fe^V = O$ fragment arises in the active centre and oxidises the alkane in accordance with the scheme



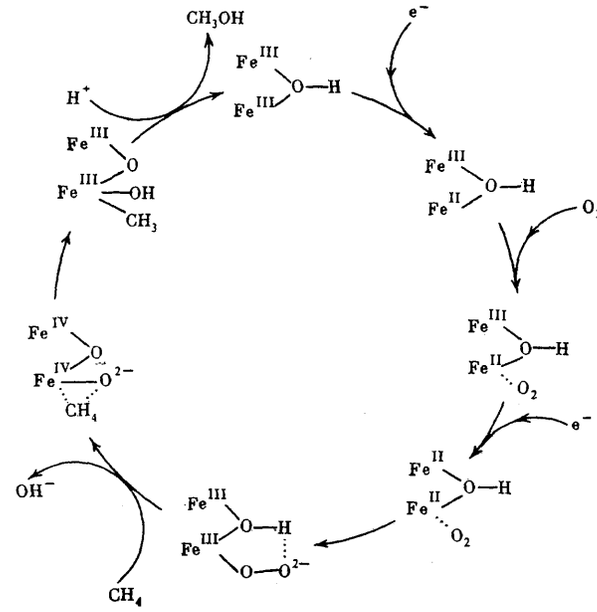
$$Fe^V{=}O + RH \rightarrow Fe^{IV}—OH + R^{\cdot} \rightarrow Fe^{III} + ROH.$$

The mechanism of the action of cytochrome P-450 has been described in detail in reviews[32,179] and other publications.[180,181]

In modelling cytochrome P-450 (see the reviews[32,175,179,182—184]), porphyrin complexes of iron(III) as well as manganese(III), chromium(III), and ruthenium(III) are usually employed as catalysts. If molecular oxygen is the oxidant, a reductant is required whose role may be assumed by an electric current.[185,186] Metallic zinc can also serve as the reductant.[187—189] The catalytic cycle involving the last system, which includes, apart from the porphyrin complex

PFe^{III}, an electron transferring agent (methylviologen MV^{2+}) and acetic anhydride, is illustrated in Scheme 3.[189]

Scheme 3



Instead of the O_2–reductant pair, one can employ oxo-compounds containing an oxygen atom which is already partly reduced: PhIO,[190] H_2O_2,[191–193] NaOCl,[194,195] $KHSO_5$,[196] and XeO_3.[197] We may note that, in the oxidation of alkanes in the presence of cytochrome P-450 or its models, the kinetic isotope effect reaches high values—up to 21.9 for the oxidation of cyclohexane by the tetramesitylporphyriniron chloride–NaOCl system.[198] For the oxygenation of hydrocarbons by various oxygen atom donors, fairly simple complexes were used as catalysts in certain studies: CrO_3 or $VOCl_2$ in the presence of α-picolinic acid (oxidation by PhIO),[199,200] $Fe(ClO_4)_2$ (oxidation by peroxybenzoates),[201] $[Fe(MeCN)_4](ClO_4)_2$ (oxidation by H_2O_2),[202] and $RuCl_2L_2$ (oxidation by LiOCl).[203]

2. Methane monoxygenase

Among the monoxygenases containing non-haem iron (the ligands are apparently aminoacid residues), methane monoxygenase (MMO) is of special interest. It catalyses the oxidation of alkanes, methane showing the highest activity among them in this reaction.[1,32] Ethane is also readily oxygenated by this enzyme.[204] It has been shown that MMO from *Methylococcus capsulatus* contains 4 atoms of non-haem iron and 1 atom of Cu per molecule with a molecular weight of 240 000.[205] The active centre of MMO apparently contains a dinuclear iron complex.[206] The proposed mechanism of the oxygenation of methane at this dinuclear centre is illustrated in Scheme 4.[207]

Scheme 4

Several systems which can serve as models of MMO in the oxidation of alkanes according to the authors have been described: the system incorporating a dinuclear μ-oxo-complex of iron, O_2, CH_3COOH, and Zn;[208] the cluster $Mn_{3-4}O_{1-2}Py_xRCOO_y^-$ combined with $(CH_3)_3COH$;[209] the complex $Fe_2O(OOCCH_3)_2Cl_2$. .$(bipy)_2$ together with $(CH_3)_3COOH$;[210] the complex $Fe_2O(bipy)_4Cl_4$ combined with H_2O_2.[211]

3. Certain other enzymes

A whole series of other enzymes containing metals capable of oxidising C–H compounds are known. They are less important than cytochrome P-450 and have been less thoroughly investigated. We shall list some of the enzymes and their models which oxidise hydrocarbons. Pteridine-dependent monoxygenases, which hydroxylate phenylalanine to tyrosine, containing non-haem iron, while the hydroxylase isolated from *Chromobacterium violaceum* incorporates copper.[212] Systems which have been known for a long time, such as Fenton's reagent, which includes iron(II), H_2O_2, and EDTA, Udenfrend's system containing iron(II), O_2, ascorbate, and EDTA, and Hamilton's system whose composition includes iron(III), O_2, and catechol, can serve as models of hydroxylases (with certain stipulations).[212] Ruthenium analogues of these systems have been proposed recently: ruthenium(III) together with H_2O_2, ascorbate, and EDTA [213] and ruthenium(III) with O_2, ascorbate, and EDTA.[214] Copper(I) complexes with chelating ligands are capable of hydroxylating the benzene ring of the ligand on treatment with O_2,[215,216] while on treatment with PhIO they promote the introduction of an OH group into the α-position in pyridine.[217]

Ketoglutarate-dependent dioxygenases oxidise C–H compounds in the presence of ketoglutaric acid which decomposes into succinic acid and CO_2 in a reaction coupled with the hydroxylation of the substrate.[1] A chemical model of such an enzyme, including an iron

compound and pyruvic acid, has been proposed.[218] In particular, catechol 1,2-oxygenase isolated from *Alcaligenes paradoxus* contains non-haem iron and catalyses the cleavage of the catechol ring.[219] A system consisting of a copper complex and an amine, which is capable of catalysing the oxidation of cyclohexanone, initially to α-hydroperoxycyclohexanone, is a model of pyrocatechase, a copper-containing dioxygenase.[220]

VI. Conclusion

The field of chemical science devoted to the activation of the C–H bond continues to develop vigorously. During the preparation of the manuscript for the press, several tens of articles describing a wide variety of processes occurring with the cleavage of the C–H bond and requiring the participation of metal complexes were published. Some of them are listed below.

Some of the communications describe the reactions of alkanes and arenes with complexes of metals in a low oxidation state, which proceed via the oxidative addition mechanism. Biscyclopentadienyltitanium(III) hydride complexes stimulate the deuterium–hydrogen exchange between methane and dihydrogen under mild conditions in solution in cyclohexane. Multiple exchange takes place in methane, while cyclohexane does not enter into the reaction.[221] The iridium-containing centre of the complex $[(PPh_3)_2IrH_2]_3PW_{12}O_{40}$ activates the C–H bond in arenes, alkanes, and allyl groups.[222] The methyl group of the substituent in a ruthenium-containing cluster undergoes oxidative addition to the ruthenium centre.[223] Oxidative addition of methane has been observed in the photolysis of the complex $CpIr(CO)H_2$ in a methane matrix at 12 K.[224] In the presence of silane, the complex $Cp_2Ta(CH_3)(PMe_3)$ reacts with benzene on photolysis (at 350 nm) or on heating (at 100 °C) with formation of methane and the compound $Cp_2Ta(C_6H_5)(PMe_3)$.[225] The silanes R_3SiH react with the hydride $ReH_7(PPh_3)_2$, which results in the cleavage of the Si–H bond and the formation of the derivative $ReH_6(SiR_3)(PPh_3)_2$ and H_2.[226] The formation of a η^2-arene complex with the $Cp^*Rh(PMe_3)$ species, which can be converted into the arylrhodium hydride $Cp^*Rh(PMe_3)(H)Ar$, has been observed.[227] The functionalisation of compounds containing C–H bonds by the insertion of the isonitrile group has been described. The complexes Cp^*ML_2 [228] or $RhCl(PR_3)_2(CNR')$ participate in this reaction.[229] The interaction of aromatic and aliphatic C–H bonds with terminal alkynes on photocatalysis by the complex $RhCl(CO)(PMe_3)_2$ results in the formation of 1,1-disubstituted ethylenes. Thus the reaction of n-hexane with phenylacetylene affords the product of the addition of hexane exclusively to the methyl group: 2-phenyloct-1-ene.[230] The intramolecular hydrogen transfer from the alkyl substituent of the phosphine ligand to the metal atom on UV irradiation of the $WH_4(PRPh_2)_4$ complexes was demonstrated even earlier and the possibility, in principle, of the photochemical activation of the methane bonds by the phosphinemolybdenum hydride complexes $MoH_4(PMePh_2)_4$ was demonstrated.[231] Cycloalkanes can be dehydrogenated under mild conditions in the presence of Group VIII metal complexes and active spongy uranium U*.[232] The interaction of the complexes $(PMe_3)_3RhMe$ with benzene or toluene at 70 °C results in the formation of the derivatives $(PMe_3)_3RhAr$.[233] The reactions of the radical species derived from the tetramesitylene-porphyrinatorhodium complex TMPRh* with methane in solution in benzene afford the complexes TMPRhMe and TMPRhH.[234] The organomagnesium compounds $C_6H_5Mg_nX$ (n = 2–4, X = halogen), formed on cocondensation of aryl halides and magnesium in the gas phase, react with alkanes even at room temperature. The degree of conversion of n-hexane per mole of the organomagnesium compound reaches 640. The composition of the products depends on the degree of reaction. A mixture of saturated C_4–C_8 hydrocarbons, mainly with a branched structure, is formed from n-hexane. With increase in the reaction time, the fraction of the C_4–C_8 products falls, but the yield of hydrocarbons containing eight and more carbon atoms increases.[235]

The mechanism of the reactions of low-valence metal complexes with alkanes and arenes has been investigated (see Ryabov's review[236]). Non-empirical calculations of the structure and relative energy characteristics of the ion-molecule complexes $Cu^+.CH_4$ and $Cu^+.C_2H_6$ have been performed. Tridentate coordination of the methane molecule is most favourable for the $Cu^+.CH_4$ ion. At moderately high temperatures, the Cu^+ cation is capable of quasi-free migration around the methane molecule.[237] Complexes of alkanes with the $W(CO)_5$ species in the gas phase[238] and the mechanism of the substitution of n-heptane by hex-1-ene in the photochemically generated species $[(n\text{-heptane})Cr(CO)_5]$ [239] have been investigated. The mechanisms of the cleavage of the Si–H bond by metal complexes has been discussed.[240,241] A detailed study has been devoted to the mechanism of the activation of C–H bonds in tetramethylsilane and mesitylene by tetrakis(triphenylphosphine)-hydridoneopentylosmium(II).[242] Finally, it has been shown that the reaction involving the photochemical dehydrogenation of alkanes in the presence of catalytic amounts of the complex $Rh(PMe_3)_2(CO)Cl$ begins with the abstraction of the CO ligand.[243]

Communications describing the oxidation of alkanes and arenes directly by high-valence metal complexes and also reactions occurring in the presence of such complexes have been published. The study[116,117] of the oxidative functionalisation of alkanes and arenes by palladium(II) acetate in trifluoroacetic acid has been continued.[244] It is essential to note that Stolyarov et al.[245] were unable to observe the oxidation of methane by a palladium(II) compound under the conditions described previously.[116,117,244] At the same time, methane is selectively oxidised by cobalt(III) trifluoroacetate with a 90 ± 10% yield of methyl trifluoroacetate relative to cobalt(III).[245] In the presence of palladium(II) acetate, cyclohexane and other alkanes are carboxylated with the aid of CO in CF_3COOH to cyclohexanecarboxylic and benzoic acids.[246,247] Irradiation of a solution of adamantane in acetonitrile with UV light under an oxygen atmosphere in the presence of palladium(II) or copper(II) trifluoroacetate leads to the formation of products resulting from the oxidation of mainly the third carbon atom.[248]

Irradiation with light of a solution of an alkane (or benzene) in CF_3COOH in the presence of the polyvanadate ions formed on dissolution of KVO_3 affords an alkyl trifluoroacetate and a ketone (or phenyl trifluoroacetate). When n-hexane is oxidised, the relative reactivities of the hydrogen atoms in the 3-, 2-, and 1-positions in n-hexane are 1.0 : 2.9 : 0.43.[249] Ruthenium(V) oxo-complexes oxidise cyclohexane and adamantane in solution in acetonitrile at 25 °C to cyclohexanone (yield 60% relative to the complex) and 1-adamantanol (40%) respectively.[250] Ruthenium(VI) and osmium(VI) dioxo-complexes oxidise alkanes on irradiation with light.[251] A number of studies have been devoted to the catalytic photochemical functionalisation of alkanes in the presence of polyoxometallates.[252–254] The photodimerisation of cyclohexene and methane on treatment with the $W_{10}O_{32}^{4-}$ ions has been investigated by the molecular orbital method.[255]

The heteropolyanion $SiRu(H_2O)W_{11}O_{39}^{5-}$ catalyses the oxidation of alkanes by persulphate, periodate, alkyl hydroperoxides, and iodosobenzene.[256] Chromium complexes catalyse the oxidation of adamantane by alkyl hydroperoxides.[257] Hydrogen peroxide in CF_3COOH in the presence of vanadium(5+) [136,137] oxidises even methane.[258] Alkanes are hydroxylated by periodate in the presence of $RuCl_3$ with the intermediate formation of RuO_4.[259] The rhodium complex of 1,2-bis(diphenylphosphino)ethane catalyses the oxidation of alkanes by hypochlorite.[260] *N*-Benzoyl-2-methylaniline is *ortho*-hydroxylated by trimethylamine oxide in the presence of a copper(II) salt with the intermediate formation of a copper(III) derivative.[261] The addition of iron(III) salts increases the quantum yields of the products of the photochemical hydroxylation of benzoic acid by hydrogen peroxide,[262] especially in the presence of methylene blue.[263] It has been concluded[264] that the abstraction of a hydride ion is the most likely mechanism of the activation of alkanes by carbonium ions and metal complexes — soft Lewis acids.

Reactions involving the oxidation of alkanes and arenes by molecular oxygen in the presence of metal complexes have been studied vigorously. It has been found that, in the gas-phase oxidation of propane (at 313 °C), the process is inhibited by the polyphthalocyanine complex of copper, whereas similar complexes of iron, cobalt, and manganese, present in small amounts, accelerate the reaction without altering the qualitative composition of the products. Analysis of the catalysts by EPR and IR spectroscopy demonstrated the absence of changes in their structure during the reaction.[265]

A whole series of studies have been devoted to the initiated radical chain oxidation of alkanes in the liquid phase[266–269] and also to cobalt bromide catalysis.[270] A trinuclear ruthenium carboxylate complex proved to be an effective catalyst of the oxidation of alkanes by atmospheric oxygen at 75 °C.[271] It has been concluded[272] that all the reactions of organic substrates with dioxygen are catalysed by metal ions which are bound to be present as impurities.

The photochemical oxygenation of alkanes and aromatic alkyl-substituted compounds by dioxygen catalysed by metal oxo-complexes, described in an earlier study[273] (see also Refs. 156–163), was developed in investigations by other workers.[274] A new system based on palladium acetate and phenanthroline, permitting the hydroxylation of benzene to phenol by molecular oxygen, was discovered.[275] Benzene is hydroxylated by dioxygen in the presence of palladium and copper complexes and molecular hydrogen.[276] The hydroxylation of benzene by dioxygen in the presence of $FeCl_3$, catechol, and pyridine in acetonitrile has also been described.[277] Finally, it has been found that methane is functionalised by cross-dimerisation with methanol in the reaction initiated by atomic oxygen; oxygen atoms are formed in their turn on interaction of photoexcited mercury atoms with N_2O.[278]

Detailed study of the Gif system[279–282] and of its models based not on dioxygen but on peroxides[283,284] and of the mechanism of the functioning of the system[285] has been continued. An analogous system incorporating a complex of iron with picolinic acid and dixoygen[286] or hydrogen peroxide[287] was proposed. Such systems can be regarded as models of oxygenases. The mechanism of the hydroxylation of aromatic compounds by the $Cu^+ - H_2O_2$ system has been discussed.[288]

Most communications have been devoted to the study of the biological and biomimetic oxidation of compounds at C–H bonds and several books have been published on this topic.[289–292] Attention has been concentrated on oxidation with participation of cytochrome P-450 [293–295] and also on the modelling of such processes (see the review of Mansuy et al.[296]), usually using porphyrin complexes of metals as catalysts.[297–306] It has been found that azidoporphyrinato-complexes and other complexes of chromium(III), manganese(III), and iron(III) catalyse the selective hydroxylation of alkanes at low temperatures by molecular oxygen in the absence of a reductant.[307–309] A fully inorganic model of cytochrome P-450 has been proposed in which the catalyst is iron deposited on a zeolite and the oxidation is effected either with H_2O_2 or with the $O_2 - H_2$ couple. In the oxidation of n-octane with participation of H_2O_2 on Fe/ZSM-5, the main product is 1-octanol.[310] The mechanism of the functioning of cytochrome P-450 and of its models has been discussed.[311–314]

The oxidation of 1,1-dimethylcyclopropane[315] and ethane[316] catalysed by MMO has been described. The substrate specificity in the oxidation by the soluble form of the above enzyme isolated from *Methyloccocus capsulatus* has been discussed in detail.[317] It was of interest that the hydroxylation of methane with participation of *Methylosinus trichosporium*, which leads to the formation of methanol, has been observed only when the microorganisms were treated with cyclopropane.[318] A dinuclear iron complex with bridging oxo-ligands can serve as a structural model of MMO.[319]

Photochemical models of the monoxygenase oxidation by dioxygen have been proposed,[320,321] the role of light consisting in exciting a sensitiser capable of generating the reducing component necessary for the reaction. The reactions involving biomimetic oxygenation by a system based on iodosobenzene and metal complexes with bleomycin, modelling cytochrome P-450, have been discussed.[322]

Data have been published on the oxidation of alkanes and arenes by other enzymes — hydroxylases,[323–327] dioxygenases,[328,329] and chloroperoxidase.[330] The reaction of dioxygen with a dinuclear copper(I) complex leads to the hydroxylation of the benzene ring of the ligand and can be regarded as a model of the process catalysed by tyrosinase[331] (see also Kitajima et al.[332]). The models of ligninase, a peroxidase which oxidises lignin (C–C bonds are then cleaved and the benzene rings are hydroxylated), are based on metalloporphyrin complexes and use hydrogen peroxide[333] or persulphate[334] as the oxidant. The model of the vanadium-containing bromoperoxidase includes a vanadyl complex,[335] while the complex $[Mn_4O_2(OCCPh_3)_6(H_2O)_2]$, modelling the oxygen-evolving centre of the photosystem II, catalyses the oxidation of alkanes by alkyl peroxides or iodosobenzene.[336] In the presence of a nitrogen-containing base in iron complexes with bisimidazolyl-methane, the methylene group is oxidised by atmospheric oxygen. Such complexes model the coordination of metal ions in certain metalloproteins, while the oxidation process itself may be similar to oxidation catalysed by lipoxygenases.[337] The complexes $V_2W_4O_{19}^{4-}$, $V_{10}O_{28}^{6-}$, and others catalyse the oxidative cleavage of catechol and model catechol dioxygenase.[338] Iron phenoxide complexes, obtained from Schiff bases, can serve as models of dioxygenases.[339] Finally, we may note that the insertion of oxygen into an aromatic ring, catalysed by complexes which are models of catechol dioxygenases, has been investigated by the extended Hückel method.[340]

Polycondensation and polyaddition processes using silylated monomers

A L Rusanov
A N Nesmeyanov Institute of Heteroorganic Compounds, Academy of Sciences of the USSR, Moscow

ABSTRACT. Polycondensation and polyaddition reactions using silylated monomers are reviewed. Means of obtaining silylated nucleophilic monomers and the influence of silylation on the reactivity of nucleophiles containing amine, hydroxyl and thiol groups have been analysed. It has been shown that in many cases the use of silylated monomers enables polycondensation processes to be carried out under mild conditions to give high molecular systems.

The bibliography contains 88 references.

I. Introduction

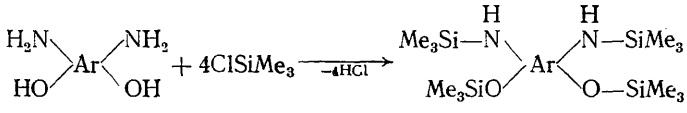
Polycondensation chemistry has been enriched in the last two decades by a series of new processes which significantly broaden the scope of linear polycondensation and polycyclocondensation. These include 'direct' polycondensation,[1,2] 'activated' polycondensation,[3] polycondensation using phase transfer catalysts,[4] reductive polyheterocyclisation,[5,6] etc. Polycondensation processes using silylated monomers,[7–10] also called 'silylated' polycondensation,[10] must be included. 'Silylated' polycondensation, like 'direct'[1,2] and 'activated'[3] polycondensation is based on a change, usually an increase, in the reactivity of one of the monomers participating in the reaction, however, in contrast to the processes mentioned above, 'silylated' polycondensation assumes a change of reactivity in electrophilic and nucleophilic monomers including diamines, bis-phenols, bis-thiophenols and multifunctional systems.[10]

This approach was used for the first time in synthetic chemistry by Klebe and collaborators[7,8] from the middle sixties to the beginning of the seventies and has been taken up once more in the last 5–10 years. Some achievements in the area of 'silylated' polycondensation have been considered,[7–10] however none of these reviews gives a complete picture of the achievements of this rapidly developing area of polycondensation. The present review is required to fill this gap.

II. Polycondensation reactions using silylated nucleophiles

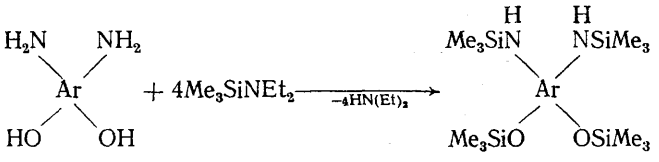
1. Methods of obtaining silylated nucleophilic monomers

The silylation of nucleophilic monomers reduces to the protection of labile hydrogen atoms in their functional groups by tris-(hydrocarbonyl)silyl residues, most frequently by trimethylsilyl or dimethylphenylsilyl groups.



The most widespread method of silylating nucleophiles is treatment of them with chloro-tris(hydrocarbonyl)silane, most frequently with chlorotrimethylsilane in inert solvents in the presence of acceptors of the hydrogen chloride released

$$HX{-}Ar{-}XH + 2Cl{-}SiR_3 \xrightarrow{-2HCl} R_3Si{-}X{-}Ar{-}X{-}SiR_3,$$
$$X = {-}NR'{-},\ {-}O{-},\ {-}S{-};\ R' = {-}H,\ {-}C_6H_5$$



This method has been used successfully for the silylation of primary diamines,[11–13] secondary diamines,[12–14] bis-phenols[15–17] and bis-thiophenols.[18] The silylation of secondary diamines, bis-phenols and bis-thiophenols leads to a bis-silylated product while analogous conversions of primary diamines may, depending on the conditions of carrying out the reaction, lead to the preparation of both bis-silylated[11–13] and *N,N,N',N'-tetrakis*-silylated diamines[19]

$$Me_3SiN{-}Ar{-}NSiMe_3 \leftarrow H_2N{-}Ar{-}NH_2 \rightarrow$$
$$\rightarrow (Me_3Si)_2N{-}Ar{-}N(SiMe_3)_2.$$

The same method of silylation was successfully used for obtaining *N,N',O,O'-tetrakis*-(trimethylsilyl)-bis(*o*-aminophenols)[20]

An alternative method of silylating bis-(*o*-aminophenols) is based on the use of trialkylsilyldialkylamines,[21–24] particularly of trimethylsilyldiethylamine in place of chlorotrimethylsilane

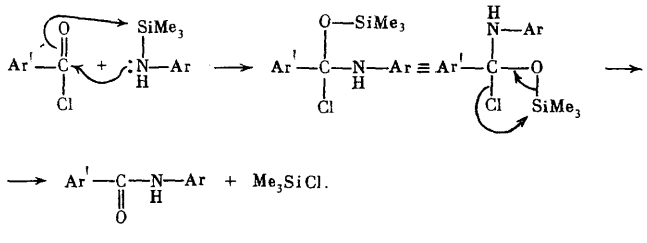
The last method has several significant advantages over silylation with chlorotrimethylsilane, such as reaction being effected in an excess of trialkylsilyldialkylamine in the absence of solvent and HCl

acceptor since the reaction byproduct is diethylamine. It is interesting to note[24] that on silylation of aminophenols the phenolic hydroxyls reacted first which made possible the isolation and characterisation of the *o*-, *m*- and *p*-isomers of the following series of compounds:

$$Me_3SiOC_6H_4\overset{H}{N}H_2,\quad Me_3SiOC_6H_4\overset{H}{N}SiMe_3,\quad Me_3SiOC_6H_4N(SiMe_3)_2.$$

Finally, silylated bis-phenols are obtained by treating various bis-phenols with hexamethyldisilazane in inert solvents[16]

$$HO—Ar—OH + Me_3Si\overset{H}{N}SiMe_3 \xrightarrow[-NH_3]{} Me_3SiO—Ar—OSiMe_3.$$



The same approach was used to obtain silylated derivatives of hydroxybenzoic acids[16]

$$HO—Ar—\overset{O}{\overset{\|}{C}}—OH + Me_3Si\overset{H}{N}SiMe_3 \xrightarrow[-NH_3]{} \rightarrow Me_3SiO—Ar—\overset{O}{\overset{\|}{C}}—OSiMe_3.$$

2. Reactivity of silylated nucleophilic monomers

As mentioned above the silylation of nucleophilic monomers is accompanied by a change in their reactivity. This problem has been considered in greatest detail when applied to silylated primary amines which possess an increased reactivity in reactions with carboxylic acid chlorides. The high reactivity of *N*-silylated amines may be explained by means of the mechanism presented below.[25]

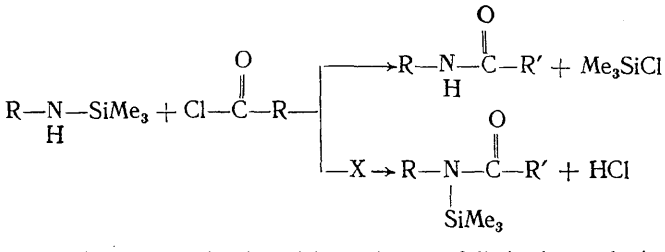
It is a characteristic of organosilicon compounds that Si atoms have a high affinity for oxygen, and for fluoride and chloride ions and also that a carbocation in a position 3 to silicon may be stabilised by the $\sigma-\pi$ effect of the latter. A two-stage addition-elimination mechanism has been proposed for the nucleophilic substitution of acyl in acid chlorides by an *N*-trimethylsilylated amine allowing for these special features of organosilicon compounds[25]

In the first stage of the reaction, attraction of the carbonyl oxygen of the acid chloride for the Si atom of the *N*-silylated amine facilitates nucleophilic attack by the nitrogen atom of the latter on the carbonyl carbon of the acid chloride, with subsequent rapid formation of a tetrahedral intermediate. In the second stage of the process elimination of a chloride ion from the intermediate is facilitated by the presence of the Si atom in the β-position which leads to rapid formation of amide together with chlorotrimethylsilane.[25]

The reactivity of *S*-trialkylsilated thiophenols may approach the reactivity of *N*-silylated amines.[18] Silylation of a hydroxyl group leads to its protection from electrophilic attack[8,26] as a result of the strong affinity of silicon for oxygen.

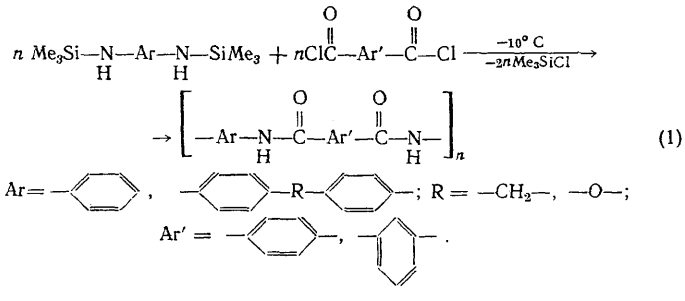
The reactivity of *S*-trimethylsilylbenzenethiol (I), *N*-trimethylsilylaniline (II) and *O*-trimethylsilylphenol (III) towards electrophiles has been compared.[18] It was found that the relative reactivities of these compounds on reaction with benzoyl chloride is expressed in the series (II) > (I) > (III) and in reaction with 1-chloro-2,4-dinitrobenzene in the series (I) > (II) > (III). *O*-Trialkylsilated phenols (trialkylsilyloxybenzenes) may react with such electrophiles as acid halides and activated organic halides only in the presence of chloride or fluoride ion

$$Ar—O—SiMe_3 + X^{\ominus} \rightarrow Ar—O^{\ominus} + Me_3SiX.$$



The silylation of such tetrafunctional nucleophiles as bis-(*o*-aminophenols) leads, in full agreement with that mentioned above, to activation of amino and deactivation of hydroxyl groups,[20] which facilitates[27,28] the selective execution of the first stage of polycyclocondensation and permits avoidance of gel formation.

3. Condensation and addition polymers based on silylated diamines

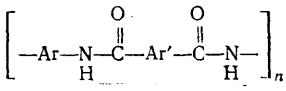


As was shown above *N*-trialkylsilylated amines are some of the most reactive organosilicon compounds. They react with various electrophiles such as acid chlorides and anhydrides, isocyanates, benzyl halides, aldehydes, etc.[8] All these reactions have been used to obtain nitrogen-containing condensation and addition polymers.[10]

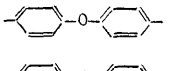
a) Synthesis of polyamides

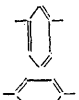
It is known[29] that on reacting *N*-trimethylsilyl-protected amines with carboxylic acid chlorides, amides are formed with the elimination of chlorotrimethylsilane as byproduct and not trimethylsilylamides with elimination of hydrogen chloride as a byproduct

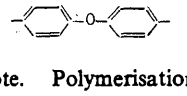
This amidation reaction is widely used successfully in the synthesis of polyamides. Thus high molecular aromatic polyamides have been obtained[25,30] by the interaction of *N,N'*-disilylated aromatic diamines with diacid chlorides of aromatic dicarboxylic acids under low temperature polycondensation conditions in solution



(1)



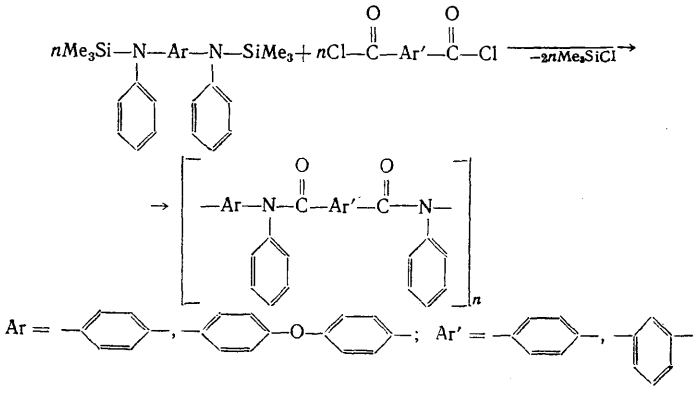




Comparison of the polyamidation process being considered with the traditional method of synthesis of aromatic polyamides, viz. reaction of diamines with diacid chlorides of dicarboxylic acids,[31–33] using the synthesis of poly-(*p*-phenyleneterephthalamide) as example, showed[30] that *N,N'*-disilylated *p*-phenylenediamine

reacts much more rapidly with terephthaloyl chloride. Polyamides with higher viscosity characteristics are obtained. Some results of syntheses of aromatic polyamides are shown in Table 1.

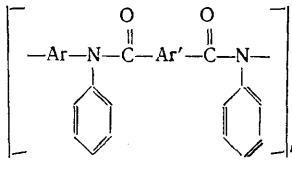
Table 1. Viscosity characteristics of aromatic polyamides of formula



(Ref.25)

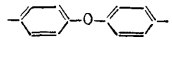
Ar	Ar′	η_{inh}, dlitre g^{-1}, conc. H_2SO_4, 30 °C	
		from *N*-silylated diamines	from unsilylated diamines
		2.45	1.03
		3.19	0.94
	 *	7.41	3.23
		2.41	1.19
		2.54	1.15
		3.21	1.40
		3.97	2.10
		3.99	1.50

Note. Polymerisation was carried out in *N*-methyl-2-pyrrolidone (NMP) containing LiCl, at −10 to −5 °C for 5 h.
*Polymerisation was carried out in a mixture of NMP and hexamethylphosphoramide (HMPA) containing LiCl at −10 to −5 °C for 12 h.



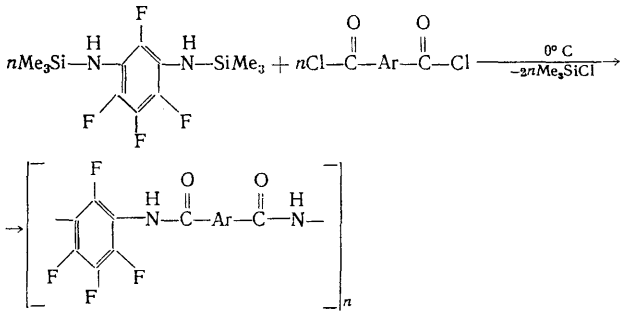
Analysis of the data shown in Table 1 indicates that without exception polyamides are obtained with significantly higher viscosity characteristics from silylated diamines than from free diamines.

The use of silylated diamines is particularly expedient in those cases when high molecular compounds cannot be obtained from free monomers of this class. The preparation of high molecular polyamides based on weakly basic diamines, which have low reactivity, is extremely problematical. The *N*-silylation of such diamines is a reliable method of activating them[12,13,34] and may be illustrated using aromatic *N,N′*-diphenyl-substituted diamines as an example.[13,34,35] These compounds, being extremely low in reactivity, are activated by silylation to such an extent that their reaction with diacid chlorides of aromatic dicarboxylic acids under high temperature polycondensation conditions in tetramethylene sulphone leads to the formation of high molecular poly-(*N*-phenyl)amides:[13,34,35]



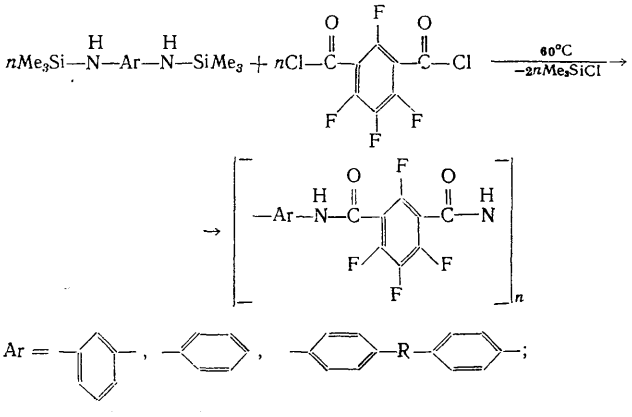
Some characteristics of the poly-(*N*-phenyl)amides synthesised are given in Table 2.

Table 2. Conditions of synthesis and viscosity characteristics of poly-(*N*-phenyl)amides of general formula



(Refs.13, 34)

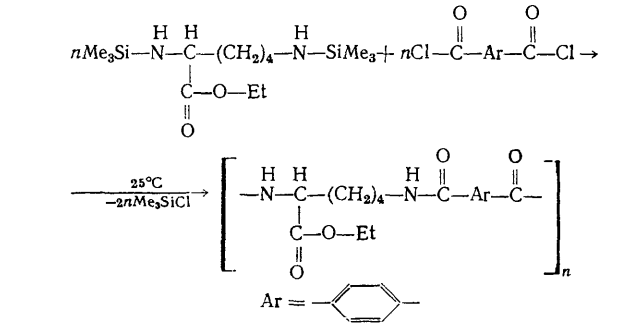
Ar	Ar′	Polycondensation conditions		η^*_{inh}, dlitre g^{-1}	T_g^{**}, °C
		T, °C	time, h		
		160	24	1.65	225
		200	6	2.21	255
		160	24	1.24	195
		200	24	1.35	215



*η_{inh} was measured in H_2SO_4 at 30 °C and a concentration of 0.5 g dlitre^{-1}; ** T_g was determined by differential thermal analysis (DTA) at a heating rate of 10 °C min^{-1}.

Analysis of the data given in Table 2 indicates that, as in the processes considered above for unsubstituted polyamides, the use of *N*-silylated diamines made it possible to obtain systems with extremely high viscosity characteristics. The poly-(*N*-phenyl)amides synthesised had T_g 195–255 °C. They dissolved in various solvents, including dimethylformamide (DMF), *m*-cresol and chloroform.

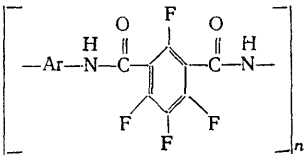
Tetrafluoro-*m*-phenylenediamine is a diamine with low basicity. It too may be activated by silylation.[36] High molecular fluorine-containing polyamides are obtained by reacting its *N,N'*-bis-trimethylsilylated derivative with diacid chlorides of aromatic dicarboxylic acids under low temperature polycondensation conditions in solution



It is interesting to note that silylated aromatic diamines form high molecular polyamides even on reaction with the poorly reactive diacid chlorides of aromatic dicarboxylic acids. The preparation of fluorine-containing polyamides by reaction of *N*-silylated aromatic diamines with tetrafluoroisophthaloyl chloride under low temperature polycondensation conditions in solution is an example[37]

R = —O—, —CH_2—.

Fluorine-containing aromatic polyamides obtained by a scheme analogous to this possessed η_{inh} equal to 0.43 dlitre g^{-1} and T_g equal to 245–280 °C (Table 3).



In addition to aromatic systems, aliphatic-aromatic polyamides have also been obtained based on *N*-silylated diamines. In particular high molecular aliphatic-aromatic polyamides are obtained by the polycondensation of *N*-silylated lysine with the diacid chloride of an aromatic dicarboxylic acid:[38]

Polyterephthalamides obtained from *N*-silylated lysine possessed η_{sp} = 1.02 [hexamethylphosphoramide (HMPA)].[38]

The interaction of silylated diamines with diacid chlorides according to Scheme (1) may be effected not only in solvents but also under conditions of solvent-free vacuum 'deposition' polycondensation (from the gas phase) making it possible to obtain thin films on appropriate substrates.[39] Thin polyamide films may also be obtained using unsilylated diamines[40,41] however a temperature of the order of 100 °C is required to remove the HCl formed during the reaction. On using *N*-silylated diamines the solvent-free vacuum 'deposition' polycondensation from the gas phase takes place at temperatures of the order of 60 °C with separation of neutral chlorotrimethylsilane. Metallic plates capable of erosion may be used as substrates and are coated with thin polyamide films. It is interesting to note that poly-*p*-phenyleneterephthalamide (Kevlar), usually a highly crystalline polymer, applied using silylated diamine, forms an amorphous transparent film.

Table 3. Some characteristics of polyamides of general formula

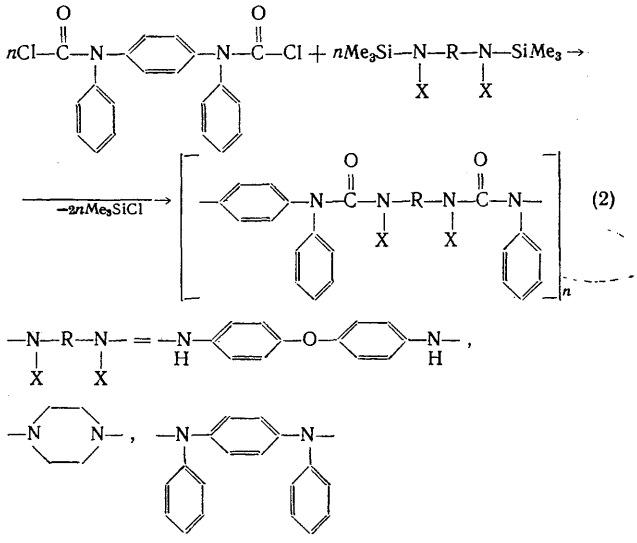
(Ref.37)

Ar	η^{*}_{inh}, dlitre g^{-1}	T^{**}_{g}, °C
	0.43	245
	0.56***	275
	0.63	280
	0.82	280

Note. Polyamide synthesis was effected in chloroform containing triethylamine hydrochloride at 60 °C for 6 h.

* η_{inh} was measured for 0.5% solutions in DMA at 30 °C;

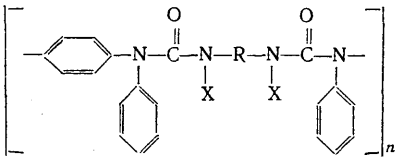
** determined by DTA at ΔT = 10° min^{-1} (air);



*** polycondensation was carried out at 0 °C for 6 h.

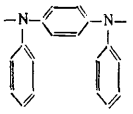
'Activated' polycondensation reactions[3] have been used for obtaining polyamides in addition to the reactions of silylated diamines with diacid chlorides. In particular silylated diamines react with bis-(2,4-dinitrophenyl) esters of dicarboxylic acids.[38] These processes, accompanied by the separation of *O*-silylated 2,4-dinitrophenol as a byproduct, are examples of polycondensation reactions using both activated nucleophiles and electrophiles. The examples given above demonstrate the application of polycondensation with silylated diamines to the efficient preparation of various polyamides.

b) Synthesis of polyureas



Silylated diamines have been used for obtaining polyureas by applying both polycondensation[12] and polyaddition[42] processes.

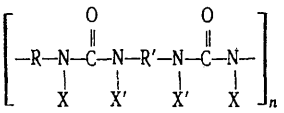
In particular, the reaction of *N,N'*-di(trimethylsilylated) aromatic diamines with *N,N'*-dichloroformyl-*p*-dianilinobenzene[12] proceeded according to Scheme 2 and *N*-phenylated polyureas were partially or completely obtained. Conditions of syntheses and individual characteristics are given in Table 4.



(2)

Table 4. Conditions of synthesis and some characteristics of polyureas of general formula

(Ref.12)



—N—R—N— (X, X)	Polycondensation conditions*			Properties of polymers

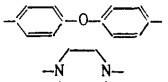
* Polycondensation was carried out by reacting 1 mmole *N,N'*-dichloroformyl-*p*-dianilinobenzene with 1 mmole silylated diamine in 3 ml solvent in a stream of N_2;

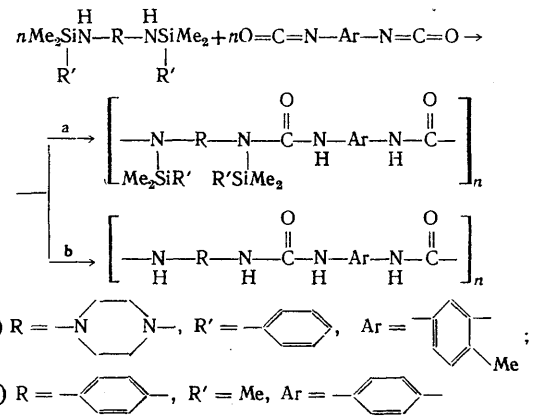


** viscosity was measured for 0.5% solutions in NMP at 30 °C;

*** viscosity was measured in conc. H_2SO_4.

Table 5. Thermal characteristics of polyureas of general formula

(Ref.12)



R	R'	X	X'	T_{dec}, °C* in air	T_{dec}, °C* in N_2
			H	265	295
		»	H	385	420
		»		520	520
	»	H	H	335	340

* T_{dec} is temperature at which polymer mass has lost 10% (TGA, ΔT = 10 °C min^{-1}).

As follows from analysis of the data given in Table 4 high molecular polymers were obtained in only one case, however the favourable influence of silylation of amines was recorded in the viscosity characteristics of the polyureas. Polymers with significantly lower viscosity characteristics were obtained from unsilylated diamines. The completely and partially phenylated polyureas obtained from silylated aromatic diamines dissolved readily in organic solvents such as dimethylacetamide (DMA), tetrahydrofuran (THF) or *m*-cresol and surpassed significantly in solubility the unsubstituted aromatic polyureas and also polymers from silylated piperazine, which are crystalline systems.

The introduction of phenyl substituents in place of comparatively labile hydrogen atoms into polyureas increases not only the solubility but also the thermal stability of these systems (Table 5) which is in agreement with the results of investigations on various classes of heterochain and heterocyclic polymers.[43]

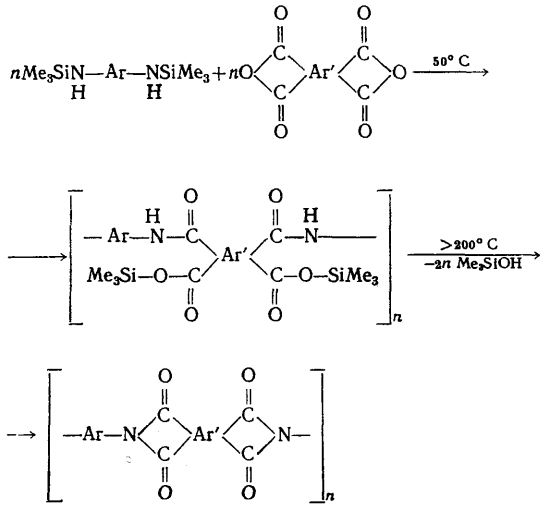
An additional method of synthesising polyureas using silylated diamines was described by Klebe in 1964.[42] It was shown that addition of *N,N'*-disilylated diamines to a diisocyanate led to the preparation of *N*-silylated polyureas which were readily methanolised into unsubstituted polyureas

a) R = , R' = , Ar = ;

b) R = , R' = Me, Ar =

The polyaddition reaction occurs under homogeneous conditions even on carrying it out in non-polar solvents (Table 6) due to the lower polarity of *N*-silylated polyureas compared to unsubstituted polyureas.[44]

Table 6. Synthesis of aromatic polyureas in various solvents.[44]



Solvent	η_{inh}, dlitre g^{-1}
DMSO	0.54
Tetramethylenesulphone	0.60
Tetrachloroethane (TCE)	0.91
Anisole	0.77
Nitrobenzene	0.65
Toluene	0.74

Note. Reaction of *N,N'*-bis(trimethylsilyl-substituted 4,4'-diaminodiphenylether was carried out at 100 °C for 10 h; viscosity was measured for 0.5% solutions in conc. H_2SO_4 at 30 °C.

It should be mentioned that polyureas obtained by the methanolysis of *N*-silylated polymers are characterised by low crystallinity and good solubility in organic solvents in difference to polyureas obtained by the usual method (diamines with diisocyanates).

c) Synthesis of polyimides

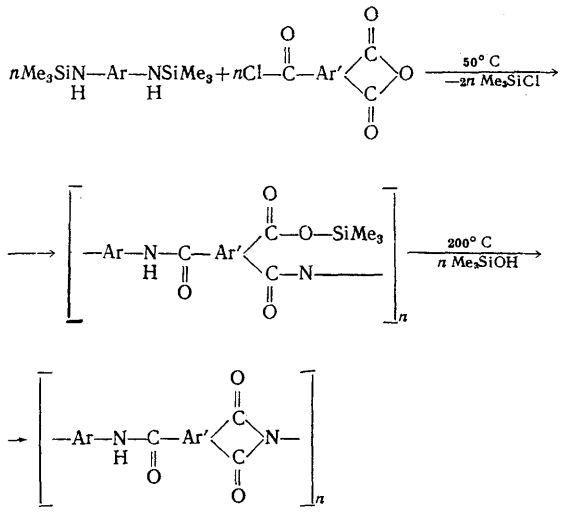
By analogy with the widespread two-step method of synthesis of polyimides[45–50] their preparation from silylated diamines occurs through the formation of intermediate polymers which are converted thermally into the desired systems.[51,52] The polyaddition of *N*-silylated aromatic diamines to dianhydrides of aromatic tetracarboxylic acids occurs with ring fission of the latter with the formation of trimethylsilyl esters of polyamidoacids which then form imides at a temperature >200 °C with the separation of trimethylsilanol

The presence of trimethylsilyl groups in the polyamidoacid esters determines the significantly greater stability of these polymers compared to unsubstituted polyamidoacids and also their increased solubility in non-polar solvents. The latter circumstance enables the synthesis of similar polymers not only in dipolar aprotic solvents of the type of DMA and *N*-methylpyrrolidone (NMP) but also in ethers or hydrocarbons. In several cases these processes are accompanied by precipitation of the polyamidoacid from solution (Table 7), however polyamidoacids with high inherent viscosities were obtained in practically all the solvents tested (Table 7).

Table 7. Synthesis of polyamidoacids in various solvents.[52]

Solvent	η_{inh}, dlitre g^{-1}	Reaction conditions
DMA	1.77	P
NMP	1.46	P
bis-Methoxyethyl ether	0.92	P
1,4-Dioxan	0.80	P
THF	0.97	P
Chloroform	0.99	P
Acetonitrile	0.88	O
Nitrobenzene	0.81	O
Toluene	0.92	O

Note. Synthesis of polyamidoacids was carried out by reacting *N,N'*-bis-(trimethylsilyl)-substituted bis-(4-aminophenyl)ether with pyromellitic anhydride at 20 °C for 1 h and then at 50 °C for 12 h; inherent viscosities were measured for 0.5% solutions in DMA at 30 °C; P denotes reaction in solution; O denotes formation of solid during reaction.



The thermal conversion of silylated polyamidoacids into polyimides occurs slowly and completion of imide formation requires higher temperatures compared with the cyclisation of unsubstituted polyamidoacids.

A single-stage process for synthesising polyimides using *N*-silylated diamines[53–55] has been applied to obtain polyimides containing residues of aliphatic diamines and polyimides difficult to obtain as high molecular systems from unsubstituted aliphatic diamines.[54] In addition these processes were used successfully to obtain polynaphthylimides distinguished by an enhanced stability towards hydrolysis.[56]

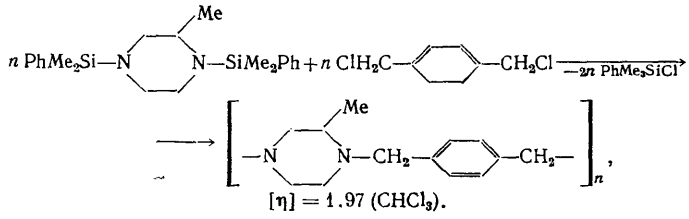
The synthesis of polyimides using *N*-silylated diamines, as when using unsubstituted diamines, may (by analogy with that suitable for polyamides[39] considered above) be used for applying thin films to appropriate substrates using solvent-free vacuum 'deposition' polycondensation from the gas phase.[57–59] In the first stage of applying thin polyimide films, the aromatic diamine and dianhydride are applied to the substrate under high vacuum which is then heated to effect imide formation.

Polycondensation using *N*-silylated diamines may also be used when appropriate with derivatives of aromatic polycarboxylic acids containing various electrophilic functional groups. Thus the

interaction of 4-chloroformylphthalic anhydride with *N,N'*-bis-(trimethylsilyl)-substituted 4,4'-diaminodiphenyl ether proceeded through a polycondensation/polyaddition reaction with the formation of the trimethylsilyl esters of polyamidoacids[60]

Results of the synthesis of intermediate polymers in various solvents are given in Table 8.

Table 8. Synthesis of copolyamido-amidoacids in various solvents.[60]

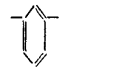


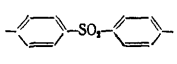
Solvent	η^{*}_{inh}, dlitre g^{-1}	Reaction conditions
DMA	1.82	P
NMP	1.48	P
Acetonitrile	1.14	O
Nitrobenzene	1.21	O
bis-Méthoxyethyl ether	1.00	O
1,4-Dioxan	0.75	O
THF	0.94	O
Chloroform	0.59	O
Benzene	0.57	O

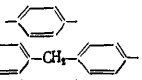
Note. Synthesis was effected by reacting *N,N'*-bis-(trimethylsilyl)-substituted 4,4'-diaminodiphenyl ether with 4-chloroformylphthalic anhydride at −5 °C for 1 h and then at 50 °C for 4 h.
* Inherent viscosities were measured for 0.5% solutions in NMR at 30 °C.

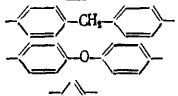
As is seen from Table 8 only reactions in NMP and DMA media proceed homogeneously. Nonetheless polymers were obtained in practically all solvents with comparatively high solution inherent viscosity. The silylated intermediate polymer may be converted into a polyamidoimide by thermal treatment under the same conditions used in the synthesis of polyimides.

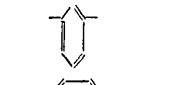
d) Synthesis of polyamines

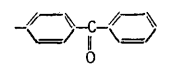


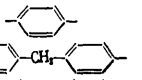


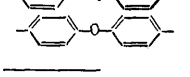


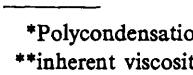












In spite of the fact that alkyl halides are aminolysed with difficulty compared with carboxylic acid chlorides, they may also interact with *N*-silylated amines.[8] According to Klebe[14] benzyl chloride reacts with *N*-silylated amines at temperatures >100 °C forming benzylamines and trialkylsilyl chloride in quantitative yield. Ammonium salts and cyclic sulphone catalytically increase the rate of the process. This reaction was extended to the synthesis of polyamines which are difficult to obtain as high molecular compounds by the reaction of diamines with dihalo compounds because of side reactions. Polycondensation of reactive dihalides of the benzyl chloride type with *N*-silylated piperazine, carried out in bulk at 150 °C, led to the formation of a high molecular polyamine[14]

$[\eta] = 1.97$ ($CHCl_3$).

Table 9. Conditions of synthesis and viscosity characteristics of aromatic polyamines of general formula

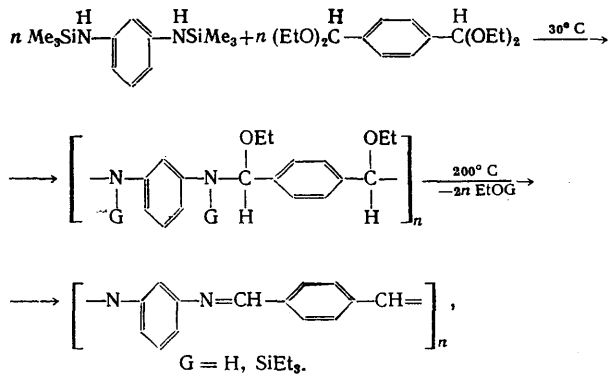
*Polycondensation was carried out in the presence of KF;
**inherent viscosities were measured for 0.5% solutions in NMP at 30 °C;
***polycondensation in tetramethylenesulphone.

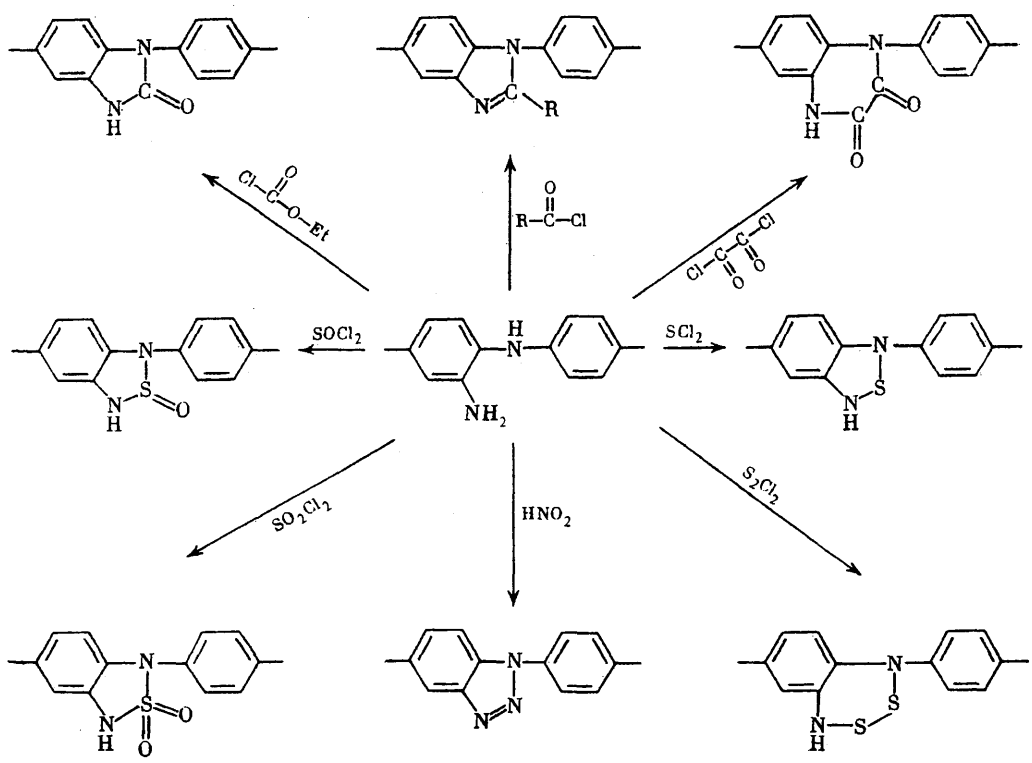
A similar substitution reaction occurs on treatment of activated haloaromatic compounds with *N*-silylated aromatic amines. In this way secondary aromatic amines were formed together with

trimethylsilyl halides.[61] Correspondingly new aromatic polyamines were successfully obtained from activated aromatic difluoro compounds and *N*-silylated aromatic diamines[61]



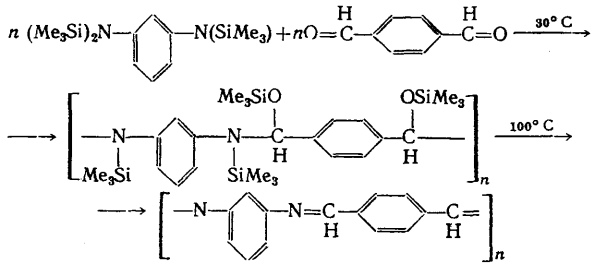
The polycondensation reaction was carried out in DMSO in the presence of fluorine-containing catalysts (KF, CsF) at 100–150 °C. Polyamines with comparatively high viscosity characteristics were obtained as a result (Table 9).

The presence of a catalyst is essential to obtain high molecular polyamines. The use of the corresponding dichlorides in place of activated aromatic difluorides led to the preparation of only low molecular polymers. Introduction of a nitro substituent into aromatic dihalo compounds increased their reactivity and led to the formation of polyamines with higher inherent viscosities. These aromatic polyamines dissolved readily in organic solvents like NMP and had $T_g \sim 200$ °C. They are potential engineering plastics.[61]



At the same time they may readily be reduced to the corresponding poly-(*o*-amino)amines[5,6,61–65] which in their turn may be used to obtain a large range of heterocyclic polymers[65]

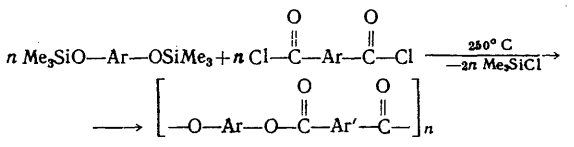
e) Synthesis of polyazomethines



The majority of aromatic polyazomethines are not obtained as high molecular compounds because of their insolubility and infusibility. Kurosaki and collaborators[16,66] have intensively investigated reactions to obtain aromatic polyazomethines and found new synthetic routes to these systems using *N*-silylated aromatic diamines. One method led to the polycondensation reaction of *N,N'*-bis-(trimethylsilyl)-substituted aromatic diamines with aromatic bis-(diethylacetals) in NMP leading to an intermediate polymer which was soluble in organic solvents. This was reprocessed into films by conversion at 200 °C into insoluble polyazomethines[66]

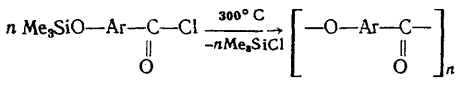
Another method is the polyaddition of *N,N,N',N'-tetrakis*-(trimethylsilyl)-substituted aromatic diamines with aromatic dialdehydes in NMP with the formation of soluble intermediate polymers, with

subsequent conversion (thermal) into insoluble polyazomethine films[19]



Similar intermediate polymers were formed in both cases in the first stages subsequently undergoing β-elimination with the formation of azomethine bonds in the main macromolecule chains.

4. Polymers based on *O*-silylated bis-phenols

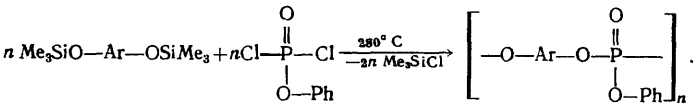


The possibility of using *O*-silylated bis-phenols to obtain high molecular compounds has been studied in detail by Kricheldorf and collaborators[15–17,67–70] who synthesised high molecular polyesters and polyethers based on these monomers.

a) Synthesis of polyesters

The possibility was shown in 1979 of synthesising polyaryl esters from *O*-silylated bis-phenols and diacid chlorides of dicarboxylic acids[15]

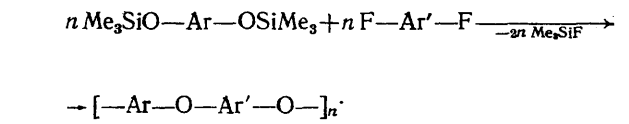
or from trimethylsilyloxybenzoyl chlorides



by polycondensation in bulk at 200–300 °C.

The drawback of the thermal polycondensation of two different monomers (A–A and B–B types) such as *O,O'*-trimethylsilyl-substituted 2,2-bis-(4-hydroxyphenyl)propane and isophthaloyl chloride is the possibility of distilling or subliming out the more volatile monomer which disturbs the stoichiometry of the starting materials and leads to a reduction in the degree of polymerisation. This drawback is eliminated in the homocondensation of monomers of the A–B type such as trimethylsilyloxybenzoyl chloride. The molecular weight of a polymer obtained from a *m*-hydroxybenzoic acid derivative (type A–B) was greater than that of a polymer from *O*-silylated bis-phenol and isophthaloyl chloride. Thus the silylation method is useful for the high temperature preparation of polyarylates from monomers of type A–B.

The homocondensation reaction of *m*- and *p*-silyloxybenzoyl chlorides has been carried out in bulk and in solution.[67,68] Polycondensation of *m*-trimethylsilyloxybenzoyl chloride in bulk at 250 °C led to the preparation of a polyaryl ester of molecular weight 10000–14000,[67] while polycondensation of the *p*-isomer in a high boiling solvent at 320 °C led to the preparation of a polymer of molecular weight 20000–50000.[68] In the latter case crystalline oligomers separated from solution in the first stage of the polycondensation, the molecular weight of which continued to grow on heating. Polycondensation was accelerated by such catalysts as triethylamine hydrochloride and benzyltriethylammonium chloride leading to polyaryl esters with large molecular weights.

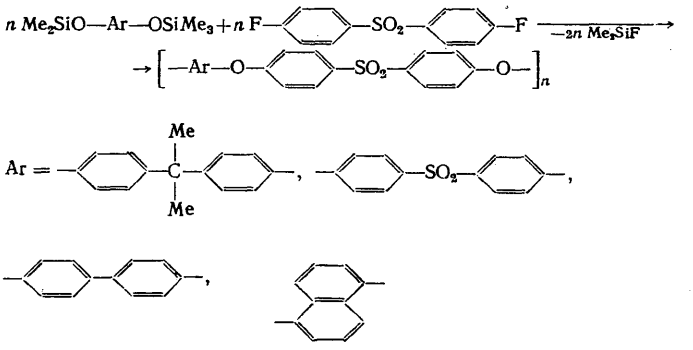


O-Silylated bis-phenols also react with aryl phosphodichloridates with the formation of aromatic polyphosphates which are polyesters in the wide sense of the word[69,70]

Polycondensation in bulk was carried out at 180–300 °C in the presence of catalytic amounts of benzyltriethylammonium chloride. Polyphosphates of molecular weight up to 12000 were obtained in this way.

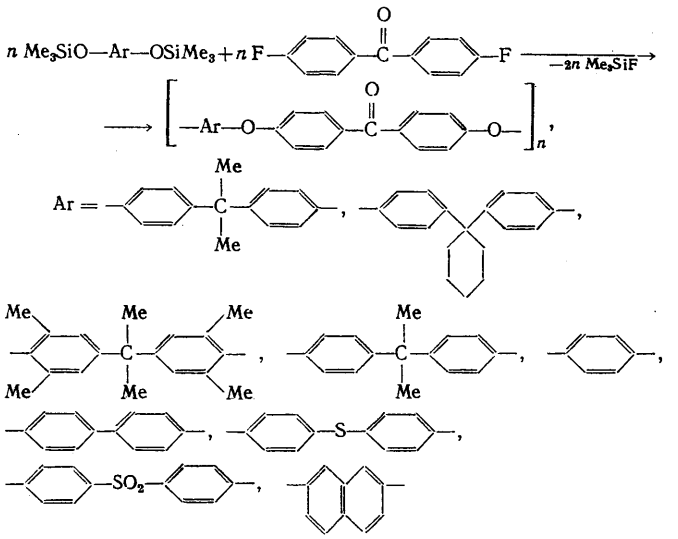
b) Synthesis of polyethers

The possibility of using *O,O'*-bis-trimethylsilylated bis-phenols to obtain polyethers in addition to polyesters has been investigated.[16,17,71,73] Activated difluoro-aromatic compounds were selected as comonomers of silylated bis-phenols



The use of the corresponding derivatives of the diphenylsulphone[16] and benzophenone[17] series as activated difluoro-aromatic compounds enabled the preparation valuable poly(ether sulphones)[16,72] and poly(ether ketones).[17,73]

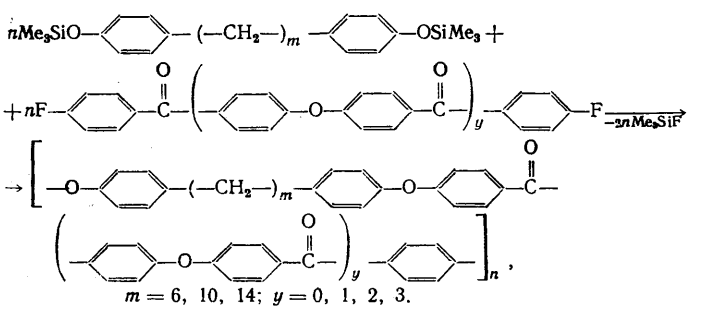
These polymers are usually obtained by high temperature polycondensation of bis-phenols with activated dihalo-aromatic compounds in solutions of alkali metal salts.[74–78] The main drawback of these processes is the need to purify the desired polymers from reaction by products, viz. metal salts, and also from the expensive high boiling solvents used in obtaining them.



The use of silylated monomers enables polymers to be obtained which require no purification from large amounts of metal salts.

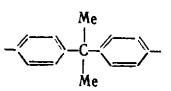
The reduction in reactivity of silylated bis-phenols requires the synthesis of polyesters to be conducted at elevated temperatures using catalysts such as KF and CsF.

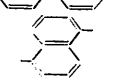
The interaction of *O,O'*-trimethylsilyl-substituted bis-phenols with 4,4'-difluorodiphenylsulphone, which was carried out in bulk at temperatures up to 340 °C (Table 10), led to the preparation of poly(ether sulphones) with molecular weights reaching 17500.[16]



The reaction of *O,O'*-dimethylsilylated bis-phenols with 4,4'-difluorobenzophenone[17] leading to polyetherketones was effected under analogous conditions.

Some characteristics of the poly(ether ketones) obtained are shown in Table 11.





As continuation of these investigations the synthesis of fatty aromatic poly(ether ketones) with alternating aliphatic 'looseners' (spacers) and aromatic ether ketone blocks has been effected[73]

$m = 6, 10, 14; y = 0, 1, 2, 3.$

Table 10. Conditions for polycondensation of 4,4'-difluorodiphenylsulphone with *O,O'*-trimethylsilyl-substituted bis-phenols and some characteristics of the poly(ether sulphones) obtained of general formula

Ar	Polycondensation conditions		Yield, %	T_g, °C
	temperature, °C	time, h		
	180/320	0.5/2.5	98	185—195

*Measured for 1% solutions in H_2SO_4 at 25 °C; **measured by osmometry in chloroform; ***measured by GLC in THF; ****determined by DSC at a temperature rise rate of 20° min^{-1}.

These processes are carried out in bulk at a maximum temperature of ~300 °C using CsF as catalyst by analogy to the synthesis of polyethers mentioned above (Table 12). As a result of

the low boiling point of 2,6-difluoropyridine (123 °C) a portion of it is removed from the reaction. Consequently the polycondensation processes were carried out with a small excess of 2,6-difluoropyridine (Table 12).

Table 12. Conditions of preparation and some characteristics of polyethers of general formula

(Ref.71)

Ar	Excess of 2,6-difluoro-pyridine, mol.	Yield, %	η_{inh}, dlitre g^{-1}

	1.0	60	0.51

* Measured for solutions (c = 2 g litre^{-1}) in a mixture of dichloromethane–formic acid–trifluoroacetic acid (molar ratios 70:10:20) at 25 °C.

The conditions for carrying out the reaction of 2,6-difluoropyridine with silylated bis-phenols and the viscosity characteristics of the polyethers obtained are shown in Table 12.

As is seen from Table 12 the polyethers were obtained in almost all cases in yields exceeding 90% and with η_{inh} lying at 0.20–1.40 dlitre g^{-1}. The best viscosity characteristics were inherent in the film-forming polyether obtained from *O,O'*-disilylated phenylhydroquinone.

The molecular weight and thermal characteristics of the products of interaction of 2,6-difluoropyridine with silylated bis-phenols are shown in Table 13.

In addition to the homopolymeric polyesters the synthesis has been undertaken of copolymeric structures using an equimolar mixture of 2,6-difluoropyridine with 4,4'-difluorobenzophenone or 4,4'-difluorophenylsulphone as electrophilic comonomers[71]

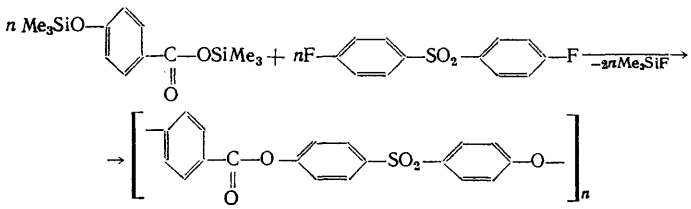
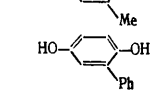
* Measured for solutions in dichloromethane (c = 2 g litre^{-1}); ** date of DSC at heating rate 20° min^{-1}.

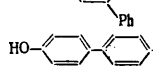
As follows from the data presented in Tables 14 and 15 polymers were obtained by copolycondensation possessing fairly high η_{inh} (0.44–1.56 dlitre g^{-1}) in combination with T_g lying within the limits 118–147 °C.

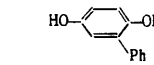
c) Synthesis of copolymers containing ether and ester groups

In addition to the synthesis of polyethers and polyesters the silylated monomers have been used for making high molecular compounds containing both ether and ester groups.[16] The reaction of di-methylsilylated *m*- and *p*-hydroxybenzoic acids with 4,4′-difluorodiphenylsulphone has been carried out for this purpose:[16]









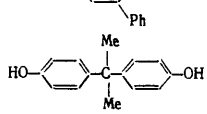


Table 14. Yields and some properties of copolymers obtained by thermal condensation of 2,6-difluoropyridine with 4,4′-difluorobenzophenone and silylated bis-phenols.[71]

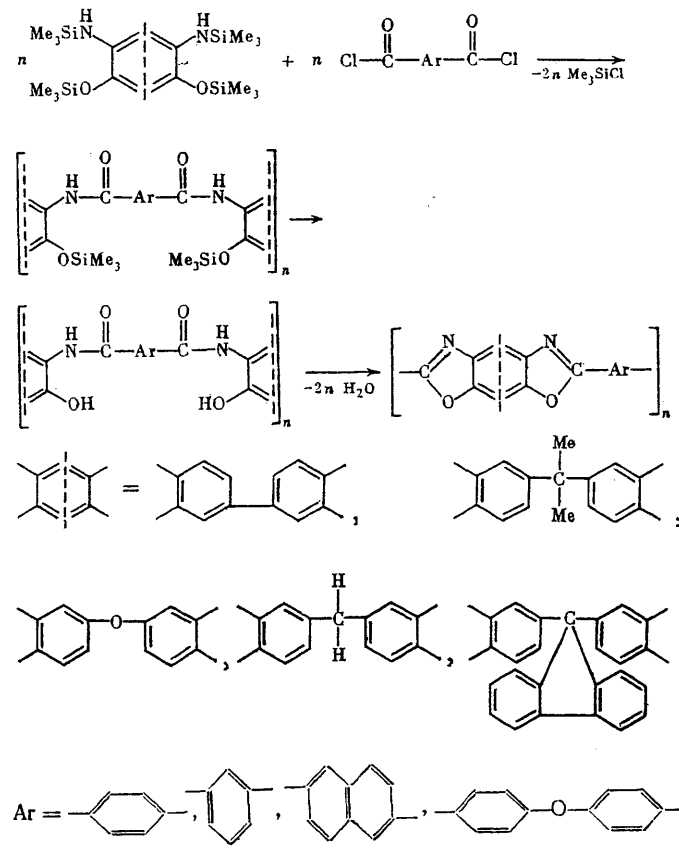
bis-Trimethylsilylated bis-phenol	Yield, %	η^*_{inh}, dlitre g^{-1}	T_g, °C
	85	0.47	131
	89	1.19	138
	94	1.55	147
	97	1.56	147



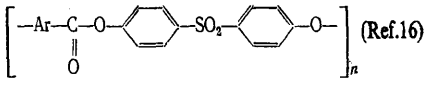
* Measured for solutions in mixtures of dichloromethane, formic and trifluoroacetic acids (70 : 10 : 20) at c = 2 g litre^{-1}.

The conditions for carrying out the polycondensation processes, yields and properties of the target copolymers are shown in Table 16.

It should be mentioned that attempts to involve activated dichloro aromatic compounds such as 4,4′-dichlorodiphenylsulphone and 4,4′-dichlorobenzophenone in reactions to obtain ester bonds proved unsuccessful. These compounds have too low a reactivity to undergo polycondensation reactions with phenolic groups rendered inert by silylation.

5. Polymers based on *N,O*-silylated aminophenols

The synthesis of polymers based on monomers containing silylated hydroxyl and amino groups is broadly represented by the synthesis of polybenzoxazoles using *N,N′,O,O′-tetrakis*-(trimethylsilyl)-bis-(*o*-aminophenols) and diacid chlorides of dicarboxylic acids.[20,22,79–81]



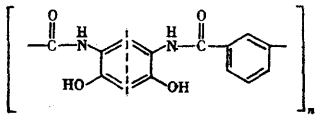
The synthesis of polybenzoxazoles based on silylated bis-(*o*-aminophenols) has been carried out by two-stage[20,79,81] and one-stage[80] methods. A detailed study of the two-stage process[20] and particularly of its first stage showed that, as in the synthesis of polyamides considered above, the use of silylated, rather than unsilylated, nucleophilic monomers led to the preparation of significantly higher molecular systems (Table 17).

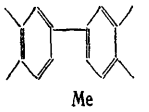
The data given in Table 17 refer to poly-(*o*-hydroxy)amides devoid of silyl protection on the phenolic hydroxyls as a result of isolation from the reaction solution with methanol. Removal of silyl protection is necessary to increase the nucleophilic reactivity of the phenolic hydroxyl at the ring-closing stage. Polycyclodehydration of the poly-(*o*-hydroxy)amides thus obtained was carried out by heating at 250–260 °C in vacuum for 30 h. The polybenzoxazoles obtained

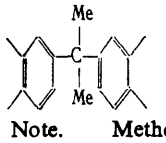
dissolved only in concentrated H_2SO_4. As a result their reprocessing into various materials such as films was effected at the stage of poly-(*o*-hydroxy)amides which are soluble in DMF, NMP, DMSO and pyridine. Some characteristics of polybenzoxazoles and films based on them are shown in Table 18.

Table 16. Conditions of carrying out block polycondensation of 4,4′-difluorodiphenylsulphone with disilylated hydroxybenzoic acids and some characteristics of the copolymers of general formula

(Ref.16)

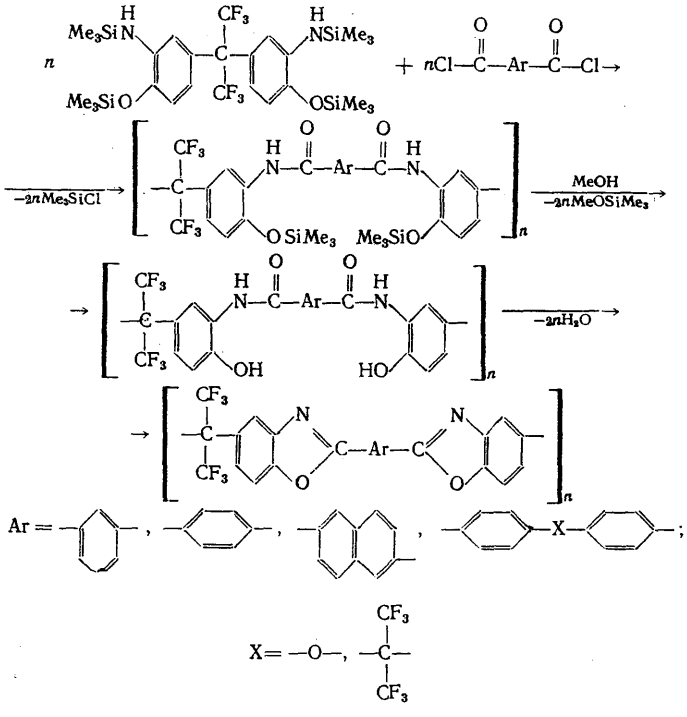






Ar	Reaction conditions		Yield, %	T_p, °C
	temperature, °C	time, h		
	250/320	0.5/2.5	91	137
	250/320	0.5/2.5	96	215

Table 17. Comparison of η_{inh} of poly-(*o*-hydroxyamides) from bis-(*o*-aminophenols) and their silylated derivatives



(Ref.20)

	Method A	Method B
	0.33	0.50
	0.16	0.55

Note. Method A was polycondensation using unsilylated bis-(*o*-aminophenol); method B was polycondensation using silylated bis-(*o*-aminophenol); polycondensation was carried out by reaction of bis-(*o*-aminophenol) (2.5 mmole) with isophthaloyl chloride (2.5 mmole) in DMA (5 ml) at 0–5 °C for 8 h in a stream of N_2; all polymers were obtained in quantitative yield; viscosities were measured in DMA at 30 °C and c = 0.5 g dlitre^{-1}.

The most interesting synthesis of polybenzoxazoles from silylated monomers is that based on weakly basic bis-*o*-aminophenols. One of such monomers is 2,2-bis-(3-amino-4-hydroxyphenyl)-1,1,1,3,3,3-hexafluoropropane. Further interest in the polymer based on it arises because aromatic polycondensates containing the hexafluoroisopropylidene group are characterised by a combination of enhanced solubility and good thermal characteristics.[82]

A detailed study of hexafluoroisopropylidine-containing polybenzoxazoles obtained according to:

showed that silylation of 2,2-bis-(3-amino-4-hydroxyphenyl)-1,1,1,3,3,3-hexafluoropropane led to an increase in the nucleophilic reactivity of this monomer.[20] Thus η_{inh} was equal to 0.08 dlitre g^{-1} for the polyisophthalamide based on the unsilylated monomer but η_{inh} was 0.64 dlitre g^{-1} for the poly-(*o*-hydroxy)amide based on the silylated monomer and synthesised under the same conditions.

Introduction of the hexafluoroisopropylidene grouping imparted increased solubility not only for the poly-(*o*-hydroxy)amide but also for the polybenzoxazole in full agreement with the previous report (Table 19).[82]

Viscosity and thermal characteristics of the hexafluoroisopropylidene-containing polybenzoxazoles and some strength characteristics of films based on them are shown in Table 20.

The thermal characteristics of hexafluoroisopropylidine-containing polybenzoxazoles shown in Table 20 surpass in some degree the corresponding characteristics of analogous systems obtained by reductive polyheterocyclisation.[5,6,83,84] This is in agreement with existing ideas[85] on the influence of the method of synthesis of polybenzazoles on their properties.

The low strength characteristics of films obtained from hexafluoroisopropylidene-containing polybenzoxazoles (Table 20) are somewhat surprising. Nonetheless these polymers are considered to be very promising thermostable polymeric materials.[20]

6. Polymers based on *S*-silylated dithiols

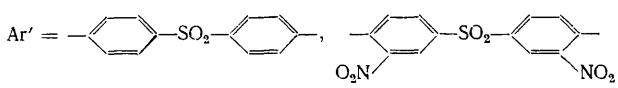
In spite of the fact that the reactivity of *S*-trialkylsilylated thiols is close to the reactivity of *N*-silylated amines, reactions of compounds containing an Si–S bond have been paid insignificant attention by

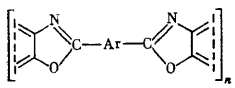
investigators. Nonetheless the reaction of *S*-silylated aromatic dithiols with activated dihalo aromatic compounds has been carried out:[18]

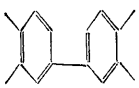
$$n\mathrm{Me_3Si{-}S{-}Ar{-}S{-}SiMe_3} + n\mathrm{X{-}Ar'{-}X} \xrightarrow[-2n\mathrm{Me_3SiX}]{} \mathrm{[{-}S{-}Ar{-}S{-}Ar'{-}]}_n,$$

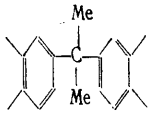
Ar =  ;

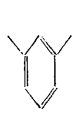
X = F, Cl;











Ar′ = 

Table 18. Some characteristics of polybenzoxazoles of general formula

and polybenzoxazole films.[20]

	Ar	T_g^*, °C	T_{dec}^{**}, °C		Properties of films	
			in air	in N_2	σ_s, kg.cm^{-2}	ε_{rel}, %
		290	570	620	1980	7

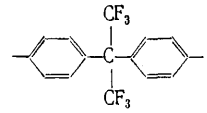
* Determined by thermomechanical analysis at a heating rate of 10° min^{-1} in air;

** temperature for loss of 10% initial weight (TGA, heating rate 10° min^{-1}).

The properties of the polysulphides obtained are shown in Table 21. As is seen from Table 21 aromatic polysulphides with moderate η_{inh} (0.6–0.7 dlitre g^{-1}) were obtained from the reaction (HMPA, 50 °C) of *S*-silylated dithiols with bis-(4-chloro-3-nitrophenyl)sulphone. Bis-(4-fluorophenyl)sulphone possesses little reactivity. Its reaction in solution with *S*-silylated dithiols was effected in TMS at 220 °C using CsF as catalyst. The polysulphides obtained possessed η_{inh} close to 0.3 dlitre g^{-1}.

Summing up all the above mentioned results on polycondensation and polyaddition reactions using silylated nucleophiles[10] it should be noted that:

1) silylation of nucleophilic monomers leads to compounds which are easy to purify, in particular, silylated products may be purified by distillation;



2) the majority of silylated monomers are readily soluble in organic solvents which facilitates polycondensation and polyaddition reactions in various reaction media, from low to high boiling and/or polar solvents;

3) polycondensation processes using silylated monomers may be carried out in neutral media with separation of neutral compounds as byproducts, particularly chlorotrimethylsilane, which may be used once again to obtain silylated monomers;

4) in several cases silylation of nucleophilic monomers leads to an increase in reactivity which makes it possible to carry out the synthesis of polymers under milder conditions and at higher rates. In individual cases silylation is an effective route to involve unreactive compounds in polymer synthesis;

5) the silylation of multifunctional monomers used in polyheterocyclisation reactions may lead to an increase in the difference in reactivity of neighbouring reaction centres thus enabling a smoother course for selective polyacylation.

Table 19. Solubility of hexafluoroisopropylidene-containing poly-(*o*-hydroxy)amides and polybenzoxazoles.[20]

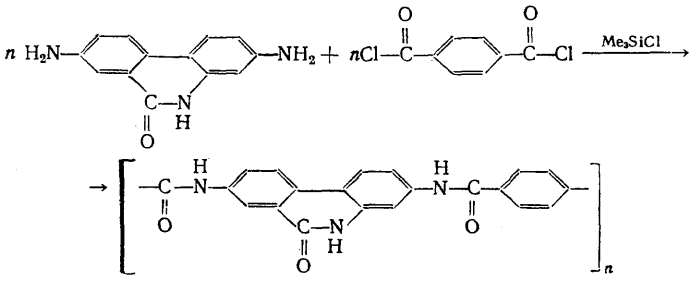
Note. (++) denotes soluble at room temperature; (+) partially soluble or swells; (–) insoluble.

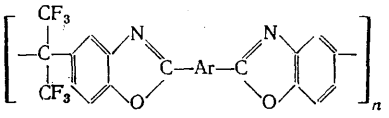
The discussed merits of reactions using silylated monomers have swung the interest of investigators towards polycondensation reactions in the presence of silylated agents.

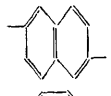
III. Polycondensation reactions in the presence of silylating agents

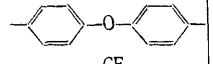
Since the synthesis of polymers using silylated monomers requires previous synthesis and purification of the latter a simpler way of obtaining polymers would be their synthesis in the presence of

silylating agents. Thus on reacting 3,8-diaminophenanthridine with terephthaloyl chloride in a mixture of NMP and HMPA at 0 °C in the presence of chlorotrimethylsilane, a higher molecular polyamide was obtained than in the presence of such widely used additives as LiCl and $CaCl_2$ (Table 22).









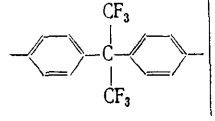


Table 20. Some characteristics of polybenzoxazoles of general formula

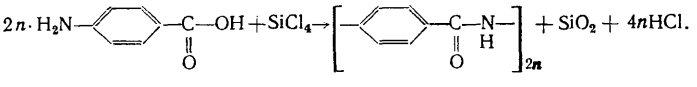

and films based on them.[20]

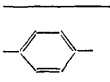
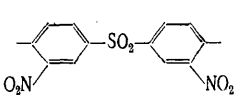
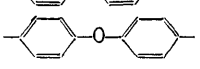
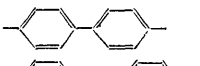
	0.46	295	545	555	680	3

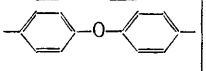
Determined by thermomechanical analysis at a heating rate of 10° min^{-1} in air.











A similar approach to obtaining high molecular polyamides has been used in copolymer synthesis.[87]

Another example of carrying out a polycondensation in the presence of a silylating agent is the homocondensation of *p*-aminobenzoic acid in pyridine in the presence of $SiCl_4$.

Tetrachlorosilane has also been used as silylating agent in the reaction of *p*-phenylenediamine with terephthalic acid and of *m*-phenylenediamine with isophthalic acid.[88] The results of these processes, belonging to a variety of 'direct' polycondensation,[1,2] are shown in Table 23.

Table 21. Conditions of synthesis and viscosity characteristics of aromatic polysulphides of general formula $[-S-Ar-S-Ar'-]_n$.[18]

*1 mole LiCl per mole diamine, etc.

As follows from the data shown in Table 23 an oligomer is obtained in 41% yield when a stoichiometric amount of $SiCl_4$ is used. On using a 20% excess of $SiCl_4$ the polyamide was obtained in quantitative yield and its molecular weight was 13 400. Polyamides with lower molecular weight characteristics were

obtained on reacting *p*-phenylenediamine with terephthalic acid. This is evidently linked with the low solubility of terephthalic acid in the reaction medium.

Table 23. Conditions of synthesis of aromatic polyamides in the presence of $SiCl_4$.[88]

Monomers	Molar ratio $SiCl_4$: :monomer	[Monomer], mol.litre^{-1}	Yield, %	[η]*, dlitre g^{-1}	M_n

	0.80	0.56	94	0.60	5 300
	0.62	0.66	98	0.51	—

Note. Polycondensation was carried out at 0 °C for 24 h.

*Measured in H_2SO_4 at 30 °C; **solvent pyridine; *** solvent chlorobenzene : pyridine (2 : 1).

An interesting aspect of this synthetic method is the formation of filler materials in the reaction process. SiO_2 is formed as a result of the polycondensation.

— o0o —

It has been shown that the silylation method, particularly processes using *N*-silylated diamines, is an easy and promising route for the synthesis of high molecular condensation polymers. New polycondensation reactions using silylated monomers are at the development stage at the present time. However, in the main this area continues to remain little studied. The most characteristic distinguishing feature of the silylation method is the fact that silylated nucleophilic monomers differ markedly in reactivity from the initial nucleophiles. This method may therefore find new regions of application for making new condensation polymers and for developing new synthetic routes for obtaining various known polymers.

Aromatisation of low-molecular-weight paraffins on pentasil group zeolites

Kh M Minachev, A A Dergachev
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. Experimental data on the application of pentasil group zeolites in the aromatisation of low-molecular-weight paraffins are surveyed. Modern ideas concerning the mechanism of the aromatisation and the nature of the active centres in pentasil are examined. Examples of the application of pentasil-containing catalysts in technological processing of gaseous hydrocarbons are presented.

The bibliography includes 235 references.

I. Introduction

Low-molecular-weight hydrocarbons are a readily available and cheap raw material for the synthesis of polymeric materials, high-octane components of motor fuel (C_6-C_8 isoalkanes and aromatic hydrocarbons), as well as various intermediates in fine organic synthesis.[1–3] Among the principal sources of lower paraffins, one should distinguish in the first place the byproduct petroleum gas (C_2-C_5 alkane content up to 70%) and natural gas (overall content of ethane, propane, and butanes up to 25%),[4,5] the scale of the extraction of which runs into tens and hundreds of billions of cubic metres per year respectively. A tendency has arisen recently towards a more complete utilisation of petroleum by processing also its heavy fractions and towards an increase of the output of apparatus for thermal and catalytic cracking—the principal degradative processes used in modern petrochemical and petroleum processing industry. This has resulted in a considerable increase in the evolution of waste gases in which C_2-C_4 paraffins predominate and which contain an appreciable amount of the corresponding alkenes. The processes based on CO and H_2—the gaseous coal processing products—also occupy a fairly important place in the manufacture of lower hydrocarbons.[6,7] Until recently, a considerable proportion of the components of natural, byproduct, and petroleum industrial gases have been used merely as industrial fuels and have not found applications in the synthesis of chemical products.

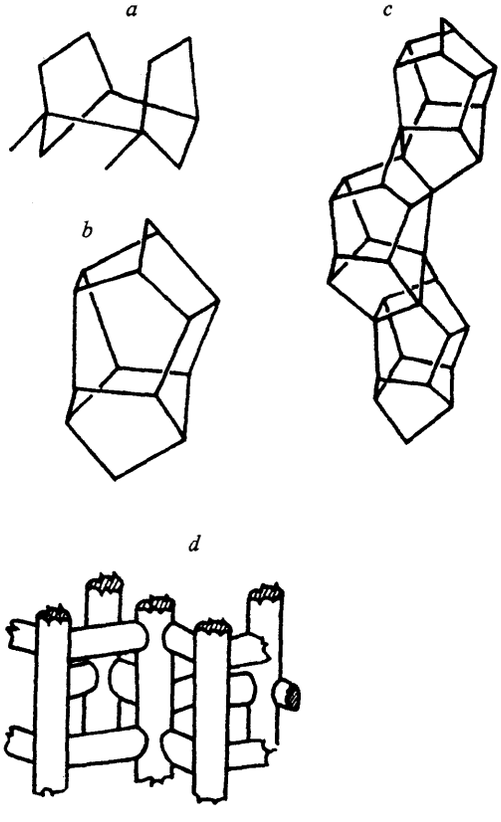
The task involving the effective utilisation of hydrocarbon gases has stimulated the search for new catalysts, among which synthetic zeolites occupy a special place.[8,9] The first generation zeolites (faujasites, mordenite, erionite, etc.) are replacing traditional catalysts based on amorphous aluminosilicates in petroleum cracking processes, in the alkylation of paraffins and aromatic hydrocarbons, and in the oligomerisation of lower alkenes. A new stage in the development of zeolite catalysis involves the synthesis of high-silica pentasil group zeolites.[1–3,10] Zeolites of this structural type, which have no natural analogues, were first synthesised by the Mobil Oil Company at the beginning of the 1970's. They were given the abbreviated designations ZSM-5 and ZSM-11.[11–17] In the Soviet Union, analogues of these zeolites are referred to as pentasils of the TsVK and TsVM types and ultrasil.[15] New methods of synthesis of pentasils, in the lattices of which aluminium atoms have been replaced by boron, iron, gallium, germanium, zinc, and chromium atoms as well as atoms of other elements, have been developed recently.[18–20]

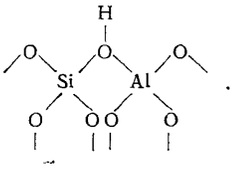
Pentasil-based catalysts have found applications in many large-scale petroleum processes such as isomerisation, disproportionation, and alkylation of aromatic hydrocarbons,[21–23] the cracking of gas oil fractions,[3,24] deparaffinisation of petroleum fractions,[24] the conversion of methanol into hydrocarbons,[25–27] etc. In these processes, pentasils proved to be more effective as selective catalysts than the previously employed first generation zeolites or non-zeolitic systems of various compositions. In addition, pentasils possess the unique ability to convert lower paraffins and alkenes into higher-molecular-weight products.[3,27–32] C_2-C_4 alkenes are almost quantitatively converted into high-octane components of motor fuel on pentasils at atmospheric pressure and at temperatures in the range 300–350 °C.[11–13,28–30] During the last 4–5 years, there has been a growth of interest in pentasils as catalysts of the aromatisation of lower paraffins. The modification of pentasils by the addition of various transition elements made it possible to obtain catalytic systems for the conversion of propane and butanes into C_6-C_{10} aromatic hydrocarbons with a selectivity of 60–70%.[31–34]

The results of the study of the catalytic properties of zeolites, including pentasils, in various reactions have been treated systematically in a number of reviews[1–3,16,22–27,35,36] published at the beginning of the 1980's. The aim of the present review is to survey and analyse the information accumulated during the last 5–6 years about the reactions of low-molecular-weight paraffins in the presence of pentasils of various compositions, to discuss the possible mechanisms of these reactions, and to consider certain technological aspects of the use of pentasil-based catalysts in the processing of hydrocarbon gases.

II. Structure and active centres of pentasils

The skeleton of zeolites—crystalline aluminosilicates—consists of aluminium–oxygen and silicon–oxygen tetrahedra, which have common vertices and form the structural elements of the lattice—tetrahedral and hexahedral prisms, cancrinite and sodalite cells, cubooctahedra, etc.[37,38] Without going into details, which have been described in a number of reviews and monographs,[8,9,16,37,38] we shall note only the principal features of the structure of pentasils. The pentasil skeleton is based on five-membered rings formed predominantly by silicon–oxygen tetrahedra, since the concentration of aluminium in these zeolites is low (not more than 5 atoms per unit cell, which corresponds to the ratio Si/Al ranging from about fifteen to tens of thousands).[3,14,38] The five-membered rings are joined up into cells consisting of eight such rings and form chains which are combined into layers, each chain in the layer representing the mirror image of the neighbouring chain (Fig. 1). In the skeleton of pentasils of type ZSM-5 and ZSM-11 there exists a system of pores consisting of channels intersecting at right angles, which are produced by ten-membered rings. The porous structure of the ZSM-5 zeolite includes both straight (0.54 × 0.56 nm) channels with an elliptical cross-section and sinusoidal (0.51 × 0.55 nm) channels with a circular cross-section. The pore system of the ZSM-11 pentasil consists of straight channels with an elliptical cross-section.





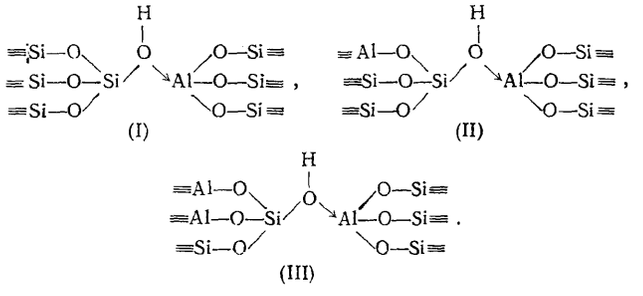


Figure 1. The structure of pentasil: *a*, structural element; *b*, cell made up of eight five-membered rings; *c*, chain made up of cells; *d*, schematic representation of the channel structure of pentasil.[3]

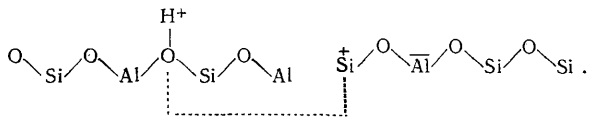
It must be emphasised that the aluminium atoms occupy a special position in the crystal lattice of zeolites. They substitute isomorphously the silicon atoms in the structural skeleton but are involved in tetrahedral coordination with respect to oxygen atoms. As a result of this, the coordination number and valence of aluminium are not the same, which leads to the appearance of an excess negative charge on the aluminium–oxygen tetrahedron AlO_4^-. This charge may be compensated either by a metal cation or by a proton (in the decationated forms of the zeolite). The compensating proton forms a covalent bond with one of the four oxygen atoms in the AlO_4^- tetrahedron, which creates isolated structural hydroxy-groups of the bridging type:

An IR spectroscopic study of the interaction of the OH bridging groups with the molecules of adsorbed bases[39–49] established that they are strong Brønsted acid centres (B-centres). According to modern ideas[42,47–52] based on quantum-chemical calculations and experimental IR data, the entire wide variety of the acid hydroxy-groups reduces to three principal types with different numbers of aluminium atoms in the immediate structural environment of the hydroxyl.



The acid properties of the hydroxyls are weakened on passing from (I) to (III) and further to silanol groups Si–OH, which have no proton-donating capacity. High-silica pentasils and mordenites contain type (I) OH groups and terminal silanol hydroxyls similar to the surface hydroxy-groups on silica gel.[46,49,50] Apart from the isolated bridging hydroxyls, pentasils include bridging OH groups forming fairly strong hydrogen bonds with the lattice oxygen atoms.[46,53] The concentration of such hydroxyls can reach 20% of the total number of OH groups.[46] According to Medin et al.,[53] these groups have unusual properties. For example, at room temperature they are capable of interacting with adsorbed paraffin molecules, while at elevated temperatures they undergo a transition to an isolated state. According to quantum-chemical calculations,[54] hydroxyls of this type should have stronger electron-donating properties than isolated bridging OH groups.

Apart from B-centres, zeolites contain aprotic (Lewis) acid centres (L-centres) possessing electron-accepting properties. Various coordinatively unsaturated lattice atoms or ions having an unoccupied *p* orbital as well as exchange cations with a positive charge constitute the zeolite L-centres. In the structure of dehydroxylated hydrogen-forms of zeolites, AlO_4^- tetrahedra lacking

a proton compensating their charge and having the properties of a Lewis base, are also present.

The results of IR spectroscopic studies[46–53] have shown that, on dehydroxylation of decationated pentasils and mordenites obtained by direct hydrothermal synthesis, aprotic acid centres of three types are formed: one of them consists of coordinatively unsaturated lattice aluminium atoms, others consist of silicon ions, and finally the third group comprises aluminium atoms outside the lattice. In the dealuminated mordenites, L-centres of only one type—tricoordinate lattice silicon ions—are formed after the removal of OH groups.

According to the results of a number of studies,[17,55,56] high-silica zeolites of the type of pentasil and mordenite contain also a smaller amount of very acid ("superacid") centres. These are protic centres whose acidity has been enhanced as a result of the inductive effect of a neighbouring Lewis centre.[57]

Thus acid centres of different nature have been identified in zeolites by the IR spectroscopy of adsorbed molecules. The ratio of the concentrations of the L- and B-centres depends on the structure of the zeolite, the composition of the skeleton, the thermal stability of the hydroxyl coating, and the chemical nature of the substances used to modify the inner and outer surfaces of the catalyst.[8,9,34]

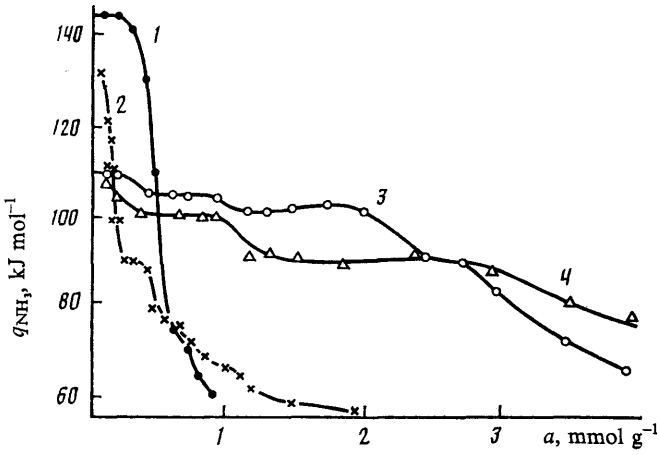


Figure 2. Differential heats of adsorption of ammonia on zeolites at 30 °C:[59] *1*, dealuminated mordenite with Si/Al = 24; *2*, pentasil of the type H-TsVK with Si/Al = 40; *3*, HNaY (degree of decationation α = 80%); *4*, HNaX (degree of decationation α = 80%).

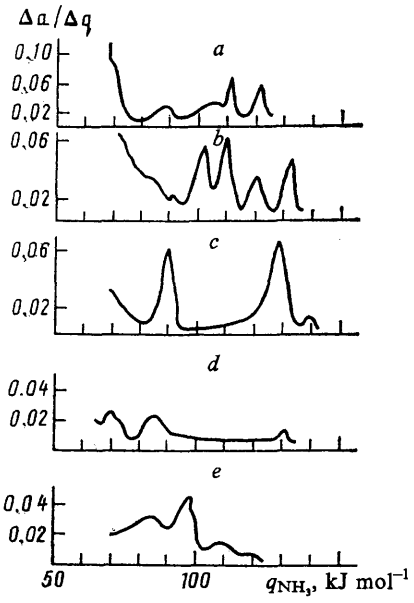
Apart from IR spectroscopy, adsorption microcalorimetry,[40,58–66] heterophase isotope exchange between deuterium and hydroxy-groups,[67–71] programmed thermal desorption of ammonia and organic nitrogen-containing bases,[72,73] etc. have been used to investigate the acidity of zeolites of different structure, including pentasils. Adsorption microcalorimetry, based on the direct measurement of the differential heats of adsorption of nitrogen-containing bases and especially of ammonia, is most suitable for the quantitative estimation of the concentration and strength of the acid centres. The stepwise character of the curves reflecting the dependence of the differential heat of adsorption of ammonia q_{NH_3} on the amount of adsorbed ammonia Q shows that the inhomogeneity of the adsorption centres of zeolites is discrete in nature (Fig. 2). The acidity spectra of certain zeolites having different compositions and structures (Fig. 3) contain bands with the same q_{NH_3}. These indicate the presence of centres of identical strength in different zeolites but at different concentrations. With increase in Si/Al, a trend is observed towards an increase in the strength of the acid centres and a decrease in their number.[63–66] Comparison of the acidity spectra has shown that both pentasils and mordenites contain strong acid centres with $q_{NH_3} > 120$ kJ mol^{-1}.[61–63] However, in contrast to mordenites, pentasils contain no centres adsorbing ammonia with $q_{NH_3} > 130$ kJ mol^{-1}.



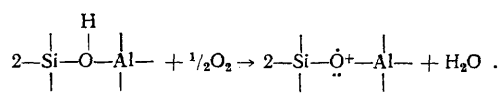


Figure 3. Distribution of acid centres of different structure with respect to energy:[63] *a*, zeolite L (α = 82%); *b*, mordenite (α = 90%); *c*, dealuminated mordenite with Si/Al = 9; *d*, pentasil of type H-TsVK with Si/Al = 30; *e*, pentasil of type H-TsVM with Si/Al = 20 ($\Delta a/\Delta q$ = fraction of acid centres with a specific q_{NH_3}).

The acid centres of pentasils are distinguished by a high thermal stability. The results of measurements of the concentration of hydroxy-groups by heterophase isotope exchange and adsorption microcalorimetric methods[63,71] showed that the protic centres of pentasils begin to decompose above 700 °C and that, even after heat treatment at 800 °C, about 40% of the hydroxyls persist on the surface. Pentasil vacuum heat-treated at 800 °C contains strong acid centres which adsorb ammonia with q_{NH_3} = 110–130 kJ mol^{-1}.[63] The number of these centres is approximately three times smaller than for the specimen heated at 500 °C.

Together with acid centres of different nature, the zeolites contain oxidation-reduction centres, which were identified by the EPR method.[74] The Brønsted acid centres of pentasils can be converted into centres of another type—solid state defects—as a result of high-temperature heat treatment (> 500 °C):[75]

When these centres interact with ionisable organic molecules, radical-cations can be produced.

III. Aromatisation of low-molecular-weight paraffins

The first communications about the catalytic conversion of low-molecular-weight paraffins into aromatic hydrocarbons appeared at the beginning of the 1970's.[76–79] According to thermodynamic calculations,[79] at 627 °C the equilibrium constant of the reaction $3C_2H_6 \rightleftarrows C_6H_6 + 6H_2$ is ~21, which corresponds to 78% of benzene in the equilibrium mixture at atmospheric pressure. The equilibrium constant of the reaction 2 iso-$C_4H_{10} \rightleftarrows C_6H_4(CH_3)_2 + 5H_2$ is 16.2 at 427 °C and 1.2×10^4 at 527 °C.[76] Table 1 presents the calculated temperatures at which the free energies ($\Delta G°$) of the alkane aromatisation and dehydrogenation reactions become zero. The conversion of ethane, propane, and hexane into benzene requires much lower temperatures than their dehydrogenation.[80]

Table 1. Temperature (°C) at which benzene and olefins are formed from various alkanes with $\Delta G° = 0$.[80]

Alkane	Benzene	Alkenes
Methane	1075	1350 (C_2H_4)
Ethane	575	774 (C_2H_4)
Propane	450	655 (C_3H_6)
n-Hexane	320	575 (C_6H_{12})*

*2-Methylpentene.

By analogy with the dehydrocyclisation of paraffins containing six and more carbon atoms, bifunctional deposited metallic reforming catalysts, which exhibit a dehydrogenating activity, were used initially for the conversion of light alkanes.[76–79,81–89]

Ethane may be aromatised in the presence of an M/Al_2O_3 catalyst, where M = Pt, Pd, Ru, Rh, or Ir.[79,81–83] Aluminoplatinum catalysts exhibited an appreciable activity in the aromatisation reactions of propane,[77,84,85] butanes,[76,86] and pentane.[77] Aromatic hydrocarbons have also been obtained from n-butane in the presence of Mo, W, Cr, V, and Mn oxides deposited on Al_2O_3.[78] The aromatisation reactions of lower paraffins on non-zeolitic catalysts have been examined in detail in a number of reviews.[87–89] We may note that, in the presence of the M/Al_2O_3 catalysts the selectivity in the formation of aromatic hydrocarbons S_{arom}, defined as the ratio of the yield of the aromatisation products to the overall degree of conversion, does not exceed 20%. Most of the initial hydrocarbon is converted into cracking and condensation products. As a result of the deposition of these products on the surface, the activity of the catalyst falls rapidly during the reaction.

A new stage in the study of the conversion of lower paraffins with less than six carbon atoms into aromatic hydrocarbons is associated with the use of zeolites of the pentasil group. In the decationated form, these zeolites are capable of aromatising saturated hydrocarbons even in the absence of dehydrogenating components. Modification of pentasils by various metals made it possible to increase significantly the degree of conversion of paraffins and S_{arom}.

All the promoting elements can be divided arbitrarily into two groups. The first includes noble metals (Pt, Rh, Pd), which increase the degree of conversion and the yield of aromatic hydrocarbons, while the second group includes certain Group II and III elements (Zn, Cd, Ga), in the presence of which S_{arom} increases sharply. Examples of the aromatisation of C_2-C_5 paraffins in the presence of pentasils in the hydrogen-form and modified catalysts are examined below.

1. Decationated pentasils

Pentasils of the type H-TsVM exhibit an appreciable activity in the aromatisation of ethane.[90–96] At 600 °C and for a contact time $\tau \simeq 30$ s, the yield of aromatic hydrocarbons relative to the paraffin passed through the system ($A_{C_2H_6}$) was 10% on a specimen Si/Al = 18. Under the same conditions, the degree of conversion of propane was appreciably higher. In the range 500–600 °C, the degree of conversion of propane ($x_{C_3H_8}$) varied from 72 to 98%, while $A_{C_3H_8}$ varied from 14 to 37%. At $T \geqslant 600$ °C and for $\tau \geqslant 20$ s, propane undergoes a thermal transformation: $x_{C_3H_8} = 40-80\%$.[97,98] In the presence of a pentasil of the type of ultrasil with Si/Al = 22 for $x_{C_3H_8} = 93\%$ and $A_{C_3H_8} = 24\%$ (600 °C, $\tau = 30$ s), most of the propane was converted into methane (37%), ethane (21%), and C_2-C_4 alkenes (14%).[99,100] On silicalite containing less than 0.03 wt.% Al, the main reaction pathway at 630 °C and for $\tau \simeq 5$ s was the formation of C_1-C_3 hydrocarbons (88%), while $A_{C_3H_8}$ did not exceed 3%.[101] On type H-TsVK pentasil (Si/Al = 30), at 600 °C and for $\tau = 8$ s, $S_{arom} \simeq 10\%$ for $x_{C_3H_8} = 67\%$.[102] Under these conditions, ethane was not converted into aromatic hydrocarbons, while in the reaction with isobutane A reached 23%.

The aromatisation of propane has also been studied under relatively mild conditions (500–550 °C, $\tau \leqslant 10$ s, $p_{C_3H_8} = 0.01-0.1$ MPa) where the contribution of the thermal process is insignificant.[101–104] The liquid catalytic reaction mixture consisted, as at 600 °C, only of aromatic hydrocarbons, among which benzene, toluene, and xylenes predominated. Despite the fact that the reaction conditions and the compositions of the catalyst in a number of studies were different,[101–103] S_{arom} and the proportions of the aromatic C_6-C_8 hydrocarbons at 500–550 °C proved to be almost identical: 25–30% of benzene, 46–50% of toluene, and 20–26% of xylenes plus ethylbenzene with $S_{arom} = 25-30\%$. Only in some instances[104,105] did S_{arom} reach ~50% at 500–650 °C.

Apart from temperature and contact time, an important factor influencing the degree and nature of the transformation of lower paraffins in the presence of pentasils is the ratio of the concentrations of silicon and aluminium in their lattices. The role of the composition of the skeleton of decationated pentasils in the aromatisation of propane and isobutane has been studied.[100,106–111]

An increase in the Si/Al ratio in ultrasils from 22 to 95 led to a decrease in $x_{C_3H_8}$ from almost 100 to 42% (at 600 °C and for $\tau \simeq 30$ s).[106] Simultaneously with the falling degree of conversion, the activity of the catalyst fell in the aromatisation, cracking, and coke formation reactions and to a lesser extent in the dehydrogenation of propane.[100]

The activity of pentasils of type H-TsVK and H-TsVM with Si/Al = 15–140 in the transformations of propane and isobutane[108–110] also increased appreciably with increase in the content of aluminium [Al] in the skeleton (Fig. 4). The quantity $x_{C_3H_8}$, which increases monotonically with increase in [Al], reaches ~80% at 600 °C and for $V = 450$ h^{-1} on specimens with Si/Al = 15–24. The dependence of $A_{C_3H_8}$ on the composition of pentasils has a somewhat different character (Fig. 4, curve *2*). The plot shows clearly two sections, one of which corresponds to the variation of A with increase in [Al] from 0.3 to 1.4 wt.% and the other corresponds to the variation of A as [Al] increases from 1.4 to 3.2 wt.%. On zeolites containing ≤1.4 wt.% Al, $A_{C_3H_8}$ ranges from 5 to 8%, which is almost identical with the yield of aromatic hydrocarbons on quartz, i.e. under the conditions of the thermal conversion of propane. The aromatisation of the more reactive isobutane does not require as much Al in the skeleton as for the transformation of propane,[109] but the maximum value of $A_{C_4H_{10}}$ (42% at 600 °C and for $V = 450$ h^{-1}) was obtained on the catalyst with Si/Al = 20.

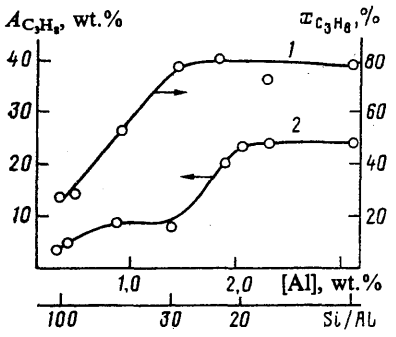

Figure 4. Dependence of the degree of conversion of propane (curve *1*) and of the yield of aromatic hydrocarbons at 600 °C (curve *2*) on the aluminium concentration in the pentasil skeletons.[109]

The composition of the skeleton influences significantly not only the activity of pentasils but also the selectivity of their action. Fig. 5 presents the dependence of $A_{C_3H_8}$ on $x_{C_3H_8}$. The degree of conversion was varied by varying the temperature for constant τ. The principal characteristic feature of the relations obtained is the linear variation of A, the straight lines on the plot starting from the origin of coordinates. This indicates the constancy of S_{arom} within the limits of each series of catalysts. All the pentasils in the H-form investigated can be divided into two groups. The first contains specimens with Si/Al ranging from 49 to 140; in their presence, propane is converted into aromatic hydrocarbons with the lowest selectivity (S_{arom} = 15%). The second group comprises pentasils with a comparatively high [Al] (Si/Al = 18–24), on which S_{arom} = 28%.

It is noteworthy that the principal pathway followed in the conversion of C_3–C_5 paraffins on decationated pentasils is the cleavage of the molecules of the initial hydrocarbons and reactions involving the resulting C_2–C_3 unsaturated products. For example, on a specimen of the H-TsVK pentasil with Si/Al = 140, the degree of conversion of isobutane at 600 °C reached 60%, whereas $A_{C_4H_{10}}$ did not exceed 13%.[109] The principal isobutane conversion products under these conditions were methane, ethane, and propene, whose overall yield was 40%. Pentane is cracked on pentasils at lower temperatures than propane and isobutane.[112,113] At 450 °C on an H-ZSM-5 specimen with Si/Al = 26, ~50% of pentane is converted into propane with $S_{arom} \simeq 15\%$.[112] As for the transformations of the C_3–C_4 paraffins, the activity of the decationated pentasils in the aromatisation of pentane depends on the composition of the skeleton and increases sharply with increase in [Al]. However, there is a simultaneous increase in the overall degree of conversion, so that S_{arom}, measured for constant x, changes little as Si/Al is varied from 26 to 450.[112]

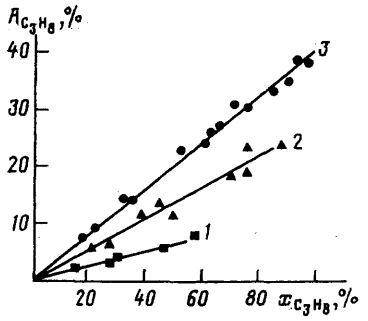

Figure 5. Dependence of the yield of aromatic hydrocarbons on the degree of conversion of propane in the presence of H-pentasils (curves *1* and *2*) and Zn-pentasils (curve *3*) with different Si/Al ratios:[110] *1*, 49–140; *2*, 18–24; *3*, 20–140.

Thus decationated pentasils of different composition are capable of converting C_2–C_5 paraffins into aromatic hydrocarbons, but the ratio of the rates of the target dehydrocyclisation reaction and the cracking side reaction is always appreciably less than unity.

2. Pentasils containing group VIII metals

As mentioned above, catalysts with bifunctional activity, which are active in dehydrogenation and are capable of converting the resulting alkenes into aromatic hydrocarbons, are most suitable for the aromatisation of C_2–C_4 alkanes.

Since decationated pentasils exhibit a high activity in the aromatisation of low-molecular-weight alkenes[3,28,114–124] (and to some extent even paraffins), one might expect that the introduction of a dehydrogenating component into their composition would promote the aromatisation of saturated hydrocarbons. Such bifunctional catalysts should also retain the principal advantages of pentasils—molecular sieve properties[16,17,125] and high resistance to coke formation.

According to patent data,[126] on Pt/H-ZSM-5 at 600 °C ethane is converted to a slight extent into a mixture of benzene, toluene, and xylenes. Detailed study of the catalytic properties of pentasils of the

H-TsVM type, containing Pt, Rh, or Pd, in the aromatisation of ethane and propane[90–97,127–130] led to the discovery of the specific features of the catalytic effect of each element, determined by its nature, in particular the unequal capacities of the M^{n+} cations for undergoing a change in the oxidation state in the oxidation-reduction treatment, and also by the possible differences in the degree of dispersion and in the distribution of the metallic phase within the channels and on the surface of the zeolite component of the catalyst.

It follows from Table 2 that $A_{C_2H_6}$ on Pt/H-TsVM is approximately twice as high as on the initial H-form. On metal-containing pentasils, the reaction proceeds at a lower temperature than on H-TsVM. Comparison with the results obtained on a Pt/Na-TsVM specimen showed that protic acid centres play an important role in the conversion of lower paraffins. If such centres are absent, then the reaction pathway changes radically—the principal ethane conversion products become ethylene and methane, while aromatic hydrocarbons are not formed. It was observed similarly that the main propane conversion product at 300 °C on Pt/Na-ZSM-5 is propene.[131] Catalysts modified by Pd and Rh exhibit a lower activity in the aromatisation of ethane than Pt/H-TsVM.[96,129,130] On raising the temperature to 600 °C, the degree of formation of methane increases and $A_{C_2H_6}$ falls sharply on Rh/H-TsVM.

Table 2. The transformations of C_2H_6 on modified pentasils *.[94]

*Flow system, space velocity 120 h^{-1}, treatment of the catalyst with air at 550 °C for 5 h.

**Treatment of the catalyst with air (5 h, 550 °C) and hydrogen (5 h and 550 °C).

Metal–pentasil catalytic systems possess a number of characteristic features. In the first place, the activity of the catalysts depends to a large extent on the conditions in their preliminary treatment. Specimens treated with air or with air and hydrogen in succession are much more active than catalysts reduced directly with hydrogen without preliminary heating in a stream of air (Table 3). The study of the catalyst by X-ray photoelectron spectroscopy (XPES) and electron microscopy made it possible to explain the results of the catalytic experiments.[94,96,97,127–130] Direct treatment with hydrogen leads to the complete reduction of platinum to the zerovalent state and induces the migration of metal particles to the outer surface. Large crystallites, approximately 10 mm in size, are then formed. On heat treatment in air without reduction, approximately 60% of platinum is present as Pt^{2+} ions. Oxidative treatment at 350–500 °C promotes the migration of cations into the interior of the channels. An appreciable proportion of the Pt^{2+} cations then remain in an isolated state. Heat treatment in air is accompanied by the reduction of some of the metal cations to an intermediate or zerovalent state.[130] The Si/Al ratio in the surface layer also increases on heat treatment. This may be caused by the migration of the aluminium outside the skeleton or by the "shielding" of the aluminium as a consequence of the localisation of the cations near the aluminium–oxygen tetrahedra. If the catalysts are treated with air before reduction, it is possible to obtain extremely finely dispersed particles (< 1 nm) with a very narrow distribution with respect to size.[127–130,132] The platinum particle size in the Pt/H-TsVM catalyst was estimated by electron microscopy[127,130,131] and by H_2–O_2 titration,[133] similar results being obtained in both cases. According to the present authors' data,[129] fine metal particles are more active in aromatisation and hydrogenolysis reactions.

Table 3. The influence of the state of the metal and of the degree of its dispersion on the catalytic properties of the M/H-ZSM systems in ethane aromatisation and hydrogenolysis reactions.[129]

M	Treatment of catalyst**	State of metal (%)	Particle size, nm	Aromatisation*		Hydrogenolysis
				yield of AH***, %	S_{arom}	turnover number, s^{-1}
Pt	1	Pt^{2+} (60) Pt^0 (40)	1–2	18	18–20	—
	2	Pt^0 (100)	0,8	15	13–17	9,6
	3	Pt^0 (100)	10	1,5	4,5	0,55
Rh	2	Rh^0 (65) Rh^+ (35)	1–2	13	25	0,54
	3	Rh^0 (75)	3–5	0,9	7.5	0,05

*The aromatisation temperatures for Pt and Rh were 550 and 450 °C; the corresponding temperatures for hydrogenolysis were 420 and 250 °C.

** *1*, At 550 °C in air; *2*, at 550 °C in air and at 450–520 °C in H_2; *3*, at 450–520 °C in H_2.

***AH = aromatic hydrocarbons.

The influence of the conditions in the preliminary treatment of Pt/H-ZSM-5 on the degree of dispersion of the metallic phase has also been observed in other studies.[134–136] According to the data of Engelin et al.,[134] finely dispersed platinum particles (1–2 mm) are formed on slow heating (1 K min^{-1}) of the catalyst in a stream of oxygen diluted with helium. Appreciably larger crystals (⩾10 nm) are formed at a heating rate up to 10 K min^{-1} and only a small proportion of the platinum is localised within the channels. In order to obtain platinum crystallites whose size is less than 1 nm, preliminary stepwise heating of the catalyst in a stream of air (180–300 °C) at a rate of 1 K min^{-1} followed by reduction by

hydrogen and subsequent flushing with nitrogen at 530 °C necessary.[135]

The data examined have shown that the reduction of platinum in pentasils leads, as in faujasites,[137,138] to the localisation of metal atoms or clusters in the zeolite structure and to their partial migration to the outer surface. Such behaviour is also characteristic of the Rh/H-TsVM catalyst.[130]

Another characteristic feature of the catalytic effect of metal-containing pentasils consists in the so-called "running in" of the catalyst during the reaction. This effect is strikingly manifested when aromatisation is carried out under pulse conditions, "running in" not being observed on hydrogen-forms without the metal. One of the possible causes of this phenomenon may be a change in the oxidation state of the metal during the reaction owing to its interaction with the carrier and the catalytic reaction products. The influence of the reaction medium on the formation of the active state of the metal has been investigated in relation to the aromatisation of ethane in the presence of platinum- and rhodium-containing pentasils of the type H-TsVM.[96,97,127,129,130] In order to elucidate the causes of the "running in" phenomenon, a study was made, simultaneously with the study of the catalytic activity of Pt/H-TsVM, of the electronic state of platinum during aromatisation by comparing the X-ray photoelectron spectra of the specimens transferred from the catalytic reactor to the spectrometer. In a specimen heat-treated in a stream of air (Fig. 6, curve *1*), platinum was readily reduced with increase in the number of ethane pulses and the yield of the aromatic hydrocarbons rose and reached a maximum. At this point, the platinum has a positive charge $\delta+$. On a catalyst reduced in a stream of H_2, the nature of the dependence of the yield on the number of pulses remain the same and the maximum yield also corresponded to the appearance of a charge $\delta+$. According to X-ray photoelectron spectroscopic data, the Pt4*f* parameters changed appreciably during the "running in" of the catalyst.[96,127,129,130] Analysis of the photoelectron spectra made it possible to differentiate two types of platinum centres differing in their spectroscopic characteristics: (1) platinum particles whose X-ray photoelectron spectra have been appreciably displaced (by 1.2 eV) relative to the spectrum of the metal; (2) platinum particles in the spectra of which there is no positive shift or a slight negative shift is observed (for example, after ten ethane pulses). It has been suggested[127,129,130] that the positive shift is at least partly due to the transfer of electron density from platinum to the electron-accepting sections of the carrier. During the "running in" of the catalyst, the positive charge on the platinum increases (Fig. 6) and then, after the attainment of the maximum activity, diminishes somewhat, although some of the metallic centres carry a more positive charge both in the initial and in the deactivated specimens.

Large platinum crystallites localised on the outer surface of the zeolite belong to centres of the second type. On the basis of modern ideas concerning the strong interaction of the metal with the carrier,[139] it has been suggested[127,129,130] that under severe reaction conditions (550–600 °C, hydrocarbons, hydrogen), oxygen vacancies may be formed in the pentasil lattice and Al^{3+} ions located in the vicinity of the platinum particles may be reduced. The interaction of platinum atoms or clusters with such electron-donating centres should lead to the appearance of an excess electron density on platinum, which has in fact been observed experimentally by X-ray photoelectron photoscopy.

Summarising data on the state of platinum in Pt/H-TsVM catalysts and taking into account at the same time the change in catalytic properties, one may postulate that there exists a special form of platinum ($Pt^{\delta+}$ with a shift of approximately 1.2 eV) which in fact determines the activity of the catalysts in the aromatisation of ethane.

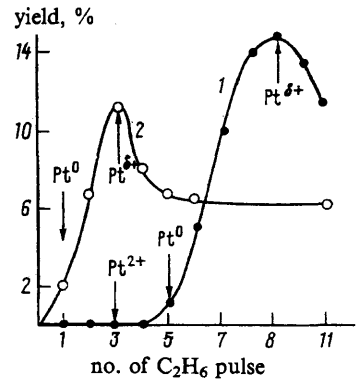

Figure 6. Dependence of the yield of the ethane aromatisation products in the presence of Pt/H-TsVM on the number of pulses:[129] *1*, treatment with air; *2*, treatment with hydrogen.

The Rh-form of the H-TsVM pentasil behaves similarly to the platinum-form.[129,130] After treatment with hydrogen at 400–450 °C, an appreciable portion of rhodium (~40%) in the zeolite remains unreduced. Analysis of the X-ray photoelectron spectra during the aromatisation of ethane demonstrated the presence of two states of rhodium: a state close to the metallic state and one formally corresponding to Rh^+. The change of their relative contributions with increase in the number of ethane pulses is caused by the additional reduction of rhodium and the interaction of the zerovalent metal with the reaction mixture. A similar interaction had been observed earlier for aluminorhodium catalysts of the cyclotrimerisation of ethylene.[130] During the reaction, a significant change in the activity of the catalyst and in the electronic state of the metal occurred. A positive charge arose on rhodium clusters [the maximum shift was $\Delta E_b Rh3d_{5/2} \simeq 0.7$ eV].

A combined study of the catalytic properties of metal-containing pentasils and of the physicochemical properties of the platinum, rhodium, and palladium surfaces[90,92,94–97,127–130] made it possible to elucidate the role of the oxidation state and of the degree of dispersion of metals in the aromatisation of ethane. Evidently the same factors should determine the activity of similar catalysts also in reactions involving C_3-C_4 paraffins. It has been established that the method used to prepare the Pt/H-ZSM-5 catalysts has an appreciable influence on the degree of conversion of propane.[140,141] The specimen obtained by the ion exchange method proved appreciably more active than that in which platinum was introduced by impregnation with a $[Pt(NH_3)_4]Cl_2$ solution. These data were confirmed in other studies.[131,134,135] If part of the platinum is on the outer surface of the zeolite (which is characteristic of catalysts obtained by the impregnation method), then during the first 30–60 min of the experiment these particular metal particles are deactivated and the activity then varies during a long period, since the platinum surface centres located near the structural OH groups are very resistant to coke formation by virtue of the molecular sieve properties of pentasils.[134]

Thus the introduction of noble metals, in the first place platinum, leads to a significant increase in the yield of the products of the aromatisation of lower paraffins and in the selectivity of this process.

3. Pentasils modified by Group II and III elements in the periodic system

As mentioned in the preceding section, pentasils modified by platinum and other noble metals exhibit a high activity in the reactions of lower alkanes, but the selectivity of the aromatisation in their presence does not exceed 30%. In order to increase S_{arom}, pentasils modified by different elements (Ni, Co, Mo, W, Cd, Zn, Ga) were used, but the best results were obtained with the aid of zinc, cadmium, and gallium.[142–152] The modifying elements are introduced in different ways: by ion exchange, by impregnation, by the mechanical mixing of powders, and finally by the isomorphous substitution of aluminium in the lattice with formation of gallosilicates or zinc-silicates.[18,19,80,153–155]

The catalytic properties of Zn/H-ZSM-5 specimens prepared by ion exchange and of the initial decationated form of pentasil have been compared[101,103,156] in propane conversion processes at 450–550 °C and atmospheric pressure. The introduction of Zn^{2+} cations increases $x_{C_3H_8}$ by a factor of 1.5 and S_{arom} by a factor of 2. In aromatic products of the reaction of Zn/H-ZSM-5, the fraction of benzene and toluene is higher, while the content of C_8-C_9 alkylbenzenes is lower than on the unmodified zeolite.[102,103] The proportions of the gaseous hydrocarbons also change appreciably. Modification with zinc leads to a sharp decrease in the degree of conversion of propane into methane and to an increase in the ethane concentration.[101,102,109]

Higher temperature and longer contact times τ are required for the aromatisation of ethane on Zn-pentasils than for the aromatisation of propane. Zinc has an appreciable promoting effect in the aromatisation of ethane on H-TsVM and H-TsVK pentasils with different compositions.[98,157] With decrease in the Si/Al ratio from 32 to 15, $x_{C_2H_6}$ increased at 600 °C and τ = 30 s from 27 to 57%.[157] The maximum value S_{arom} = 35% was obtained on a specimen with Si/Al = 23 at 650 °C. With increase in the aluminium concentration in the zeolite skeleton, the yield of methane and naphthalenes increased and that of hydrogen and C_8 alkylbenzenes fell. On a type H-TsVM (Si/Al = 15) pentasil containing 0.5 wt.% of zinc, $x_{C_2H_6}$ = 32% and $S_{arom} \simeq$ 60% at 600 °C.[98]

Catalysts prepared by the ion exchange method have been used in some studies.[98,101,103] However, the ion exchange capacity of pentasils is low,[158] which precludes the variation of the concentration of the promoting agent within wide limits. According to calculations,[80] the maximum zinc content in pentasil cannot exceed 2 wt.% when the metal is introduced by ion exchange with Na^+ or NH_4^+ ions. Nevertheless the activity of the catalyst should evidently depend on the concentration of the modifying element.[80,117,118,159] A larger amount of the metal can be introduced by the impregnation method into pentasil than by ion exchange. Comparison of the H-TsVK pentasil specimens (Si/Al = 30), containing 0.5, 1.4, and 10 wt.% ZnO showed that the quantities $x_{C_2H_6}$ and $A_{C_2H_6}$ in their presence are greater the higher the zinc content, while in the propane and isobutane conversion reactions the specimens with 1.4 and 10 wt.% ZnO have similar activities.[102]

As in the case of the H-forms, the composition of the skeleton influences the catalytic activity of the Zn-containing pentasils.[103,108–111] On pentasils with Si/Al = 20, 49, 100, and 140, containing 1.5 wt.% Zn, the quantities $A_{C_3H_8}$ and $A_{C_4H_{10}}$ increase appreciably with increase in [Al].[109,110] At the same time, the composition of the skeleton does not affect S_{arom} for catalysts modified with zinc. It follows from Fig. 5 that all the points corresponding to the zinc-containing catalysts with different aluminium contents in the lattice lie on a single straight line starting from the origin of coordinates. The slope of this line corresponds to $S_{arom} \simeq$ 42%, which is greater by 1.5 than on similar unmodified pentasils.

The independence of S_{arom} of x indicates the simultaneous conversion of lower alkanes into aromatisation and cracking products. The increase in S_{arom} as a result of the modification with zinc is caused by the increase in the rate of aromatisation. This relation is evidently independent of the composition of the skeleton of Zn-pentasils and is determined solely by the content of the promoting element in the catalyst.

The composition of the skeleton of Zn-pentasils affects not only the overall catalytic activity but also the ratios of the individual aromatisation products. This is manifested particularly clearly when one examines the isobutane conversion products on pentasils with Si/Al = 20 and 140.[109] The ratios of the concentrations of C_8-C_{10} alkylbenzenes change most significantly. The relative yield of xylenes and ethylbenzenes increases with decrease in [Al]. An important feature of the conversion of lower alkanes on pentasils is the formation of condensed aromatic hydrocarbons, principally naphthalene and its alkyl derivatives. An increase in [Al] in the skeletons of Zn-pentasils favours the formation of naphthalene: the yield of these products at 600 °C is approximately 7 times greater on the specimen with Si/Al = 20 than on the catalyst with Si/Al = 140.

It is known[62,63] that the concentration of the acid centres of pentasils is proportional to [Al] and that their strength is independent of the ratio Si/Al. Consequently the catalytic activity of pentasils of different composition in aromatisation is determined by the number of acid centres, which is consistent with experimental data (see Figs. 4 and 5).

In order to elucidate the role of the acidity of the zeolite carrier in the aromatisation of propane, the catalytic properties of Zn/H-ZSM-5 and Zn/borosilicate specimens were compared.[103] It is known[160–162] that the acidity of borosilicates is significantly lower than that of H-ZSM-5 pentasils. At 550 °C and $P_{C_3H_8}$ = 101 kPa, neither the H-form of the borosilicate nor the borosilicate modified with zinc showed an appreciable activity ($x_{C_3H_8} \simeq$ 1.2–2.0%). The authors explained the inactivity of the H-form by the fact that the weak acid centres of the borosilicate are incapable of activating the propane molecules. However, Zn/borosilicate also proved to be inactive. The aromatisation of propane apparently requires the presence of not only zinc but also of a certain number of acid centres, such as, for example, those in the H-TsVK pentasil with Si/Al = 140.[108–110]

The introduction of another Group II element, namely cadmium, leads to an appreciable rise in activity and S_{arom}. The available information about the promoting effect of cadmium is contained principally in the patent literature.[163–165] A number of studies have been devoted to the systematic investigation of the role of cadmium in the aromatisation of lower paraffins on pentasils.[113,166,167] An almost twofold increase in $A_{C_4H_{10}}$ and S_{arom} has been observed after the introduction of even extremely small (~0.7 wt.%) amounts of cadmium. The degree of conversion of the initial paraffins did not increase after the introduction of cadmium. It is quite likely that the increase in S_{arom} as a result of the modification is associated with the decrease in the cracking activity due to the blocking of the strong protic centres of pentasil by cadmium.

Yet another extremely effective promoting agent for the catalysts of the aromatisation of lower paraffins is gallium.[80,103–105,112,143,144,168–171] According to patent data,[143,144,168] the selectivity of the aromatisation of ethane on Ga/H-ZSM-5 is $S_{arom} \sim 30\%$. An appreciably higher value of S_{arom} (60%) has been observed on the 2% Ga/H-TsVM catalyst at 600 °C and for $\tau \sim 30$ s.[171]

Gallium-containing pentasils, prepared by the ion exchange method, acquire an increased capacity for aromatising lower alkanes after heat treatment in the range 400–700 °C.[80] The influence of the method of preparation of Ga-pentasils on their activity in the aromatisation of C_2-C_4 alkanes has been investigated.[171] Catalysts based on the H-TsVM pentasil (Si/Al = 15) have been prepared in three different ways: by combining the ion exchange of the NH_4^+ cations for Ga^{3+} with subsequent impregnation of the zeolite with the mother liquor (method A); by impregnating the H-form of the zeolite with a solution of gallium nitrate (method B); by the dry mixing of pentasil and gallium oxide powders with subsequent heat treatment in a stream of air at 550 °C by a procedure similar to that of Kucherov and Slinkin[172,173] (method C). Specimen A proved to be the most active, with specimen C showing an appreciably lower activity. A 1:1 mechanical mixture of H-ZSM-5 and Ga_2O_3 has an appreciably higher activity in the aromatisation of propane than pure H-ZSM-5.[174,175]

The catalytic properties of pentasils containing different amounts of gallium in the reactions of C_2-C_5 paraffins have been studied in detail.[103–105,112,170,171,176,177] The introduction of even 0.5 wt.% of gallium appreciably accelerates the aromatisation of ethane and propane and increases A by a factor of 1.3–1.5 compared with the H-form.[171] A gallium concentration of approximately 2 wt.% appears optimal. In the presence of the 2% Ga/H-TsVM catalyst, the quantity A ranges from 30% for ethane to 55–60% for propane and isobutane. In another study,[176] the 6% Ga/H-ZSM-5 catalyst proved to be most active in the conversion of propane. According to Kitagawa et al.,[104] S_{arom} for propane increases sharply after the introduction of ~1 wt.% of gallium and reaches the maximum value (70%) on the 1.6% Ga/H-ZSM-5 (Si/Al = 31) specimen at 500 °C. An even higher selectivity in the aromatisation of propane (up to 85%) on Ga-pentasils was achieved by Tan et al.,[105] S_{arom} being somewhat higher on the Ga/Na-ZSM-5 specimen than on Ga/H-ZSM-5. However, these results do not agree with the data of other investigators[80,103,104,112,170] and are apparently too high.

Ga-pentasils also exhibit a much higher efficiency in the aromatisation of pentane than the decationated specimens.[112] Whereas the maximum value S_{arom} = 38% on H-ZSM-5 (Si/Al = 26) at 600 °C, on the Ga-pentasil with the same composition of the skeleton more than 50% of pentane is converted into aromatisation products. For low degrees of conversion of pentane ($x < 20\%$), the yields of the reaction products on Ga- and H-pentasils are approximately the same. The formation of aromatic hydrocarbons becomes appreciable only for $x_{C_5H_{12}} > 20\%$ and on Ga/H-ZSM-5 the quantities $A_{C_5H_{12}}$ and S_{arom} are significantly higher than on the unmodified catalyst and cracking takes place to an appreciably smaller extent.

The activity of gallium-modified pentasils depends significantly on the composition of the carrier skeleton.[170,177] Active and selective catalysts are obtained only when pentasils with a comparatively high aluminium content (Si/Al = 20) are used. In this case, the values of S_{arom} for isobutane and propane are respectively 60 and 50%. When a carrier with a low aluminium content (Si/Al = 140) is used, S_{arom} diminishes by a factor of approximately 1.5. Similar changes in A and S_{arom} as a function of the Si/Al ratio have been observed also in the aromatisation of pentane.[112] This relation is characteristic only of Ga-pentasils. As mentioned above, on Zn-pentasils with different compositions of the skeleton the aromatisation of propane occurred with identical selectivities.[109,110] The formation of highly active aromatising centres in Ga-pentasils probably requires a combination of a large number of strong B-centres of the carrier and gallium atoms.

The capacity for the activation and aromatisation of lower paraffins is possessed also by certain elementosilicates with the pentasil structure.[18,19,34,153–155,178–187] The modifying element is introduced into such systems in the stage involving hydrothermal synthesis.[37,38] There is then a possibility of obtaining crystalline silicates with a pentasil structure containing skeletal atoms of other elements instead of aluminium. We may note that proof of the isomorphous substitution of silicon atoms in the lattice is frequently either lacking or is inadequate. Gallosilicate, where the presence of Ga atoms in the skeleton has been reliably established by different physical methods, is an exception.[188] These questions have been discussed in detail in a number of communications.[18,19,38] Among the elementosilicates containing Mn, V, Co, Cr, Ti, Ni, Ga, and Zn[179] which have been investigated, the greatest selectivity in relation to aromatisation is shown by zinc-silicates and gallium-silicates.[34,180,181,185–187] On Zn-silicates, where Si/Zn = 140 at 600 °C, V = 2000 h^{-1}, and $N_2/C_3H_8 = 4$, we have $x_{C_3H_8} = 62-64\%$ with $S_{arom} = 43-44\%$.[179,186,187] In contrast to this, the activity and selectivity of Ga-silicates depends to a large extent on the composition of the skeleton. With decrease in Si/Ga from 40 to 15, the quantity $x_{C_3H_8}$ rises from 26 to 84% and S_{arom} increases from 38 to 67%.[34,156,179,186] On the H-ZSM-5 pentasil (Si/Al = 24), S_{arom} did not exceed 30% under similar conditions.[103] Comparison of the results obtained on Ga-silicates and Ga/H-ZSM-5 shows that the isomorphous substitution of silicon by gallium leads to an appreciably greater increase in S_{arom} than treatment with gallium aluminosilicate salts having the pentasil structure.

An important feature of Ga-silicates is the dependence of the activity and selectivity of the conditions on the duration of the reaction and the preliminary activation. With increase in the number of "reaction–regeneration" cycles, both A and S_{arom} in the propane aromatisation reaction on the Ga-silicate increased.[182] According to IR spectroscopic data, such a change in catalytic properties is associated with the emergence of gallium atoms from the skeleton.[182] The increase in the activity of Ga-silicate in the cracking of n-butane after the hydrothermal treatment of the catalyst has been explained by the appearance of extra-skeletal gallium in the form of amorphous Ga_2O_3.[183]

The data presented above referred to Zn- and Ga-silicates synthesised under hydrothermal conditions from reaction mixture in which the aluminium-containing component had been replaced by zinc or gallium salts in the gel-formation stage.[180,181,185,189] Another method of synthesis of gallosilicates has been proposed.[178] It consists in the isomorphous substitution of Si^{4+} ions in the silicalite II lattice (its structure is identical with that of the ZnSM-11 pentasil) by Ga^{3+} cations by treating the silicalite with an aqueous sodium gallate solution at 100 °C. According to X-ray diffraction and NMR spectroscopic data, the material thus obtained is a pentasil containing Ga^{3+} cations in its skeleton. The introduction of gallium into the silicate lattice leads to the manifestation by the latter of an appreciable catalytic activity in the n-butane aromatisation reaction (at 550 °C, $A_{C_4H_{10}}$ = 29%). We may note, however, that the conclusion that silicon ions are substituted by gallium ions[178] was not confirmed in a later investigation.[190]

The use of bimetallic catalysts with the pentasil structure—Pt/Zn-silicates and Pt/Ga-silicates—for the aromatisation of lower paraffins is of great interest.[34,179,180,185] The characteristic features of the catalytic action are determined by the combination of the striking dehydrogenating properties of platinum with the unusual molecular sieve and acid properties of elementosilicates, which are capable of converting C_3-C_5 paraffins and alkenes into aromatic hydrocarbons with a high selectivity. Fig. 7 illustrates the temperature dependence of the degree of conversion of ethane, propane, n-butane, and n-pentane on a Pt/Ga-silicate.[19] Other conditions being equal, the degree of conversion is higher the higher the molecular weight of the paraffin. The quantities S_{arom} are 41.5% for C_2H_6, 57.6% for C_3H_8, 31.9% for n-C_4H_{10}, and 35.8% for n-C_5H_{12}. These results were obtained at 500 °C and $V = 2000\ h^{-1}$ and for a paraffin:carrier gas (nitrogen) concentration ratio of 1:4. In the propane conversion reaction, Pt/Ga-silicates are more active than the initial carriers with Si/Ga = 15–40; the quantities S_{arom} for these systems are similar and are much higher than for the Pt/H-ZSM-5 catalysts.

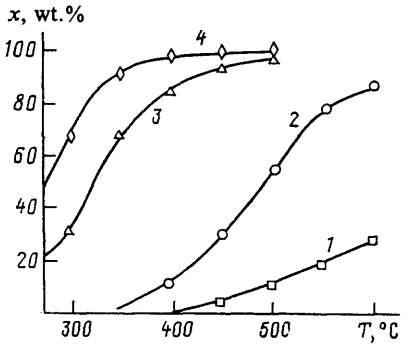

Figure 7. Temperature dependence of the degree of conversion of C_2-C_5 paraffins on the Pt/Ga-silicate catalyst (Si/Ga = 21):[19] *1*, C_2H_6; *2*, C_3H_8; *3*, C_4H_{10}; *4*, C_5H_{12}.

The introduction of platinum into Ga- and Zn-silicates retards the deactivation of the catalysts.[34,178,180] Whereas $x_{C_3H_8}$ fell from 80 to 40% in 10 h on the initial decationated specimens, on platinum-containing catalysts it remained above 50% even after 24 h. Such increase in stability has been attributed[179,180] to the hydrogen spill-over effect.[191–193] The hydrogen activated on platinum can interact with condensed aromatic structures and can "clean" the surface by removing adsorbed condensation products. This hypothesis has been confirmed by the results of a number of studies[133,194,195] in which the role of the hydrogen spill-over in adsorption processes on platinum-, palladium-, and nickel-containing pentasils was investigated. For example, activated hydrogen ("spill-over hydrogen") is capable of displacing chemisorbed CO and CH_4 molecules from the platinum surface.[133,194]

Bifunctional Pt/elementosilicate catalysts are extremely promising for practical use, because they retain their activity in the aromatisation of lower alkanes much longer than other modified pentasils. According to a number of workers,[34,179,196] the activity of the Pt/Ga-silicate catalyst, estimated from $x_{C_3H_8}$, remained unchanged for 1000 h in the "reaction (25 h)–regeneration (0.5 h)" regime at 550 °C and $V = 2000\ h^{-1}$ and for the ratio $C_3H_8:N_2 = 1:4$.

4. The mechanism of the aromatisation of lower paraffins on pentasils

As shown above, the H-forms of pentasils exhibit an appreciable activity in the reactions of C_2-C_5 paraffins. The ability of these catalysts to activate saturated molecules is due to the presence of strong B-centres on which the degradation and conversion of alkenes takes place. Analysis of the dependence of the proportions of the lower paraffin conversion products on the degree of conversion makes it possible to discuss the possible routes to the formation of aromatic and aliphatic hydrocarbons with participation of acid protic centres of pentasils. Fig. 8 presents the dependence of the yields of certain pentane,[112] isobutane,[177] and propane[104] conversion products on x. The character of these curves shows that aromatic hydrocarbons are not the primary reaction products. For low degrees of conversion ($x \leqslant 20\%$), pentane and isobutane are converted into propane with a selectivity in excess of 60%.[113,167]

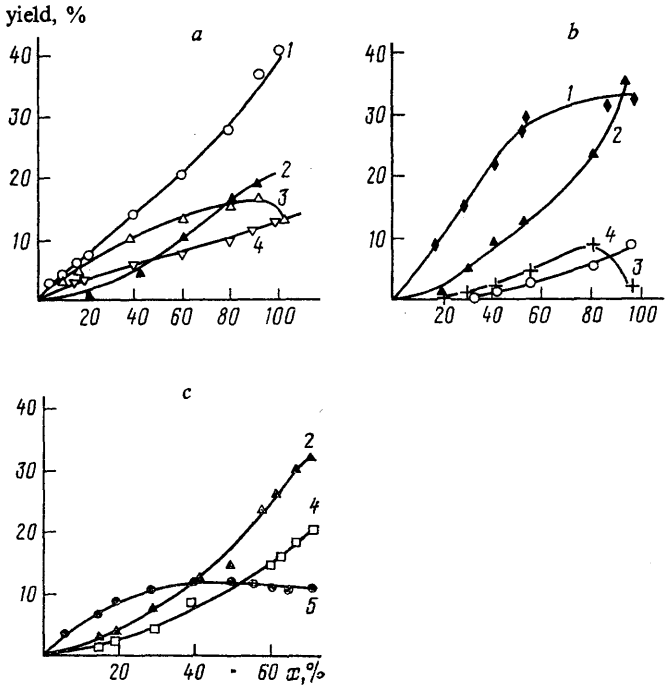

Figure 8. Dependence of the yield of the pentane (*a*), isobutane (*b*), and propane (*c*) conversion products in the presence of H-pentasils on the degree of conversion:[104,112,177] *1*, yield of propane; *2*, overall yield of aromatic hydrocarbons: *3*, overall yield of propene and butenes; *4*, overall yield of ethane and ethylene; *5*, overall yield of ethylene and propene.

Small amounts of propene and butenes are formed simultaneously. The yield of C_3-C_4 alkenes passes through a maximum, which indicates the participation of unsaturated hydrocarbons in subsequent reactions. For $x \leqslant 20-30\%$, propane is converted

mainly into ethylene and methane. These hydrocarbons can be formed via a stage in which propane decomposes to methane and the $C_2H_5^+$ cation with participation of protons in accordance with the scheme

$$C_3H_8 + H^+ \rightarrow \left[\begin{matrix} H_3C \\ \diagdown \\ H \end{matrix} \cdots\cdots CH_2CH_3\right]^+ \rightarrow CH_4 + \overset{+}{C}H_2{-}CH_3.$$

The possibility of the occurrence of this reaction has been demonstrated for the conversion of propane in a strongly acid medium[197] and of C_4 alkanes in the presence of solid superacids.[198]

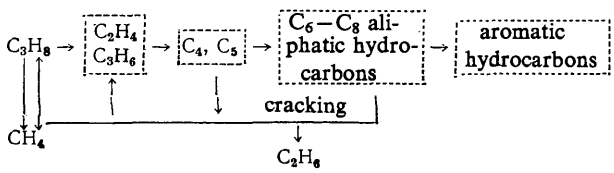
The question of the contribution of the cracking reaction to the overall conversion of lower alkanes on zeolite active centres is of fundamental importance for the understanding of the mechanism of the catalytic action of decationated pentasils. For low conversions, n-butanes and isobutanes undergo the following transformations:[199]

$$\text{n-}C_4H_{10} \swarrow \searrow \begin{matrix} C_2H_6 + C_2H_4 \\ CH_4 + C_3H_6, \end{matrix} \qquad \text{iso-}C_4H_{10} \rightarrow CH_4 + C_3H_6.$$

Two mechanisms of the cracking of lower alkenes are known: the carbenium ion and radical mechanisms. A scheme taking into account the participation of protic centres in the formation of carbenium ions was presented above. On Lewis acid centres, a hydride ion may be abstracted from the alkane molecule:

$$CH_3CH_2CH_2CH_3 \rightarrow CH_3CH_2\overset{+}{C}HCH_3 + H^- .$$

According to the results of two investigations,[199,200] the radical reactions of lower alkanes make a considerable contribution on solid amorphous superacids—HU and H-ZSM-5 zeolites. In this case, the initial stage in the cracking process involves the appearance of radical-cations, which are subsequently converted into alkenes. For example, the formation of isobutene from isobutane can proceed via a stage involving the formation and subsequent decomposition of a surface radical-cation with participation of electron-accepting (EA) centres:



$$\text{iso-}C_4H_{10} + EA \xrightarrow{k_1} [\text{iso-}C_4H_{10}^+][EA^-]$$

$$\begin{matrix} \text{iso-}C_4H_8 + H_2 + EA & C_3H_6 + CH_4 + EA \end{matrix} \quad (k_1 \mid k_2)$$

It is believed[104] that under the conditions of high conversion, propane molecules are activated as a result of the abstraction of a hydride ion by the carbenium ion R^+:

$$C_3H_8 + R^+ \rightarrow RH + \overset{+}{C}H_3CHCH_3.$$

The $C_3H_7^+$ ion formed is converted either into propene or into a carbonium ion with a larger number of carbon atoms. The overall mechanism of the propane conversion reaction on H-ZSM-5 assumes the following form:

Thus the capacity of the decationated forms of pentasils for the deactivation and subsequent dehydrocyclisation of lower paraffin molecules is determined by the presence of strong acid centres on which protonation, hydride ion abstraction, and cracking reactions take place and lead to the formation of unsaturated structures. The reactions of lower paraffins on the acid centres of pentasils apparently proceed with participation of both carbenium ions and radical-cations. The important role of the acidity of the H-forms of pentasils in the aromatisation of lower paraffins is indicated, in particular, by data[104] according to which the dependence of $x_{C_3H_8}$ on the activation temperature in the presence of NH_4-ZSM-5 passes through an extremum. The catalyst heated in a stream of dry air at 580 °C shows the maximum activity. The decrease in the degree of conversion on further increase in the activation temperature is induced directly by the decrease in the concentration of acid hydroxy-groups owing to dehydroxylation.

In contrast to the decationated forms, pentasils modified by Group (II), (III), and (VIII) metals are bifunctional catalysts to the activities of which both the protic acid centres of the carrier and the centres containing metal atoms contribute.

It follows from the data presented that pentasils containing platinum or other Group (VIII) metals are effective catalysts of the aromatisation of lower paraffins and that in terms of activity and selectivity they are superior to the M/Al_2O_3 catalysts. In the first studies on the aromatisation of C_3-C_5 paraffins in the presence of Pt/Al_2O_3, a possible mechanism of this reaction taking into account the bifunctional nature of the deposited metallic catalysts was already proposed.[86,87] We shall examine certain principal conclusions arising from these studies, because the characteristic features of the conversion of lower paraffins on metal-containing pentasils and Al_2O_3-based catalysts are undoubtedly similar.

A consecutive mechanism of the dehydrocyclodimerisation of alkanes includes three stages: (1) the dehydrogenation of alkanes to alkenes and alkadienes; (2) the dimerisation of the alkenes formed—mainly on acid centres and to some extent by a thermal pathway via conjugated dienes; (3) the aromatisation of unsaturated hydrocarbons on the metallic component and on the acid centres. The side reactions are the isomerisation and disproportionation of the aromatic alkyl-substituted products as well as the cracking of the aliphatic hydrocarbons and coke formation. The selectivity in the conversion of lower paraffins into various products must be determined by the relative rates of the individual stages. The set of reactions of n-butane is presented below:[86]

$$C_4H_{10} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} C_4H_8 \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} C_8H_{16} \xrightarrow{k_3} C_6H_4(CH_3)_2 .$$

$$\downarrow k_4 \qquad \downarrow k_5$$

$$H_4C + C_3C_3 \qquad + C_5$$

According to Csicsery's ideas,[86] on the optimum aromatisation catalyst the rate of dehydrogenation should be higher than the rate of dimerisation ($k_1 > k_2$). In addition, the condition $k_3 > k_2$ should hold and it is most important that the aromatisation should occur much faster than cracking ($k_5 \ll k_3 \geqslant k_2$).

We shall now compare data for the aromatisation of lower paraffins on Pt/Al_2O_3 with the results of kinetic studies[135] on Pt/H-ZSM-5. Analysis of the dependence of the proportions of the isobutane conversion products on the contact time in the presence of 0.8% Pt/Al_2O_3 [76,87] and of the dependence of the yield of propane conversion products on the degree of conversion in the presence of 0.5% Pt/H-ZSM-5 (Fig. 9) shows that in both cases the

aromatisation consists of a set of consecutive and parallel reactions, where the key reaction is the dehydrogenation of the initial paraffin. The presence of an extremum in the variation of the content of the corresponding alkenes (butenes and propene) shows that they are the primary products of the conversion of the alkanes. Both catalysts are extremely active in cracking: the content of C_1-C_2 hydrocarbons exceeds the content of aromatic products, especially on Pt/Al_2O_3. On Pt/H-ZSM-5, S_{arom} can reach very large values, although a considerable proportion of the initial propane is also converted into methane and ethane. The nature of the carrier plays an important role in the aromatisation of saturated hydrocarbons. Whereas alumina is inactive in the reactions of lower paraffins and its activity is low in the aromatisation of alkenes,[201–203] the decationated pentasils readily convert propane and isobutane into aromatic hydrocarbons (see above). Thus both the metallic component and the carrier contribute to the activity of the Pt/H-ZSM-5 catalyst. Another cause of the increased aromatising capacity of Pt/H-ZSM-5 compared with Pt/Al_2O_3 is resistance to coke formation. Whereas Pt/Al_2O_3 is deactivated 15–20 min after the start of the experiment,[76,87] the stable operation of Pt/H-ZSM-5 continues for about 6 h.[134,135]

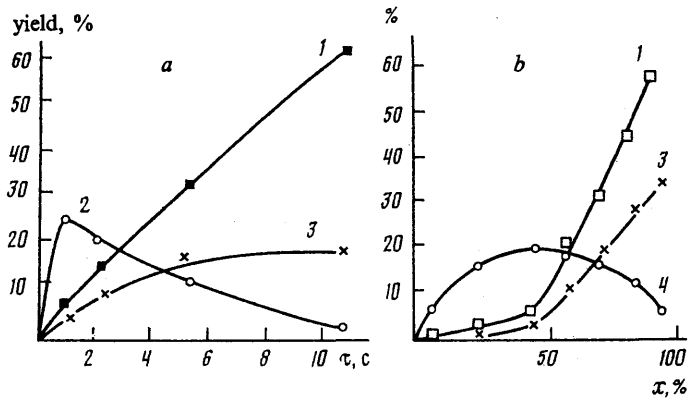


Figure 9. The proportions of the isobutane conversion products on Pt/Al_2O_3 (*a*) at 550 °C and of propane conversion products on Pt/H-ZSM-5 (*b*) at 530 °C:[76,135] *1*, overall yield of methane and C_2 hydrocarbons; *2*, yield of butenes; *3*, overall yield of aromatic hydrocarbons; *4*, yield of propene.

Judging from the data of Gnep et al.,[135] the rate of hydrogenolysis of the initial propane on Pt/H-ZSM-5 is clearly lower than the rate of hydrogenation of ethylene—one of the primary propane conversion products on H-ZSM-5. Thus platinum participates not only in the dissociation of C–C bonds but also in the formation of new C–H bonds as a result of hydrogenation and hydrogenolysis reactions. These two reactions always accompany the aromatisation of lower paraffins on platinum-containing pentasils and are the main cause of the decrease in S_{arom}.

The promoting effect of zinc, cadmium, and gallium as well as the cooperative effect of deposited Group VIII metals are due to the dehydrogenating properties of the M–pentasil systems. Kinetic data, which have been analysed in a number of studies,[104,167,176,177] lead to this conclusion.

Fig. 10 presents curves for the accumulation and consumption of the individual propane, isobutane, and n-pentane conversion products on Zn- and Ga-pentasils. An extremum in the dependence of the yield of C_3-C_5 alkenes on x or τ is characteristic of these catalysts as well as Group VIII metal–pentasil systems, which can be regarded as evidence for the intermediate formation of unsaturated structures from lower paraffins and their subsequent conversion into aromatic hydrocarbons. The principal unsaturated propane conversion product is propene. Apart from butenes, propene is formed from isobutane; olefinic pentane conversion products contain ethylene, propene, butenes, and pentenes.

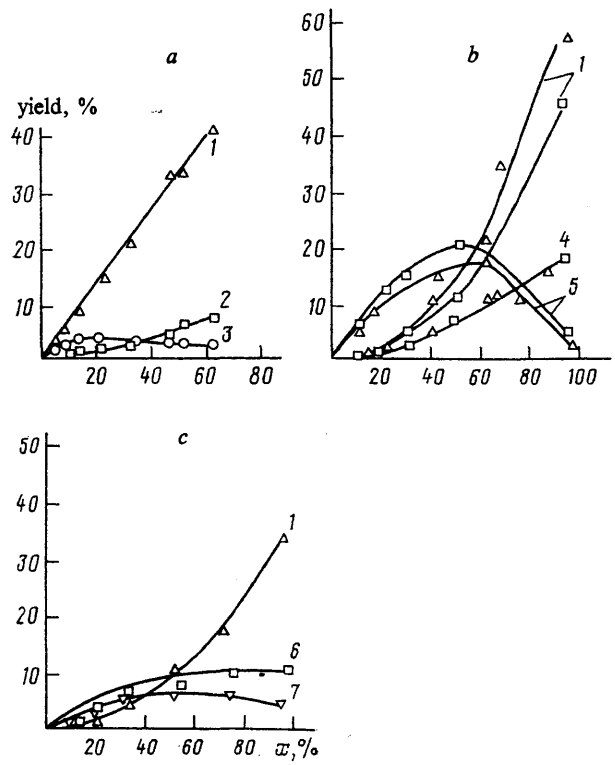

Figure 10. The proportions of the propane conversion products on Ga/ZSM-5 (*a*), the isobutane conversion products on Zn/ZSM-5 (squares) and Ga/ZSM-5 (triangles) (*b*), and the pentane conversion products on Ga/ZSM-5 (*c*) at 500 °C:[112,177] *1*, overall yield of aromatic hydrocarbons; *2*, overall yield of ethane and ethylene; *3*, overall yield of ethylene and propene; *4*, yield of propane; *5*, overall yield of propene and butenes; *6*, overall yield of butanes and butenes; *7*, yield of propene.

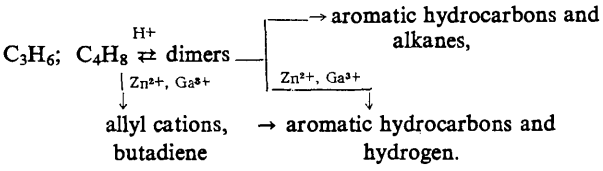
According to Bondarenko et al.,[177] under the conditions of low conversion the principal pathway in the reaction of isobutane on Zn- and Ga-pentasils is dehydrogenation, while on the H-form it is cracking. Appreciable amounts of aromatic hydrocarbons are formed only for comparatively high values of $x_{C_4H_{10}}$. Thus $A_{C_4H_{10}} \simeq 10\%$ is obtained for $x \simeq 50\%$ on Ga-pentasil, for 60% on Zn-pentasil, and for 85% on H-pentasil. The results of the calculation of the rate of accumulation of aromatic hydrocarbons for

x = const. $\simeq$ 50% showed that the aromatisation of isobutane on Zn- and Ga-pentasils takes place 9 and 12.5 times faster respectively than on the H-form.[177] The activity of Cd-pentasil differs little from the activity of Ga-containing specimens.[166,167]

Thus the aromatisation of lower paraffins on pentasils modified with zinc, cadmium, and gallium includes an alkene formation stage, as happens in the presence of bifunctional platinum-containing catalysts based on pentasil or Al_2O_3. The abstraction of a hydride ion from the alkane molecule with participation of Zn^{2+} cations on the surface (s) may proceed in accordance with the following scheme:[101,108]

$$C_3H_8 + Zn^{2+}_{(s)} \rightarrow \text{iso-}C_3H^+_{7(s)} + [Zn-H]^+_{(s)}.$$



In this case, the zinc cation plays the role of a hydride ion acceptor. According to the result of Kokes and Dent,[204] zinc oxide is capable of effecting the heterolytic dissociation of the C–H bond with formation of intermediate $[Zn-H]^+$ structures. It is generally believed[101,103,105,108–110] that the composition of the paraffin dehydrogenation centres includes promoting elements and that subsequent reactions of the unsaturated compounds formed occur as a result of the interaction of these compounds with protic acid centres of the pentasils. The mechanism of the alkene conversion reactions on pentasils has been discussed in detail in a number of publications.[3,33,119,203,205]

Apart from the first stage (the dehydrogenation of saturated hydrocarbons), zinc and gallium introduced into pentasils participate also in the stage involving the abstraction of a hydride ion from alkene molecules with formation of intermediate allylic compounds.

This conclusion was reached from the analysis of kinetic data for the conversion of but-1-ene into aromatic hydrocarbons on Zn/H-ZSM-5.[206] The introduction of zinc into pentasil led to a sharp increase in S_{arom}. A similar effect has been observed on comparing the activities of H-, Zn-, and Ga-pentasils in the aromatisation of isobutene[170,177] as well as propene.[103] The dependence of the proportions of the but-1-ene conversion products on τ shows that, for low values of x, lower alkenes (ethylene and propene) as well as aliphatic hydrocarbons with a higher molecular weight predominate.[206] These data confirm that the formation of aromatic products is preceded by the oligomerisation of the initial alkene accompanied by the partial cracking of the oligomers. We may note that similar conclusions were reached previously[119,203,207] from the analysis of kinetic data for the conversion of isobutene and propene on type H-TsVK and H-TsVM pentasils. An appreciable amount of butadiene was observed in the but-1-ene conversion products on the Zn-borosilicate catalyst[206] (the selectivity in the formation of butadiene reached 77% for x = 10%), which indicates the dehydrogenation of the initial alkene. The participation of zinc cations in this reaction is confirmed by the finding that the molar ratio of the concentrations of alkanes and aromatic hydrocarbons in the but-1-ene conversion products on Zn-pentasils is 0.9, whereas on H-ZSM-5 it is 2.9. In the presence of Zn-pentasils, the first stage in the activation of but-1-ene may be one involving the formation of allylic (butenyl) structures. The dimerisation of these structures and the subsequent abstraction of hydrogen atoms led to the formation of aromatic hydrocarbons. The capacity of zinc oxides for the formation of allylic structures has been confirmed by spectroscopic methods.[204,208]

On the basis of experimental data, a scheme for the conversion of lower alkenes on pentasils modified with zinc or gallium has been put forward:[206]

Lower alkenes dimerise via the carbenium ion mechanism on the B-centres of decationated pentasils.[3,205,209–211] The dimers can subsequently isomerise and be cleaved to reform the lower alkenes or can be converted into carbenium ions. On subsequent deprotonation and redistribution of hydrogen, aromatic hydrocarbons and alkanes are produced. The formation of one molecule of the aromatic hydrocarbon is accompanied by the formation of three alkane molecules[205] and the yield of alkene aromatisation products is limited by these proportions.

As stated above, in the presence of Zn-pentasils a hydride ion can be abstracted from the molecules of the initial alkenes or converted into allylic intermediates. Aromatic hydrocarbons can be formed in their turn both as a result of the subsequent abstraction of hydride ions from the molecules of alkenes with higher molecular weights (in which the number of carbon atoms is not less than six) and via the direct interaction of two allylic structures with the simultaneous elimination of a hydrogen molecule. This pathway to the formation of aromatic structures does not require the obligatory simultaneous formation of alkanes and therefore in this case the yield of aromatic hydrocarbons is not limited by the stoichiometric relation. This explains the higher yield of the products of the aromatisation of lower alkenes on Zn-pentasils. A similar sequence of transformations of C_2-C_5 alkanes and alkenes is apparently characteristic also of Cd- and Ga-pentasils.

5. The nature of the active centres of the modified pentasils

The results examined in the previous Section show that the modified pentasils possess dehydrogenating properties. In the case of Pt/H-ZSM-5 and other deposited Group VIII metals, the abstraction of hydrogen from saturated molecules takes place with participation of metal clusters dispersed in the zeolite. The nature, structure, and location of the active centres of Zn-, Cd-, and Ga-pentasils are less clear.

As mentioned previously, the catalytic activity of pentasils is determined by the number of acid centres of different nature. Modification with zinc and cadmium alters significantly the acid properties of zeolites. The influence of these promoting agents on the concentration, strength, and nature of the acid centres active in the aromatisation of lower alkanes has been studied in detail.[108–111,166,167,177,212] For this purpose, the hydroxyl coating and the interaction of pyridine molecules with the L- and B-centres of H-, Cd-, and Zn-pentasils, differing in the ratio of the concentrations of aluminium and silicon in the lattice, were investigated by IR spectroscopy.

Three absorption bands with maxima at 3745, 3610, and 3330 cm^{-1} were recorded in the IR spectra of the H-forms of the pentasils in the region of the principal stretching vibrations of the hydroxy-groups.[48–50] They correspond respectively to non-acid silanol and

acid bridging hydroxyls in a free state (3610 cm^{-1}) and in the hydrogen-bonded state (3300 cm^{-1}).[48,50,52] The bands of the acid OH groups in pentasil with Si/Al = 20 are much more intense than in the specimen with Si/Al = 140.[170,177,212]

The introduction of zinc into pentasils leads to some decrease in the intensity of the 3610 and 3330 cm^{-1} bands as a result of the blocking of some of the aluminium–oxygen tetrahedra by zinc cations. Furthermore, an additional absorption band appears at 3520 cm^{-1}. It has been assigned to hydroxyls bound to the Zn^{2+} cations.[212]

Absorption bands referring to the generated pyridinium ions (1550 cm^{-1}, B-centres) and to coordinated pyridine (1448–1453 cm^{-1}, L-centres) have been observed in the range 1300–1600 cm^{-1} in the IR spectra of pyridine adsorbed on H-, Cd-, and Zn-pentasils of the TsVK and TsVM types.[108–111,113,166] By analogy with zeolites of other structural types (faujasites, mordenites, etc.), containing transition metal cations,[39] the band with a maximum at 1453 cm^{-1} in the spectra of all the specimens modified with zinc and cadmium was assigned to pyridine coordinated to the cations of the modifying element. The position of this band is determined by the nature of the cation and the hypsochromic shift (from 1448 to 1453 cm^{-1}) is induced by the increase in the electrostatic field strength and the strength of the aprotic centres.

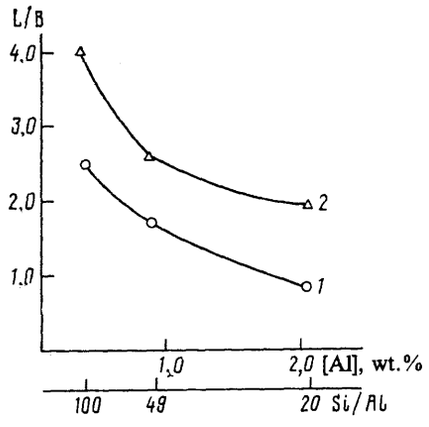


Figure 11. Variation of the L/B ratio with the Al concentration in the skeletons of H-pentasils (curve *1*) and Zn-pentasils (curve *2*).[110]

Fig. 11 illustrates the variation of the ratio of the intensities of these bands (L/B) as a function of [Al] in the lattices of the H- and Zn-forms of the pentasils. A common feature is characteristic of both series of catalysts—the increase in the L/B ratio with increase in Si/Al. This is due to the decrease in the number of B-centres, which is approximately proportional to the number of aluminium atoms in the unit cells of pentasils. As a result of the modification with zinc, the L/B ratio increased by a factor of ~1.5, which indicates the appearance of a large number of new L-centres. A similar picture was observed also for Cd-pentasils. The number of aprotic centres formed depends on the concentration of the promoting agent. Fig. 12 shows how the intensities of the absorption bands of the coordinated pyridine (L), the pyridinium ion (B), as well as the L/B ratio vary with the cadmium concentration. With increase in [Cd] to 2.5 wt.%, L and L/B increase monotonically, while B remains constant. This means that the ratio L/B increases only as a result of the appearance of new L-centres. Further increase in the cadmium content to 5 wt.% lowers the number of protic B-centres, which can be explained by the blocking of the bridging hydroxy-groups by cadmium.

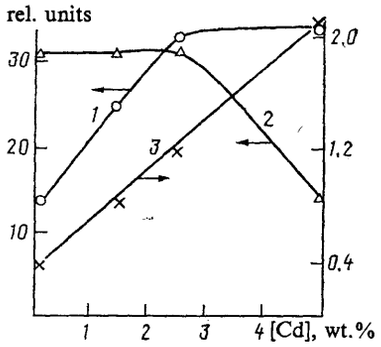

Figure 12. Dependence of L (curve *1*), B (curve *2*), and L/B (curve *3*) on the Cd concentration in type H-TsVM pentasil (Si/Al = 20).[166]

In order to estimate the strengths of the L- and B-centres, a study was made of the thermal desorption of pyridine from the surfaces of pentasils of different composition.[108,111,113] The "(I^t/I°)–desorption temperature" thermal desorption plots are illustrated in Fig. 13.

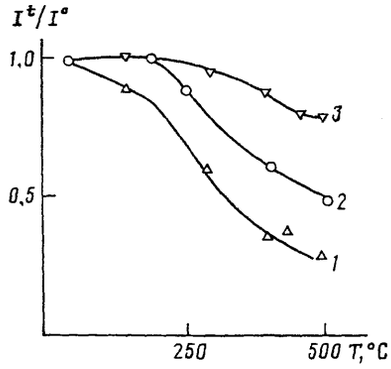

Figure 13. Variation of the relative intensities of the absorption bands of coordinated pyridine as a function of the desorption temperature:[113] *1*, H-TsVM; *2*, 1.5% Cd/H-TsVM; *3*, 1.5% Zn/H-TsVM.

Here I^t is the intensity of the 1448 (1453) cm^{-1} absorption band due to the coordinated pyridine after desorption at the corresponding temperature and I° is the maximum initial intensity of this band before desorption. In the case of unmodified zeolites, an

appreciable desorption of pyridine from the L-centres is observed even at $T < 300$ °C virtually without change in the intensity of the band corresponding to the pyridinium ion; on the other hand, even at 500 °C pyridine remains strongly bound to the B-centres. These data indicate the presence of strong B-centres on the surfaces of the decationated forms of pentasils, which agrees with the result obtained by adsorption microcalorimetry.[61–66] A different picture is observed in the case of pentasils modified with zinc and cadmium. The strength of the coordinate bonds between pyridine and the zinc and cadmium cations is much greater than the strength of the bond with the L-centres of the decationated specimens: more than half the molecules of the adsorbed base remain on the surface at 500 °C.

The properties of the aprotic acid centres of the Zn-pentasils have been investigated by diffuse scattering IR spectroscopy.[170,177,212] Hydrogen (adsorption temperature –196 °C) and carbon monoxide (adsorption temperature 25 °C) were used as probe molecules. The small size of the adsorbate molecules, the large shift of the stretching vibration frequency following polarisation on centres of different nature, the low desorption temperature, and at the same time the possibility of a quantitative determination of the concentration of the active centres impart certain advantages to this research technique.[48,50]

Absorption bands at 4105–4110 and 4125–4130 cm^{-1} have been observed in the IR spectra of hydrogen adsorbed on H- and Zn-pentasils (Fig. 14). They characterise the interaction of molecular hydrogen with bridging and silanol hydroxyls respectively.[46,48–50] Apart from these bands, additional lines appear in the spectra on Zn-pentasils at 3955, 4015, and 4075 cm^{-1}. They refer to complexes of hydrogen with aprotic acid centres of different types. The principal components of such centres are the $Zn^{2+}-O^{2-}$ acid–base pairs.[170,177,212] Since a single line is manifested at 4019 cm^{-1} in the IR spectra following the adsorption of hydrogen on massive zinc oxide,[213] presumably the properties of the ZnO deposited on the surfaces of pentasils differ from those of the massive oxide.

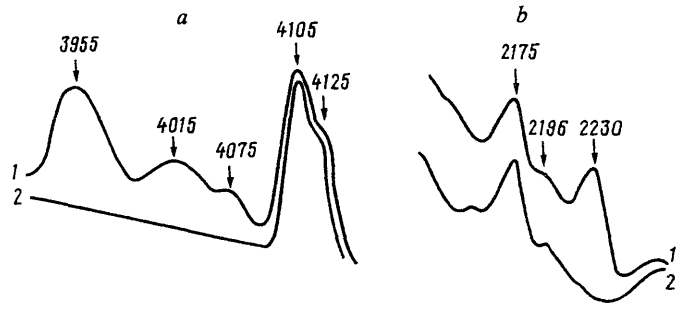

Figure 14. IR spectra of H_2 (*a*) and CO (*b*) adsorbed on Zn-pentasil (curves *1*) and the unmodified H-TsVM (curves *2*).[170,177]

The band at 3955 cm^{-1} undergoes the greatest shift ($\Delta\nu_{H-H}$ = 210 cm^{-1}) relative to the vibration frequency of gaseous hydrogen.[48] It has been shown[212] that at room temperature hydrogen is dissociatively adsorbed on these centres. Furthermore, the $Zn^{2+}-O^{2-}$ acid–base pairs are capable of strongly polarising the C–H bonds in the molecules of lower alkanes. Additional bands at 2805 cm^{-1} (for CH_4) and 2745 cm^{-1} (for C_2H_6), which have undergone bathochromic shifts by 200 and 250 cm^{-1} respectively, have been observed in the IR spectra of methane and ethane adsorbed on Zn-pentasils.[212]

Aprotic acid centres containing zinc cations can be formed on different sections of the pentasil structure. For example, centres to which the absorption bands at 3955 and 4015 cm^{-1} have been attributed are located directly on the aluminium–oxygen tetrahedra, while the band at 4075 cm^{-1} characterises the formation of the ZnO phase which is not linked to the pentasil lattice.

Analysis of the spectra of adsorbed carbon monoxide[177] also leads to the conclusion that new L-centres are formed as a result of the modification of pentasil with zinc (Fig. 14*b*). Bands at 2175, 2195, and 2230 cm^{-1} have been observed in the IR spectra of the modified specimens. The first two bands, present also in the spectra obtained for the H-form, refer respectively to complexes with bridging hydroxy-groups and weak aprotic centres. The band at 2230 cm^{-1} appears only after the introduction of zinc and refers to complexes of CO with fairly strong electron-accepting centres.[42] The preliminary adsorption of molecular hydrogen at room temperature, leading to its dissociation, prevents the appearance of the band at 2230 cm^{-1}, which means that CO is adsorbed on the L-centres responsible for the polarisation of the H–H and C–H bonds in the adsorbed hydrogen molecules and lower paraffins respectively.

Analysis of the IR spectra of adsorbed CO and H_2 demonstrated a fundamental difference in the character of the interaction of these molecules with the acid centres of Zn- and Ga-pentasils.[177,214] Modification with gallium does not lead to the appearance of absorption bands corresponding to aprotic acid centres: the spectra of the H- and Ga-pentasils are identical. The use of other adsorbates (CH_4, CH_3CN) also did not permit the detection of L-centres bound to gallium. It has been suggested[177,214] that one of the causes of the absence of the interaction of these probe molecules with the aprotic centres of Ga-pentasils may be the preferential localisation of gallium on the outer surfaces of the crystallites. It is known[215] that it is very difficult to introduce triply charged cations into pentasils by ion exchange because their solvation shell has a large radius. Furthermore, there is a possibility of electrostatic difficulties associated with the compensation of the isolated negative charges in the lattice by multicharged cations. If gallium is distributed on the outer surface of pentasil, which constitutes approximately 2.5–3.0% of the total surface,[37,38,216] the concentration of centres incorporating Ga^{3+} ions should be low. It is not easy to detect and record such centres by IR spectroscopy owing to the inadequate sensitivity of the method. The paramagnetic probe method,[216–218] based on the analysis of the EPR spectra of various stable radicals adsorbed on the surfaces of catalysts, is much more sensitive. On formation of complexes between radicals and metal ions involved in coordination with low coordination numbers, whose nuclear spin is non-zero, a characteristic EPR spectrum with a hyperfine structure due to the corresponding nuclei is observed. It has been established[177,214,218] that a large (~1.1 nm) stable nitroxyl radical—2,2,6,6-tetramethylpiperidin-1-yloxyl (tanane)—forms donor–acceptor complexes with coordinatively unsaturated Ga^{3+} ions introduced into pentasils. The interaction of the unpaired electron of tanane with the nuclei of the ^{69}Ga and ^{71}Ga isotopes, which have a nuclear spin $I = 3/2$, is characteristic of these complexes. This leads to the appearance of a well resolved quartet with a constant B_{Ga} = 38 Oe for splitting by the gallium nuclei. The results obtained by the paramagnetic probe method show that the coordinatively unsaturated Ga^{3+} cations are localised preferentially on the outer surface of the crystallites,

forming ion pairs of the $Ga^{3+}-O^{2-}$ type. Evidently these cations possess electron-accepting properties like the zinc and cadmium cations located within channels of pentasils.

The aprotic acid centres arising as a result of the introduction of gallium have been detected by the paramagnetic probe method on the outer surface of gallosilicates after they have been heated at 500–600 °C and after the propane aromatisation reaction has been carried out.[182] In this case, the appearance of L-centres is caused by the migration of the extraskeletal gallium onto the outer surface under the influence of the reaction medium.

Electron-accepting centres incorporating gallium ions possess certain specific features which distinguish them from the centres formed by zinc or cadmium cations. Thus, after the successive treatment of a Ga/H-ZSM-5 specimen with hydrogen and oxygen at 450 °C, the ability of the catalyst to adsorb hydrogen increases sharply and the reduction of Ga^{3+} to Ga^{+} is facilitated.[105] According to Guo's data,[169] after Ga-pentasils have been heated in hydrogen at 550 °C, the Ga $2p_{3/2}$ binding energy diminishes by approximately 5 eV, which indicates the partial reduction of gallium. In contrast to this, an appreciable decrease in the Ga $2p_{3/2}$ binding energy was not observed after treatment of the Ga/H-TsVM catalyst with hydrogen, although the composition of the surface layer changed significantly.[171] Under the influence of hydrogen, the surface concentration of gallium diminishes sharply, which may be due to its migration into the bulk phase.

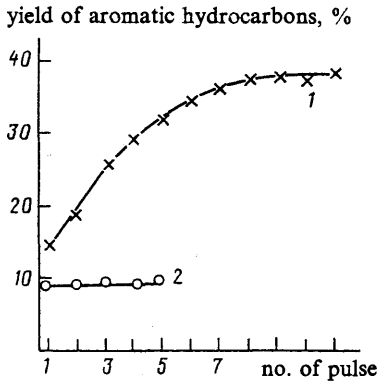

Figure 15. Dependence of the yield of aromatic hydrocarbons on the number of propane pulses:[171] *1*, 2% Ga/H-TsVM; *2*, H-TsVM.

The "running-in" of the Ga-pentasils in the course of the aromatisation of propane under pulse conditions constitutes indirect confirmation of the change in the oxidation state of gallium under the influence of reductants[169,171] (Fig. 15). It is believed[171] that one of the causes of this phenomenon may be the change in the electronic state of gallium resembling the situation arising with platinum and rhodium.[127,129,130] Furthermore, gallium can be redistributed in the zeolite matrix under the influence of the reaction medium. However, we may note that the mechanism of the formation of the active centres in the gallium-containing zeolites requires further study.

Thus one may conclude that, as a result of the introduction of zinc, cadmium or gallium into pentasils, strong L-centres are formed. By virtue of their electron-accepting properties, these are capable of activating the molecules of lower paraffins and of catalysing the dehydrogenation reaction—the key stage in the aromatisation of saturated hydrocarbons.

IV. Application of pentasil-based catalysts in technological processes for the preparation of valuable chemical products from hydrocarbon gases

The dynamics of the development of the manufacture and utilisation of low-molecular-weight hydrocarbons is such that at the beginning of the 1990's an excess of effluent gases from petrochemical industries should arise.[6,7,33] On the other hand, there is an acute problem as regards the rational employment of the components of natural and by-product gases. Such a situation has stimulated the development of new effective processes designed to utilise gaseous hydrocarbons.

Hitherto various foreign companies have suggested several catalytic processes for the conversion of gaseous hydrocarbon raw material in which pentasil-group zeolites are employed. Among them, the following three processes, which are at the introduction stage, may be regarded as the most promising.

(1) MOGD (Mobil Olefin to Gasoline and Distillate) designed to convert gaseous alkenes into high-octane petrol (gasoline) and middle distillates.

(2) "M2-forming" ensuring the formation of concentrates of aromatic hydrocarbons, predominantly the benzene–toluene–xylenes (BTX) fraction from low-boiling alkenes, paraffins, and naphthenes.

(3) "Cyclar"—designed to convert low-molecular-weight paraffins, namely propane and butanes, into aromatic products.

The MOGD process, developed by the Mobil Oil Company is designed to manufacture petrol from diesel fuel.[23,219–221] It is based on reactions involving the oligomerisation of C_2-C_4 alkenes on decationated pentasils of the ZSM-5 and ZSM-11 types.[23,29,30,220,222–224] Information has been published recently concerning the possibility of using borosilicates, ferrosilicates, gallosilicates, silicoaluminophosphates, and other materials with a zeolite structure as catalysts of alkene conversion processes.[19,20,162,225] Under identical process conditions (temperature, pressure, and contact time), the composition of the products formed depends little on the molecular weight of the starting material. Both pure alkenes (ranging from ethylene to hydrocarbons with a boiling point of 204 °C) and various mixtures (fractions) with a fairly high content of unsaturated hydrocarbons can be processed. The liquid catalytic mixture consists of C_5-C_{20} hydrocarbons. The petrol fraction with a high octane number (>85) includes C_5-C_{10} compounds, heavier hydrocarbons being converted after hydrogenation into diesel fuel with a high cetane number (~56).[219] One of the most important features of the MOGD process is the high exothermicity of the alkene oligomerisation reaction—1550 kJ kg^{-1}.[220] In order to remove the heat and maintain isothermal conditions in the reactor, extra-reactor cooling and recirculation of petrol are used. Recirculation results in an increase in the yield of middle distillates. By varying the recirculation conditions, it is possible to regulate the proportions of the petrol and diesel fractions from 100:0 to 10:90.[219,221] Tests of the catalysts on real C_3-C_4 raw

material containing 62% of unsaturated hydrocarbons showed that the reaction products consist of alkenes to the extent of 94%.[219]

Active and stable catalysts based on pentasils of the type H-TsVM and H-TsVK have been developed for the preparation of high-octane petrol from the flame gases in the manufacture of polyethylene (97% ethylene, 2.5% propane).[221,226] During pilot tests, the degree of conversion of ethylene remained at the level of 72–77% for 120 h and the yield of the petrol fraction was 49–57%.

The technological scheme for the MOGD process includes four reactors with a fluidised catalyst bed.[219] The flexibility of the technology, which ensures the possibility of obtaining either petrol or diesel fuel from gaseous alkenes, should be included among the significant advantages of the MOGD process. The process may find extensive applications in petroleum processing, petrochemistry, and the manufacture of synthetic fuels. In the last instance, MOGD can be used in combination with Fischer–Tropsch processes[24,27] or processes for the conversion of methanol into alkenes[26,27] in order to obtain high quality diesel fuel.

The "M2-forming" process is carried out on decationated zeolites of the H-ZSM-5 type at $T > 500$ °C and a pressure of 1–20 atm.[23,227] The ability of the hydrogen-forms of pentasils to convert aliphatic compounds into aromatic hydrocarbons is used in this process. The raw material is a broad fraction comprising C_2–C_8 alkenes and paraffins and containing up to 15% of naphthenes.[227] In contrast to the MOGD process, all the hydrocarbons, except ethane, enter into the aromatisation reactions under the conditions of the M2-forming process. The main bulk of the aromatic products consists of the BTX fraction. The yield of the aromatic pentane and hexane conversion products at 540–580 °C reaches 31–32%. The process includes cracking and hydrogen redistribution reactions, whose contribution increases with increase in temperature.

A common feature of the M2-forming and MOGD processes is a low sensitivity of the composition of the reaction products to the proportions of the components in the starting material.[23] On the other hand, the process temperature is determined by the composition of the starting material. If the initial mixtures are enriched olefins, diolefins, and naphthenes, then aromatic hydrocarbons are formed at comparatively low temperatures. Thus the aromatisation of the petrol fraction of the products of the thermal cracking of low-sulphur masout (12% of aromatic hydrocarbons, 41% of unsaturated hydrocarbons, 47% of paraffin-naphthene hydrocarbons), boiling in the range 35–180 °C, began already at 300 °C.[228] Under these conditions, the content of aromatic hydrocarbons in petrol increased compared with the initial content by a factor of approximately 2. We may note that the content of aromatic hydrocarbons in the M2-forming product can be extremely large, which makes it possible to isolate directly the BTX fraction without an additional extraction stage.[227] For example, petrol having the following composition was obtained at 425 °C:[228] aromatic hydrocarbons—78%, unsaturated hydrocarbons—2%, paraffins and naphthenes—20%. These data indicate a fairly high efficiency of the pentasil-based catalysts in the aromatisation reactions of low-quality petrols obtained as a result of thermodegradative processes.

Apart from low-octane petrols, paraffin-enriched petroleums as well as the effluent gases from petrochemical industries, in particular catalytic cracking gases, can be subjected to the M2-forming process. According to predictions,[227] the M2-forming process together with the MOGD process can become one of the main ways of obtaining high-octane components of motor fuel from olefin-containing gases.

As reported above, modified pentasils are highly effective catalysts of the aromatisation of low-molecular-weight hydrocarbons. Judging from patent data,[142–149] binary catalytic systems are frequently employed for this purpose. Thus, copper, rhenium, platinum, palladium, and gallium are added to stabilise the zinc introduced into pentasils.[144,229–235] A technology for the conversion of light paraffins into aromatic hydrocarbons and hydrogen has been developed by the British Petroleum and the UOP companies in 1984. This process was called "Cyclar".[31–33]

In the "Cyclar" process, active and selective catalysts based on modified pentasils are subjected to constant regeneration, which is ensured by their continuous circulation. As a result, the starting material always comes into contact with the regenerated catalyst and a high level of activity and selectivity is therefore maintained for a long time.

The developments used previously by the UOP Company for the platforming process[31] were used in the technological scheme of the "Cyclar" process. They included a design in which the reactors are placed one on top of the other, a radial flow of the starting material, the use of intermediate heaters, and continuous regeneration of the catalyst. The catalyst for the "Cyclar" process, created on the basis of modified pentasils, satisfies all the principal requirements for industrial catalysts. It is resistant to coke formation and to the action of sulphur, water, and other oxygen-containing compounds and its mechanical strength is high. Either individual propane and butane or propane–propene and butane–butene fractions as well as mixtures of C_2–C_6 hydrocarbons are used as the starting material. On the apparatus for the processing of butane, the yield of aromatic hydrocarbons reaches 67.5% (calculated relative to the starting material which has reacted), while the yield of hydrogen is 5.5%. the overall yield of propane aromatisation products is 63.6%, while the yield of hydrogen is 6%. The proportions of the aromatic propane and butane conversion products are approximately the same. The octane number of the fraction of aromatic hydrocarbons is approximately 112.

---o0o---

The results examined above indicate considerable advances in the creation on the basis of pentasil-type zeolites of effective catalysts for the aromatisation of lower paraffins as well as progress in the study of the mechanism of their catalytic action and in the development of technological processes for gaining valuable chemical products from hydrocarbon gases. The latest advances in the synthesis of zeolites and zeolite-like materials should constitute a basis for the creation of new more active and more selective catalytic systems.

α-Fluoroacrylates: synthesis, properties and use

L S Boguslavskaya, I Yu Panteleeva, T V Morozova, A V Kartashov, N N Chuvatkin
Scientific-Research Institute of Polymers, Dzerzhinsk

ABSTRACT. Studies on the synthesis and properties of a new class of monomers—α-fluoroacrylic acid derivatives—are reviewed. Promising areas for the application of synthetic polymeric materials based on α-fluoroacrylates are examined.

The bibliography includes 115 references.

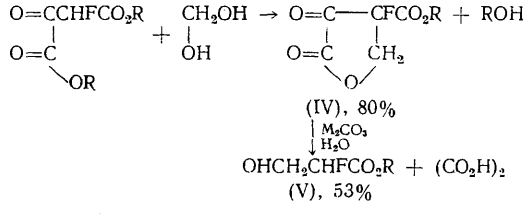
I. Introduction

Polymers based on acrylates are of fundamental importance in current engineering and technology. In this class of polymers a special position is occupied by poly(methyl methacrylate)—a transparent, impact-resistant, heat-resistant material used in optics. It was known even at the beginning of the 1950's that poly(methyl α-fluoroacrylate) is considerably superior to poly(methyl methacrylate) as regards its physicomechanical properties. However, at that time methods had not been developed for the synthesis of α-fluoroacrylates, which would have provided the opportunity for an extensive study of the properties of materials based on monomers of this class. Research into convenient methods for the synthesis of α-fluoroacrylic acid and its derivatives was systematically conducted in many developed countries of the world during recent decades but it was only in the 1980's that the results of comprehensive studies on poly(α-fluoroacrylates) were published, specifying potential areas of application of these fluoropolymers.

In the present article we review the published studies on α-fluoroacrylates and their polymers with the aim not only of demonstrating the existing progress in this field of chemistry but also of determining the direction of studies that could lead to the very rapid practical application of these excellent synthetic materials.

II. Methods of synthesis of α-fluoroacrylic acid and its derivatives

1. Methods based on condensation reactions of derivatives of fluoroacetic and fluoromalonic acids with carbonyl compounds



Until recently one of the most widely used methods for the synthesis of α-fluoroacrylates was a method based on a crossed Claisen condensation of alkyl monofluoroacetates with esters of formic and oxalic acid in the presence of strong bases.

The reaction is usually carried out in a solvent (tetrahydrofuran, ether, benzene, methylene chloride) and alkali metal hydrides and alkoxides are used as bases. It is assumed that at the first stage of this reaction nucleophilic addition of a carbanion from fluoroacetate (I) to ester (II) takes place, giving a formyl-, monofluoroacetyl- or oxalyl-acetate (III a–c).[1–5]

$$\underset{\text{(I)}}{CH_2FCO_2R} + \underset{\text{(II)}}{R'CO_2R} \xrightarrow{ROM} \underset{\text{(IIIa–c)}}{R'COCHFCO_2R}$$

R′ = H (a), CH_2F (b), CO_2R (c); R = alkyl (C_{1-7}); M = Li, Na, K.

The majority of the studies in which reproducible results on the synthesis of α-fluoroacrylates have been obtained are based on the use of oxalylfluoroacetates (III c),[6–9] which are condensed with paraformaldehyde to give a lactone (IV). In two studies[6,7] this lactone (IV), R = Et, was isolated and characterised.

Hydrolysis of lactone (IV) in the presence of weak bases (alkali metal carbonates or bicarbonates) gives 2-fluoro-3-hydroxyesters (V).[6–11]

In certain patents the conversion of esters (V) to α-fluoroacrylates (VI) is effected by dehydration.[12,13]

$$\underset{\text{(V)}}{OHCH_2CHFCO_2R} \xrightarrow[-H_2O]{} \underset{\text{(VI)}}{CH_2{=}CFCO_2R}.$$

2-Fluoro-3-hydroxyesters (V) can be converted to esters of 2-fluoro-3-halopropionic acids (VII) by treating them with thionyl chloride or phosphorus tribromide in the presence of pyridine.[14] When treated with bases (hydroxides of alkali and alkaline

earth metals, ammonia, primary, secondary, and tertiary amines), esters (VII) readily eliminate a hydrogen halide to form α-fluoroacrylates (VI).[15,16]

$$\underset{\text{(V)}}{OHCH_2CHFCO_2R} \xrightarrow[C_5H_5N]{SOCl_2(PBr_3)} \underset{\text{(VII)}}{HalCH_2CHFCO_2R} \xrightarrow{\text{base}} \underset{\text{(VI)}}{CH_2{=}CFCO_2R}.$$

Methods for converting esters (V) to the tosyloxy derivatives (VIII) by treating them with *p*-toluenesulphonyl chloride have been reported.[10,11]

$$HOCH_2CHFCO_2R + p\text{-}CH_3C_6H_4SO_2Cl \xrightarrow{C_5H_5N} \underset{\text{(VIII)}}{p\text{-}CH_3C_6H_4SO_2OCH_2CHFCO_2R} \xrightarrow[\text{99\%}]{K_2CO_3,\ \text{60\%}} \underset{\text{(VI)}}{CH_2{=}CFCO_2R}.$$

It is also possible to obtain α-fluoroacrylamide by using 2-fluoro-3-tosyloxy derivatives (VIII). In order to achieve this, ester (V) after treatment with ammonia gives 2-fluoro-3-hydroxypropionamide (IX), which is converted to the tosyloxy derivative (X). α-Fluoroacrylamide (XI) is obtained by treating tosylate (X) with sodium methoxide or potassium phthalimide.[10,11]

By dehydrating amide (X) with thionyl chloride in dimethylformamide or trifluoroacetic anhydride it is possible to obtain 2-fluoro-3-tosyloxypropionitrile (XII),[17,18] treatment of which with potassium phthalimide gives α-fluoroacrylonitrile (XIII).

$$\underset{\text{(V)}}{HOCH_2CHFCO_2R} \xrightarrow{NH_3} \underset{\text{(IX), 100\%}}{HOCH_2CHFCO_2NH_2} \xrightarrow[C_5H_5N]{p\text{-}CH_3C_6H_4SO_2Cl} \underset{\text{(X), 92\%}}{p\text{-}CH_3C_6H_4SO_2OCH_2CHFCONH_2} \xrightarrow{\text{base}} \underset{\text{(XI)}}{CH_2{=}CFCONH_2}$$

$$\underset{\text{(XII)}}{p\text{-}CH_3C_6H_4SO_2OCH_2CHFCN} \xrightarrow[\text{DMF}]{SOCl_2,\ \text{60\%}} \xrightarrow[\text{90\%}]{(CF_3CO)_2O} \underset{\text{(XIII), 70\%}}{CH_2{=}CFCN}$$

Nitrile (XIII) can be obtained directly by dehydration of α-fluoroacrylamide (XI) with phosphorus pentoxide, but the yield of nitrile using this method is considerably lower.[9,10]

The synthesis of aryl α-fluoroacrylates based on lactone (IV) is carried out via the isolation of a salt of α-fluoroacrylic acid (XIV).[20,21] This is because in lactone (IV) R can only be an alkyl group and not an aryl group, since alkali metal phenolates are not sufficiently strong bases to be able to initiate the Claisen reaction in the synthesis of lactone (IV). Salt (XIV) is converted to α-fluoroacrylyl chloride (XV) by treatment with benzoyl chloride[11] or with thionyl chloride.[20,21] Reaction of acid chloride (XV) with phenol using trimethylamine as an acceptor of HCl gives phenyl α-fluoroacrylate (VIb). The yield of crude product calculated on the basis of monofluoroacetate (I) is 60% of theoretical.

$$\underset{\text{(IV)}}{O{=}C{<}\begin{matrix}CFCO_2Et\\ CH_2\end{matrix}{>}O{=}C} + NaOH \xrightarrow[-(CO_2H)_2]{} \underset{\text{(XIV)}}{CH_2{=}CFCO_2Na} \xrightarrow[PhCOCl]{SOCl_2,\ 160^\circ C} \underset{\text{(XV)}}{CH_2{=}CFCOCl} \xrightarrow{PhOH,\ Et_3N} \underset{\text{(VIb)}}{CH_2{=}CFCO_2Ph},$$

The nucleophilic addition of dialkyl fluoromalonates to formaldehyde in the presence of bases (piperidine, alkali metal carbonates and bicarbonates) has recently begun to be used for the synthesis of α-fluoroacrylate esters.[19,22–27]

The primary products of this reaction are dialkyl α-fluoro-α-hydroxymethylmalonates (XVI). Esters (XVI) are hydrolysed and decarboxylated in an acidic medium at elevated temperatures. The resulting acid (XVII) is converted to its ammonium salt, and aryl and alkyl α-fluoroacrylates are then obtained by the usual methods (VI).

$$\begin{matrix}CO_2R\\ |\\ CHF\\ |\\ CO_2R\end{matrix} + CH_2O \xrightarrow{KHCO_3,\ H_2O} \underset{\text{(XVI)}}{\begin{matrix}CO_2R\\ |\\ FC{-}CH_2OH\\ |\\ CO_2R\end{matrix}} \xrightarrow[100^\circ C]{HCl} \underset{\text{(XVII)}}{[CH_2{=}CFCO_2H]} \xrightarrow{NH_3} CH_2{=}CFCO_2NH_4.$$

The yield of α-fluoromalonates (VI) does not exceed 50% calculated on the basis of fluoromalonates.

2. Methods based on the reactions of conjugated halofluorination of propene compounds

Since the discovery by Bowers of the method of conjugated halofluorination of unsaturated compounds with *N*-haloamides in anhydrous hydrogen fluoride,[28,29] certain research workers have investigated ways of introducing fluorine into the α-position relative to the carbonyl group.[30–33]

As expected, electrophilic halofluorination of methyl acrylate with *N*-haloamides (*N*-bromoacetamide, 1,3-dibromo-5,5-dimethylhydantoin, hexachloromelamine) in HF gives 3-fluoro-2-halopropionates in moderate yield, regardless of the type of solvent added or reaction temperature (in the range 0 to −78 °C):

$$CH_2{=}CHCO_2Me \xrightarrow[HF]{>N{-}Hal} \underset{\text{30—50\%}}{CH_2FCHHalCO_2Me}$$

2-fluoro-3-halopropionates are only formed in these reactions in small quantities.[33,34] The synthesis of the precursors of α-fluoroacrylates — 2-fluoro-3-halopropionates — is achieved by halofluorination of allyl alcohol, allyl acetate, allyl trichloroacetate.[33,35] The chlorofluorination of allyl alcohol with hexachloromelamine and anhydrous HF in methanol has been studied in the greatest detail.[35,36] Even under optimum conditions for this reaction the yield of 2-fluoro-3-chloropropanol (XVIII) does not exceed 50%. The reaction is accompanied by a large number of side reactions — the formation of isomeric fluorochloropropanol

(XIX), methoxychloro- and dichloro-propanols, and also the oxidation of allyl alcohol to acrolein:

$$CH_2{=}CHCH_2OH \xrightarrow[MeOH,CHCl_3,0°C]{NCl_3,HF} CH_2ClCHFCH_2OH + \underset{(XVIII),\ 45-47\%}{}$$

$$+ CH_2FCHClCH_2OH + CH_3OCH_2CHClCH_2OH +$$
$$(XIX),\ 5-6\% \qquad 9-10\%$$

$$+ CH_2ClCHCH_2OH + CH_2{=}CHCHOCH_3$$
$$\quad OCH_3 \qquad\qquad OH$$
$$5-6\% \qquad 18-25\%$$

Chlorofluoropropanol (XVIII) that is isolated is oxidised in high yield by nitric acid to give 2-fluoro-3-chloropropionic acid (XX), which after dehydrochlorination with a solution of NaOH in methanol and acidification gives α-fluoroacrylic acid (XVII):

$$CH_2ClCHFCH_2OH \xrightarrow[80-100°C]{HNO_3} \underset{(XX),\ 88\%}{CH_2ClCHFCO_2H} \xrightarrow[2)\ H_2SO_4]{1)\ NaOH}$$

$$\longrightarrow \underset{(XVII),\ 60\%}{CH_2{=}CFCO_2H}.$$

Attempts to improve the yield of 2-fluoro-3-chloropropanol (XVIII) by protecting the hydroxyl group of allyl alcohol from being oxidised to acrolein (chlorofluorination of allyl acetate, allyl trichloroacetate and allyl trifluoroacetate) did not produce the desired result,[36] since the yield of the isomeric chlorofluoropropanol (XIX) increased significantly. The presence of this alcohol in 2-fluoro-3-chloropropanol (XVIII) during the subsequent oxidation and dehydrohalogenation gives rise to an impurity that is difficult to separate—α-chloroacrylic acid.[35]

3. Methods based on the fluorination of propene and halopropane derivatives with halogen fluorides

The first attempts to use bromine trifluoride for the synthesis of α-fluoroacrylates were undertaken by Yakubovich et al.[37] Reaction of methyl acrylate with BrF_3 (molar ratio of acrylate to BrF_3 = 2:1) in freon-113 gave a mixture of dihalopropionates with a total yield of 63%:

$$CH_2{=}CHCO_2Me \xrightarrow[freon\text{-}113,0\ °C]{BrF_3} \underset{19\%}{CH_2FCHFCO_2Me} +$$
$$+ \underset{13\%}{CH_2BrCHFCO_2Me} + \underset{31\%}{CH_2FCHBrCO_2Me}.$$

Methyl α-fluoroacrylate was obtained in low yield from this mixture by dehydrohalogenation with triethylamine.

The preparative possibilities of using halogen fluorides for this purpose were investigated again subsequently.[38–42]

The chlorofluorination of methyl methacrylate and allylic esters with a stoichiometric quantity of chlorine monofluoride in inert solvents ($CHCl_3$, CCl_4, CCl_2FCClF_2) has been studied.[38] Under these conditions ClF readily adds to the C=C bonds of these unsaturated esters, although the yield of the α-fluoroacrylate precursors—esters (XXI) and (XXIIIa–c)—does not exceed 50% because of the lack of regiospecificity in addition:

$$CH_2{=}CHCO_2Me \xrightarrow[CHCl_3,\ 25°C]{ClF} \underset{(XXI),\ 28\%}{CH_2ClCHFCO_2Me} + \underset{(XXII),\ 61\%}{CH_2FCHClCO_2Me},$$

$$CH_2{=}CHCH_2OC(O)R \xrightarrow{ClF} CH_2ClCHFCH_2OC(O)R +$$
$$(XXIIIa–c)$$
$$R_a = H\ 30\%$$
$$R_b = CH_3\ 42\%$$
$$R_c = CCl_3\ 50\%$$
$$+ CH_2FCHClCH_2OC(O)R.$$
$$(XXIVa–c)$$
$$18\%$$
$$28\%$$
$$32\%$$

The use of HF as the medium for chlorofluorination in the case of allylic derivatives does not improve the yield of the required regioisomers (XXIIIa–c), while for methyl methacrylate the yield of isomer (XXI) is sharply reduced.[36]

The ability of halogen fluorides to replace a bromine atom on saturated carbon by a fluorine atom is utilised for the synthesis of α-fluoroacrylic acid derivatives.[39–43] In a number of cases this reaction is more selective than addition to a multiple bond. Starting from 1,2-dibromo-3-chloropropane (XXV), which is obtained in quantitative yield by bromination of allyl chloride, methods for the synthesis of two key fluorinated compounds—1-bromo-2-fluoro-3-chloropropane (XXVI) and 1,2-difluoro-3-chloro-propane (XXVIII)—have been developed.[43]

$$CH_2BrCHBrCH_2Cl \text{ (XXV)} \xrightarrow{1/3BrF_3} \underset{(XXVI),\ 60\%}{CH_2BrCHFCH_2Cl} + \underset{(XXVII),\ 25\%}{CH_2FCHBrCH_2Cl}$$
$$\xrightarrow{2/3BrF_3} \underset{(XXVIII),\ 85\%}{CH_2FCHFCH_2Cl}$$

Bromofluorochloropropane (XXVI) is readily separated from its isomer (XXVII). Reaction of (XXVI) with potassium acetate in dimethylformamide in the presence of the phase-transfer catalyst triethylbenzylammonium chloride gives 2-fluoro-3-chloropropyl acetate (XXIX) in good yield. Acetate (XXIX) is readily and in high yield oxidised by nitric acid to 2-fluoro-3-chloropropionic acid (XX), and the latter reacts with thionyl chloride to give the corresponding acid chloride (XXX). In the presence of a catalytic quantity of tertiary amines acid chloride (XXX) gives α-fluoroacrylyl chloride (XV) in high yield.

$$\underset{(XXVI)}{CH_2ClCHFCH_2Br} \xrightarrow[DMF]{AcOK,\ 80°C} \underset{(XXIX),\ 75\%}{CH_2ClCHFCH_2OAc} \xrightarrow[80-100°C]{HNO_3}$$
$$\rightarrow \underset{(XX),\ 85\%}{CH_2ClCHFCO_2H} \xrightarrow[80-100°C]{SOCl_2} \underset{(XXX),\ 90\%}{CH_2ClCHFCOCl} \xrightarrow[100-130°C]{R_3N(5\%)} \underset{(XV),\ 90\%}{CH_2{=}CFCOCl}.$$

High yields of alkyl, fluoroalkyl, aryl, and organophosphorus esters of α-fluoroacrylic acid are obtained by traditional methods from acid chloride (XV).[43–45] α-Fluoroacrylyl fluoride (XXXI) is obtained in a similar manner from difluorochloropropane (XXVIII).

These methods are multistage and the yield of α-fluoroacrylates based on dibromochloropropane does not exceed 35%, but the degree of purity of the monomers obtained in this way is very high.

Methyl α-fluoroacrylate (VIc) can be obtained by a simpler method — from methyl 2,3-dibromo-2-chloropropionate (XXXII).[43]

$$CH_2BrCClBrCO_2Me \xrightarrow[\text{freon-113}]{1/3BrF_3} CH_2BrCClFCO_2Me \rightarrow$$
(XXXII) 85%

$$\xrightarrow[H_2O]{Zn,H^+,100^\circ C} CH_2{=}CFCO_2Me$$
(VI в), 85%

α-Fluoroacrylonitrile (XIII) is readily obtained from 2-fluoro-3-chloropropionyl chloride (XXX):

$$CH_2ClCHFCOCl \xrightarrow{MeOH} CH_2ClCHFCO_2Me \xrightarrow{NH_3} CH_2ClCHFCONH_2 \rightarrow$$
(XXX) (XXI), 95% 90%

$$\rightarrow \xrightarrow[180-250^\circ C]{P_2O_5} CH_2ClCHFCN \xrightarrow{base} CH_2{=}CFCN.$$
70% (XIII), 85%

4. Other methods for the synthesis of α-fluoroacrylates

The most recent method for the synthesis of α-fluoroacrylates is based on the substitution of organobromine derivatives by mercuric fluoride followed by dehalogenation of the fluorine derivative with zinc dust.[46–49] The corresponding esters are formed in very low yield (5–15%).

$$CH_2{=}CHCO_2R \xrightarrow{Br_2} CH_2BrCHBrCO_2R \xrightarrow{quinoline} CH_2{=}CBrCO_2R \rightarrow$$
$$\xrightarrow{Br_2} CH_2BrCBr_2CO_2R \xrightarrow{HgF_2} CH_2BrCBrFCO_2R \xrightarrow[Et_2O]{Zn} CH_2{=}CFCO_2R.$$

Fluoroalkyl α-fluoroacrylates can be obtained in a similar manner from the corresponding acrylate analogues.[50]

The Prince reaction was used in a number of studies for the synthesis of different α-fluoro-substituted propionic acids.[12,13,15,51,52] For example, the condensation of paraformaldehyde with 1,2-difluoro-1,2-dichloroethylene, which takes place most effectively in chlorosulphonic or fluorosulphonic acid, gives the α-fluoroacrylate precursors (XXXIII) and (XXXIV).

$$CClF{=}CClF + CH_2O \begin{cases} \xrightarrow[2)\ HCl,KCl]{1)\ ClOSO_3H} HOCH_2CFClCO_2H \\ \text{(XXXIII), 45—50\%} \\ \xrightarrow[2)\ HCl,KCl]{1)\ FOSO_3H} HalCH_2CClFCO_2H \\ \text{(XXXIV), 45—50\%} \end{cases}$$

The condensation of paraformaldehyde with trifluoroethylene occurs under similar conditions, giving 2-fluoro-3-hydroxypropionic and 2-fluoro-3-halopropionic acids.[13,15] Alkyl α-fluoroacrylates are obtained from these acids by various methods, as described in the previous sections.[12–17]

Subsequent studies on the possibility of using the Prince reaction for the synthesis of α-fluoroacrylates resulted in the development of a new starting compound for this purpose — 2,2,3,3-tetrafluoroxetane (XXXV).[53–57]

$$CF_2{=}CF_2 + CH_2O \xrightarrow[8\ atm]{HF,80^\circ C} \underset{\text{(XXXV), 17\%}}{\overset{CF_2-CF_2}{\underset{CH_2-O}{|\quad|}}} \xrightarrow[DMF]{ROH,NaI,Zn,60^\circ C} CH_2{=}CFCO_2R.$$
(VII), 50—80%

Reaction of tetrafluoroxetane, alkali metal halides, and a dehalogenating agent (molar ratio of 1 : 0.1–1.5 : 0.3–3 respectively) in aprotic bipolar solvents in the presence of a radical polymerisation inhibitor gave α-fluoroacrylyl fluoride (XXXI), which was converted to esters by reaction with the respective alcohols.[55–57] According to the information from patents, the esters can be prepared in one stage without isolation of the acid fluoride. Thus, methyl α-fluoro-deuteroacrylate with a yield of 76% based on oxetane (XXXV) was also obtained by this method.[55]

Original methods for the synthesis of α-fluoroacrylates are based on the addition of chlorofluorocarbene to vinyl ethers.[58–64] Thus, the large-scale synthesis of one of the precursors of α-fluoroacrylates — 2-fluoroacrolein (XXXIX) — has been reported by Molines et al.[58]

$$CH_2{=}CHOR + CHFCl_2 \xrightarrow[Et_4NBr,5^\circ C]{NaOH,CH_2Cl_2,H_2O} \rightarrow$$
$R = n\text{-}C_4H_9$

$$\rightarrow \underset{\text{(XXXVI), 79\%}}{CH_2-\overset{Cl}{\overset{|}{C}}(F)-CHOR} \xrightarrow{C_5H_5N} \underset{\text{(XXXVII)}}{\left[CH_2{=}C(F)-\overset{+}{C}HOR\right]} \xrightarrow{ROH} \rightarrow$$

$$\rightarrow \underset{\text{(XXXVIII), 80\%}}{CH_2{=}CFCH(OR)_2} \xrightarrow{H^+} \underset{\text{(XXXIX), 83\%}}{CH_2{=}CFCHO}$$

Reaction of chlorofluorocarbene with butyl vinyl ether results in the formation of 1-fluoro-1-chloro-2-butoxycyclopropane (XXXVI). Thermal scission of the ring occurs via the formation of allyl cation (XXXVII) to give the dialkyl acetal (XXXVIII), decomposition of which yields fluoroacrolein (XXXIX). This method was used to obtain 15 kg of α-fluoroacrolein.

Fluoroacrolein was subsequently used to prepare phenyl α-fluoroacrylate.[59] The synthesis was conducted in the following manner:

$$CH_2{=}CFCOH \xrightarrow[h\nu]{Br_2} \underset{\text{(XXXIV)}}{CH_2BrCFBrCOBr} \rightarrow$$
(XL)

$$\xrightarrow[C_5H_5N,CCl_4]{PhOH} \underset{\text{(XLI), 78\%}}{CH_2BrCBrFCO_2Ph} \xrightarrow[(iso\text{-}Pr)_2O]{Zn} CH_2{=}CFCO_2Ph.$$
(VIb), 79%

Fluoroacrolein (XXXIX) was mixed with liquid bromine at −5 °C, and the mixture was then refluxed while exposed to UV radiation from a mercury lamp. The resulting acid bromide (XL) was converted in the usual manner to phenyl 2,3-dibromo-2-fluoropropionate (XLI). Dehalogenation of ester (XLI) gives phenyl α-fluoroacrylate (VIb) (61% yield based on α-fluoroacrolein).

A further method for preparing phenyl α-fluoroacrylate (XLII), starting from 1-ethoxy-1-phenoxyethylene, has been developed.[60–64]

$$\underset{\text{(XLII)}}{CH_2{=}C(OEt)(OPh)} \xrightarrow[R_4NCl,CH_2Cl_2]{CHFCl_2,KOH,0^\circ C} \underset{\text{(XLIII), 76\%}}{CH_2-\overset{F}{\overset{|}{C}}(Cl)-C(OEt)(OPh)} \xrightarrow[160\ mm\ Hg]{200^\circ C} CH_2{=}CFCO_2Ph.$$
(VIb), 77%

Note. [a] m.p. = 50—51 °C; [b] m.p. = 51.5—52 °C; [c] m.p. = 115—116 °C; [d] m.p. = 116 °C; [e] m.p. = 93—95 °C; [f] m.p. = 114—144.5 °C; [g] yield of crude product is given. [h] Heumüller et al.[24] also report the m.ps. and b.p. of other esters with the formula $CH_2=CFCO_2R$, where R = *o*-, *m*-, and *p*-substituted phenyl groups. [i] In one patent[25] b.ps. are given for compounds with the general formula $CH_2=CFCO_2C(CF_3)_2R$, where R = *m*- and *p*-substituted phenyl groups, furyl and thienyl groups. [j] Lapin et al.[44,45] also give the m.ps. of α-fluoroacrylates of the *ortho*- and *meta*-derivatives of hydroxyphenyldiphenylphosphine oxide.

The unsaturated acetal (XLII), on reaction with chlorofluorocarbene, forms 1-fluoro-2-phenoxy-1-chloro-2-ethoxycyclopropane (XLIII). Thermolysis of cyclopropane (XLIII) under vacuum gives phenyl α-fluoroacrylate (VIb) in good yield.

Recently an original three-stage method for the synthesis of α-fluoroacrylyl fluoride (XXXI) from tetrafluoro- and trifluoro-chloro-propanol was proposed.[65]

$$\underset{\text{(XLIV)}}{HCFXCF_2CH_2OH} \xrightarrow{2RLi} \underset{\text{(XLV)}}{CFX{=}CFCH_2OH} \xrightarrow{H^+} \underset{\text{(XXXI)}}{CH_2{=}CFCOF}.$$

X=Cl, F; R=Me, Bu.

At the first stage alcohol (XLIV) is dehydrofluorinated by alkyl lithium and the resulting allyl alcohol (XLV) is converted to acid fluoride (XXXI) by heating with concentrated sulphuric acid.

III. Physical and chemical properties of α-fluoroacrylic acid derivatives

1. Physical properties

During the last few years a large number of α-fluoroacrylic acid derivatives—halides, amides, nitriles, and alkyl, fluoroalkyl, and aryl esters—have been obtained. The syntheses of most of these compounds have been carried out mainly in order to obtain from them homo- and co-polymers with valuable properties. Therefore, most of the available data on the properties of α-fluoroacrylic acid derivatives appears in patent literature and only a few scientific publications have been devoted to a study of the chemical properties of alkyl and fluoroalkyl α-fluoroacrylates. All of the published data on the physical properties of α-fluoroacrylic acid derivatives are given in Table 1, with the methods of preparation, yields of these monomers, and the literature sources being indicated.

2. Heterolytic reactions of α-fluoroacrylates

Information about the reactivity of α-fluoroacrylate esters towards nucleophilic and electrophilic reagents is extremely limited.[41,47,66,67] Nucleophilic reagents such as alcohols, mercaptans, malonate and acetaminomalonate esters in the presence of alkali metal alkoxides readily add to ethyl α-fluoroacrylate. The direction of addition is such that the nucleophile adds to terminal electron-deficient methylene group of the C=C double bond:[66]

$$CH_2{=}CFCO_2Et \left\{ \begin{array}{ll} \xrightarrow{EtOH,EtONa} & EtOCH_2CHFCO_2Et \ (66\%) \\ \xrightarrow{BuSH,BuOK} & BuSCH_2CHFCO_2Et \ (90\%) \\ \xrightarrow{CH_2(CO_2Et)_2,EtONa} & (EtOCO)_2CHCH_2CHFCO_2Et \ (41\%) \end{array} \right.$$

This is completely analogous to the direction of addition of nucleophiles to unsubstituted acrylates and α-chloro- and α-bromo-acrylates.[68]

Ammonia and amines do not add to the C=C bond of ethyl α-fluoroacrylate but give α-fluoroacrylamides,[66] whereas ammonia readily adds to alkyl α-bromoacrylates to form 2-bromo-3-amino-propionate esters.[69]

Electrophilic reagents such as nitronium fluoride,[66] mercuric nitrate,[66] and bromine monofluoride[41] can also add to the carbon–carbon double bonds of alkyl α-fluoroacrylates. In contrast to unsubstituted acrylates,[70] α-fluoroacrylates add the positively polarised residues of electrophilic reagents to the β-carbon atom:

$$CH_2{=}CFCO_2R \left\{ \begin{array}{ll} \xrightarrow{HNO_3,HF} & O_2NCH_2CF_2CO_2R \ (53\%) \\ \xrightarrow[EtOH]{Hg(NO_3)_2} & O_2NOHgCH_2CFCO_2R \ (48\%) \\ & \quad | \\ & \quad OEt \\ \xrightarrow{1/3(BrF_3+Br_2)} & CH_2BrCF_2CO_2R \ (39\%) \end{array} \right.$$

Electrophilic reagents add to methyl α-chloroacrylate in a similar manner.[41,66] However, the direction of addition of such typical electrophiles as methyl- and phenyl-sulphenyl chlorides to alkyl α-fluoroacrylates is different—the alkylthio and arylthio residues mainly add to the α-carbon atom.[67]

$$CH_2{=}CFCO_2Et \left\{ \begin{array}{ll} \xrightarrow{MeSCl} & CH_2ClCF(SMe)CO_2Et \ (90\%) \\ \xrightarrow{PhSCl} & CH_2ClCF(SPh)CO_2Et \ (68\%) + PhSCH_2CFClCO_2Et \ (22\%) \end{array} \right.$$

Methyl α-fluoroacrylate does not absorb molecular chloride but in the presence of 1–2% tetramethylammonium bromide the reaction with chlorine is very vigorous with evolution of heat, and subsequently on heating α-fluoroacrylate almost the theoretical quantity of Cl_2 is absorbed. It appears that this reaction does not occur by an anionic mechanism as was previously thought[71] but by a free-radical mechanism, since the dimers formed as by-products on chlorination have a structure identical to radical telomers of acrylates:[72]

$$CH_2{=}CFCO_2Me \xrightarrow[Me_4NBr]{Cl_2} CH_2ClCFCO_2Me \xrightarrow{Cl_2} CH_2ClCFClCO_2Me$$

$$CH_2ClCFCO_2Me \xrightarrow{CH_2{=}CFCO_2Me} \underset{\displaystyle\xrightarrow{Cl_2}}{CH_2ClCFCO_2Me} \quad CH_2ClCFCO_2Me$$

$$\begin{array}{ll} CH_2CFCO_2Me & CH_2CFClCO_2Me \end{array}$$

Methyl α-chloroacrylate is chlorinated in a similar manner, whereas methyl methacrylate reacts with Cl_2 by an electrophilic mechanism and forms chlorinated dimers through the formation of new C–O rather than C–C bonds.[71]

3. Free-radical reactions of α-fluoroacrylates

a) Radical polymerisation

As was noted in the previous section, the syntheses of α-fluoroacrylic acid derivatives are complex and have multiple stages, so the preparation of significant quantities of the highly pure monomers necessary for studying the kinetics of polymerisation is an extremely laborious process. It is likely that as a result of this, systematic studies on the kinetics of polymerisation of α-fluoroacrylic monomers have not been carried out. Up to the present time only a few studies devoted to this subject have been carried out.[73–79]

Thus, Yamada et al.[73] have studied the radical polymerisation of ethyl α-fluoroacrylate (EFA) in bulk at 30 °C. The fundamental rate constants for chain propagation (K_p) and chain termination (K_t) have been determined, and these are given in Table 2. For comparison, the rate constants for chain propagation and chain termination of other α-substituted acrylates are also shown in Table 2.

The radical copolymerisation of ethyl α-fluoroacrylate with a number of vinyl monomers has been studied and the copolymerisation rate constants determined. From these data it was possible to calculate the fundamental rate constants $K_{2,1}$ and $K_{1,2}$ for ethyl α-fluoroacrylate and the poly(ethyl α-fluoroacrylic) radical. These results and also the corresponding rate constants for methyl acrylate (MA) and ethyl α-chloroacrylate (ECA) are given in Tables 3 and 4.

Table 2. Rate constants of chain propagation (K_p) and termination (K_t) for α-substituted acrylates at 30 °C.[73]

$CH_2=C(X)CO_2R$		$K_p^2/K_t\times10^3$, litre mol^{-1} s^{-1}	K_p, litre mol^{-1} s^{-1}	$K_t\times10^7$, litre mol^{-1} s^{-1}
X	R			
Cl	Et	8.27	1660	48.0
F	Et	2.58	1120	33.3
Me	Me	4.82	450	4.2
H	Me	0.16	720	0.43

Table 3. Reactivity of polymer radicals towards MA, EFA, and ECA at 30 °C.[73]

Monomer	$K_{2,1}$, litre mol^{-1} s^{-1}				
	polystyrene	poly(MMA)	poly(MA)	poly(EFA)	poly(ECA)
MA	141	176	720	6588	516
EFA	240	216	1000	1120	272
ECA	1514	940	7579	5333	1660

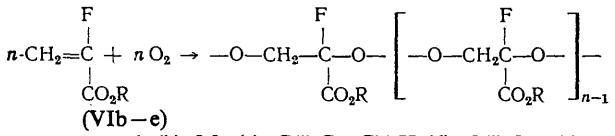
Table 4. Reactivity of monomers towards polymer radicals of MA, EFA, and ECA at 30 °C.[73]

Radical	$K_{1,2}$, litre mol^{-1} s^{-1}					
	styrene	MMA	MA	EFA	ECA	AN
poly(MA)	4000	2182	720	1000	7200	1004
poly(EFA)	6222	3394	6588	1120	5333	1120
poly(ECA)	5533	830	520	516	1660	572

[AN = acrylonitrile].

An analysis of these data shows that ethyl α-fluoroacrylate is 3–7 times less reactive than ethyl α-chloroacrylate and has a similar reactivity to that of methyl acrylate. Comparison of the reactivity of the polyradicals of MA, EFA, and ECA also reveals the similarity between the poly(methyl acrylic) and poly(ethyl α-fluoroacrylic) radicals, which are more reactive than the poly(ethyl α-chloroacrylic) radical. These characteristics apparently occur because the fluorine atom stabilises the resulting radical to a much lesser degree than the chlorine atom. This results in ECA having a higher reactivity than EFA and correspondingly the polymer radical of ECA being less reactive than the poly(ethyl α-fluoroacrylic) radical. Gal'perina et al.[76] studied the effect of the solvent on the rate constants of chain propagation and termination in the radical polymerisation of acrylic acid (AA) and α-fluoroacrylic acid (FAA). Water, formamide, and DMSO were used as solvents. The results are given in Table 5.

Table 5. Rate constants of propagation and termination for the polymerisation of AA and FAA in different solvents at 20 °C.[76]



Solvent	FAA		AA	
	K_p, litre mol^{-1} s^{-1}	$K_t\times10^{-8}$, litre mol^{-1} s^{-1}	K_p, litre mol^{-1} s^{-1}	$K_t\times10^{-8}$, litre mol^{-1} s^{-1}
Water	2600±200	0.87±0.07	27 200±200	1.8±0.15
Formamide	2200±200	0.74±0.07	4 200±20	1.0±0.2
DMSO	850±50	0.49±0.01	500±50	0.2±0.01

As can be seen from the results presented, the rate constants of propagation decrease on going from water to DMSO, which is due to the fact that DMSO has the greatest capacity to form complexes with a polymer radical. The marked difference between the values of K_p in the polymerisation of FAA and AA in water is apparently governed by the reactivity of the polymer radicals. The presence of a fluorine atom at the α-position causes a reduction in density of the unpaired electron in a polymer radical, which results in a decrease in reactivity of the polymer radicals of FAA. The difference between the values of K_p in polymerisation between a polymer radical and solvent is considerably less. In the polymerisation of FAA the probability of forming such a complex is much less than in the polymerisation of AA, which leads to a greater decrease in reactivity of AA.

The kinetics of the polymerisation of 2,2,3,3-tetrafluoropropyl α-fluoroacrylate (FN-1) and its methacrylate analogue were recently studied.[79] It was shown that under the same conditions 2,2,3,3-tetrafluoropropyl α-fluoroacrylate polymerises at a much higher rate than 2,2,3,3-tetrapropyl methacrylate (MN-1) and its polymerisation is accompanied by a greater reaction enthalpy. Thus, K_p/K_t is 1.15 (litre mol^{-1} s^{-1})$^{0.5}$ for FN-1 and 0.22 (litre mol^{-1} s^{-1})$^{0.5}$ for MN-1. The polymerisation enthalpy is equal to −73 kJ mol^{-1} for FN-1 and is −57 kJ mol^{-1} for MN-1.

b) Autooxidation by atmospheric oxygen

α-Fluoroacrylates, in the same way as other vinyl monomers,[80–82] are oxidised by atmospheric oxygen to give peroxides that consist of alternating copolymers of monomers and oxygen.[83,84]

(VIb–e)

R = Ph (b), Me (c), $CH_2CF_2CF_2H$ (d), CH_2CF_3 (e); $n = 10 - 20$.

Other conditions being equal, α-fluoroacrylate esters absorb oxygen much more rapidly (by a factor of 100 or more) than their acrylate and methacrylate analogues (Table 6). It would appear that there are no parallels amongst acrylic or other vinyl monomers with respect to the rate of oxidation of α-fluoroacrylates by air.

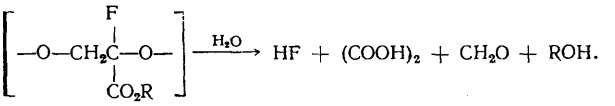


Table 6. Absolute and relative rates of oxidation (W) of monomers $CH_2=CXCO_2R$ by atmospheric oxygen at 50 °C (concentration of initiator AIBN = 8.6×10^{-2} mol litre^{-1}).[83]

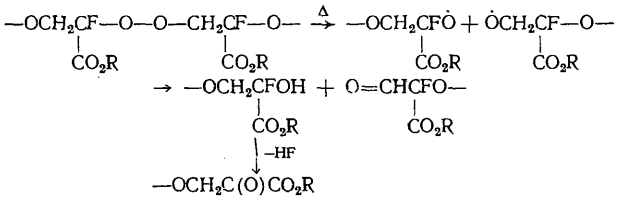
Monomer		$W \times 10^5$, mol litre^{-1} s^{-1}	W_{rel}
X	R		
H	$CH_2(CF_2)_2H$	0.05	1
Me	$CH_2(CF_2)_2H$	0.17	3.4
F	Me	10.7	210
F	$CH_2(CF_2)_2H$	11.9	240
F	CH_2CF_3	43.0	360

In two studies[4,5] the greatest attention was given to phenyl and tetrafluoropropyl esters of α-fluoroacrylic acid and to the properties of their polyperoxides. The rate of oxidation of tetrafluoropropyl α-fluoroacrylate initiated by azobis(isobutyronitrile) (AIBN) on temperature was studied and the ratio of the rate constants of chain propagation (K_p) and chain termination (K_t) was calculated as $(K_p/K_t) = 7.4 \times 10^3 e^{-7034/RT}$.

As is evident from this equation, the oxidation of tetrafluoropropyl α-fluoroacrylate over the temperature range 40–60 °C has an energy of activation (7 kcal mol^{-1}) that is much lower than that of methyl methacrylate (10.5 kcal mol^{-1}).[80]



The peroxides of fluoroalkyl and aryl α-fluoroacrylates readily decompose when treated with nucleophilic reagents such as alkalis, alcohols, and water. The hydrolysis products of the peroxides of tetrafluoropropyl and phenyl α-fluoroacrylate provide confirmation that their structure consists of alternating copolymers with oxygen:

R = Ph (VIb), $CH_2CF_2CF_2H$ (VId)

The hydrolytic decomposition of the peroxides of these monomers in dioxan and tetrahydrofuran occurs at temperatures considerably below the temperature range of their thermal decomposition.[83,84]

The thermolysis of peroxides of tetrafluoropropyl and phenyl α-fluoroacrylates takes place with the evolution of gaseous HF (0.5 to 0.8 moles per mole equivalent of peroxide). Panteleeva et al.[83,84] attribute the evolution of HF to the disproportionation of primary radicals in the solvent cage, as a result of which unstable fluorohydroxy compounds are formed:

The kinetics of the thermal decomposition of peroxides of phenyl and fluoroalkyl α-fluoroacrylates in hydrophobic solvents have been studied. Kinetic data on the thermolysis of these peroxides correlated against similar data on their acrylate, methacrylate, and α-chloroacrylate analogues and benzoyl peroxide are given in Table 7.[83–85] It is clear from these data that the temperature range of thermolysis of peroxides of α-haloacrylates is considerably lower than for their acrylate and methacrylate analogues. The thermolysis characteristics of α-fluoroacrylate peroxides are similar to those of the widely used medium-temperature radical initiator—benzoyl peroxide. It is probable that the high rate of oxidation of α-fluoroacrylates at normal temperatures is due to the relatively low temperature range of thermal decomposition of their own peroxides, as a result of which these peroxides effectively initiate the radical chain autooxidation of the monomers.

Table 7. Kinetic data on the thermal decomposition of peroxides $-(-OCH_2CXO-)-$ in solution* (initial concentration of peroxides = $4-20 \times 10^{-2}$ equivalents litre^{-1}.

No.	X	R	T, °C	$K \times 10^5$, s^{-1}	E, kcal mol^{-1}	Refs.
1	H	Ph	120.0	8.3	28.0	[85]
2	Me	Ph	100.0	6.8	32.4	[85]
3	Cl	Ph	75.3	7.9	25.6	[85]
4	F	Ph	75.0	2.9	27.5	[84]
5	F	$CH_2(CF_2)_2H$	73.0	5.6	31.5	[83]
6	F	CH_2CF_3	72.5	8.2	29.9	[83]
7	benzoyl peroxide		79.9	3.3	32.7	[86]

*Peroxides 1–4 and 7 in chlorobenzene, peroxides 5 and 6 in $MeCO_2CH_2CF_2CF_2H$.

Thus, the low thermal and hydrolytic stability of α-fluoroacrylate polyperoxides assists on the one hand the rapid formation of polyperoxides in monomers and on the other hand their rapid

decomposition, which accompanies the formation of decomposition products. Taking into account the high rate of radical polymerisation of these monomers, it may be assumed that stabilisation of their properties will present a more complex problem than the stabilisation of acrylates and methacrylates.

IV. Properties and use of polymers

Fluorinated polymers have played a very large role in present-day technology because of their stability when used under extreme conditions.[87–89]

Studies of recent years have shown that α-fluoroacrylate polymers have many working characteristics that are significantly superior to those of their methacrylate analogues. The introduction of fluorine into the α-position relative to the acrylate ester group resulted in an improvement in the properties of block organic glass on the basis of its heat resistance and impact resistance.[21,90,91] Amongst polymers of this class poly(phenyl α-fluoroacrylate) has the best properties, so it could be recommended as a construction material for the glazing of cockpits in high-speed aircraft.[21,59,91]

In Table 8 the effect of introducing fluorine into the α-position on the heat-resistance of block acrylic homopolymers is demonstrated.

Table 8. Softening point of block homopolymers of α-substituted acrylate esters.

Monomer	T_s, °C	Refs.	Monomer	T_s, °C	Refs.
$CH_2=CHCO_2Me$	3	[73]	$CH_2=CClCO_2Me$	145	[73]
$CH_2=CHCO_2Et$	−22	[73]	$CH_2=CClCO_2Et$	94	[73]
$CH_2=CHCO_2Ph$	55	[92]	$CH_2=CFCO_2Me$	142	[73]
$CH_2=C(CH_3)CO_2Me$	120	[73]	$CH_2=CFCO_2Et$	94	[73]
$CH_2=C(CH_3)CO_2Et$	65	[92]	$CH_2=CFCO_2Ph$	180	[91]
$CH_2=C(CH_3)CO_2Ph$	110	[92]			

These data indicate that the heat resistance of polyacrylic polymers is significantly affected not only by the substituent at the α-position relative to the ester group but also by the structure of the substituent in the ester part of the molecule. Usually polar and bulky substituents increase the softening point of the polymers.[92] α-Halogenated polyacrylate esters have the greatest heat resistance, with α-chloro- and α-fluoro-acrylic polymers having the same value of T_s. However, more fundamental studies on these polymers showed that α-fluoroacrylates are very much superior to α-chloroacrylates in terms of their thermal stability (from the loss of weight at elevated temperatures).[73] Thermogravimetric analysis of poly(methyl fluoroacrylate) [poly(MFA)], poly(ethyl fluoroacrylate) [poly(EFA)], and poly(ethyl chloroacrylate) [poly(ECA)] showed that polyacrylic polymers undergo thermal depolymerisation over a narrow temperature range with a maximum rate of decomposition at 400 °C for poly(MFA) and 370° for poly(EFA). The decomposition of poly(ECA) starts at as low a temperture as 180 °C, it is a more complex process and involves not only depolymerisation but also dehydrochorination.[73] Research workers attribute the high thermal stability of α-fluoroacrylates to the greater stereoregularity of poly(α-fluoroacrylate) radicals, namely, to their higher content of isotactic diads.[73,93,94]

The high chemical stability of polymethyl and polyphenyl α-fluoroacrylates is also likely to be related to structural features.

The thermal decomposition of certain poly(α-fluoroacrylates) has been studied.[95,96] The rates of weight loss of polymers (w) when the degree of decomposition is 10% and the energy of activation of thermal decomposition (E) of poly(methyl α-fluoroacrylate) (PMFA) and poly(1,1,5-trihydrooctafluoroamyl α-fluoroacrylate) (PFAFA) correlated with their acrylate analogues—poly(methyl methacrylate) (PMMA) and poly(1,1,5-trihydrooctafluoroamyl acrylate) (PFAA)—are given in Table 9.

Table 9. Kinetic data on thermal decomposition of polymers.[95]

Polymer	$w \times 10^2$, % s^{-1} at a temperature of (°C):						E, kcal mol^{-1}
	300	310	320	330	340	350	
PMA	0.11	0.15	0.31	0.83	1.52	3.18	45.4
PMFA	0.07	0.13	0.17	0.34	0.64	1.29	50.2
PFAA	0.05	0.12	0.17	0.40	0.59	1.05	28.7
PFAFA	0.06	0.12	0.26	0.46	0.83	1.46	44.2

The data on the thermal decomposition of poly(α-fluoroacrylates) show that the latter have comparable thermal stability to that of polyacrylates that are unsubstituted at the α-position. Gorelov et al.[95,96] attribute the substantial difference in the values of the energy of activation to the different types of reactions that occur during thermal decomposition.

Further studies on poly(α-fluoroacrylates) revealed another promising area of their application—as optical materials in the priority area of the present-day technology of information communication and transmission, namely, fibre optics.[97,99–107] The outstanding optical properties of these polymers combined with their improved heat resistance, flexibility, and moisture resistance give them a considerable advantage over fluorine-containing methacrylates which have been widely studied and used in fibre optics. At the present time many new α-fluoroacrylic monomers and polymers have been synthesised and patented; they have a wide range of refractive index (1.36–1.50), so they could be used as materials for a light-guiding centre and light-reflective membrane.[99–107]

Boguslavskaya et al.[97] carried out a comparative study of the optical and physicomechanical properties of fluoroalkyl α-fluoroacrylate and methacrylate polymers. The molecular weight of block polymers are usually in the range 1 000 000–5 000 000. The properties of the polymers were correlated according to the following parameters: the transmission factor (K_{tr}), refractive index (n_D), softening point (T_s), impact strength (a_n), tensile strength at break (σ_b), specific elongation at break (ε_b), and also the thermal stability relative to visible degradation (T_{stab}). In this case the thermal stability denotes the maximum temperature at which heating a sample for 2 h does not produce any defects (bubbles, cracking, etc.). The results are given in Table 10.

Table 10. Properties of block polymers.

Monomers	K_{tr}, %	n_D^{20}	T_s, °C	a_n, kJ m^{-2}	σ_b, MPa	ε_b, %	T_{stab}	Refs.
$CH_2=CFCO_2R$								
R=Me	91	1.459	140	22	96	4.6	240	[97]
$CH_2CF_2CF_2H$	91	1.398	95	21	54	66	230	[97,99]

C_6F_5	—	1.487	115	—	—	—	—	[102]

It can be seen from Table 10 that block poly(fluoroalkyl α-fluoroacrylates) with relatively short fluoroalkyl residues (1–3 carbon atoms) have considerably higher values of the softening point (more than 20 °C) and thermal stability (40–60 °C) than their methacrylate analogues. Poly(α-fluoroacrylates) are superior to their methacrylate analogues in terms of impact strength, tensile strength, and elasticity, and they have a higher level of deformation-strength properties at high temperatures.[97,108] Moreover, α-fluoroacrylic polymers are more stable towards various ageing factors (effect of heat and moisture) than the corresponding methacrylates.[97,99] In addition to fibre optics, fluoroalkyl α-fluoroacrylates can be used as materials for optical storage systems such as optical disks.[102,109]

Highly fluorinated compounds usually dissolve oxygen effectively. This property of poly(fluoroalkyl α-fluoroarylates) has been utilised when they were patented as effective gas-separation membranes[110–112] that are superior to their methacrylate analogues in terms of oxygen permeability and mechanical strength.

$$-(-CH_2-\underset{\displaystyle CO_2(CH_2)_m CFX(OCH_2CFX)_n OPr}{\underset{|}{CF}}-)-$$

X=F, fluoroalkyl (C_{1-3}); $m=1-3$; $n=0-5$.

Fluoroacrylic polymers which contain OH groups in the ester part of the molecule have been suggested as materials for contact lenses.[113,114]

$$-(-CH_2)-\underset{\displaystyle CO_2(CH_2)_m R}{\underset{|}{CF}}-)-$$

R – fluoroalkyl with OH group; $m=1-5$.

α-Fluoroacrylic polymers with improved mechanical strength have been patented as dental prosthetic materials.[115] Poly(methyl α-fluoroacrylate) can undergo decomposition when exposed to certain forms of radiation (UV, X-rays) and can be used in semiconductor technology for the manufacture of photoresistors.[74,87] Fluoroacrylic polymers can also be used in other areas of industry such as in paint production.[12,13,15]

The unique properties of polymeric α-fluoroacrylates, as is evident from the previous section of this review, when they are widely applied can give rise to substantial progress in many areas of technology and medicine.

A restriction on the application of these materials arises from the fact that so far no methods exist for preparing monomers of this class that are suitable for the development of an industrial process. Not one of the methods examined in Section II satisfies the current strict requirements for simplicity of design, safety, and ecological purity. Whilst amongst the group of traditional acrylic monomers, acrylic and methacrylic acids are the main members of the series and constitute starting materials for the synthesis of the remaining monomers, it is unlikely that α-fluoroacrylic acid could be used as a starting material for α-fluoroacrylates. In contrast to liquid acrylic and methacrylic acids, α-fluoroacrylic acid is a solid (m.p. 51 °C), so that it is extremely difficult to stabilise it against uncontrolled polymerisation. Consequently, the methods of preparation of α-fluoroacrylates are fundamentally different from those for acrylates and methacrylates, and even when produced on a small scale α-fluoroacrylates can have a considerable impact on the development of novel systems and compounds providing current technological progress. Therefore, future research into improved methods of

obtaining α-fluoroacrylic monomers, polymers, and composite materials is a promising area of organofluorine synthesis.

Chemistry of the atmosphere and the climate

K Ya Kondrat'ev
Institute for Lake Studies, USSR Academy of Sciences, Leningrad

ABSTRACT. The influence of the chemical composition of the atmosphere on the greenhouse effect and climate is analysed, and the major role of the biosphere in regulating this composition is discussed. Evidence of the observed variation trends of concentrations of small admixtures of optically active atmospheric components is presented, and the attendant possible changes in climate are outlined. A brief characterisation of the main properties of the atmospheric aerosol is given, and its role in shaping climate assessed.

The bibliography includes 26 references.

I. Introduction

The climate and its changes are governed by the complex interaction between the components of a system composed of the atmosphere, the hydrosphere, the lithosphere, the cryosphere, and the biosphere. This system functions under conditions where solar radiation is practically the only source of energy. The atmosphere plays an important part in the development of the greenhouse effect because it contains a large number of optically active trace gaseous and aerosol components (TGAC).[1–13] Clouds are the most essential climate-forming component of the atmosphere. Their formation is associated with TGAC.[14] This fact determines the key role of chemical and photochemical processes as shapers of climate.

Information concerning the direct influence of various atmospheric chemical components on its absorption of UV radiation, the greenhouse effect, the photochemical formation of oxidants, the acidity of precipitation, and the corrosion of materials is presented in Table 1.[15] The choice of the key atmospheric phenomena is of course arbitrary and may vary according to the specific features of the problem under investigation.

It is also important to consider the large number of indirect influences (e.g. the effect of halocarbons on the ozone content, etc.). The synergism resulting from the interaction between various chemical processes in the atmosphere and biosphere should likewise be taken into account.

Table 2 shows the effect of diverse factors on the development of the chemical composition of the atmosphere.[15]

II. Chemistry of the atmosphere and the greenhouse effect

Table 3 lists the trace gas components (TGC) that exert a significant influence on the development of the greenhouse effect and related chemical processes in the atmosphere. Sixteen different characteristics of these components are presented.[12,13] The degree of reliability of available data on the sources of these components, their concentration and the variation trends for the latter, their lifetime in the atmosphere, their chemical activity, and their contribution to the greenhouse effect, has been assessed. There are still many gaps in our knowledge of the cycle of such important TGC as CH_4, CO, N_2O, and NO_x. The fact that our data on the contribution of processes connected with fossil fuel combustion (for the generation of energy) are not completely reliable, is a matter for great concern, because these contributions may account for 75% of the total anthropogenic emissions. For a clearer picture of the impact of the greenhouse effect on climate, studies of climatic chemical phenomena should be continued.

The reliability of estimates of anthropogenic influences on the chemical composition of the atmosphere, and of the environmental changes they cause is greatly limited by our inadequate knowledge of the relevant physical, chemical, and biological processes. Within a time scale of about a decade, the atmosphere, the continents and the seas represent a single system. The physical and chemical processes in the atmosphere which are subjected to increasing anthropogenic loads play a vital part in the development of biogeochemical cycles. Life on our planet depends on these cycles.

The main feature of the atmosphere is its heterogeneity. A fundamental feature of the atmosphere is its heterogeneous nature. Water in all its states plays a major role in the chemistry of the atmosphere. In particular, it is a source of hydroxyl OH (the main participant in gas-phase reactions), and of peroxide H_2O_2 (a critical oxidising agent in reactions between liquid components). Water in its liquid form (clouds and rain) has a significant effect on the chemical transformations of various compounds as well as on the tropospheric cycles of sulphur, nitrogen, carbon, halogens, and other elements. It is impossible to give an adequate description of these cycles without a detailed investigation of the processes of transformation of gas into particles and the part played by clouds and rain in these events.

Studies of the heterogeneous chemical processes in the atmosphere are of crucial importance for an understanding of the special features of the development of biogeochemical cycles. Such studies are expected to: (1) establish the relationship between homogeneous and heterogeneous processes and the rates of the gas-phase reactions; (2) establish the role of heterogeneous processes in transport phenomena, physical and chemical transformations, and washout mechanisms—all of which govern the spatiotemporal variability of the key components of the biogeochemical cycles (rain clouds,

rainless clouds, aerosols etc.); and (3) reveal the contribution of heterogeneous processes as factors responsible for changes in weather and climate.

The anthropogenic influences on climate are multiple and diverse. Without going into the subject of micro- and mesoclimate, let us discuss the global processes resulting from changes in the amount of optically active trace gas and aerosol atmospheric components that have an impact on the greenhouse effect. In this connection the problem of increasing concentrations of atmospheric CO_2 becomes important, as well as the assessment of its effect on climate.[16]

Such an estimate is necessary for: (1) predicting industrial development and its effect on the biosphere in the coming 50–100 years; (2) establishing the regularities of the global carbon cycle; (3) developing a reliable climatic theory. However, at present there are too many uncertainties for us to be able to solve these three problems. By way of example, let us consider the current state of knowledge of the carbon cycle. There are conflicting estimates of the contribution of marine and continental biota to this cycle. Research over the last 10–15 years has clearly established that there is a large number of TGAC and that their contribution to the greenhouse effect is considerable.[4] Hence it is hard to get sufficiently reliable predictions for the next 50–100 years of climatic changes due to anthropogenic factors, though there is no question of the urgent need for these.

Table 1. Effect of the chemical components of the atmosphere on its most important phenomena.[15]

Constituents	Absorption of UV radiation	Greenhouse effect	Photochemical formation of oxidants	Acidity of precipitation	Decreased visibility	Corrosion of materials
C (soot)		+			+	
CO_2		+				
CO						
CH_4		+				
C_xH_y			+		+	
NO_x			+	+	+	
N_2O		+				
NH_3/NH_4^+				+		
SO_x		+		+	+	+
H_2S						+
COS						
Organic sulphur						
Halocarbons		+				+
Other halides						
Trace constituents						+
O_3	+	+	+			+

Note. + shows that this component affects the respective phenomenon.

Atmospheric composition is largley determined by the processes occurring in the biosphere. This is why the anthropogenic influences on the biosphere that change the cycles of its various components exert a considerable influence on the climate.[17,19]

Continuous synthesis and degradation of organic matter take place in the biosphere. The chemical composition of the environment is maintained in a stable state by virtue of the closed cycles of substances in the biosphere. In the pre-industrial period with its slight anthropogenic disturbances of biospheric processes, balance of the flow of substances reached a level of ~0.01% as a result of synthesis and breakdown in the biosphere.[17] This happened because there were naturally selected correlated communities of living organisms involving a huge number of species. The anthropogenic effect resulting from the synthesis and breakdown of organic matter and industrial products causes an imbalance in the fluxes of substances. This fact calls for the immediate solution of the following fundamental ecological problems: (1) ascertaining to what extent the cycles of substances in an undisturbed atmosphere are closed; (2) determining the maximum disturbances that do not cause irreversible biospheric and environmental changes; (3) obtaining data on the current state of the biosphere and environment, particularly on the extent of closure of the cycles of substances.

Table 2. Main factors affecting the chemical composition of the amtosphere.

Constituents	Oceans and estuaries	Marshland	Crops	Wild vegetation	Domestic animals	Wild animals	Biomass combustion	Petrol combustion	Coal combustion	Industrial processes
C							+	+	+	
CO_2	+		+	+			+	+	+	
CO	+			+			+	+	+	+
CH_4		+	+	+	+	+	+			
C_xH_y	+		+	+			+			
NO_x	+		+				+	+	+	+
N_2O	+		+	+			+	+	+	
NH_3/NH_4^+		+	+	+	+	+	+		+	
SO_x								+	+	+
H_2S	+	+	+	+						
COS	+	+		+						
Organic compounds	+	+		+						
Halocarbons										+
Other halides								+	+	+
Trace constituents							+	+	+	+

Note: x means that this factor affects the content of the respective component.

An analysis of biospheric energy permitted the establishment of the distribution of energy fluxes and of biogens in organisms, depending on their size.[17] It appears that 99% of the biospherical energy flux can be attributed to organisms less than 1 cm in size. Highly closed biogeochemical cycles become feasible if less than 1% of the energy flux is utilised by organisms larger than 1 cm in size. These conclusions confirm empirical data for natural communities undisturbed by anthropogenic effects.[17]

Studies of the extent of carbon cycle closure, based on the changes in carbon isotope composition of tree growth rings, are of fundamental importance.[18] The redistribution of carbon may occur mainly between four reservoirs: atmosphere, oceans, fossil fuel, and

the biosphere. Carbon "leakage" beyond the confines of these reservoirs can be disregarded. In order to establish the changes in the carbon content of the ocean and the biosphere, it is enough to find them just for one of these two reservoirs. The changes in the second one can be calculated from the equilibrium equation (law of the conservation of matter). Oceanic carbon absorption is described by two constants. The first is determined by the physicochemical absorption resistance to changes in the total carbon content, including bicarbonates and carbonates. The second is governed by the absorption resistance to concentration changes of dissolved gaseous CO_2 alone. This latter constant corresponds to changes in biological activity.

Table 3. Influence of various trace gas components in terms of their effect on the chemical processes in the atmosphere and on global climate.[12,13]

Constituent	Effect on		
	chemical processes	climate	climato-chemical phenomena
Carbon dioxide	0	2	1
Ozone	2	2	2
Methane	2	1	1
Carbon monoxide	2	0	1
Nitrous oxide	2	1	1
NO and NO_2	2	0	1
Hydroxyl	2	0	1
Trichlorofluoromethane	2	1	1
Dichlorodifluoromethane	2	1	1
Bromochlorodifluoromethane	2	0	1
Bromotrifluoromethane	2	0	1
Sulphur dioxide	1	0	1
Carbonyl sulphide	1	0	1

Note. The following notation is used: 2, strong effect; 1, moderate effect; 0, weak effect.

Because of the buffer effect on the absorption of the main ^{12}C isotope and the absence of such an effect on the absorption of the other carbon isotopes (the Bolin–Eriksson effect), these two specific constants appear in different combinations in the balance equation.[19] This allows us to estimate two independent combinations of constants from the changes in ^{14}C and ^{13}C carbon isotopes in the growth rings. In addition, an empirical buffer factor of resistance to CO_2 penetration through the atmosphere–ocean interface is used in the calculations, and corrections are made for the ^{13}C isotope fractionating. In this case no information about processes taking place in the ocean and biosphere or about their structure is required.

According to known estimates[17–19] with a significance level above 70% the emission of carbon from land biota is greater than that caused by the combustion of fossil fuel. The seas absorb the biosphere emissions, changing in the process their biological activity. As a result, the carbon content in the biosphere as a whole, including land and sea, remains essentially unchanged. On the other hand, carbon content changes separately in the land and marine parts of the biosphere, and the atmospheric carbon fluxes that reflect these changes are considerably greater than the emission due to fossil fuel combustion.

No notice has been taken to date of the possible changes in oceanic biological activity. For this reason, it was believed that carbon emissions from land biota were lower than from fossil fuel combustion. If this factor is not taken into account, agreement with the carbon balance equation has a lower than 30% significance level. It is evident that carbon cycle studies demand a new approach to the problem of anthropogenic influences on climate.

In studies of the impact of increasing amounts of atmospheric CO_2 on climate, an effect that should raise the tropospheric and lower the stratospheric temperature, feedback mechanisms have not been sufficiently considered till now. Thus, higher tropospheric temperatures should affect the distribution of water vapour, cloud, wind, rainfall, sea ice, etc. It is by no means clear in advance what the total effect of the respective feedbacks would be: would it lead to a mutual compensation of opposite effects or to an increased CO_2 effect? The same is true for the stratosphere, where changes in temperature conditions may affect photochemical processes and lead to a redistribution of such an optically active component as ozone. We are still very far from a good understanding of the mechanism of the CO_2 effect on climate. Additionally, the atmosphere is subject to the effect of many other optically active trace gas components (e.g. nitrogen oxides, freons, etc.).[3–7] Accordingly, this calls for: (1) reliable parametrisation of the radiative properties of various gases and establishment of their priority in climate models (e.g. the climatic consequences of an increase in tropospheric ozone content should be taken into account); (2) development of atmosphere models that take into account the typical features of fields of concentration of significant low-concentration gas components; (3) long-term observations to define the trends for such components; (4) development of such photochemical blocks of climate models as would permit us to turn the concentrations of optically active trace gas components into internal variables of such models; (5) continuing laboratory investigations to specify the rates of various photochemical reactions and to enlarge the database of fine structure parameters for the absorption spectra of optically active atmospheric compounds; (6) improvement of climatic models for assessing the effect of atmospheric composition on climate by interactive consideration of oceanic processes, also in the presence of ice on the water.

III. Trends in changes of content of atmospheric trace gas components and their effect on climate

It is now generally accepted that anomalies of the radiative effect on the atmosphere due to increasing amounts of anthropogenic trace gas components (TGC) may become a dominating factor in climatic changes over several decades or longer, though there is as yet no conclusive cause and effect explanation for the changes in climate in the last 125 years.[20] Climatic changes over several decades can, for instance, be caused by the intrinsic variability of the system "atmosphere–ocean–land–cryosphere", the basis of which is the inconstancy of oceanic, sea ice and glacial heat reserves.

It was important that studies of the greenhouse TGC established that the contribution of several polyatomic TGC per molecule to the greenhouse effect was much greater than that of CO_2.[7] Thus, for instance, the contribution of freons-11 ($CFCl_3$) and -12(CF_2Cl_2) is 10^4 times greater than that of CO_2. This calls for a serious study of the part played by numerous TGC in the development of the greenhouse effect.

The results of studies of the influence of stratospheric ozone disturbances on tropospheric climate effected through the radiative-dynamic stratosphere-troposphere interaction are very important. Recent calculations also show that an increase in tropospheric content promotes development of the greenhouse effect.[7]

Computational modelling has demonstrated that should the concentrations of numerous TGC's retain their rate of increase during several future decades, the resulting rise of ground surface air temperature (GSAT) may exceed the rise in temperature observed in the last 100 years. It can cause an effect comparable to that caused by the rise in CO_2 concentration. Stratospheric changes caused by anthropogenic factors may also considerably exceed natural decennial fluctuations. In particular, calculations have established the dependence of tropical tropopause temperature on concentrations of ozone and freons.[6]

Today, first and foremost, it is necessary to study the interaction between radiative, chemical, and dynamic processes which determine in particular the ozone layer resistance to chemical factors. The "radiative-dynamic" interaction of the tropo- and stratosphere, as well as the exchange of LCGC between them are major aspects of the anthropogenic effects on climate. These problems are connected with the need to take into account stratospheric water vapour and ozone content. Observations on long term trends in the content not only of CO_2 but also of O_3, water, and of such TCGC as methane, nitrous oxide, freons, etc., are becoming increasingly urgent.

Accordingly, various aspects of the TGC effect on climate are discussed in detail.[20] Analysis of data on the greenhouse effect of TGC showed that this had grown in the last few decades at a rate 3 to 10 times higher than in 1850–1960. The cumulative balanced rise in GST due to CO_2 and other TGC after 1850 should by 1960 have reached a level of 0.7 to 2 K, the TGC contribution being about 30% (the indeterminacy being mainly due to the unreliable estimate of climatic sensitivity to radiative disturbances). Approximate calculations within the framework of a nonstationary one-dimensional model (observing diffusion in the ocean) showed that by 1980 the heating was likely to have reached 0.4–0.8 K (with the range of balanced heating equalling 0.7–2.0 K).

Calculations of heating, according to various assumptions on the temporal dynamics of TGC content, led to the conclusion that the possible GSAT rise between 1980 and 2030 will range form 0.8 to 4.1 K. Hence in 180 years (1850–2030) the cumulative heating of the system in equilibrium can reach 1.5–6.1 K. However, because of the huge thermal inertia of the seas, only 40–50% of this heating is likely to take place by 2030.

If the current growth rate for TGC remains unaltered in future decades as well, the climatic system will become increasingly unbalanced. One should keep in mind that, although several freons[10,114,115,14,13B] with a life span of ~100–500 years do not contribute appreciably to the greenhouse effect today (nor will they in the coming 50–100 years), their continued emission at the same rate might lead to considerable climatic changes in the centuries to come.

The interaction of chemical, reactive and dynamic processes in the atmosphere, as well as adequate consideration of the seas and clouds as climate-forming factors, are of special interest. So far even the sign of the cloud feedback has not been reliably established, while the assessed values for the decelerating influence of the seas range from several decades to a hundred years. As the spatial-temporal distribution of TGC is highly heterogeneous, assessment of its effect on climate in 1-dimensional models should be regarded as purely illustrative. Two- and three-dimensional models allow more reliable calculations.

Problems which should be given top priority include the following: (1) establishment of the role of chemical reactions and transport (advection, diffusion) as determinants for ozone concentration fields, as well as of nitrogen oxides and CO; (2) consideration of the temperature feedback affecting water vapour content and chemical reactions in which hydroxyl participates; (3) analysis of the contribution of biogenic sources of methane and nitrous oxide; (4) investigation of the dependence of stratospheric water vapour content on temperature at tropical tropopause level, because water vapour reaches the stratosphere mainly through breaks in the tropical tropopause.

Regular observations of TGC are becoming crucial, because the regularities of the spatiotemporal distribution of such important TGC as CO, O_3 and nitrogen oxides are still poorly understood. Direct measurement of the TGC radiative effect reflected in the special distribution of short and long wave radiation in the free atmosphere (up to the upper boundary of its optically active layer) is also unquestionably an urgent problem. Temperature changes at ground level in the tropo- and stratosphere remain an important field of study. The spectral parameters of TGC call for further investigation. Reliable evaluation of the TGC contribution to the greenhouse effect depends on their correct determination.

In order to obtain more reliable estimates of the effect of CO_2 concentrations on climate, several external climate-forming factors were analysed. These include the concentrations of TGC and tropo- and stratospheric aerosol, the solar constant, the characteristics of the underlying surface, and the volume of industrial heat release (with TGC concentration being the main factor).[11]

Table 4. Concentrations of "greenhouse" TGC and their rate of increase.[7]

Component	Concentration, p.p.m.*	Current rate of increase (%/year)
Carbon dioxide	340	0.4
Stratospheric ozone	(0.1–10)	0–0.3
Tropospheric	(0.02–0.1)	0–0.7
Methane	1.7	1.2
Carbon monoxide	0.12	?
Trichlorofluoromethane	$1.9 \cdot 10^{-4}$	5–8
Dichlorodifluoromethane	$3.5 \cdot 10^{-4}$	5–8
1,1,1-Trichloroethane	$1.3 \cdot 10^{-4}$	5–8
Freon-113	$0.3 \cdot 10^{-4}$	15–20
Carbon tetrachloride	$1.5 \cdot 10^{-4}$	1–3
Ethylene and other carbohydrates	10^{-3}	?
Nitrous oxide	0.3	0.2
Nitrogen oxides	$(3 \cdot 10^{-3}$–$0.015)$	?
Carbon disulphide	$0.3 \cdot 10^{-4}$	?
Carbonyl sulphide	$5 \cdot 10^{-4}$	?
Sulphur dioxide	$1.0 \cdot 10^{-4}$	?
Stratospheric water vapour	3–5	?

*Possible limits of changes in concentrations are shown in parentheses.

Table 4 presents current data on the values of the mixing ratio (weight fraction) for various TGC and the respective rates of increase.[7] The high rate of increase of methane concentration is very important, but the reason for this is not yet clear. It could include intensified anthropogenic emission (due to growing population, the expanding area of paddy fields, burning of vegetation, etc.), and the drop in hydroxyl concentrations (the reaction with OH is the main CH_4 sink in the atmosphere). The factors that determine the rise in nitrous oxide concentrations (combustion of fossil fuels, denitrification of fertilisers, etc.) have also not been sufficiently deeply studied. It seems that fossil fuel combustion and fertiliser denitrification are the major processes increasing the nitrogen oxide content of the lower troposphere.

Table 5. Sensitivity of ground surface air temperature (GSAT) and total ozone content to TGC concentration changes (ppm, parts per million; ppb, parts per billion).

Component	Change in TGC concentration	Change in GSAT, °C	Change in total ozone, %
CO_2	330→600 p.p.m.	1.5–4.5	3.1
Methane	1.7→3.4 p.p.m.	0.2–0.4	2.1–3.3
Chlorocarbons	0→1.0 p.p.b. ($CFCl_3$)*	0.5	−3.3 to −5.5
	0→2.7 p.p.b. (CF_2Cl_2)*		
	0→1.8 p.p.b. ($CFCl_3$)**	1.0	−15.7
	0→5.0 p.p.b. (CF_2Cl_2)**		
	0→1.5 p.p.b. (CH_3CCl_3)**		
Nitrous oxide	0.3→0.6 p.p.m.	0.3–0.4	−8.7 to −10.7
Ozone	doubling of tropospheric concentration	0.9	
Water	3–6 p.p.m. in stratosphere	0.6	

*Steady emissions at 1977 level.
**Doubled steady emissions at 1983 level.

The TCG effect on climate has three known mechanisms: (1) direct radiative action; (2) climatochemical interaction (TCG-created changes in atmospheric chemical composition); (3) dynamics-dependent feedback. Table 5 contains data on the effect of rises in concentration of various TGC on globally averaged values for ground surface air temperatures (GSAT) and on ozone concentration. This evidence was obtained on one-dimensional models.[7] In computer climate modelling, the influence of the tropospheric aerosol is not as a rule considered. However, it should be remembered that it could increase the amount of solar radiation reaching the Earth by 5 W m^{-2}. This is comparable to the effect of doubled CO_2 concentrations. The considerable uncertainty seen in the evaluation of anthropogenic effects on climate is due to the absence of reliable data on the parameters of cloud formation.

Table 6 shows how high the GSAT may rise under the influence of CO_2 and other TGS.[11] Calculations were carried out at predetermined values for relative humidity, the height of the top cloud edge, and the ice cover albedo. A similar study is described in Ref. 2.

Table 6. Possible rise in ground surface air temperature (GSAT) due to CO_2 and other TGC.[11]

Component	GSAT rise, °C	
	1950–1980	1980–2010
CO_2	0.25	0.39
$CO_2+NO_x+CH_4+NO_2+O_3+$ chlorocarbons	0.50	0.80

IV. Aerosol and climate

The atmospheric aerosol is a product of a complicated set of chemical and physical processes. Because these processes are so complex, and the life of the aerosol is relatively short, the chemical and physical characteristics of the latter are highly variable.[4] This variability is so great and the observational data are so fragmentary, that so far it has proved impossible to make a sufficiently reliable estimate of the total balance of different types of aerosol. The available estimates of the strength of the global sources of natural and anthropogenic aerosol are purely tentative.

However, there is no doubt that the estimates for anthropogenic aerosol are the more reliable (it is especially difficult to assess natural aerosol concentrations over inaccessible parts of the ocean and the continents). This is the reason for the low reliability of data on natural/anthropogenic aerosol ratios, though on a global scale the effect of man's economic activity on the sulphur and nitrogen cycles can be clearly seen.

Depending on composition and sources, one can classify natural aerosols as follows: (1) products of sea spray evaporation; (2) mineral dust carried into the atmosphere by wind; (3) volcanic aerosols (both directly emitted into the atmosphere and resulting from gas-phase reactions); (4) particles of biogenic origin (again, both directly emitted or the product of gas-phase reactions); (5) smoke from biota combustion on land; (6) products of natural gas-phase reactions (e.g. sulphates formed by the oxidation of sulphur derived from the ocean surface).

Similarly, there are several types of anthropogenic aerosols: (1) direct industrial emissions (e.g. particles of soot, smoke, and road dust, etc.); (2) products of gas-phase reactions. Besides that, we should distinguish tropospheric and stratospheric (mainly volcanic) aerosols. Aerosols may be formed in gas-phase reactions as a result of the following processes: (1) homogeneous homomolecular nucleation (formation of tiny new liquid or solid stable particles in the gas phase in the presence of only one gaseous component); (2) homogeneous heteromolecular nucleation (a similar process but with two or more gases participating); (3) heterogeneous heteromolecular condensation (already formed particles increasing in size due to gas adsorption).

The photochemical reactions responsible for the initial transformation of the "highly volatile" gas into a gas component which becomes a source of aerosol formation are very complex and as yet have been poorly described. The following processes appear to be the most important: (1) reactions of sulphur dioxide with hydroxyl radicals which lead to the formation of molecules of sulphuric acid and sulphuric aerosol; (2) reactions between non-methane hydrocarbons and ozone and/or hydroxyl radicals. As a

result, aldehydes, alcohols, carbonic and dicarbonic acids are formed (as a rule the secondary products of these reactions interact with nitrogen oxides, forming organic nitrates). Ozone and HO and HO_2 radicals play a very important part in atmospheric chemistry. These radicals are either direct or indirect products of photochemical reactions (this is why the gas-phase processes resulting in particle formation are usually highy dependent on daylight.

Organic particles are some of the most important types of atmospheric aerosols. Because the organic compounds emitted into the atmosphere are so diverse and participate in so many reactions, it is extremely difficult to study them. The concentration of soot particles is very high. Over oceans it reaches mean values of about 0.5 $\mu g\ m^{-3}$, which is comparable with mineral aerosol concentrations. It seems that the origin of the organic aerosol is half natural and half anthropogenic. The ocean accounts for about half of the natural aerosol.

As a rule, the effect of aerosol on various processes is determined by a whole combination of chemical and physical processes. These are significantly influenced by the size of the aerosol particles. In order to obtain an adequate description of a real aerosol, it is necessary to carry out a comprehensive appraisal of its various characteristics. In most cases it is the mass concentration of the aerosol that is determined. But this characteristic is usually the least informative one, because it carries no information about the sources, composition and possible effects of the aerosol.

Aerosol cycles are closely connected with moisture transformation in the atmosphere: clouds and rain play an important part in the formation and transformation of the aerosol and its removal from the atmosphere. The aerosol in its turn has a significant effect on microphysical processes in the clouds. It is not just a coincidence that the life of the aerosol in the lower and upper troposphere is one to two weeks, while that of water vapour is ten days. It is impossible to have a full understanding of the processes of aerosol formation and transformation without reliable data on cloud physics and chemistry. For this reason, studies of the nucleation mechanism are extremely important.

There is good reason to fear that the increase in anthropogenic aerosol content may affect the climate by altering both the global radiation regime and the hydrological cycle. Though there is much evidence that natural and anthropogenic aerosol is dispersed to great distances from its source, there are still no reliable data to confirm the connection between man's economic activity and the trend of the global aerosol content to increase. The great spatiotemporal variability of the aerosol makes it difficult to isolate the anthropogenic component. This would become feasible only after the cause of this variability has been established. But for this an extensive programme of combined studies of the atmospheric aerosol would have to be carried out.

The aerosol affects climate mainly through its influence on the transmission of short and long wavelength radiation. Besides that, climatic changes can induce regional and global alterations in the content and composition of atmospheric aerosols.[4] In addition to the direct radiative effects, one should also take into account the indirect effects, e.g. the effects that are connected with changes in the microphysical characteristics of clouds. The great variability of the spatial distribution and properties of aerosols from different sources (wind erosion of soil, volcanic eruptions, sea foam, forest fires, biospheric and anthropogenic sources, gas-phase reactions, etc.) and shortage of data prevent us from obtaining a reliable picture of aerosol distribution over the globe. The optical properties of the aerosol depend on its concentration, its microstructure, and the complex refractive index.

It is convenient to use four parameters in examining the radiative effects of the aerosol: the relationship between the absorption strength of the particles in the short wavelength radiation range and backward scattering, the long wavelength radiative strength, underlying surface albedo, and the height of the sun. Priority should be given to the following objectives: (1) development of realistic aerosol models suitable for studying climatic sensitivity to aerosol effects; (2) development of parametric models for radiation transmission and the assessment of the radiative effect of aerosols in the above models; (3) application of the parametric models in climatic models in order to evaluate radiative effects; (4) development of the means for obtaining global information on aerosols (recommended for this reason it is that a draft programme for global aerosol monitoring be prepared).

It is especially important for us to study volcanic aerosols, because volcanic eruptions can be regarded as a natural "experiment" that allows us to really test models for the study of climatic effects.[6,7,9,10] Accordingly, it is important that a special international programme of observation, ready for implementation at the next big eruption, should be prepared. This would allow us to obtain comprehensive documentation of the climatic consequences of the eruption and other associated phenomena.

It is only very recently that the first attempts were made to use complicated three-dimensional climatic models to assess the climate-forming role of aerosols. The study by Coaxley and Cass is an interesting example of such computer modelling of the climate.[21]

Usually, the natural tropospheric background aerosol is not taken into account in computer modelling of the general atmospheric circulation (GAC). However, calculations show that the aerosol causes a reduction by 5.0 $W\ m^{-2}$ in the short wavelength radiation balance at the underlying surface level and one of 3.5 $W\ m^{-2}$ at the top of the atmosphere. This means that it creates radiation disturbances of about the same magnitude (but with the opposite sign) as doubling of CO_2 concentration (one should of course also take into account the effect of aerosol on the heat radiation field).

In contrast to the relatively homogeneous global radiative disturbances caused by CO_2, aerosol has a spatially heterogeneous effect on the radiation regime. This is connected with the spatial variability of the aerosol content and the underlying surface albedo, as well as with the varying height of the sun above the horizon. Calculations of climatic sensitivity to the effect of aerosol were carried out on a GAC model developed at the National Centre for Atmospheric Research, USA (NCAR). Present disturbances of short wavelength radiative heat flux similar to that received in July was initially introduced into the model.[21] The distribution of snow cover, sea ice, and ocean surface temperature (OST) were also fixed, as was the sun's height.

As the OST distribution in this model is rigidly fixed, the aerosol should have a weak effect on the temperature field. Special attention was given to isolating the weak aerosol signal from the intrinsic climatic background variability common for this model. An aerosol-created radiative disturbnce equivalent to the above mentioned 1.5 $W\ m^{-2}$ increase in the radiation absorbed by the atmosphere was introduced on the (arbitrary) 201st day of integration. Subsequently it lasted up to 600 days (the same period as the control experiment with no aerosol). An analysis of the averaged results for seven thirty-day intervals from the last 350 arbitrary days was carried out: these intervals were divided by

20-day breaks to ensure the statistical independence of the averaged results.

Examination of the averaged meridional profile of the surface temperature shows that there is a general cooling with local subarctic warming. The aerosol-induced large scale cooling can be considered statistically significant. The average global temperature drop is 0.08 K (with fixed OST this corresponds to a drop of 0.32 K). Computation of the average vertical temperature profile for the northern hemisphere points to a cooling of the whole thickness of the atmosphere. A statistically significant (90% confidence level) cooling of the lower troposphere (1000–500 hPa) amounted to 0.17 K. Computation of the surface temperature on the basis of the energy-balance climate model (EBCM) shows that the changes should be greater by an order of magnitude. This discrepancy can be attributed, first, to the fact that the EBCM takes the albedo feedback into account; second, that it deals with average annual conditions; and third, that it assumes that an equilibrium has been achieved. In a GAC model the latter depends to a great extent on the preset OST.[7] The internal variability of the model itself is extremely important. Without it, errors may arise which will impart to the aerosol effect a wrong sign.[21]

The effect of the atmospheric aerosol (in all its various types) on the development of the temperature field can be assessed with the help of a 15-level global spectral model of the climate (which deals with wavenumbers up to 15). It was developed at the European Centre for Medium Range Weather Forecasting (ECMWF).[22] Fifteen series of integrations over a 90-day period with averaging of the last 30 days (summer weather conditions) at fixed ocean surface temperatures were carried out. Eight of the series were used to evaluate the aerosol effect in different seasons.

Table 7. Optical parameters specific to various types of aerosol.[4]

Type of aerosol	$\tilde{w}_0$ (0.55 μm)	$1-g$	$\tilde{w}_0$ (10 μm)	$\frac{\sigma_e\ (10\ \mu m)}{\sigma_e\ (0.55\ \mu m)}$
Soot	0.209	0.66	0	0.038
Oceanic	1	0.22	0.692	0.250
Dust	0.653	0.12	0.558	1.08
Water soluble	0.957	0.37	0.209	0.019
Marine	0.989	0.26	0.680	0.19
Continental	0.891	0.36	0.486	0.097
Urban	0.647	0.41	0.173	0.033
Sulphuric acid (75% H_2SO_4)	1	0.27	0.010	0.050
Volcanic	0.947	0.30	0.130	0.035

An analysis of the zone-averaged temperature fields indicates that the induced heating of the stratosphere by about 2 K due to the presence of the aerosol is compensated by greater cooling at long wavelengths. This means that in conditions of a stratospheric disturbance, radiative equilibrium is restored. At the same time, in the troposphere (and first of all near the underlying surface) the heating caused by absorption of short wavelength radiation by the aerosol is balanced mainly by nonradiative factors (IR-cooling reduced the heating only by about a quarter). As a result, there is no significant change of the temperature field. The higher the location of the aerosol, the greater its effect.

Two geographical features are typical of the aerosol effect during all four seasons. One is that desert aerosol reduces net radiation. In the Sahara desert and on the Arabian peninsula the net radiation decrease amounts to 60 W m^{-2}. This leads to an appreciable drop in ground surface temperature (up to 3 K near a 20°N., 30°W. location). The other feature that becomes evident in the field of disappearing long wavelength radiation is the reduction of cloud cover in the strip from the north-eastern coast of Brazil to Texas. The maximum reduction of cloud cover observed near 15°N., 50°W. location amounted to 0.1 and caused an abnormal increase in radiation.

A rough averaged estimate gives the following values for aerosol-induced changes in the radiation regime:[1] transmitted long wavelength radiation, 0; global albedo, +0.0075; absorbed short wavelength radiation, −3.5 W m^{-2}; radiation from the ground, −1.5 W m^{-2}; total radiation, −8.5 W m^{-2}; cloud cover −0.007; terrestrial surface temperature, −0.3 K; average ambient temperature, +0.5 K.

The other 7 computer modelling series of the abovementioned 15 were used for evaluating the contributions of 7 different types of aerosol (summer weather conditions). For this purpose, one (arbitrarily chosen) type of aerosol was excluded from the computation in each series. Computations revealed the well defined nonlinear nature of the interaction between different contributions. The sum of the effects differs considerably from the effect of the sum (sometimes even the sign changes). If one compares the overall effect of all types of aerosols with the effect of a single type one can see that the closest parallelism is observed in the case of the stratospheric aerosol. The background tropospheric aerosol takes second place. The stratospheric aerosol inhibits to some degree the Hadley circulation, and also slows down the zonal air transfer in the tropical and subtropical upper troposphere.

Further studies of the atmospheric aerosol and its impact on climate should develop along the following main lines:[23] (1) effect of aerosol on climate; (2) influence of aerosol on long distance observation from satellites of climatic parameters; (3) properties of aerosols; (4) climatology of aerosols; (5) consideration of aerosol in the modelling of climate. Investigation of the climate-forming role of aerosol includes four main objectives: observation of the spatiotemporal variability of the content and properties of the tropospheric and stratospheric aerosol; development of realistic aerosol-radiation models suitable for computer climate modelling; consideration of affects of aerosol in the theory of climate; study of the interdependence between aerosol content and various climate-forming processes (land transformation, glaciation, etc.) for the purpose of developing models that would take interactive account of the presence of aerosol.

The following basic characteristics determine the influence of the aerosol on radiation transmission and its corresponding effect on climate: the bulk extinction coefficient σ_e (data on the vertical profile of σ_e allow us to calculate the optical thickness of the atmosphere τ), the bulk scattering coefficient σ_s (or the albedo of a single scattering $\tilde{\omega}_0 = \sigma_s/\sigma_e$) and the bulk scattering indicatrix. The latter can be approximately described by introducing the indicatrix asymmetry coefficient g. The ratio of the optical thickness in the 8–12 μm transparency window to the averaged optical thickness for the visible range of the spectrum is an important parameter. Some of these parameters for various types of aerosols that conform to the standard atmospheric radiation model developed by the International Radiation Committee are listed in Table 7.[4]

Assessment of the effect of aerosol on climate is reduced in most cases to computation of the influence of the aerosol parameters on the global radiation balance (GRB) and the temperature of the ground surface. Changes in GRB are mainly determined by the albedo variation of the "ground surface–atmosphere" system. In a cloudless atmosphere, the sign of the change in the albedo of the system (increase or decrease) is determined by the content and optical properties of the aerosol (in the first place by the single-scattering albedo), the underlying surface albedo, and the height of the sun. It would appear that, overall, there is a decrease of the overall GRB because of the aerosol-induced increase of the albedo.

The chemistry of OH and HO_2 radicals in the earth's atmosphere

Yu M Gershenzon, S G Zvenigorodskii, V B Rozenshtein
Semenov Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. In the present review the main photochemical mechanisms for reaction of OH and HO_2 with atmospheric components are examined and possible alternative methods of studying them are analysed. The mechanisms governing the change in concentrations of OH and HO_2 radicals cannot be represented without a consideration of other stable and labile minor gas components in the atmosphere. Amongst the latter the most important are ozone, ozone-active radicals and their precursors, stable molecules. In addition to OH and HO_2, NO, NO_2, as well as Cl and ClO are also reactive towards ozone. The destruction cycles for ozone involving these radicals and reactions related to them are also briefly examined in this review together with the heterogeneous processes involving OH and HO_2 that can also substantially affect the gaseous composition of the atmosphere.

The bibliography includes 72 references.

I. Introduction

Atmospheric photochemistry was only recognised and started to develop as an independent branch of chemistry in the middle of the 1970s, although the basic principles of the photochemical theory of the atmosphere had been formulated more than half a century ago.[1,2] This was assisted in many respects by the rapid development of technique for measuring rate constants of fundamental chemical and photochemical processes and of numerical methods for simulating the kinetics of multicomponent chemical systems using computer technology. By using the experience gained in solving kinetic problems in plasma chemistry and photochemistry and also in the calculations of different processes in chemical reactors, it was possible to achieve real progress in the understanding of the nature of chemical processes in the atmosphere and to develop the idea of it as a multicomponent non-equilibrium chemical system. The photochemical models developed from this concept made it possible to predict the gaseous composition of the atmosphere containing many chemical compounds as minor components, which was subsequently confirmed in full-scale experiments. The rapid development of studies in the field of atmospheric chemistry has recently led to its having a reverse effect on traditional areas of chemistry, which has manifested itself in particular in the revision of a whole series of kinetic data of fundamental significance for the representation of photochemical processes in the atmosphere and the development of new experimental methods for measuring rate constants of reactions involving minor gas components.

Although the present-day chemistry of the atmosphere makes use of dozens of molecular and ion-molecule reactions, photodissociation and photoionisation reactions, a special place is occupied amongst them by processes involving OH and HO_2 radicals, which because of their high chemical activity are initiators of a whole range of oxidative reactions in different regions of the atmosphere. The existing theoretical and experimental results provide convincing evidence of the key role of hydrogen radicals in a whole set of problems in atmospheric chemistry. In the lower atmosphere (troposphere) hydroxyl initiates the oxidation of CO, CH_4, C_2H_6, H_2, CH_3Cl, CH_3CCl_3, CH_3Br, H_2S, SO_2, and a number of other components of natural and anthropogenic origin. In the upper atmosphere (stratosphere and mesosphere) reactions involving OH and HO_2 are responsible for changes in the ozone content. Moreover, many questions related to a determination of the strength of atmospheric photochemical sources and sinks of OH and HO_2 and their content in the atmosphere have given rise to considerable controversy.

II. The atmosphere as a multicomponent chemical system

The earth's atmosphere contains a large number of chemical compounds, of which N_2 and O_2 are the most abundant. An important role in atmospheric photochemistry is played by the so-called precursor gases—N_2O, H_2O, CH_4, and freons of natural and anthropogenic origin. When they are oxidised in the lower atmosphere and undergo photodissociation or react with photolysis products in the upper atmosphere, these gases become sources of free radicals and other minor gas components. The content of some of the most important components at different altitudes and their sources are shown in Table 1. More detailed information about the vertical and latitudinal distribution of the minor gas components, their time variations, and determination of the total strengths of their sources can be found in two reviews.[6,7]

In restricting the discussion solely to the neutral components, we shall examine the key channels of photochemical transformation of the gas precursors.

1. Oxygen components

The photodissociation of O_2 results in the formation of atomic oxygen in the ground (^3P) and excited (^1D) states

$$O_2+h\nu\rightarrow O(^1D)+O(^3P),\ (135\ \text{nm} < \lambda < 175\ \text{nm}), \quad (1)$$

$$O_2+h\nu\rightarrow 2O(^3P),\ (175\ \text{nm} < \lambda < 250\ \text{nm}). \quad (2)$$

Ozone is formed as a result of the termolecular reaction

$$O+O_2+M\rightarrow O_3+M, \quad (3)$$

where M are air molecules.

Table 1. Some properties of the most important minor components of the atmosphere.

Gas	Background concentration, mole fractions		Extent of study of global distribution	Main sources	Main sinks
	T	S			
CH_4	$1.6\cdot10^{-6}$	$(15-6)\cdot10^{-7}$	++	B	P
N_2O	$3.2\cdot10^{-7}$	$3\cdot10^{-7}\div3\cdot10^{-10}$	++	B	P
O_3	$(4\div10)\cdot10^{-8}$	$(1\div10)\cdot10^{-6}$	+++	P	P
NO_x	$(4\div10)\cdot10^{-11}$	$1\cdot10^{-10}\div3\cdot10^{-8}$	+++(T), ++(S)	A, P storms	P, W (T)
HNO_3	$(2\div10)\cdot10^{-10}$	$8\cdot10^{-9}\div1\cdot10^{-10}$	++	P	P, W(T)
OH	$1\cdot10^{-13}\div1\cdot10^{-14}$	$3\cdot10^{-13}\div8\cdot10^{-10}$	+	P	P
HO_2	$1\cdot10^{-11}\div1\cdot10^{-14}$	$1\cdot10^{-12}\div6\cdot10^{-10}$	+	P	P
H_2O_2	$1\cdot10^{-9}\div5\cdot10^{-10}$	$1\cdot10^{-12}\div5\cdot10^{-10}$	o	P	P, W (T)
H_2CO	$4\cdot10^{-10}\div2\cdot10^{-11}$	$1\cdot10^{-11}\div1\cdot10^{-10}$	+	P	P
H_2	$5.7\cdot10^{-7}$	$5\cdot10^{-7}\div1\cdot10^{-8}$	++	B, P	P
H_2O	$1\cdot10^{-2}\div2\cdot10^{-5}$	$(1\div6)\cdot10^{-6}$	+++(T), ++(S)	H	W (T), P (S)
CO	$(2\div8)\cdot10^{-8}$	$(0.2\div10)\cdot10^{-8}$	++	A, P	P

Note. The concentrations of minor components are annual average globally mean values and are given mainly from the results of one-dimensional simulation[3] and from the data of four studies.[4-7] Conventional notation: T = troposphere, S = stratosphere, A = anthropogenic, W = rainout, P = photochemical, B = biogenic, o = no reliable measurements, + = individual measurements carried out, ++ = special series of measurements carried out, +++ = regular inspection made, NO_x = NO + NO_2, H = hydrosphere.

Oxygen atoms are consumed in the reactions

$$O+O+M\rightarrow O_2+M, \quad (4)$$

$$O+O_3\rightarrow 2O_2. \quad (5)$$

On photodissociation of ozone, oxygen atoms are again formed in their ground or excited states:

$$O_3+h\nu\rightarrow O_2+O(^3P),\ (\lambda > 320\ \text{nm}), \quad (6)$$

$$O_3+h\nu\rightarrow O_2+O(^1D),\ (\lambda < 310\ \text{nm}). \quad (7)$$

This reaction sequence, proposed by Chapman[1,2] was for a long time considered to be the main route for formation of atmospheric ozone. The sequence of stages (1)–(7) represents a chain reaction for conversion of "odd" oxygen—O and O_3—and it is sometimes called the "odd" oxygen cycle.

2. Sources of OH and HO_2

The reaction of an excited oxygen atom with a water molecule was first regarded as a photochemical source of hydroxyl by Nicolet and Bates.[8,9]

$$H_2O+O(^1D)\rightarrow OH+OH. \quad (8)$$

The formation of OH is also possible in a number of other reactions of $O(^1D)$ with minor atmospheric components:

$$CH_4+O(^1D)\rightarrow CH_3+OH, \quad (9)$$

$$H_2+O(^1D)\rightarrow H+OH. \quad (10)$$

OH and HO_2 are interconverted in reactions involving oxygen species:

$$O_3+OH\rightarrow HO_2+O_2, \quad (11)$$

$$O+HO_2\rightarrow OH+O_2. \quad (12)$$

3. Sources of nitrogen oxides

According to Crutzen[10] the following reaction represents a photochemical source of nitric oxide in the atmosphere:

$$N_2O+O(^1D)\rightarrow 2NO. \quad (13)$$

The concentration of N_2O—a product of the activity of bacteria under anaerobic conditions—rapidly decreases with altitude, ranging from 10^{12} cm^{-3} on the earth's surface to 10^8 cm^{-3} at an altitude of 35–40 km (see Table 1). A photochemical equilibrium in the system NO–NO_2 with a typical time of several tens of seconds[6] is established in the atmosphere, being determined mainly by the following reactions:

$$NO+O_3\rightarrow NO_2+O_2, \quad (14)$$

$$NO_2+O\rightarrow NO+O_2, \quad (15)$$

$$NO_2+h\nu\rightarrow NO+O. \quad (16)$$

The photochemistry of the minor gas components, taking into account the specific nature of reactions in different regions of the atmosphere, will be examined in greater detail in subsequent sections.

4. Main cycles of destruction of ozone

One of the principal problems of atmospheric chemistry is the effect of photochemical processes on the protective layer of ozone. It is evident that with the concentrations of ozone that actually exist in the stratosphere, being several orders higher than the concentration of components that are chemically active towards them (see Table 1), the destruction of ozone may be due solely to catalytic cycles of the type

$$\begin{array}{l} X + O_3 \rightarrow XO + O_2, \\ XO + O \rightarrow X + O_2, \\ \hline O_3 + O \rightarrow O_2 + O_2, \end{array} \quad (17)$$

or

$$\begin{array}{l} X + O_3 \rightarrow XO + O_2, \\ XO + O_3 \rightarrow X + 2\,O_2, \\ \hline 2\,O_3 \rightarrow 3\,O_2, \end{array} \quad (18)$$

where X = OH, NO, or a chlorine atom which is formed in the

stratosphere by photodissociation of freons. The cycles of ozone destruction involving OH, NO, and Cl are known as the hydrogen, nitrogen, and chlorine cycles respectively. Bromine atoms are also highly effective, but they are present in the atmosphere to a much lesser extent than Cl atoms. A large number of studies have been devoted to stratospheric cycles of ozone destruction, amongst which the two fundamental publications of Johnston[11,12] can be given special mention. The efficiency of action of a catalyst molecule in destruction cycles is determined by the concentration of catalyst in the atmosphere, which depends on the rates of its generation and removal from the cycle.[13] The ratio of the rate of destruction of odd oxygen to the rate of removal of catalyst from the cycle represents the chain length and corresponds to the number of O and O_3 molecules destroyed by a single catalyst molecule. The number of recurrences in the cycle can reach 10^6. In the stratosphere the nitrogen, hydrogen, and chlorine cycles (in order of increasing contribution) are active. Terminations of the chains in the cycles occur as a result of a cross interaction of the homogeneous catalysts between each other

$$OH+HO_2 \rightarrow H_2O+O_2,$$

$$OH+NO_2+M \rightarrow HNO_3+M,$$

$$ClO+NO_2+M \rightarrow ClONO_2+M$$

or as a result of the heterogeneous destruction of radicals or reservoir gases (HNO_3, $ClONO_2$) on aerosols and water droplets. However, in a number of cases termination is governed not by chemical reactions but by a process of turbulent transfer, resulting in the removal of the catalyst molecule from the stratosphere. Thus, dynamic processes affect the length of the cycles and prove to be an additional important factor that is necessary to take into consideration in simulating the gaseous composition of the atmosphere.

5. Models of the atmosphere

In photochemical models of the atmosphere use is made of a system of non-stationary diffusion kinetic equations of continuity that generally take the following form:

$$\frac{\partial [n_i]}{\partial t} = P_i - L_i [n_i] - \sum_j \frac{\partial F_{ij}}{\partial x_j}. \qquad (19)$$

Here $[n_i]$ is the concentration of the ith component, P_i and L_i are its photochemical sources and sinks respectively, x_j are Cartesian coordinates, F_{ij} are component fluxes, and t is time. In one-dimensional models, which are the most widely used, only the vertical flux component is considered

$$F_{iz} = K_z [M] \frac{\partial}{\partial z} \left(\frac{[n_i]}{[M]} \right) \qquad (20)$$

where K_z is the globally averaged vertical component of the tensor of the coefficient of diffusion transfer (turbulent or molecular), [M] is the total concentration of air molecules. In the solution of certain problems and at a given ratio between the lifetime in photochemical reactions $\tau_{chem} = 1/L_i$ and the characteristic time of dynamic transfer $\tau_{dyn} = H^2/K_z$, the equation system (19) can be simplified ($H = RT/mg$, the height of uniform atmosphere, R is the gas constant, m is the molecular weight, and g is the acceleration due to gravity).

Quasi-stationary conditions (diagnostic problem), $\partial[n_i]/\partial t = 0$. For long-lived components ($\tau_{dyn} \ll \tau_{chem}$) the system of equations in (19) takes the following form:

$$P_i - L_i [n_i] - \frac{\partial F_{iz}}{\partial z} = 0. \qquad (21)$$

In the case of short-lived components ($\tau_{chem} \ll \tau_{dyn}$) the following photochemical equilibrium is established:

$$P_i - L_i [n_i] = 0. \qquad (22)$$

Within the framework of the diagnostic problem the photochemical balance between the minor gas components is calculated in given regions of the atmosphere and the sensitivity of the equilibrium model concentrations to different perturbation mechanisms and the internal parameters of the model is determined.

Non-equilibrium conditions (prognostic problem). The whole equation system (19) is solved in this case for long-lived components, while in equations for short-lived components the transport term $\partial F_{iz}/\partial z$ can be omitted. The solution of the prognostic problem makes it possible to study the mechanism of the relaxation of the system to equilibrium conditions and to simulate the change in concentration of the minor gas components under atmospheric conditions and to predict the chemical composition in air in the atmosphere at different moments in time.

The relationship between the dynamic and photochemical lifetimes in the atmosphere is relative in nature, since the clearly defined non-uniformity of the atmosphere causes considerable changes (by several orders of magnitude) in τ_{chem} and τ_{dyn}. This factor considerably complicates a numerical solution of system (19), since the retention of the transport component on its right-hand side results in the need to solve a system of second-order partial differential equations when there is a close relationship between the equations because of the high rates of the chemical reactions.

In current photochemical models of the atmosphere, adaptation of the numerical algorithms of system (19) to include transport is considered to be one of the most complex and topical problems. Elucidation of this problem is outside the scope of the present review, but the details can be obtained from four studies.[14–17] Moreover, the need to overcome the difficulties in the calculations had led to the development of a new approach to the analysis of the photochemical parts of the model equations — the application of the concept of families.

This idea involves separating from the whole collection of components included in the scheme of reactions individual groups (families), within which the conditions of photochemical equilibrium are assumed to be fulfilled, whereas dynamic transfer is calculated for the complete family as a whole. This makes it possible to simplify considerably the numerical solution of system (19), having reduced the number of complete equations. In most photochemical models of the atmosphere the following families are usually distinguished: "odd" oxygen $O_y = O(^3P) + O(^1D) + O_3$, "odd" nitrogen $NO_y = N + NO + NO_2 + 2N_2O_5 + HO_2NO_2 + NO_3 + ClONO_2$, "odd" hydrogen $HO_y = H + OH + HO_2 + 2H_2O_2$, and "odd" chlorine $Cl_y = Cl + ClO + HOCl + ClONO_2$. The combination of components on the right sides can be modified according to the choice of reaction scheme and the atmospheric conditions under which they occur. The altitude profiles of the interconversion times for components within a single family [$OH \longleftrightarrow HO_2$ (*1*), $NO \longleftrightarrow NO_2$ (*2*)], the lifetimes of OH radicals (*3*) and families HO_y (*4*) and NO_y (*5*), the conversion time of $HNO_3 \longleftrightarrow NO_y$ (*6*),

and the lifetimes of the chemically inactive gases H_2O and CH_4 are presented in Fig. 1. The high rate of interconversion of the species of the HO_y and NO_y families and the marked difference between the lifetimes of active species and stable gases can clearly be seen in Fig. 1.

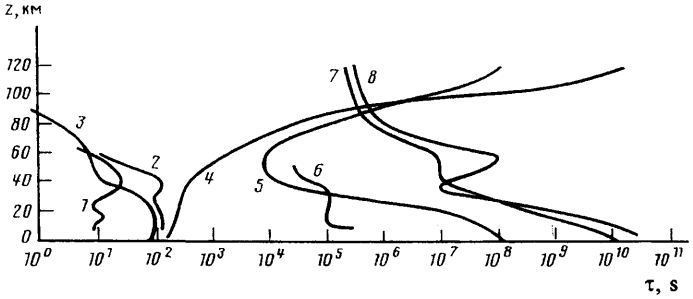

Figure 1. Lifetimes of components of the photochemical reactions of OH (*3*), NO_y (*5*), HO_y (*4*) and the gas precursors CH_4 (*8*) and H_2O (*7*), and also the time for reaching photochemical equilibrium in the systems OH/HO_2 (*1*), NO/NO_2 (*2*), and HNO_3/NO_y (*6*).[6,18]

A distinctive feature of the atmosphere as a medium for photochemical processes is the presence in it of a number of vertically divided regions, each of which is characterised by well-defined specific chemical and physical properties. The lowest region of the atmosphere—the troposphere (up to 12–15 km in altitude)—is characterised by the presence of a considerable amount of water in different aggregate states and an active lower boundary. In photochemical terms this denotes, firstly, the existence of intense heterogeneous reactions involving water droplets, aerosol particles and the earth's surface and, secondly, a greater variability of the chemical composition compared to other regions of the atmosphere as a result of the entry of anthropogenic and natural gases from the lower boundary. In this sense the troposphere may be regarded as a type of filter that limits the transfer of chemically active and water-soluble gas components into the upper layers of the atmosphere.

The stratosphere is considerably less susceptible to the effect of terrestrial sources. The only exception to this is nitrous oxide, from which nitric oxide is formed according to reaction (13), and the "odd" chlorine family, since N_2O and freons, which are inert in the troposphere, are vigorously decomposed in the stratosphere by solar UV radiation. The principal minor gas components O_3, NO, NO_2, OH, HO_2, etc. have only internal photochemical sources in the stratosphere. Also, the stratosphere is quite dry, the relative water vapour content amounting to 10^{-6} and being subject to much smaller variations than in the troposphere. The background concentration of aerosol particles in this region is also small (no more than 20–30 particles per cm^3 in a local maximum—the Junge layer—at an altitude of 16–18 km). All this makes it possible to simulate photochemical processes occurring in the stratosphere in the gas phase, and the stratosphere is characterised as the most favourable region for detailed comparison of theoretical schemes with the results of full-scale observations.

In the upper region of the atmosphere (an altitude range of 50–120 km) the role of photodissociation and photoionisation reactions increases, which helps to increase the concentrations of the atomic components of radicals and causes the formation of excited and ionised molecules and atoms. However, a leading role in the photochemistry of the neutral component of the mesosphere and lower thermosphere is played by OH and HO_2 radicals, which to a considerable extent control the content of components such as O and O_3.

III. Photochemical balance between OH, HO_2, and ozone in the stratosphere

The magnitudes of different sources and sinks of radicals of the hydrogen family are shown in Figs. 2 and 3.

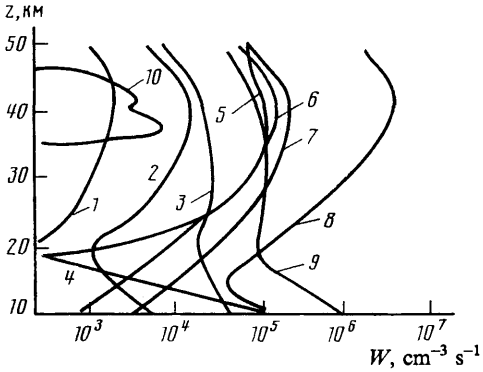

Figure 2. Rates of photochemical formation of radicals of the hydrogen family in the stratosphere:[18] *1*, Cl + H_2; *2*, Cl + H_2CO; *3*, Cl + CH_4; *4*, $CH_3COOH + h\nu \rightarrow CH_3O + OH$; *5*, $H_2O + h\nu \rightarrow H + OH$; *6*, $H_2 + O(^1D)$; *7*, $CH_4 + O(^1D)$; *8*, $H_2O + O(^1D)$; *9*, $H_2CO + h\nu \rightarrow HCO + H$; *10*, generation of OH caused by HNO_3 transport; the rates of processes *5*, *6*, *8*, and *9* are shown on a double scale.

Above 20 km the main source of "odd" hydrogen is provided by the destruction of water vapour

$$O(^1D) + H_2O \rightarrow OH + OH. \quad (23)$$

In the lower stratosphere a similar contribution is made by the photolysis of formaldehyde—one of the intermediates of the oxidation of methane:

$$H_2CO + h\nu \rightarrow HCO + H, (\lambda < 340 \text{ nm}). \quad (24)$$

An alternative channel exists for the photodissociation of formaldehyde

$$H_2CO + h\nu \rightarrow CO + H_2, (\lambda < 340 \text{ nm}) \quad (25)$$

which does not result in the formation of components of the family of "odd" hydrogen. According to Cariolle,[18] the accuracy in determining the quantum yields of these processes is about 40% and for a more rigorous determination of the magnitude of photochemical sources of HO_x in the lower stratosphere careful experimental verification of the relative contribution of each channel in the photodissociation of H_2CO is required.

The photochemical destruction of "odd" hydrogen occurs by a number of processes, resulting in the formation of water molecules:

$$OH+HO_2 \rightarrow H_2O+O_2, \quad (26)$$

$$OH+HNO_3 \rightarrow H_2O+NO_3, \quad (27)$$

$$OH+HO_2NO_2 \rightarrow H_2O+O_2+NO_2. \quad (28)$$

At altitudes of more than 30 km reaction (26) predominates (see Fig. 3). Processes (27) and (28) are predominant at altitudes of 15–30 km. According to one report,[20] the uncertainty factors for the rate constants of these reactions are 1.4 and 2 respectively. Greater accuracy of the kinetic parameters of reactions (23)–(28) is of particular interest currently for processes in the lower stratosphere, where "odd" hydrogen is a key component of the photochemical destruction of ozone.

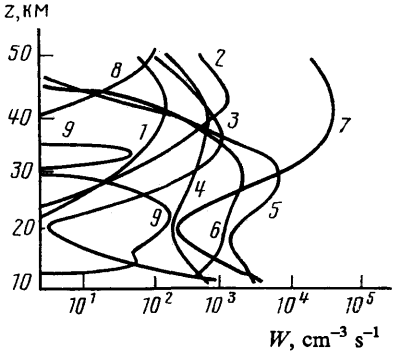

Figure 3. Rates of photochemical destruction of HO_x in the stratosphere[18] (rates of processes *2*, *3*, *5*–*8* are shown on a double scale): *1*, Cl + HO_2; *2*, OH + OH; *3*, OH + H_2O_2; *4*, OH + HCl; *5*, HO_2NO_2 + OH; *6*, OH + HNO_3; *7*, OH + HO_2; *8*, H + HO_2; *9*, depletion of HO_y caused by HNO_3 transport.

The time for equilibrium to be established between the concentrations of OH and HO_2 at stratospheric altitudes does not exceed 10 s (Fig. 1). This is due to the occurrence of a large number of rapid interconversions of OH to HO_2 and the reverse. The vertical profiles of the rates of these reactions are given in Fig. 4.

Despite the comparatively short photochemical lifetimes of the complete family of "odd" hydrogen as a whole and even more so for its individual components (see Fig. 1), dynamic factors can have an averaging effect on the content of HO_y, giving rise to a redistribution of concentrations of the components H_2O and HNO_3 that are important for the balance of HO_y, the lifetimes of which are considerably longer in photochemical reactions.

Virtually all studies in stratospheric photochemistry are in one way or another related to atmospheric ozone—the main component of the oxygen family at these altitudes. The evident progress achieved in this area in recent times does not in any way signify the absence of problems or controversial conclusions, as is reflected by a number of reviews and monographs.[6,7,21–23] We shall only examine certain of those that from our standpoint are of fundamental importance.

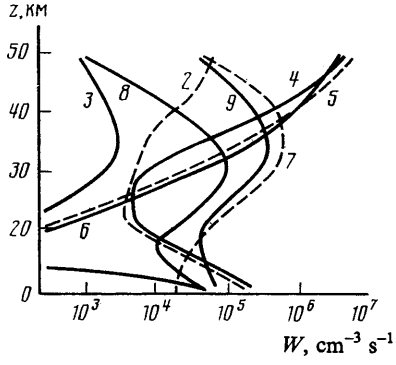

Figure 4. Rates of conversions in the HO_y system (the rates of processes *1* and *3* are shown on a double scale): *1*, $H_2O_2 + h\nu \rightarrow 2OH$; *2*, CO + OH; *3*, $H_2O_2 + h\nu$; *4*, H + O_2 + M; *5*, O + OH; *6*, O + HO_2; *7*, OH + O_3; *8*, HO_2 + O_3; *9*, NO + HO_2.

For several decades the mechanism for the formation and destruction of ozone in the oxygen cycle [reactions (1)–(7)], as proposed by Chapman back in the 1930s, fairly adequately accounted for the results of the majority of full-scale experiments. However, the development of experimental techniques and a refinement of the reaction rate parameters necessitated a review of Chapman's theory, since the stratospheric concentrations of O_3 (particularly in the lower region of the stratosphere) determined by theoretical calculations were considerably higher than the observed concentrations. The possibility that ozone is destroyed in reactions with hydrogen radicals was first demonstrated at the beginning of the 1950s.[8] Subsequently the photochemical destruction of ozone involving nitrogen oxides was examined.[10] A detailed study of the global ozone balance[11] confirmed that in the stratosphere the photochemical generation of ozone substantially exceeds its destruction by the reaction of O + $O_3 \rightarrow 2O_2$, which only accounts for removal of about 20% of the O_3 formed by photolysis of oxygen. The flow of ozone through the tropopause does not exceed 1%. The relative contributions of the nitrogen and hydrogen cycles to the overall photochemical destruction of O_3 (not taking into account the chlorine cycle) from the results of one-dimensional simulation are shown in Table 2. These data are very provisional since similar calculations carried out by different authors suggest that such determinations are sensitive to the rate constants of different reactions and reveal certain quantitative discrepancies. The vertical profiles of the magnitudes of the photochemical destruction of ozone in different cycles are given in Fig. 5.[24] According to current theories the main role in the destruction of ozone in the upper and lower stratosphere is played by the hydrogen cycle while in the middle stratosphere the main role is played by the nitrogen cycle and, to a lesser degree, the hydrogen and chlorine cycles. For the

upper stratosphere the following cycle involving OH and HO_2 is important:

$$\begin{array}{l} OH + O \rightarrow H + O_2, \\ H + O_2 + M \rightarrow HO_2 + M, \\ \hline HO_2 + O \rightarrow OH + O_2, \\ 2O \rightarrow O_2 \end{array} \quad (29)$$

In the mesosphere another series of reactions for the destruction of "odd" oxygen is of greater significance:

$$\begin{array}{l} OH + O \rightarrow H + O_2, \\ H + O_3 \rightarrow OH + O_2, \\ \hline O + O_3 \rightarrow 2O_2. \end{array} \quad (30)$$

In the region of maximum concentration, destruction occurs via the nitrogen cycle:

$$\begin{array}{l} NO + O_3 \rightarrow NO_2 + O_2, \\ NO_2 + O \rightarrow NO + O_2, \\ \hline O + O_3 \rightarrow 2O_2. \end{array} \quad (31)$$

Below 20 km the principle depletion of ozone takes place by a two-step mechanism

$$\begin{array}{l} OH + O_3 \rightarrow HO_2 + O_2, \\ HO_2 + O_3 \rightarrow OH + 2O_2, \\ \hline 2O_3 \rightarrow 3O_2. \end{array} \quad (32)$$

However, at these altitudes when certain ratios exist between the background atmospheric concentrations of components of the families of "odd" nitrogen and hydrogen, the radicals can also become involved in competing "zero" cycles:

$$\begin{array}{l} OH + O_3 \rightarrow HO_2 + O_2, \\ HO_2 + NO \rightarrow NO_2 + OH, \\ NO_2 + h\nu \rightarrow NO + O, \\ O_2 + O + M \rightarrow O_3 + M, \end{array} \quad (33)$$

or

$$\begin{array}{l} OH + O_3 \rightarrow HO_2 + O_2, \\ HO_2 + NO + M \rightarrow HNO_3 + M, \\ HNO_3 + h\nu \rightarrow NO_2 + OH, \\ NO_2 + h\nu \rightarrow NO + O, \\ O_2 + O + M \rightarrow O_3 + M. \end{array} \quad (34)$$

Cycles of this type play the role of a unique buffer, linking the chemically active nitrogen and hydrogen components and reducing the efficiency of ozone destruction.

Moreover, in the lower stratosphere an important photochemical source of ozone is provided by the oxidation of CO, catalysed by nitrogen oxides

$$\begin{array}{l} CO + OH \rightarrow CO_2 + H, \\ H + O_2 + M \rightarrow HO_2 + M, \\ NO + HO_2 \rightarrow OH + NO_2, \\ NO_2 + h\nu \rightarrow NO + O, \\ \hline O + O_2 + M \rightarrow O_3 + M, \\ CO + 2O_2 \rightarrow CO_2 + O_3 \end{array} \quad (35)$$

The source of carbon monoxide in the lower stratosphere (15–20 km) is transport from the troposphere, where CO is mainly formed by oxidation of methane. The strength of this source of ozone (see Table 2) depends mainly on the background concentrations of OH and HO_2 in the lower stratosphere, which remain a subject of controversy even at the present time. That is possibly the reason why in a study of the photochemical balance of the stratosphere[24] carried out using current kinetic data and the results of satellite probing of the global distribution of the most important minor gas components, an imbalance of ozone (an excess of production over destruction in the range 25–60%) was again found at altitudes corresponding to the lower stratosphere. Another source of uncertainty in the determination of the photochemical balance of ozone is the presence of two inconsistent sets of data on the cross-sections of molecular oxygen absorption.[25,26] The use of different data on the cross-sections of O_2 absorption results in a corresponding change in magnitude of the imbalance, as is reflected in Fig. 5. The relative contribution of the different cycles of destruction and formation of ozone can vary considerably as a function of the conditions (altitude, time of day, etc.). For example, the roles of the reactions

$$NO_2 + O \rightarrow NO + O_2,$$

and

$$NO_2 + h\nu \rightarrow NO + O,$$

are quite different. In the first reaction an oxygen atom is consumed while in the second it is formed. Destruction (31) or production (35) of ozone takes place in the nitrogen cycle depending on the ratio of rates of these reactions. Therefore, in the middle stratosphere nitrogen oxides catalyse the destruction of ozone while in the lower stratosphere and in the troposphere the same oxides, being catalysts of the oxidation of CO or hydrocarbons (see Table 2 and below), enable an additional amount of it to be produced.

Table 2. Formation and destruction of ozone in the troposphere (0–14 km) and stratosphere (14–50 km).[39]

Method of calculation	Formation of O_3					Destruction of O_3				
	Process	in the troposphere		in the stratosphere		Process	in the troposphere		in the stratosphere	
		Rate 10^{11} mol cm^{-2} s^{-1}	%	Rate 10^{11} mol cm^{-2} s^{-1}	%		Rate 10^{11} mol cm^{-2} s^{-1}	%	Rate 10^{11} mol cm^{-2} s^{-1}	%
A	Via CH_4	2.9	59.2	0.78	0.3	In the O_x cycle	0.13	0.05	13	5.65
						In the HO_x cycle	3.5	71.4	86	37.4
	Flux from above	2.0	40.8	—	—	In the NO_x cycle	—	—	130	56.5
						Depletion on the earth's surface	1.4	28.6	—	—
B	Via CH_4	33.1	95	12.2	5	In the O_x cycle	—	—	10.1	4,2
						In the HO_x cycle	28.7	83	132	54.5
	Flux from above	1.74	5	—	—	In the NO_x cycle	—	—	100	41.3
						Depletion on the earth's surface	5.9	17	—	—

Note. *A*—when $F_{NO_x} = 10^9$ cm^{-2} s^{-1} and $[CH_4]/[M]$ $(z = 0) = 1.6 \times 10^{-6}$; *B*—when $F_{NO_x} = 10^{10}$ mol cm^{-2} s^{-1} and $[CH_4]/M$ $(z = 0) = 25 \times 10^{-6}$; F_{NO_x} is the flux of nitrogen oxides from the earth's surface, $[CH_4]/[M]$ $(z = 0)$ is the ground level mole fraction of methane.

The depletion of ozone in the chlorine cycle

$$\begin{array}{l} Cl + O_3 \rightarrow ClO + O_2, \\ \underline{O + ClO \rightarrow Cl + O_2,} \\ O + O_3 \rightarrow 2\,O_2 \end{array} \qquad (36)$$

is most significant at high altitudes (30–50 km). The maximum decrease in $[O_3]$ through reactions (36) at the currently accepted levels of freon emissions is estimated at 70% for an altitude of 40 km.[27] In the region of maximum concentration of ozone (20–30 km) the content of ClO and Cl are such ($\sim 10^{-10}$ of [M] at an altitude of 25 km) that the chlorine cycle is not able to compete with the nitrogen cycle (31). Hence, with the flux of freons from the earth currently accepted in calculations, there should be no decrease, rather an increase in $[O_3]$ at altitudes of 15–30 km. The increase in $[O_3]$ is due to the following reaction taking place

$$ClO + NO_2 + M \rightarrow ClONO_2 + M,$$

as a result of which NO_2, the main agent responsible for destruction of ozone, undergoes binding, and hence there is a decrease in photochemical ozone destruction. The increase in concentration of stratospheric ozone due to the flux of freons at altitudes of 15–30 km is 3%. It is thought[27] that at present freons do not cause a significant change in the total content of ozone at middle latitudes, but prognostic calculations indicate the necessity for urgent curtailment of their production.

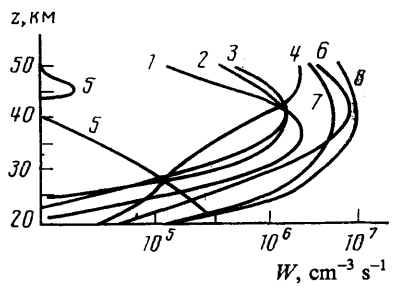

Figure 5. Rates of photochemical destruction and production of ozone in the stratosphere:[24] *1*, nitrogen cycle; *2*, chlorine cycle; *3*, oxygen cycle; *4*, hydrogen cycle; *5*, depletion of ozone through migration; *6*, overall destruction; *7*, overall production at low values of absorption cross-section σ_{O_2}; *8*, the same at higher values of σ_{O_2}.

The decrease in concentration of nitrogen oxides in the middle stratosphere assists an increase in concentration of OH through a reduction in rate of the reaction

$$OH + NO_2 + M \rightarrow HNO_3 + M.$$

On the other hand, an increase in [OH] is inhibited by the reaction

$$OH + HCl \rightarrow H_2O + Cl,$$

in which the primary loss of ClO and Cl is compensated.

Thus, all the families and destruction cycles of ozone prove to be interrelated by a system of complex feedbacks.

An example of the effect of freons is evidently provided by the recently discovered vernal (October–November) "holes" in the ozone layer in Antarctica.[28] The vernal decrease in $[O_3]$ above Antarctica was first noticed in 1979 when it amounted to 10%. From 1959 to 1979 this phenomenon had apparently not yet occurred, while in 1986 the fall in the concentration of ozone was as high as 50%. This recently developed vernal fall in the concentration of Antarctic ozone is most probably due to the effect of ClO radicals.[29–31]

IV. Reactions of OH and HO_2 in the troposphere and oxidation of hydrocarbons. Tropospheric ozone

1. Sources and sinks of "odd" hydrogen in the troposphere

Photochemical sources of HO_x in the troposphere are similar to those in the stratosphere—reaction of water molecules with $O(^1D)$ and the photolysis of formaldehyde, an intermediate in the oxidation of methane. However, under tropospheric conditions, in contrast to those of the stratosphere, it is a considerably more complex task to determine the relative contribution of each of the channels for formation of HO_x in view of the well-known variability of the background concentrations of H_2O and the passage of solar radiation in the region of photodissociation of H_2CO and O_3 and also because of a number of other factors, some of which will be examined below. The mean daily profiles of intensity of the above-mentioned channels under standard atmospheric conditions at 15 and 45 °N are shown in Fig. 6.[32]

The gas-phase photochemical sinks of HO_x in the troposphere are related to reactions in which H_2O molecules are formed:

$$OH + H_2O_2 \rightarrow H_2O + HO_2, \qquad (37)$$

$$OH + CH_3OOH \rightarrow CH_3OO + H_2O, \qquad (38)$$

$$OH + HO_2 \rightarrow H_2O + O_2. \qquad (39)$$

Morover, the presence of water in liquid droplet form in the lower troposphere results in an increased role of heterogeneous processes in the destruction of "odd" hydrogen. This, in particular, denotes that the rainout of a number of reservoir components formed by reactions involving OH and HO_2 in the gas phase

$$OH + NO_2 + M \rightarrow HNO_3 + M, \qquad (40)$$

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2 \qquad (41)$$

constitutes a depletion for the HO_x family in the lower troposphere (Fig. 6).

In the troposphere hydroxyl plays a special role by acting as a unique "cleaning agent". In fact, as follows from Fig. 7, the vast majority of oxidative cycles involving anthropogenic and natural components of gases start with a reaction in which OH participates. At the same time the change in concentrations of hydroxyl and its global distribution have not been studied in sufficient detail in full-scale experiments. This is suggested particularly by the lack of consistency in the results of measurements of the OH content in the troposphere. One of the methods, in which ^{14}CO is used as a tracer for the determination of the average concentrations of tropospheric hydroxyl, yields a value of 1.2×10^6 molecules cm^{-3} for the northern hemisphere.[33] Another, more recent, method is based on measurement of the content of methylchloroform CH_3CCl_3.[34]

This component has an anthropogenic origin that is amenable to global quantitative determination and its sole photochemical tropospheric depletion process is the reaction with OH.

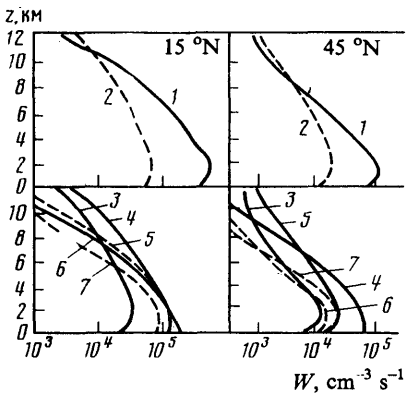

Figure 6. Mean daily rates of photochemical production and destruction of HO_x in the troposphere at 15 and 45 °N:[32] *1*, $O(^1D) + H_2O$; *2*, $H_2CO + h\nu \rightarrow H + HCO$; *3*, $OH + HO_2$; *4*, rainout of H_2O_2; *5*, $OH + H_2O_2$; *6*, $CH_3OH + OH$; *7*, rainout of CH_3OOH.

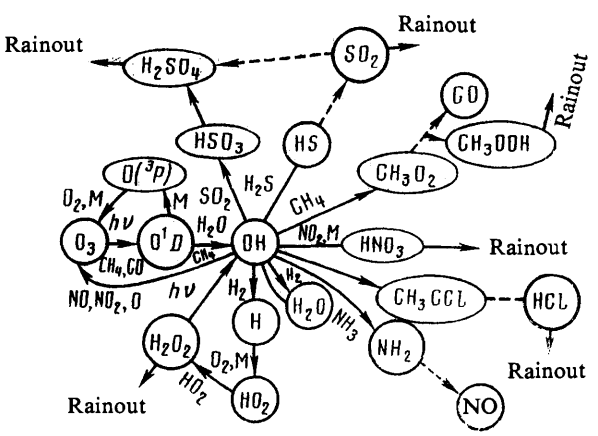

Figure 7. Scheme of photochemical processes involving OH in the troposphere.

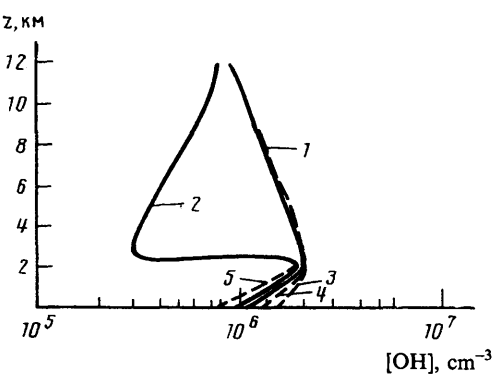
Using this method the concentration of hydroxyl is estimated at $3-5 \times 10^5$ molecules cm^{-3} for the northern hemisphere and $0.8-2 \times 10^6$ molecules cm^{-3} for the southern hemisphere.[34] On the whole lower concentrations were generally obtained in model calculations of the global distribution of hydroxyl which were carried out recently compared to the original theoretical predictions.[35] The considerable differences in the content of tropospheric hydroxyl and hydroperoxyl may be due to certain natural factors. Thus, for example, the content of water vapour in the lower troposphere may change over relatively short intervals of time by a factor of 10 or more.[36] Then, since the rate of photolysis of gases in the atmosphere is determined as a convolution of the form

$$j_{A\rightarrow B} = \int_{\Delta\lambda} \sigma_\lambda^A q_\lambda^{A\rightarrow B} F_\lambda d\lambda, \qquad (42)$$

where $\Delta\lambda$ is the spectroscopic range of photodissociation, σ_λ^A is the cross-section of absorption of gas A at wavelength λ, $q_\lambda^{A\rightarrow B}$ is the quantum yield of the reaction, and F_λ is the flux of radiation at that wavelength. The dependence of the average concentrations of OH and HO_2 on incoming solar radiation is evident. The magnitude of F_λ, calculated from the numerical integration of the equation for transmission of solar radiation in the atmosphere, depends on the content of ozone in a column of the atmosphere, molecular and aerosol dispersion, cloud cover, etc.,[32,37] which in turn leads to different concentrations of OH and HO_2. The role of all of the factors listed above is illustrated in Fig. 8, where calculated profiles of the concentration of hydroxyl in the troposphere under different conditions are shown.



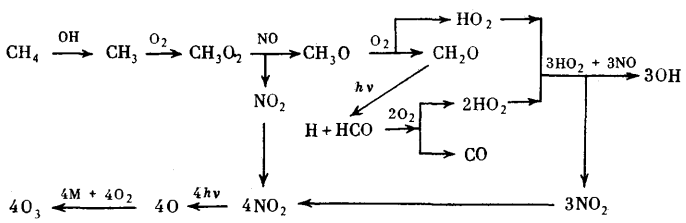


Figure 8. Vertical profiles of the mean daily concentrations of OH for different initial assumptions: *1*, standard atmosphere, contribution of molecular scattering to the photolysis of ozone not taken into account; *2*, profile of H_2O concentration from study of Mastenbrook[36] used for the calculation; *3*, standard atmosphere, contribution of molecular scattering taken into account; *4*, standard atmosphere, molecular scattering and absorption by aerosol taken into account; *5*, standard atmosphere, molecular scattering and absorption by aerosol as well as the effect of globally averaged cloud cover taken into account.

2. Oxidation of methane in the troposphere

The oxidation of CH_4 has a central place amongst the whole set of problems in tropospheric chemistry.[38] It is clear from a simplified scheme of this process that it occurs as a branched chain reaction with degenerate photochemical branching which occurs by photodissociation of formaldehyde. According to scheme (43), three hydroxyl radicals are formed in this case from a single initial one. In reality the branching is of comparatively small importance since a non-radical channel of photodissociation of H_2CO and H_2 and CO exists and because of the high probability of chain termination. It is clear from scheme (43) that on oxidation of a single CH_4 molecule a

maximum of four O_3 molecules can be formed. A further O_3 molecule can be

(43)

formed from carbon monoxide in accordance with reactions (35). In reality less than five ozone molecules are formed by oxidation of a single methane molecule because of destruction of ozone on the earth's surface and in the reactions

$$OH+O_3 \rightarrow HO_2+O_2,$$
$$HO_2+O_3 \rightarrow OH+2O_2,$$

as well as by chain termination in the reactions

$$2HO_2 \rightarrow H_2O_2+O_2,$$
$$HO_2+OH \rightarrow H_2O+O_2,$$
$$OH+NO_2+M \rightarrow HNO_3+M,$$
$$HO_2+NO_2+M \rightarrow HO_2NO_2+M,$$
$$H_2O_2,\ HNO_3,\ HO_2NO_2,\ CH_2O \rightarrow \text{rainout}$$
$$OH,\ HO_2+\text{aerosol} \rightarrow \text{destruction}.$$

The contribution of the oxidation of methane to the production of O_3 in the troposphere was indicated in Table 2. The concentration of the active species OH, HO_2, and O_3 in the troposphere is markedly dependent on the content of methane and on the rate of its oxidation. The latter in turn is a function of the concentration of nitrogen oxides. Nitrogen oxides enter the troposphere directly from the earth and from the stratosphere, where they are formed by the destruction of N_2O. The best agreement between calculations[39] and the results of measuring the average global concentration of tropospheric ozone is achieved when there is a relative concentration of surface methane of 1.6×10^{-6} and a flux of NO_x from the earth of 1×10^{10} molecules $cm^{-2}\ s^{-1}$. The effect of the flux of nitrogen oxides from the earth and the surface concentration of methane on the minor tropospheric components OH, HO_2, O_3, NO_x are illustrated in Figs. 9–11.

The relationship between the photochemical and dynamic factors that affect the shape of the concentration profile of ozone in the troposphere has been the subject of lively debate for more than two decades.[40] At the beginning of the 1960s, when it was established as a result of a series of full-scale measurements that there was a considerable quantity of ozone in the troposphere, its formation there was linked to a flow from the stratosphere through the tropopause (the "transport" theory of tropospheric ozone).[41] At the beginning of the 1980s quite high positive correlations were found between the content of ozone in the troposphere and a number of radioactive products (^7Be) of stratospheric origin,[42] which served as an additional argument in favour of the transport theory. At the end of the 1970s a theory concerning the presence of considerable local photochemical sources of ozone in the troposphere was advanced in parallel.[38] The discovery of the possibility of generating O_3 by oxidising hydrocarbons in the presence of nitrogen oxides was the basis of this. Subsequent measurements and analysis showed, firstly, that there was a close interrelationship between the content of the gas precursors CO and NO_x and the content of ozone in the troposphere and, secondly, that there was an abnormal distribution of O_3 between the northern and southern hemispheres.[43] The latter fact is due, according to current estimates, to a corresponding lack of similarity in global anthropogenic sources of CO and NO_x in the two hemispheres.

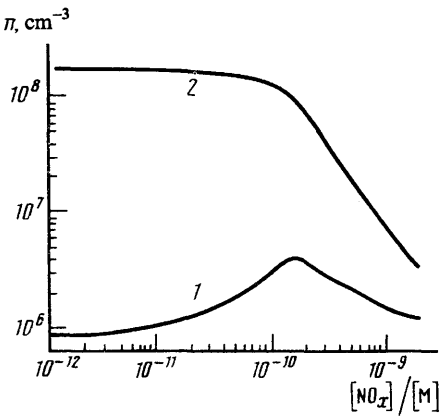

Figure 9. Surface concentrations of OH (*1*) and HO_2 (*2*) as a function of the relative concentration of NO_x, calculated using a one-dimensional model for midday conditions at 45 °N under standard atmospheric conditions ($[CH_4]_{z=0} = 1.6 \times 10^{-6}$).[32]

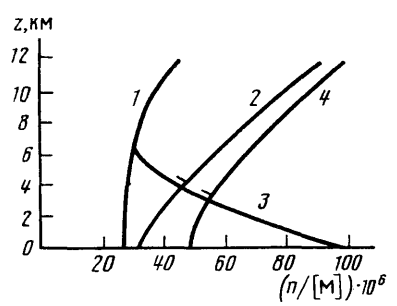

Figure 10. Model concentrations of NO_x (*1* and *3*) and O_3 (*2* and *4*) with different assumptions about the flux of NO_x from the earth's surface[40] and $[CH_4]/[M] = 1.6 \times 10^{-6}$: *1*, *2*, zero flow; *3*, *4*, 2.5×10^{10} molecules $cm^{-2}\ s^{-1}$.

Moreover, there are many feedbacks between the dynamics and photochemistry of tropospheric ozone, which is exhibited particularly in the photochemical destruction of O_3 (including that of stratospheric origin) in the "odd" hydrogen cycle—the main remover of ozone in the troposphere. Furthermore, when there is a high background content of CO, CH_4, and NOx resulting from intense anthropogenic or natural emissions, the role of the photochemical source of ozone increases, the content of O_3 increases

in the troposphere and its flux from the stratosphere to the troposphere decreases because of the levelling out of the vertical gradient of the mole fraction of O_3. The results of numerical simulation, given in Figs. 10 and 11, serve to illustrate the above conclusions. We should note also that all possible types of vertical distribution of ozone concentration in the troposphere observed in full-scale measurements can in principle be simulated by matching the values of the strength of surface sources of the gas precursors of O_3 and the vertical component of the coefficient of turbulent diffusion.[44]

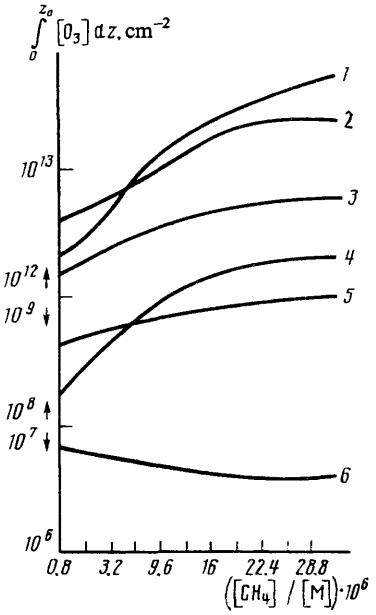

Figure 11. Content of a number of minor gas components in a column of troposphere (0–14 km) as a function of the surface concentrations of methane as determined by one-dimensional simulation.[39] $S_{NO_x} = 10^{10}$ cm^{-2} s^{-1}. *1*, CO × 10^{-5}; *2*, O_3 × 0.5 × 10^{-5}; *3*, NO_2 × 10^{-2}; *4*, CH_3O_2 × 10^{-5}; *5*, HO_2 × 10^{-5}; *6*, OH × 10^{-5}.

The scheme for the oxidation of methane described above can be extended to other members of the hydrocarbon series that are present in the atmosphere of towns and regions with dense anthropogenic sources. Thus, for example, the following sequence of reactions was proposed for ethane:[41]

$$C_2H_6+OH \rightarrow C_2H_5+H_2O,$$
$$C_2H_5+O_2+M \rightarrow C_2H_5O_2+M,$$
$$C_2H_5O_2+NO \rightarrow C_2H_5O+NO_2,$$
$$C_2H_5O+O_2 \rightarrow CH_3CHO+HO_2,$$
$$CH_3CHO+h\nu \rightarrow CH_3+CHO$$

and so on in accordance with the methane oxidation scheme (43). The absence of reliable information about the content of C_2H_6 and the intermediate products of its oxidation in the atmosphere and also the insufficient data on the numerical values of the reaction rate constants makes it difficult to determine the role of C_2H_6, C_3H_8, etc. in the photochemistry of the troposphere.

V. Effect of heterogeneous reactions on the gaseous composition of the troposphere and stratosphere

In addition to a large number of different gases, aerosols also form part of the atmosphere. Aerosols are defined as systems in which particles of a solid and liquid substance are dispersed in a gaseous medium, in this case in the air of the atmosphere.[45,46] The size of aerosol particles can vary from several molecular radii to several tens of microns. It is thought that the main ways of forming aerosols are wind erosion of the soil and the release of particles of salt as a result of the bursting of air bubbles in the break-up of ocean waves. In addition to that, a considerable contribution is provided by anthropogenic sources, the relative proportion of which shows a steady tendency to increase. The difference in the mechanisms of formation and the non-uniformity of the global distribution of sources lead to a considerable variability in chemical composition, size of particles, and concentration of the atmospheric aerosol. In the present review we shall confine ourselves to a very brief examination of the physical and chemical properties of an aerosol in relation to the mechanisms of the possible action of aerosol ensembles on the gaseous composition of different regions of the atmosphere.

1. Tropospheric aerosol

In recent studies of tropospheric aerosol[47–49] it has been customary to subdivide it according to the size of particles into three characteristic bands (modes). The first mode—condensation nuclei—is made up by particles with a radius of less than 0.2 μm, the second mode contains chemically formed and growing particles of radius 0.2–1 μm, and particles with a radius of more than 1μm belong to the third mode—the dispersion mode. The distribution in size of a tropospheric aerosol is usually represented by various approximating relationships using exponential or gamma functions. The vertical profiles of particle concentration can be conveniently defined as exponential functions, the parameters of which are determined from the conditions of the full-scale experiment:

$$N_z = N_0 e^{-z/H_0}, \quad (44)$$

where N_z is the concentration of particles at altitude z, N_0 is their concentration at the surface, H_0 is an experimentally determined parameter. The following model of altitude distribution of an aerosol in the troposphere has been put forward on the basis of statistical treatment of the results of full-scale soundings:[49] the first mode: $N_0 = 10^3-10^5$ cm^{-3}, $H_0 = 2-3$ km; second mode: $N_0 = 5-300$ cm^{-3}, $H_0 = 1.5-2$ km; third mode: $N_0 = 10^{-2}-10^{-4}$ cm^{-3}, $H_0 = 0.5-1$ km. The selection of parameters N_0 and H_0 for specific calculations is determined by the characteristics of the region and the atmospheric conditions (temperature, humidity, etc.).

In the aerosol model of Toon and Pollock[50] the following particle composition in the troposphere was postulated: up to an altitude of 3 km—sulphates 50% [ammonium sulphate $(NH_4)_2SO_4$ is the main form], soil particles (SiO_2, Al_2O_3, Fe_2O_3, etc.) 35%, sea salt (NaCl) 15%; above 3 km—sulphates 60% and soil particles 40%.

According to this model the soil particles have the following elemental composition: SiO_2 53%, Al_2O_3 17%, Fe_2O_3 7%, and other compounds 23%.

2. Stratospheric aerosol

From numerous studies on samples of stratospheric aerosol it can be considered an established fact that its main chemical component under background (undisturbed) conditions is a 75% solution of H_2SO_4. The chemical homogeneity and unimodal distribution of particles by size (usually approximated by the ZOLD function) suggests that a single mechanism for formation of aerosol in the stratosphere predominates It is assumed that this mechanism involves the photochemical conversion of sulphur dioxide and carbonyl sulphide (COS) to sulphuric acid vapour followed by generation of the dispersion fraction as a result of nucleation and condensation. The nature of these processes has so far not been established with sufficient certainty but the most probable channel of SO_2 oxidation is thought to be the following sequence of reactions:

$$SO_2+OH+M\rightarrow HSO_3+M, \quad (45)$$

$$HSO_3+OH\rightarrow H_2O+SO_3 \quad (46)$$

or

$$HSO_3+O_2\rightarrow SO_3+HO_2, \quad (47)$$

$$SO_3+H_2O\rightarrow H_2SO_4. \quad (48)$$

Considerable disturbances of the chemical composition and concentrations of stratospheric aerosol occur after volcanic eruptions. This is due to the injection of a large quantity of sulphur compounds and particles of volcanic ash having a varied elemental composition through the tropopause. Typical profiles of the concentration of aerosol particles under different conditions are shown in Fig. 12.

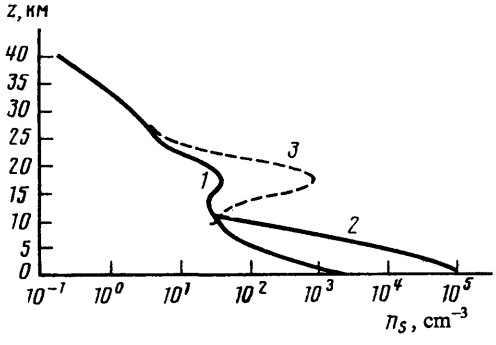

Figure 12. Vertical profiles of the concentration of aerosol particles under different atmospheric conditions: *1*, background (pure) atmosphere; *2*, urban areas; *3*, volcanic clouds.

3. Interaction in the system gases — aerosol. Heterogeneous reactions

Because of the presence of a large number of particles of varied chemical composition in the atmosphere the question as to whether a homogeneous model is applicable for the representation of atmospheric photochemical processes can be raised. In fact, it may be assumed that in a number of situations (urban areas, volcanic aerosol clouds, etc.) heterogeneous destruction on the surface of certain aerosol particles can be an additional form of depletion for chemically active minor gas components. Assuming that under the conditions of a free-molecule system ($Kn = l/\bar{r} \gg 1$) that is characteristic of the stratosphere heterogeneous decomposition occurs as a first-order reaction, the flux of molecules on to a unit surface of aerosol can be given by

$$P = \frac{[n_i]\,\bar{v}}{4} \quad (49)$$

where l is the length of the mean free path, $\bar{r}$ is the average radius of aerosol particles, Kn is the Knudsen number, $\bar{v} = (8RT/\pi\mu)^{1/2}$ is the average arithmetical thermal velocity of the molecules. If γ is the probability of a reaction occurring on collision of a molecule with an aerosol particle, then the number of interactions per unit area per second is

$$Q = \frac{[n_i]\,\bar{v}}{4}\cdot\gamma \quad (50)$$

For a spherical particle the rate of heterogeneous depletion of gas is given by the relationship[51]

$$\frac{d[n_i]}{dt} = -\frac{1}{4}\left\{\frac{8RT}{\pi\mu}\right\}^{1/2}\cdot A\cdot\left(\sum_{j=1}^{k}\gamma_j n_j\right)\cdot[n_i], \quad (51)$$

where $[n_i]$ is the concentration of reacting gas, R is the universal gas constant, T is the temperature, μ is the molecular weight, n_j is the proportion of an aerosol substance of type j relative to the total weight of aerosol, k is the number of possible chemical fractions in the aerosol, $A = 4\pi\bar{r}^2N$ is the specific surface of aerosol particles, $\bar{r}$ is the root-mean-square radius, N is the concentration of aerosol. The last two quantities can be found as the corresponding moments of the given size distribution function of aerosol particles. For small Knudsen numbers ($Kn \lesssim 1$), which is possible in the troposphere, the flow on to a unit of surface can be given by the more general expression:[52]

$$P_1 = \frac{D\,[n_i]}{\bar{r}\,(1+\lambda_0(\gamma))\cdot l/\bar{r}}, \quad (52)$$

where $D = {}^1/_3\bar{v}l$ is the diffusion coefficient, $\lambda_0(\gamma) = \lambda_0(1) + \frac{4(1-\gamma)}{3\gamma}$, with $\lambda_0(1)$ varying monotonically from 1.3 when $Kn \to \infty$ to 0.7 when $Kn = 0$. When $Kn > 1$ and $\gamma \ll 1$ Eqn. (52) transforms to (50). From the relationships obtained it it possible to include heterogeneous processes in equations of the photochemical balance for gas components reacting with the surface of aerosol particles when the corresponding information about their kinetics is available.

4. Model determinations of the possible effect of heterogeneous processes on the gaseous composition of the atmosphere

Before we consider how to represent the results of full-scale studies on the transformation of the gaseous composition of air in the atmosphere in localised zones of aerosol clouds and to a review of laboratory measurements of the rate constants of heterogeneous reactions, let us examine certain boundary measurements obtained with a one-dimensional photochemical model of the atmosphere.[3] The results shown in Figs. 11–13 reflect the degrees of possible variation of the gaseous composition when a model aerosol with given chemical and physical properties is introduced into the

atmosphere. An altitude-invariant profile of the average specific surface of aerosol particles (20 μm^2 cm^{-3}), corresponding to the content of an aerosol in stratospheric volcanic clouds, was used in the calculations.[53] By choosing an altitude-invariant profile it is possible to make a clearer assessment of the sensitivity of different regions of the atmosphere to the introduction of aerosol with given chemical properties. The probability of heterogeneous destruction of the most important minor gas components of the HO_x, O_x, and NO_x families varied over a range of $1-10^{-5}$. The calculations were carried out for a relative surface concentration of methane of 1.6×10^{-6} and a flux of nitrogen oxides $S_{NO_x} = 10^{10}$ molecules cm^{-2} s^{-1}.

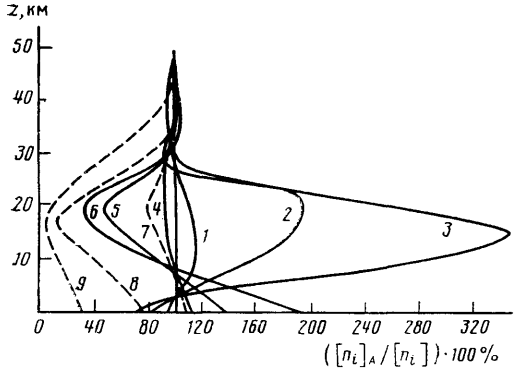

Figure 13. The change in calculated concentrations of certain gases for heterogeneous destruction of O_3 on aerosol particles for different values of y (compared to a purely homogeneous process): *1*, NO_x, $y = 10^{-4}$; *2*, NO_x, $y = 10^{-3}$; *3*, NO_x, $y = 10^{-2}$; *4*, HO_x, $y = 10^{-4}$; *5*, HO_x, $y = 10^{-3}$; *6*, HO_x, $y = 10^{-2}$; *7*, O_3, $y = 10^{-4}$; *8*, O_3, $y = 10^{-3}$; *9*, O_3, $y = 10^{-2}$.

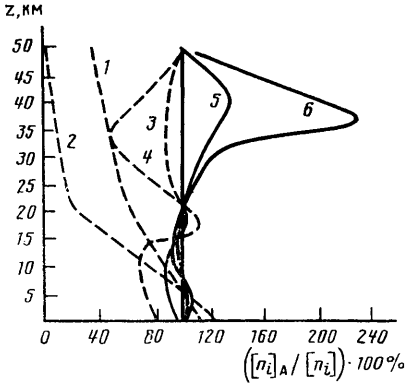

Figure 14. The same as in Fig. 13 but for the case of the destruction of NO_x: *1*, NO_x, $y = 10^{-5}$; *2*, NO_x, $y = 10^{-3}$; *3*, HO_x, $y = 10^{-5}$; *4*, HO_x, $y = 10^{-3}$; *5*, O_3, $y = 10^{-5}$; *6*, O_3, $y = 10^{-3}$.

The changes in concentrations of different gases when an aerosol that destroys O_3 is introduced are shown in Fig. 13. We should note that there is a perceptible deficiency of ozone when $y \geqslant 10^{-4}$, and that heterogeneous destruction of O_3 in the lower stratosphere and upper troposphere (altitude 10–25 km) has the greatest effect on the gas composition. A decrease in the concentration of ozone as a result of its heterogeneous destruction gives rise to a corresponding change in the concentrations of the other components that react with O_3, since the photochemical equilibrium of the system as a whole undergoes an overall shift. It can be established that the calculated deviations in the content of HO_2 and NO_x are generally in good agreement with the main photochemical mechanisms of the stratosphere and troposphere that were examined in the previous sections. Thus, for example, the depletion of ozone in the stratosphere, where the nitrogen cycle is the main cycle of its destruction in the gas phase, results in an increase in concentration of NO_x at these altitudes. In the troposphere, where the destruction of ozone in the hydrogen cycle predominates, the concentration of gases of this family, in particular HO_2, increases.

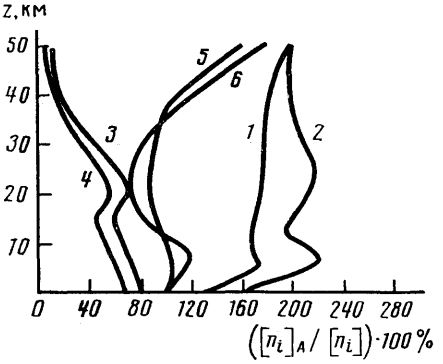

Figure 15. The same as in Fig. 13 but for the case of the destruction of OH: *1*, NO_x, $y = 0.1$; *2*, NO_x, $y = 1$; *3*, OH, $y = 0.1$; *4*, OH, $y = 1$; *5*, O_3, $y = 0.1$; *6*, O_3, $y = 1$.

The second group of model calculations involves a study of the reaction of the system when the heterogeneous destruction of NO_x is introduced (Fig. 14). The critical value of y in this case is about 10^{-5} and the most sensitive region is the upper part of the stratosphere. The nature of the deviations in concentrations of NO_x and HO in Fig. 14 can readily be attributed to the fact that a reduction in $[NO_x]$ causes an increase in O_3 content and increases the consumption of OH and HO_2 in the destruction of ozone. At the same time the content of NO_x increases quite unexpectedly in the lower part of the troposphere despite the development of an additional heterogeneous depletion. This effect may serve as a good illustration of the existence of non-linear feedbacks between the troposphere and stratosphere within the atmospheric photochemical system. In fact the increase in ozone content in the stratosphere as y increases results in a decrease in intensity of the photolysis of ozone via the channel in which $O(^1D)$ is formed in the troposphere because of the screening of UV radiation and hence in a corresponding decrease in the rate of formation of OH by the reaction $H_2O + O(^1D) \rightarrow OH + OH$. This process has the greatest effect on the balance of hydroxyl precisely at altitudes corresponding to the lower troposphere. With a reduced OH content the concentration of NO_x increases, since the effectiveness of its main channel of consumption—$OH + NO_2 + M \rightarrow HNO_3 + M$—is reduced. This

effect more than compensates the heterogeneous destruction of nitrogen oxides in the lower troposphere and becomes more significant when y increases. The calculated data on the change in concentration of the components OH, O_3, NO_x when the heterogeneous destruction of OH is introduced into the model are shown in Fig. 15. A significant change in gaseous composition of the atmosphere is to be expected in this case when $y = 0.1-1$. This change is more apparent in the upper part of the stratosphere, which is quite in accordance with theory. Firstly, the lifetime of HO_x in this region increases in photochemical gas-phase reactions (see Fig. 1), and as a result the relative contribution of heterogeneous depletion to the total destruction of HO_x increases. Secondly, since the hydrogen cycle plays a predominant part in the destruction of ozone in the upper stratosphere, the concentration of O_x increases significantly at altitudes of the order of 40 km when the content of the components at the HO_x family decreases. The introduction of other minor gas components into the balanced equations of heterogeneous depletion has only a slight effect on the calculated concentrations if the aerosol has a specific surface of 20 μm^2 cm^{-3} that is typical of the stratosphere.

Table 3. Probabilities of capture of atmospheric gases by surfaces of different materials.

Gas	Chemical surface	Probability of destruction	Refs.
H_2O_2	H_2SO_4	$7.8\cdot10^{-4}$	[54]
HNO_3	H_2SO_4	$2.4\cdot10^{-4}$	[54]
HO_2NO_2	H_2SO_4	$2.7\cdot10^{-5}$	[54]
N_2O_5	H_2SO_4	$3.8\cdot10^{-5}$	[54]
H_2O	H_2SO_4	$2\cdot10^{-3}$	[54]
NH_3	H_2SO_4	10^{-3}	[54]
OH	H_2SO_4	$5\cdot10^{-4}$	[54]
OH	H_2SO_4	0,1—1	[55]
O_3	Al_2O_3	$(2.3\div8.8)\cdot10^{-5}$	[56]
O_3	H_2SO_4	$\leqslant10^{-8}$	[57]
O_3	H_2SO_4	10^{-10}	[58]
O_3	SiO_2	$\leqslant10^{-4}$	[54]
O_3	Al_2O_3	$5\cdot10^{-5}$	[59]
O_3	SiO_2	10^{-9}	[58]
HO_2	Al_2O_3, Fe_2O_3	$3\cdot10^{-3}$	[60]
OH	SiO_2	$\sim10^{-2}$	[55]

5. Laboratory experiments and stratospheric processes

Examination of models of the chemical composition and the vertical distribution of atmospheric aerosol in combination with the results of numerical simulation indicate that a study of the reactions, of O_3, OH, and NO_x with the surfaces of the most common aerosol particles — H_2SO_4, SiO_2, Al_2O_3, and Fe_2O_3 — is of the greatest interest. In contrast to the rate constants of reactions in the gas phase, comparatively few constants of heterogeneous reactions have been measured, and they have mainly been obtained at room temperature. The existing values, as presented in Table 3, have been obtained during the last 15 years using various experimental techniques. Some of them have been repeatedly verified over this period, since the photochemical balance of ozone is considerably dependent on them. Thus, for example, according to Harker and Ho,[57] the decomposition of O_3 on H_2SO_4 can make a significant contribution to the destruction of stratospheric ozone under background conditions if $\gamma_{O_3} \gtrsim 10^{-4}$. Subsequent experimental measurements[57,58] showed that it does not exceed 10^{-8} even when the surface of sulphuric acid is activated with various metal cations. Thus, even in the presence of volcanic sulphuric acid clouds when the concentration of stratospheric aerosol increases by a factor of 10—100, this process cannot have any substantial effect on ozone depletion. At the same time the results of full-scale probing of the gaseous composition of the stratosphere in localised zones of volcanic aerosol clouds after the powerful eruptions of Agung, St. Helens, and El Chichón suggest that steady negative correlations exist between the concentrations of ozone and aerosol.[61—63] From the value of the probability (0.1—1) of the destruction of OH on the surface of H_2SO_4 obtained using EPR/LMR, Elanskii[63] et al. proposed another mechanism for the deficit of ozone occurring in these situations. It is known from the experimental data that the deficit of ozone in a cloud, reaching a maximum of 30% and with an average value of 7—8%, occurs when the cloud is centred at an altitude of about 20 km. The nitrogen cycle of ozone destruction is characteristic of the photochemistry of the stratosphere in this region, and the conversion of active nitrogen oxides to the buffer components HNO_3 and HO_2NO_2, which are inert towards O_3, mainly involves the members of the family of "odd" hydrogen:

$$OH+NO_2+M\rightarrow HNO_3+M$$

and

$$HO_2+NO_2+M\rightarrow HO_2NO_2+M.$$

It is evident that when there is intense heterogeneous depletion of OH on the volcancic sulphuric acid aerosol, the content of hydroxyl and hydroperoxyl must decrease and the concentrations of nitrogen oxides increase in parallel intensifying the destruction of ozone in the gas-phase photochemical "odd" nitrogen cycle. This mechanism was taken as the basis for a one-dimensional simulation[63] (Fig. 16) using actual aerosol profiles obtained in probes of volcanic clouds after an eruption of the El Chichón volcano.[53] Another probable mechanism for the destruction of O_3 involves its decomposition on an aerosol containing Al_2O_3. However, although the aerosol particles containing Al_2O_3 can pass into the stratosphere together with volcanic ash during powerful eruptions, they are not likely to have a significant effect on ozone because of rapid precipitation. The emission of this type of aerosol into the stratosphere in quantities that are capable of giving rise to a competing gas-phase depletion are only possible with intense artificial effects, in particular, from nuclear explosions on the earth's surface. This situation has been analysed in detail by Zvenigorodskii et al.[3]

In summing up let us make two observations of a general nature.

1) Despite the fact that the decomposition constants of O_3 on Al_2O_3 obtained by different authors are in good agreement, the question of the degree of correspondence between the properties of a laboratory sample (pellets of pure Al_2O_3) and those of a real aerosol, in which Al_2O_3 is in the form of conglomerates and undergoes natural ageing and the effect of water vapour, remains open.

2) It is unlikely that the catalytic properties of a stratospheric sulphuric acid aerosol differ very much from the properties of the surface of H_2SO_4 in laboratory experiments. Therefore, the experimentally determined rate constants of the reactions of different gases with H_2SO_4 can be reliably used in solving problems of

atmospheric chemistry. Nevertheless, there is no significant information about the catalytic activity of H_2SO_4 towards nitrogen oxides.

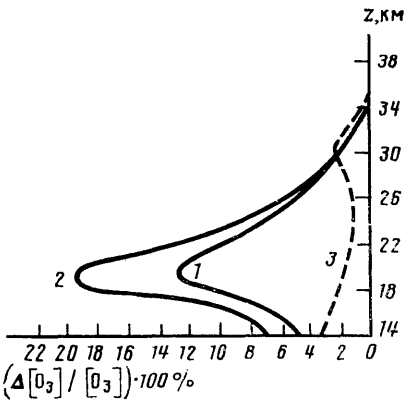

Figure 16. Decrease in the concentrations of ozone in the stratosphere in relation to the capacity and altitude of the maximum of a volcanic aerosol cloud:[63] *1*, maximum at an altitude of 20 km, A_{max} = 20 μm² cm⁻³; *2*, the same, A_{max} = 50 μm² cm⁻³; *3*, maximum at an altitude of 30 km, A_{max} = 20 μm² cm⁻³.

6. Heterogeneous processes in the troposphere

The aerosol fraction in the troposphere varies according to its chemical composition and aggregate state—droplets of moisture and ice crystals, irrigated and unirrigated aerosol particles. If the well-defined variability in the composition of a tropospheric aerosol is also taken into account, this all considerably hinders determinations of the effect of heterogeneous factors on photochemical processes in this region. Moreover, the active lower boundary—the underlying surface—is a sink on a global scale for a whole number of gas components. Originally, in studying heterogeneous processes in the troposphere research workers confined themselves to two mechanisms: rainout of gases that are soluble in water by precipitation (wet rainout) and the destruction of gas-phase components on the underlying surface (dry deposition). The dry deposition of gases occurs through their adsorption or destruction in chemical reactions on the surface. The evident consequence of a chemically active lower boundary is the presence of a concentration gradient and diffusive flow of molecules directed towards the surface that react with the earth, which in atmospheric chemistry can be identified with the "deposition" of a complete column of reacting gas. The rates of dry deposition of a number of gases have been measured under artificial conditions[64–66] above different underlying surfaces. This process can have a definite effect on the content of chemically active gases in the lower part of the troposphere, for example, in seasonal changes in the nature of the surface (Fig. 17).[67]

Wet rainout in the troposphere was for a long time reduced to the removal of precipitation of soluble gases and those reacting in water. A typical time for this process according to initial estimates corresponds to the time of global cycle of tropospheric moisture and amounts to about 10 days. It is evident that such a scheme for representing heterogeneous processes in the troposphere, also accepted in a number of current photochemical models designed for studying mechanisms of the global distribution of gas components, is a considerable simplification of the real picture.

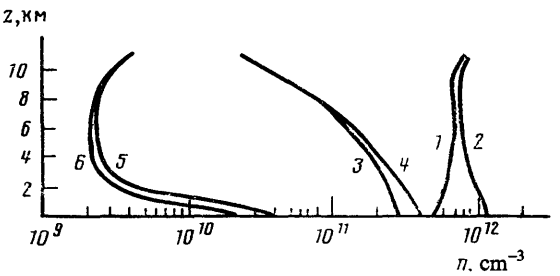

Figure 17. Vertical profiles, of O_3, NO_x, and HO_2 concentrations in the troposphere for different rates of ozone deposition on the surface:[67] *1*, concentration of O_3 for a rate of deposition W_{O_3} = 0.6 cm s⁻¹ (earth); *2*, the same for W_{O_3} = 0.02 cm s⁻¹ (snow); *3*, $[HO_x] \times 10^3$, W_{O_3} = 0.06 cm s⁻¹ (earth); *4*, $[HO_x] \times 10^3$, W_{O_3} = 0.02 cm s⁻¹ (snow); *5*, $[NO_x] \times 10$, W_{O_3} = 0.6 cm s⁻¹ (earth); *6*, $[NO_x] \times 10$, W_{O_3} = 0.02 cm s⁻¹ (snow).

Firstly, atmospheric gases have varying solubility, as determined by Henry's constant.

Secondly, the partial return to the atmosphere of gases that are not dissociated in water on evaporation of water droplets is not taken into account.

Thirdly, an important role is played in the troposphere by heterogeneous processes involving an irrigated and unirrigated aerosol.

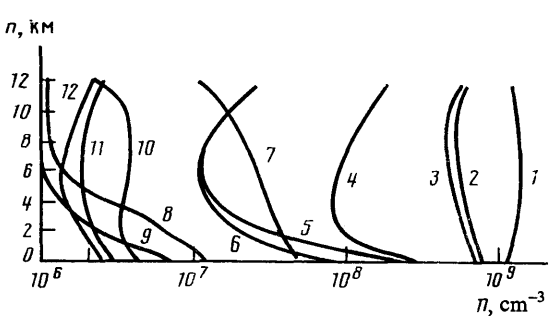

Figure 18. Calculated concentrations of HNO_3 (*1–4*), NO_x (*5–8*), and HO_x (*9–12*) for rate constants of rainout K_z, s⁻¹ of: 0 (*1, 5, 9*); 1.15 × 10⁻⁶ (*2, 6, 10*); 5 × 10⁻⁶ (*3, 7, 11*); 10⁻⁵ (*4, 8, 12*).[67]

It is clear that a description of heterogeneous chemical processes in the troposphere must be based on a consideration of all types of reactions taking into account the individual properties of a reacting

gas. Up to the present time the complete absence of experimental data on the probabilities of capture of molecules which interact with an aqueous surface remains the main problem. The calculation of the integrated rate of washout of gases in atmospheric cloud and aerosol systems based on the solution of kinetic equations for a single particle followed by generalising it for an ensemble of particles with a given size distribution function does not present major difficulties, but in all the overall relationships thus obtained the probability of capture appears as a parameter.[68] The only current method for independent determination of the rates of rainout is based on measurement of the chemical composition of the deposits. However, in this case other sources of uncertainty arise, related to assumptions about the exposure time of the droplet, the chemistry of liquid-phase processes, and errors in the measurements themselves, which considerably reduce the accuracy of the estimates obtained.

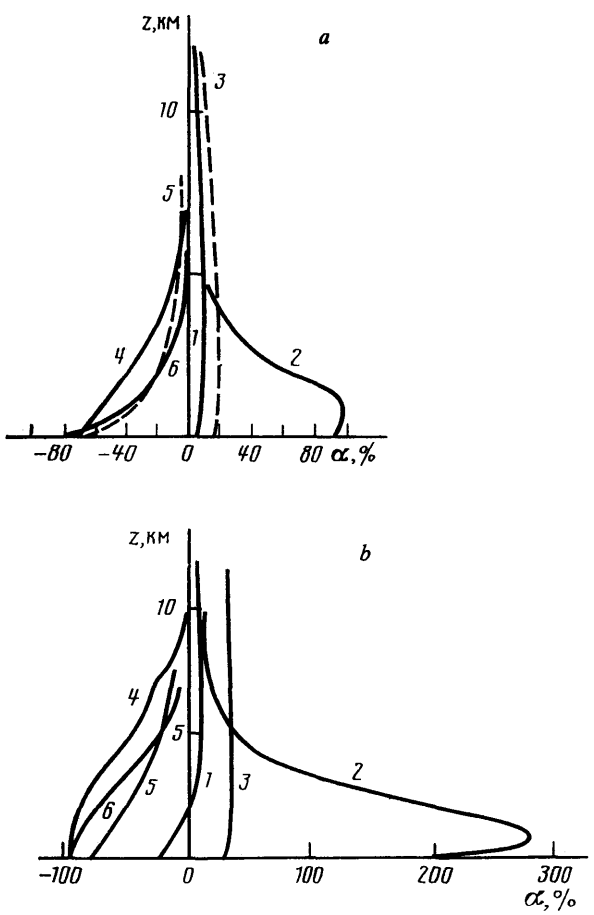

Figure 19. Change in the relative concentrations of O_3 (*1*), NO_2 (*2*), CO (*3*), H_2O_2 (*4*), OH (*5*), and HO_2 (*6*) when the destruction of OH (*a*) and HO_2 (*b*) radicals on aerosols is taken into account: *a*, $\gamma_{OH} = 1$; $N = 5 \times 10^4 \exp(-z)$ cm^{-3}; *b*, $\gamma_{HO_2} = 8 \times 10^{-3}$; $N = 5 \times 10^5 \exp(-z)$ cm^3.

Because of these factors, it would seem natural to assume that the washout constants in the existing photochemical models of the troposphere must differ considerably. And in fact, a scatter of the order of magnitude of 10^{-5} to 10^{-6} s^{-1} is reached. Thus, Logan[32] recommended that for the simulation of wet rainout of H_2O_2, HNO_2, HNO_3, HO_2NO_2, H_2CO, and CH_3OOH the following values of the constants should be used: up to an altitude of $z = 4$ km, $k = 2.31 \times 10^{-6} \exp(1.6-0.4z)$ s^{-1}; and when $z > 4$ km, $k = 2.31 \times 10^{-6}$ s^{-1}. The rate constant of the additional depletion of H_2O_2 on an irrigated aerosol in the continental troposphere was given by the expression: $2 \times 10^{-6} \exp(-z/1.2) + 4 \times 10^{-8}$ s^{-1}. The latter relationship was obtained with the assumption that the whole aerosol is irrigated, H_2O_2 is irreversibly destroyed in the aqueous shell of aerosol particles by interacting with the ferrous cation Fe^{2+} and the probability of capture is the same as for the surface of sulphuric acid,[54] namely 10^{-3}. It has already been mentioned that a general deficiency of current photochemical models of the troposphere that represent rainout of gases by precipitation is the use of the same relationships for a whole series of components that are susceptible to rainout for a determination of the parameters of this process, without taking into account their individual properties. At the same time even the few results of analysis of the chemical composition of deposits show that in the hydrocarbon series, for example, H_2CO is rained out to a much lesser extent than other members of the series, since the concentrations of formaldehyde in the analysed samples of rainwater are low.[69,70] Moreover, as is demonstrated by model calculations, the concentrations of the minor gases in the lower part of the troposphere are very dependent on the rainout rate constants. Numerical experiments to determine the concentrations of minor gases when the rate constants of rainout vary over the wide range of $0-10^{-5}$ s^{-1} (Fig. 18) show that in this case these concentrations vary over several hundred percent.[67]

In recent times because of the problem of acid rain, composite photochemical models of the troposphere that combine theories about the chemical processes in the vapour and liquid phases have started to be developed.[70,71] However, a weak point of these models is still the same lack of data on the coefficients of capture.

Heterogeneous reactions on the surface of an unirrigated aerosol should also be made the subject of careful study. As was indicated earlier, attempts to examine the interaction between an aerosol and gases in the atmosphere that are based on the assumption that the whole aerosol is irrigated frequently yield results that do not correspond to current ideas about the physicochemical processes in this region. The clearest example is provided by the study of Isaksen and Crutzen,[72] in which a similar approach using the assumption of an aerosol sink results in the deviations of the calculated concentrations of H_2O_2 and HO_2 from those observed reaching two orders of magnitudes. The incorrectness of such an approach is suggested also by the results of many experiments on irrigation of aerosols in clouds and mists. Thus, for example, it was found that 100% irrigation only occurs for large submicron particles, whereas out of the total number of particles with a radius of < 0.4 μm, in which about 90% of the total surface of a stratospheric aerosol is concentrated, not more than 2% is irrigated.[46] Thus, it is evident that the role which an unirrigated tropospheric aerosol plays in heterogeneous chemical processes in the troposphere is at least comparable to the role of irrigated and droplet aerosols. Gershenzon et al.[4] studied the change in gaseous composition of the troposphere taking into account the possibility of heterogeneous destruction of OH and HO_2 radicals on the surface of model aerosols. From the results of two studies[55,60] typical values for a tropospheric aerosol are $\gamma_{OH} = 0.1-1$ and $\gamma_{HO_2} = 10^{-3}-10^{-2}$. The results of a calculation[4] of the values of $\alpha = [(n_A - n)/n] \times 100$

(n_A and n are the concentrations of the minor components in aerosol and molecular atmospheres respectively) are presented in Fig. 19. The calculations were carried out for aerosols with an average radius of 10^{-5} for an altitude distribution of their concentration in accordance with the equation $N = N_0 \exp(-z)$. The results suggest that there is a decrease in concentrations of the active compounds of the hydrogen family (OH, HO_2, H_2O_2) and an increase in content of CO, O_3, and NO_x in the aerosol troposphere as a result of the heterogeneous destruction of OH and HO_2.

Expert evaluation of kinetic data for use in research on atmospheric modelling

J A Kerr
Federal Institute of Water Resources, Switzerland

ABSTRACT. The development of data banks on chemical kinetics and photochemistry for use in modelling the atmosphere is examined. A table representing a compilation of data on the chemistry of the formation of stratospheric ozone in which the reactions are grouped into families (O_x, HO_x, NO_x, ClO_x, and organic reactions) is published. An approach to the selection of the recommended values of kinetic and photochemical quantities, developed by CODATA/IUPAC experts, is described in detail. The review is completed by a brief discussion of the immediate prospects for the development of expert evaluations of data for atmospheric chemistry.

The bibliography includes 40 references.

I. Introduction

Studies on expert evaluations of kinetic data for use in atmospheric modelling were initiated in 1971 by the Information Centre on Chemical Kinetics at the National Bureau of Standards (Washington). They were stimulated by the suggestion that, as a consequence of chemical reactions involving nitric oxide ejected by supersonic aeroplanes, a significant decrease in the ozone content of the stratosphere might take place[1,2]. Studies on expert evaluations of kinetic data at the National Bureau of Standards soon included in the Program for the Evaluation of Influences on the Climate (Department of Transportation of the USA). This program was started in 1970–1971 with the aim of determining the possible ecological consequences of the pollution of the stratosphere by aeroplane exhausts. A characteristic feature of the program involved studies designed to estimate the photochemical and kinetic parameters of stratospheric reactions: these investigations were published in the open press and also in the reports of the National Bureau of Standards[3,4].

In September 1975 the CODATA Expert Panel on Chemical Kinetics held an international symposium on "Kinetic Data for the Upper and Lower Atmosphere". This symposium and its published proceedings[5] constituted the cornerstone in establishing the importance of kinetic information for the chemistry of the atmosphere.

In 1976 the National Aeronautics and Space Administration of the USA (NASA) assumed the duty of assessing the influence of the released **u**reons on stratospheric ozone. The next landmark in the creation of surveys of data on atmospheric processes was the NASA publication 1010 "Chlorofluoromethanes and the Stratosphere"[6]. This publication became the first of the regular surveys of kinetic and photochemical data for stratospheric modelling which are prepared by the NASA Expert Panel, and is published by the Jet Propulsion Laboratory in Pasadena (California). Approximately one review has been published every 18 months in this series since 1977. Communication No. 9 has already been published and work of this kind is being continued.

Together with the start of the NASA publications, the necessity for organising an international Expert Panel for the preparation of surveys of kinetic parameters for reactions relevant to atmospheric chemistry was recognised. The principal feature of this approach was the global nature of the object of study. The CODATA Working Group on Chemical Kinetics has been newly created under the aegis of the International Council of Scientific Societies. The first publication of this international group[8] dates back to 1980. Supplements were issued in 1982, 1984, and 1989.[9] The last of these communications was prepared by the IUPAC Subcommittee for the evaluation of data for atmospheric chemistry which has replaced the CODATA Working Group and has continued to work on surveys of kinetic data.

The NASA Expert Panel and the CODATA/IUPAC Group have collaborated closely during the last 13 years. The NASA surveys are published more frequently and are aimed at stratospheric chemistry whereas the CODATA/IUPAC surveys include both stratospheric and tropospheric reactions. Both groups have prepared a general survey of data for inclusion in the report by the World Meteorological Organisation "the Stratosphere" [10].

The creation of these two independent Expert Panels, supplementing one another, has made it possible to solve the difficult problem of evaluating kinetic and photochemical data on a collective basis. The NASA Panel (USA) has at its disposal the national system for the dissemination of data whereas the IUPAC International Subcommittee has a broader base but publishes its surveys more rarely.

This communication considers the approach used and the results of the surveys of the IUPAC Subcommittee on Kinetic and Photochemical Data for Atmospheric Chemistry.

As an illustration, a list of data for one of the reactions is given and there is also a complete list of reactions together with the recommended rate constants and errors

II. Families of reactions in atmospheric chemistry

In 1930 Chapman put forward a photochemical theory of the formation of stratospheric ozone in reactions involving species containing oxygen alone[11,12]:

$$O_2 + h\nu \rightarrow O + O, \quad (1)$$

$$O + O_2 + M \rightarrow O_3 + M, \quad (2)$$

$$O_3 + h\nu \rightarrow O + O_2, \quad (3)$$

$$O + O_3 \rightarrow 2O_2. \quad (4)$$

These reactions constitute the basis of the O_x family. Reactions of vibrationally and electronically excited species were recently added to this family (see Section V).

The measurements of the rate constants for reaction (4) carried out in the 1950s showed that the reaction is much slower than had been believed at the time when Chapman proposed his theory. The concentration of ozone calculated on the basis of reactions (1)–(4) by the method of stationary concentrations proved to be higher than that observed in the atmosphere. In order to account for this discrepancy, Hunt[13] suggested that the HO_x species (H, HO, HO_2), first introduced by Bates and Nicolet[14], participate in the ozone destruction catalytic cycles:

$$H + O_3 \rightarrow HO + O_2, \quad (5)$$

$$\frac{HO + O \rightarrow H + O_2,}{\text{total } O + O_3 = 2O_2.} \quad (6)$$

$$HO + O_3 \rightarrow HO_2 + O_2, \quad (7)$$

$$\frac{HO_2 + O \rightarrow HO + O_2,}{O + O_3 = 2O_2.} \quad (8)$$

$$HO_2 + O_3 \rightarrow HO + 2O_2, \quad (9)$$

$$\frac{HO + O_3 \rightarrow HO_2 + O_2,}{O_3 + O_3 = 3O_2.} \quad (10)$$

Reactions (5)–(10) form part of the family of the HO_x reactions presented below in Table 2.

The next step in the development of the theory of the photochemical formation of ozone occurred at the beginning of the 1970s when Crutzen[1] proposed a catalytic cycle with participation of NO_x. Johnston[2] suggested soon afterwards that the nitrogen oxides from the exhausts of supersonic aeroplanes lead to the depletion of the ozone layer, which has serious consequences as a result of the increase in the transparency of the atmosphere to ultraviolet rays.

$$NO + O_3 \rightarrow NO_2 + O_2, \quad (11)$$

$$\frac{NO_2 + O \rightarrow NO + O_2,}{O + O_3 = 2O_2.} \quad (12)$$

The family of the NO_x reactions, presented below in Table 2, was thus introduced into consideration. It shows that there is an appreciable interaction between the catalytic NO_x cycle, the HO_x and ClO_x families (see below). One of the pathways in such interaction involves reactions which have a direct influence on the conversion of the NO_x and ClO_x species into other active forms, for example:

$$HO_2 + NO \rightarrow HO + NO_2, \quad (13)$$

$$ClO + NO \rightarrow Cl + NO_2. \quad (14)$$

The hypothesis by Molina and Rowland[15] that the chlorine atoms formed on photochemical decomposition of chlorofluorocarbons (CFC) in the upper atmosphere can lead to an appreciable destruction of ozone in the catalytic cycle

$$Cl + O_3 \rightarrow ClO + O_2, \quad (15)$$

$$\frac{ClO + O \rightarrow Cl + O_2,}{O + O_3 = 2O_2.} \quad (16)$$

made the problem of the decomposition of the ozone layer still more acute. Subsequently an appreciable number of supplementary reactions were added to the ClO_x family (see Table 2 below).

Chlorofluorocarbons accumulate rapidly in the atmosphere and, because of their long lifetime, it would be impossible to neutralise their influence in the foreseeable future. A need therefore arises for predictive mathematical models capable of describing the behaviour of atmospheric ozone now and in the future. Such models have been vigorously developed during the past 15 years. One-dimensional models with transport are being replaced nowadays by two-dimensional (width–height) models. Both types of models include 150 elementary gas phase chemical and photochemical reactions. The characteristics of these models as well as kinetic data banks have been periodically considered in reviews, so that the prediction of the changes in the ozone content rests on a reliable scientific basis.

The report[16] of a significant decrease in the amount of ozone during springtime over the Antarctic ("ozone hole") in 1985 was very unexpected. Models did not predict such changes. The subsequent vigorous field and laboratory studies revealed new chemical processes in the lower stratosphere. These include heterogeneous reactions on the surfaces of polar stratospheric clouds which are formed on condensation of water vapour with an admixture of nitric acid. These reactions convert a large proportion of chlorine into a catalytically active form. Thus it was shown that chlorine constitutes a serious threat to ozone. These studies led to attempts to replace the long-lived chlorofluorocarbons by substances with similar properties but more readily removed from the atmosphere, for example, by reaction with the HO radicals in the troposphere.

Tropospheric chemistry has become a rapidly developing field after it was suggested that there are high stationary concentrations of HO and HO_2 in the troposphere in the presence of sunlight.[17] Since HO radicals are highly reactive, the reactions with them constitute an important sink for the majority of trace impurities. Further progress in tropospheric chemistry is associated with the study of the photochemical formation of oxidants or smog. Demerjian et al.[18] were the first to formulate the mechanisms of the oxidation of hydrocarbons in the presence of NO_x with formation of ozone in polluted air. Kinetic data for the modelling of tropospheric chemistry are presented in Table 2 in the "Organic reactions" Section.

The complexity of both tropospheric and stratospheric chemistry requires accurate data for a multiplicity of elementary gas-phase reactions. Expert evaluation of data has played a major role in combining experimental and theoretical information. In the sections which follow in this review, an approach is described to the evaluation of data for atmospheric chemistry.

III. Format for the presentation of data

At the beginning of studies concerning the expert evaluation of chemical and photochemical data, the CODATA Working Group had to select a suitable format for the presentation of data. Previous reviews were either detailed, involving a detailed consideration of individual measurements, for example, the reviews on high-temperature kinetics[19], or were abbreviated, as in the early Tables of the National Bureau of Standards[4]. The CODATA Group selected an intermediate degree of detail: the experimental methods and conditions are indicated and the discrepancies between the results of different studies are discussed. This was achieved by employing the "list of data" approach in which information is compiled and discussed in a standardised form for each elementary reaction. The reactions were grouped in terms of the O_x, HO_x, NO_x, organic, SO_x, FO_x, ClO_x, BrO_x, and IO_x families.

IV. Compilation of lists of data

1. Thermal reactions

The list of data[19] is begun with the formation of the reaction equation taking into account all of its feasible pathways. Next, the enthalpy change at 298 K is quoted. The available kinetic data are presented in four sections—the rate constants obtained from absolute and relative measurements, branching parameters, and recommended constants with an indication of the Expert Panel.

Since all the reactions considered are elementary chemical processes, the expression for the rate of reaction is formulated in accordance with the reaction equation:

$$A + A \rightarrow B + C,$$
$$-1/2\frac{d[A]}{dt} = \frac{d[B]}{dt} = \frac{d[C]}{dt} = k[A]^2.$$

Thus the stoichiometric coefficient 2 for A appears in the denominator before the rate of change of [A] {it is equal to $2k[A^2]$} and in the power exponent in the right-hand side of the equation.

The rate constants for reactions are presented in the form of the simple Arrhenius equation: $k = A\exp(-B/T)$, where $B = E/R$ can be both positive and negative. For the pressure-dependent recombination and dissociation rate constants, a non-Arrhenius temperature variation is used, which is discussed in the next Section.

The kinetic data are provided with commentaries in which experimental details are described. The recommended rate constants are quoted for 298 K and also in the form of a temperature variation equation for the temperature range indicated. The errors in $\lg k$ at 298 K and in the values of E/R in the temperature range of the recommended rate constants are indicated. The choice of the recommended values is justified in the commentary and other relevant information is presented.

A typical list of data for the thermal reaction $HO + HCHO \rightarrow H_2O + HCO$ is presented in Table 1.

2. Recombination and dissociation reactions

The rates of recombination and dissociation reactions depend on the temperature T, the nature of the species, and the concentration of the third body M:

$$A + B + M \rightarrow AB + M.$$

Table 1. Typical list of data from a CODATA survey[9]

$HO + HCHO \rightarrow H_2O + HCO$, (1)
$HO + HCHO \rightarrow H + HCOOH$, (2)
$\Delta H°(1) = -135.3$ kJ mol^{-1},
$\Delta H°(2) = -91.5$ kJ mol^{-1}
The rate constant $k = k_1 + k_2$.

k, cm^3 s^{-1}	T, K	Refs.	Remarks**
Absolute measurement

$(1.66\pm0.20)\cdot10^{-11}\exp(-86/T)$	296—576	[21]	2
$(1.25\pm0.11)\cdot10^{-11}$	298		
Relative measurements			
$(8.4\pm0.5)\cdot10^{-12}$	299	[22]	3
Branching parameters			
$k_1/k = 1.00\pm0.05$	296	[20]	1
$k_2/k < 0.02$	299	[22]	3
Values recommended previously			
$1.1\cdot10^{-11}$	200—425	[23]	4
$5.0\cdot10^{-11}\exp(-600/T)$	300—2500	[24]	5
$1.0\cdot10^{-11}$	228—426	[25]	6
$9.0\cdot10^{-12}$	228—426	[26]	7
$5.7\cdot10^{-15}T\,1.18\exp(225/T)$	300—1660	[27]	8
$1.0\cdot10^{-11}$	228—426	[28]	6
Recommended values*			
$1.1\cdot10^{-11}$	298	—	—
$1.6\cdot10^{-11}\exp(-110/T)$	230—580	—	—
$k_1/k = 1.0$	298	—	—

Reliability
$\Delta\lg k = \pm0.1$ at 298 K
Determination of errors
$\Delta(E/R) = \pm150$ K;
$\Delta(k_1/k) = \pm0.1$ at 298 K

* The recommended values were obtained by the method of least squares using the absolute rate constants determined in a number of investigations[20,21,30,31] and agreeing well with one another at room temperature. The results of relative measurements obtained in several investigations[22,29,34] correspond to the recommended values at 298 K. Analysis of the products[20,22] showed that at 298 K this reaction proceeds predominantly via pathway 1 with formation of H_2O + HCO.

** The figures in the remarks column have the following significance; (1) discharge flow—detection of HO and HCO radicals by the laser magnetic resonance method. The ratio k_1/k was obtained by comparing the amount of HCO formed with the amount of HO which had reacted; (2) laser photolysis—detection of HO by the laser-induced fluorescence method; (3) method of relative rates. The HO radicals were generated by the photolysis of $CH_3ONO-NO-$air and $C_2H_5ONO-NO-$air mixtures at an overall air pressure of 700 mmHg. The rates of disappearance of $H^{13}CHO$ and C_2H_4 were determined by IR spectroscopy. The rate constant ratio $k/k(HO + C_2H_4) = 0.99 \pm 0.06$ was converted into the absolute value assuming that $k(HO + C_2H_4) = 8.5 \times 10^{-12}$ cm^3 s^{-1} [26]. The ^{13}C isotope effect was neglected. The ratio $k_2/k = 0.02$ was estimated on the basis of the absence of $H^{13}COOH$ from the products; (4) obtained as the average of the rate constants determined in a number of studies[29—31]; (5) based mainly on rate constant data[30,32,33]; (6) the rate constant at 298 K is the mean of the absolute values determined in two studies[30,31]. These data do not indicate any temperature dependence of the rate constants; (7) obtained from values determined in a number of investigations[20,22,30,31] on the assumption that the rate constant is independent of temperature[24,30]; (8) based on a number of data[30—33].

The rate constants for such reactions should be expressed in a more complex form than the rate constants for simple bimolecular reactions. Recombination reactions are described in terms of a pseudo-second order law:

$$\frac{d[AB]}{dt} = k[A][B].$$

Here the second-order rate constant k depends on [M]. The low pressure limit for the third-order rate constant is characterised by a quantity k_0 proportional to [M]:

$$k_0 = \lim_{[M]\to 0} k([M]).$$

The high pressure limit (the bimolecular constant) is characterised by a quantity k_∞ which is independent of [M]:

$$k_\infty = \lim_{[M]\to \infty} k([M]).$$

For recombination reactions in the region of low pressures, Table 1 presents second-order rate constants expressed as the product of the third-order rate constant and the concentration of the third species. The transition between third- and second-order regions is described by the equation quoted for the decrease in k/k_∞ as a function of

$$k_0/k_\infty = [M]/[M]_c,$$

where the "centre of the decrease curve" $[M]_c$ denotes the concentration of the third species at which the extrapolated value of k_0 coincides with k_∞. This is illustrated in uig. 1. The dependence of k on [M] is generally speaking complex and the theory of unimolecular reactions has to be applied in its analysis. However, for moderately complex molecules in the region of not unduly high temperatures, an approximate expression is applicable:

$$k = \frac{k_0 k_\infty}{k_0 + k_\infty} F = k_0 \frac{1}{1 + [M]/[M]_c} F = k_\infty \frac{[M]/[M]_c}{1 + [M]/[M]_c} F,$$

where the first terms represent the Lindeman–Hinshelwood equation and the additional expanding multiplier F at not unduly high temperatures is specified[35–37] by

$$\lg F \simeq \frac{\lg F_c}{1 + [\lg([M]/[M]_c)]^2}.$$

Thus, three quantities—k_0, k_∞, and F_c together with

$$[M]_c = \frac{k_\infty}{k_0/[M]}$$

characterise the decrease curves for the purpose under consideration. It is also possible to employ the quantities k_∞, $[M]_c$, and F_c or k_0, $[M]_c$, and F_c. The temperature variation of F_c, which is significant in certain cases, can be estimated by Troe's method[35–37]. The results are usually represented by the approximate equation

$$F_c = (1-a)\exp(-T/T^{***}) + a\exp(-T/T^{*}) + \exp(-T^{**}/T).$$

The first two terms are significant under atmospheric conditions, while the third term begins to contribute in most cases at much higher temperatures. In the first reviews, it was assumed for simplicity that $a = 1$ and that $T_c^{**} \simeq 4T^{*}$. If the values of F_c are known for only one temperature, then the approach remains the same. The term $\exp(-T^{**}/T)$ is frequently negligible at temperatures below 300 K. However, for a more detailed consideration, it is necessary to determine a, T^{***}, T^{*}, and T^{**}. Theoretical predictions[35–37] have been made with the aid of rigorous models of the RRKM type taking into account the influence of weak collisions. For reactions which are significant in the atmosphere, systematic calculations of this type have been published by Patrick and Golden[38]. The question whether these calculations are applicable to barrier-free radical recombination reactions, where rotation effects are important, remains open. The changes in F_c may require changes in the limiting quantities k_0 and k_∞. For the purposes of the present review, this is insignificant in most cases if the recommended values of k_0 and k_∞ agree with the recommended F_c.

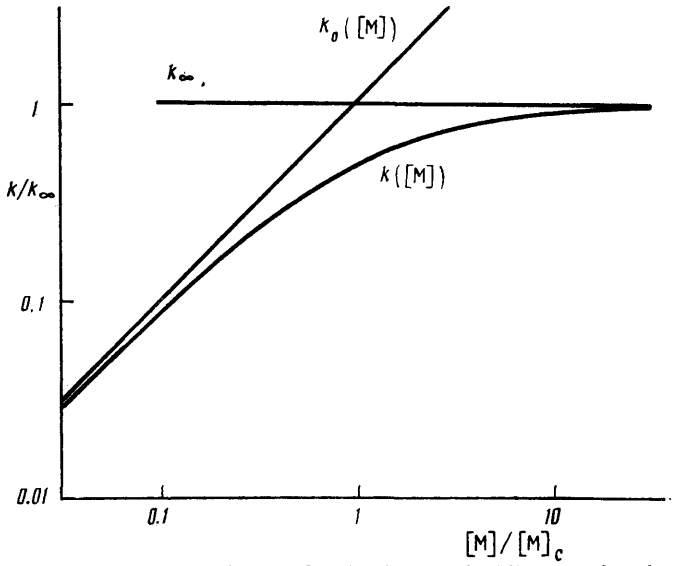

Figure 1. The reduced curve for the decrease in k/k_∞ as a function of $[M]/[M]_c$.

The dependence of k_0 and k_∞ on the temperature T has the form of a power function: $K \propto T^{-n}$ (except in cases with an appreciable energy barrier). This form of the temperature variation has therefore been used because it frequently yields a better agreement with experimental data over a wide temperature range than the Arrhenius law. The dependence of k_0 on the nature of the third species is usually reflected in the relative efficiencies of M_1 and M_2:

$$\{k_0(M_1)/[M_1]\} : \{k_0(M_2)/[M_2]\}.$$

Several thermal dissociation reactions of interest have been examined similarly to recombination reactions with pseudo-first order constants $k(M)$. The rate constants, expressed in s^{-1}, are designated in the Tables by the symbols k_0/s^{-1} and k_∞/s^{-1}. The multiplier F_c has the same significance in recombination and dissociation reactions.

Table 2. Compilation of data for reactions and the recommended rate constants.

Reaction	k_{298}, $cm^3\ s^{-1}$	$\Delta \lg k_{298}$	Temperature dependence of K, $cm^3\ s^{-1}$	Temperatures range, K	$\Delta (E/R)$, K
		O_x reactions			
$O+O_2+M \rightarrow O_3+M$	$6.2\cdot10^{-34}$ $[O_2]$ (k_0)	±0.1	$6.2\cdot10^{-34}(T/300)^{-2}[O_2]$	200—300	$\Delta n=\pm0.5$

3. Photochemical reactions

In CODATA/IUPAC reviews, tables of data begin with a list of the primary photochemical transitions at wavelengths not less than 170 nm. Also presented are the corresponding enthalpy changes at 0 K when this is possible, otherwise the values of 298 K are given. Also listed are the threshold wavelengths corresponding to these enthalpy changes. Next, the existing experimental data for the absorption cross-sections and quantum yields are compiled. These data are accompanied by commentaries. After that, the recommended absorption cross-sections and quantum yields for different wavelengths are listed wherever possible at 5 nm intervals. In many cases diagrams illustrating the dependence of the absorption cross-sections and quantum yields on the wavelength are shown as well. The choice of the recommended values is justified in the commentaries and certain other questions are considered.

4. Absorption cross-sections

In the CODATA/IUPAC compilations of data, these quantities are listed under the heading "absorption cross-sections per molecule to base e". They were determined in accordance with the equation

$$I/I_0 = \exp(-\sigma N l),$$
$$\sigma = (1/(Nl)) \cdot \ln(I_0/I),$$

where I_0 and I are the intensities of the incident and transmitted light, σ is the absorption cross-section (cm^2), N the number of particles of the absorbing substance (cm^{-3}) and l the distance traversed by the beam (cm). Other definitions and units of the measurement are also used. The closely related "absorption coefficient" and "extinction coefficients" are frequently quoted, but their definitions should not be confused. It is always necessary to draw attention to the units of the measurement of concentration, the traversed distance, and also the type of logarithm used in the definition (natural or decadic).

5. Determination of errors

The estimates of the absolute errors of the recommended values of k at 298 K and of the quantities E/R in the temperature range indicated are listed in the CODATA/IUPAC tables under the heading "reliability". These limits of errors are also given below in Table 2. The errors of the recommended rate constants at 298 K are expressed by the term

$$\Delta \lg k = D; \quad \lg k = C \pm D.$$

This is equivalent to the determination of k to within a multiplier F, where $D = \lg F$. The accuracy of the recommended values of E/R is expressed by the term $\Delta(E/R)$, where $\Delta(E/R) = G$ and G is defined by the equation $E/R = H \pm G$.

The absolute errors in k and E/R were determined by the Expert Panel. Experience has shown that, for the reactions of atoms and free radicals in the gas phase, the accuracy (reproducibility) of the measurements is usually good. Thus, for a separate investigation of a specified reaction by this method, the standard deviation (or even the 90% confidence interval) is, as stated in the literature, not more than $\pm 10\%$. Unfortunately, when data obtained by different groups of investigators using different methods for the same reaction are compared, it is frequently found that the rate constants differ by a factor of 2 or even more. This means that one or several investigations involve large systematic errors, which are difficult to detect. This is not surprising since, in contrast to molecular reactions, it is not always possible to investigate the reactions of atoms and radicals in isolation and hence experimental difficulties frequently arise.

The critical evaluations of errors in the CODATA/IUPAC selections are based mainly on the state of our knowledge for a particular reaction, which depends on the number of studies carried out and on the number of methods employed. Overall, the limits of error have been expanded. Thus in the case of a single study by one method not confirmed by independent investigations, limits of at least double errors indicated are adopted.

V. Table of reactions and recommended kinetic quantities

A complete list of chemical reactions and recommended kinetic parameters from the latest IUPAC survey is presented in Table 2. Unfortunately, it was not possible to present photochemical data in a compact form and we refer the reader to the complete CODATA/IUPAC publications[9].

* * *

At the time of the publication of the CODATA (Supplement 11) [39] and NASA (No. 7) [40] surveys, it was believed that the principal features of stratospheric gas-phase chemistry, including the constants of the key reactions, had been thoroughly established. At the present time additional requirements as regards the heterogeneous chemistry of polar stratospheric clouds, which may help to explain the appearance of Antarctic "ozone holes", must be added to this statement. A kinetic data bank for the chemistry of polar stratospheric clouds is being rapidly created at the present time, which should be reflected in extended surveys by both the NASA Group and the IUPAC Subcommittee for the Estimation of Gas-Kinetic Data for Atmospheric Chemistry. The second of these groups has begun to formulate a survey of kinetic data for reactions, mainly of organic species, which play a key role in the chemistry of the troposphere.

The author expresses his indebtedness for the great contribution made to this review by his colleagues on the IUPAC Subcommittee Roger Atkinson, Don Baulch, Tony Cox, Bob Hampson, and Jurgen Troe.

Problems of the distribution of the global aerosol

R Jaenicke
Institute of Meteorology, Mainz University, Federal Republic of Germany

ABSTRACT. In view of the short residence time of the aerosol in the atmosphere, knowledge of its distribution in space is essential for the understanding of many processes associated with this distribution, for example, the formation of clouds and hence of the entire cloud cover over the Earth's sphere. This review considers both the distribution of aerosol particles with respect to size (from the standpoint of chemical and physical characteristics) and the distribution of aerosols in space in a broad sense of this term.

The bibliography includes 55 references.

I. Introduction

Apart from the main gases (nitrogen and oxygen), the atmosphere contains small admixtures of other substances. Investigators working in the following fields of meteorology and atmospheric chemistry are concerned with the study of these admixtures: (1) the physics and chemistry of clouds (water); (2) the chemistry of gaseous impurities; (3) the physics and chemistry of aerosols.

Compared with the bulk of the main gases contained in one cubic metre of dry air, which is ~1300 g (this quantity depends on temperature), the overall content of water in all three states of aggregation is less than 10 g, that of gaseous admixtures (excluding water) is up to 0.5 g, and that of aerosol particles is up to 50 mg. Thus the mass concentration of the aerosol does not exceed that of minor gaseous admixtures. For this reason many scientists and unfortunately society in general underestimate the importance of aerosols in view of the low ratio of the mass concentration of the aerosol to the mass concentration of the gaseous admixtures.

Nevertheless, aerosols play a key role in the atmosphere. For example, certain aerosol particles serve as condensation nuclei for water vapour in clouds, so that the turnover of water in the absence of these particles would change significantly and hence the climate of the Earth would also change.

For example, half of the total amount of the aerosol is formed as a result of the gas–particle transformation (including both homogeneous and heterogeneous condensation) and this process is therefore an important route leading to the removal of many gaseous species from the atmosphere.

Aerosol particles consist of a large set of chemical substances (organic and inorganic) minerals, and particles of biogenic origin. The influence of aerosol on man and the environment is due to the presence of these compounds, whose concentrations are sometimes very low (of the order of a nanogram per cubic metre as in the case of certain specific organic compounds or pollen particles).

The question arises why aerosols play such an important role in the atmosphere. Firstly, they influence the field of the Earth's electromagnetic radiation as a whole, since they absorb and scatter a large proportion of the incident solar radiation; secondly, they ensure the presence, directly in the gas phase, of a large surface area for the occurrence of chemical reactions of various gaseous substances; thirdly, they influence the turnover of atmospheric water, since they serve as condensation nuclei in clouds; fourthly, they provide a surface on which natural radioactive nuclides are adsorbed; fifthly, they influence the chemical and radiation (albedo) properties of the surface of the planet as a result of the dry and wet precipitation on its surface; sixthly, they alter the electric field of the atmosphere, since aerosol particles can be charged; finally, they promote the spread of plants and diseases.

It is difficult to estimate the influence of the aerosol on the state of the atmosphere, because in a geochemical sense the aerosol particles have a very short lifetime. Furthermore, there are additional meteorological characteristics (horizontal, vertical, and time distributions of the aerosol) and there exists a distribution of the particles with respect to size (the number, surface, and mass concentrations, the chemical properties, and the refractive index are different for particles of different size) which hinders in its turn the determination of their influence. It is also noteworthy that, among all the components of the atmosphere, the suspended substances are unique as regards the complexity of their chemical composition.[1]

To facilitate the description and study of such a complex system and to investigate its influence on the environment, scientists have introduced various parameters such as the electrical conductivity of air, the mass concentration of the aerosol, the extinction coefficient, etc. The present state of knowledge about the entire wide variety of the parameters of the atmospheric aerosol will be described in this review.

II. Distribution of the aerosol in space and time

The term "distribution" has many meanings even if it is understood in a fairly narrow sense. In the physics and chemistry of aerosols, this term usually means the number or volume distribution of particles with respect to size and more rarely the spatial or geographical distribution.

Henceforth we shall discuss the fact that aerosol particles have a polydisperse distribution with respect to size associated with different mechanisms of their formation. After their appearance, aerosol particles undergo a change in their chemical and disperse compositions.

Meteorological processes mix the aerosol in the vertical and horizontal directions. This process involves all the particles regardless of their size and chemical composition.

Other processes act only on specific particles depending on their size and chemical properties. Gravitational influences on the largest particles regardless of their composition forces them to move towards the surface of the Earth. Brownian motion is responsible for the process called "thermal diffusion", which is also independent of the chemical nature of the particles. As a result of thermal diffusion, small particles, having the maximum mobility, collide with other particles and thus coagulate. Cloud drops are formed on aerosol particles with a specific chemical composition, coagulate into larger drops, and are finally precipitated as rain or evaporate once more.[2]

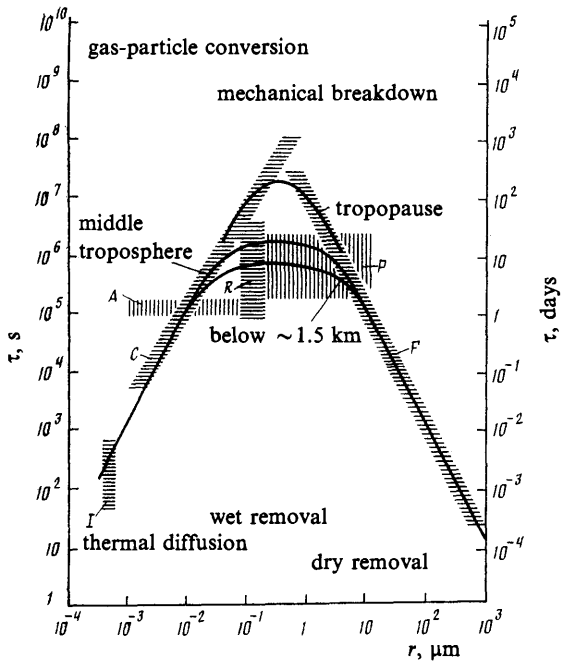

Figure 1. Dependence of the lifetime (τ) of aerosol particles on their radius.[3] The calculation was performed taking into account different independent data: *A*—distribution of Aitken particles in space; *C*—diffusion of the aerosol in dynamic equilibrium; *R*—radioactivity data; *P*—results of studies of the atmospheric water cycle; *F*—sedimentation data.[4]

All these processes limit the residence time of the aerosol particles in the atmosphere, altering thereby their size distribution. The principal result of the influence of these processes is the removal from the atmosphere of the smallest and largest particles and hence the conversion of the polydisperse aerosol into a monodisperse aerosol. This process is called "ageing". Fig. 1 illustrates the dependence of the lifetime of the aerosol particles in the atmosphere on their radius.[3] Small and large particles have shorter lifetimes and only particles with radii in the range 0.1–1 μm exist longer in the suspended state. This time might be longer in the absence of interactions of the aerosol with clouds, a situation which occurs in the upper troposphere and in the stratosphere.

In this connection, it must be emphasised that the term "lifetime" used in this article is not identical with the chemical or geochemical concept of the lifetime of a chemical compound, since the compounds contained in aerosols can continue to be present in the atmosphere after the coagulation of the aerosol particles. There is also another possibility: chemicals can pass from one set of particles to another, differing in size and behaving quite differently in the atmosphere. Yet another remark may be made—the significance of the lifetime in a reactor such as the atmosphere is that of the period during which the concentration of the compound diminishes by a factor *e*. Fig. 1 shows that the lifetime is a maximum for particles with radii in the range 0.1–1 μm and amounts to ~8 days (for the lower troposphere).

It has been suggested[5] that there is an inverse relation between fluctuations in time and space and the lifetime. Substances with a long lifetime are distributed more uniformly. Atmospheric oxygen, for which only rare, episodic measurements of its concentration have been recommended, may serve as a good example.[6] The lifetime of sulphur dioxide is short and SO_2 therefore exhibits pronounced fluctuations in time and space. An equation describing these fluctuations was obtained subsequently[7] using a simple model:

$$V^2 = \frac{1 - \exp(-2T_{max}/T)}{2[1 - \exp(-T_{max}/T)]^2} \frac{T_{max}}{T} - 1,$$

where V is the relative standard deviation (variance), T the lifetime in arbitrary units of time, and T_{max} the "maximum" time (in arbitrary units) during which the admixture exists as an individual compound (T_{max} varies from 10 h to 30 days).

It must be emphasised that there are contradictory attitudes to this statistical approach.[8] Nevertheless, there is qualitative agreement concerning the inverse proportionality between the lifetime and the fluctuation and also about the fact that substances with a lifetime amounting to days should have a standard deviation in their distribution in time and space equal to ~2, while for substances with a shorter lifetime the standard deviation should be much greater.

The dependence of the lifetime of aerosol particles on their size influences the behaviour of the aerosol as a function of time and its distribution in space.

In evaluating the data presented in this review, one must take into account the possible long-time changes in the characteristics of the aerosol under the influence of natural and anthropogenic factors. To some extent, such changes have been summarised in the author's previous communication.[3] Thus any aerosol distribution can reflect the situation only at the time to which it refers.

III. Distribution of aerosol particles with respect to size

Among all the types of distribution of the atmospheric aerosol with respect to size, the most important is the distribution of the number concentration of the particles with respect to diameter,

Table 1. Parameters of the number distribution of the aerosol and its integral characteristics for the size ranges indicated and for the aerosol as a whole.

Type of aerosol	Size ranges	Subrange $10^{-7} < r < 10^{-5}$ cm			Subrange $10^{-7} < r < 10^{-4}$ cm			Subrange $r > 10^{-4}$ cm			Total range $r > 10^{-1}$ cm

Note. n_i (i = 1, 2, 3) is the number concentration (in cm^{-3}) for the logarithmic-normal distribution of particles in different size ranges. The primed quantities indicate the additive contribution of various modes to the number (N', cm^{-3}), surface (S', cm^{-1}), and volume (V') particle concentrations in each size range indicated.

surface area, and volume. We shall therefore distinguish this type of distribution from the distributions of other parameters which will be discussed below.

The first continuous distribution of the number concentration with respect to size was proposed by Junge[9] in 1952 as a power function. This function was updated[10] in the following form:

$$dN(r)/d\lg r = n^*(r_0)(r/r_0)^{-\nu^*},$$

where $dN(r)/d\lg r$ is the density of the distribution of the number concentration, $N(r)$ the number concentration of particles with a radius greater than r, r the particle radius, r_0 an arbitrarily selected radius, $n^*(r_0)$ the density of the distribution for $r = r_0$, and ν^* the power exponent.

This formulation of the equation has the advantage that the distribution density has the dimensions of concentration despite the fact that it is the concentration density. The form of the distribution of particles with sizes in the range 0.1–10 μm is represented, according to this equation, by a straight line in terms of double logarithmic coordinates.

The advantage of this well known Junge distribution is its simplicity—only three parameters are used: the minimum radius r_0 of the fiducial recovery of the function, the coefficient $n^*(r_0)$ of the expression, and the power exponent $-\nu^*$. This distribution describes satisfactorily certain optical characteristics of the atmosphere.[11] Nevertheless, it does not describe the behaviour of the particles outside the range of their sizes indicated.

Studies carried out during the last two decades have yielded much new information about the distribution of the atmospheric aerosol with respect to size and this required a refinement of the formula describing the distribution.

At the beginning of the 1970's,[12] attempts were made to introduce for the description of the distribution with respect to size the Gaussian probability function related to the aerosol formation and transformation processes. As a result of this approach, certain particle size ranges were differentiated as "modes": nuclear, accumulation, and coarsely disperse.

Although the legitimacy of this approach is still questionable, the use of logarithmic-normal functions and their superposition leads to the following form of the equation for the distribution function:

$$\frac{dN}{d\lg r} = \sum_{i=1}^{3} n_i \frac{1}{\lg \sigma_i \sqrt{2\pi}} \exp\left\{-\frac{[\lg (r/R_i)]^2}{2(\lg \sigma_i)^2}\right\},$$

where $\lg \sigma_i$ is the degree of polydispersity of each logarithmic-normal distribution, R_i the average radius for each mode, and n_i the weight multiplier for the ith distribution.

In this equation, there are nine parameters but it can cover the entire range of sizes of the atmospheric aerosol—from 0.001 μm to several hundreds of microns.

The number distribution can be converted into a distribution with respect to the surface or volume (mass) of the particles, bearing in mind that

$$S = 4\pi r^2 \text{ and } V = {}^4/_3\pi r^3,$$

where S is the surface area of the sphere and V its volume.

Table 1 presents the parameters for all types of aerosol which are nowadays believed to be present in the atmosphere. The data quoted refer to the average relative humidity and a wind strength equal to 4 points on the Beaufort scale. Fig. 2 presents the corresponding types of distributions. The "polar" aerosol denotes particles of the layer near the Earth's surface in the Arctic and Antarctic regions.[13–15] The term "background tropospheric" aerosol is understood as the aerosol at heights above 5 km over dry land and above 3 km over the surface of oceans. This aerosol is fairly homogenous and occupies ~70% of the volume of the troposphere. The "background tropospheric" aerosol has been studied in mountain [observation] stations in air masses which move from above downwards and over the surface of oceans in order to exclude sea salt aerosol.[16–22] Together with sea salt aerosol, the background aerosol constitutes the "marine" aerosol. However, owing to the approximate nature of the averaging procedure, a claim of the type "marine aerosol – background aerosol = salt aerosol" is incorrect.[16,23,24] The term "background continental" aerosol refers to the aerosol in regions not subject to anthropogenic influences.[10,22,25] However, there is a minimal amount of information about this aerosol. The "dust sandstorm" aerosol was differentiated as a special type of natural aerosol in view of the enormous power of the source of these particles, their ability to travel over long distances, and their possible influence on the climate.[24,26,27] The "aerosol in agricultural regions"[10,28–30] near populated agricultural areas as well as the "aerosol in industrial regions",[10,29] formed as a result of anthropogenic influences, have been differentiated as separate types. The "stratospheric aerosol" differs from all the types indicated above by the fact that it is described by a unimodal logarithmic-normal distribution and is fairly monodisperse.[31] It is noteworthy that, after volcanic eruptions, the concentration of particles in the layer of stratospheric aerosol is a maximum but then rapidly diminishes.[32] The data presented on the stratospheric aerosol refer to a height of 7 km above the tropopause and the samples were taken one year after volcanic eruptions during the period between 1970 and 1981. This type of distribution is in fact to be expected bearing in mind the ageing effect and the long residence time of the particles in the stratosphere.

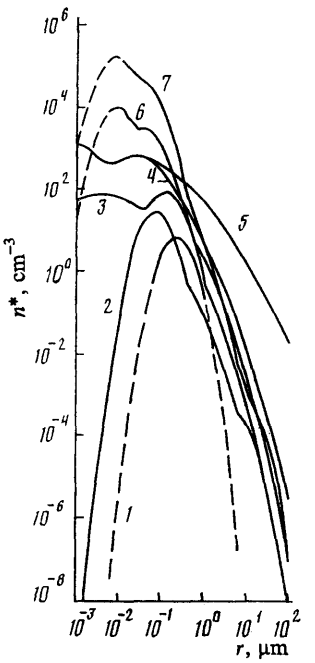

Figure 2. Distribution of the number concentrations of different types of aerosol in the form of the dependence of $dN/d\lg r$ on the particle radius. Type of aerosol: (*1*) stratospheric; (*2*) polar; (*3*) background tropospheric; (*4*) background continental; (*5*) desert sandstorm aerosol; (*6*) aerosol from agricultural regions; (*7*) aerosols from industrial regions.

Fig. 2 illustrates interesting features in the size distribution of the particles of different aerosols. The polar and stratospheric aerosols have fairly narrow, monodisperse distributions typical for "aged" aerosols. Therefore, in this case, on passing from the number distribution to the surface or volume distribution, the form of the distribution does not change while the average radius undergoes a slight alteration. The dust storm aerosol differs from the background continental aerosol only by the higher concentration of particles whose size exceeds 0.1 μm and such particles constitute the main bulk of the aerosol. Although in dust storms the number concentration of the Aitken particles exceeds very slightly that for the particles of the background continental aerosol,[24] their mass concentration is much higher.

The background tropospheric aerosol is of great interest. It has been suggested[33] that this aerosol represents the aged continental background aerosol with a number concentration of ~300 particles cm^{-3}. Indeed, the number concentration is of this order of magnitude but the form of the distribution of the background tropospheric aerosol shows that in this case a continuous gas–particle transformation process takes place, since the fraction of fine particles is high. It is unlikely that such an aerosol is "aged". Similar gas–particle transformation processes have been observed for the background continental aerosol and also for aerosols from agricultural areas and industrial regions. This was in fact to be expected. However, it is essential to note that the distribution of these submicron particles with respect to size has been inadequately studied and further investigations are needed. The concentration of the aerosol with particles larger than 0.1 μm diminishes with increase in the particle radius, as predicted by the Junge distribution. On passing to the distribution of the particles with respect to volume, the distribution function assumes the form of a fairly even plateau and in the determination of the mass of the aerosol this range of sizes is therefore most important, while the Aitken particles make an insignificant contribution.

In conclusion yet another important remark has to be made. For all types of aerosols, the most significant differences in the form of the distribution are observed in the case of the finest and largest particles. For particles of intermediate size, such differences are insignificant. It seems that this finding confirms the earlier hypothesis of a relationship between the lifetime of the aerosol and the fluctuations in its parameters: the maximum variations occur for particles with a minimal lifetime in the atmosphere.

Fig. 2 does not present the confidence intervals for individual distributions. The latter are therefore in no way a result of a large number of averaging steps but are rather a result of certain hypotheses and approximations based on the few published data. The main reason for the deficiency of information is the enormous experimental difficulty of measuring the distribution of particles over the entire range of sizes. Much still remains to be done in this field in the future.

IV. Dependence of the properties of the aerosol on the particle size

In this section we shall not discuss the properties of the aerosol which can be readily calculated from the particle distribution function with respect to size, such as the rate of deposition, mobility, and others, but shall concentrate attention on the measurable properties of the aerosol. The parameters describing the distribution of these properties are important for all types of aerosols and not only for the atmospheric aerosols. The majority of these parameters are calculated on the assumption that the aerosol particles are spherical.

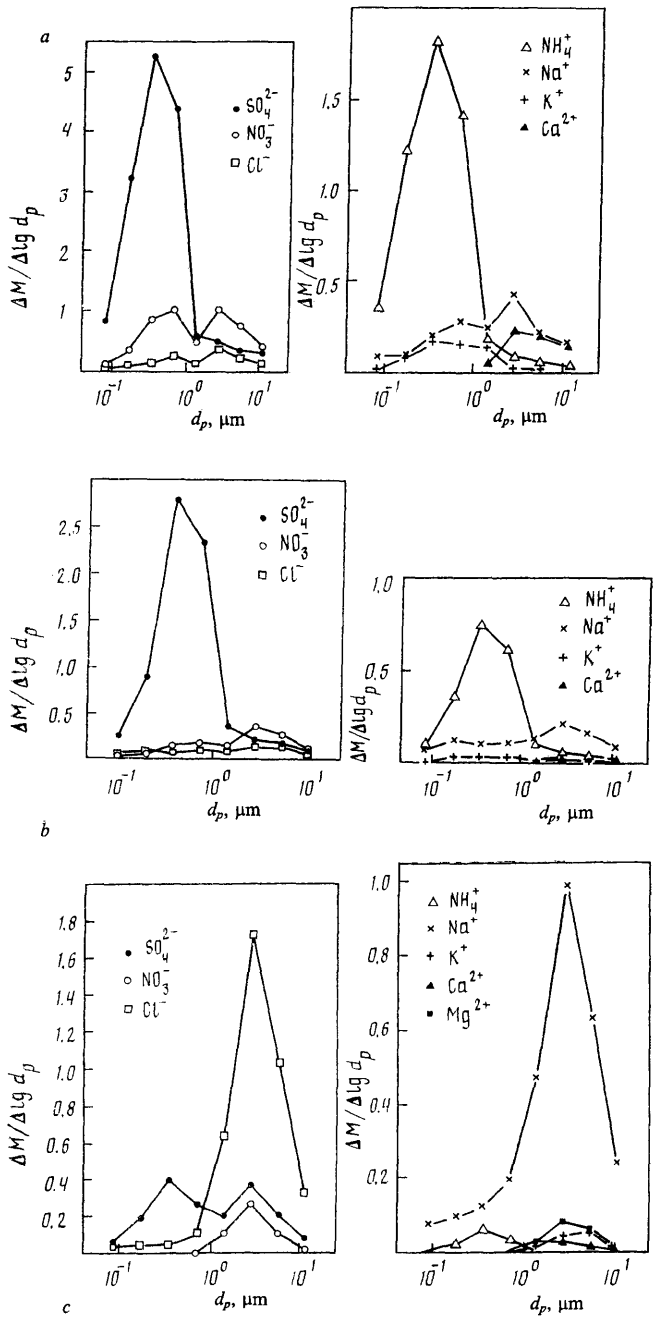

Figure 3. Differential mass distribution of the aerosol $\Delta M/\Delta \lg d_p$ (μg m^{-3}) with respect to size (diameter d_p, μm) of the most widely distributed ions for industrial (*a*), marine (*b*), and background continental (*c*) types of aerosol.[37] Data obtained using impactors.

In order to investigate the distribution of any kind of properties of the aerosol, it is essential to know the size distribution of the particles. In most cases, in order to be able to investigate properties of the aerosol such as the elemental or ionic composition, it is necessary to accumulate a sufficient mass of the substance. Such accumulation usually requires a long time (several days or even weeks). During this period, the aerosol can change or can be contaminated by impurities from local random sources. In order to avoid this and to obtain reliable results, it is necessary to exercise much caution. One of the ways of avoiding such faults, involves a decrease in the sampling time although it is then sometimes necessary to sacrifice information about the size distribution of particles. The distribution function is very frequently not measured and only the overall mass concentration of the aerosol, its overall chemical composition, or the content of only one chemical compound are investigated. Investigators sometimes restrict their study to only specific particles, for example, giant aerosol particles. The main bulk of the substance of the aerosol is very frequently concentrated in such particles.

One should always remember, particularly in the study of the dependence of the elemental or chemical composition of the aerosol on the particle size, that the aerosol has a mixed composition.[34] It is necessary to distinguish external and internal mixing of the chemical composition. By external mixing, one understands the presence of a multiplicity of particles having different chemical compositions, each particle consisting of one pure substance or specific set of compounds, determined by the source of the aerosol, for example, ammonium sulphate of sea salt. Internal mixing describes various stages of the disappearance of this "purity", which leads ultimately to the formation of a mixture of substances in each particle. Evidently particles of the first type are encountered only in the vicinity of specific sources of the aerosol, while those of the second type are a result of a secondary transformation of the aerosol (ageing). In describing the chemical composition of a mixed aerosol, the authors frequently do not indicate how the reported results have been treated. Evidently the content of any substance in the aerosol can be represented by the dependence on the effective size of a particle seemingly consisting of only the given pure substance or by the dependence on the true size of the particle (containing also other substances) whose composition includes the given compound.[35] The concentration of ions and not chemical compounds is more frequently quoted.

The first studies of the dependence of the ionic composition of large and giant aerosol particles on their size were carried out in 1953.[36] Fig. 3 illustrates the dependence of the concentration of sulphate ions on the size of aerosol particles. The data were obtained at a [research] station in an agricultural locality in the Federal Republic of Germany. This dependence has several maxima in the range of sizes 0.1 – 10 μm. Their positions coincide with the positions of the maxima in the distribution of the mass concentration of the NH_4^+ ions, which confirms the claim that the most widely distributed water-soluble compound in aerosols is ammonium sulphate. The maxima in the distribution of the concentrations of other ions investigated (K^+, Na^+, Ca^{2+}, NO_3^-, and Cl^-) are in the range of sizes 1 – 10 μm.

Similar measurements have been carried out in England for the marine aerosol and the aerosol from industrial regions.[38] If the contents of cations and anion are compared with aerosol particles whose sizes are in the range 0.1 – 1 μm, a deficiency of cations is observed. It seems to the author that the main cation which was not taken into account in these investigations was H^+. The above hypothesis has also been confirmed by studies of other investigators.[39] Hence one may conclude that the atmospheric aerosol should possess acid properties.

The most widely distributed ions over the surface of oceans are sodium and chloride ions. The maximum in their mass distribution lies in the range of aerosol sizes 1 – 10 μm. It is most likely that these are water droplets containing sea salt. It would appear that exactly the same distribution should have been observed also for the NH_4^+ and SO_4^{2-} ions if the origin of ammonium sulphate had been similar. However, sulphate ions are mainly supplied by aerosol particles with sizes in the range 0.1 – 1 μm brought from the continents (the so called "excess" sulphates[40]). Only one communication[16] reports the distribution of ammonium sulphate over the entire range of sizes of aerosol particles. The number distribution of the $(NH_4)_2SO_4$ concentration has a distinct maximum in the range of sizes 0.01 – 0.1 μm, after which the concentration of the sulphate diminishes with increase in particle size. If one goes over to the differential mass distribution, then a second maximum appears in the range 0.1 – 1 μm (the results were obtained from an electron microscope analysis of the morphology of the particles). These data are open to some doubt because the ammonium sulphate particles can vaporise *in vacuo* during preparatory operations.

CO_3^{2-}: 1.7±1.1 (0.7–4.2) n=6 (28 nequiv. m^{-3})

Note. The aerosol was collected in April–June 1986 on the outskirts of Toronto (Canada). The arithmetical-mean mass concentrations and standard deviations (in μg m^{-3}) are presented. The number of measurements on which the averaging is based is indicated in brackets. The steps of the impactor are designated by the letters *A*, *B*, and *C* (*F* is the output filter). Abbreviations: QU = quartz, CA = calcite, DOL = dolomite, GYP = gypsum, FELD = feldspar, NaCl = halite, AmCl = NH_4Cl, AmS = $(NH_4)_2SO_4$, AmS2N = $(NH_4)_2SO_4.2NH_4NO_3$, AmS3N = $(NH_4)_2SO_4.3NH_4NO_3$, CaAmS = koktaite, PbAmS = $PbSO_4.(NH_4)_2SO_4$, LET = letovicite, TSP = total suspended particles, and %XTAL = percentage fraction of substances analysed by X-ray diffraction.

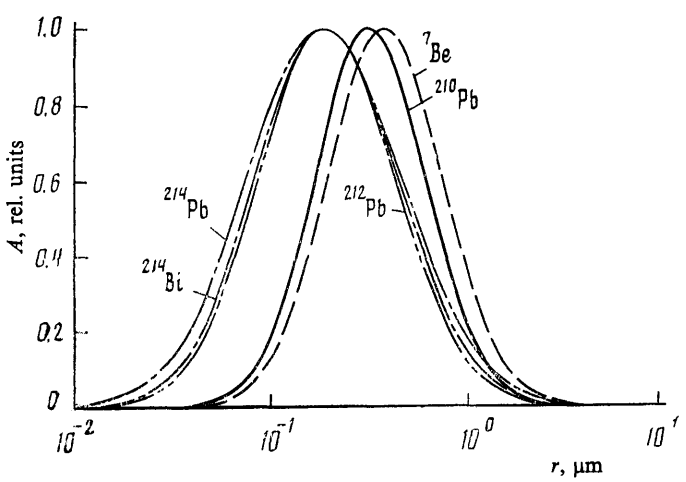

Figure 5. Dependence of the radioactivity *A* (in arbitrary units) on the radius of aerosol particles (for natural radionuclides).

The dependence of the concentrations of ions such as Br^-, Mg^{2+} [39] as well as substances of mineral origin (Al_2O_3, SiO_2, Fe_2O_3, CaO) on the particle size is not described in the literature. The dependence of the composition on particle size is also not available for the organic aerosol.

The distribution of water-insoluble minerals with respect to particle size has been reported.[27] Fig. 4 illustrates the number distribution of the continental aerosol compared with the marine aerosol. In all cases the maximum in the distribution is observed for particles with a radius less than 0.1 μm. The decrease in concentration with increase in particle radius is non-monotonic. On passing to the mass distribution, maxima arise in the range of sizes 1–10 μm, 10–100 μm, and higher.

The first studies on the distribution of minerals with respect to particle size in the continental aerosol have been reported.† Table 2 presents the results of the analysis of specimens selected in the Spring and in the Summer. It was established that minerals constitute ~50% of the mass of the aerosol. These compounds are present over the entire range of particle sizes.

The natural radionuclides entering the atmosphere are rapidly adsorbed on aerosol particles and, since such adsorption is due to diffusion, the distribution of the radioactivity of the aerosol depends on its distribution with respect to the size and surface area of the particles. Although theoretical calculations predict that the maximum radioactivity should be observed for particles whose size is about 0.1 μm, the latest results of the study of the distribution of the

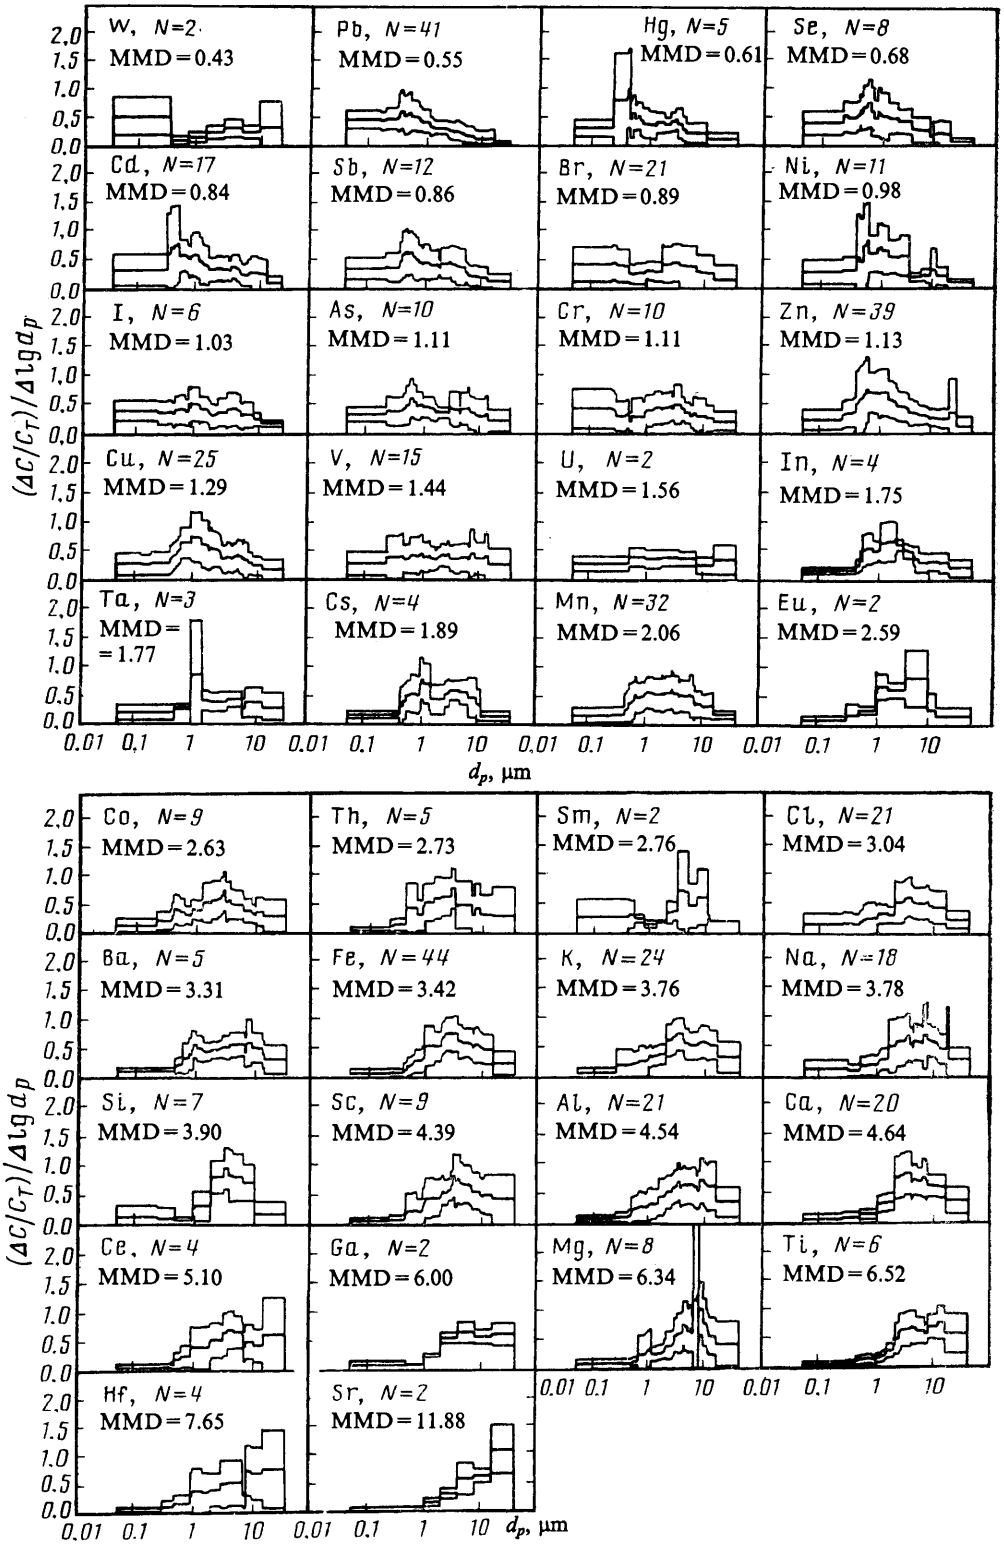

Figure 6. Normalised differential mass distributions for 38 microelements. The data (central line) are presented together with standard deviations (upper and lower lines). *N*—number of averaged distributions; MMD—median mass diameter d_p.[43] The distributions are arranged in order of increasing MMD.

radioactivity of ^{214}Pb and ^{212}Pb in the aerosol from agricultural and industrial regions show[41] that the maximum radioactivity is observed for particles whose radius is about 0.2 μm and in the case of the radioactivity of ^{7}Be and ^{210}Po for particles with a radius of 0.4 μm (Fig. 5). The size distribution for the isotopes formed during tests of nuclear weapons has not been analysed.

Biological aerosols have so far been rarely differentiated as a separate type. Such aerosols contain not only pollen, spores, and bacteria (living organisms) but also ground up pieces of plants and insects and in general decomposing organic material. Pollen, spores, and bacteria are very often considered separately from other types of aerosol. These particles are fairly monodisperse. The distribution of the biological aerosols with respect to the sizes of particles having a radius greater than 2 μm has been investigated.[42] It was found that during Summertime the number concentration of the biogenic aerosol in agricultural localities within the Federal Republic of Germany is between 20 and 40% of the total number concentration of the aerosol.

The aerosol particles can carry an electrical charge, forming the so-called large ions. Ideas concerning the electrical properties and the distribution of large ions have not changed significantly compared with the 1930's. However, the study of these "ionic" spectra has in fact led ultimately to the concept of a continuous distribution of particles with respect to size.[9]

Investigators have devoted much attention to the microelemental composition of the atmospheric aerosol. There are numerous data on this question. A fairly detailed review[43] quotes 38 elements as present in their aerosol particles with diameters ranging from 0.05 to 40 μm (Fig. 6). The curves for the distribution of the elements with respect to particle size for aerosols collected at different times (over a period greater than 20 years) and by different methods (each of which has its limitations) agreed fairly well as regards their shape. A small number of distributions have a fairly monodisperse character (for example, for Mg and Ta). (Naturally, only in the case of distributions of this kind does a parameter such as the median mass diameter have a physical significance.) On the other hand, the majority of distributions are polydisperse without a distinct average radius. A typical example here is provided by vanadium. Elements for which less than two distributions are known from the literature are not considered in this list. Microelements such as sulphur are also not included, since they could not be determined by the methods employed (neutron activation analysis, X-ray fluorescence, and proton-induced X-ray emission).

V. Horizontal or geographical distribution of the aerosol

The distribution of the global atmospheric aerosol is subject to appreciable fluctuations in view of its short lifetime. This is particularly notable if one considers the two hemispheres. Thus the time required for the exchange of the atmospheric aerosol between the Southern and Northern Hemispheres is of the order of two years. This exchange time is significantly greater than the lifetime of the aerosol and it is therefore unlikely that any aerosol particles from the Northern Hemisphere could enter the Southern Hemisphere. In order to achieve a reliable statistical study of the expected fluctuations in the aerosol characteristics, an enormous number of measurements are necessary. Clearly, such a large volume of information can be obtained only for certain parameters of the aerosol and for the majority of the parameters data concerning the distribution of the particles with respect to size are lacking.

An approximate idea about the distribution of the aerosol in space can be obtained by considering the data in Tables 1 and 2 where the characteristics of the polar and background continental aerosols, the dust sandstorm aerosol, as well as the aerosols from agricultural and industrial regions are presented. Fig. 7 illustrates the overall number, surface, and volume concentrations of particles in order of increasing number concentrations. In most cases, these quantities are correlated. The dust sandstorm aerosol is an exception. Whereas the surface area and volume of this aerosol are much higher, the number concentration remains comparable to the number concentration of the particles of the background continental aerosol. The total areas and volumes of the agricultural and background continental aerosols are comparable, but the number concentration of the particles in the agricultural aerosol is significantly higher, which indicates a greater strength of the gas–particle transformation.

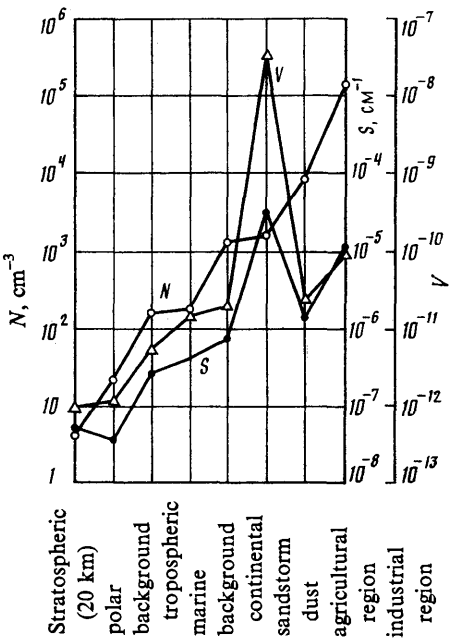

Figure 7. Total number (N), surface (S), and volume concentrations for the types of aerosol presented in Table 1 (in order of increasing number concentration of the particles).[3]

When the detailed distribution in space is described in the literature, the treatment is confined to homogeneous localities. Apparently the authors feel more confident when selecting data on the assumption that a fairly homogeneous source of the aerosol is present or a fairly homogeneous mechanism for the removal of the particles from the atmosphere operates.

Fig. 8 presents a map of the distribution of the number concentration of the condensation nuclei (Aitken particles) over the ocean. Evidently, in the central regions of the oceans the

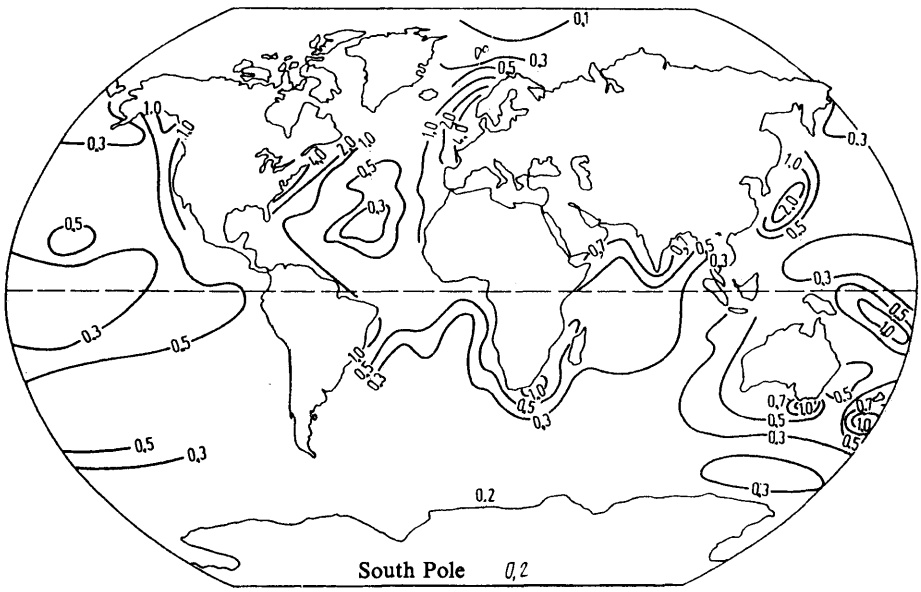

Figure 8. Map of the distribution of the average concentration of Aitken nuclei (10^3 cm^{-3}) over the surface of the oceans. Data taken from Jaenicke[3] and Podzimek.[44]

concentration of Aitken particles diminishes. This does not conflict with the seasonal maps published in 1966 for particles of sea salt greater than 0.7 μm.[45] The data were calculated on the basis of a climatic atlas of the world[46] using the relation between the mass concentration of these particles, transported by air, and the percentage frequency of the repetition of winds with a specified force. One may conclude that the map reflects the storm activity of the oceans. It can be refined by using new data for the relation between the mass concentration of sea salt particles and the wind strength.[3] A similar map can be plotted by using the published[3] relations between the mass concentration of the mineral dust and the wind velocity in the desert. We may note that the mass concentration of this dust is approximately 10 times greater than the mass concentration of the oceanic aerosol.

A minimum concentration of the aerosol (Fig. 8) is observed in polar regions. This was in fact to be expected, since the principal aerosol sources are absent here. The concentration of the particles increases when approaching the continents, which are active sources of aerosol. A more detailed map has been published for the Arctic part of Europe,[13] showing that the average concentration of the aerosol is below 300 particles cm^{-3}. Near populated areas and territories, subject to anthropogenic activity, the concentration of aerosol is higher.

In many industrial countries, the parameters of atmospheric pollution, including certain characteristics of the atmospheric aerosol, are measured at meteorological stations. This is done mainly in order to avoid the formation of smog, acid rain, and the destruction of forests. Thus, using a network of meteorological stations, the extinction coefficients have been calculated for the surface air in the eastern part of the USA.‡ As early as 1948, an increase in the number of sites where the surface air has high extinction coefficients was observed. During the period 1970–1974, a high value of this coefficient was noted for regions along the Great Lakes and the urban conurbation on the Atlantic littoral. As one moves West, the extinction coefficient falls.

Table 3. Concentrations (μg m^{-3}) of organic substances of different classes in certain types of aerosol at the standard pressure and temperature.[3]

Substance	Marine aerosol		Background continental aerosol	Aerosol from agricultural regions	Aerosol from industrial regions
	Northern Hemisphere	Southern Hemisphere			
Total organic carbon	0.60	0.36	1.1	2.5	
Aliphatic neutral substances	0.29		0.26	0.53	6.8
Aromatic neutral substances	0.25	0.25	0.12	0.26	3.1
Polar neutral compounds	0.16		0.20	0.35	4.9
Acids	0.29	0.18	0.20	0.70	10
Bases	0.08	0.09	0.03	0.20	2.0
Total hydrocarbons ($>C_{15}$)	0.014		0.14		0.27
Normal aliphatic acids and ketones	0.09		0.27		0.27
Normal aliphatic alcohols			0.83		1.64
Formaldehyde	0.0054			0.041	

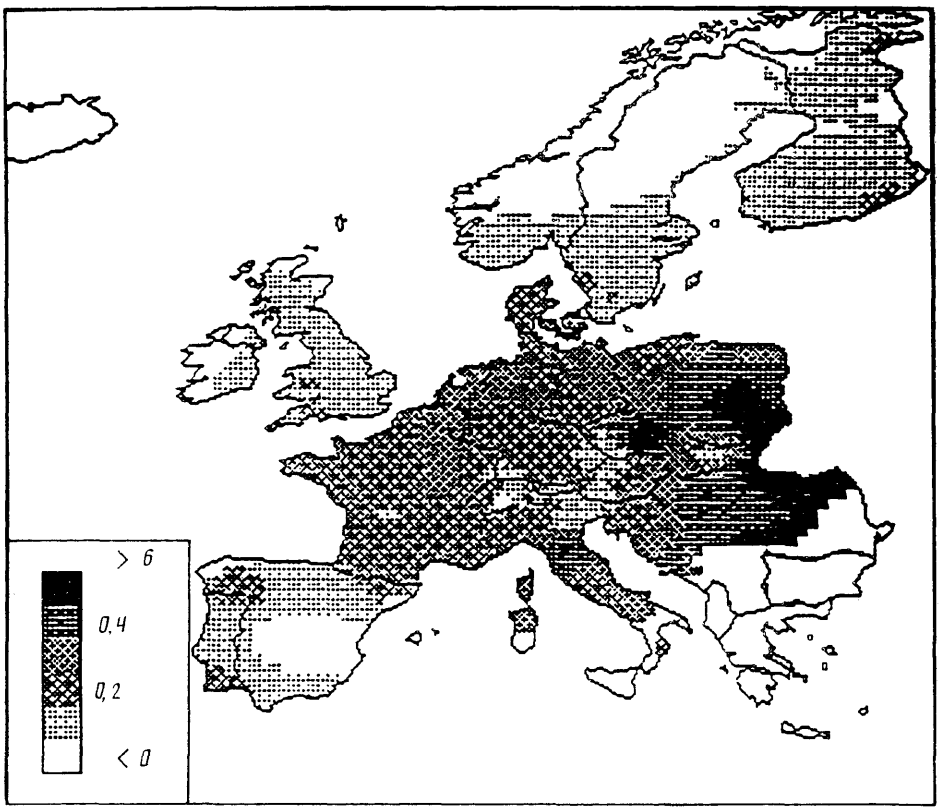

Figure 9. Map of the distribution of SO_4^{2-} in aerosols (in μg S m^{-3}) based on measurements within the framework of the combined program on the monitoring and evaluation of the large scale transport of pollutants in the atmosphere (EMEP).[47]

A map of the distribution of sulphates as aerosol over certain regions of Europe was published recently.[47] Fig. 9 shows that the concentration of sulphate is low over the sea littoral of northern Europe and the Mediterranean and is high in the eastern part of the continent.

The study of organic compounds in the aerosol is extremely difficult because of the great variety of these substances and their low concentration. Concentration data are available for only 95 compounds out of more than 1000 present in the marine and background continental aerosols.[3] Table 3 presents the concentrations of organic compounds of different classes in the marine aerosol of the Southern and Northern Hemispheres, the background continental aerosols and in the aerosols of the agricultural and industrial regions. The contents of organic substances in the marine aerosol and the aerosol from industrial regions differ by ~2 orders of magnitude.

VI. Vertical distribution of the aerosol

The types of distributions presented above show approximately, in relation to the background tropospheric and stratospheric aerosols, how the distribution of the particles with respect to size can vary with height.

As regards the distribution of the aerosol with respect to size as a function of the height over sea level, such studies have only just begun. Measurements performed over the Pacific Ocean in the course of the GAMETAG experiment[48] are most probably subject to instrumental errors. In the continental part of the USA, impactors for the study of the size distribution of the aerosol (in the range of particle sizes 0.2–3 μm) were inserted into the troposphere at heights up to 9 km. Fig. 10 presents data for the size distribution of the particles. At low altitudes, the concentration of the aerosol diminishes with increase in the particle radius. In the free troposphere, this decrease in concentration is modulated. This fact indicates a change in the form of the size distribution of the aerosol from that typical for the background continental aerosol to one characteristic of the background tropospheric aerosol.

The vertical distribution of the sea salt aerosol has been studied up to the height of the cloud cover (~1000 m).[50] The mass concentration of the salt diminishes from 2 mg m^{-3} in the layer where large spray particles are present (at a height of 0.1 m) to 1 μg m^{-3} at an altitude of 2000 m. A similar inversion of the salt layer under the cloud layer is a fairly common phenomenon. Above the cloud layer, the concentration of sea salt is so low that it is not susceptible to measurement.

A cross-section of the spatial distribution of the mass concentration at an altitude of 5.5 km from the South Pole to the North Pole was constructed for the tropospheric background aerosol.[3] At this altitude, the average concentration of the aerosol in the Southern Hemisphere is less than 0.3 μg m^{-3}. The maximum in the mass concentration is observed between 40 °S and 50 °S and amounts to 2.2 μg m^{-3}. In Arctic regions, the concentration of the aerosol is 1 μg m^{-3}.

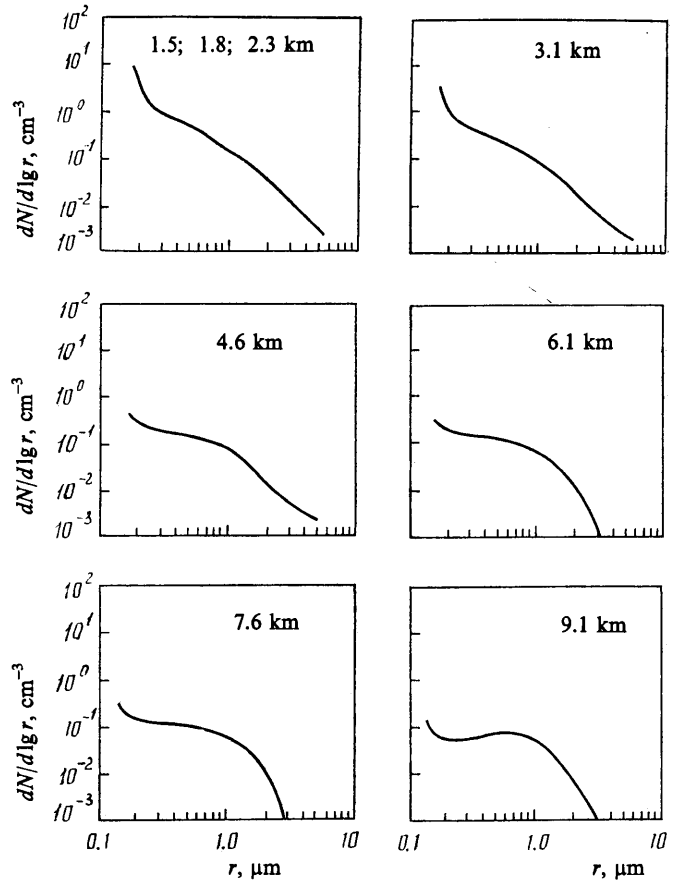

Figure 10. Average distribution functions for the number concentration of the aerosol at different heights in the continental part of the USA.[49]

A vertical section through the distribution of the number concentration of the aerosol was constructed in 1972–1973[51] and is shown in Fig. 11. One can easily note the decrease in the concentration of particles on moving from the surface of the Earth to the tropopause. In the stratosphere there is a layer with the distinctly enhanced concentration of particles. This so called "Junge layer" or the "sulphate layer" is located approximately 7 km over the tropopause. The concentration of the aerosol in this layer is a maximum over the equator. During periods of high volcanic activity, particles enter the Junge layer directly from the volcanic eruptions and this layer then undergoes marked changes. These changes were manifested particularly strikingly in a lidar study of the vertical distribution of the background scattering coefficient before and after the eruption of the El Chichon volcano (Mexico) in 1982[52] (Fig. 12).

The Junge layer continues to exist also during the period of low volcanic activity. During this time, it consists mainly of sulphuric acid particles, formed mainly as a result of the gas–particle transformation from dimethyl sulphide, which is the gaseous tropospheric precursor of H_2SO_4.[53] This layer has been thoroughly investigated from satellites and by terrestrial lidars, because it influences the transparency of the atmosphere, which is an important factor for the Earth's climate. Polar stratospheric clouds are part of this layer, influencing the geochemical ozone cycle and determining the dynamics of the development of the Antarctic ozone hole.

The vertical distribution of the mass concentration of the aerosol over deserts is naturally different. As already reported, mineral particles are distributed uniformly up to a height of ~6 km and this is probably characteristic of all deserts.

The vertical distribution of the number concentration of Aitken particles differs significantly from that for the majority of other particles. In it, there is no distinct layer in the stratosphere. The concentration of these particles diminishes with increased altitude and assumes a value of 1–10 particles cm^{-3} in the middle stratosphere.[54] The number concentration of condensation nuclei

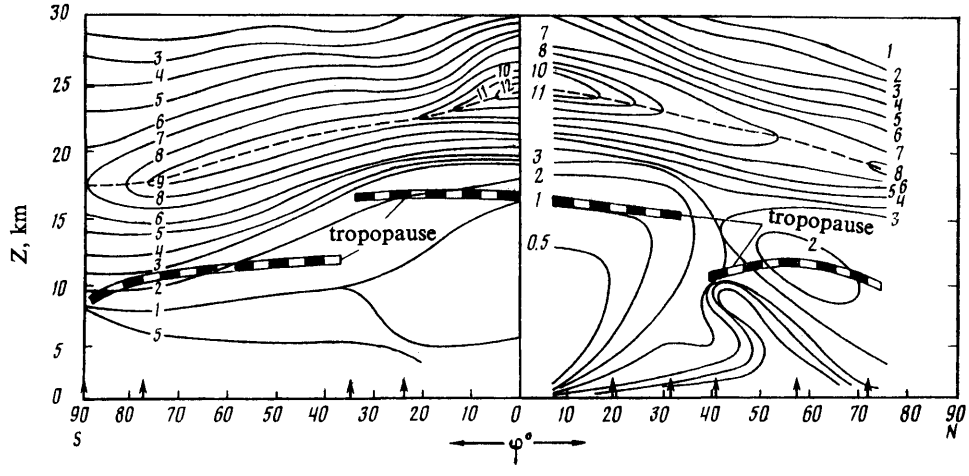

Figure 11. Number concentration contour lines for aerosol particles larger than 0.15 μm in radius as a function of the geographical latitude and height above sea level. The data refer to the period 1972–1973.[51]

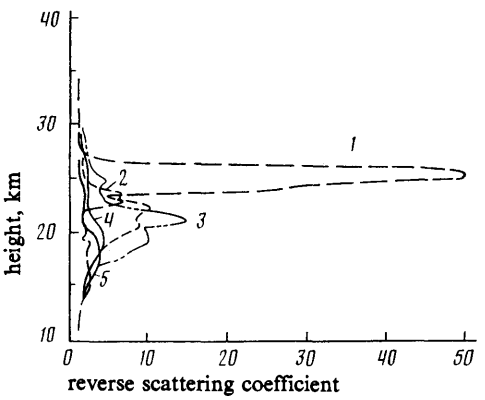
increases only for a short time after volcanic eruptions.[55] Fig. 13 illustrates typical examples of the distribution of these particles.



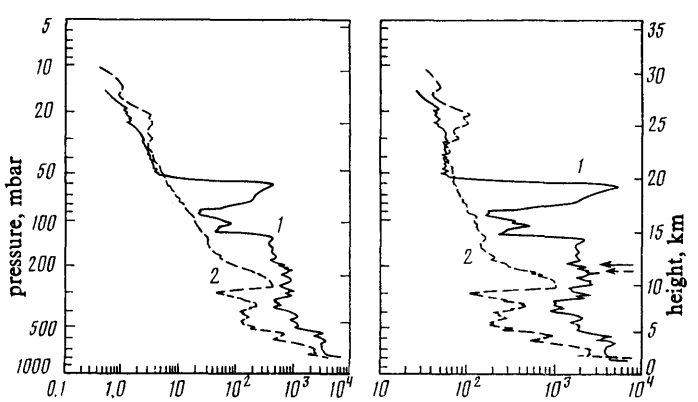


Figure 12. Vertical distribution of the coefficient of backward scattering obtained in terrestrial lidar studies in the region 37 °N, 76 °W. Probing laser wavelength—0.6943 μm:[52] (*1*) data for 1st July 1982; (*2*) data for 27th October 1982; (*3*) data for 3rd January 1983; (*4*) data for 30th June 1983; (*5*) data for 8th November 1983.

concentration of condensation nuclei, no. of particles in 1 mg of air

cm^{-3}

VII. Conclusion

In the last decade, our knowledge about the global distribution of the atmospheric aerosol increased immeasurably. Nevertheless, it is seen from the present review that we still know too little about it. A complete global map cannot be drawn for any one individual parameter of the aerosol and we are therefore forced to make do with incomplete information. This situation is unsatisfactory at a time when problems of vital importance for humanity, such as the changes in the climate and in the air require a detailed understanding of the state of the atmosphere, including the aerosol. The global computer meterological and climatic models suffer particularly from the deficiency of information about the distribution of the aerosol. Hitherto the question of the influence of the aerosol on the climate has given rise to controversy. Nevertheless, it may be that the facts presented in this review will inspire investigators to fill the existing gaps.

Catalytic methods for lowering the amount of nitrogen oxides in exhaust gases on combustion of fuel

Z R Ismagilov, M A Kerzhentsev, T L Susharina

ABSTRACT. The catalytic methods for reducing the amount of nitrogen oxides in exhaust gases on combustion of different types of fuel are analysed: the catalytic combustion method and the method involving the selective catalytic reduction of nitrogen oxides by ammonia.

The bibliography includes 187 references.

I. Introduction

Nitrogen oxides NO_x (NO and NO_2) are some of the most dangerous contaminants of air. Extremely low maximum permitted concentrations (MPC) have been established in all industrially developed countries for these compounds, which have a pronounced general toxic and irritant activity. Together with sulphur oxides, nitrogen oxides make a large contribution to the formation of acid rain, which leads to the destruction of forests, the poisoning of water reservoirs, and the formation of smog[1].

Considerable amounts of NO_x (up to 770 million tonnes annually) are formed as a result of natural processes—nitrification, forest fires, and storms. As a result of human activity, about 60 million tonnes of NO_x (calculated as NO_2) is produced annually[1,2], but anthropogenic waste is concentrated, in contrast to natural ones, in populated regions and lead to high local ground level NO_x concentrations. The principal sources of nitrogen oxides in industrially developed countries are power generation and transport, giving rise to approximately 95% of NO_x waste, the contribution of chemical industry being less than 5% [2]. Thus the principal amount of anthropogenic NO_x is produced as a result of the combustion of gas, petroleum fuel, coal, and other solid fuels. Further increase in the amount of NO_x waste can lead to irreversible ecological consequences on a global scale and therefore questions concerning the reduction of the amount of such waste are of extremely great current interest. A combined approach, including both the purification of smoke gases and the reduction or prevention of the formation of NO_x in combustion processes is required for the solution of this problem.

II. Sources of nitrogen oxides in fuel combustion processes

Nitrogen oxides can be formed on combustion of fuel both from atmospheric nitrogen ("thermal" and "fast" NO_x) and from bound nitrogen forming part of the composition of nitrogen-containing compounds ("fuel" NO_x).

1. Thermal nitrogen oxides

Thermal nitrogen oxides are formed as a result of the high-temperature oxidation of atmospheric nitrogen via Zel'dovich's radical chain mechanism[1,3]:

$$O_2 + M \overset{k_1}{\rightleftarrows} 2O + M, \quad (1)$$

$$N_2 + O \overset{k_2}{\rightleftarrows} NO + N, \quad (2)$$

$$O_2 + N \overset{k_3}{\rightleftarrows} NO + O, \quad (3)$$

where M is any species. Reaction (3) proceeds much faster than reaction (2) and the rate of formation of NO is therefore specified by the equation

$$\frac{d[NO]}{dt} = 2k_2[O][N_2] = k_{eff}K^{1/2}[O_2]^{1/2}[N_2],$$

where $k_{eff} = 2k_2$ is the effective rate constant and K is the equilibrium constant of reaction (1).

The temperature dependence of the yield of thermal NO_x is exponential. In the temperature range characteristic of the flame combustion of fuel in air (1800 K and above), the equilibrium concentration of NO exceeds 1500 p.p.m. Considerable amounts of NO (up to 500 p.p.m.) can be formed already at 1500 K.

2. Fast nitrogen oxides

Fast nitrogen oxides are formed in the combustion of hydrocarbons as a result of the interaction of hydrocarbon radicals with atmospheric nitrogen. These processes take place mainly in the presence of a deficiency of oxygen[1,2,4]:

$$N_2+HC\rightarrow HCN+N,$$
$$N+OH\rightarrow H+NO,$$
$$HCN+(H, OH)\rightarrow CN+(H_2, H_2O),$$
$$CN+O_2\rightarrow CO+NO,$$
$$CN+OH\rightarrow CO+NH,$$
$$NH+OH\rightarrow NO+H_2,$$
$$NH+NO\rightarrow N_2+OH.$$

3. Fuel nitrogen oxides

Nitrogen-containing compounds entering into the composition of fuels (including basic compounds—derivatives of pyridine, quinoline and acridine, and neutral compounds—various amides, nitriles, derivatives of pyrrole, indole, and carbazole, and other compounds[5]) are also sources leading to the formation of nitrogen oxides.

The formation of NO_x from fuel nitrogen proceeds via a series of intermediates; in particular, in the oxidation of pyridine and pyrrole, cyclic nitriles and CO are formed as intermediates[6]. One of the intermediates is hydrogen cyanide whose formation has been noted in the pyrolysis of pyridine[7] and in the oxidation of various nitrogen-containing compounds in mixtures with fuel in the presence of a deficiency of oxygen.[8,9] Regardless of the nature of the nitrogen-containing additive (NO, NH_3, CH_3CN, pyridine), bound nitrogen is almost fully converted into HCN in the reaction zone of the flame. On moving away from the reaction zone, the amount of HCN diminishes as a result of its conversion into N_2 and NO_x. Ammonia may also be detected together with N_2, HCN, and NO_x in the products of the combustion of nitrogen-containing fuels in the presence of a deficiency of nitrogen[10].

The mechanism of the interconversion of nitrogen-containing compounds in the flame has been considered in a number of studies[9,10–13]. The following mechanism for the conversion of fuel nitrogen has been proposed:

$$\boxed{\text{Fuel nitrogen}} \rightarrow \text{HCN} \rightarrow \text{NH}_x \begin{cases} \rightarrow \text{NO}_x, \\ \rightarrow \text{N}_2 . \end{cases}$$

According to experimental data, the conversion of fuel nitrogen into HCN is rapid and the rate-limiting stage is the oxidation of HCN [13]. The degree of conversion of fuel nitrogen into oxides in flame combustion is 20–50% and above[14–16]; the yield of NO_x is influenced by the content of nitrogen in the fuel (N_f) [14–16], the coefficient of the excess of air α† [17–19], and, to a lesser extent, the combustion temperature[20].

4. Methods for the suppression of the formation of NO_x in flame combustion

In order to combust the waste products comprising thermal nitrogen oxides, methods promoting a decrease in temperature in the combustion zone are employed: recirculation of the combustion products supplied to the combustion chamber, injection of water or steam into the combustion chamber, reduction of the additional heating of air[2,21,22]. These measures are insufficiently effective for the suppression of the formation of fuel NO_x whose sensitivity to temperature is low. The principal methods for the reduction of the amount of fuel NO_x waste involved a decrease in the coefficient of the excess of air and stepwise (two-stage) combustion[23]. In the latter method, air is supplied into the primary combustion zone in an amount less than that required theoretically. This results in a decrease in the O_2 concentration and in the flame temperature and hence in a decrease in the formation of both fuel and thermal NO_x. An amount of air insufficient for the combustion of uncombusted components is introduced to the secondary zone. The temperature in the secondary zone does not then reach the level sufficient for the formation of appreciable amounts of NO_x.

The improvement of the technology of flame combustion and design and technical measures make it possible to reduce somewhat the amount of waste comprising nitrogen oxides from combustion devices, but these possibilities are limited. Furthermore, the application of methods for the suppression of the formation of NO_x such as the recirculation of the combustion products, multistage combustion, and a decrease in the coefficient of the excess of air usually lead to an increase in the content of carbon monoxide, soot, and carcinogenic substances in the effluent gases and also to a breakdown in the stability of the combustion.[24,25] The principal methods for reducing the amount of NO_x waste have been described[21] (Fig. 1).

Norms for the content of NO_x in air have been established in our country[26] and standards are being developed for the maximum permissible amounts of waste (MPW) comprising NO_x for individual undertakings and industrial complexes.[2,27] The requirements for the maximum permissible amounts of waste NO_x have already been established in a number of countries[28,29]. Thus in Japan the NO_x MPW is 60 p.p.m. for large gas-operated boilers, 150 p.p.m. for masout-operated boilers, and 200 p.p.m. for carbon dust-operated boilers[29]. The existing methods for suppressing the formation of NO_x in the flame combustion of fuels cannot ensure the fulfillment of such rigorous requirements as regards the purity of smoke gases and it is therefore necessary to resort to expensive measures such as the catalytic elimination of NO_x from gases[30]. The best results have been obtained in the catalytic reduction of nitrogen oxides by ammonia and this method has been widely adopted in recent years in industrial boiler aggregates in a number of countries.

III. Selective catalytic reduction of nitrogen oxides by ammonia

1. Principles of the method

In contrast to the methods involving the improvement of the technology of flame combustion, the processes in which smoke gases are purified ensure a much greater reduction in the amount of NO_x waste—by 60–90%. The methods for the elimination of NO_x from smoke gases[21,31–33] have come to be divided into "wet" and "dry" (Fig. 1). The wet methods, based on the absorption of nitrogen oxides by aqueous solutions of various compounds, have not found extensive application, since under these conditions there arises, firstly, the problem of the utilisation of the waste water, and, secondly, it becomes necessary to heat the gases after purification before ejection into the smoke tube, which requires a large comsumption of fuel. Among the dry methods, the reduction of NO_x to molecular nitrogen, which need not be utilised, are of greatest interest for practical employment[32].

The non-selective reduction of nitric oxide by natural gas, hydrogen, or carbon monoxide occurs at 520–670 K in the presence of catalysts[2]:

$$4NO+CH_4 \rightarrow 2N_2+CO_2+2H_2O, \quad (4)$$

$$2NO+2H_2 \rightarrow N_2+2H_2O, \quad (5)$$

$$2NO+2CO \rightarrow N_2+2CO_2. \quad (6)$$

† The coefficient of the excess of air α is defined as the ratio of the amount of air supplied for the combustion of the fuel to the amount of air required theoretically for the combustion of the given mass of fuel.

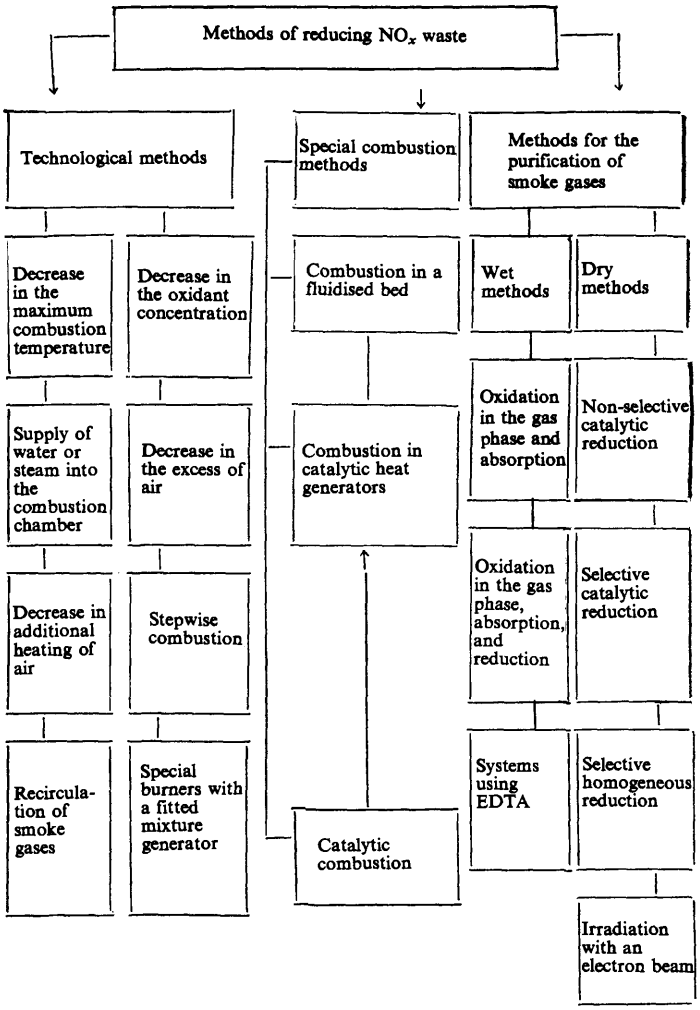

Figure 1. Methods for the reduction of NO_x waste[21].

These processes occur in a medium which contains virtually no oxygen and the first stage of the non-selective catalytic purification is therefore the "burning-off" of the oxygen in the smoke gases by the excess reductant. This consumes an amount of reductant tens of times greater than that consumed in the reaction with nitrogen oxides and methods for the non-selective catalytic reduction have not therefore found applications for the purification of smoke gases from boilers and their employment is limited to the purification of residual gases from plants for the manufacture of nitric acid[31].

The catalytic reduction of NO_x by ammonia with formation of nitrogen and water is at present regarded as the most promising of the catalytic procedures for the purification of smoke gases. This is associated with the fact that, in contrast to other reductants (methane, hydrogen, carbon monoxide, and hydrocarbons), ammonia is capable of reducing selectively nitrogen oxides in the presence of an excess of oxygen in the smoke gases[31].

The method for the selective catalytic reduction (SCR) makes it possible to reduce the amount of NO_x waste in the ideal case by more than 90%, although in practice, owing to the limitations imposed by the volume of the catalytic reactor and the permissible breakthrough of ammonia, a degree of purification of 65–80% is usually attained[32,33].

In the absence of oxygen, the interaction between ammonia and nitric oxide is described by the equation

$$4NH_3+6NO\rightarrow 5N_2+6H_2O. \quad (7)$$

In the presence of oxygen, the reduction of nitric oxide is accelerated[32] and the reaction

$$4NH_3+4NO+O_2\rightarrow 4N_2+6H_2O, \quad (8)$$

takes place. The role of oxygen consists in the reoxidation of the catalyst surface, which is converted into the reduced form following the adsorption of ammonia[31,32]. There exist data[34,35] showing that the rate of reaction of nitrogen dioxide with ammonia is independent of the oxygen concentration. The reaction proceeds in accordance with the equation

$$3NO_2+4NH_3\rightarrow 3{,}5N_2+6H_2O. \quad (9)$$

In an equimolar $NO-NO_2$ mixture, nitrogen oxides are reduced via the reaction[36]

$$NO_2+NO+2NH_3\rightarrow 2N_2+3H_2O. \quad (10)$$

Reaction (10) is the fastest of those occurring in the $NO_x-O_2-NH_3$ system[34].

Reaction (8) plays the main role in the SCR process, because in most smoke gases 90–95% of nitrogen oxides consists of NO. According to the stoichiometry of reactions (8) and (10), the molar ratio of NO_x and NH_3 should be close to unity. It has been stated[32] that a decrease in the amount of NO_x waste by 60–85% requires that the NH_3:NO molar ratio should be 0.6–0.9 and that the residual ammonia in the effluent smoke gases should be less than 1–5 p.p.m. The temperature necessary to reduce NO_x depends on the type of catalyst and is usually 570–670 K. In order to attain such temperatures without additional heating of the smoke gases, the SCR reactor is as a rule placed between the economiser and the air heater.

In the practical organisation of the elimination of NO_x from gases, it is necessary to take into account all the possible processes which may occur in the system containing the catalyst, ammonia, and smoke gases.

In the presence of oxygen, the ammonia oxidation reactions take place on the catalyst[36]:

$$2NH_3+1.5O_2\rightarrow N_2+3H_2O, \quad (11)$$

$$2NH_3+2O_2\rightarrow N_2O+3H_2O, \quad (12)$$

$$2NH_3+2.5O_2\rightarrow 2NO+3H_2O. \quad (13)$$

Reaction (13), whose occurrence can lead to an increase in the NO concentration compared with its concentration in the initial gas, is especially undesirable. Furthermore, the majority of the catalysts used accelerate the reaction[37]

$$2SO_2+O_2\rightarrow 2SO_3. \quad (14)$$

Following the breakthrough of ammonia and in the presence of SO_3 in the smoke gases, the following reactions can occur:

$$NH_3+H_2O+SO_3\rightarrow NH_4HSO_4, \quad (15)$$

$$2NH_3+H_2O+SO_3\rightarrow (NH_4)_2SO_4. \quad (16)$$

Ammonium sulphate and hydrogen sulphate are formed in these processes. A decrease in the temperature of smoke gases can lead to the contamination by the latter of the heating surfaces or of the catalyst itself. There is a possibility of a version in which the catalytic reactor is placed beyond the apparatus for the desulphurisation of the smoke gases, but in this case the latter must be heated additionally (approximately from 340 to 620 K) by combusting the gas or masout[37], i.e. as a result of an additional consumption of fuel.

Thus the most important requirements which must be met by the SCR catalysts are their high activity in the temperature range 570–670 K and their high selectivity, excluding the appreciable occurrence of the undesirable reactions (11)–(16). The requirements include[38] high resistance to erosion by the ash formed on combustion of the solid fuel, resistance to catalytic poisons present in the ash, the optimum porous structure excluding the blocking of the catalyst pores by dust, and a low hydraulic resistance.

2. Catalysts for selective catalytic reduction

SCR catalysts containing titanium, tungsten, tin, manganese, nickel[39], vanadium, molybdenum, tantalum, boron[40], chromium, iron, copper, cobalt, lanthanide[41], and uranium[42] oxides, platinum metals[43,44], cerium, iron, and manganese halides[45], transition metal ferrites[46], transition metal salts formed by the Si–W, Si–Mo, P–W, and P–Mo heteropolyacids[47], transition metal carbides[48], copper alloys[49], intermetallic compounds of platinum group metals with aluminium, scandium, titanium, and other metals[50], and zeolites[51,52] have been patented as SCR catalysts.

The catalyst carriers employed are aluminium oxide[53,54], aluminosilicates[55,56], alumina, silica[57], calcium silicate[58], titanium dioxide[59,60], a mixture of titanium dioxide and silicon dioxide[61], and zeolites[62,63]. Carriers consisting of sheet metal[64], metallic mesh[65], and ceramic honeycomb blocks[54,66,67] have been patented.

Analysis of the patent literature shows that the principal component of the catalyst carriers used to ensure the safety of the smoke gases from thermal electric power stations is titanium dioxide, which is highly stable as regards the sulphur oxides present in the smoke gases. Titanium dioxide is used both in a pure form[59,60] and together with other oxide additives: SiO_2 [61], WO_3 [68,69], MoO_3 [69], various SiO_2, Al_2O_3, ZrO_2, or ThO_2 compositions[67], as well as clay substances of the type of kaolin, montmorillonite, halloysite, pyrophyllite, or their mixtures[70]. Compounds of vanadium (V_2O_5 [59,62,63], $VOSO_4$ [71], or vanadium oxides with added TiO_2 or other metal oxides), niobium[67], silicon or zirconium[72], tungsten or molybdenum[73,74], the lanthanides[75,76], and tin[74,77,78] are usually employed as the active components of industrial catalysts. The oxides of elements in the following combinations can also serve as active components: Mn and Sn, Mn and Cd, Fe and Ni, Fe and Bi, Cr and Ni, Cr and Sb, Cu and Mo, and Co and Pb[79]. Other combinations of metal oxides, chosen from the following groups have also been proposed: Cu, Mn and Cr, on the one hand, and V, Mo, Cl, and Sn, on the other[80]. Group VB, VIB, VIIB, and VIII metal oxides are also active SCR catalysts[81].

Noble metals exhibit a high activity at 370–470 K, but their use is limited by the reduction of NO_x in the pure gases, in which there are no catalytic poisons, especially SO_2 [82]. Platinum can be employed in the range 440–520 K: the lower limit is determined by the possibility of the deposition of explosive ammonium nitrite and nitrate and the upper is set by the reaction involving the oxidation of ammonia to nitrogen oxides.

The activity of metals (deposited on Al_2O_3) diminishes in the sequence Pt $\simeq$ Pd $\gg$ Ru > Ni for the $NO-NH_3$ system, Pt $\gg$ Pd $\gg$ Ru > Ni for the $NO-NH_3-O_2$ system, Ru $\gg$ Pt, Pd, Ni for the $NO-NH_3-SO_2$ system, and Pt $\gg$ Pd, Ru > Ni for the $NO-NH_3-SO_2-O_2$ system[83,84].

In the absence of SO_2, oxygen accelerates the reduction of NO_x on platinum, ruthenium, and nickel catalysts but lowers the rate of reaction on the palladium catalyst, which can be explained by the reversible oxidation of the metal surface. In the presence of SO_2, the metal surface is covered by a monolayer of S^{2-} ions and the activity falls by 3–5 orders of magnitude; the ruthenium catalyst, whose activity falls only by a factor of 4, exhibits a notable resistance to poisoning by sulphur. The addition of oxygen to this system leads to the partial restoration of activity. Noble metals promote the ammonia oxidation side reactions in the presence of oxygen, the main one being the N_2O formation reaction (12) [83].

The activity of substituted type Y zeolites containing transition metals varies in the sequence $Pt^{II}-Y > Fe^{III}-Y > Ni^{II}-Y > Co^{II}-Y$ [85]. The zeolites are active in the temperature range 370–470 K. The presence of oxygen increases the rate of reduction of NO_x. Sulphur dioxide lowers the degree of conversion at T > 530 K, inducing the partial decomposition of the zeolite with formation of sulphates, in particular $(NH_4)_3Al(SO_4)_3$. Their deactivation in the presence of water vapour is a significant disadvantage of zeolites[86].

The activity of transition metal oxides increases in the sequence Ni < Ti, Sn, Co, Zn < W < Mo < Cr < V, Fe, Cu, Mn [31,87]. The oxides are also poisoned by sulphur, iron and vanadium oxides being the most stable. Apart from oxides, transition metal salts are active in SCR reactions: in terms of their influence on the relative catalytic activities of catalysts containing copper or iron, the counterions can be arranged in the sequence $Br^- > Cl^- > SO_4^{2-} > O^{2-}$ [88]. In the conformity with this, copper and iron oxide are less active in the absence of SO_2 than the sulphates; on the other hand, in the presence of SO_2, the oxides are converted into sulphates and their activities become similar. The activities of metal oxides in the presence of SO_2 diminish in the sequence $CuO > Fe_2O_3 > Co_3O_4 >$ NiO, while water vapour has hardly any influence[87]. Under industrial conditions, the majority of oxide catalysts, including even the most active and sulphur-resistant iron and iron-chromium catalysts deposited on alumina, lose their activity after working for several hundreds of hours as a result of poisoning by sulphur. The industrial application of the SCR method has become possible only as a result of the development of TiO_2-based catalysts, which possess a high activity and resistance to poisoning by sulphur over a wide temperature range (470–720 K) [89].

Industrial SCR catalysts usually consist of TiO_2 and a second component chosen from the oxides V_2O_5, MoO_3, WO_3, Fe_2O_3, CoO, NiO, MnO_2, Cr_2O_3, CuO, etc. Catalysts comprising TiO_2 and semiconducting *n*-type oxides (V_2O_5, $Mn_2O_3.Fe_2O_3$) are the most active in the reaction $NO+NH_3\rightarrow N_2+H_2O$, while the most active catalysts in the NO_2 reduction reaction are those based on TiO_2 and *p*-type semiconducting oxides (CoO, NiO). The anionic vacancies in the catalysts of the first type apparently promote the adsorption of

NO, while the cationic vacancies in catalysts of the second type favour the adsorption of NO_2.

It may be that TiO_2 plays the role of not only the carrier but also of a promoting agent, since the activity of mixed catalysts based on TiO_2 is higher than that of the individual oxides forming part of their composition[89].

The activity of the TiO_2-based catalysts hardly changes over a period of 2000 h and their useful lifetime during industrial employment has been estimated as 5 years. The SCR reactions on various catalysts containing the Fe, Cr, Cu, Al, Ti, and Mg oxides have been studied[89]. The $Fe_2(SO_4)_3-\alpha$-$Fe_2O_3-TiO_2$ catalyst is one of the most active both in the presence and absence of SO_x. The addition of MoO_3 or WO_3 to this catalyst increases its resistance to poisoning by sulphur and the selectivity of the reduction of NO.[89] The study of the reaction of NO with NH_3 in the presence of O_2 on V_2O_5/TiO_2 and V_2O_5/Al_2O_3 shows that the first of these catalysts is more active than the second[90]. This has been explained by the greater number of V=O surface groups participating in the reaction on the catalyst deposited on TiO_2.

3. Kinetics and mechanism of the selective catalytic reduction reactions

Reviews of studies on the kinetics of the reduction of NO by ammonia have been published[31,32,91]. On platinum, the observed reaction order with respect to NH_3 is close to unity, while the order with respect to NO is 0–0.5 [31]. Apart from nitrogen, N_2O is formed during the reaction. The mechanism of the reaction on platinum has been established with the aid of labelled nitrogen ^{15}N incorporated in the composition of NO and NH_3 [92]:

$$NH_3 \rightleftarrows NH_3(ads.),$$
$$NH_3(ads.) \rightleftarrows NH_2(ads.) + H(ads.),$$
$$NO \rightleftarrows NO(ads.),$$
$$NO(ads.) + NH_2(ads.) \rightarrow [\text{surface complex (I)}] \rightarrow N_2 + H_2O,$$
$$\vdots \quad \ldots\ldots\ldots\ldots \rightarrow N_2O + 2H(ads.),$$
$$H(ads.) + NO(ads.) \rightarrow HNO(ads.),$$
$$2HNO(ads.) \rightarrow [\text{surface complex (II)}] \rightarrow N_2O + H_2O,$$
$$\vdots \quad + 2H(ads.) \rightarrow N_2 + 2H_2O.$$

The rate of the reaction of NH_3 with NO on copper-containing zeolites is described by the kinetic equation[86]

$$w = \frac{kK_{NO}K_{NH_3}p_{NO}p_{NH_3}}{(1 + K_{NH_3}p_{NH_3} + K_{H_2O}p_{H_2O})^2},$$

where k is the rate constant for the reaction of the adsorbed NH_3 and NO, K_i the equilibrium constant for the adsorption of the corresponding components of the reaction mixture, and p_i are the corresponding partial pressures. This equation corresponds to the mechanism in which the rate-limiting stage is the interaction of the strongly adsorbed NH_3 with the weakly coordinated NO. The equation indicates the cause of the inhibition of the reaction by water: water displaces ammonia, competing with it for the surface centres.

The following mechanism has been postulated for the SCR reaction on copper oxide and copper sulphate catalysts[87]:

$$NO \rightleftarrows NO(ads.),$$
$$NH_3 \rightleftarrows NH_2(ads.) + H(ads.),$$
$$O_2 \rightleftarrows 2O(ads.),$$
$$2H(ads.) + O(ads.) \rightleftarrows H_2O,$$
$$NO(ads.) + NH_2(ads.) \rightleftarrows N_2 + H_2O.$$

According to this mechanism, the overall rate of the process is determined by the rate of the stage involving the reaction of the adsorbed NO with the dissociatively adsorbed NH_3.

In a study[91] of the kinetics of the reaction of NO with NH_3 on the $V_2O_5/SiO_2.TiO_2$ industrial catalysts, the rate of the process was fitted by the kinetic equation $w = kc_{NO}^{n_1}c_{NH_3}^{n_2}c_{O_2}^{n_3}$. At temperatures in the range 550–650 K, the reaction orders are 0.7–0.8 with respect to NO, 0.1–0.3 with respect to NH_3, and 0.1–0.3 with respect to oxygen. Internal diffusion conditions occur in this temperature range and the activation energy is 28 kJ mol^{-1}. The mechanism of the reaction on V_2O_5 proposed by Miamoto et al.[90] relates the activity of the catalyst to the concentration of the surface V=O groups:

$$V{=}O + NH_3 + NO \rightarrow V{-}OH + N_2 + H_2O,$$
$$3V{=}O + 2NH_3 \rightarrow 3V\square + N_2 + 3H_2O,$$
$$V\square + 0.5O_2 \rightarrow V{=}O,$$
$$V\square + NO \rightarrow V{=}O + 0.5N_2,$$

where V□ is a V–OH group or an oxygen vacancy on the surface. In contrast to this, it has been shown[93] that N_2 is formed predominantly on the single crystal faces coated by hydroxy-groups and that there is a correlation between the number of adsorbed NH_4^+ ions and the amount of N_2 formed. The following mechanism is consistent with similar ideas:

$$V^{5+}{-}OH + NH_3 \rightarrow V^{5+}{-}ONH_4,$$
$$2V^{5+}{-}ONH_4 + V^{5+}{-}O{-}V^{5+} + 2NO \rightarrow$$
$$2N_2 + 3H_2O + V^{5+}OH + V^{4+}\square V^{4+},$$
$$V^{4+}\square V^{4+} + 0.5O_2 \rightarrow V^{5+}{-}O{-}V^{5+},$$

where □ is an oxygen vacancy on the surface.

4. Industrial use of selective catalytic reduction

In order to eliminate NO_x from smoke gases with a high content of SO_x and solid particles, mainly only two types of block catalysts are employed in industry: lamellar catalysts made from cast metal plates and monolithic catalysts with a ceramic honeycomb structure.

The lamellar catalysts developed by the Hitachi company (Japan) consist of steel sheets plated by the plasma sputtering of stainless steel with subsequent deposition of the catalytic mass. The catalyst plates, the gap between which is 5–6 mm, are assembled into 450 × 450 × 500 mm blocks. Jointly assembled 10–20 blocks comprise catalyst modules weighing from 1.11 to 2.02 tonnes.

The reduction temperature is 570–690 K. Depending on the temperature of the gases and their content of SO_x and ash, different modifications of the catalysts are employed[94].

Different types of honeycomb catalysts on a ceramic base have been developed by the Mitsubishi and Sakai companies (Japan). Depending on the type of fuel, different ratios of the active substances—titanium dioxide, tungsten trioxide, and vanadium pentoxide—are used. The catalysts are made in the form of rectangular blocks 500–1000 mm long and with a 150 × 150 mm cross-section. In each block there are 20 × 20 or 33 × 33 honeycomb cells; the longitudinal cross-sections through the honeycomb cells range from 3.5 × 3.5 to 6 × 6 mm. The surface of the catalyst varies from 430 to 678 m^2 per m^3 of its volume. The catalysts are assembled into modules containing between 36 and 100 blocks[95].

The SCR method has found the most extensive application in Japan, where 20 devices, fitted on large carbon dust energy units, began to operate in 1980–1986. In addition, towards the end of 1985, a further 200 devices for the catalytic purification of smoke gases operated in Japan on thermal electric power station boilers with an overall power of 30 GW[33].

Industrial SCR devices are being introduced in the Federal Republic of Germany[96], Australia[97], and West Berlin[98]. Experimental studies on SCR are being prosecuted in Sweden[99].

The experience gained in the use of industrial SCR devices has shown that the guaranteed useful lifetime of the catalysts is between 1 and 2 years. In fact, the average useful lifetime reaches 5 years in the combustion of liquid fuel and 7 years in the combustion of gas[100]. In order to prolong the useful lifetime of the catalyst, it is essential to free the gases from dust, which erodes the active surface. However, fine dust particles, which are difficult to remove, can block the pores of the catalyst, which also reduces its useful lifetime[100].

Each MW of the measured power of the energy unit usually requires 2 m^3 of the catalyst, costing 30000 German marks (10000 roubles) per m^3[101].

The specific cost of the purification of smoke gases using the SCR method depends comparatively little on the power of the plant and varies from 106 to 222 German marks per kilowatt (40–80 roubles/kW) for energy units with power ranging from 150 to 700 MW. The cost of the catalyst itself is then 40% of the overall cost of the apparatus[33].

The requirements which must be met by the catalysts in the purification of gases by the SCR method are more stringent than in the catalytic combustion of fuels. In many cases, especially in the generation of heat for domestic purposes or for various technological processes, ecologically pure catalytic combustion can compete with flame combustion combined with purification of smoke gases.

IV. Catalytic combustion as a method of preventing the formation of nitrogen oxides

1. Principles of catalytic combustion

The catalytic combustion of fuels is a special case of total oxidation. The specific features of catalytic combustion consist in the fact that the catalyst should ensure the complete combustion of highly concentrated mixtures of hydrocarbons under conditions where the ratios of the reaction components are close to the stoichiometric ratios and when a large amount of heat is evolved. The total oxidation catalyst can therefore be used, in principle, also for catalytic combustion. However, these catalysts must exhibit an improved heat resistance, stability, and resistance to catalytic poisons which may be present in the fuel. The history of the problem and the principles governing the selection of catalysts have already been examined in detail[102–109]. The principal results of the latest studies on the catalytic combustion of fuels have been described in reviews[108–112].

Studies on the use of catalytic combustion for domestic, energy generating, and technological requirements are developing in several directions. Small catalytic heat sources for the heating of domestic and industrial accommodation and means of transportation are being created[113–124]. Extensive studies are being prosecuted on the catalytic combustion in the combustion chambers of gas turbines[125–134]. The catalytic combustion of gases with a low heat of combustion and a low temperature of the effluent gases in a number of industrial undertakings is believed to be extremely promising[135]. In all the devices listed, the fuels are combusted in a stationary catalyst bed consisting of noble metals deposited on fibrous and block carriers at temperatures in the range 1100–1600 K.

The principal advantage of the catalytic combustion of fuels is believed by the majority of workers to be the possibility of a significant decrease in the amount of harmful waste[131,132]. Indeed, the use of a catalyst makes it possible to increase the degree of conversion of the hydrocarbon fuel and to eliminate the formation of CO and of carcinogenic hydrocarbons usually formed in flame combustion. In the catalytic combustion of fuels which do not contain bound nitrogen in gas turbines at 1200–1500 K, the concentration of NO_x in the effluent gases diminishes from 150 to 2 p.p.m.[129,130] In model boiler plants with catalytic combustion of a gaseous fuel at 1400–1600 K, a tenfold decrease in the amount of NO_x waste (from 150 to 15 p.p.m.) is achieved[130]. The advances made concern principally pure fuels (petroleum gas and petroleum distillates) and arise from the fact that the decrease in temperature makes it possible to rule out completely the formation of high-temperature "thermal" nitrogen oxides. At the same time the problem of reducing the amount of waste "fuel" nitrogen oxides in working experimental devices has apparently not yet been solved. Thus, in the combustion of nitrogen-containing fuels, an almost complete conversion of the nitrogen of the fuel into nitrogen oxides has been observed in the catalytic chamber of the gas turbine[130]. Other difficulties and limitations accompanying the employment of devices with a stationary catalyst bed in the form of honeycomb structures or other blocks have also been discovered. The catalytic combustion is accompanied by extensive adiabatic heating, as a consequence of which the catalyst blocks must possess a series of unique properties. On the one hand, they must have a minimal wall thickness and must be characterised by a minimal hydraulic resistance and, on the other hand, they should exhibit the maximum stability as regards large temperature drops during prolonged use. The employment of platinum group metals as the active component leads to an appreciable increase in the cost of the catalytic devices. Platinum and palladium may be poisoned by catalytic poisons and are suitable only for the combustion of fuel free from such poisons[135]. The devices described are not suitable for the combustion of liquid fuels obtained by the hydrogenation of coal or masout, since they contain catalytic poisons and cannot be fully vaporised to be supplied into the catalytic chamber in the vapour phase.

Catalytic heat generators (CHG) for the combustion of fuel have been developed by the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences[103,111,136–138]. The combustion of

fuels in CHG is based on four principles: (1) the use of total oxidation catalysts; (2) the use of a fluidised bed of catalyst particles; (3) the combustion of nearly stoichiometric fuel–air mixtures; (4) the combination of heat evolution and heat removal in a single catalyst bed.

Thus the non-flame combustion of fuels in CHG takes place on the surface of catalyst particles in a fluidised state. Like any fluidised bed apparatus, the CHG consists of a hollow vessel in the lower section of which there is an air distributing grid. Fluidisation occurs during the ascending movement of a mixture of air with the fuel as well as the combustion products through the bed of spherical catalyst particles. The useful removal of heat from the CHG is achieved either through the surface of a heat exchanger in contact with the fluidised catalyst bed or via a working body in direct contact with the catalyst. The fundamental advantage distinguishing the CHG from the devices described in the literature for the combustion of fuels in a fluidised catalyst bed[139–145] is the presence of a horizontal sectioning grid with a specified live section and a rigorously specified diameter of the apertures. This results in the creation of two zones of a free fluidised bed—below the sectioning grid and above it. The height of the lower zone should be such that complete oxidation of the fuel is ensured. The sectioning grid limits the circulation of the catalyst particles and hence the thermal conductivity of the bed. It plays the role of a non-isothermal packing and divides the apparatus along its height into two isothermal zones: the lower zone whose temperature is necessary for the complete oxidation of the fuel (700–1000 K) and the upper zone whose temperature is determined by the conditions in the heating of the working body[111,146,147] (Fig. 2). The presence of the non-isothermal packing and the removal of heat from the upper part of the apparatus make it possible to reduce the temperature of the effluent gases to 420–450 K.

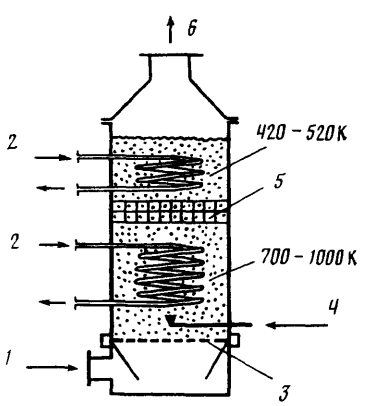

Figure 2. Schematic illustration of a non-isothermal catalytic heat generator[111]: *1*, air; *2*, water; *3*, gas distributing grid; *4*, fuel; *5*, non-isothermal head-piece; *6*, effluent gases.

Analysis showed that catalytic combustion makes it possible to solve the ecological problems arising in the use of the so called "pure fuels" without bound nitrogen. Unfortunately the fraction of such fuels with diminish as the trends which have arisen towards the employment of coal, masout, and coal liquefaction products intensify. Such fuels contain bound nitrogen which can form during catalytic combustion an amount of nitrogen oxides which is not less than in flame combustion. The specific features of the extensive oxidation reactions of nitrogen-containing compounds consist in the fact that both molecular nitrogen and nitrogen oxides can be formed from them:

$$RN + O_2 \rightarrow CO_2 + H_2O + N_2, \quad (17)$$

$$RN + O_2 \rightarrow CO_2 + H_2O + NO_x. \quad (18)$$

In catalytic combustion processes, it is important to achieve a decrease in the yield of fuel NO_x via reaction (18) as a result of the preferential occurrence of reaction (17). To solve this problem, it is essential to investigate the kinetics and mechanism of the catalytic oxidation of nitrogen-containing compounds of different classes.

2. Kinetics and mechanism of the catalytic oxidation of nitrogen-containing compounds

(a) Oxidation of ammonia and hydrogen cyanide. The catalytic oxidation of ammonia has been studied in very great detail, since this reaction is one of the most important processes in heterogeneous catalysis[148,149]. It can proceed via three principal pathways described by Eqns. (11)–(13). All the reactions indicated are almost irreversible.

The present state of the theory of catalytic oxidation of ammonia has been described satisfactorily by Il'chenko[150]. By analogy with the oxidation of organic compounds, molecular nitrogen should be regarded as the product of mild oxidation, while nitrogen oxides are products of extensive oxidation. In the presence of many catalysts, three nitrogen-containing products (N_2, N_2O, NO) in various proportions are formed simultaneously at 673–773 K. On the other hand, by using selective catalysts and by carrying out the reaction under specified conditions, one can ensure the preferential occurrence of one of the processes. Thus at high temperatures (1073–1173 K) on platinum catalysts, the yield of nitrogen oxides can reach 96–99%, which is achieved in practice in the manufacture of nitric acid. The oxidation of ammonia on platinum begins at 423–473 K where the only nitrogen-containing reaction product is molecular nitrogen. With increase in temperature, N_2O appears, its yield passing through a maximum. At temperatures of the order of 573 K, the formation of nitric oxide begins. The yield of this product gradually increases and can exceed 90% at 973–1273 K [148,150].

The oxidation of ammonia on other catalysts proceeds similarly but the temperature limits in the formation of the products of mild and extensive oxidation can be different. The specific catalytic activity of metals in the oxidation process decreases in the sequence Pt > Pd > Cu > Ag > Ni > Au > Fe > W > Ti. The corresponding activity series for oxide catalysts has also been found: Co_3O_4, MnO_2 > CuO > ZnO > CaO_2 > NiO > Bi_2O_3 > Fe_2O_3 > V_2O_5 > TiO_2 > CdO > PbO > SnO_2 > ZrO_2 > MoO_3 > WO_3 [149–152]. The decrease in activity is associated with the increase in the bond energy between oxygen and the metal surface. The selectivity in the extensive oxidation (to N_2O and NO) diminishes in approximately the same sequence. The point is that, in the extensive oxidation process, a larger number of oxygen–catalyst bonds are broken that in the formation of the mild oxidation product (N_2). With increase in the bond energy between oxygen and the metal surface, the rate of extensive oxidation should therefore

diminish more rapidly than the rate of mild oxidation, which in fact leads to a change in selectivity in the series quoted above[148,149].

A similar behaviour has been observed in the study of the catalytic oxidation of hydrogen cyanide[153]. In this case, the activity and selectivity of the catalysts are also determined by the bond energy between oxygen and the catalyst surface[148].

(b) Oxidation of organic nitrogen-containing compounds. Comparatively few data on the kinetics of the extensive oxidation of organic nitrogen-containing compounds have been described in the literature. The studies carried out have been devoted mainly to the selection of conditions governing the use of catalysts for the additional combustion of the waste from different industries.

Thus the oxidation of dimethylformamide has been studied on the AVK-10 (10% V_2O_5/Al_2O_3), NIIOGAZ-7D ($Cr_2O_3+CuO+V_2O_5$), ShPK (0.2% Pt/Al_2O_3), and AP-56 (0.5% Pt/Al_2O_3) industrial catalysts at 573–623 K [154]. The formation of nitrogen oxides at concentrations up to 18 p.p.m. has been observed on platinum catalysts. On oxide catalysts, NO_x were either not formed or were evolved in trace amounts.

The kinetics of the oxidation of dimethylacetamide in the presence of the NIIOGAZ-7D catalyst were investigated on a flow-circulation apparatus in the temperature range 503–653 K [155]. The amount of nitrogen oxides formed increased with increase in the initial dimethylacetamide concentration and temperature.

The possibility of making safe the dimethylamine-containing waste water by the vapour phase catalytic oxidation of dimethylamine has been studied on a flow apparatus[156]. At 700–750 K and at a vapour–gas flow rate of 2000–4000 h^{-1}, the GIPKh-105 catalyst ensured 94% conversion of dimethylamine via the reaction

$$4(CH_3)_2NH+15O_2\rightarrow 2N_2+8CO_2+14H_2O.$$

The formation of nitrogen oxides in the catalytic oxidation of ammonia and ethylenediamine has been investigated in flow apparatus on AP-56, NTK-1 (53% ZnO, 24% Cr_2O_3, and 12% CuO) and GIPKh-105 (40% CuO and 40% Cr_2O_3) catalysts[157], whose efficiency was estimated from the degrees of conversion of the compounds indicated in extensive oxidation reactions. The GIPKh-105 catalyst, ensuring 100% conversion of both ethylenediamine and ammonia at 573 K, a 15000 h^{-1} space velocity, and a concentration of 10 mg $litre^{-1}$ proved to be best. In the oxidation of ammonia (c = 15 mg $litre^{-1}$) the degree of conversion of the bound nitrogen into oxides was 3% at 623 K, while the degree of conversion in the oxidation of ethylenediamine (c = 6.8 mg $litre^{-1}$) was 38%. On reducing the temperature to 473 K, the concentration of NO_x diminishes severalfold. In the joint presence of ethylenediamine and ammonia, the yield of nitrogen oxides is appreciably lower than in their separate oxidation. The authors believe[157] that one of the stages involved the reaction of nitric oxide, formed in the oxidation of ethylenediamine, with the ammonia present in the gas mixture in accordance with the scheme

$$NO(ads.)+NH_3(ads.)+O(ads.)\rightarrow N_2+H_2O+OH(ads.).$$

As a result of this, the yield of nitrogen oxides in the oxidation of a mixture of ethylenediamine and ammonia is significantly reduced. The complete elimination of pyridine from the waste in chemopharmaceutical industries is achieved on aluminoplatinum, copper–chromium, copper–manganese, and aluminocopper catalysts at a temperature of about 623 K [158–160]. The selectivity with respect to N_2 is 85–92% [159].

The extensive aniline oxidation reaction in the presence of the aluminoplatinum catalyst has been studied in greatest detail[161,162]. The experiments were performed in a flow-circulation apparatus at an initial aniline concentration of (0.5–240) × 10^{-6} M and at space velocities of the stream of 250–10000 h^{-1}. The rate of oxidation of aniline obeys the equation

$$w = k\frac{c_A c_{O_2}^{0.5}}{1+k'c_A},$$

where c_A and c_{O_2} are the stationary concentrations of aniline and oxygen respectively, $k = 8.14\times10^{10}\,e^{-84018/RT}$ $litre^{1.5}\,mol^{0.5}\,h^{-1}\,g^{-1}$, $k' = 2.24\times10^{3}\,e^{21736/RT}$ litre mol^{-1}. The contents of nitrogen oxides in the reaction products for a degree of conversion of aniline of 0.9 and at 473, 573, and 673 K are respectively 0.2, 5.1, and 10.7% relative to the aniline which has reacted. The extensive aniline oxidation reaction has been described by a scheme incorporating twelve stages[162] of which the first five concern the reaction of bound nitrogen:

(1) $O_2\rightleftarrows 2O(ads.)$,

(2) $C_6H_5NH_2+O(ads.)\rightleftarrows C_6H_5NH_2O(ads.)$,

(3) $C_6H_5NH_2O(ads.)+O(ads.)\rightleftarrows C_6H_5NOOH_2(ads.)$,

(4) $C_6H_5NOOH_2(ads.)\rightleftarrows C_6H_5(ads.)+NO+H_2O$,

(5) $C_6H_5NH_2O(ads.)+NO\rightarrow C_6H_5O(ads.)+N_2+H_2O$.

It has been suggested that stages 1–3 virtually correspond to equilibrium, stage 4, representing the decomposition of compounds of the peroxide type, is slow, while stage 5 as well as the remaining stages not quoted here are rapid and irreversible. The following kinetic equations follow from the above scheme on the assumption of high coverages of the catalyst surface:

$$w = k_4\frac{K_1K_2K_3p_{O_2}p_A}{K_1p_{O_2}^{0.5}+K_1K_2p_{O_2}^{0.5}p_A+K_1K_2K_3p_{O_2}p_A},$$

where K_1, K_2, and K_3 are the equilibrium constants of stages 1, 2, and 3 and k_4 is the rate constant for stage 4. This equation is converted into the experimental expression when $K_1K_3 \ll 1$.[162]

The above scheme makes it possible to account for the virtually complete absence of nitrogen oxides in the oxidation of aniline on the catalyst: NO is formed slowly in stage 4 but is rapidly consumed in stage 5. Indeed, in the oxidation of aniline adsorbed on the catalyst by nitric oxide, mainly molecular nitrogen was formed. Detailed kinetic studies on the extensive catalytic oxidation reactions of a series of nitrogen-containing compounds were carried out in order to establish the principles governing the decrease in the NO_x concentration in the catalytic combustion of nitrogen-containing fuels[163–169]. The objects of study were compounds differing in the nitrogen-containing functional groups. Catalysts developed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences for catalytic heat generators as well as a series of other typical total oxidation catalysts, especially industrial final combustion catalysts IK-12-1 and AK-64, were used.

In the study of the pyridine oxidation reaction[163,164,169] in the temperature range 513–820 K, the initial pyridine concentration was varied in the range 0.05–2.0 vol.% and the oxygen concentration

was varied in the range 4.2–50 vol.%. The oxidation products were CO_2, H_2O, N_2, and NO_x (NO and NO_2). In the kinetic region (at 633 K and below), the order of the extensive oxidation reaction with respect to pyridine was zero and that with respect to oxygen was close to unity on all the deposited catalysts. The NO_x formation reaction was also zero order with respect to pyridine. The kinetic parameters of the extensive oxidation reactions and the nitrogen oxide formation reactions as well as the degrees of conversion of bound nitrogen into oxides (X_{NO_x}) on certain catalysts are listed in Table 1. A significantly smaller amount of NO_x is formed on oxide catalysts than on the platinum catalyst under the same conditions. Oxide catalysts propagate the oxidation to molecular nitrogen with a high selectivity, the degree of conversion of bound nitrogen into oxides not exceeding as a rule several per cent. In the presence of the copper–chromium catalysts, the rate of formation of nitrogen oxides increases with increase in the content of copper chromite in the catalyst.

Table 1. Kinetics of the catalytic oxidation of pyridine (c_{RN} = 0.5%)[163,164,169].

Catalyst	Sample, g	Extensive oxidation		Formation of NO_x

* Found by extrapolating the experimental data to temperatures above 623 K.
** At 543 K.
*** At 623 K.

The catalytic oxidation of acetonitrile, nitromethane, and dimethylformamide has been investigated[165,167]. Their extensive oxidation reactions were investigated in the presence of the 30% $CuCr_2O_4/\gamma$-Al_2O_3 catalyst in the range of initial acetonitrile concentrations from 0.12 to 3.0 vol.%, nitromethane concentrations from 0.24 to 1.95 vol.%, and dimethylformamide (DMF) concentrations from 0.01 to 0.68 vol.%. The oxygen concentration in the oxidation of CH_3CN was varied from 13 to 50 vol.%, while in the oxidation of CH_3NO_2 and DMF it was always 50 vol.%. The studies were performed on flow-circulation apparatus in the temperature range 453–793 K. The principal kinetic parameters of the extensive oxidation reactions are listed in Table 2.

Above 623 K, the nitrogen-containing compounds are fully converted into oxidation products. The degree of conversion of bound nitrogen into NO_x in such a complete reaction is determined by the nature of the active component of the catalyst employed, the concentrations of the substance oxidised and oxygen in the reaction mixture, and temperature. In the oxidation of pyridine, acetonitrile, and DMF in the presence of oxide catalysts, the main bulk of the bound nitrogen is converted into N_2, while the yield of nitrogen oxides does not exceed several per cent. An appreciably higher degree of conversion of bound nitrogen into NO_x is characteristic of the platinum catalyst—up to 40% in the case of pyridine and up to 90% in the case of acetonitrile (Fig. 3). At a constant temperature and in an excess of oxygen, the quantity X_{NO_x} in the presence of all the catalysts investigated falls with increase in the initial concentration of the oxidised substance in the reaction mixture.

Table 2. Kinetics of the extensive oxidation of certain nitrogen-containing compounds in the presence of the 30% $CuCr_2O_4/\gamma$-Al_2O_3 (c_{RN} = 0.5%) catalyst[165–167]

Compound	T, K	10^{-10} w, molecules cm^{-2} s^{-1}	E_{act}, kJ mol^{-1}	Reaction order	
				w.r.t. RN	w.r.t. O_2
Acetonitrile	573	29.0	100	0	0.9
Nitromethane	573	100	100	0	—
Dimethylformamide	513	10	53	0.5	—

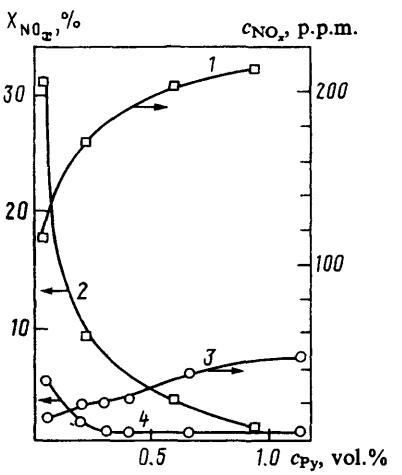

Figure 3. Dependence of the NO_x concentration (curves *1* and *3*) and of the degree of conversion of bound nitrogen into NO_x (curves *2* and *4*) on the initial pyridine concentration at 673 K in the presence of the 0.64% Pt/γ-Al_2O_3 (curves *1* and *2*) and 5% $CuCr_2O_4/\gamma$-Al_2O_3 (curves *3* and *4*) catalysts[164].

The NO_x concentration depends little on the oxygen concentration, while the coefficient of the excess of oxygen $\alpha > 1.5$ and diminishes sharply as the reaction mixture approaches the stoichiometric composition. An increase in temperature entails an increase in X_{NO_x}. For copper–chromium catalysts, the dependence of the amount of

nitrogen oxide formed and X_{NO_x} on the concentration of the active component ($CuCr_2O_4$) in the catalyst was obtained. The NO_x concentration and X_{NO_x} increase in the sequence γ-Al_2O_3 < 5% $CuCr_2O_4/\gamma$-Al_2O_3 < 11% $CuCr_2O_4/\gamma$-Al_2O_3 < 30% $CuCr_2O_4/\gamma$-Al_2O_3.

Table 3. The formation of nitrogen oxides in the complete oxidation of nitrogen-containing compounds in the presence of the 30% $CuCr_2O_4/\gamma$-Al_2O_3 catalyst[165–167].

Compound	Catalyst sample, g	c_{RN}, vol.%	T, K	c_{NO_x}, p.p.m.	X_{NO_x}, %

	3.17	0.66	723	234	3.6
Pyridine	2.28	1.09	673	122	1.1
	2.28	1.09	723	588	5.4
	15.06	0.95	793	1 336	14.4
Nitromethane	1.19	1.07	673	7 940	76.8
	6.05	1.07	758	10 220	99.2

Table 3 presents data concerning the influence of the nature of the oxidised compound on the yield of NO_x in the range of high temperatures (>620 K) in the presence of the 30% $CuCr_2O_4/\gamma$-Al_2O_3 catalyst. The maximum amount of NO_x is formed in the oxidation of nitromethane, which is apparently associated with the presence of the NO_2 group in the molecule. On the basis of the set of kinetic relations obtained as well as literature data concerning the forms of adsorption of pyridine and the extensive oxidation of organic compounds, the following mechanism for the conversion of pyridine has been proposed[168,169]:

$$C_5H_5N \xrightarrow{k_1} C_5H_5N(ads.),$$

$$C_5H_5N(ads.) + O_2 \xrightarrow{k_2} HN-C_5H_4OO(ads.),$$

$$HNC_5H_4OO(ads.) + O_2 \xrightarrow{k_3} NH(ads.) + CO_2 + C_4H_4OO(ads.) \xrightarrow[fast]{}$$

$$\rightarrow CO_2, H_2O, N_2, NO_x.$$

In the first stage, pyridine is adsorbed on the surface, in the second stage the aromatic ring is cleaved, while in the third stage a C–N bond is ruptured with formation of surface groups. The kinetic equation which follows from the last scheme on the assumption that $k_1 p_{C_5H_5N} \gg k_2 p_{O_2}$ and $k_3 p_{O_2}$ has the form $w = k p_{O_2}$. It describes adequately the experimental data. It must be emphasised that all observations indicate the dissociation of C–N bonds in the first stages of the oxidation process. Compounds with such a bond, including HCN, were not detected in the reaction products. Furthermore, in special experiments on the oxidation of pyridine and acetonitrile under the conditions of a deficiency of oxygen, the degree of conversion of bound nitrogen into NH_3 reached 10%, while HCN was formed in trace amounts. The oxidative reactions of the type NH_x surface groups formed apparently proceed via the mechanism proposed for the ammonia oxidation reaction[148]:

(1) $NH(ads.) + O(ads.) \rightleftarrows HNO(ads.)$,

(2) $NH(ads.) + HNO(ads.) \rightleftarrows N_2 + H_2O$,

(3) $HNO(ads.) + HNO(ads.) + O(ads.) \rightleftarrows 2NO + H_2O$,

(4) $NO + O(ads.) \rightleftarrows NO_2$.

Apparently stages 1 and 2 take place preferentially on oxide catalysts, while on aluminoplatinum catalysts stages 3 and 4 also make a significant contribution, i.e. the catalysts differ in the ratio of the rate constants for the corresponding stages.

The above investigations have led to the conclusion that the possible routes to a decrease in the waste nitrogen oxides in the catalytic combustion of nitrogen-containing fuels involve the use of oxide catalysts, a decrease in temperature, and a decrease in the coefficient of the excess of air.

3. Characteristic features of the formation of fuel NO_x in the catalytic combustion fuels

A series of studies on the reactions of nitrogen in fuels during catalytic combustion have been published[130,134,170–182]. The yield of fuel NO_x is influenced by the combustion temperature, the coefficient of the excess of air α, the nitrogen content in the fuel, and the nature of the catalyst (Table 4).

It has been established[171] that in the combustion of mixtures of propane with ammonia and methylamine, the form of the nitrogen-containing additive does not affect the yield of nitrogen oxides. The degree of conversion of nitrogen into NO_x increases with increase in temperature[171,172]. Thus, in the combustion of propane with added NH_3 and CH_3NH_2, the quantity X_{NO_x} increases from 30% at 1100 K to 80% at 1400 K. A further increase in temperature to 1600 K hardly affects the increase in X_{NO_x}, which is 80–90%[171].

The dependence of the degree of conversion of the fuel nitrogen into NO_x on the coefficient of excess of air α has been studied in greatest detail. In the range $1.2 \leqslant \alpha \leqslant 2.0$, the degree of conversion of bound nitrogen into oxides depends little on α and diminishes by a factor of 2–3 as the fuel–air mixture approaches the stoichiometric composition[130,170–181]. For $\alpha \leqslant 1$, the combustion products contain ammonia and hydrogen cyanide. Under these conditions, a decrease in the amount of air leads to a further decrease in the NO_x concentration owing to the increase in the N_2, NH_3, and HCN concentrations[130,131,170]. For certain values of α, which are usually in the range 0.6–0.9, the maximum degree of conversion of bound nitrogen into N_2 is attained (up to 80–90%). It has therefore been suggested[171] that the catalytic combustion be carried out in two stages: $\alpha < 1$ is established in the first stage (usually between 0.5 and 0.9), while in the second stage an excess of air is supplied to achieve the final combustion of the uncombusted substances. On average $\alpha \geqslant 1$ for the entire process. The two-stage catalytic combustion at 1400–1500 K ensures a decrease in the degree of conversion of fuel nitrogen into oxides from 80–100% (for single-stage combustion) to 10–30%[130,172,176,177]. However, an increased deactivation of the catalyst as a consequence of its saturation by coke is then observed in the first stage[172]. A scheme for the two-stage combustion of liquid nitrogen-containing fuels using a catalyst only in the second stage has been proposed.[134]

Table 4. The formation of NO_x in the catalytic combustion of fuel (literature data).

Fuel combusted	Catalyst	Nitrogen-containing additive	N_f^*, %	T, K	α	Studied dependence of X_{NO_x} on				Refs.
						α	N_f	type of catalyst	temperature	
$CO+H_2+CH_4+N_2$ (model mixture)	2.1–6.3% Pt on a monolithic carrier with a variable cross-section of channels	NH_3	0.0471	1273	0.4–2.3	+	–	–	–	[174]
CH_4	ditto	NH_3	0.9417	1273	0.4–2.3	+	–	–	–	[174]
CH_4, C_3H_8	Pt, NiO+Pt on a monolithic carrier	NH_3 or CH_3NH_2	0.003–3.6	1100–1600	0.6–2.2	+	+	+	+	[171]
C_3H_8	0.18% Pt on monolithic cordierite ite covered with Al_2O_3	NH_3	2.0	1000	0.8–1.0	+	+	–	–	[175]

Masout	Monolithic catalyst with a variable cross-section of channels	none	0.85	1370–1930	0.8–3.0	+	–	–	–	[170]

Note. For liquid fuels, the nitrogen content in the fuel is indicated in weight percentages, while for gaseous fuels it is indicated in volume percentages.

A significant decrease in the yield of NO_x is achieved as a result of the interaction of the nitrogen oxides formed with soot:

$$2NO+C\rightarrow N_2+CO_2.$$

A decrease in the NO_x concentration in the effluent gases on apparatus of this type can occur also by virtue of the interaction of NO with CO [172].

The nature of the catalyst exerts a major influence on the yield of fuel nitrogen oxides. The use of oxide catalysts makes it possible to attain lower degrees of conversion of bound nitrogen into NO_x than in the case where catalysts based on noble metals are employed. In the single-stage combustion of a gaseous fuel with added NH_3 in an excess of air [177], the degree of conversion of bound nitrogen into NO_x reaches 70–80% in the presence of the NiO/ZrO_2 catalyst and 90–95% in the presence of the Pt/Al_2O_3 catalyst (combustion temperature 700–900 K). In the multistage combustion using the NiO/ZrO_2 catalyst in the first stage, the degree of conversion of bound nitrogen into NO_x is 10%, while in the presence of the platinum catalyst 35% of the fuel nitrogen is converted into oxides.

The combustion of mixtures of propane with ammonia has been studied on a catalyst containing chromium and cobalt oxides [178]. The temperature profile in the catalyst bed affects the yield of nitrogen oxides. Under optimum conditions with $\alpha > 1$, it is possible to decrease the degree of conversion of bound nitrogen into NO_x to 5–20%.

With increase in pressure, the yield of NO_x can both increase [179] and decrease [172,176]. Data concerning the influence of the nitrogen content in the fuel on the degree of conversion of bound nitrogen into oxides are just as uncertain: an increase in the concentration of bound nitrogen (in the form of NH_3) in the gaseous fuel was accompanied by a decrease [171] and an increase [175] in X_{NO_x}. An increase in the pyridine content in the liquid fuel resulted in some decrease in X_{NO_x} [179]. Overall, the problem of reducing the fuel NO_x waste in the combustion of fuels in a stationary catalyst bed requires further work.

The characteristics of the formation of nitrogen oxide in the combustion of nitrogen-containing fuels in a fluidised bed of granulated catalysts, specially developed for catalytic heat generators, have been examined [164,183–187]. The experiments were performed on a pilot apparatus with a power of 20 kW. Experiments were performed initially on the combustion, in catalytic heat generators, of fuels virtually free of bound nitrogen in order to determine the possible contribution of thermal NO_x to the overall amount of nitrogen oxides. In the combustion of n-decane and diesel and furnace fuels on catalysts containing 5 and 30% $CuCr_2O_4$

on γ-Al_2O_3, the observed values of c_{NO_x} did not exceed 10 p.p.m., i.e. the equilibrium concentration calculated for 1000 K and $\alpha = 11$ [164].

The characteristic features of the formation of fuel NO_x were investigated by combusting both a fuel with the natural abundance of bound nitrogen of 0.1% (masouts M100 and M40) and specially prepared mixtures of fuels with nitrogen-containing additives. In the combustion of diesel fuel with added pyridine, giving rise to a nitrogen concentration up to $N_f = 1$ wt.%, the CO_2 and NO_x concentration profiles increased in parallel along the reactor height and attained a constant level at the height corresponding to the complete conversion of the fuel (500–600 mm) [164]. Nitrogen oxides were formed in the catalytic oxidation of the fuel in the fluidised catalyst bed and additional formation of NO_x over the bed was not observed.

In the combustion of model mixtures of isopropyl alcohol with nitrogen-containing compounds (caprolactam, acetonitrile, monoethanolamine, or pyridine) the degree of conversion of bound nitrogen into NO_x was determined mainly by the combustion conditions and depended little on the nature of the oxidised nitrogen-containing substance. At a catalyst bed temperature of 1023 K, $N_f = 1$ wt.%, and $\alpha = 1.22$, the degree of conversion of nitrogen into NO_x is 11–15% [185,187].

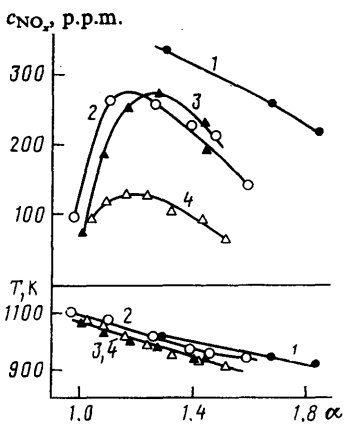

Figure 4. Dependence of the NO_x concentration and catalyst bed temperature on α in the combustion of a mixture of diesel fuel with pyridine [187] in the presence of different catalysts: *1*, Pt/γ-Al_2O_3; *2*, chromium oxide catalyst; *3*, 25% $CuCr_2O_4/\gamma$-Al_2O_3; *4*, 5% $CuCr_2O_4/\gamma$-Al_2O_3.

The dependence of the NO_x concentration on α was investigated in the combustion of masouts M40 and M100 with added ammonium nitrate and pyridine in the presence of the $CuCr_2O_4/\gamma$-Al_2O_3 catalyst [183,184]. The curves obtained had a maximum and the concentration of NO_x fell as α approached unity. For a bound nitrogen content of 0.2%, the NO_x concentration was 40–80 p.p.m., while for $N_f = 1$% it amounted to 80–150 p.p.m., which is much lower than in the flame combustion of such fuels [4,21]. The degree of conversion of bound nitrogen into NO_x is between 5 and 15%.

The dependence of X_{NO_x} on N_f was investigated by combusting mixtures of isopropyl alcohol with pyridine and of diesel fuel with pyridine [185,187]. With increase in N_f, the NO_x concentration rises, but the degree of conversion X_{NO_x} falls. Industrial waste with a high content of bound nitrogen can be made safe by its combustion in a catalytic heat generator. Even for $N_f = 8$%, the NO_x concentration is less than 520–540 p.p.m., which is significantly lower than the value 3000–5000 p.p.m. expected in the flame combustion of a similar mixture [185,187].

The nature of the active component of the catalyst used in the catalytic heat generator also affects the formation of NO_x in the combustion of nitrogen-containing fuels (Fig. 4). Aluminoplatinum catalysts afford the greatest amount of nitrogen oxides, while oxide catalysts produce a smaller amount of such oxides. In full agreement with experiment [186,187], a decrease in the concentration of the active component of the deposited catalyst promotes a decrease in the emission of nitrogen oxides (Fig. 4). An increase in temperature leads to an increase in the concentration of nitrogen oxides (as the temperature rises by 150 K, the NO_x concentration is doubled) [187].

We shall now analyse the problem of the amount of nitrogen oxides evolved in the combustion of fuels in a catalytic heat generator and in the traditional flame combustion [1,2,21] relative to the c_{NO_x} level calculated from the equilibrium constants of the reaction $N_2 + O_2 \rightleftarrows 2NO$ for $\alpha = 1.1$ (Fig. 5). In the temperature range (1500–2000 K) where real combustion takes place, the calculated equilibrium NO_x concentration varies from 400 to 2500 p.p.m.[1] The NO_x concentrations observed in flame combustion are lower than these values, because, owing to the insufficiently long residence time of the fuel–air mixture in the combustion chamber, equilibrium cannot be attained. In the catalytic combustion, the yield of thermal NO_x is extremely low (less than 5 p.p.m.) while the concentration of fuel NO_x is higher than the equilibrium values corresponding to the temperature range of this method of combustion but is lower by a factor of 5–10 than in flame combustion in devices with a combustion chamber.

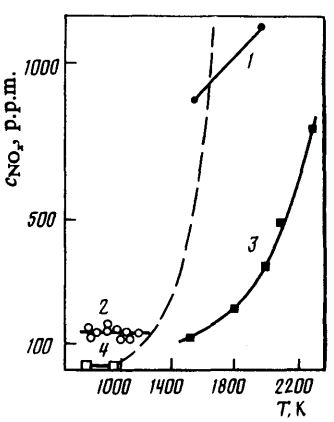

Figure 5. Dependence of the concentrations of fuel (curves *1* and *2*) and thermal (curves *3* and *4*) NO_x on temperature in the flame (curves *1* and *3*) and catalytic (curves *2* and *4*) combustion ($\alpha = 1.1$); the data for the fuel NO_x were obtained at $N_f = 1$ wt.%; dashed line—equilibrium NO_x concentrations [1,2,187].

Catalytic combustion can be used successfully in various domestic and industrial combustion chamber devices in order to decrease the degree of incomplete chemical combustion and the amount of thermal NO_x waste. However, the problem of reducing the fuel NO_x waste formed in the combustion of fuels containing bound nitrogen in devices with platinum catalysts operating at high temperatures and under severe thermal conditions has not yet been solved. The study of the kinetics of the oxidation of nitrogen-containing compounds on solid catalysts has shown that a decrease in the yield of fuel NO_x can be attained by using oxide catalysts instead of platinum catalysts, by reducing the temperature, and by adjusting the coefficient of the excess of air to values close to unity. A decrease in temperature is usually accompanied by a fall in the power and efficiency of the device. The use of a fluidised bed in catalytic heat generators makes it possible to carry out technological processes with much heat evolution and at a low temperature in the combustion zone (770–1070 K) by combining the heat evolution and heat removal processes in a single catalyst bed. It is important to emphasise that a decrease in the concentration of nitrogen oxides in catalytic combustion is ensured by the method of combustion itself and by the selection of the optimum process conditions and catalysts. There is then no need for the expensive removal of nitrogen oxides from smoke gases.

Procedures for making gaseous industrial waste safe

Yu Sh Matros, A S Noskov

ABSTRACT. The application of various methods (adsorption, absorption, thermal afterburning, catalytic purification, and others) for the removal of sulphur and nitrogen oxides, toxic organic compounds, hydrogen sulphide, and carbon monoxide from industrial waste gases is described. Much attention is devoted to the catalytic procedure for making the gases safe using an energy collecting non-stationary method (reversible process).

The advantages and limitations of various gas purification methods are considered.

The bibliography includes 279 references.

I. Introduction

The formation of gaseous compounds contaminating the atmosphere is caused mainly by the combustion of mineral fuels, industrial technological processes, and natural phenomena. The development of industry has led to a constant increase in the amount of waste. Thus in the USA the dominant contribution to the sulphur dioxide waste (76%) is made by fuel combustion processes in stationary plants. Carbon monoxide enters the atmosphere to a large extent as a result of the operation of the engines of automobiles and other means of transportation (76%). Industrial organic solvents and petroleum gas processing are sources responsible for 29% of the emitted hydrocarbons, while 38% is contributed by transport. In the Federal Republic of Germany, the fraction of transport waste in 1982 was 55%, while that of waste generated by thermal electric power stations (TES) was 28% relative to the total amount of nitrogen oxides of industrial origin. In terms of the SO_2 (~150 million tonnes annually) and hydrocarbons (~70 million tonnes annually) ejected into the atmosphere, industry has already become comparable to natural sources.[1,2] The main contribution to the contamination of the atmosphere by carbon monoxide (300 million tonnes annually) also comes from man's industrial activity.[1] Only the amount of nitrogen oxides originating from natural sources is approximately ten times greater than that arising from anthropogenic sources (700 million tonnes annually against 50 million tonnes annually).[1,2] However, as a result of the localisation of this type of waste at sites with the highest population density their negative effect is considerable.

The main procedure for reducing the amount of toxic waste ejected into the atmosphere in technological processes involves the improvement of the latter. For example, in order to reduce the sulphur dioxide waste in the combustion of fuel, use is made of the preliminary elimination of sulphur and its binding during the combustion process.[1,3–6] A decrease in the formation of nitrogen oxides is achieved using a stepwise combustion of fuel,[7,8] with the aid of special types of burners,[8–10] and by a number of other measures. However, in most cases the improvement of technological methods, especially the existing methods, does not permit the attainment of the permissible norms and special additional purification of waste gases to remove toxic impurities is necessary.

The industrial methods for making safe gaseous waste can be divided into the following main groups:[1,11] (1) condensation; (2) absorption; (3) adsorption; (4) thermal combustion; (5) chemical conversion of impurities into non-toxic or readily utilisable compounds; (6) catalytic methods; (7) membrane separation; (8) biochemical purification.

II. Absorption methods

Absorption involves the dissolution of the gaseous component in a liquid solvent. In practice absorption is usually accompanied by a rapid chemical reaction in the liquid phase.

Absorption systems can be divided into aqueous and non-aqueous. In the latter case, involatile organic liquids are usually employed. A liquid is used for absorption only once or it is regenerated with the isolation of the contaminant in a pure form.[1,11] Schemes with a single employment of the absorbers are used in those cases where absorption leads directly to the formation of the finished product or intermediate. As examples, one may point to the synthesis of inorganic acids (absorption of SO_3 in the manufacture of sulphuric acid,[12] the absorption of nitrogen oxides with formation of nitric acid[13]), salts (absorption of nitrogen oxides by alkaline solutions with formation of nitrite-nitrate liquors, absorption by aqueous lime or limestone solutions with formation of calcium sulphate[14]), and other substances (absorption of NH_3 by water to obtain aqueous ammonia[15]).

Schemes with the repeated use of absorbers (cyclic processes) are more common. They are used to trap hydrocarbons,[11] to eliminate SO_2 from TES smoke gases,[16] to eliminate hydrogen sulphide from venting gases by the iron-soda method with formation of elemental sulphur,[17] and for the monoethanolamine removal of CO_2 from gases in the nitrogen industry.[15]

Depending on the method used to generate the phase contact surface, one can distinguish surface, bubbling, and spraying (atomising) types of absorption apparatus. In the first group of

devices, the contact surface between the phases consists of a liquid mirror or of the surface of a flowing film of liquid. Packed absorbers, in which the liquid flows down the surface of the packing immersed in it and made up from bodies of different shapes are also included in this group. In the second group of absorbers the contact surface is increased by dispersing the gas streams in the liquid into bubbles and jets. Bubbling is achieved by passing the gas through a liquid-filled apparatus or in apparatus of column type with plates of different kinds. In the third group, the contact surface is created by spraying the liquid into the bulk of the gas. The contact surface and the efficiency of the process are determined overall by the degree of dispersion of the sprayed liquid.

Packed (surface) and bubbling plate absorbers have come to be most widely used.[1,16] The trapped component must be readily dissolved in the absorption medium and frequently interacts chemically with water, as happens, for example, in the elimination of HCl, HF, NH_3, and NO_2 from gases. In order to absorb gases with a lower solubility (SO_2, Cl_2, H_2S), use is made of alkaline solutions based on NaOH or $Ca(OH)_2$. The addition of chemical reagents increases in many instances the efficiency of the absorption by virtue of the occurrence of chemical reactions in a film.[1,18] An increase in the degree of purification can also be achieved by carrying out the absorption process in two stages.[19] There exist various modifying additives to aqueous solutions. Thus coal tar is introduced to trap naphthalene or formaldehyde,[20,21] phenol is trapped by sodium hydroxide solutions,[22] and the use of alkali metals and tertiary C_3-C_{20} amines is effective for the elimination of phosgene from gases.[23] Gases containing HCl, NH_3, and hydrocarbons are purified by being absorbed in aqueous solutions of formaldehyde and subsequent oxidation.[24] The application of solutions of urea or its derivatives is recommended for the trapping of formaldehyde.[25] Systems in which finely dispersed activated charcoal is added to the absorption liquid to increase the trapping efficiency should be mentioned specially.[26–28] In order to improve the removal of organic substances from gases, an oxidant is also introduced simultaneously into the system.

Absorption or more precisely absorption-chemical procedures for making safe the smoke gases from TES, metallurgical industries, and other objects by removing SO_2 has come to be widely used recently. The first large industrial apparatus in the world for the removal of sulphur, operating on the basis of the wet limestone method and having a productivity corresponding to 3 million $m^3\ h^{-1}$ of combined gases, began to operate at the Magnitogorsk Metallurgical Unit in 1961. At the present time, this plant traps about 100 000 tonnes of sulphur dioxide annually.[14] The volume of TES gases freed from SO_2 now reaches $10^9\ m^3\ h^{-1}$ in Japan, the USA, and the Federal Republic of Germany and the total number of plants is approximately 250.[14,29]

Absorption methods in which a calcium sorbent is employed are most widely used in the purification of TES smoke gases.[30–32] When the wet lime (limestone) process is used,[1,23] a sludge consisting of calcium sulphites and sulphates, which can be stabilised (for example, by heating) in the form of gypsum, is produced. Smoke gases freed from ash pass to a plate absorber irrigated with water containing finely ground limestone and neutralisation products. The purified gases pass through a spray trapping unit and after heating (to prevent condensation) are ejected into the smoke tube. After the absorption of SO_2, the acidified liquid passes through a compartment to which a fresh limestone suspension is added. After the accumulation of 10–15 wt.% of calcium salts in the irrigating liquid, part of the suspension is removed to special compartments and subsequently the resulting sludge is eliminated from the system. In order to produce gypsum, the scheme is supplemented by a line involving the oxidation of calcium sulphite to calcium sulphate and the removal of the salts. Under industrial operating conditions, a stable removal of SO_2 from gases with 90% efficiency is achieved.

A semi-dry method (spray absorption) for the removal of SO_2 from smoke gases[1,14,31] is used in the combustion of types of coal containing between 0.5 and 1.5 wt.% of sulphur. The principal stage is the absorption of SO_2 by droplets of a lime solution evaporating in the waste gases. For this purpose, smoke gases are passed through a spray absorber, whose geometry and hydrodynamic conditions ensure the complete evaporation of the droplets. The reaction product is a dry mixture of calcium sulphite and sulphate. The principal technical difficulty consists in the organisation of the effective mass exchange between the liquid and the smoke gases. For example, the spray driers of the Lurgi company make it possible to obtain droplets 80–100 μm in size with an overall surface of 60 m^2 per litre of liquid.[34] The absence of waste water and the formation of the product in a dry form make it easier to use this method in industry.[16]

Organic absorbents such as dimethylaniline, amines,[1] the dimethyl ether of tetraethylene glycol, and the dimethyl ether of poly(ethylene glycol)[2] are used in non-aqueous systems. Hydrocarbon oils are employed to remove mercaptans.[35–37] Absorption by organic solvents has proved to be most effective for the elimination of organic gaseous impurities. An obligatory condition is naturally a low pressure of the vapour of the wash liquid itself (not more than 1 Pa).

In the vast majority of cases, the non-aqueous absorber and the absorbed substance do not interact chemically. A typical example of the use of the absorption method may be the removal of benzene vapour from gases by means of a heavy oil (for example, hexadecane).[37] After absorption, the absorbing solution is heated and transferred to the desorber. Since water does not mix with benzene and the oil, the desorption is carried out using hot steam. The vapour emerging from the desorber is directed to a condensing unit to trap the absorber and partly water vapour. After their separation in the separator, the condensed absorber is returned to the cycle. The mixture of water vapour and benzene is recondensed. The non-condensing gases are separated from the liquid in the separator and liquid benzene is separated from water using the difference between their densities.

In conclusion we may note that absorption is most widely used in industry to trap acid components from effluent gases and for the removal of SO_2 from smoke gases.

III. Adsorption methods

Adsorption methods constitute one of the most widely used procedures for the protection of air from contamination. In the USA alone, tens of thousands of adsorption systems have been introduced and used successfully.[38] The principal industrial adsorbents are activated charcoals, complex oxides, and impregnated sorbents. Activated charcoal (AC) is neutral in relation to polar and non-polar molecules of the adsorbed compounds. It is less selective than other adsorbents and is one of the few adsorbents suitable for use in moist gas streams. Activated charcoal is used in particular for the removal of substances with an unpleasant smell from gases, for the recovery of solvents, etc.[1,39]

Oxide adsorbents (OA) exhibit a higher selectivity in relation to polar molecules by virtue of the intrinsic non-uniform distribution of the electrical potential. Their disadvantage is the decrease in efficiency in the presence of moisture. Silica gels, synthetic zeolites, and aluminium oxides belong to the class of oxide adsorbents.

Impregnated adsorbents (IA) are divided into three groups:

(1) Adsorbents impregnated by a chemical reagent. As a result of the occurrence of a chemical reaction on such impregnated adsorbents, the adsorption of substances which are difficult to adsorb is facilitated. For example, the introduction of iodine improves the adsorption of mercury or ethylene vapour on activated charcoal.

(2) Impregnated adsorbents in which the impregnating substance plays the role of the catalyst of the extensive oxidation of the trapped impurities. Catalysis is ensured, for example, by introducing into the activated charcoal oxygen-containing compounds promoting the oxidation of impurities in oxygen-free gases.

(3) Periodically activated impregnated adsorbents. The activation is carried out, for example, by the cyclic increase in temperature after the completion of the adsorption of impurities.

It is possible to differentiate the following principal ways of carrying out adsorption purification processes.[39–41]

1. After adsorption, desorption is carried out and the trapped components are extracted for reuse. Various solvents,[11] carbon disulphide in the manufacture of artificial fibres,[41] and a number of other impurities[42] are trapped in this way.

2. After adsorption, the mixtures are not neutralised but are subjected to thermal or catalytic afterburning.[39,41,43,44] This method is used to purify the gases from chemopharmaceutical and paint and varnish undertakings, the food industry, and a number of other industries. This variety of adsorption purification is economically justified by low concentrations of the contaminating substances and (or) when the contaminants consist of numerous components.[39,41]

3. After purification, the adsorbent is not regenerated but is, for example, stored or combusted together with the strongly chemisorbed contaminant.[1] This procedure is suitable when cheap natural adsorbents are employed.[42]

To desorb the impurities, the adsorbent is heated, evacuated, or flushed by an inert gas while the impurities are displaced by a more readily adsorbed substance, for example water vapour.[1,40,41] Attention has been concentrated recently on the desorption of impurities by evacuation.[45–51] Under these conditions, it is frequently possible to utilise them readily.

A wide variety of different types of apparatus have been developed for adsorption processes.[1,39,41,52,53] The most common are adsorbers with a fluidised bed of a granulated or honeycomb adsorbent. The continuity of the adsorption and adsorbent regeneration processes is ensured by using apparatus with a fluidised bed. The theory of adsorption in fluidised beds has been examined in greatest detail by Krishnaiah and co-workers.[54,55] There also exist adsorbers with a "flowing" adsorbent. By arranging appropriately the sites where the particles are introduced and removed, it is possible to organise the "flow" of the adsorbent along different lines. Adsorbents with a rotating bed are more rarely used in practice.[40,56,57] A variety of the process in which the adsorbent is sprayed into the stream of the gas being purified to produce a finely dispersed aerosol with subsequent trapping and regeneration of the latter has been proposed.[58] Fibrous sorption-active materials have been used increasingly in recent years.[57,59–66] Differing little from granulated adsorbents in their capacity, they are greatly superior to the latter in terms of a number of other parameters. For example, they are distinguished by high thermal and chemical stabilities, the uniformity of their polar structure, the large volume of micropores, and a higher mass transfer coefficient (greater by a factor of 10–100 than for granular sorption materials).[52] Devices employing fibrous materials occupy a much smaller area.[59,60] The mass of the adsorbent in procedures employing fibrous materials is smaller by a factor of 15–100 than in the case where an activated charcoal is used while the mass of the apparatus is smaller by a factor of 10. The resistance of the bed does not then exceed 100 Pa. The technical-economical parameters, of the existing processes can be increased also by the optimum organisation of the desorption stage,[67,68] For example, by means of a programmed temperature rise.[68]

The high efficiency of purification on activated charcoals with a honeycomb (cellular) structure, which exhibits improved hydraulic characteristics, is noteworthy. Such sorbents can be obtained by depositing specific compositions with a charcoal powder on a synthetic resin foam[45,69–71] or by foaming a mixture of specified composition containing the activated charcoal.[69] They can also be produced by burning away a filler from a mixture incorporating an activated charcoal together with a binder.[71]

Yet another way of improving adsorption purification methods involved the development of new modifications of adsorbents—silica gels and zeolites with improved thermal and mechanical stabilities. However, the hydrophilic nature of these adsorbents makes their application difficult. In order to make silica gel hydrophobic, it is modified, for example, by high-molecular-weight organic compounds.[72,73] High-silica and ultrahigh-silica zeolites (UHS-zeolites) in which the $SiO_2:Al_2O_3$ ratio can reach 100 and above making them more hydrophobic, were synthesised in recent years.[52]

The largest-scale adsorption purification apparatus is apparently used in the manufacture of artificial fibres.[38] A chemical fibre plant with average productivity ejects approximately 1.5 million $m^3 h^{-1}$ of venting gases containing H_2S and CS_2. Depending on the H_2S concentration two modifications of the adsorption method for the purification of these gases are distinguished. Since in the presence of oxygen hydrogen sulphide may be oxidised on activated charcoal to sulphur and sulphuric acid, at high H_2S concentrations the gases are subjected to preliminary absorption purification to a residual content of 20–50 mg m^{-3}. After this CS_2 is eliminated by the adsorption method. At low initial H_2S concentrations (not more than 3 g m^{-3}), there is a possibility of the joint removal of hydrogen and carbon sulphides by the adsorption purification of gases. The sulphuric acid formed on the surface of the adsorbent-catalyst is periodically neutralised, for example, with ammonia, after which the salts are washed away with water and the sulphur is removed by washing with solvent (usually with carbon disulphide).

The adsorption purification methods have found an application also in the detoxification of industrial gases by removing mercury vapour.[74] In this case, impregnated charcoals are used for the purification. Activated charcoal is usually impregnated with hydrogen halides (HCl and HI).

Adsorption methods for the extraction of solvents, including organochlorine solvents, from effluent gases have come to be most widely used.[38,40,41,52,53,75] This is associated with the high efficiency of the gas purification process (95–99%), the absence of chemical reactions leading to the formation of secondary contaminants and the short period in which the recovery apparatus pays for itself (usually 2–3 years) as a result of the reuse of the solvents and the long (up to 10 years) useful life of the activated charcoal.[40] Active

studies are being prosecuted on the adsorption extraction of sulphur and nitrogen oxides from gases,[76–78] but these have not been applied on an industrial scale so far.

IV. Condensation methods

Condensation is used to remove impurities from gases by cooling them to a temperature below the dew points of the substances to be removed. This method is most effective and is most often used for the removal (utilisation) of hydrocarbons and other organic compounds which have fairly high boiling points under the usual conditions and are present in the gas phase in considerable amounts.[2,79] The elimination of such contaminants is achieved in condensers with water and air cooling. For more volatile contaminants, two-stage condensation is used: water cooling in the first stage and cooling to low temperatures in the second.[11] Cooling to low temperatures solely with the aim of removing contaminants is not effective, since the purification process cannot be achieved with a sufficient degree of completion. For example, even at 213 K and atmospheric pressure the residual concentrations of different solvents are as follows (mg m^{-3}): 1775 for acetone, 275 for methanol, 8 for toluene, and 0.75 for isopropyl alcohol.[11] In most cases condensation can be usefully treated as a preliminary stage serving for the isolation of valuable solvents and for the reduction of the amount of contaminants before the subsequent treatment of gases.

Condensation is carried out both with direct contact and via indirect cooling. In the former case, the gas to be purified is brought into direct contact with the cooled liquid, while in the latter a tubular surface condenser is used. In direct cooling, the subsequent separation of the heat exchanger and of the trapped impurities is important. For this purpose, one selects components such that under certain conditions they form as a result of phase transitions constituents which can be readily separated.[80,81] Condensation is also carried out by the adiabatic expansion of gases supplied under pressure for purification.[82] In order to separate different impurities present in the cooled gases, ionisation and fractionation in an electric field are employed.[83]

The application of the condensation method is complicated by the formation of a mist on extensive cooling of the gas to be purified. This occurs when the rate of heat transfer greatly exceeds the rate of mass transfer and the main bulk of the gas is cooled to a temperature appreciably below the dew points of the condensed impurities. To prevent mist formation, indirect condensation is used, since in this case the main bulk of the gas is in contact with cooled surfaces (liquid drops or film) and condensate particles are not formed in the bulk phase.[11]

V. Membrane methods

Membrane separation processes include stages involving the transfer of the initial mixture to a membrane, the permeation of the mixture components into the membrane, their transfer through the membrane, and the subsequent removal of the separated products.[84] In practice one uses metallic membranes based on palladium, its alloys, silver, and ruthenium as well as synthetic membranes[85] and ceramic-based membranes.[86] Synthetic membranes are made from polymers based on styrene, acrylonitrile, isoprene, silicone, and other elementary components.[85]

Membrane methods have already proved very useful in the manufacture of pure hydrogen,[86] in the extraction of helium from natural gas,[87] and in the purification of gas waste from atomic power stations.[88]

The solubilities of the following substances and their permeation into polymers have been investigated recently: toluene in polystyrene,[89] alcohols, dichloromethane, and benzene in polyvinylpyridine,[90] ethyl acetate, acetone, methyl chloride, and ethanol in cellulose nitrate,[91] and toluene, xylene, and cyclohexane in 1,2-polybutadiene.[92] It has been shown[93] that the rates of permeation of the vapours of various organic substances through polypropylene and Teflon films are tens and hundreds of times greater than the rate of permeation of water (toluene/water = 200 at 60 °C; n-heptane/water = 360). This makes it possible to create gas purification membrane systems. For example, in order to extract organic solvents from air discarded from painting chambers,[11,94] the air stream is passed through a membrane module whose material consists of polydimethylsiloxane on a polysulphone support. The vapours of organic solvents diffuse across the membrane, while the air "depleted" in the solvent circulates through the painting chamber. A vacuum pump creating a rarefraction to the extent of 10^{-3} Pa ensures effective transport through the membrane. The solvent vapour is then condensed in the heat exchanger. The air flow rate is ~ 500 m^3 h^{-1} and the content of the solvent in the air stream is ~ 20 g m^{-3} at the inlet, the amount of extracted solvent is ~ 10 kg h^{-1}, the surface area of the membrane is ~ 80 m^2, and its useful lifetime is 2 g. The necessary power of the pump required to generate the required vacuum is 10 kW.

Composite membranes, whose permeability to solvents is 60–160 times greater than their permeability to nitrogen, have been developed.[95] This makes it possible to ensure a high efficiency of membrane and various combined procedures for the purification of gases. For example, membrane separation and absorption trapping have been used in succession.[96]

VI. Thermal afterburning

Afterburning constitutes a method for making gases safe by the thermal oxidation of various harmful substances, mainly organic, to virtually harmless or less harmful materials—mainly CO_2 and H_2O. The usual afterburning temperatures for the majority of compounds are in the range 750–1200 °C. The application of the thermal afterburning method makes it possible to attain 99% purification of gases.[11,97] The small size of the devices, the simplicity of their operation, and the low operating costs even at high concentrations of the impurities have led to the extensive application of this method. For example, more than 2000 thermal afterburning devices operated in the USA in the 1970's.[2]

When the possibility and usefulness of thermal detoxification methods are considered, it is essential to take into account the nature of the combustion products formed. The products of the combustion of gases containing sulphur, halogen, and phosphorus compounds can be more toxic than the initial gaseous waste. In this case, additional purification is essential. Thermal afterburning is extremely effective in making safe gases containing toxic substances in the form of solid inclusions of organic origin (soot, carbon particles, sawdust, etc.).[2,98]

The most important factors determining the usefulness of thermal detoxification are the expenditure of energy (fuel) to ensure high temperatures in the reaction zone, the calorie content of the mixture

subjected to detoxification, and the possibility of preliminary heating of the gases being purified. An increase in the concentration of the mixtures subjected to afterburning leads to an appreciable diminution of the consumption of fuel. In some cases the process can take place under autothermal conditions, i.e. the working conditions are maintained solely by the heat of the extensive oxidation reactions of the harmful impurities and by the preliminary heating of the initial mixture by the detoxified effluent gases.

There exist several different systems for thermal detoxification differing from one another by the process temperature, the hydrodynamic conditions in the reaction zone, and the residence time of the gases in the reaction zone.[2,11,99–101] Chamber furnaces, furnaces with cyclone movement of gases, regenerative devices for thermal detoxification, apparatus with flow mixing, and detoxification systems in technological apparatus (for example in boilers) can be distinguished.

Box furnaces[2,98] are some of the first industrial thermal purification devices. The working space within the furnace is usually divided into two chambers: the chamber for the combustion of the fuel introduced into the system and the mixing chamber where the air to be purified is introduced. The hydrodynamic conditions in the above zones within the furnaces differ significantly and special mixing of the streams is therefore required. The residence time of the gases in the mixing chamber is 3–5 s and the specific consumption of heat on the detoxification process is 270–280 kcal per m^3 of the gas to be purified. Thermal detoxification furnaces using the cyclone gas flow principle are nowadays more common. The cyclone principle ensures vigorous mixing of the streams and hence effective afterburning for shorter residence times of the gases in the reaction chamber (0.1–0.5 s) than in box furnaces. Such furnaces are used for the afterburning of gases in the manufacture of bitumen, synthetic aliphatic acids, in petroleum processing factories, and in current lead enamelling workshops of electrotechnical undertakings. The cyclone gas flow permits an appreciable reduction of the consumption of heat (to 200 kcal per m^3 of the purified gas) compared with the afterburning in a box furnace.[2,98,102,103]

Devices with flow mixing of the components to be detoxified are differentiated as a separate group of apparatus. The principal element of the design of such apparatus is a burner with a stabiliser made in the form of a poorly streamlined body which gives rise to a high turbulence.[2] The use of such burners, placed within the stream of the gas to be purified, makes it possible to reduce the temperature of the extensive purification of gases ranging from CO to CH_4 compared with box furnaces by 150–200 °C.

In many instances, oxygen-containing waste is combusted in combustion chambers of boiler and other technological aggregates[98,104,105] where the contaminated air is used to generate the blast. The degree of elimination of organic acids and aldehydes from gases by this procedure reaches 99–100%.[98] Thermal detoxification processes are used in the manufacture of technical carbon for the afterburning of waste gases whose composition is usually (vol.%) 7–8 H_2, 6–7 CO, 0.5–0.7 CH_4, 2–3 O_2, 2 CO_2, 40 N_2, and 40 H_2O. Furthermore, these gases contain up to 2 g m^{-3} of residual soot (carbon). The high heat generating capacity of the gases (360–500 kcal m^{-3}) permits their use as fuel in special boiler aggregates.[106]

One of the most economical and promising methods is believed to be thermal detoxification using heat exchangers capable of being regenerated.[2,107–121] These devices consist of a combustion chamber and two (or more) layers of the regenerative packing. The periodic alteration of the direction of motion of the detoxified gases through the layers of packing or the rotation of the latter for a constant direction of motion of the gases ensure the regeneration of the heat of the hot purified gases and the heating of the initial gas to be purified.[2,110,111,122] The Retherm afterburning devices[108] with a productivity up to 100 000 m^3 h^{-1}, which make it possible to utilise up to 95% of the heat of the gases being purified,[122] have come to be most widely used. Their design rules out the possibility of the release of gas during the switching of the gas streams, which is achieved by employing five regenerative heat exchangers. A similar design has been proposed also in the USSR.[115] When much heat is evolved, it is also possible to utilise the heat given up as a result of the combustion of impurities.[121]

Overall, recent years have been characterised by a vigorous development of thermal detoxification methods based on the regenerative principle of heat exchange.[109–120] In some cases, attempts have been made to combine catalytic and thermal methods by incorporating in the apparatus both burners and layers of extensive oxidation catalyst.[112,118–123] Thermal afterburning has found applications in the most varied branches of industry. Simple versions of afterburning (for example, flame afterburning) are used in metallurgical[98] and chemical (petrochemical) undertakings.[124] Thus thermal afterburning is widely employed for the detoxification of waste gases from cast iron cupolas. The principal combustible component of cupola gases is carbon monoxide, whose content reaches 8–15 vol.%. For CO contents from 11 to 15 vol.% the gas at a temperature of 300–350 °C can be burnt virtually without the consumption of fuel. When the CO content is reduced, an additional supply of natural gas is needed.[98] The converters available at present operate predominantly with the afterburning of the blast gases in the so called cooling units for smoke gases or directly in the flame. The concentration of carbon monoxide in gases changes during the blasting of the converter from 40 to 98%. The temperature of the waste gases is 1100–1400 °C and the residual maximum CO content after afterburning does not exceed 0.2–0.5 vol.%.

Thermal detoxification is used also for the afterburning of the effluent gases from aluminium and electrode industries. The waste generated in this case in the combustion of petroleum coke contains between 12 and 23 vol.% of gaseous combustible components (CO + H_2 + CH_4) and about 20 g m^{-3} of coke dust.[98]

The principal difficulty in using thermal afterburning arises from the formation of secondary contaminants such as nitrogen oxides, chlorine, SO_2, etc. In order to reduce the NO_x concentration, two-stage combustion is employed; in the first stage, where the process is carried out in the presence of a deficiency of oxygen, a large residual CO content is retained, while in the second stage all the combustible impurities are subjected to extensive oxidation.[125–127] A decrease in the emission of nitrogen oxides is also promoted by recirculation of gases and by the decrease in their preliminary heating.[97,99]

Thermal afterburning of gases containing organochlorine compounds is especially important for chemical industries.[128–137] In the presence of a deficiency of oxygen,[132,134,135,137] organochlorine compounds are oxidised not to elemental chlorine but to HCl, which can be readily bound by alkali. Thermal decomposition in plasmatrons[132] or in inducton arc furnaces[137] is also used for the afterburning of chlorinated hydrocarbons. In order to reduce the process temperature and the amount of chlorine formed, ultraviolet irradiation is employed[133] as well as turbulent afterburning.[136]

Sometimes the gases are passed over the surface of fused iron[138] or aluminium[139] to achieve the afterburning of toxic impurities. One cannot rule out the possibility that the oxide film formed on the metal surface plays the role of the catalyst in such cases.

Much attention has been devoted to the intensification of the existing thermal afterburning processes, for example via the thermal oxidation of impurities in a fluidised bed of heat resistant particles[140,141] or by employing electric arc furnaces.[142] The thermal gas afterburning process, under the conditions of a variable rate of their supply and a variable concentration of the impurities, can be stabilised by employing in the high-temperature zone of the furnace a packing comprising an inert (for example, ceramic) material.[143] Such packing ensures simultaneously a better mixing of the streams and increases the degree of afterburning.

The possibility of using thermal afterburning for making safe non-standard methane–air mixtures ejected from coal mines has been discussed recently. During the ventilation of the amines approximately seven hundred million m^3 of mixtures containing less than 30 vol.% of methane (conditioned mixtures) and about four thousand million m^3 of air containing between 0.5 and 0.75 vol. of methane (non-conditioned mixtures[98]) are ejected into the air annually. The combustion of the non-conditioned ejected mixtures together with solid fuel, their enrichment in natural gas, the combustion of weak mixtures using preliminary additional heating, and the connection of sources of coal mine methane to the overall (collecting) network are apparently the most promising procedures.[144]

Thermal methods have found the main application in the elimination of organic impurities from highly concentrated gases, including gases containing mechanical impurities.

VII. Catalytic methods

Catalytic gas purification methods are distinguished by their universality. With their aid, it is possible to free gases from sulphur and nitrogen oxides, hydrogen sulphide, various organic compounds, carbon monoxide, and other toxic impurities. Catalytic methods make it possible to convert harmful impurities into safe ones, less harmful ones, and even useful impurities. They make it possible to process multicomponent gases with low initial concentrations of harmful impurities, achieving high degrees of purification, to carry out the process continuously, and to avoid in most cases the formation of secondary contaminants. The application of catalytic methods is usually restricted by the difficulty of finding and preparing sufficiently cheap catalysts suitable for prolonged use. The heterogeneous-catalytic conversion of gaseous impurities is achieved in a reactor charged with a solid catalyst in the form of porous grains, rings, pellets, or blocks with a nearly honeycomb structure. Chemical conversion takes place on the extensive inner surfaces of the catalysts, reaching 10^3 $m^2 g^{-1}$.

A wide variety of substances can serve as effective catalysts used in practice. They range from minerals, which are used virtually without any preliminary treatment, and simple massive metals to complex compounds with a specified composition and structure. Catalytic activity is usually shown by solids with ionic or metallic bonds and having strong interatomic fields. One of the principal requirements which must be met by the catalyst is the stability of its structure under the reaction conditions. For example, metals should not be converted during the reaction into inactive compounds.[145,146]

Modern detoxification catalysts are characterised by a high activity and selectivity, mechanical strength, and resistance to the action of poisons and temperature. Industrial catalysts, made in the form of rings and blocks with a honeycomb structure, offer a low hydrodynamic resistance and have a high external specific surface.[146]

Catalytic methods for the detoxification of effluent gases in a stationary catalyst bed have come to be most widely used. It is possible to differentiate two fundamentally different procedures for carrying out the gas purification process—under stationary and artificially created non-stationary conditions.

1. The stationary method

Rates of chemical reactions suitable for practical use are attained in the presence of the majority of cheap industrial catalysts at 200–600 °C. After the preliminary removal of dust (up to 20 mg m^{-3}) and various catalytic poisons (As, Cl_2, etc.), the temperature of the gases is usually appreciably lower.

The gases can be heated to the required temperatures by introducing combustible smoke gases or with the aid of an electric heater. After passage through the catalyst bed, the purified gases are released into the atmosphere, which requires an appreciable energy consumption. A reduction of energy consumption can be achieved if the heat of the effluent gases is used to heat the gases entering the purification process. Regenerative tubular heat exchangers are usually employed for heating.

Under certain conditions, where the concentration of combustible impurities in the effluent gases exceeds 4–5 g m^{-3}, the process in accordance with a scheme employing a heat exchanger makes it possible to avoid additional consumption of heat. When reversible exothermic reactions take place, the attainment of a high degree of purification requires the intermediate removal of heat, which appreciably complicates the technological scheme. The processing of gases by the above method is difficult if the gas is supplied at a variable rate and when the concentration of impurities in it is not constant. The presence of an external heat exchange increases the parametric sensitivity of the system and enhances the risk of overheating and sintering of the catalyst even after a slight increase in the concentration of impurities and (or) decrease in the gas flow rate. Such devices can operate effectively only at constant concentrations (flow rates) or when ideal systems for the automatic regulation of the process are employed. These difficulties can be overcome by carrying out the gas purification under non-stationary conditions.

2. The non-stationary method (flow reversal process)

If the stationary catalyst bed is initially heated to a temperature ensuring the occurrence of the chemical reaction at an appreciable rate and the reaction mixture, whose temperature is insufficient for the occurrence of the reaction is directed to it, then after a certain time interval a thermal front is established in the bed.[148,149] It moves at a rate smaller by a factor of 100–1000 than the rate of filtration of the gas through the catalyst. A second feature of the thermal front, consisting in the fact that the difference between the maximum and inlet temperatures can greatly exceed the temperature drop due to the adiabatic heating with complete conversion of the initial mixture (ΔT_{ad}), gives rise to the possibility of a technological application of this phenomenon.

The non-stationary method is illustrated schematically in Fig. 1. It provides for the periodic alteration of the directions of filtration of the gas mixture in the catalyst bed with the aid of valves *1* and *2*.[150] The process proceeds as follows. The catalyst bed is heated initially to a temperature at which the catalytic process proceeds at a high rate. After this, the gas to be purified is supplied to the apparatus at a low temperature (T_{inp}) at which the rate of the chemical reaction is negligible. As a result of direct contact with the solid material, the gas is heated and catalytic reactions begin to

occur at an appreciable rate in the catalyst bed. Giving up its heat to the gas, the layer of the solid material (catalyst) is gradually cooled to the temperature equal to that of the gas at the inlet. Since heat is evolved during the reaction, the temperature in the bed can exceed the temperature resulting from the initial heating. A thermal wave is formed in the reactor and moves in the direction of the filtration of the reaction mixture, i.e. in the direction of the outlet from the bed. Periodic reversal of the direction of the supply of the gas makes it possible to retain the thermal wave indefinitely within the limits of the bed.

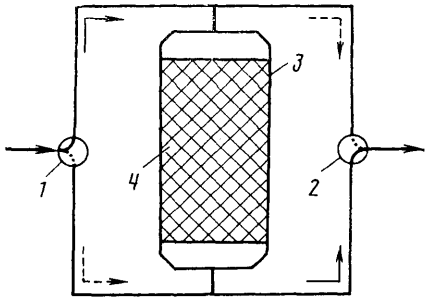

Figure 1. Technological scheme of the gas detoxification process in a non-stationary regime: *1*, and *2*, switching devices; *3*, catalytic apparatus; *4*, catalyst bed.

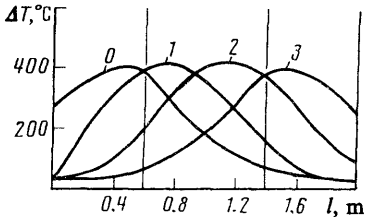

Figure 2. Variation of temperature along the length of the catalyst bed (*l*) during a half-cycle (*O*) before change of direction of filtration; *1*, *2*, and *3*, 6, 15, and 25 min respectively after the change of direction.

Fig. 2 presents typical temperature profiles along the catalyst bed at different times after the change in the direction of the supply of the initial reaction mixture. It is seen that the sections located near the inlet are gradually cooled, while in the middle part of the bed the temperature rises. The increase in temperature is caused by the accumulation of the heat of reaction within the catalyst grains, while the cooling is caused by the removal of heat by the stream of the gas mixture. After 25 min (the half-cycle time), the direction of supply is again altered and subsequently the switching is performed with the same periodicity.

An integral heat balance is maintained in the steady cyclic regime: $T^{av}_{outp} = T_{inp} + \Delta T_{ad} x^{av}_{outp}$ (x^{av}_{outp} is the degree of conversion and T^{av}_{outp} is the average temperature at the outlet). The autothermal nature of the cyclic regime is ensured solely by the heat of the exothermic chemical reaction of the impurities present in the gas undergoing purification.

The principal advantages of the non-stationary method of carrying out heterogeneous catalytic reactions are as follows:[148,150,151]

(1) The autothermal nature of the non-stationary process is achieved with a minimal adiabatic heating of the mixture (of the order of 15 °C).

(2) The complete conversion of the reacting components (or an equilibrium in the case of reversible reactions) is achieved in the catalyst bed.

(3) Variations in the concentrations of the combustible impurities and in the temperature of the input stream and in its volume flow rate do not have a significant effect on the principal parameters of the non-stationary regime in the reactor—the maximum temperature and the degree of conversion—as a consequence of the fairly high heat capacity of the catalytic unit.

(4) Heat exchange takes place within the catalyst bed itself, which not only accelerates the reaction but also ensures the regeneration of heat.

(5) In the processing of gas mixtures, whose adiabatic heating exceeds 100–150 K (which is equivalent to a content of organic substances of 3–5 g m^{-3}), non-stationary devices can become a source of secondary energy resources in the form of steam, hot water, hot gases, etc., obtained as a result of the utilisaton of heat in the zone of maximum temperatures.

(6) In the non-stationary regime, a satisfactory approximation to the theoretical optimum conditions for reversible exothermic reactions is achieved without intermediate heat exchangers. In the case of a fairly close approximation to the theoretical optimum conditions for reversible exothermic processes, the catalytic process can be significantly simplified and a single-stage process can be used instead of a multistage one.

3. The application of catalytic methods in the elimination of toxic compounds from gases

(a) Nitrogen oxides

Among all the possible ways of removing nitrogen oxides from effluent gases, catalytic procedures are most widely used nowadays since they require relatively low capital and operating costs, permit the use of comparatively simple designs, and at the same time are highly effective.[152] Among catalytic methods which have not so far gone beyond laboratory tests, the procedure for the direct decomposition of NO_x into molecular nitrogen and oxygen appears extremely attractive. However, this method is not applicable to oxygen-containing gases. The study of the catalytic activity[40] of metal oxides in the reaction involving the decomposition of NO_x into nitrogen and oxygen showed that in all cases the reaction is retarded by oxygen.[153]

The catalytic methods for the reduction of NO_x adopted in industry can be divided arbitrarily into two main groups: (1) the high-temperature reduction which occurs only in an oxygen-free medium using combustible gases as the reductant; (2) selective catalytic reduction (SCR) whose characteristic feature is the interaction of the reductant employed with nitrogen oxides in the presence of oxygen.

Hydrogen, carbon monoxide, kerosene vapour, and petroleum and natural gases are used for the high-temperature reduction of nitrogen oxides.[154] Nitrogen oxides are reduced to nitrogen, while other reaction products may be water and carbon dioxide. Metals on carriers are employed as catalysts of the high-temperature reduction process. The active components are usually platinum, palladium, and copper–chromium alloys.[155] The process tempera-

ture is normally 300–500 °C.[154] The reduction occurs only in an oxygen-free atmosphere and the first stage is therefore the "burning away" of oxygen. Since the content of nitrogen oxides does not in most cases exceed 0.2 vol.%, the consumption of combustible gases is virtually determined solely by the oxygen content in the smoke gases. In the catalytic "burning away" of 3–8 vol.% of oxygen, the gas temperature increases by 400–1000 K.[154] The disadvantages of the method considered are the high initial reaction temperature, a considerable consumption of the reductant in the removal of oxygen, the cost involved in the utilisation of the heat of the effluent gases, the necessity to maintain a definite temperature process regime, and the possibility of the presence of carbon oxides in the effluent gases as a consequence of the employment of a reducing atmosphere.[152,154,155]

In the selective catalytic reduction of nitrogen oxides, the reductant interacts with NO_x in the presence of oxygen. Under industrial conditions, NH_3 is widely used as the reductant.[156,157] Apart from gaseous ammonia, reagents which evolve it can also be used in SCR processes: various organic nitrogen compounds or the products of the decomposition of the corresponding salts;[158] compounds with amino- or imino-groups;[159] aqueous ammonia solutions.[160]

The activity of the catalyst decreases in the following sequence in reactions involving reduction by ammonia:[154] Pt > MnO_2 > V_2O_5 > CuO > Fe_2O_3 > Cr_2O_3 > CoO_3.

In industry, mainly vanadium-containing catalysts are used for the selective reduction of nitrogen oxides by ammonia.[157] Vanadium pentoxide (V_2O_5), deposited either on Al_2O_3 or TiO_2, possesses a high activity at relatively low temperatures (< 400 °C) and is highly resistant to the action of sulphur oxides, which is very important in the detoxification of sulphur-containing gases from thermoelectric power stations.[161] Attempts are being made to create industrial SCR catalysts based on iron and chromium oxides,[162,163] zeolites,[163–165] and platinum and ruthenium.[162]

The SCR method is applied mainly for the removal of NO_x from gases in the manufacture of nitric acid and in the combustion of fuel. The application of the SCR method to the purification of gases from thermal electric power stations has a number of characteristic features associated with the degree of contamination of the gases by dust, their sulphur content, and their high temperature. Dust-containing gases are purified on catalysts with a ceramic honeycomb structure (blocks) at high linear flow rates—up to 60 m s^{-1}.[166] Catalysts with this structure have walls of identical thickness and form throughout the length of the bed channels with a hydraulic diameter from 2 to 30 mm. The porosity of such a block is 50–80%. Instead of ceramic blocks the active component is sometimes deposited on the surfaces of metallic plates[167] or heat exchange tubes.[168]

In the course of the operation of catalytic reactors for the selective reduction of NO_x, the activity of the catalysts falls both as a result of the blocking of the active surface by dust and the erosion wear of the blocks and as a result of the deposition of salts (sulphites, sulphates, and nitrates). For the partial regeneration of the catalyst, the temperature at the inlet to the bed is periodically raised[169,170] or substances (alcohols, ketones, aldehydes, etc.) promoting the decomposition of the salts are introduced into the reactor.[171] For example, ammonium salts are decomposed by removing the catalyst from the reactor and regenerating it in individual devices.[172–175] Sulphates are eliminated by washing the catalyst with various aqueous solutions.[162]

The principal ways of increasing the cost effectiveness of the SCR processes in thermal electric power stations are a decrease in the energy expenditure and an increase in the useful lifetime of the catalyst. In order to increase the cost effectiveness, rotating heat exchangers are employed nowadays. The hot effluent smoke gases at a temperature of 350–400 °C are mixed with ammonia and are subsequently applied to a rotating plate reactor-heat exchanger. After passage through the reactor-heat exchanger, dust and sulphur dioxide are trapped from the NO_x gases. Fresh air for combustion enters during this period the other half of the apparatus, where it is heated and then supplied to the furnace. The rotation of the heat exchanger is regulated in such a way that a virtually constant temperature is maintained throughout its volume.[1]

Favourable catalyst operating conditions are created naturally when the SCR systems are placed beyond the devices for the removal of dust and sulphur from smoke gases. In this case, one can use much less catalyst and its useful lifetime increases to five years compared with 1–3 years when it operates in dust-contaminated gases.[176] However considerable operating and capital costs involved in heating the gases to 300–350 °C after the removal of sulphur have held back hitherto the extensive industrial application of such procedures. The endeavour to reduce energy expenditure has led in recent years to the use of regenerative heat exchangers in the application of the SCR method.[162,164,165,177]

When the flow reversal process is used to remove nitrogen oxides from gases, the catalyst is placed between inert material beds.[178–180] The ammonia for the reduction of nitrogen oxides is introduced in such a way that the formation of ammonium nitrite and nitrate is virtually ruled out. Certain technological characteristics of the industrial process are presented in Table 1. When the initial content of nitrogen oxides was varied widely and in the presence of a 15% excess of ammonia relative to its required stoichiometric amount, the degree of conversion of nitrogen oxides was not less than 98% with a virtually complete conversion of ammonia. The maximum temperatures in the reactor were in the range 350–450 °C.

The heat evolved in the reduction of NO_x by ammonia in a mixture containing 1 g m^{-3} of nitrogen oxides is sufficient to heat the mixture by 7–10 K. This is sufficient to carry out the process on block catalysts in an autothermal regime. The autothermal nature of the process on granular catalysts is ensured at an initial NO_x concentration of 1.5–2 g m^{-3}.

Table 1. Technical characteristics of industrial equipment for the catalytic detoxification of gases in a non-stationary regime.

Parameter	Oxidation of SO_2 to SO_3 (Ref.183)	Removal of organic compounds	Removal of NO_x by selective reduction
Volume of gases to be purified (10^3 m^3 h^{-1})	35.0	1.0	10–11
Concentration of removable impurities at inlet	2 vol.%	0.5–0.7 g m^{-3} (methanol, phenol, formaldehyde)	4–15 g m^{-3}
Temperature at inlet, °C	30–40	15–20	30–40
Maximum temperature in catalyst bed, °C	480–550	400–550	300–450
Degree of conversion (purification), %	95–97	Methanol—99.9; formaldehyde—99.6; phenol—97.0	98–99
Period between reversals of direction, min	20	30–45	5–25

(b) Sulphur dioxide

Sulphur dioxide, whose concentration is not less than 0.5–0.7 vol.% in effluent smoke gases, is trapped in the vast majority of cases by absorption-chemical methods.[1,14,16] At a SO_2 concentration in excess of 1 vol.%, its utilisation in the form of sulphuric acid or elemental sulphur is economically justified. In order to obtain the acid, sulphur dioxide is oxidised in the presence of a catalyst to SO_3, which is absorbed by a solution of sulphuric acid in a scrubber.[12,181,182] The effluent gases from smelting furnaces for non-ferrous metals, in which the SO_2 concentration is between 4 and 11%, are usually converted into sulphuric acid.[181] Non-ferrous metallurgy supplies about 24% of the entire sulphuric acid produced in the USSR.[12]

The industrial oxidation of sulphur dioxide is achieved in the presence of vanadium catalysts. The active component has a complex composition and one can assume to a first approximation that it consists of potassium sulpho- and pyrosulpho-vanadates dissolved in an excess of potassium pyrosulphovanadate. Under the reaction conditions, the active component is in the fused state on the surface of the solid carrier, usually silica. The liquid state of the active component is a precondition for the occurrence of the reaction in the bulk of the melt after the preliminary dissolution of the gaseous components.[145] The oxidation is as a rule carried out in multichamber reactors with intermediate removal of heat. The sulphur trioxide formed is absorbed to form commercial sulphuric acid. At initial SO_2 concentrations in excess of 5 vol.%, it is useful to employ the double contact method—double absorption, which makes it possible to utilise 99.5–99.9% of the sulphur and to achieve a SO_2 content at the outlet which is the same as after chemical purification, i.e. 0.02–0.05%.[12] The complexity and expense of the manufacture of sulphuric acid are associated with the significant reversibility of the reaction $SO_2 + {}^1/_2O_2 = SO_3$ in the temperature range 400–600 °C, where vanadium catalysts exhibit an acceptable activity.

In order to obtain sulphuric acid from gases in which the SO_2 concentration is less than 3–3.5% in multichamber apparatus, it is necessary either to heat the gases continuously to 400–450 °C or to "fortify" the dilute gas with sulphur dioxide obtained by combusting sulphur in a stream of air[182] or by the effluent gases from autogenic processes containing more than 11 vol.% of SO_2.[183]

The catalytic oxidation of SO_2 in a non-stationary regime in the presence of the traditional vanadium catalyst significantly simplifies the process and lowers its cost.[178,184] This method makes it possible to reduce the amount of metal required for the catalytic unit by a factor of 1.5–5, to decrease the hydraulic resistance by a factor of 1.5–2, to diminish the total capital cost by 30–80%, and to reduce the intrinsic cost of sulphuric acid by 5–20% compared with the existing method. It does not require the consumption of fuel for heating the mixture in the processing of gases containing more than 0.6% of SO_2, while in the presence of more than 4–5% of the dioxide additional heat can be obtained.

A characteristic feature of the non-stationary method for the oxidation of SO_2 to SO_3 is the appearance along the length of the catalyst bed of a region where the temperature decreases (Fig. 2). This gives rise to the possibility of achieving a temperature regime close to one which is theoretically optimal for irreversible exothermic processes, makes it possible to reduce the number of catalyst layers, and virtually obviates the need for intermediate heat exchangers in an industrial reactor. The use of industrial reactors[185–197] operating under periodic mixture reversal conditions showed that they can be readily regulated, permit a stable processing of gases in which the concentration of sulphur dioxide varies by an order of magnitude, and retain their working temperatures when the process is arrested even for several days. It is noteworthy that, at initial sulphur dioxide concentrations less than 2.5–3%, it is possible to achieve a degree of conversion of SO_2 into SO_3 of 97–98% on a single-bed reactor. The technical characteristics of one of the industrial catalytic types of apparatus for the oxidation of SO_2 to SO_3 on the basis of the reversal process are presented in Table 1. In terms of technological parameters (degree of purification, maximum temperatures), the experimental data obtained on industrial apparatus agree satisfactorily with the values calculated on the basis of mathematical models for non-stationary processes.[148]

(c) Hydrogen sulphide

The hydrogen sulphide contained in acid gases resulting from the processing of petroleum and natural gas is one of the main sources of sulphur.[188] The Claus process is usually employed to extract sulphur. In this method, the gas containing predominantly hydrogen sulphide and carbon dioxide is oxidised at high temperatures in a Claus furnace by air or oxygen with formation of elemental sulphur, sulphur dioxide, and also a certain amount of COS and CS_2. Air (or oxygen) is supplied in an amount such that the concentration ratio $H_2S:SO_2 = 2$ is ensured at the outlet from the furnace. The degree of conversion of hydrogen sulphide into sulphur reaches 60–70%. Next, the mixture is cooled, condensed, and the sulphur is separated, while the gases are subjected to catalytic conversion using active alumina, bauxites, titanium dioxide, etc. as catalysts.[189,190] The reversible exothermic reaction $2H_2S + SO_2 = 3S + 2H_2O$ takes place on the catalyst. The equilibrium degree of conversion increases rapidly with decrease in temperature. However, at low temperatures, the sulphur formed condenses, blocking and thereby deactivating the catalyst. The process is therefore performed in several catalytic stages with the intermediate cooling and separation of sulphur.

A degree of extraction of sulphur up to 96% (overall degree of extraction including the degree of extraction of sulphur in the Claus surface) is attained in the two-stage process, while in the three-stage process the degree of extraction is up to 98%. In order to attain higher parameters, different fairly expensive processes for the additional purification of residual gases are used: afterburning, including catalytic afterburning, to give SO_2 with subsequent processing or ejection to the atmosphere; hydrogenation to H_2S with subsequent conversion into sulphur; preparation of sulphur by the Claus method but under specific conditions.[191–195] Schemes involving "dry" additional purification of gases, based on carrying out the Claus reaction at temperatures below the dew point of the sulphur formed, have come to be most widely used.[191] The process is usually carried out as follows. The reaction is performed at 120–135 °C, which ensures a high degree of conversion, but the sulphur formed is condensed in the pores of the catalyst (alumina). After the saturation of the bed, the catalyst is regenerated at 300–350 °C, the regeneration being accompanied by the evolution and subsequent condensation of sulphur. In order to ensure the continuity of the process, it is carried out in several parallel reactors, each of which operates in succession under catalytic conditions—adsorption of sulphur, regeneration, and cooling. By 1986, about 70 industrial plants with "dry" additional purification, ensuring an average extraction of H_2S of 99–99.5%, operated throughout the world.[191]

The actively developing liquid-phase methods for the additional purification of the residual gases from the Claus process are an alternative to the "dry" methods,[191-193] but their wide scale industrial application is prevented by the high capital costs, the formation of acid waste, and the low quality of the sulphur formed.[194]

The non-stationary method for the manufacture of sulphur on the basis of the Claus method in a stationary catalyst bed under periodic mixture reversal conditions[196,197] makes it possible to reduce greatly the capital and energy (operating) expenditure.

The process is carried out as follows. The initial gas mixture at a low temperature (120–116 °C) is supplied to the catalyst bed, which was heated beforehand. The sulphur formed then condenses in the reaction zone suppressing the activity of the catalyst until its complete deactivation. After the introduction of the mixture into a "fresh" bed, the initial sections of the bed are gradually deactivated and the reaction zone slowly shifts into the bulk of the bed in the direction of the filtration of the gas. A moving "sulphur condensation front" is thus produced together with the temperature and concentration fronts associated with it. After a certain time, the direction of motion of the reaction mixture is reversed. An analogous condensation front then begins to move from the opposite side and the previously condensed sulphur vaporises as a result of the heat of reaction. The use of various modifications of the Claus flow reversal process makes it possible to achieve a degree of elimination of H_2S from the gas above 99%.

It is sometimes desirable to utilise the sulphur dioxide from sulphur-rich gases in the form of elemental sulphur.[188-190] For this purpose, SO_2 is subjected to thermal reduction by various reductants (carbon, CO, CH_4, H_2, hydrocarbons), after which the catalytic Claus reaction between SO_2 and H_2S is carried out. The SO_2 is reduced both using solid catalysts[198] and a non-catalytic procedure in a homogeneous phase.[199]

The utilisation of SO_2 from metallurgical gases can be achieved by means of the liquid-phase sulphur elimination method developed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences[200,201] based on the liquid-phase reduction of sulphur dioxide by hydrogen sulphide. The chemical sorbent, recirculating during the process, is an aqueous solution of ammoniacal phosphate salts and a homogeneous catalyst based on soluble silicon or aluminium salts, which significantly accelerate the reduction of SO_2 by hydrogen sulphide compared with other known liquid-phase methods.[201]

(d) Organic compounds

The elimination of organic compounds from gases involves the oxidation of the impurities to carbon dioxide and water. Catalytic methods are widely used to make safe the effluent gases from the manufacture of synthetic fibres,[202-204] the gaseous waste from petroleum processing and petrochemical undertakings,[205,206] the venting gases from painting and drying workshops,[207-209] and in the manufacture of electrotechnical articles.[206,210] The relevant reviews[147,211-214] show that the application of catalytic detoxification methods is expanding continuously.

Both catalysts containing precious metals (Pt, Pd)[215,216] and catalysts based on copper, chromium, cobalt, and iron oxides as well as complex oxide systems (chromites, ferrites, cobaltites, etc.)[213] are used for the catalytic afterburning of toxic impurities. Detailed data about Soviet detoxification catalysts have been published.[217] Depending on the nature of the toxic components in the gases, different catalysts are used.

Not only hydrocarbons and carbon monoxide but also nitrogen-containing[218,219] and halogen-containing organic compounds[220,221] can be trapped from gas mixtures by means of catalytic oxidation. By a successful selection of catalysts and process conditions, nitrogen-containing impurities can be oxidised to elemental nitrogen, CO_2, and water,[218] whilst chlorine-containing impurities can be oxidised to HCl, which is bound by alkali.[221]

The temperature of the gases at the inlet to the catalyst bed, required to ensure high degrees of purification, varies from 160–200 °C in the elimination of formaldehyde from gases on platinum-containing catalysts[206,213] to 400–600 °C in the elimination of isopropylbenzene and bitumen vapour from gases on oxide catalysts.[206]

Catalytic afterburning processes are being improved by creating catalysts capable of propagating the oxidation at low temperatures. For example, catalysts for the oxidation of CO to CO_2 at 30 °C have been proposed.[222] In order to reduce the hydrocarbon oxidation temperature, ozone has been introduced as the oxidant into the gas undergoing purification.[223,224] An adsorption-catalytic method is developing vigorously.[225-228] It consists of the adsorption of toxic compounds (for example, styrene[228]) on various catalysts (zeolite-containing catalysts,[225] copper chromite,[226] and a manganese catalyst[228]) with subsequent oxidation of the impurities on raising the temperature at the inlet.

A two-stage process with the intermediate removal of heat and afterconversion of impurities on a second catalyst bed is used to make safe concentrated gaseous waste.[147,229-232] Different catalysts oxidising different impurities can be used in each stage.

The improvement of catalytic processes also involves an increase in the degree of recovery of heat using heat exchangers with turbulisation of the stream.[233] This makes it possible to increase the degree of recovery of heat to 80–85% and to reduce correspondingly the amount of fuel used.

The elimination of various organic substances and CO from industrial effluent gases under conditions involving the periodic reversal of the flow of mixture through a stationary catalyst bed[234-237] ensures the following features compared with the traditional stationary procedure: (a) a decrease in the capital cost of the building of plants by a factor of 1.5–3; (b) a decrease in the intrinsic cost of the purification of gases by a factor of 1.5–2; (c) the autothermal nature of the process under the conditions of variable and low (on average above 0.5 g m^{-3}) contents of toxic impurities; (d) the generation of potentially highly useful heat in the detoxification of gases containing more than 3 g m^{-3} of toxic impurities, which can also ensure that the detoxification process is economical.

For the purification by the non-stationary method of gases at low concentrations, whereupon the adiabatic heating of the mixture (ΔT_{ad}) on complete conversion of harmful substances into CO_2 and water does not exceed 15 K, it has been suggested[235] that an additional minimum amount of fuel which would ensure, together with the toxic components, the necessary degree of heating be introduced into the gas being purified. Such a process has been developed for the detoxification of the effluent gases from painting and drying workshops.

In contrast to the reversible sulphur dioxide oxidation and Claus reactions, oxidation reactions leading to the removal of organic compounds from gases take place reversibly with formation of water and carbon dioxide. This makes it possible to purify gases under non-stationary conditions at the maximum temperatures without the use of fuel and with the minimum amount of catalysts.

The technical parameters of one of the industrial plants for the elimination of organic compounds from gases are presented in Table 1.

Industrial non-stationary catalytic methods for the elimination of the principal industrial gaseous contaminants (NO_x, SO_2, hydrocarbons) from gases have been developed on the basis of the flow reversal process and applied in industry. The efficiency of the non-stationary method has been confirmed by the vigorous development of studies on these lines both in the USSR and abroad.[238–243]

VIII. Non-catalytic chemical methods

If undesirable impurities are removed from gases as a result of a virtually irreversible chemical reaction, whose role is decisive compared with other processes, then such methods of purification will be referred to as chemical. From this standpoint, the methods for the elimination of SO_2 from effluent gases using lime or limestone, for example, are frequently referred to as absorption methods since the decisive operation involves in this case processes in the absorption scrubber. The chemical purification methods are based primarily on the chemical transformation of toxic compounds into harmless (or less toxic) ones or on the activation of chemical reactions. It is useful to include among them also radiation-chemical methods based on the employment of accelerated electrons.[244–247] In many cases, it is useful to introduce ozone into the gases undergoing purification in order to activate chemical reactions.[162,248,249] Examples of the use of chemical purification methods in industry are presented below.

The elimination of NO_x from gases involves the reduction of the impurities to N_2 and H_2O. The homogeneous reduction of NO_x by ammonia occurs mainly at 900–1000 °C. At higher temperatures, the rate of oxidation of ammonia to nitrogen oxides increases significantly, which lowers the degree of purification. This process has been developed mainly by the American Exon Company.[250] The average degree of elimination of NO_x from gases by this method does not at present exceed 60–70%.[152,251,252] The principal ways of increasing the process efficiency involve the improvement of the systems for the mixing of small amounts of ammonia with hot (900–1000 °C) smoke gases,[253] which makes it possible to raise the degree of purification to 80–90%, and the search for new reductants permitting the expansion of the temperature range in which the process can be carried out.[254] Thus it has been suggested that urea be used for the reduction and that the process be performed at 600–1100 °C.[254]

On exposure to a stream of electrons, chemical reactions in gases are appreciably accelerated. This method is suitable mainly for the elimination of NO_x and SO_2 from the smoke gases generated in thermal electric power stations.[244–247] The stream of smoke gases is initially freed from ash, after which ammonia is supplied and the gas mixture is irradiated. This results in the formation of a mixture of the salts $(NH_4)_2SO_4$ and $(NH_4)_2SO_4.2(NH_4)_2SO_3$ from ammonia, nitrogen oxides, and sulphur. After the separation of the salts (for example, on an electrofilter or on a sleeve filter), the gas is ejected through a smoke tube and the mixture of salts is used as a fertiliser. The output of the largest plant operating in the USA is 32000 $m^3 h^{-1}$. The principal advantages of the method are its simplicity and the absence of secondary contaminants, including waste water. The degree of elimination of NO_x attained is usually 70–90%.[244,245] Various modifications of the methods are being developed: with recycling of the purified gas[255] and with irradiation of the gas in two stages, whereupon most of the radiation dose is absorbed in the first stage.[256] The principal disadvantage of the method is believed to be the considerable energy expenditure. Evidence has recently appeared indicating the possibility of the laser irradiation of the gases undergoing purification.[257] The wavelength is then selected so that the preliminary absorption of radiation by sulphur and nitrogen oxides should entail their dissociation with liberation of elemental sulphur and N_2.

Ozone methods are used to remove the toxic SO_2 and NO_x from smoke gases and to deodorise the gaseous waste in industrial undertakings. The introduction of ozone accelerates the oxidation of NO to NO_2 and of SO_2 to SO_3.[257] After the formation of NO_2 and SO_3, ammonia is introduced into the smoke gases and the mixture of the complex fertilisers formed (ammonium sulphate and nitrates) is isolated. The duration of contact between the gas and ozone necessary for the removal of SO_2 (80–90%) and NO_x (70–80%) is 0.4–0.9 s. The energy expenditure on the purification of gases by the ozone method is estimated as 4–4.5% of the equivalent power output of the energy unit, which is apparently the main cause holding back the industrial application of this method.[249]

The use of ozone to destroy the odour of gaseous waste is based on the oxidative decomposition of substances with an unpleasant smell. In one group of methods, ozone is introduced directly into the gas being purified, whilst in another the gases are washed with water which was ozonised beforehand. The subsequent passage of ozonised gas through a layer of activated charcoal[257–261] or its application to the catalyst[262–264] have also been used. When ozone is introduced and the gas is subsequently passed through the catalyst, the temperature of the conversion of substances such as amines, acetaldehyde, and hydrogen sulphide is reduced to 70–80 °C. Both Pt/Al_2O_3 and copper, cobalt, and iron oxides on a carrier are used as catalysts.[263] The ozone methods for the destruction of odour have been used primarily in the purification of gases evolved in the processing of raw material of animal origin in meat (fat) processing plants.[249] This method has so far been scarcely applied in the USSR.

Either pelleted material (crushed charcoal with added lime) is used for the chemical binding of SO_2 or powdered limestone or dolomite is introduced into carbon dust in the combustion of spray-injected fuel. The use of grains containing added lime with the ratio C : S = 3 : 5 reduces the concentration of sulphur dioxide in smoke gases resulting from the combustion of fuel in grate furnaces by 50–70%.[34] In the combustion of coal dust with added lime, the degree of binding of SO_2 reaches 80%.[30] SO_2 is bound similarly after the introduction of sodium salts and in this case there is a possibility of using lower temperatures (110–150 °C).

Three filters are employed for the subsequent separation of the salts formed. The disadvantages of this method are believed to include the inadequate, in many instances, degree of elimination of SO_2 and the solubility of the salts formed.[1]

The different reactivities (differing by a factor of 5) of different kinds of limestone in relation to SO_2 have not so far been adequately explained.[30]

Chemical methods make it possible to achieve the combined elimination of compounds of different types from gases. An example is provided by the method for the simultaneous removal of sulphur dioxide and hydrocarbons from gases.[265] For this purpose, the gas is passed through a layer of hot limestone at a temperature sufficient for the cracking of the hydrocarbons. Sulphur dioxide is

simultaneously converted into calcium sulphide. The regeneration is carried out with oxygen, which affords elemental sulphur.

IX. Biochemical methods

Biochemical purification methods are based on the ability of microorganisms to decompose and transform various compounds. The substances are decomposed on treatment with enzymes generated by microorganisms in the gases undergoing purification. When the gas composition is frequently altered, the microorganisms are unable to adapt by developing new enzymes and the degree of decomposition of harmful impurities becomes incomplete. Biochemical systems are therefore most suitable for the purification of gases of constant composition.

The biochemical purification of gases is carried out either in biofilters or in bioscrubbers. In biofilters, the gas undergoing purification is passed through a layer of packing irrigated with water, which gives rise to a moisture content sufficient to maintain the vital activity of microorganisms. The surface of the packing is coated with a biologically active biofilm (BF) comprising microorganisms. In the course of their vital activity, the microorganisms of the biofilm absorb and decompose the substances contained in air, which results in the growth of their mass. The efficiency of the purification is determined to a large extent by the mass transfer from the gas phase to the biofilm and by the uniform distribution of the gas in the layer of packing. Filters of this kind are used, for example, to deodorise air.[11,266] In this case, the gas stream undergoing purification is filtered under conditions where its flow is parallel to that of the irrigating liquid containing nutrient substances. Beyond the filter, the liquid enters settling chambers and is then again directed to irrigating units.

At the present time biofilters are already used fairly widely for the removal of ammonia, phenol, cresol, formaldehyde, organic solvents introduced in the painting and drying processes, hydrogen sulphide, methanethiol, and other organosulphur compounds from effluent gases. The degree of purification of effluent gases is 95–99%.[267–269] Under normal operating conditions, complete deodorisation is observed beyond the biofilters as a result of the elimination of compounds with an unpleasant smell, for example, methanethiol and hydrogen sulphide. The hydraulic resistance of biofilters ranges from 250 to 2000 Pa and the average contact time is 10–25 s.[266,267]

Bioscrubbers are absorption devices in which the irrigating liquid (absorbent) is an aqueous suspension of active sludge with microorganisms. The gas being purified is usually supplied to the scrubber from below and passes through a packing in a countercurrent relative to the irrigating absorbent. The decomposition reactions of the trapped impurities occur in the aerator-reactor. In order to maintain the vital activity of the microorganisms, the necessary nutrient substances are continuously introduced into the system. Bioscrubbers have found applications for the purification of effluent gases from metal casting industries containing phenol, formaldehyde, ammonia, hydrocyanic acid, and cracking products[267,270] and also in the elimination of butyl acetate, xylene, and alcohols from painting workshop gases.[266]

The overall content of impurities in the gases to be purified can be 750–800 mg m^{-3}.[266] The productivity of bioscrubbers reaches 300 000 $m^3 h^{-1}$, the contact time does not usually exceed 10 s, and the hydraulic resistance is 1000–1500 Pa. The degree of purification reaches 75–98%.

Further improvement of biochemical gas purification systems involves the intensification of the decomposition reactions of the trapped impurities, which is promoted by the injection of highly dispersed activated charcoal into the irrigating liquid.[271] In this case, the microorganisms are adsorbed on the large internal surface of the charcoal.[272–274] Attempts have been made to intensify the biochemical purification by applying electric fields to the system containing the activated charcoal.[275]

The development of biochemical purification methods has led to the creation of biofilters with an artificially formed structure and a specially grown biofilm. The linear flow rates of the gases being purified in such systems can reach 0.5–1.0 m s^{-1}, which is higher by a factor of 80 than in processes involving the use of natural materials. The largest biofilters of this type are being used in the Federal Republic of Germany (70 000 $m^3 h^{-1}$).[276] This procedure is most applicable to the purification of gases with a low concentration of impurities. Polymeric materials [polyethylene, poly(vinyl chloride)] are widely used in bioscrubbers. Apart from the Federal Republic of Germany, the biochemical gas purification method has found practical applications in Japan.[266,277–279] Biological gas purification methods have been recommended for the deodorisation of the effluent gases from veterinary-sanitary product factories, food processing undertakings, sewage processing plants, etc.[277]

X. Conclusion

A large number of different methods for the removal of the principal contaminants (NO_x, SO_2, H_2S, carbon monoxide, and various organic substances) from gases have now been developed and tested in industry. We shall indicate the principal applications of these methods and their present state. The absorption methods are used mainly to trap acid components from gaseous waste (SO_2, H_2S, HCl, SO_3, NO_x, NH_3, etc.). In many cases, this makes it possible to obtain useful products—acids and salts. This method is used in practice much more rarely for the removal of hydrocarbons from gases, which is caused primarily by the high cost of absorbents. The principal disadvantages of absorption methods are the formation of liquid waste and the cumbersome apparatus used.

The adsorption methods are some of the most widely used industrial procedures for the purification of gases. Their application makes it possible to return to industry many valuable compounds. At impurity concentrations in the gases more than 2–5 g m^{-3}, the purification is actually profitable. The principal disadvantage of the adsorption method is the large energy consumption in the desorption and subsequent separation stages, which greatly complicates its application to the purification of multicomponent mixtures.

Thermal methods are widely used to eliminate toxic combustible compounds from effluent gases. The afterburning plants developed in recent years are distinguished by their compactness and low energy expenditure. The application of thermal methods is effective for the afterburning of multicomponent and dust-saturated effluent gases.

The principal aspects of the development of catalytic methods are the creation of cheap catalysts operating effectively at low temperatures and resistant to various poisons as well as the development of energy saving technological processes with low capital costs for equipment. Catalytic methods have found the largest-scale application in the elimination of nitrogen oxides from gases, in the detoxification and utilisation of a wide variety of

sulphur compounds, and in the detoxification of organic compounds and CO.

Condensation methods are used on an industrial scale normally in the presence of high concentrations of the impurities to be trapped. In order to attain the necessary degree of purification after condensation, it is as a rule essential to employ some other methods, for example, catalytic methods.

The development of chemical methods is associated with the search for effective procedures for the activation of chemical gas-purification reactions. Methods involving the homogeneous reduction of NO_x and ozone methods for the deodorisation of compounds with an unpleasant smell found fairly extensive industrial applications.

The experience gained in the prolonged use of biochemical plants and the simplicity of their technical operation and the apparatus involved make it possible to recommend this procedure for extensive application, primarily for the elimination of organic compounds from gaseous waste with low concentrations of impurities. Among the disadvantages of biochemical methods, one should include, firstly, the low rate of biochemical reactions, which increases the size of the equipment, secondly, the specificity (high selectivity) of the strains of microorganisms, which hinders the processing of multicomponent mixtures, and, thirdly, the difficulty of processing variable-composition mixtures.

The industrial application of membrane methods is being held back so far by the low specific productivity of membranes, the low degree of purification, the necessity to generate a high excess pressure, the large size of the equipment, and the large capital and operating costs.

The improvement of traditional purification methods (adsorption, absorption, thermal afterburning, and condensation) and the development of new ones (catalytic, membrane, chemical, and biochemical) tend to reduce the capital and operating costs (mainly energy expenditure) involved in their application. In most cases, the problems associated with the purification of effluent gases can be solved in different ways. For example, solvents can be removed from gases with the aid of adsorption, by thermal and catalytic oxidation, and by biochemical and absorption methods, each procedure permitting the attainment of virtually any degree of purification. In every specific case, the choice of the detoxification method is an economic problem. There are no poor and good methods. There are only expensive and cheap ones.

Heterogeneous processes in the Earth's atmosphere and their ecological consequences†

Yu M Gershenzon, A P Purmal'
Semenov Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The principal information about the heterogeneous reactions involving ozone and other minor constituents of the atmosphere is described. The influence of the simplest heterogeneous reactions on the gas composition of the atmosphere in the middle latitudes and on tropospheric stratospheric coupling is examined on the basis of model estimates. The real situations and certain scenarios for an appreciable improvement of the gas composition of the atmosphere as a result of heterogeneous reactions are analysed. The oxidation of sulphate ions in cloud droplets is considered.

The bibliography includes 105 references.

I. Introduction

The heterogenous chemical processes in the atmosphere have been attracting an increasing amount of attention.[1] The interest in this field of chemistry has intensified especially during recent years in connection with the appearance of ideas about the effective influence of heterogeneous reactions on the decomposition of the ozone layer in the Antarctic during spring.

For ecology, three problems associated with heterogeneous chemical phenomena in the atmosphere are of greatest importance; (1) the change in the gas composition under the influence of heterogeneous processes; (2) dissolution and reactions in drops leading to acid rain; (3) chemical formation and growth of aerosols. Attention will be concentrated on the first two problems in this review. We shall endeavour to base the review on specific examples, concentrating attention on the problem of the content of ozone and hydroxyl radicals in the atmosphere and the problem of acid rain. The results of laboratory studies on the interaction of atmospheric gases with the surfaces of solids and liquids whose compositions are similar to those of atmospheric aerosols are also represented although without a detailed analysis.

† The five articles at the beginning of this issue are a continuation of issue No. 10 devoted to the "chemistry of the atmosphere".

The problem of the influence of changes in the radiation balance and in the intensity of the solar radiation passing through the atmosphere on the composition of the latter are outside the scope of this review. As a rule, we shall consider the situations in which the chemical action of aerosol particles on the gas composition of the atmosphere is more effective than the optical or thermochemical influences.

II. Brief information about atmospheric aerosols

1. Chemical composition

Primary aerosol particles appear in the atmosphere as a result of soil erosion, while in the layer near the water over the oceans there are salt particles. Anthropogenic sources also make an appreciable and increasing contribution. Secondary aerosols are formed in the atmosphere itself as a result of the chemical reactions of gases of natural and anthropogenic origin. The commonest of these are sulphuric acid particles — the principal aerosols of the stratosphere. It is believed that sulphuric acid is formed as a result of the photochemical transformation of carbon oxide sulphide COS into sulphur dioxide and the subsequent oxidation of the latter to H_2SO_4.[2,3] The chemical homogeneity and a single-peaked distribution of the particles with respect to size throughout the middle latitudes may serve as confirmation of a unique mechanism for the formation of the stratospheric sulphuric acid aerosol. In the troposphere, where COS is not photolysed and does not react with atomic oxygen, the formation of sulphuric acid particles is due to the chemical reactions of the SO_2 molecules arriving from the earth. Review information about the mechanisms of the formation of secondary aerosols is available in monographs.[2–5]

In the aerosol model of photochemical reactions, it is postulated that under normal (background) conditions the particles of the troposphere have the following composition[6]: up to a height of 3 km — 50% of sulphates (the main form is ammonium sulphate), 35% of soil particles, and 15% of sea salt (NaCl); above 3 km — 60% of sulphates and 40% of soil particles. According to this model, the soil particles consist of 53% SiO_2, 17% Al_2O_3, 7% of Fe_2O_3, and 23% of other compounds. The chemical composition of the aerosols in industrial regions may be different. For example, the aerosol over Houston (USA) consists of sulphuric acid to the extent of 30%[7], and in certain cases the H_2SO_4 content in aerosol over cities may reach 50%[2]. In city aerosols the fraction of SiO_2 may be 30%, while the contribution of aluminium oxide is up to 10% and that of iron oxides is several per cent[2]. In extreme situations (large amounts of industrial waste, forest fires, volcanic eruptions, nuclear explosions), the composition and concentration of aerosol particles

may change significantly. More detailed information about the physicochemical properties of aerosols is available in other publications [1,2,8].

As already stated, the stratospheric aerosol in the middle latitudes consists under background conditions mainly of sulphuric acid particles (the Junge layer, height $Z = 18-20$ km). Immediately after volcanic eruptions, a large amount of sulphur compounds and particles of volcanic ash penetrate into the lower layers of the stratosphere. These have the following approximate composition: 60% SiO_2, 20% Al_2O_3, 3% Fe_2O_3, 2% MgO, 5% CaO, 5% Na_2O. The primary volcanic stratospheric aerosol particles are apparently to a large extent coated by sulphuric acid and water. As a result of chemical reactions involving the sulphur compounds H_2S and SO_2, ejected in volcanic eruptions to a height of 25–30 km, aqueous sulphuric acid aerosols, containing between 60 and 80% of H_2SO_4, are produced. They then fall downwards and concentrate in the lower part of the stratosphere at a height of 18–20 km.

The composition of the stratospheric polar clouds, formed during the winter in the Arctic and the Antarctic, is more homogeneous. These are mainly ice particles with dissolved nitric and hydrochloric acid molecules [9,10]. The ice particles and water drops are the natural constituents of the stratospheric and tropospheric aerosols.

2. The size, distribution with respect to height and the number concentration of particles

Tropospheric aerosols can be subdivided according to particle size into three characteristic ranges (modes) [2,11,12]. The first mode consists of condensation nuclei which are particles with a radius less than 0.2 μm, the second mode comprises growing particles with a radius of 0.2–1 μm, and the third mode includes particles with a radius from 1 to 10 μm. The concentration of the solid non-hydrated particles constituting the first mode in the troposphere is highest and the main bulk of the surface of the solid particles per unit volume (the specific surface A) actually corresponds to them. The average particle radius which contributes most A is 0.13 μm [2]. The growing particles of the second mode are as a rule non-uniform in composition and appreciable amounts of water may be present on their surfaces. Large particles ($r > 1$ μm) are mainly highly hydrated forms or water drops.

The distribution of the concentration of solid particles in the troposphere with respect to height can be conveniently represented in an exponential form:

$$N_Z = N_0 e^{-Z/Z_0}. \quad (1)$$

The concentration N_0 at the Earth's surface and the characteristic height Z_0 depend on specific conditions (region, temperature, humidity). The following model is available for the distribution of aerosol particles of the troposphere with respect to height [2]: first mode—$N_0 = 10^3-10^5$ cm^{-3}, $Z_0 = 2-3$ km; second mode—$N_0 = 5-300$ cm^{-3}, $Z_0 = 1.5-2$ km; third mode—$N_0 = 10^{-2}-10^{-4}$ cm^{-3}, $Z_0 = 0.5-1$ km. The stratospheric aerosol in the middle latitudes is located at a height of 16–22 km (the Junge layer). The concentration of sulphuric acid particles is a maximum at a height of 18–20 km and their average radius is 0.05–0.1 μm. During volcanic eruptions, the concentration of aerosol particles in the stratosphere increases by a factor of 20–30, approaching the background concentration of aerosols near the Earth's surface ($\sim 10^3$ cm^{-3}).

The specific aerosol surface A in the troposhere near the Earth's surface under normal conditions, in volcanic clouds [13], and also in cold polar stratospheric clouds [9,10,14] is approximately the same and amounts to 10–50 μm^2 and cm^{-3} or $(1-5) \times 10^{-7}$ cm^{-1}. The polar stratospheric clouds are concentrated in regions with a temperature below −85 °C [15]. In the cold Antarctic stratosphere, the maximum density of aerosol particles is attained at a height of 16–18 km and there are several sharp concentration peaks in this region.[16]

3. The rate constant for a heterogeneous reaction

The interaction of molecules with the surface includes a series of stages: adsorption and desorption, diffusion within the liquid aerosol and evaporation, and reactions of the adsorbed molecules with one another and with the molecules of the adsorbent or the molecules incident from the gas phase. The probability of the reactions γ depends both on the parameters of the atmosphere (temperature, pressure, humidity) and on its gas composition. Furthermore, the chemical composition of the aerosols themselves is a function of the state of the atmosphere. This gives rise to considerable complications as regards a self-consistent description of the composition of the atmosphere taking into account its multiphase nature and the presence of definite relations between the heterogeneous and homogeneous phases (see, for example, Carmichael et al.[17]). In view of the complexity of the problem, the heterogeneous fraction is parametrised by specifying the average particle size r, the concentration of aerosol particles N, and the reaction probability γ or by introducing the specific surface A and γ. The parameters r, N, and A are determined from the results of experiments under natural conditions and the values of γ are based on laboratory data.

The rate of consumption of gases in a reaction involving spherical atmospheric particles is described by the equation for a unimolecular first-order process with an effective rate constant [18] given by

$$K_{het} = \frac{4\pi r N D}{1 + \lambda l/r}, \quad (2)$$

where D is the molecular diffusion coefficient, l the length of the free path in the gas, and

$$\lambda(\gamma) = \lambda_{\gamma=1} + \frac{4(1-\gamma)}{3\gamma}. \quad (3)$$

Here $\lambda_{(\gamma=1)} \simeq 1$ is a function weakly dependent on the Knudsen number $K_n = l/r$. The value of the function varies from 0.71 to 1.3 as l/r varies from 0 to ∞. At atmospheric pressure, $l \simeq 0.1$ μm, which is close to the radius of the solid tropospheric particles making the main contribution to the specific surface and the parameter $\gamma l/r$ almost always exceeds unity. Only a small region of the atmosphere near the Earth's surface, where $\lambda l/r$ is close to unity for $\gamma \simeq 1$, is an exception. Therefore, under atmospheric conditions, the limiting case of the destruction of molecules on solid particles in the kinetic region, where $\lambda l r \gg 1$, occurs most widely. In this case, the heterogeneous consumption constant is

$$K_{het} \simeq \frac{c\gamma}{4} A, \quad (4)$$

where c is the average thermal velocity of the molecules (it is assumed that $D = lc/3$. Eqn. (4) yields the number of active collisions of the molecules with the surface, per unit volume, in 1 s. The approximate form of the dependences of A on the height [8,19] is illustrated in Fig. 1. The values of A in the background atmosphere near the Earth's surface (~ 100 μm^3 cm^{-3}) and in volcanic and polar clouds (10–50 μm^2 cm^{-3}) are approximately the same. In urbanised regions, A at the Earth's surface is higher by two orders of

magnitude than the background value, while in the Junge layer under background conditions $A \simeq 1$ μm^2 cm^{-3}. The values of γ required for the calculation of K_{het} are presented below.

III. The influence of heterogeneous reactions on the concentrations of ozone and other minor constituents of the atmosphere

1. Model estimates for the atmosphere in the middle latitudes

Together with oxygen and nitrogen, the atmosphere contains many other constitutes at a low concentration (the so called minor constituents). These comprise primarily the gases H_2O, CH_4, N_2O, NO_x, etc. ariving from the Earth and entering into various reactions, the reservoir gases H_2O_2, N_2O_5, HNO_3, HCl, HOCl, $ClONO_2$, HO_2NO_2, etc. formed in photochemical reactions, as well as the radicals H, OH, HO_2, $O(^3P)$, $O(^1D)$, NO, NO_2, Cl, ClO, etc. In the modelling of the minor constituents, all the gases are divided into families[3]. The oxygen family includes $O(^1D)$, $O(^3P)$, and O_3. The active odd hydrogen family comprises the H, OH, and HO_2 radical species. The OH and HO_2 radicals play a decisive role in establishing the gas composition of the stratosphere and especially the troposphere. Their concentration depends to a large extent on the content of hydrogen peroxide, which is the principal reservoir of the hydrogen family and supplies OH radicals by its photolysis. The odd nitrogen family $NO_x = NO + NO_2$ is closely related to the NO_y family, which incorporates the reservoir gases N_2O_5, HNO_3, $ClONO_2$, and HO_2NO_2, whose photolysis leads to the formation of NO_2. The calculated and experimental concentrations of many gas constituents have been published in monogrphs[3,4] and in a review[8]. The heterogeneous decomposition of long-lived components of the atmosphere, whose chemical reactions are slower than their vertical transport, must be taken into account for $\tau_{het} \lesssim 10\tau_D$, where $\tau_{het} = K_{het}^{-1}$ and $\tau_D = H^2/K$ are respectively the characteristic heterogeneous decomposition and vertical transport times. The height of the uniform atmosphere $H = 5-7$ km and the turbulent transport (eddy diffusion) coefficient $K \simeq (10^4-10^5)$ cm^2 s^{-1}. The contribution of heterogeneous decomposition is appreciable if

$$\gamma > \frac{0.4K}{cH^2A} \simeq \frac{(10^{-12}-10^{-13})}{A} \text{ cm}^{-1}. \quad (5)$$

A specific surface $A \simeq 10^{-7}-10^{-6}$ cm^{-1} is characteristic of the background troposphere near the Earth's surface and stratospheric clouds (see Fig. 1) and heterogeneous processes must therefore be taken into account if

$$\gamma_1 > 10^{-7}-10^{-5}. \quad (6)$$

Over highly polluted cities, A reaches $10^{-4}-10^{-5}$ cm^{-1} and heterogeneous reactions may prove to be significant already when

$$\gamma_2 > 10^{-9}-10^{-7}. \quad (7)$$

The long-lived components of the atmosphere include methane, N_2O, and fully substituted chlorofluorocarbons (Freons). Generally speaking, low values of γ such as $10^{-9}-10^{-7}$ may be entirely realistic characteristics of the catalytic oxidation of methane, for example, on the surfaces of the oxides Al_2O_3 and Fe_2O_3, or of the heterogeneous decomposition of N_2O. However, there is apparently no direct evidence for the occurrence of heterogeneous-catalytic reactions in the atmosphere.

It is more difficult to select a criterion of the need to include heterogeneous reactions when one is dealing with chemically reactive gases whose lifetime is shorter than the vertical or horizontal transport time. This applies primarily to radicals. For example, the rate of the heterogeneous destruction of the OH or HO_2 radicals must be compared with the rate of descent of these radicals and reservoir gases, in which they are "stored". In particular, the main radical destruction processes of the radicals of the hydrogen family, OH and HO_2, in the troposphere are the reaction $\dot{O}H + H_2O_2 \rightarrow H_2O$ and $H\dot{O}_2$ and the heterogeneous elution of hydrogen peroxide. Their overall rate at the surface of the Earth is $W \simeq 10^5$ cm^{-3} s^{-1} [8,20-22]. With increase in height, the rate of destruction falls.

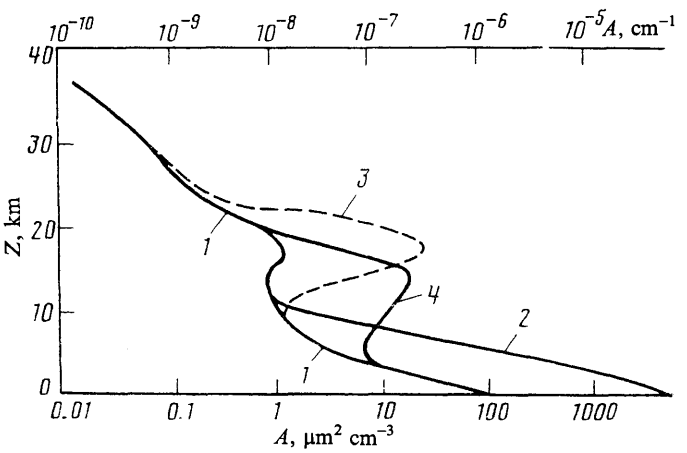

Figure 1. An approximate illustration of the distribution of the specific aerosol surface[19,20]: *1*, background atmosphere; *2*, urbanised regions; *3*, stratospheric volcanic clouds; *4*, polar stratospheric clouds.

The aerosol decomposition of OH or HO_2 must be taken into account when

$$W_A = K_{het}[R] > 0.1W \quad (8)$$

or

$$\gamma \geq \frac{0.4W}{c[R]}. \quad (9)$$

Here $[R]$ is the concentration of radicals. At the Earth's surface, [OH] $\simeq 10^6$ cm^{-3}, [HO_2] $\simeq 10^8$ cm^{-3} [8,22], and condition (9) assumes the form

$$\gamma_{OH} > \frac{10^{-6} \text{ cm}^{-1}}{A} \text{ and } \gamma_{HO_2} > \frac{10^{-8} \text{ cm}^{-1}}{A}. \quad (10)$$

Fig. 1 makes it possible to trace the range of values of γ for which it is necessary to take into account the heterogeneous destruction of OH and HO_2. Under background conditions, $\gamma_{OH} \simeq 0.3-1$ and $\gamma_{HO_2} \gtrsim 10^{-2}$. For polluted cities, the estimates are displaced by two orders of magnitude: $\gamma_{OH} \gtrsim 10^{-2}$ and $\gamma_{HO_2} \gtrsim 10^{-4}$.

Probable estimates for heterogeneous O_3, NO_x, and HO_x decomposition processes on aerosols, carried out in accordance with different models, have been published in a review.[8] In the

calculations based on the one-dimensional model, use was made of the average specific surface of the aerosol (20 μm^{-2} cm^{-3}), which does not vary along the height and corresponds to the particle content in the background atmosphere and also in the stratospheric volcanic and polar clouds. The hypothesis that the specific surface profile is constant as a function of height makes it possible to estimate the sensitivity of the atmosphere to the aerosol decomposition of various compounds in the troposphere and the stratosphere. Direct heterogeneous decomposition of ozone affects its content and the concentrations of other minor constituents (NO_x, HO_x) for $\gamma_{O_3} \gtrsim 10^{-4}$ and the process is most significant at a height of 18–20 km, i.e. at the height corresponding to the stratification of volcanic clouds. The direct decomposition of ozone leads to concomitant changes in the concentrations of other minor constitutents. In the stratosphere, where the homogeneous decomposition of O_3 is mainly caused by the reactions of the nitrogen cycle

$$\begin{aligned} NO + O_3 &\rightarrow NO_2 + O_2 \ , \\ \underline{NO_2 + O} &\underline{\rightarrow NO + O_2} \ , \\ O + O_3 &\rightarrow 2O_2 \ , \end{aligned}$$

the decrease in $[O_3]$ leads to an increase in the NO and NO_2 concentrations, while in the troposphere, where the destruction of ozone is associated with the reactions of the hydrogen cycle

$$\begin{aligned} OH + O_3 &\rightarrow HO_2 + O_2 \ , \\ \underline{HO_2 + O_3} &\underline{\rightarrow OH + 2O_2} \ , \\ 2O_3 &\rightarrow 3O_2 \ , \end{aligned}$$

the concentration of gases of the given family increases.

The critical value of γ_{NO_x}, beyond which the gas composition diminishes owing to the capture of NO and NO_2 by the aerosol surface, is 10^{-5}. However, for $\gamma_{NO_x} \simeq 10^{-5}$, large changes in concentration occur only in the upper stratosphere ($Z > 30$ km), where the specific surface of the aerosols apparently never reaches the value 20 μm^2 cm^{-3} adopted in the model under consideration. It is of interest that the presence of the stratospheric-tropospheric coupling leads to an increase in the amount of NO_x in the troposphere even if there is an additional heterogeneous NO_x sink. This is associated with the fact that the additional destruction of NO_x in the stratosphere induces a marked increase in the content of stratospheric ozone and a decrease in the intensity of the radiation penetrating the troposphere. This diminishes the rate of photodissociation of O_3 $[O_3 + h\nu \rightarrow O(^1D) + O_2]$ and the rate of the main OH radical formation reaction in the troposphere $O(^1D) + H_2O \rightarrow 2OH$. The decrease in the concentration of the tropospheric hydroxyls as a result of the heterogeneous destruction of NO_x in the stratosphere decreases the rate of removal of NO_x via the principal homogeneous reaction $\dot{O}H + NO_2 + M \rightarrow HNO_3 + M$. The contribution of this process, which exceeds the contribution of the direct heterogeneous destruction of NO_x in the troposphere, becomes increasingly significant with increase in γ_{NO_x}.

The critical values of γ_{OH} and γ_{HO_2} under the conditions near the Earth's surface were given above. For a uniform distribution of the aerosol with $A = 20$ μm^2 cm^{-3}, the contribution of the heterogeneous OH destruction to the change in the composition of the atmosphere should be higher than for the background distribution.

The influences of the heterogeneous destruction of the hydrogen family radicals OH and HO_2 on the content of tropospheric and stratospheric ozone are qualitatively different. In the troposphere, where O_3 is decomposed mainly in the hydrogen cycle, the additional decrease in the OH and HO_2 concentrations entails an increase in the ozone content, while in the stratosphere an increase in the NO_x concentration as a result of the diminution of the OH concentration (the rate of the reaction $\dot{O}H + NO_x + M \rightarrow HONO_x + M$ falls) leads to additional decomposition of O_3 in the nitrogen cycle. The results of modern calculations performed for $\gamma_{OH} = 0.1$ [8] have shown that a decrease in the OH concentration is accompanied by an increase in the NO_x content at all heights. On the other hand, the ozone concentrations in the troposphere and the stratosphere vary in different ways.

2. Laboratory studies on the heterogeneous decomposition of ozone and the $\dot{O}H$ and $H\dot{O}_2$ radicals

The first systematic studies on the heterogeneous interaction of the gases distributed in the atmosphere with substances whose compositions are close to those of the aerosols were carried out in 1979.[23] The interaction of the carbon particles and sulphuric acid drops characteristic of the polluted atmosphere of cities was considered. The reactions on the H_2SO_4 surface at 300 K were studied most thoroughly. For the majority of gases, including O_3, NO, NO_2, alkenes, alkanes, CF_4, CCl_2F_2, and atomic O and N, $\gamma < 10^{-6}$. The results of measurements for other gases, more reactive in relation to H_2SO_4, are presented below:

Molecule	H_2O	NH_3	H_2O_2	OH	HNO_3	N_2O_5	HO_2NO_2	$ClONO_2$
γ	$\sim 2\cdot10^{-3}$	$>10^{-3}$	$7.8\cdot10^{-4}$	$4.9\cdot10^{-4}$	>2 $4\cdot10^{-4}$	$3.8\cdot10^{-5}$	$2.7\cdot10^{-5}$	10^{-5}

The authors[23] reached the important conclusion that the tropospheric sulphuric acid aerosol can alter the gas composition of the atmosphere in polluted cities. However, a quantitative estimate was not made.

Numerous studies have been devoted to the heterogeneous decomposition of ozone. In this respect, the stratospheric aerosols are naturally of principal interest.

The interaction of ozone with various surfaces [ice, HNO_3, SiO_2, soot, NH_4NO_3, $(NH_4)_2SO_4$, NaCl, H_2SO_4] was studied in greater detail recently and fairly numerous measurements of the values of γ_{O_3} were made.[24] For the majority of materials investigated, $\gamma_{O_3} < 10^{-6}$ and, under the conditions of the stratosphere in the middle latitudes, including volcanic clouds, ozone is therefore only slightly subjected to heterogeneous decomposition. Values of γ greater than or approximately equal to 10^{-5} were obtained for the Al_2O_3 [25,26] and soot[24] surfaces. Such surfaces can influence the concentration of stratospheric ozone in certain extreme situations. For example, the scenario of a nuclear explosion in mines, whereupon large amounts of soil basalt can enter the atmosphere, has been considered.[27] When the amount of Al_2O_3 ejected reaches 17%, the column of ozone will diminish as a result of direct heterogeneous decomposition to the extent of 30–40%.

It follows from literature data[24,28,29] that the probability of the heterogeneous decomposition of O_3 on the liquid acid depends greatly on a series of factors difficult to take into account, such as the ratio of H_2SO_4 and H_2O, the presence of impurity Fe^{2+} ions,[29] and the duration of the action of O_3 on the surface. Nevertheless, in all cases the values of γ_{O_3} for H_2SO_4 do not exceed 10^{-6}.

The vigorous investigation of the heterogeneous destruction of $\dot{O}H$ and $H\dot{O}_2$ radicals has been promoted in recent years by the development of highly sensitive methods for their detection. The first study of the destruction of OH radicals on the surface of one of the tropospheric aerosols (carbon) was performed in 1975 [30]. The value

$\gamma_{OH} = 5 \times 10^{-2}$ obtained is sufficiently large for the heterogeneous destruction of OH to be taken into account in the modelling of the composition of the atmosphere in polluted cities. The heterogeneous destruction of $\dot{O}H$ [31,32] and $H\dot{O}_2$ [33–35] in the atmosphere was investigated. Table 1 shows that, in the case of typical atmospheric salt aerosols, γ_{OH} is fairly large, amounting to between 8.5×10^{-3} and 0.24 [31]. High values of γ_{OH} are also characeristic of silicon and metal oxides and especially of ice and sulphuric acid.[32] The value $\gamma_{OH} \simeq 1$ obtained for sulphuric acid[32] differs greatly from the value of 4.9×10^{-4} found in another study[23]. Although in both cases concentrated sulphuric acid was used, the surfaces themselves were apparently different. Gershenzon et al.[32] generated a liquid film on a quartz rod by immersing it in liquid sulphuric acid. Baldwin and Golden[23] poured concentrated sulphuric acid onto the bottom of a chamber directing a stream of radicals onto it. In contrast to the study of Baldwin and Golden[23], where the OH recombination products on the surface (most probably water) together with the unreacted OH radicals were directed to a mass spectrometer in which particles with an atomic weight of 17 were detected, Gershenzon et al.[32] used the direct EPR method for the detection of $\dot{O}H$ radicals. It will be shown below that information about the value of γ_{OH} for interaction with a volcanic sulphuric acid aerosol is of fundamental importance for the understanding of the effect of a decrease in ozone concentration after powerful volcanic eruptions.

Table 1. Probabilities of the heterogeneous destruction of $\dot{O}H$ radicals on aerosol-like surfaces.

Surface	γ	T, K	Refs	Surface	γ	T, K	Refs.
$Pb(NO_3)_2$	0.24 ± 0.12	300	[31]	NH_4NO_3	0.01 ± 0.002	300	[31]
NH_4Cl	0.13 ± 0.03	300	[31]	$(NH_4)_2SO_4$	$(8.5\pm1.7)\cdot10^{-3}$	300	[31]

Na_2SO_4	0.018 ± 0.01	300	[31]	SiO_2	$(5.6\pm2)\cdot10^{-3}$	250—350	[32]

Table 2. Probabilities of the heterogeneous destruction of $H\dot{O}_2$ radicals on aerosol-like surfaces.

Surface	SiO_2	NaCl	Ag oxide	Fe oxide	Ni oxide	H_2O
γ	$(1-8)\cdot10^{-3}$	$7.5\cdot10^{-3}$	$1.2\cdot10^{-2}$	$1.7\cdot10^{-2}$	$<10^{-3}$	0.2
Refs.	[33—35]	[34, 35]	[33]	[33]	[33]	[36]

For the vast majority of aerosol materials, the values of γ_{OH} are comparatively high and are in the range from 0.1 to 1, although $\gamma_{OH} \simeq 10^{-2}$ for a series of salts and SiO_2 (Table 1).

Although fairly numerous studies on the destruction of $H\dot{O}_2$ radicals on various surfaces have been carried out in recent years, aerosol surfaces have been investigated comparatively little. It follows from Table 2 that the values of $\gamma_{HO_2} \times 10^{-2}$ may be regarded as typical for tropospheric aerosols. It has been noted[33–35] that γ_{HO_2} depends on the presence of water vapour and hydrocarbons in the gas. However, the main factor determining the value of γ_{HO_2} is nevertheless the material of the surface. The temperature dependence of γ_{HO_2} is as a rule negative[34].

The probability of the mass accommodation of HO_2 on finely dispersed water drops saturated with $LiNO_3$ or NH_4HSO_4 has been measured[36]. The apparatus made it possible to model the behaviour of HO_2 in cloud formations, although the size of the aerosol drops in the experiment (0.05—0.1 μm) was appreciably smaller than the size of the cloud drops. The value $\gamma_{HO_2} = 0.2$ obtained is fairly high, which can influence appreciably our ideas about both the composition of the gas in clouds and mist and about the oxidation processes occurring in the water drops (see Section IV).

There is as yet insufficient information about the heterogeneous OH and HO_2 destruction processes. In particular, it is essential to measure γ_{HO_2} for ice, sulphuric acid, and salts of nitric and sulphuric acids [NH_4NO_3, $(NH_4)_2SO_4$, etc.]. Nevertheless, as suggested in a study by one of the authors[37], it is possible to adopt on the basis of the data in Tables 1 and 2 the typical values $\gamma_{OH} \simeq 0.1-1$ and $\gamma_{HO_2} \simeq 10^{-2}$ for all tropospheric aerosols.

3. The influence of heterogeneous processes on the gas composition of the troposphere and on the tropospheric-stratospheric coupling

In the modern molecular models of the atmosphere, account is taken as a rule of only two heterogeneous processes occurring in the troposphere and on the surface of the Earth. The first is associated with the elution of soluble gases or gases reacting with water ("moist elution") and the second involves the precipitation and decomposition of molecules on a supporting surface ("dry deposition").

(a) Dry deposition, moist elution, and the scattering of sunlight by the cloud cover. Dry deposition occurs when gases are adsorbed on the surfaces of the oceans and dry land, after which the adsorbed gases decompose. The destruction of gases at the boundary of the atmosphere as a result of heterogeneous reactions leads to the appearance of a diffusional flux towards the surface. In the chemistry of the atmosphere, this phenomenon is regarded as the deposition of the entire column of gas at a rate V_{de}. The characteristic rate of deposition of O_3 is 0.02 cm s^{-1} on the snow cover and 0.6 cm s^{-1} on soil[8]. In the solution of the problem of the transfer of the SO_2 impurity, the value $V_{de}^{SO_2} = 0.8$ cm s^{-1} was used[38]. The characteristic time of the vertical deposition of the column of gases

$$\tau_{de} = H/V_{de}' \simeq 10^6 - 10^7 \text{ s}$$

is comparable to the time of the turbulent transport in a homogeneous atmosphere to a height $H = 5-7$ km. Model calculations for the summer and winter deposition of ozone[8] have shown that, with decrease in V_{de} by a factor of 30 (from 0.6 to 0.2 cm s^{-1}), the concentration of O_3 at the surface of the Earth increases during the winter by a factor of approximately two. On the

other hand, at a height of 3–5 km the gas composition of the atmosphere virtually no longer depends on the rate of deposition of O_3.

The moist elution of gases readily soluble in water (with a Henry constant greater than 10^3 mol litre^{-1} atm^{-1}) is usually regarded as a first-order process. The distribution of the rate constants for this process with respect to height is consistent with the results of measurements of the content of the minor constitutents carried out in nature. The rate constants for the elution of many gases with different solubilities (H_2O_2, CH_2O, CH_3OOH, HNO_3, etc.) are believed to be the same. This is apparently a fairly rough approximation. According to Logan[22], the elution constants at different heights are

$$K_z = 2.3 \times 10^{-6} \exp[1.6 - 0.4Z]\ \text{s}^{-1} \text{ for } Z < 4 \text{ km},$$

$$K_z = 2.3 \times 10^{-6}\ \text{s}^{-1} \text{ for } Z > 4 \text{ km}. \quad (11)$$

The H_2O_2 moist elution process is decisive in the balance within the hydrogen family in the troposphere. As already pointed out, the loss of this family occurs principally as a result of the elution of hydrogen peroxide[8]. The results of model calculations[39] of the dependence of the concentrations of the minor constituents on the elution constant have been analysed in a review[8]. Variation of K_Z in the range from 10^{-6} to 10^{-5} alters the calculated values of $[HNO_3]$, $[NO_x]$, and $[HO_x]$ by tens and hundreds per cent. The concentrations of the OH and HO_2 radicals undergo a particularly marked change. Thus, with increase in K_Z from 1.15×10^{-6} to 5×10^{-6} s^{-1}, the concentration of radicals at different heights falls by a factor of 1.5–2. Together with the heterogeneous-chemical factors examined above, the gas composition of the troposphere is also affected by the scattering of the solar radiation by cloud drops.

Radicals of the hydrogen family are generated in the troposphere mainly as a result of the reaction $O(^1D) + H_2O \rightarrow 2OH$ and the photolysis of formaldehyde $H_2CO + h\nu \rightarrow H + HCO$. The $O(^1D)$ atoms in the troposphere also appear as a result of photolysis: $O_3 + h\nu \rightarrow O(^1D) + O_2$. The rate of generation of HO_x radicals in the lower troposphere therefore depends markedly on the cloud cover, which scatters solar radiation.

(b) The influence of the heterogeneous destruction of the OH and HO_2 radicals on aerosols on the concentration of tropospheric hydroxyl radicals and other minor constituents of the atmosphere. Under background conditions, one cannot expect appreciable variations in the concentration of hydroxyl radicals as a result of the heterogeneous destruction of OH or HO_2. The destruction of OH and HO_2 radicals on aerosols becomes the main cause of the loss of gases of the hydrogen family in urbanised regions, while the specific aerosol surface increases by more than two orders of magnitude compared with the background value. The gas composition of air over polluted cities has been modelled[38]. The results of one of the calculations of the deviations of the height profiles of the O_3, CO, NO_x, $\dot{O}H$, $H\dot{O}_2$, and H_2O_2 concentrations are presented in Fig. 2. The calculations were performed for $\gamma_{OH} = 1$ and the height profile of the distribution of the aerosol concentration was specified by Eqn. (1), where $N_0 = 10^4$ cm^{-3} and $Z_0 = 1$ km. The average radius of the aerosol particles was assumed to be 0.1 μm. According to theoretical calculations[40] and experimental measurements,[32] the diffusion coefficient of the OH radicals is

$$D_{OH} = \frac{1.41 \cdot 10^{-2} T^{1.72}}{p}\ \text{cm}^2\ \text{s}^{-1}, \quad (12)$$

the pressure p being expressed in mmHg.

Fig. 2 illustrates the percentage deviations of the concentrations of various substituents according to the aerosol model from the concentrations calculated in accordance with the molecular model:

$$\alpha = \frac{[n]_A - [n]_M}{[n]_M}. \quad (13)$$

Fig. 2 shows that the gas composition of the atmosphere in the presence of the aerosol is appreciably modified: the calculated content of the NO_x, CO, and O_3 gases, which are harmful to animals and plants, increases. Furthermore, the content of hydroxyl and perhydroxyl radicals falls by a factor of approximately 4–5. The effect becomes even greater if account is taken of the heterogeneous destruction of HO_2 radicals. For $\gamma_{HO_2} \simeq 10^{-2}$, the concentration of OH radicals near the Earth's surface by a factor of approximately five and that of HO_2 diminishes by a factor greater than 10.

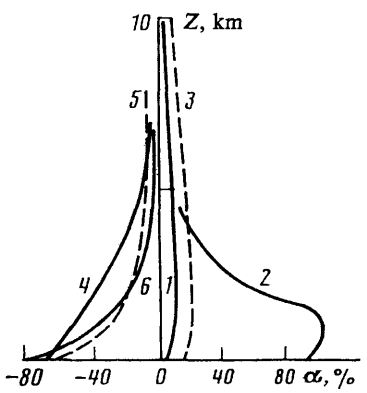

Figure 2. The height profiles of the deviations of the concentration of minor constituents in urbanised regions[38]: *1*, O_3; *2*, NO_2; *3*, CO; *4*, H_2O_2; *5*, $\dot{O}H$; *6*, $H\dot{O}_2$.

(c) The influence of tropospheric heterogeneous processes on the concentration of stratospheric ozone and the oxidation of Freons. OH radicals are known to be the "cleaners" of the atmosphere, ensuring the oxidation of the impurities arriving from the Earth. The self-cleaning of the atmosphere takes place mainly in the lower part of the troposphere, because the temperature and hence the rate of the reactions of OH with impurities decrease with increase in height. We saw above that a number of heterogeneous processes affect the concentration of OH radicals: (1) the scattering of radiation by the cloud cover; (2) dry deposition of O_3; (3) moist elution of H_2O_2; (4) heterogeneous destruction of OH and HO_2 radicals on aerosols. Incomplete allowance for these factors leads to considerable uncertainty in the determination of the concentration of OH radicals. We shall consider in that way this can affect predictions concerning the ozone layer of the atmosphere. The

desruptive effect of Freons is associated with the fact that they do not react with the tropospheric radicals but penetrate freely into the stratosphere. The photodissociation of Freons in the stratosphere leads to the formation of Cl and the decomposition of O_3 in the chlorine cycle:

$$\begin{aligned} &Cl + O_3 \rightarrow ClO + O_2 \ , \\ &\underline{ClO + O \rightarrow Cl + O_2 \ ,} \\ &O + O_3 \rightarrow 2O_2 \ , \end{aligned}$$

The increase in the rate of destruction of the ozone layer associated with the growing manufacture of chlorofluorocarbons, predicted at the present time, can be arrested if an alternative to the Freons can be found[41]. The manufacture of fully halogenated Freons has been prohibited by the Montreal Protocol. It has been recommended that eight chlorofluorohydrocarbons, the simplest of which is Freon-22 (CF_2HCl), be used as an alternative[42]. It is believed that Freon-22 is much less dangerous to the ozone layer than Freons such as $CFCl_3$ and CF_2Cl_2, because it reacts comparatively rapidly with OH radicals, i.e.

$$CF_2HCl + OH \rightarrow CF_2Cl + H_2O,$$

the rate constant being $k = 1.2 \times 10^{-12} \exp -(1100 \pm 150)/T \text{ cm}^3 \text{ s}^{-1}$, and penetrates the stratosphere to a much lesser extent. Thus through the interaction of the OH radicals with the alternative Freons, a tropospheric-stratospheric coupling is established between the chlorine family of anthropogenic origin and the ozone layer. Freons exert the principal destructive influence at a height of ~40 km where the rate of their photodissociation becomes appreciable.

The influence of heterogeneous tropospheric factors on the stratospheric ozone was estimated by the present authors together with Zvenigorodskii and Smyshlyaev. In particular, the following scenario was examined.

Suppose that the release of all the Freons is modelled by the release of Freon CF_2HCl in an amount of one million tonnes per year. In this case, a steady state would be established after approximately eighty years in which the O_3 content at a height of 38 km would diminish by 8% relative to the Freon-free atmosphere. By varying the rate constants for elution and the scattering of radiation by the cloud cover within reasonable limits and by postulating the heterogeneous destruction of OH and HO_2 radicals on the tropospheric background aerosol, it is easy to obtain a two–three-fold diminution of the concentration of tropospheric hydroxyls. This would lead in its turn to an additional decrease in the ozone concentration at a height of about 40 km by 10%, so that the overall fall in the content of O_3 at these heights would be by 18%. The total degradation of the ozone column after 80 years would be 3% under these conditions. Thus heterogeneous processes controlling the content of $\dot{O}H$ radicals determine also the ozone content in the upper stratosphere. The aerosol contaminants of the troposphere, leading to a decrease in its $\dot{O}H$ content and to an impairment of the purity of the troposphere, promote under these conditions the entry of the alternative Freons into the ozonosphere and an increase in the risk of the decomposition of the ozone layer.

The principal products of the oxidation of the majority of alternative Freons are compounds of the phosgene series[42]; in particular, in the case of CF_2HCl the product is CF_2O. The higher the concentration of tropospheric hydroxyls, the smaller the amount of Freons penetrating the stratosphere. However, vigorous oxidation of Freon occurs closer to the Earth's surface the lower the content of aerosols. The intensification of the reactions of $\dot{O}H$ with Freon leads to the accumulation of toxic compounds (phosgenes) in the lower part of the atmosphere. Thus by ejecting alternative Freons into the atmosphere, we can be faced by the extremely sad prospect of the replacement of the ozone problem by the phosgene problem. Such trade-off between the ecological and toxicological problems is merely a hypothetical variant. It may be that the decomposition of phosgenes in water drops, i.e.

$$CF_2O + (H_2O)_{ж} \rightarrow CO_2 + 2HF$$

will eliminate the toxicological risk of the alternative Freons. All this requires more complete quantitative tests.

4. Heterogeneous reactions in polar stratospheric clouds and Antarctic spring ozone holes

The sensational phenomenon of the sharp decrease in the concentration of ozone in the Antarctic during the spring, observed comparatively recently[43], has been adequately discussed in the scientific literature and in the publications for general consumption (see, for example, Karol'[20]). A central place has been assigned to this problem in the annual international reviews of the state of the ozone layer, including the latest collection.[44] We shall concentrate attention on the heterogeneous processes which are believed to occur in the establishment of the precritical spring situation and possibly also during the development of the ozone "hole". Without going into the details of the dynamics of the development and of the scale of the Antarctic ozone holes, we shall only emphasise that, according to the observations at the Halley Bay station (76° S, 27° W), the spring decrease in the ozone content in the Antarctic during the period from 1957 to 1985[43] did not begin until 1979. From 1979 until 1985, the overall ozone content in October fell from 300 to 200 Dobson units (1000 Dobson units correspond to a 1 cm thickness of the ozone layer at atmospheric pressure). Evidently the primary cause of this phenomenon is the anthropogenic release of Freons.[19]

It is believed at the present time that during the winter, when the stratosphere cools down and particles condense in polar stratospheric clouds (PSC), chemical processes leading to the removal of nitrogen oxides from the gas phase and the generation of molecules of the chlorine reservoir take place. These photochemically active chlorine components do not react during the winter with the PSC particles or with ozone in the gas phase or on the surface. During sunrise in the spring period, the reservoir chlorine molecules undergo photodissociation and are converted into a radical form which initiates the chain decomposition of ozone. This multistage concept is hardly complete in our view. We suggest that heterogeneous reactions can be also a direct and not merely an indirect cause of the decomposition of the Antarctic ozone. During the initial period of the polar night, after sunset there is a fairly rapid recombination of the active atmospheric components ($\dot{O}H$, ClO, and $\dot{H}O_2$) as well as the nitrogen oxides NO_x, which are converted into the reservoir gases H_2O, HCl, H_2O_5, HNO_3, H_2SO_4, and $ClONO_2$. The subsequent fate of the reservoir gases has been investigated in experiments under natural and laboratory conditions. In particular, it has been established that the coefficient of adhesion of the molecules of the acids HCl and HNO_3 to the surface of ice is close to unity[45,46] and that the composition of the PSC condensate is close to that of the nitric acid trihydrate[10] or contains 0.02–0.35 mol of HCl per mole of water[46] at temperatures below 195 K. Laboratory studies confirmed the conclusions reached from observations under

natural conditions that gas denitrification and dehydration reactions take place during winter (Scheme 1):

Scheme 1

(1) $N_2O_5 + (H_2O)_S \rightarrow 2(HNO_3)_S$,

(2) $N_2O_5 + (HCl/H_2O)_S \rightarrow (ClNO_2)_G + (HNO_3)_S$,

(3) $ClONO_2 + (H_2O)_S - (HOCl)_G + (HNO_3)_S$,

(4) $ClONO_2 + (HCl/H_2O)_S \rightarrow (Cl_2)_G + (HNO_3)_S$.

The subscripts G and S denote the gas and condensed phases respectively. In reactions (2)–(4) (Scheme 1), the chlorine component is converted into a new form, affording the readily photolysed reservoir gases Cl_2, HOCl, and $ClNO_2$ (or ClONO). They in fact ensure the development of the dramatic spring situation.

The values $\gamma_{O_3} \approx 10^{-6}$ attained under laboratory conditions in the study of the decomposition of ozone on ice and nitric acid particles[24] indicate the possibility, in principle, of the direct breakdown of O_3 during the long polar night.

Table 3. Heterophase reactions occuring under the conditions of the polar Antarctic night.

(4)	$[HCl]/[H_2O] = 0.015 \div 0.04$; 195 K	0.27	[45]
	$[HCl]/[H_2O] = 0.003 \div 0.01$; 200 K	$0.05 \div 0.1$	[50]

Measurements[24] are not inconsistent with estimates[47] according to which γ_{O_3}, γ_{NO}, and $\gamma_{NO_2} < 10^{-4}$ for ice. The results of studies on reactions (1)–(4) under conditions close to those during the Antarctic polar night (180–200 K) are presented in Table 3. It is seen that in all cases these low-temperature reactions proceed extremely effectively. Thus their characteristic time in polar stratospheric clouds does not exceed 24 h. The condensation of nitric acid has been reliably demonstrated in all four reactions. On the other hand, the gas-phase products and the possible routes to their further conversion have been less thoroughly investigated. In experiments[47,48] carried out using mass-spectrometric analysis, the products ClONO and $ClNO_2$ proved to be indistinguishable. Furthermore, one cannot rule out the possibility of their subsequent heterogeneous reactions.[45] It has been shown that HOCl is the gas-phase product of reaction (3). However, this is apparently merely an unstable intermediate, which reacts with ice, at least in the presence of $ClONO_2$, with formation of Cl_2O [50].

Although the measured rates of reaction (3) differ from one another by a factor of 6, they are nevertheless fairly high, so that this is not the reaction which limits the heterogeneous reaction of $ClONO_2$ in wintertime. The composition of products of reactions (2) and (3) (Scheme 1) and their behaviour in the presence of PSC require further refinement.

The heterogeneous reactions (1)–(4) in Scheme 1 lead to the capture of gas-phase nitrogen oxides and the formation of photochemically active gaseous Cl_2, HOCl, Cl_2O, and $ClNO_2$ molecules. It is at present difficult to say which of these makes the greatest contribution to the photolytic generation of Cl atoms at sunrise. However, the very fact of the high chlorine content in the radical form has been demonstrated by direct measurements of the concentration of ClO radicals[51,52,58], which at the beginning of the spring (September) at a height of about 20 km exceeds by a factor of 100 their concentration in the middle latitudes. Already in October, when the polar clouds break up and O_3 degradation processes cease, the Cl content in the Antarctic does not differ appreciably from its content in the middle latitudes. Apparently the main O_3 decomposition cycle is determined, as suggested by Molina and Milina[53] by the reactions

$$\begin{aligned} ClO + ClO + M &\rightarrow Cl_2O_2 + M \quad , \\ Cl_2O_2 + h\nu &\rightarrow Cl + ClO_2 \quad , \\ ClO_2 + M &\rightarrow Cl + O_2 + M \quad , \\ 2(Cl + O_3) &\rightarrow 2(ClO + O_2) \quad , \\ \hline 2O_3 + h\nu &\rightarrow 3O_2 \quad . \end{aligned}$$

The first, termolecular reaction which has been invetigated[54,55] limits the decomposition of O_3. Knowing the concentration ClO and the rate constant for this reaction, it is possible to calculate the rate of degradation of ozone, which proves to be close to the experimentally measured value. If the formation of Cl_2O_2 is indeed the rate-determining stage of the spring decomposition of O_3, then, by virtue of its non-linearity in relation to the chlorine content, its rate should change sharply with increase in the amount of Freons released into the atmosphere. This picture has in fact been observed since 1979 [43]. The recombination of ClO radicals can become dominant only in the presence of a low NO_2 content, but the rate of their reaction $ClO + NO_2 + M \rightarrow ClONO_2 + M$ is low. During the winter, the reservoir nitrogen oxide gases are converted into condensed nitric acid as a result of the occurrence of the heterogeneous reactions (1)–(4) (Scheme 1). Nitrogen oxides can therefore appear only after the evaporation of the PSC, which begins in October. The low NO_2 content in the winter and spring Antarctic atmospheres has been confirmed by many observations[55]. Apart from the purely chlorine-based zone decomposition cycle, a further two synergistic cycles with participation of BrO [56] or OH and HO_2 [57] radicals have been proposed. In the synergistic cycle

$$\begin{aligned} ClO + BrO &\rightarrow Cl + Br + O_2 \quad , \\ Cl + O_3 &\rightarrow ClO + O_2 \quad , \\ Br + O_3 &\rightarrow BrO + O_2 \quad , \\ \hline 2O_3 &\rightarrow 3O_2 \quad , \end{aligned}$$

note more than 10% of ozone relative to the purely chlorine-based cycle can decompose, since the BrO concentration is low compared

with that of ClO.[58] The hydrogen chloride cycle[57]

$$\begin{aligned} HOCl + h\nu &\rightarrow OH + Cl \quad , \\ Cl + O_3 &\rightarrow ClO + O_2 \quad , \\ OH + O_3 &\rightarrow HO_2 + O_2 \quad , \\ ClO + HO_2 &\rightarrow HOCl + O_2 \quad , \\ \hline 2O_3 &\xrightarrow{h\nu} 3O_2 \quad , \end{aligned}$$

is apparently relatively ineffective owing to the high probability of the destruction of OH radicals on the ice particles.[32] Thus the chlorine-based O_3 decomposition cycle with participation of the Cl_2O_2 dimer is apparently most effective.

After this review had been written, one of the authors received the manuscripts of papers[58,59] prepared for publication, which were sent by Prof. Brune. Brune and co-workers[59] carried out a detailed analysis of the contributions of various Antarctic ozone decomposition cycles on the basis of simultaneous measurements of the absolute concentrations of ClO, BrO, and O_3 carried out with an aeroplane in 1987 [58]. The latest data for the rate constants for the rate-limiting stages of the above homogeneous cycles (the ClO + ClO + M and ClO + BrO reactions[60]) and measurements under natural conditions[58] permitted the conclusion that the main contribution to the spring decomposition of ozone comes from the chlorine cycle and the chlorine-bromine cross cycle. In order to refine the contribution of the hydrogen chloride cycle, it is necessary to have direct measurements of the concentration of OH (or HO_2). According to estimates,[53] it is not more than 4%. The contribution of the first two cycles to the observed rate of the spring decomposition of O_3 can reach 40 and 20% respectively. In order to abolish the underestimate in the calculated rate, yet another catalytic cycle has been proposed:[59]

$$\begin{aligned} &ClO + O_3 + M \rightarrow ClO.O_3 + M (k = 2 \times 10^{-35} \text{ cm}^6 \text{ s}^{-1} \text{ at 200 K}), \\ &ClO \cdot O_3 + h\nu \rightarrow ClO_2 + O_2 \quad , \\ &ClO_2 + M \rightarrow Cl + O_2 + M \quad , \\ &Cl + O_3 \rightarrow ClO + O_2 \quad , \\ \hline &2O_3 + h\nu \rightarrow 3O_2 \quad . \end{aligned}$$

Having included in the consideration also this sequence of reactions with the rate constant for the formation of complex $ClO.O_3$ indicated, it is possible to reconcile completely the experimentally observed kinetic relations for the spring decomposition of O_3 with the diurnal concentration of the ClO and BrO radicals. However, we believe that there is no need to introduce into consideration an exotic species such as the complex $ClO.O_3$. In order to account for the underestimate of the rate of the spring decomposition of ozone, one can examine the additional heterogeneous-homogeneous photolytic cycle

$$\begin{aligned} &ClO + PSC \rightarrow \tfrac{1}{2}(Cl_2 + O_2), \\ &Cl_2 + h\nu \rightarrow 2Cl \quad , \\ &2(Cl + O_3) \rightarrow 2(ClO + O_2) \quad , \\ \hline &2O_3 + PSC + h\nu \rightarrow 3O_2. \end{aligned}$$

The possibility of the existence of this hypothetical cycle has been confirmed by preliminary measurements of the probability of the destruction of ClO on the surface of ice ($\gamma_{ClO} \simeq 10^{-2}$).[47] A simple estimate showed that, when [ClO] = 2×10^9 cm^{-3}, the rate of decomposition of O_3 in the heterogeneous cycle can be close to the rate of its degradation in the homogeneous chlorine cycle. More detailed studies on the heterogeneous interaction of ClO radicals with the surface of ice are apparently necessary.

Yet another important heterogeneous reaction in the Antarctic spring may prove to be the process

$$ClO + (O_3)_{ads} \rightarrow OClO + O_2,$$

where $(O_3)_{ads}$ is the ozone molecule adsorbed on the PSC surface. This reaction can account for the variation of the ClO concentration over a period of 24 h. It is known that during the night ClO is almost fully converted into OClO. However, this does not lead to a change in $[O_3]$ because ozone molecules are regenerated during the day by the reactions:

$$\begin{aligned} &OClO + h\nu \rightarrow O + ClO, \\ &O + O_2 + M \rightarrow O_3 + M. \end{aligned}$$

The heterogeneous catalytic reactions

$$ClO + (H_2O)_s \rightarrow \tfrac{1}{2}(Cl_2 + O_2) + (H_2O)_s,$$

and

$$ClO + (O_3).(H_2O)_s \rightarrow OClO + O_2 + (H_2O)_s,$$

proposed here can undoubtedly play a definite part in the chemical reactions occurring in the spring in the Antarctic. As regards the winter preparatory period, here too the heterogeneous reactions of the ClO precursor gases (HOCl, Cl_2O, $ClNO_2$, and ClONO) with solid PSC particles can be important. Apart from the study of these heterogeneous reactions, it is also essential to carry out measurements of the HOCl, Cl_2O, $ClNO_2$, and ClONO concentrations under natural conditions. We should like to point out also the possible influence of the direct decomposition of O_3 on PSC particles on the dynamics of the formation of the ozone hole in the Antarctic spring. A model of this process includes the change in the vertical air circulation in springtime, when the warm air of the troposphere, depleted in ozone, rises to the stratosphere, diminishing thereby the ozone concentration in the lower stratosphere. Measurements[24] indicate the possible decomposition of O_3 (within the limits of 10%) on PSC particles during the long polar night. This can afford additional support to the dynamic model, because during the winter the circulation of air is directed downwards and one cannot rule out the possibility that towards spring the troposphere is more depleted in ozone than in the absence of the direct decomposition of stratospheric ozone.

5. The influence of volcanic eruptions on the ozone content of the stratosphere

Powerful volcanic eruptions, which include a series of eruptions of the Mexcian El Chichon volcano (17° N latitute) at the beginning of April 1982 have exerted a large-scale influence on the stratosphere. Thus the aerosol cloud formed after the eruption of El Chichon extended from the equator to 50° N latitude, whilst the duration of its development and relaxation exceeded one year (Fig. 3). The scale of the eruption can be imagined from the amount of SO_2 ejected (3.3 million tonnes). The photochemistry of the stratosphere can be influenced greatly also by the ejection of HCl and water vapour. The components of the ejected material are apparently initially concentrated at a height of 25–35 km. However, after a time, as a result of photochemical oxidation mainly in the Junge layer, sulphuric acid aerosols containing 75% H_2SO_4 and 25% H_2O accumulate. Fig. 3 shows a distinct negative correlation between the content of the aerosol component and the amount of ozone, which has been the subject of controversy since the instant of its

observation during the winter of 1982–1983. Without being able to consider at length problems of the formation of volcanic clouds and the modelling of the effects of a volcanic eruption on the thermal and radiation conditions in the stratosphere, we shall merely point out that, according to estimates[21,61,62], the observed decrease in the concentration of ozone cannot be accounted solely by the change in temperature and in the solar radiation fluxes. The O_3 content begins to decrease not sooner than half a year after the eruption and is correlated with the formation of secondary sulphuric aerosols in the Junge layer.

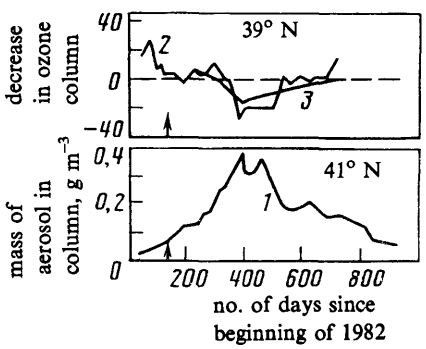

Figure 3. Variation of the contents of aerosols and ozone in the course of the evolution of the eruption cloud; *1*, aerosol; *2*, observed decrease in the amount of ozone of Dobson units (according to the data of Tolbert et al.[63]); *3*, calculated decrease in the amount of ozone for $\gamma_{OH} = 1$ (according to Anderson et al.[59]); the instant of the eruption of the El Chichon volcano is indicated by an arrow.

Two alternative models explaining the decrease in the amount of O_3 by the occurrence of heterogeneous reactions have been put forward recently. According to the first hypothesis[8,61,62], the decrease in the O_3 content in the cloud is caused by the heterogeneous destruction of OH radicals on the aerosol particles. The decrease in [OH] leads to an increase in [NO] and in the contribution of the nitrogen cycle (see above). The results of numerical modelling[59], based on the value $\gamma_{OH} = 1$, adopted on the basis of the measurements of γ_{OH} for ice and sulphuric acid[32] are presented in Fig. 3. Evidently the proposed hypothesis makes it possible to describe quantitatively the sharp diminution in the concentration of ozone in the volcanic cloud.

The second hypothesis is based on the measurements of the probabilities of the capture of HCl, $ClONO_2$ [63] and N_2O_5 [64] by the sulphuric acid solution and the temperature of the stratospheric volcanic clouds in wintertime (−65 °C). It follows from Table 4 that N_2O_5 is captured particularly effectively. On the hypothesis that nitric acid, evolved into the gas phase, is the product of the reaction of N_2O_5 with the H_2SO_4/H_2O surface and that the heterogeneous interaction of HCl and $ClONO_2$ leads to the generation of active chlorine, it has been possible to demonstrate[21] a decrease in the O_3 content in volcanic clouds after the eruption of the El Chichon volcano. Aerosols apparently exert an extremely varied influence. On the one hand, they convert N_2O_5 and nitrogen oxide into nitric acid, reducing the strength of the nitrogen-based O_3 decomposition cycle. On the other hand, their reactions with HCl and $ClONO_2$ generate chlorine, which initiates the operation of the chlorine-based ozone decomposition cycle:

$$\begin{array}{l} Cl + O_3 \rightarrow ClO + O_2 \quad , \\ \underline{O + ClO \rightarrow Cl + O_2 \quad ,} \\ O + O_3 \rightarrow 2O_2 \quad . \end{array}$$

Under the usual conditions, the effectiveness of this cycle in the lower stratosphere is low.

Table 4. Probabilities of the capture of HCl, N_2O_5, and $ClONO_2$ by the sulphuric acid surface at −65 °C.

γ	H_2SO_4, %			Refs.
	65	70	75	
γ_{HCl}	$1.5 \cdot 10^{-3}$	$2.5 \cdot 10^{-4}$	$8 \cdot 10^{-5}$	[63]
γ_{ClONO_2}	—	$2.5 \cdot 10^{-3}$	$2 \cdot 10^{-4}$	[63]
$\gamma_{N_2O_5}$	—	—	0.06	[64]

The second model of the heterogeneous decomposition of ozone in volcanic clouds is significantly more complex than the first, associated with the heterogeneous destruction of OH radicals. It contains more non-monitored parameters.

IV. Chemical processes in cloud drops

1. General characteristics of the aqueous component of the troposphere

In the set of objects and phenomena in the heterogeneous chemistry of the atmosphere, the chemistry of the processes in the liquid drop phase—in clouds, rain drops, mists, and smoke—is an important component which has been studied inadequately. Certain physical and physicochemical characteristics of these heterogeneous components of the troposphere are listed in Table 5.

On average, 54% of the Earth's firmanent is covered by clouds,[68] the thickness of the cloud layer amounting to tens and thousands of metres. Thus an appreciable proportion of the troposphere is constantly filled with clouds having a high moisture content. The air also moves constantly through the cloud layer at a velocity ranging from 0.1 to 10 m s^{-1} [69]. This flow of gases leads to a constant renewal of the gaseous environment of the cloud drops and hence to a virtual constancy of the gas composition outside and within the cloud layer. For these reasons, attention will be concentrated below on the cloud drops and the rain drops "associated" with them. The characteristic lifetime of the drops (from minutes for rain drops to a period of the order of 1 h for cloud drops) should be included among their main properties[70].

The dynamics of the formation and growth of cloud drops has been examined from different standpoints, with and without allowance for the dissolution in the drops of gaseous substances,

with variation of the size distribution for the condensation centres-nuclei, etc. These questions have been discussed fairly widely by Hill[71] and in the Proceedings of the Leningrad Conference on "Models of the Contamination of the Atmosphere and Their Employment" (1986). In the first seconds of drop formation, their size distribution ranging from 1 to 5 μm is characterised by a descending curve. In the 300th second of the life of the drops, a fairly narrow size distribution is attained with the most probable diameter $d \simeq 8$ μm. The average size of the cloud drops listed in Table 5 is a result of the averaging of the size distribution during the lifetime of the drop, which varies as a function of time.

Table 5. Physicochemical characteristics of the liquid drop constituents of atmospheric moisture.

Medium	Drop radius, μm	Moisture content, g m^{-3}	pH	Ionic strength	Refs.
Smoke	0.3—3	10^{-5}—10^{-4}	1—8	1	[65]
Mist	10	0.02—0.2	2—6	10^{-3}—10^{-2}	[66]
Cloud	10	0.1—3	3—6	10^{-3}—10^{-2}	[67]
Rain	200—2000	0.1—1	4—5	10^{-4}	[67]

An interesting effect of the growth of the drops with increase in their sulphuric acid content, first observed by Foster[72], has been thoroughly analysed[73]. On the whole, the physical picture of the formation and evolution of cloud drops has been studied in greater detail than the chemical processes in them.

Under natural conditions, chemical reactions take place in an open heterogeneous gas—liquid system; on the other hand, in the majority of laboratory studies, the reaction is investigated in solutions in the absence of transfer of substances from one phase to another.

The chemical process in cloud drops is accompanied by a change in the pH of the medium by 1—3 units and the corresponding change in the concentrations of the substances (including catalysts) in the ionised form; on the other hand, under laboratory conditions, one endeavours to discover the dependence of the rate of reactions on a particular parameter while keeping the remaining parameters constant.

The characteristic concentrations of stable substances in cloud drops (10^{-10}—10^{-5} M) are much lower than in the usual laboratory studies (10^{-4}—10^{-2} M). For such a large difference between the concentrations parameters, the extrapolation of the kinetic relations to the region of low concentrations is riddled with errors whose scale is difficult or impossible to estimate.

2. Kinetic analysis of processes leading to the formation of sulphate ions in cloud drops

The origin of the chemistry of clouds can be traced back to 1852 when Smith detected sulphate ions in the rain water of Manchester[74]. Subsequently ammonium ions and nitric acid were found in rain[75]. These are in fact the three main components of rain water whose concentration reaches 10^{-3} M for NH_4^+ and SO_4^{2-} and 10^{-4} M for NO_3^- in acid rain drops.

As industry developed and the analytical methods became more sensitive in the twentieth century, increasingly concentrations of the iron, manganese, lead, arsenic, mercury, etc. impurities began to be detected in rain deposits and in the snow cover. However, chemico-atmospheric studies during the last decade have shown that most of these substances are absent from cloud drops and are entrained by rain drops or are deposited on the snow cover from the layers of the troposphere near the earth. On the other hand, direct measurements have established the presence in cloud drops of iron (10^{-7}—10^{-4}) and manganese (10^{-8}—10^{-5} M) ions[76]. The anthropogenic origin of these ions is indicated by the approximately fivefold difference beween the contents of transition metal (predominantly iron) compounds in air over cities and over regions remote from cities. Hydrogen peroxide[77,78], formaldehyde, formic acid[79], methanesulphonic acid[80], and other substances have been detected in rain and cloud drops at variable concentrations, their amount being usually an order of magnitude smaller than that of sulphate, ammonium, and nitrate ions.

Analysis of the composition of rain drops does not require special aerological equipment. However, rain drop data are not particularly suitable as a quantitative characteristic of the composition of cloud drops. Despite the short time of their flight through the lower layers of the troposphere, they succeed in absorbing various gaseous substances and dust particles. Other processes also take place, as a result of which rain drops and cloud drops differ not only in composition but also in other fundamental properties (Table 5). The concentration of basic components in rain drops is usually lower than in cloud drops, although the opposite instances are also encountered. However, at a qualitative level, one can infer the "basic" chemical composition of cloud drops from the composition of the rain water.

Aerochemical studies have played and continue to play an important role in the understanding of the liquid-phase processes in the troposphere. Unfortunately, the present authors are unaware of any aerochemical study in which the dynamics of the increase in the NH_4^+, SO_4^{2-}, and H^+ concentrations in the drops of the cloud layer was traced and which was supplemented by measurements of the local gas-phase SO_2, H_2SO_4, HNO_3, NH_3, O_3, and H_2O_2 concentrations in this layer. Without these data, the question of the role of cloud drops—*concentrators* of the water-soluble oxidation products formed in the gas phase or *reactors* in which oxidation processes occur at a rate which is greater than, comparable to, or lower than in the gas phase—cannot be resolved with complete certainty. One should add that such measurements are by themselves not informative because the cloud is not an assembly of drops of "equal age"—drops are being constantly formed in the cloud. Formal kinetic analysis of the processes occurring in cloud drops is thus all the more important. The aim of such analysis is to establish the relations governing the formation of the oxidation products using the results of studies on oxidation processes in solutions. At the level of the mechanism of elementary reactions in the absence of adequate information about the rate constants, this problem reduces to determining the numerical rate constants for which oxidation products may be formed at the concentrations corresponding to the aerochemical data. An independent but important aspect of tropospheric calculations is comparison of the rates of the gas-phase and liquid-phase reactions involving the loss of free radicals, in the first place OH and HO_2. In particular, information about the Henry constants for substances A, i.e. $K_H = [A]/p_A$ mol litre^{-1} atm^{-1} (Table 6), is essential for the solution of such problems.

At pH $\leqslant$ 6 typical for cloud drops, the real solubility is characterised by the K_H of only the substances which do not enter into further reversible, chemical interactions with water. Among the substances listed in Table 6, this applies to only NO, CH_3OH, O_2, O_3, and H_2O_2. In order to calculate the equilibrium concentrations of other substances, it is necessary to take into account the proportions of the various forms in solution, so that the values of K_H characterise only the ratio $[A.H_2O]/p_A$. Thus the real solubility of CH_2O, which is in equilibrium with the free diol form $CH_2(OH)_2$, is reflected by the effective constant $K'_H = 6.3 \times 10^3$ mol litre atm^{-1}. Sulphur dioxide is present in solution in the forms $SO_2.H_2O$ (H_2SO_3), HSO_3^-, and SO_3^{2-} and the dissociation constants K_1, K_2, etc. have to be known in order to calculate the solubility. The characteristic time of attainment of acid-base equilibria of the substances in solutions is incomparably shorter than the rates of their possible chemical reactions.

Table 6. Henry constants (mol $litre^{-1}$ atm^{-1}) for various substances present in the troposphere at 298 K.

Substance	K_H	Substance	K_H
SO_2	1.23	CH_3OH	220
NH_3	58	CH_2O	2
NO	$2 \cdot 10^{-3}$	HCOOH	83
NO_2	$7 \cdot 10^{-3}$	O_2	$1.6 \cdot 10^{-3}$
HNO_2	50	O_3	$1.1 \cdot 10^{-2}$
HNO_3	$2 \cdot 10^5$	H_2O_2	$1.6 \cdot 10^5$

The problem of the characteristic time of attainment of the gas–liquid equilibrium is more complex, since its solution requires that account be taken of the molecular diffusion of substances from the surface into the bulk of the drop, of the gas flux, of the drop diameter, etc. Analysis carried out in relation to SO_2 [81–83] showed that, at pH $\leqslant$ 6 and at the characteristic tropospheric SO_2 concentrations, the time of attainment of the gas–liquid equilibrium is negligible (< 1 s) compared with the lifetime of the drop. Thus, in the analysis of the reactions of substances in drops, one can use the equilibrium values of $[HSO_3^-]$ as well as $[O_2]$ and $[O_3]$, since the solubilities of the latter substances are low and the O_2 and O_3 fluxes are intense. Turning to substances with a high solubility (H_2SO_4, HNO_3, H_2O_2, NH_3), it is essential to estimate quantitatively their transfer to the drops at the specified concentrations of the substances in the gas and for the specified drop diameters. The equilibrium concentrations of the substances in the drops at different temperatures and at different concentrations of the substances in the gas phase are calculated from the equations[84]:

$$[SO_2]_0 = p_{SO_2}(1.23 \exp\{3120\, t\})\{1 + (1.7 \cdot 10^{-2} \exp 2090t)/[H^+]\},$$

$$[NH_3]_0 = p_{NH_3}(58 \exp\{4035\, t\})\{1 + 1.7 \cdot 10^{-5} \exp(-4325t)/[OH^-]\},$$

$$[O_3]_0 = p_{O_3} \times 1.1 \times 10^{-2} \exp\{2500t\},$$

$$[H_2O_2]_0 = p_{H_2O_2} \times 1.6 \times 10^5 \exp\{6600t\}, \text{ etc.}$$

where $t = 1/T - 1/298$.

At heights of 1–5 km, the temperature differs from the terrestrial temperature by 6–30 K. At an average height of 1.5 km, which is close to the height of the maximum moisture content, the solubilities of the gases in the drops are assumed equal to the solubilities at 280 K. The concentrations of the test substances in the gas phase corresponding to this height[85] are listed in Table 7.

Table 7. Characteristic concentrations of SO_2 and of its potential oxidants in the background atmosphere at a height of 1.5 km at 280 K [85].

Substance X	$[X]_G$, cm^{-3}	p, atm	$[X]_{soln}$, M
SO_2	$3 \cdot 10^9$ (Ref.86)	$1.1 \cdot 10^{-10}$	$7.8 \cdot 10^{-12}/[H^+]$
O_2	$4 \cdot 10^{18}$	0.15	$2.7 \cdot 10^{-4}$
O_3	$7 \cdot 10^{11}$	$2.6 \cdot 10^{-8}$	$5.2 \cdot 10^{-10}$
H_2O_2	$1.1 \cdot 10^{10}$	$4 \cdot 10^{-10}$	$3 \cdot 10^{-4}$

The quoted concentration of H_2O_2 in solution is a maximum, since all the concentrations of the substances belonging to the odd hydrogen family were calculated on the assumption of a high intensity of illumination and a high humidity[85]. Under the conditions of the real background atmosphere, the H_2O_2, HO_2, and OH concentrations can be several times smaller. Taking into account this correction, one can assume that the value of $[H_2O_2]_{soln}$ agrees with the experimental concentration of hydrogen peroxide in the rain drops[78,79].

The problem of the nature of the drops at pH→3, which fall in the form of acid rain and have negative ecological consequences for soil and water catchment areas, is important in the chemistry of the cloud layer. Clouds consisting of such drops are formed in the presence of an SO_2 content many times greater than its content in the background atmosphere.

We are unaware of attempts at a chemical interpretation of the mechanism of the formation of acid cloud drops. As regards the background atmosphere, the potential possibility of the occurrence in the latter of processes involving the oxidation of sulphite ions by oxygen, ozone, and hydrogen peroxide and of the catalytic acceleration of the oxidation of sulphide ions under the influence of iron and manganese ions has been considered.

During the lifetime of a cloud drop in the background atmosphere ($\sim 10^3$ s), approximately 10^{-4} M sulphate ions accumulate together with a comparable amount of ammonium ions and the characteristic pH is 4.5–4.7.[87] At pH 3–6, the dominant form in which SO_2 is present in solution is HSO_3^-, since $K_1 = 1.7 \times 10^{-2}$ and $K_2 = 6 \times 10^{-8}$ M.

$$[SO_2]_0 = p_{SO_2} K_H \{1 + K_1/[H^+] + K_1K_2/[H^+]^2\}\, M.$$

The maximum HSO_3^- concentration at pH 6 is 8×10^{-6} M; as sulphate is formed and the acidity increases to pH 4.7, the maximum HSO_3^- concentration diminishes by a factor of approximately 20. The transition from HSO_3^- to SO_4^{2-} as $\overline{[HSO_3^-]} \simeq 2 \times 10^{-6}$ M takes place at an average rate $\overline{W} \simeq 10^{-4}/10^{-3} = 10^{-7}$ mol $litre^{-1}$ s^{-1}.

We shall compare the above value of $\overline{W}$ with the available rates of oxidation of sulphite ions by oxygen, ozone, and hydrogen peroxide. Their oxidation by oxygen and ozone and an analysis of all the previous studies has been carried out in greatest detail by Larson et al.[87] In the pH range 4–12, the rate of oxidation is described by the expression

$$\frac{d[SO_4^{2-}]}{dt} = \{4.8\cdot10^{-3} + 8.9[H^+]^{0.5} + 3.9\cdot10^{-12}[H^+]^{-1}p_{O_2}\}\cdot\frac{6\cdot10^{-8}[HSO_3^-]}{[H^+]}$$

for O_2 and by

$$\frac{d[SO_4^{2-}]}{dt} = 4.4\times10^4[O_3][HSO_3^-][H^+]^{0.1} \text{ mol litre}^{-1}\text{ s}^{-1}.$$

for the oxidation by ozone.

At concentrations characteristic of cloud drops, these rates are of the order of 10^{-9} and 10^{-11} mol litre^{-1} s^{-1} respectively.

The catalytic oxidation of sulphite in the presence of iron ions at the real HSO_3^- and Fe^{3+} concentrations in the pH range 4–12 was investigated using radiochemical monitoring[88]. At pH 4.9, we have

$$-\frac{d[HSO_3^-]}{dt} = 10^2[Fe^{3+}]_0[HSO_3^-] \text{ mol litre}^{-1}\text{ s}^{-1}.$$

According to the data of Brimblecome and Spedding[88], the pH dependence of the rate constant has a maximum at pH 6. Using the maximum value ($\sim2.5\times10^2$) and the HSO_3^- concentration corresponding to pH 6, it is possible to estimate the minimum concentration of iron ions at which $\overline{W} = 10^{-7}$ mol litre^{-1} s^{-1} as 5×10^{-5} M. This value lies in the range of the limiting concentrations of Fe^{3+} in cloud drops[76], which, however, corresponds not to the background atmosphere but to a highly polluted atmosphere.

Unfortunately such accurate studies on the catalysis of oxidation by manganese ions at concentrations close to those obtained in nature have not been found in the literature. It has been noted that Mn^{2+} ions are more effective as a catalyst of the oxidation of sulphite ions than iron ions[89]. On the other hand, quantitative studies have been carried out in the ranges of $[Mn^{2+}]$ and $[HSO_3^-]$ which differ from the real concentration ranges. Thus the following expression has been put forward[90]:

$$-\frac{d[HSO_3^-]}{dt} = 16[Mn^{2+}]^2.$$

It was obtained for $[Mn^{2+}] = (0.2-5)\times10^{-3}$ M and $[HSO_3^-] = 10^{-3}$ M.

In a later study[91] the equation

$$W = 4.7[H^+][Mn^{2+}]^2,$$

was proposed for the ranges pH 0–3, $[Mn^{2+}] = 10^{-5}-10^{-3}$ M, and $[HSO_3^-] = 10^{-4}-10^{-3}$ M. The equation

$$W = 25[H^+][Mn^{2+}][HSO_3^-],$$

was put forward for the same pH range and $[Mn^{2+}]$ and $[HSO_3^-] \leqslant 10^{-6}$ M.

When this relation is extrapolated to pH 6, it is found that, in order to attain $W = 10^{-7}$, it is sufficient to have a concentration $[Mn^{2+}] \simeq 10^{-9}$ M.

However, in the presence of ferric ions the effective rate constant, which in the given instance is $25[H^+]^{-1}$, by no means varies linearly with $[H^+]^{-1}$ in the region with pH > 4 (this is apparently associated with the hydrolysis of metal ions). Whatever the true state of affairs, before catalysis by Mn^{2+} ions is subjected to a study similar to that carried out for ferric ions[88] the problem of the possible accumulation of sulphates in drops of the background atmosphere as a result of the catalytic oxidation of sulphite in the presence of manganese ions will remain open.

The interaction of sulphite ions with H_2O_2 constitutes the basis of the analytical method for the determination of SO_2, H_2SO_3, and HSO_3^-. The process is autocatalytic. The dependence of the rate of reaction on the reactant concentrations in the pH range 4–8 assumes the following form according to Hoffman and Edwards[92]:

$$-\frac{d[SO_2]_0}{dt} = [H_2O_2][SO_2]_0\{[H^+]/[H^+] + 6\cdot10^{-8}\}(5.8\cdot10^7[H^+] + 7.2\cdot10^2[HA])^{\ddagger}$$

At pH 6 and the corresponding H_2O_2 and HSO_3^- concentrations (see Table 7), the rate of reaction $W = 1.3\times10^{-7}$ mol litre^{-1} s^{-1}, which agrees with the value of $\overline{W}$.

The process considered differs from all those examined previously by the fact that its rate under the conditions of cloud drops does not diminish with decrease in the HSO_3^- concentration, since the fall in the equilibrium value of $[HSO_3^-]$ induces an increase in $[H^+]$ in strict agreement[92] with the stoichiometry of the reaction

$$2HSO_3^- + H_2O_2 \rightarrow + 2SO_4^{2-} + 2H^+.$$

The approximate kinetic analysis carried out leads to the conclusion that the most probable oxidation process in the cloud drops of the background atmosphere is the interaction of HSO_3^- with H_2O_2. In recent years, a similar view has been expressed frequently in a qualitative form, but attention has not been turned to the catalytic nature of this reaction. In mathematical models (see, for example, Hill et al.[93]), the rate of formation of sulphate ions was described by the equation

$$\frac{d[SO_4^{2-}]}{dt} = k_{H_2O_2}[H_2O_2][HSO_3^-] + k_{O_3}[O_3][HSO_3^-],$$

i.e. without taking into account the role of hydrogen ions as the catalyst. Nor can one rule out the possibility of the catalytic oxidation of HSO_3^- with participation of Mn^{2+} ions, although the characteristics of this process at the concentrations attained in cloud drops are not available.

3. Gas–liquid models of the formation of acid drops in the background and contaminated atmospheres

In a contaminated atmosphere, the average rate of oxidation of sulphite ions should be ten and more times higher than in the background atmosphere in order to ensure the formation of 10^{-3} M SO_4^{2-} after approximately 10^3 s. At first sight, the formation of sulphate can be explained by the autocatalytic oxidation of sulphite by hydrogen peroxide, by substituting in the corresponding equation the values of p_{SO_2} which exceed by a factor of 10 or more the values

‡ A misprint occurred in the communication of Hoffman and Edwards[92]: instead of 5.8×10^7, 5.8×10^1 is printed in the text. It is easy to demonstrate that the latter figure is erroneous by carrying out an approximate calculation of the characteristic reaction time at pH 4.5, which, was stated by the authors[92] becomes less than 2.5 ms and measurements by the stopped flow method become impossible.

of p_{SO_2} in the background atmosphere. However, in a contaminated atmosphere not only p_{SO_2} but also p_{CO} is higher than in the background atmosphere. On the other hand, the reaction of CO with OH constitutes one of the most important pathways leading to the loss of OH. An increase in p_{CO} entails a decrease in the stationary OH, HO_2, and H_2O_2 concentrations. On the other hand, when the H_2O_2 concentration diminishes by an order of magnitude, the possibility of such explanation evidently disappears. Attention should be drawn also to the fact that the bulk of sulphate ions (from 10^{-4} to 10^{-3} M) should be formed in the pH range from 4 to 3, i.e. for $[HSO_3^-]_0$ lower by a factor of 10 than in the background atmosphere. All these factors preclude the justification of a chemical mechanism of the formation of drops in acid clouds on the basis of the reactions considered. One cannot rule out in any way the possibility that in this case a physical mechanism of the absorption of H_2SO_4 by drops, and not a chemical mechanism, acquires decisive importance. The distribution of H_2SO_4 and HNO_3 between the gas and liquid phases is displaced towards the latter so much that at their typical concentrations in acid drops (10^{-3} and 10^{-4} M) and in the gas (10^{-11} and 10^{-10} atm [86]) the acid concentration can be regarded as equal to the product of the lifetime of the drops and the flux of the acid from the gas to the drops. For $[H_2SO_4]_G \simeq 2 \times 10^8$ cm^{-3} and for a drop diameter of 10 μm, the total H_2SO_4 flux is $\sim 10^5$ mol^{-1} s^{-1}.

Thus for an accommodation coefficient $\gamma \simeq 10^{-1}$, the accumulation of sulphate ions in drops can be explained by the absorption of H_2SO_4 from the gas phase.

Assuming that $\gamma \simeq 10^{-2}$ for H_2SO_4, as is usually done in the literature in the absence of measured values, we shall consider all the possibilities of the chemical route to the accumulation of sulphuric acid. The most important factor is that the flux of HO_2 and OH from the gas to the drops can significantly exceed the rate of formation of these radicals in the drops as a result of the photolysis of O_3 and H_2O_2 if the values of γ for the radicals are assumed to be 10^{-2} [94–96].

The first chemical-mathematical model of the oxidation processes in the drops of sea clouds taking into account the OH and HO_2 fluxes[97] included the following reactions (Scheme 2);

Scheme 2

(1) $\dot{O}H + HSO_3^- \rightarrow \ldots \rightarrow SO_4^{2-} + 2H^+$,
(2) $\dot{O}H + HSO_3^- \rightarrow H_2O + \dot{SO}_4^-$,
(3) $OH + CH_2(OH)_2 \rightarrow HCOOH + \dot{H}O_2$,
(4) $\dot{O}H + HCOOH \rightarrow CO_2 + H_2O + \dot{H}O_2$,
(5) $OH + H_2O_2 \rightarrow H_2O + HO_2$ and the equilibria $H\dot{O}_2 \rightleftarrows H^+ + \dot{O}_2^-$ and $\dot{C}l + Cl^- \rightleftarrows \dot{Cl}_2^-$,
(6) $\dot{H}O_2 + O_3 \rightarrow 2O_2 + \dot{O}H$,
(7) $S\dot{O}_4^- + Cl^- \rightarrow SO_4^{2-} + \dot{C}l$,
(8) $\dot{C}l + \dot{O}_2^- \rightarrow Cl^- + O_2$,
(9) $\dot{H}O_2 + \dot{O}_2^- \rightarrow HO_2^- + O_2$.

On the assumption that $\gamma \simeq 10^{-2}$, the $H\dot{O}_2$ and $\dot{O}H$ fluxes were assumed to be 9×10^{-9} and 1.4×10^{-9} mol litre^{-1} s^{-1} respectively, while $[H_2O_2] = 5 \times 10^{-5}$ M.

Within the framework of this model it proved possible to obtain the value $[SO_4^{2-}] = 8 \times 10^{-6}$ M, which is close to the value characteristic of sea clouds. The study quoted above[97] is particularly important also, because the rate constants for the elementary radical reactions were used in it for the first time in considering the oxidation processes in cloud drops. The reason why the ratio of the $H\dot{O}_2$ and $\dot{O}H$ fluxes in the above studies[97] is approximately 7 whereas in the tropospheric zone $[H\dot{O}_2]_G/[\dot{O}H]_G > 10^2$ and the molecular-kinetic characteristics of $H\dot{O}_2$ and $\dot{O}H$ do not differ all that much remains obscure.

In subsequent years it proved possible to determine experimentally the accommodation coefficients of all three tropospheric substances. These values are 0.11 for SO_2 [98], 0.18 for H_2O_2 [98], and 0.27 for $H\dot{O}_2$ [36] The last figure is particularly important, because it increases the calculated $H\dot{O}_2$ flux into the drops by a factor of approximately 30. In this connection, we attempted the mathematical modelling of the sulphite oxidation process in cloud drops via a radical mechanism. It is noteworthy that the true mechanism of this process—one of the first examples of radical chain reactions in solutions[99]—has not been ultimately elucidated to this day[100]. It is the general view that microadmixtures of variable-valence metal ions participate in the initiation stage. The radical-chain mechanism put forward by Backstrom[101] can be represented in the form (Scheme 3)

Scheme 3

$$i \rightarrow H\dot{S}O_3 (SO_3^{\cdot-})$$
(1) $SO_3^- + O_2 \rightarrow SO_5^{\cdot-}$
(2) $SO_5^{\cdot-} + SO_3^{2-} \rightarrow SO_5^{2-} + SO_3^{\cdot-}$ } ν
(3) $SO_5^{2-} + SO_3^{2-} \rightarrow 2SO_4^{2-}$
(0) $SO_5^- + SO_3^{\cdot-} \rightarrow O_2 + S_2O_6^{2-}$.

The reaction is sensitive to copper ion microimpurities present in solution at concentration of the order of 10^{-12} M (in an alkaline medium)[101]. When carefully purified reagents and deionised triply distilled water are used, initiation is effective by iron ions at concentrations of the order of 10^{-8} M [88]. The unsatisfactory reproducibility of the experiments and the high sensitivity of the rates reactions to small amounts of added alcohols and other inhibitors indicate a considerable chain length. As kinetic data accumulate, indicating that at pH < 6 the rate of reaction is independent of p_{O_2} [87], the chain termination reaction has come to be represented in the form

$$SO_5^- + SO_5^- \rightarrow S_2O_6^{2-} + 2O_2.$$

The ideas about the chain propagation put forward by Hayon et al.[102] are based on the study of the reactions of sulphur–oxygen radical-ions ranging from SO_2^- to SO_5^-. The authors[102] concluded that, after the formation of the sulphate ion and the SO_4^- radical-ion, the chain propagation in reaction (2) takes place as a result of the following process:

$$SO_4^{\cdot-} + HSO_3^- \rightarrow SO_4^{2-} + H^+ + SO_3^-.$$

The legitimacy of including in the process mechanism of reactions involving SO_4^- has been confirmed by measurements of the rate constants for the reactions of SO_5^- and SO_4^- with alcohol[102]. The interaction of alcohol with SO_4^-, and not with SO_5^-, is more effective.

Comparison of the values of pK for H_2O and $H\dot{O}$ and also for H_2O_2 and $H\dot{O}_2$ makes it possible to assume with a high degree of probability that in the range 3 < pH < 6 the dominant species are SO_3^- (and not $H\dot{S}O_3$) and $H\dot{S}O_5$ (and not SO_5^-) ($K_2 \simeq 10^{-10}$ mol litre^{-1} for H_2SO_5). Taking into account all the considerations

described, the mechanism of the oxidation of HSO_3^- can be represented by Scheme 4:

Scheme 4

$$i \rightarrow SO_3^{\cdot-}$$

(1) $SO_3^{\cdot-} + O_2 \xrightarrow{H} H\dot{S}O_5$,

(2) $H\dot{S}O_5 + HSO_3^- \rightarrow 2H^+ + SO_4^{2-} + SO_4^{\cdot-}$,

(3) $SO_4^{\cdot-} + HSO_3^- \rightarrow SO_4^{2-} + H^+ + SO_3^{\cdot-}$,

(0) $H\dot{S}O_5 + H\dot{S}O_5 \rightarrow 2O_2 + 2H^+ + S_2O_6^{2-}$.

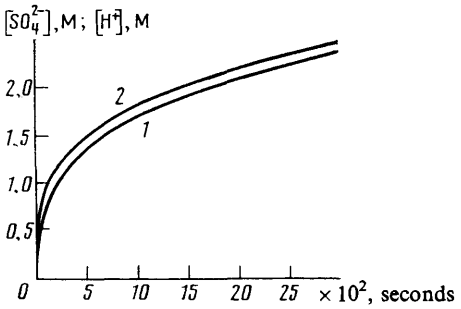

Figure 4. Kinetics of the accumulation of SO_4^{2-} (curve *1*) and H^+ (curve *2*) ions in water drops (calculated data).

We may note that the nature of the initiation reactions still remains obscure. This can be easily demonstrated by comparing the mechanism just presented or the one considered previously, without the participation of $SO_4^{\cdot-}$, with the experimental expression for the rate of reaction:

$$W = (k + k_2[H^+]^{0.5})[HSO_3^-],$$

which follows from studies analysed by Larson et al.[87] Taking into account the large chain length for the oxidation of sulphite, we obtain

$$W_i = k_0 W^2/k_2^2[HSO_3^-]^2 \quad \text{or} \quad W = [HSO_3^-]\, k_2^{0.5} \sqrt{W_i}/k_0^{0.5},$$

i.e. W_1 is independent of both $[O_2]$ and $[HSO_3^-]$. The question concerning the nature of initiation loses its importance in the presence of an external source of free radicals. In our model, as in the study of Chameides and Kiang,[97] the initiation reaction is that between HSO_3^- and the $\dot{O}H$ radicals entering the drops from the gas phase. Since the $H\dot{O}_2$ concentration and hence the flux of $H\dot{O}_2$ into the drop are approximately 10^2 higher than the flux of $\dot{O}H$, we included in the model the following chain termination reaction

$$H\dot{S}O_5 + H\dot{O}_2 \rightarrow HSO_5^- + H^+ + O_2,$$

as well as the reaction of HSO_3^- with H_2O_2 considered above. Apart from the $\dot{O}H$ and $H\dot{O}_2$ fluxes, account was also taken of the fluxes of H_2O_2 and NH_3 into the drop from the gas phase.

$\gamma \simeq 0.1$ was adopted for OH. The fluxes of H_2O_2 both into the drop and from the drop were taken into account. Analysis based on Smoluchowski's formula showed that an equilibrium distribution of H_2O_2 between the gas and liquid phases is established after 10 s (for drops with $d = 10$ μm). The NH_3 flux was regarded as a variable parameter normalised by the condition that in an acid drop $[NH_4^+]$ should be close to $[SO_4^{2-}]$. The values of $[H\dot{O}_2]_G$, $[\dot{O}H]_G$, and $[H_2O_2]_G$ were assumed to be 10 times smaller than in the background atmosphere. Thus the scheme includes the following fluxes of species from the gas into the drop:

$$OH \rightarrow 10^{-8}\ HO_2 \rightarrow 5 \times 10^{-7}\ NH_3 \rightarrow 10^{-5}\ H_2O_2 \rightarrow 10^{-5}\ \text{mol litre}^{-1}\ \text{s}^{-1},$$

and the following elementary reactions (Scheme 5)

Scheme 5

(1) $\dot{O}H + HSO_3^- \rightarrow H_2O + SO_3^{\cdot-}$, $k_1 = 9.5 \cdot 10^9$ litre mol^{-1} s^{-1} (Ref.103)

(2) $SO_3^{\cdot-} + O_2 \xrightarrow{H^+} H\dot{S}O_5$, $k_2 = 3 \cdot 10^9$ » (Ref.102)

(3) $H\dot{S}O_5 + HSO_3^- \rightarrow 2H^+ + SO_4^{2-} + SO_4^{\cdot-}$, $k_3 = 5 \cdot 10^9$ » —

(4) $SO_4^{\cdot-} + HSO_3^- \rightarrow SO_4^{2-} + H^+ + SO_3^{\cdot-}$, $k_4 = 1.5 \cdot 10^9$ » (Ref.102)

(5) $H\dot{S}O_5 + H\dot{S}O_5 \rightarrow 2H^+ + S_2O_6^{2-}$, $k_5 = 1.0 \cdot 10^7$ » (Ref.102)

(6) $H\dot{S}O_5 + H\dot{O}_2 \rightarrow O_2 + H^+ + HSO_5^-$, $k_6 = 10^8$ » —

(7) $\dot{O}H + H_2O_2 \rightarrow H_2O + H\dot{O}_2$, $k_7 = 4.5 \cdot 10^7$ » (Ref.103)

(8) $\dot{O}H + H\dot{O}_2 \rightarrow H_2O + O_2$, $k_8 = 7.0 \cdot 10^9$ » (Ref.103)

(9) $H\dot{O}_2 + H\dot{O}_2 \rightarrow H_2O_2 + O_2$, $k_9 = 8.1 \cdot 10^5$ » (Ref.103)

(10) $H\dot{O}_2 + O_2^{\cdot-} \rightarrow HO_2^- + O_2$, $k_{10} = 9.5 \cdot 10^7$ » (Ref.103)

(11) $H_2O_2 + H^+ + HSO_3^- \rightarrow H_2O + 2H^+ + SO_4^{2-}$, $k_{11} = 5.8 \cdot 10^7$ » (Ref.92)

Apart from the values of k_i and $pK_{HO_2} = 4.88$ known from the literature[104], the approximate values of k_3 and k_6 were used in the calculation. In the estimation of k_3, it was assumed that the $H\dot{S}O_5$ radicals and not $SO_3^{\cdot-}$ participate in the chain termination reaction, i.e. that $[H\dot{S}O_5]\,[SO_3^{\cdot-}]$, while the rates of the chain termination reactions (2) and (3) (Scheme 5) are equal. The value of k_6 adopted may be too high, but the result of the calculation is relatively insensitive to changes in this rate constant by even one or several orders of magnitude. The principal chain termination reaction is stage (5) of Scheme 5. We did not take into account the possible interaction of HSO_5^- with HSO_3^-, which was regarded in Backstrom's mechanism[101] as the principal route to the formation of SO_4^{2-}. In the mechanism presented, the contribution of this reaction to the overall rate of formation of sulphate ions is much smaller than the contribution of reactions (3) and (4) of Scheme 5. We assume that $[SO_2]_G$ is 10 times greater while $[H\dot{O}_2]_G$, $[\dot{O}H]_G$, and $[H_2O_2]_G$ are 10 times smaller than in the background atmosphere. We note particularly that, if we neglected the NH_3 flux, then not only would we be unable to account for the presence of NH_4^+ in the drops but an appreciable decrease in the final value of $[SO_4^{2-}]$ would have resulted. The results of the calculation are illustrated in Fig. 4. Without over-estimating the importance of this calculation, we may note that it allows the possibility of a chemical explanation of the formation of acid drops at pH→3. The choice between the chemical and absorption mechanisms can be made after determining the accommodation coefficient of H_2SO_4.

It is noteworthy that, as shown by the calculation, a further increase in $[SO_2]_G$ does not lead to appreciable changes in $[SO_4^{2-}]$ and $[H^+]$, i.e. an increase in the amount of SO_2 waste ejected, which increases the volume of precipitated acid rain, should not entail an increase in its acidity. The results of the mathematical modelling of drop processes in contaminated and background atmospheres resorting to experimental data will be described in greater detail in a separate publication by Purmal' and Travin[105], whom the authors thank.

In conclusion, we may note that the rapid reactions of $\dot{O}H$ with HSO_3^- and of $H\dot{O}_2$ with O_2^- in drops necessitate taking into account the loss of OH_G and $H\dot{O}_{2G}$ to the drop when calculating their tropospheric concentrations in the cloud zone. Our estimates have shown that the losses cease to be negligible when the coefficient of the volume saturation of the gas phase by drops is 10^{-6} and less.

Mathematical modelling in problems of the chemistry of the atmosphere

V V Penenko, G I Skubnevskaya
Computer Centre of the Siberian Division of the USSR Academy of Sciences
Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences

ABSTRACT. The characteristics of the mathematical modelling of chemical processes in the atmosphere, their relationship with geophysical processes, their classification in terms of space-time scales, and the sensitivity of the models are examined. The possibilities of modelling the photochemical mechanisms of the reactions of oxygen-, hydrogen-, nitrogen-, sulphur-, and carbon-containing compounds in the background atmosphere and in air in polluted regions and the selection of the parametrisation conditions in conformity with the aims of the given tasks and the hydrometeorological regime are analysed.

The experience gained in the practical use of models of the quality of air in designing a monitoring strategy and measures for the protection of nature is surveyed.

The bibliography includes 133 references.

I. Introduction

Phenomena such as climate warming, the change in the ozone layer, acid rain, the inhibition of plant growth and destruction of forests, and smog phenomena in polluted industrial regions have been attributed to the breakdown of the natural chemical balance in the composition of the atmosphere[1–5]. The appearance of large amounts of toxicants in the atmosphere inevitably affects the ecosystem as a whole[6–9]. An adequate description of the chemical processes occurring in a complex reactor such as the atmosphere is possible only by resorting to mathematical models, which are capable, in conjunction with monitoring systems, of reflecting the entire wide variety of the phenomena and their interaction and permitting an assessment of the consequences of the chemical perturbations of the natural composition of the atmosphere by different sources.

Considerable progress in fundamental research into the atmosphere[10–15], in particular into the modelling of the processes of the dispersion and reactions of the natural and anthropogenic impurities in the atmosphere[16–19], has been achieved in recent years. The advances in chemical kinetics associated with the study of the mechanisms of chemical reactions has made it possible to describe the cycles of reactions of chemicals under natural atmospheric conditions and in the atmospheres of polluted industrial regions. Detailed study of the processes at the level of an elementary chemical step revealed the important role of atoms and short-lived free radicals in processes leading to the transformation of substances[10,11,20,21].

The assemblies of species playing a significant role in the reactions of chemical elements have been combined for convenience into families of O-, H-, N-, S-, C-, Cl-, Br-, and I-containing compounds[10–13]. Organic substances, the mechanisms of the reactions of which have been studied particularly vigorously in recent times in connection with the need to understand the reactions of organic impurities in air over motorways, over forests, and under the conditions of a polluted atmosphere, have been segregated in a separate group[11,12,14]. The experimental data on the chemical kinetics and photochemistry of the gas-phase reactions have been recently surveyed by an Expert Panel within the framework of the IUPAC Subcommittee for Gas-Phase Kinetics, which periodically publishes compilations of kinetic and photochemical data concerning the chemistry of the atmosphere[22,23].

A quantitative description of individual families of reactions, close to the real conditions, is achieved with the aid of mathematical models of different degrees of complexity and with different degrees of detail, depending on the aims of the studies and their practical applications[24–29]. The mathematical models based on data obtained by chemical monitoring using highly sensitive and rapid analytical methods make it possible to approach a solution to problems concerning the prediction of the chemical composition of the atmosphere on both global and local scales.

In the present review, attention is concentrated on the mathematical models used in the study of the photochemical reactions in the atmosphere. This has been done for two reasons. Firstly, the photochemical mechanism of the reactions of substances under the influence of solar radiation is the most common to all the layers of the atmosphere. It establishes the chemical composition of the atmosphere as a whole and its heat balance[2,10,11,13]. Secondly, the mathematical models for the description of photochemical reactions in the atmosphere have been fairly thoroughly developed and a great variety of them are available, which makes it possible to demonstrate the possibilities of mathematical modelling in the

solution of theoretical and applied problems in atmospheric chemistry.

II. Characteristic features of the construction of mathematical models for the description of chemical processes in the atmosphere

The laws of conservation of energy, momentum, and mass, which together with the fundamental rules of thermodynamics and chemistry describe the establishment of atmospheric motions and the transport and transformation of various substances against the background of the latter, constitute the theoretical basis of the mathematical models describing the geophysical and chemical processes in the atmosphere. In terms of mathematics, these are systems of equations for the hydrothermodynamics of the atmosphere (taking into account the transport and transformation of moisture) and systems of equations for transport processes and the reactions of impurities which describe both positive and negative feedback[17]. The complexity of the interrelations between the geophysical and chemical processes in the atmosphere as well as the incomplete knowledge of this field have led to ambiguity in the formulation of problems and in the selection of ways of solving them. The wide variety of approaches to the construction of mathematical models for the transport and transformation of impurities in the atmosphere and the principles governing their practical application have been described in fair detail in the Proceedings of the International Symposium held in 1986 in Leningrad[18].

In order to discover the characteristic features of the physical and chemical phenomena in the atmosphere, an open version of mathematical models is usually employed, in which the elements of the hydrometeorological regime in the atmospheric circulation are assumed to be known and the occurrence of chemical reactions against the background of atmospheric motions is investigated. Three cases are then distinguished depending on the relation between the characteristic chemical and dynamic time scales (t_c, d_d). If $t_c < t_d$ (for example, for short-lived atoms and free radicals), then the chemical reactions can be considered regardless of the atmospheric dynamics. On the other hand, when $t_c > t_d$, the role of dynamics is great (this happens, for example, in the study of trace species such as chlorofluoromethane, carbonyl sulphide, nitrous oxide, etc.). The case where $t_c \simeq t_d$ is most complex and the interpretation of the observations under natural conditions can therefore also be far from unambiguous (for example, for ozone and nitrogen oxides). In order to describe the behaviour (variation of the concentation) of a given impurity and to estimate its residence time in the atmosphere, it is as a rule necessary to carry out a joint analysis of hydrometeorological, physical, and chemical processes.

Analysis of the space-time scales determines the formulation of the problems of atmospheric chemistry which can be arbitrarily divided into the chemistry of the stratosphere, the chemistry of the troposphere, and the chemistry of industrial regions.

The overall structure of models of the transport and transformation of impurities in the atmosphere includes a system of equations of the following type:

$$\frac{\partial c_i}{\partial t} + \operatorname{div} c_i\mathbf{u} - \operatorname{div}_S \mu \operatorname{grad}_S c_i - \frac{\partial}{\partial z}\nu\frac{\partial c_i}{\partial z} + B_i(\mathbf{C}) = f_i, \tag{1}$$

where c_i is the concentration of the ith component at a point $\mathbf{x}$ in space at a time t, $\mathbf{u}$ the velocity vector of the air masses and impurities, μ and ν are the coefficients of the turbulent mixing of impurities in the horizontal (x, y) and vertical (z) directions, $\mathbf{C} = \{c_i(i = \overline{1, n})\}$ the impurity concentration vector, n the number of impurities, $B(\mathbf{C}) = \{B_i(\mathbf{C}), (i = \overline{1, n})\}$ the operator describing the impurity transformation processes, and $f_i(\mathbf{x}, t)$ $(i = \overline{1, n})$ are sources of impurities. The divergence and gradient operators are determined in the usual way in the selected coordinate system. The subscript S denotes operators acting in horizontal directions.

The problem is considered in the region where $D = \{D \times [0, \bar{t}]\}$, where $[0, \bar{t}]$ is the range of variation of the time t, D the region of the spatial coordinates $\mathbf{x} = \{x_\alpha, \alpha = \overline{1, k}, k \leqslant 3\}$, and k is the number of dimensions of the space.

In this case the velocity vector $\mathbf{u}$ can be represented by $\mathbf{u} = \{u_\alpha, \alpha = \overline{1, k}, k \leqslant 3\}$, where u_α is the component in the direction of the coordinate x_α. In the three-dimensional case, one usually employs the designation $\mathbf{x} = (x, y, z)$. The sources $f_i(\mathbf{x}, t)$ $(i = \overline{1, n})$ are specified as the input parameters of the model in the form of functions of spatial coordinates and time. One then takes into account sources of natural and anthropogenic origin.

To complete the description of the model, one specifies the initial and boundary conditions:

$$\text{when } z = Z_S(x, y) \quad R_{1_i}(\mathbf{C}) = f_{1_i}(x, y, t), \tag{2}$$

$$\text{when } z = H \qquad R_{2_i}(\mathbf{C}) = f_{2_i}(x, y, t), \quad i = \overline{1, n}. \tag{3}$$

Here R_{1_i} and R_{2_i} are certain operators and f_{1_i} and f_{2_i} are the sources and sinks of impurities at the $[z = Z_S(x, y)]$ and upper $(z = H)$ limits of the region D. The operators $R_{1_i}(\mathbf{C})$ describe the interaction of the impurities with one another and with the Earth's surface including the exchange processes between air, water, soil, the plant cover, etc., while the operators $R_{2_i}(\mathbf{C})$ describe the behaviour of impurities at the upper limits of the air masses. The descriptions of the operators $B_i(\mathbf{C})$, $R_{1_i}(\mathbf{C})$, and $R_{2_i}(\mathbf{C})$ are specified for each specific problem.

The conditions governing the periodicity of all the functions on the surface of a sphere and, for models designed for a limited area, the conditions governing the concentration field at the lateral boundaries are specified in terms of horizontal variables for the global model. In the vertical velocity, one takes into account the rate of gravitational precipitation of impurity particles which are heavier than air or the rise of particles which are lighter than air at the corresponding height as a result of buoyancy forces.

The first four terms in Eqn. (1) constitute the linear part of the model. The transport and turbulent exchange processes for each substance take place independently of other processes. The operator $B(\mathbf{C})$ is in the general case non-linear, describing the rate of change of the concentrations $\mathbf{C} = \{C_i, i = \overline{1, n}\}$ as a result of chemical and photochemical reactions. Since we are dealing with multicomponent impurities, the number of components n is an input parameter of the model. In practice, n is determined by the model for the transformation of impurities or by the number of substances involved in the reactions.

The hydrometeorological regime in the air masses against the background of which the impurity transport and transformation processes take place is described by the fields of the components of the wind velocity vector $\mathbf{u}$ and the turbulent exchange coefficients $\mu(\mathbf{x}, t)$ and $\nu(\mathbf{x}, t)$. In addition, the temperature, density, and

pressure fields as well as the characteristics of the humidity field, which are in general necessary for the description of the impurity transformation models and for the calculation of the reaction rates, are specified parametrically. The parameters of the hydrometeorological regime are usually assumed to be specified. Naturally, such separation of hydrothermodynamic and chemical processes in the model is extremely arbitrary and can be acceptable for relatively short time intervals and only for the sake of the simplification of the description of the overall structure and content of the impurity transport and transformation models.

The point is that in the general situation one cannot do without negative feedbacks. Many of the impurities belong to the class of optically active substances and influence the radiation processes in the atmosphere, while some influence also the moisture transformation processes, acting, for example, as condensation nuclei. All this leads to changes in the thermal and humidity-dependent processes in the atmosphere and ultimately to changes in hydrometeorological regime, i.e. in the velocity fields and in the turbulent exchange. The problem consists in the evaluation of the characteristic time scales of such negative feedbacks and of the intensity of the changes in the background processes determined by the effects of their negative feedbacks.

As a result of the modification of the formulation of the problem defined by Eqn. (1)–(3), different types of models are obtained. These modifications are determined by the following features:

the way in which the parameters of the hydrometeorological regime — the turbulent exchange models — are specified;

the procedures used to describe the boundary conditions and sources — the interactions of impurities with the underlying surface;

the choice of the space-time structure of the region, i.e. the dimensions of the problem and the hypotheses concerning the nature of the dependence of the investigated phenomena on the variables x, y, z, and t;

the procedure used to describe the impurity transformation operators;

the space-time scales of the phenomena investigated — the procedures used for a discrete description of the models and the methods of their application on a computer;

the combinations of the variants described.

An important stage in the construction of numerical models is the discrete specification of the initial problems in a differential formulation. Different procedures for such discrete specification are used nowadays — finite-difference, finite-elementary, spectroscopic, spectroscopic-difference, and their various combinations. The choice of a specific scheme is determined by the ratios of the space-time scales of the processes taken into account in the model. Together with models with rigorously determined formulations, models based on statistical modelling methods (the Monte Carlo method) are being developed.

III. Classification of models in terms of space-time scales

In relation to time, the model can be stationary or non-stationary, while in relation to spatial variables we have "point", one-dimensional, two-dimensional, and three-dimensional models.

In point (or box) models, there is no description of transport processes. Such models arise when the characteristics of the composition of the atmosphere are averaged out on the assumption of spatial homogeneity and account is taken of only stationary and non-stationary impurity transformation processes. They are convenient for the interpretation of laboratory experiments, for example in smog chambers[30–33]. Chemical processes, including all the elementary stages, are studied in detail in such models. Integration of a short time interval is used in the study of the kinetics of the reactions of reactants and products. Comparison of the results of such modelling with the results of measurements sometimes stimulates a specific search for new processes, the allowance for which would promote the reconciliation of the results of modelling and experiments[34].

One-dimensional models are usually employed when the changes in the impurity concentration fields as a result of transport and turbulent exchange are significant mainly in one direction, while in other directions once can restrict the treatment to the assumption of uniformity. This occurs, for example, in the solution of problems of the stratosphere in connection with the study of vertical motions and of problems of the boundary layer of the atmosphere over a homogeneous area of the Earth's surface[25,35–43].

1. Photochemical models of the stratosphere

The chemistry of the stratosphere is relatively simple and is described in terms of compact models. Usually 20–30 chemical species, 100–200 reactions, a temperature of 200–300 K, and a pressure of 1–100 torr are involved. The most important aspect of these problems is the photochemistry of ozone[21]. Here it is necessary to take into account four groups of species[13]: (1) "odd" oxygen O_3, $O(^1D)$, and $O(^3P)$ whose reactions are based on the classical Chapman cycle; (2) long-lived gases of tropospheric or biospheric origin, such as H_2O, O_2, N_2, CO, CH_4, H_2, CH_3Cl, CF_2Cl_2, COS, etc; (3) short-lived radicals, for example OH, HO_2, and Cl, participating in catalytic ozone decomposition cycles (we may note that allowance for these has made it possible to eliminate a number of problems concerning the ozone balance[11]); (4) the products of the reactions of short-lived radicals such as HNO_2, HNO_3, HO_2NO_2, $ClONO_2$, H_2SO_4, and H_2O_2. The most important criterion of the adequacy of such models is the agreement between the calculated and measured concentration profiles of the species most sensitive to variations in the input parameters of the models. In terms of such models, one investigates either the diurnal changes in the short-lived species or one calculates the height profile of the concentrations of the molecules averaged over long time (t) intervals. The increased interest in the chemistry of ozone in the stratosphere has led in recent years to the search for additional chemical processes which may occur in a polluted stratosphere. Thus, in order to account for the observed decrease in the amount of ozone in polar regions[26], it is necessary to resort to heterogeneous reactions involving ozone.

The attempts to understand further and to predict the changes in the content of impurities in the stratosphere under the influence of anthropogenic perturbations are nowadays based mainly on two-dimensional models which are capable of modelling the changes in concentrations as a function of two spatial variables — height and one horizontal dimension, as well as the season and the time of day. The spatial-temporal resolution and the algorithmic possibilities of such models are determined by the speed and the size of the memory of the computers employed.

Two-dimensional models are more realistic than one-dimensional models, but they too describe only individual features of the investigated phenomena. Since in recent years appreciable progress has been observed in the method for the determination of certain impurities in the atmosphere and of their dynamics, it has become

possible to compare the calculated and measured concentrations. This has stimulated a rethinking of the ideas concerning the role of certain reactions in the atmosphere.

Three-dimensional models are most consistent with the conditions in the real atmosphere. They usually combine the species transport processes, the interaction with radiation, and the photochemical reactions of the species and constitute an effective instrument for discovering the characteristic features of the establishment of the concentration profiles for impurities such as O_3, CO, CO_2, nitrogen- and sulphur-containing substances, etc. and for the determination of the level and consequences of the anthropogenic stimuli[45–48]. In three-dimensional models, much attention is devoted to their ability to describe diurnal and seasonal changes in concentration fields. Some models make it possible to calculate rapid chemical transformations of impurities on the assumption of slow changes in other parameters under the influence of external conditions. Conversely, others do not permit calculations for rapid processes but do make it possible to take into account the types of sources, sinks, and the transfer and transport of long-lived impurities. The decisive external parameters under these conditions are the concentrations of short-lived species, for example, the OH radical[13]. Models in which large averaging scales in space and time are postulated are usually employed for climatic predictions.

Much attention has been devoted recently to the development of three-dimensional models for the study of the chemistry of the polluted atmosphere of industrial regions[44–61]. The multiplicity of approaches to the construction and application of such models have been tried. Thus models of the dispersal of impurities arising from powerful sources take into account the transport processes on a regional scale but neglect the details of the chemical transformations. Local models of the "quality of air" include the chemistry of atmospheric contaminants usually with parameterised decriptions of the transport processes. Such models are as a rule designed for ecological predictions on a regional scale (including different countries).

Table 1. Classification of the models in terms of characteristic space-time scales of the processes and typical problems solved with the aid of the models.

Horizontal scale, km	Vertical scale, km	Specific features of ecological problems
1–10	1–5	Influence of open-cast mining, chemical and aerosol methods in agriculture, and large industrial units on the environment
10–100	5–10	The microclimate and pollution of urban atmospheres
10–100	10–20	Effect of powerful anthropogenic heat sources on the environment with evolution of polluting impurities
100–1000	10	Environmental protection problems for large territorial-industrial complexes and influence of large hydrotechnical units on the hydrothermodynamics of the atmosphere
1000–10000	10	Studies on the cyclogenesis and the long-range transport of impurities
Global	10–30	Energy and mass exchange in climatic system and the global transport of impurities in the atmosphere

Questions concerning allowance for feedback effects, which arise in the joint consideration of chemical processes together with processes involving the hydrothermodynamics of the atmosphere may be regarded as little developed aspects of three-dimensional models. The construction of complex models greatly complicates the formulation of the problem and requires the solution of the problem of a self-consistent description of processes on different space-time scales. Thus the specific problem and the range of phenomena considered dictate the choice of the structure of the model, its discrete analogues, and the methods of parametrising chemical and physical factors. Table 1 presents a classification of models in terms of space-time scales, which provides an idea about certain possible combinations of hydrothermodynamic models with models of the chemical transformations of mixtures.

The technology of the modelling of chemical processes in the atmosphere consists of several stages, which are common to the majority of models. The structure of numerical algorithms for the application of the model on a computer depends in many respects on the choice of a particular transformation mechanism (photochemical mechanism, reactions in drops, heterogeneous reactions, combustion processes), in order to take into account in the model of the atmosphere, and on the degree of its development.

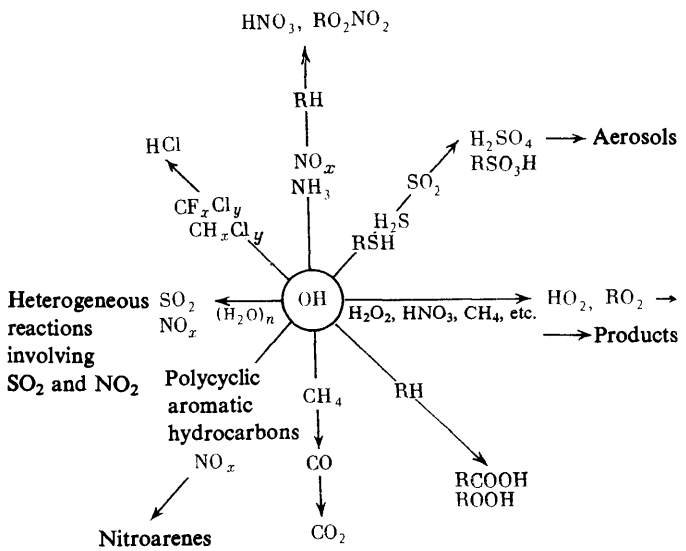
The modelling of a photochemical process consists of the following stages.

1. The formation of a data base of reaction rate constants and establishment of a system of kinetic equations.
2. Determination of the dependence of the rate constants on temperature, pressure, intensity of solar radiation, moisture, etc.
3. Establishment of a system of differential equations describing the kinetics of the processes.
4. Analysis of the characteristic time scales of the chemical reactions and estimation of the lifetimes of the species taken into account in the system of equations.
5. The study of the properties of the solution of the system of differential equations for specified reaction rate constants and initial concentrations of impurities.
6. Analysis of the sensitivity and the stability of the defining equations with respect to variations in the input parameters.
7. The selection of a scheme for the integration of the system of equations for the transformation of impurities. The study, on the basis of an analysis of the time scale and of the sensitivity of the model to variations in the input parameters, of the possibility of the "contraction" of the system of equations in terms of a specified criterion with retention of the material balance and of the properties of the solution.
8. Interpretation of the results of numerical modelling and their comparison with data derived from experimental studies and measurements under natural conditions. If necessary, the parameters of the models can be identified on the basis of factual information.

It is noteworthy that problems concerning the mathematical modelling of chemical processes occurring in the atmosphere are of independent interest from the standpoint of computational mathematics[17]. The systems of differential equations for their description are as a rule non-linear. The number of reactions in real problems may reach several hundreds and they occur at each point in a three-dimensional region against the background of relatively slow hydrothermodynamic circulation of the atmosphere. The reaction rate constants differ by several orders of magnitude. The systems of defining differential equations can be classified in terms of their properties as so called "stiff" systems. All the foregoing factors indicate the complexity of the solution of such problems on modern computers.

One of the convenient methods for the algorithmic application of the models is the cleavage method. The method is interesting because it makes it possible to model processes over a short time

interval in such a way that in one stage the calculation of transport proceeds in parallel and independently for each species throughout the region, while in another the set of systems of equations describing the transformation of the impurities at each point in space is solved for all the species simultaneously and independently of their solution at other points. Such organisation of the model makes it possible to reconcile the characteristic scales of different processes and to facilitate significantly the solution of problems of the parametrisation of impurity transformation processes when their characteristic time scales are short compared with the steps used in the specification of the model in a discrete form as a function of time. The computational algorithms then obtained are simple to apply and economical as regards the number of arithmetical operations.



2. Photochemical models of the troposphere

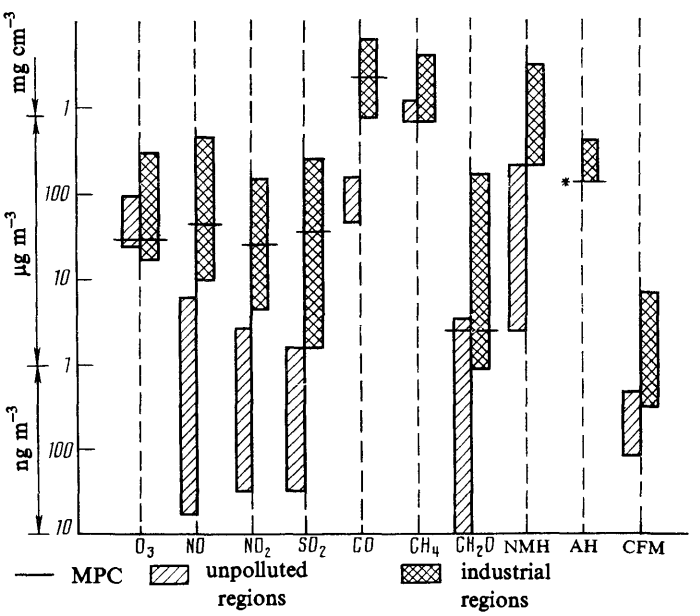
The chemical models of the troposphere are much more complex than the stratospheric models for a number of reasons. Firstly, much more complex impurity transport and diffusion processes take place in the troposphere, in which turbulence, characterised by a marked spatial-temporal variability, plays an important role. Secondly, owing to filtration by the ozone layer, only light at wavelengths longer than 290 nm penetrates into the troposphere. The primary photochemical processes therefore take place in the troposphere with different rate constants. Among them, the reactions involving the photolysis of ozone and of nitrogen oxides with formation of atomic oxygen are the most important. The reaction of $O(^1D)$ with the admixtures of water vapour in the atmosphere, i.e.

$$O(^1D) + H_2O \rightarrow 2OH$$

to form the hydroxyl radical OH, plays a key role in the chemistry of the troposphere (Scheme 1)[10-12]:

Scheme 1

The quantitative and qualitative composition of the impurities in the troposphere is incomparably more varied than in the stratosphere. There are considerable differences between the compositions of the atmosphere in the layer near the Earth's surface over different regions. Fig. 1 compares the concentrations of impurities typical for the air of unpolluted and industrial regions. The horizontal lines indicate the levels of the maximum permissible concentrations (MPC) recommended as health norms for quality of the atmosphere. Fig. 1 shows that the concentrations of the impurities vary by several orders of magnitude in both unpolluted and polluted atmospheres. The chemical compositions of the impurities in air over the oceans, forests, and desert are usually significantly different.



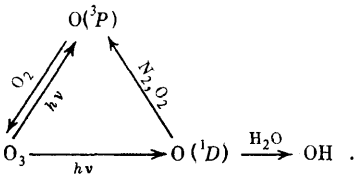


Figure 1. Concentrations of typical impurities in the air of unpolluted and industrial regions: NMH—non-methane hydrocarbons; AH—aromatic hydrocarbons; CFM—chlorofluoromethanes. *The maximum permissible concentration (MPC) of xylene, the most widely distributed aromatic hydrocarbon in cities, is indicated[8,14,15,62,63].

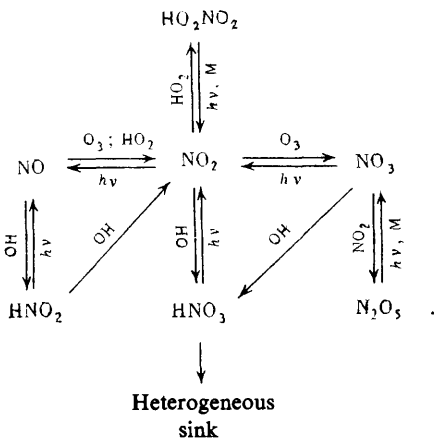
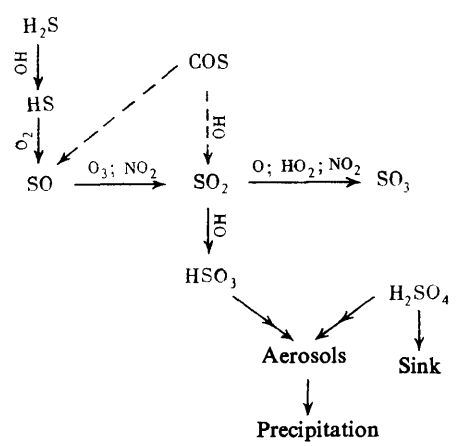
The concept of the "background" atmosphere, whose composition is recommended as a reference standard for the estimation of air quality, has therefore been adopted. In a polluted atmosphere, one uses for this purpose the values of MPC which can be adopted by convention as a norm of the "purity" of the polluted air. The modelling of chemical processes in the background and polluted atmospheres in different regions therefore constitutes problems with different degrees of complexity and the input parameters for their solution must be based on data for the composition of air in both the background atmosphere and the polluted atmosphere of a particular region.



(a) The background troposphere. The chemistry of the background troposphere is in many respects similar to the chemistry of the stratosphere. Thus the same reactions (Scheme 2–4) take place in the families of the O-, N-, S- and C-containing compounds as in the stratosphere, but the number of possible reaction pathways is greater and additional species appear as a consequence of the greater variety

of the impurities and of their concentrations in the troposphere. We may note that the halogens are actively involved in the chemical reactions occurring in air over the seas[10,13,49,63].



Scheme 2

Scheme 3

Scheme 4

Organic compounds occupy a special place in the photochemistry of the troposphere. Whereas only a few of relatively stable substances at low concentrations (for example, chlorofluoromethanes, carbonyl sulphide) penetrate into the stratosphere from the Earth, in the troposphere the situation is significantly different. An insignificant increase in complexity compared with the stratosphere is observed only in the atmosphere over the seas. Owing to the presence of terpenes in the air over forests, the scheme of the transformations of the impurities is supplemented by the reactions of terpenes with ozone and nitrogen oxides[63,64].

Hydrocarbons in general differ sharply in their reactivities and reaction mechanisms from other compounds. Their potential capacities to generate secondary contaminants are also not the same.

In such situations, it is necessary to take into account the multicomponent nature and the pronounced spatial-temporal non-uniformity of the distribution of these compounds. In the study of the photochemistry of the troposphere in the 1970s, the consideration of individual organic compounds was therefore replaced by the study of multistage photochemical mechanisms[32]. Proof of the validity of this treatment of atmosphere chemistry was obtained in numerous kinetic laboratory experiments and in smog chambers both in the investigation of simple mixtures and for real waste products[30,53,65–67].

Analysis of the results obtained in carrying out the programme of the Global Tropospheric Experiment[68–70] in order to test the existing photochemical models confirmed in many respects the validity of the ideas about the photochemistry of the atmosphere and has raised a number of problems requiring a more detailed study. Investigations of the atmosphere over polluted regions in order to develop a strategy for the monitoring of air in the atmosphere using mathematical modelling for such purposes belong to the range of studies of greatest current interest.

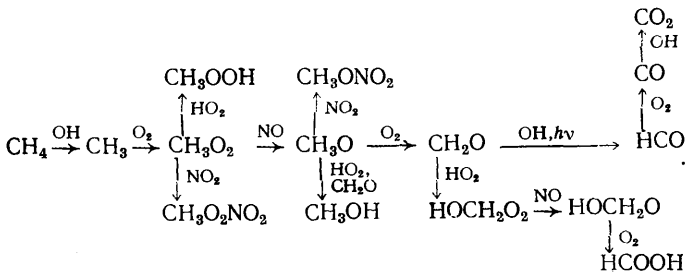
(b) Models of the atmosphere over polluted regions. The monitoring of the composition of the atmosphere over polluted regions revealed a series of factors which require interpretation, especially under smog conditions. Apart from carbon monoxide, nitrogen oxides, sulphur dioxide, and hydrocarbons, which are present at increased concentrations in automobile transport exhausts, in the flames generated in thermal electric power stations, and elsewhere, substances which are not characteristic of the primary industrial waste were also recorded, for example, peroxynitrates, organic sulphur- and nitrogen-containing compounds, organic acids, and peroxides. Furthermore, anomalies were noted in the diurnal variation of the concentrations of ozone[11,12,15,71]. This shows that secondary photochemical oxidants are formed in all kinds of photochemical smog[11,26,51,53,57].

Models of the chemistry of the atmosphere in areas with an increased anthropogenic input, characteristic of industrially developed regions, make it possible to describe the dynamics of the appearance and development of smog situations. As an example, we shall describe briefly one such model of the transport and transformation of impurities against the background of the hydrometeorological regime of an industrial region[17,72,73]. Its structure is typical for models of this class known in the literature[18,19]. Two versions of calculations are usually employed—in the linear and non-linear approximations, and the model is as rule tested in relation to the most typical waste ejected into the atmosphere in industrial regions—SO_2, NO, NO_2, CO, CH_4, and CH_2O. The chemical reactions of these compounds are initiated by sunlight which results in the activation of photoactive molecules, for example, SO_2, NO_2, and CH_2O. Atoms and free radicals as well as certain products together with the initial waste participate in the intermediate stages of the chemical reactions.

The linear approximation is based on the application of the method of quasi-stationary concentrations of active species (atoms, free radicals, and electronically excited molecules). The reaction rate constants used in the calculations are available in familiar handbooks on atmospheric chemistry[22,23,74]. Apart from atoms and free radicals, the photochemical reactions result in the appearance and accumulation of products which were not present in the initial

waste, for example, nitric, nitrous, and sulphuric acids as well as hydrogen peroxide.

The non-linear model is used in calculations for the set of reactions of nitrogen, sulphur-, and carbon-containing compounds most characteristic of the atmosphere in industrial regions.



In mathematical models, there is a possibility of different modifications in the descriptions of the mechanisms of the transformation of organic compounds. A classification of hydrocarbons into three groups was adopted in 1977: alkanes, alkenes, and aldehydes[32]. Aromatic compounds have not been considered separately hitherto. Among all these compounds, the photochemistry of methane has been studied in greatest detail in view of its possible climatic consequences[2,75,76].

For these purposes, a simplified scheme of the reactions of methane is usually considered:

$$CH_4 \rightarrow CH_2O \rightarrow CO \rightarrow CO_2 .$$

It is employed, for example, in global models in estimating the greenhouse effect. High concentrations of CH_4, CH_2O, and CO and more complex combinations of impurities in the polluted atmosphere require a more complete methane oxidation scheme (Scheme 5). This is necessary in the assessment of the overall toxicity of the air in polluted regions. Analysis of the results obtained within the framework of both simplified and complete methane oxidation schemes[73] revealed the necessity to increase the number of methane reactions considered under the conditions of polluted air. The complete computational scheme takes into account about 200 elementary stages, while in the simplified scheme the number of such stages is only 40.

Scheme 5

As a consequence of the non-linearity of the problem being solved, it is of interest to elucidate the influence of the level of waste products on the final chemical composition of the contaminated air. Certain examples of such calculations are presented below. In the first of these (Fig. 2), the amount of CH_4 waste varies over three orders of magnitude. It is found that the increased amount of methane emitted is accompanied by a non-linear growth of the concentrations of peroxides, formic acid, and carbon dioxide. The dependence of the yield of products on the amount of formaldehyde waste is more complex (Fig. 3). The concentrations of many intermediate and final products [$O(^3P)$, O_3, OH, HO_2, NO_3, CH_3O_2, H_2O_2, CH_3OH, CH_3OOH, HCOOH, HNO_2, HNO_3, HO_2NO_2 (Fig. 4)] are influenced by the level of waste nitrogen dioxides. The dependence on NO_x is non-linear. This is manifested in two ways: the content of the acids HNO_2 and HNO_3 increases and that of other products—peroxides, organic acids, and peroxynitrate—falls. The concentration of ozone changes little under these conditions, because only the NO_2/NO ratio is important in determining it.

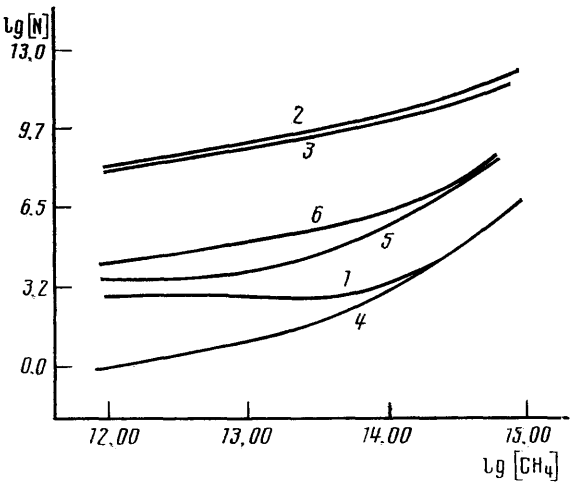


Figure 2. Logarithmic dependence of the formation of H_2O_2 (curve *1*), CH_2O (curve *2*), CO (curve *3*), CH_3OOH (curve *4*), HCOOH (curve *5*), and CO_2 (curve *6*) on the methane concentration (cm^{-3}) for t = 12 h (the accompanying concentrations are 10^{11} cm^{-3} for NO_x and 2.6 × 10^{11} cm^{-3} for O_3) [73].

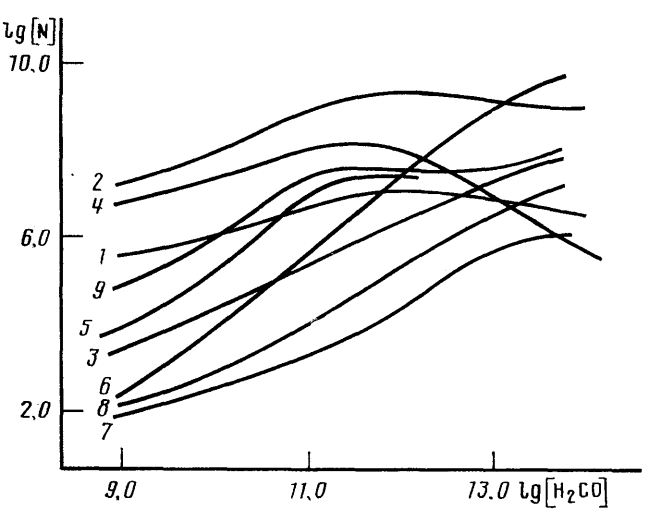

Figure 3. Sensitivity of the OH (curve *1*), HO_2 (curve *2*), CO × 10^{-7} (curve *3*), CH_3O_2 (curve *4*), CH_3OOH × 10^{-3} (curve *5*), HCOOH × 10^{-4} (curve *6*), CH_3ONO_2 × 10^{-4} (curve *7*), HO_2NO_2 × 10^{-5} (curve *8*), and CH_3OH (curve *9*) concentrations to variations in the amount of formaldehyde on the logarithmic scale for t = 12 h (accompanying concentrations 10^9 cm^{-3} for NO_x and 3 × 10 cm^{-3} for CH_4) [73].

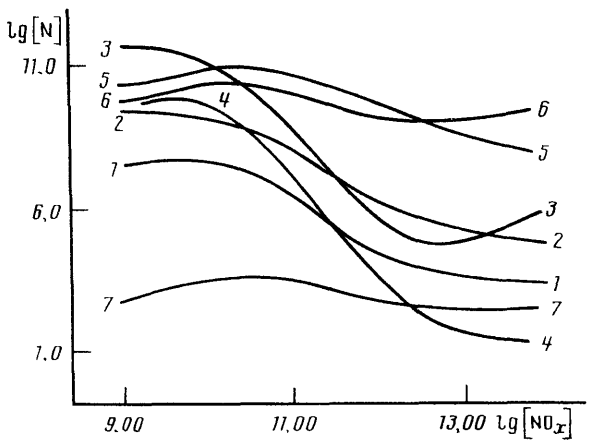

Figure 4. Sensitivity of the CH_3O_2 (curve *1*), HO_2 (curve *2*), H_2O_2 (curve *3*), CH_3OOH (curve *4*), HCOOH (curve *5*), HO_2NO_2 (curve *6*), and CH_3O (curve *7*) concentrations to variations in the amount of NO_x on a logarithmic scale for t = 12 h (accompanying waste products 2 × 10^{13} cm^{-3} for CO, 3 × 10^{13} for CH_4, and 2.4 × 10^{11} cm^{-3} for CH_2O) [73].

Fig. 5 shows that under polluted conditions, the diurnal variation of the concentration of OH radicals did not follow exactly the diurnal movement of the sun in the chemistry of both the stratosphere and the background troposphere—its maximum may be observed also at other times in the morning and in the evening.

Thus consideration of the photochemical oxidation of methane alone in a polluted atmosphere shows how great is the increase in the complexity of both the problem itself and of the conclusions reached on its basis and of their interpretation. Fig. 6 presents an example of such a calculation under urban conditions.

Experience has shown that one cannot transfer mechanically the results of calculations, obtained using a model adapted to a particular region, to other regions. The marked non-linearity of the process (i.e. the dependence on the concomitant impurities, for example nitrogen oxides) does not allow the fitting of simple relations to its rate.

The photochemical model was developed further in the 1980s when a data base for non-methane hydrocarbons was created, which made it possible to introduce the latter into the mathematical models for different levels[28,76–81]. As a consequence of this, the degree of understanding of the principal features of the dynamics of photochemical smog increased. A special place has been assigned recently to the chemistry of the nighttime atmosphere as an after-effect of the daytime photochemistry. In these processes, a leading role is attributed to the NO_3 radical, whose maximum concentrations are observed in the atmosphere after sunset[22].

Since the majority of the models involve very laborious computations, one usually endeavours to simplify as far as possible the schemes for the chemical reactions of organic impurities. It is noteworthy that, before simplifying the reaction scheme, it is desirable to carry out calculations within the framework of the most complete scheme and to make sure with the aid of tests that the simplified scheme reproduces the principal results in conformity with the aims of the investigations.

Calvert and Madronich[79] recently examined the detailed chemical mechanism of the oxidation of hydrocarbons in the atmosphere. It included 26 alkanes (C_1-C_8), alkenes (ethylene and propene), aromatic hydrocarbons (benzene, toluene, and xylenes), and terpenes (isoprene and α-pinene). It was shown that, in the absence of nitrogen oxides and in the presence of NO_x at appreciable concentrations in the atmosphere, the oxidation products are significantly different. A rigorous specificity of the products, their concentrations, and their lifetimes is expected for each class of hydrocarbon depending on the conditions, which may serve as a useful indicator of the behaviour of air masses as a function of time.

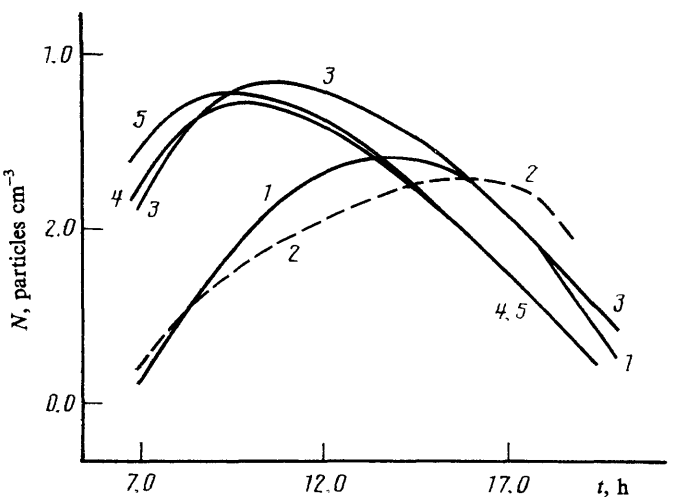

Figure 5. Diurnal variation of the concentrations of the hydroxyl radical OH as a function of the NO/NO_2 ratio (accompanying concentrations 3 × 10^{13} cm^{-3} for CH_4, 2 × 10^{13} cm^{-3} for CO, and 2.4 × 10^{11} cm^{-3} for CH_2O): *1*, [OH] = 0.5 × 10^{-6} cm^{-3} (10^{14} cm^{-3} for NO, 10^{12} cm^{-3} for NO_2); *2*, [OH] = 2 × 10^{-6} cm^{-3} (10^{13} cm^{-3} for NO, 10^{12} cm^{-3} for NO_2); *3*, [OH] = 0.4 × 10^{-5} cm^{-3} (10^{12} cm^{-3} for NO, 10^{12} cm^{-3} for NO_2); *4*, [OH] = 3 × 10^{-6} cm^{-3} (10^{11} cm^{-3} for NO, 10^{12} cm^{-3} for NO_2); *5*, [OH] = 0.8 × 10^{-6} cm^{-3} (10^{11} cm^{-3} for NO, 10^{11} cm^{-3} for NO_2). {Note by Ed. of Translation: all exponents for [OH] should be positive not negative}.

Another aspect of the chemistry of organic substances in the atmosphere was developed by Atkinson and co-workers[74,77,78]. Comparison of the reactivities (rate constants for the reaction of the OH radical) with the physicochemical properties of organic molecules (ionisation potentials, electrophilic substitution constants, etc.) yielded empirical relations for the calculation of the rate constants for reactions of compounds of different classes with free radicals and ozone. Correlations were discovered between the rate constants for reactions occurring between the OH radical and $O(^3P)$ and also between the NO_3 radical and ozone. This approach makes it possible to estimate the rates of reactions and the lifetimes of many organic compounds and their homologues in the atmosphere and to formulate the principal schemes for the reactions of organic impurities in a polluted atmosphere.

Theoretical studies in the field of tropospheric chemistry of organic compounds have served as a basis for the estimation of the potential toxicity of the entire set of impurities. They are useful in the consideration of pathways leading to the decomposition of substances, for the estimation of their lifetimes in the troposphere, and for the possibility of the appearance and further transformation of secondary products.

IV. Analysis of the sensitivity of the models

The study of the sensitivity of the models to variations in the input parameters and in the rate constants for individual reactions is an essential stage of numerical modelling. It includes the calculation of the partial derivatives of a specified set of characteristics and the estimation of the changes in the functions of state of the model process in terms of the investigated parameters. Here several approaches are used, which make it possible to elucidate the relative significance and the degree of uncertainty in individual stages of the complete scheme, the possibility of its simplification, and also the trends in the development of the principal relations[67,76,83–91]. Such approaches include the direct modelling method, methods based on the solution of variational problems, variational methods using coupled problems, and modelling of the response of the system to specified perturbations.

The simplest and frequently employed procedure is the direct modelling method. It is based on repeated solutions of the defining system of equations with variation of the input parameters. However, repeated solutions become impractical in complex systems with many parameters.

The principal uncertainty in the photochemical mechanism involves the estimation of the rate of photolysis of compounds under real conditions. A clear example is provided by the photolysis of acetone. It was found that in the atmosphere the quantum yield of this reaction is only 0.08–0.15 [69] instead of 1, obtained under laboratory conditions[92]. Demerjian et al.[92] tabulated certain data in the photolysis of a number of molecules as a function of the latitude and the zenithal angle under real atmospheric conditions, but the absorption cross-sections of the molecules and the quantum yields of the photochemical reactions of many compounds have not yet been adequately investigated. The uncertainty is enhanced by the hydrometeorological conditions, for example, the cloud cover.

Whereas the rate constants for reactions involving inorganic compounds have been studied in fair detail, as regards reactions with organic impurities there are considerable uncertainties both in the rate constants and in the products themselves. In 1979, Seinfeld and co-workers[83] analysed the uncertainties in the photochemical mechanism and outlined the priorities in their investigations. Over ten years, there has been considerable progress in these fields: the reactions of ozone with alkenes and the products formed under these conditions were investigated in detail and the parameters of the formation and decomposition of peroxynitrates were refined. In the field of the reactions of aromatic compounds in the atmosphere, qualitatively new and important information has appeared[11,12,23,71,77,93]. The progress which has occurred in the measurement of photochemically active impurities in the atmosphere has made it possible to determine with greater accuracy the initial parameters of the models[68–71].

Analysis of the sensitivity and uncertainty of individual stages of the complete reaction scheme is a useful aid to the formulation of experiments and identification of the parameters exerting the greatest influence on the quality of the prediction. The "counter species" technique has been used[28] for the analysis of complex mechanisms with a large number of stages which makes it possible to test the internal self-consistence of the complex reaction mechanism under different conditions.

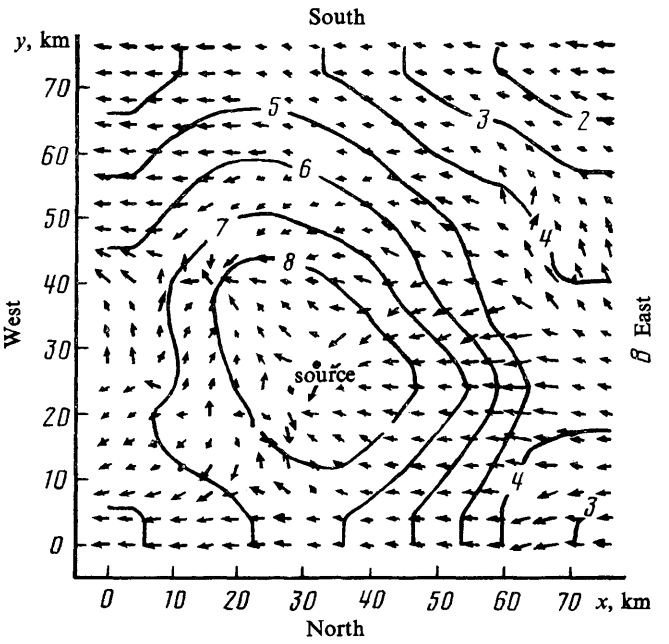

Figure 6. Contours for the variation of the concentrations (continuous lines) of hydrogen peroxide H_2O_2 (on a logarithmic scale) and of the vector field $\mathbf{V} = |V^2 + U^2|$ (arrows) for $t = 12$ h under urban conditions[73].

Studies on the sensitivity of different schemes used in models have thrown light on many questions, for example, on the contribution of aldehydes and aromatic hydrocarbons to the conversion of NO into NO_2, and have made it possible to compare several versions of the schemes describing the system and to formulate the principles of the arrangement of hydrocarbons in groups without prejudicing the quality of the prediction.

V. Models of chemical reactions of impurities in drops and clouds

One of the serious global problems is the formation of acid residues as a consequence of the pollution of the atmosphere by gaseous impurities, which lead to the formation of acid products—the inorganic acids H_2SO_4, HNO_2, and HNO_3, and organic acids, for example HCOOH. Recently the problems of the modelling of such processes have been attacked vigorously[76,94–97]. The gas-phase photochemical reactions examined above precede the acidification reactions and the alteration of the chemical composition of drops. In these models, it is essential to consider in addition the

processes involved in gas–liquid phase equilibria[11,98] and to take into account the possibility of the occurrence of heterogeneous and liquid-phase reactions. For example, in the interpretation of the results of observations in nature for the content of sulphate in precipitates, it proved insufficient to examine only the gas-phase transformations of sulphur dioxide into sulphates with subsequent dissolution and the concept of the chain mechanism of the oxidation of sulphur dioxide in the liquid phase was therefore invoked[99].

The oxidation of NO_2 to HNO_3 in clouds is now considered not only from the standpoint of photochemistry but to a large extent the idea of the reactions of nitrogen oxide in the dark, the so called "night chemistry"[82,97], is also invoked.

Overall, mathematical models throw light on the characteristic features of the formation of acid deposits and their transport processes on both global and regional scales and reveal the possible ecological consequences of these precipitations, for example, the causes of the large scale destruction of forests[3,5].

It is noteworthy that a specific feature of the construction of these models involves the need to build into the model the occurrence of microphysical moisture transformation processes in the atmosphere, self consistent in terms of space-time scales, which itself constitutes a fairly complex physico-mathematical problem.

VI. Characteristic features of the mathematical models of the photochemical formation of aerosols

Phenomena in the climatic systems such as the existence of an aerosol layer is the upper troposphere (for example, the Junge layer) and the decrease in the transparency of air in regions with increased gas-phase pollution are associated under certain conditions with aerosol formation processes under the influence of light[4,11].

The precursors of the relatively involatile products (stimulators of the formation of aerosols) are gas-phase photochemical reactions whose modelling was considered above. The modelling of aerosol formation is therefore a natural development of the models of the transformation of impurities designed to follow the sections of geochemical substance transformation cycles occurring in the atmosphere from the instant of their formation to the instant of their disappearance, because the concentrations of impurities in air are a result of a dynamic equilibrium between their sources and sinks.

For the modelling of the kinetics of the formation of atmospheric aerosols and the establishment of their particle dimensions and chemical composition, it is necessary to take into account the chemical processes leading to the appearance of aerosol products, the transport of gases to the surfaces of the particles, the appearance of new particles as a result of nucleation and coagulation, and equilibrium between the particles and the local gas composition of the medium[11]. The key problems in the modelling of the evolution of the urban aerosol have been solved in a series of studies[52,58,100–105]. The combination of such a model with a three-dimensional model of atmospheric dynamics has made it possible to compare the results of calculations with measurements in nature. The model predicts the daytime and nighttime compositions of the inorganic aerosols for different humidities and permits the estimation of the influence of volatile organic components. For example, it has been concluded that the formaldehyde impurity in clouds inhibits the formation of sulphates and stimulates the formation of formic acid[106]. A sectional model of aerosol dynamics has been developed[107] and the results of modelling have been compared with the results of experiments carried out in smog chambers.

VII. The use of mathematical models for monitoring the quality of air

This section presents certain examples of the application of mathematical models using the photochemical mechanism in the development of a strategy for monitoring the quality of air.

The involvement of sulphur dioxide in the photochemical mechanism has been analysed[53,108]. Determinations, under natural conditions, of the structure and evolution of a plume which contains SO_2, NO_x, and hydrocarbons are inherent in the model taking into account both the photochemistry and the transport processes of these compounds. The rate of conversion of sulphur dioxide into sulphates usually observed in a polluted atmosphere increases from 1–4% per hour (in plumes with a high content of hydrocarbons) to 12–13% per hour. Comparative analysis of the results of measurements and calculations yielded a satisfactory explanation of the sharply rising rate of oxidation of SO_2. It is attributed to the notable influence of hydrocarbons on the transfer of the chain reaction from hydroxyl radicals to peroxy-radicals. It is to be expected that this mechanism can lead to an increase in the rate of reaction of SO_2 to 40% per hour[99].

An especially large amount of attention has been devoted to the elucidation of the problem of the formation of ozone in the atmospheres of polluted regions[12,55,60–62,89,108]. This is due to the fact that ozone belongs to the class of the most significant indicators of air quality and is a representative measure of the secondary pollution of the atmosphere as a result of photochemical reactions[44,45,108–113].

Models corresponding to different levels are used to investigate the chemistry of ozone. Thus the dependence of the concentration of ozone on the ratio $[HC]/[NO_x]$ was investigated in a study[56] where twelve hydrocarbons (HC) were considered. It was found that, for low values of this ratio, the nature of the hydrocarbons themselves is important, while for high values the formation of ozone is limited by the concentration of nitrogen oxides. In another model[55], account was taken of 37 hydrocarbons, 169 species, and 320 reactions. Here attention was concentrated on the characteristic features of the hydrometeorological regime in the atmosphere and on different concentrations of the gases in the sources of pollution. The contribution of individual sources and of different classes of compounds to the formation of ozone was estimated. It was concluded that the exhausts from automobile transport is the most important source.

A regional model, whose development was initiated by the observation of anomalous concentrations of ozone in the atmospheres of polluted regions, constitutes the basis of a strategy for the monitoring of exhaust waste products in the USA. It describes the dynamics of atmospheric and chemical processes on different scales—from global to local. The content of ozone and its diurnal variation are being predicted and the sources (ozone precursors) not taken into account hitherto are being discovered. The very detailed specification of the model helps in its employment for practical purposes on a regional scale[44,45].

A model proposed by Thompson et al.[89] is devoted to the problem of the chemistry of ozone in the troposphere. Here emphasis is laid on the interrelation of the consequences of pollution by methane, carbon monoxide, and nitrogen oxides. It was shown how specific features of the injection of one impurity lead to changes in the concentration of O_3, which depends on the level of the remaining impurities. A hybrid model has been developed[108] for the estimation of the behaviour of waste products from different point sources.

It combines the treatment of data obtained in measurements under natural conditions with subsequent calculation. The conclusions for the development of a monitoring strategy and for the improvement of the quality of the prediction are that in smog situations the normalisation of the ozone content requires in the first place a decrease in the amount of non-methane hydrocarbon waste, while the level of pollution by nitrogen oxides is less important. This conclusion concerning the priority of measures to be taken to reduce the hydrocarbon waste products was reached also in other investigations. Studies in recent years have demonstrated the importance of monitoring hydrocarbons in order to develop the optimum strategy for the improvement of air quality.

A scientific strategy for the monitoring and control of air quality has been developed on this basis. The use of mathematical models combined with a monitoring system makes it possible to predict the chemical situation and to elucidate the key features in its establishment and also to formulate the necessary program of observations. In the development of measures to protect nature, mathematical models constitute a convenient instrument for reconciling economic, chemical, geophysical, and other aspects of this problem.

VIII. Conclusion

Thus mathematical modelling helps to expand the possibilities of studying the reactions of chemical compounds starting from the instant of their entry into the atmosphere to their removal from the atmosphere. Further progress in atmospheric chemistry can be achieved provided that programs for experimental measurements of the chemical composition of the atmosphere and of the rates of chemical reactions are improved and also provided that combined chemical and hydrothermodynamic models are developed in order to investigate the turnover of substances and the interaction of chemical and geophysical processes in the atmosphere. The joint consideration of atmospheric processes together with the dynamics of chemical reactions makes it possible to specify the phenomena which are responsible for the reactions of chemical substances under the influence of natural and anthropogenic factors.

Numerical modelling is used widely as an instrument for the study and development of a strategy for the monitoring of pollution and for the improvement of the quality of air in order to prevent negative ecological consequences. Since this problem has many aspects and is interdisciplinary in character, a promising approach to its solution involves the creation of expert systems for the control of the quality of the natural environment based on logical mathematical models of physicochemical and climatic processes coupled with an ecological monitoring system.

Emission of toxic metals into the atmosphere and their accumulation in the surface layer of the Earth

S G Malakhov, E P Makhon'ko
Institute of Experimental Meteorology 'Taifun' Combine, Obninsk

ABSTRACT. Natural emissions of metals and certain metalloids into the atmosphere are compared with anthropogenic emissions. The physico-chemical properties of metal-containing aerosols are discussed from the standpoint of the danger of environmental pollution and the distances to which these metals get dispersed in the atmosphere. The results of pollution of objects in the environment with metals on local, regional, and global levels are analysed. An assessment is made of the likely future pollution of the soil with metals.

The bibliography includes 221 references.

I. Introduction

Polution of the environment by toxic metals and their compounds is a problem with several specific features. It is common knowledge that metals and other elements are subject to natural processes of migration and circulation. They systematically enter the atmosphere from terrestrial and ocean surfaces and from the space. They are also emitted by volcanic eruptions, forest fires, and other natural phenomena. Metals enter the atmosphere and disperse in it; then, after being washed out and precipitated, they are once again deposited on land and ocean surfaces. Human activity leads to additional amounts of these metals—some of them toxic—being extracted from the interior of the Earth and transported into the biosphere. As a result in certain instances environmental pollution may reach levels that are dangerous not only to the biota but also to humans. There is also an increased flow of toxic metals into layers of the biosphere supporting life and an interference with natural circulation of these metals. The picture of pollution of the biosphere and individual ecosystems is complicated by the fact that several metals and trace elements are necessary for the life-supporting processes in the biota. There are many geochemical regions on the Earth where biological objects experience a shortage of certain elements, including metals. Here the introduction of additional amounts of these elements has a beneficial effect on the biota, not a detrimental one. To assess the danger of introducing extra amounts of metals into the environment we shall use the concept of maximum permissible concentration (MPC) in each individual case. For soil we shall also make comparisons with natural background pollution.

We shall make a distinction between local pollution around the source of emission (to a distance of several kilometres, or several tens of kilometres, regional pollution (to a distance of several hundred or thousand kilometres), and global pollution (on a hemispherical or global scale). The high levels of environmental pollution in specific localities and areas where metals are processed or mined are very worrying, of course. But human activities today are conducted on such a large scale that it is the danger of global environmental pollution that has become the acute problem. Metal pollution of the environment on a global scale does not have, as yet, such tangible negative consequences as the rise in atmospheric concentrations of CO_2 or freon. But one should take into account the dynamics of global changes in metal content.

In this review we shall concentrate on pollution of the environment with such metals as Pb, Cd, As, Hg. Nature preservation experts believe that these metals should be the first to be studied.[1,2] We shall also discuss several toxic elements presenting first- and second-degree danger (Se, Cu, Co, Ni, Cr, Sb).[3] In individual cases we shall discuss, for comparison, data on certain trace elements.

II. Comparison of natural and anthropogenic sources of metals and some metalloids emitted into the atmosphere

Under natural conditions metals and metalloids are introduced into the atmosphere in the form of aerosols and vapours. These originate from dust swept up by the wind from the surface of the soil (wind erosion), from volcanic eruptions, forest fires, and cosmic dust. They also originate from the transfer of these elements through the ocean surface, from the flow of submicrometer particles and cold emission from vegetative cover, and from evaporation from the Earth's surface. It is customary to estimate the natural input of metals in the form of aerosols into the atmosphere by the product of the total amount of dust from a specific source and its elemental content. This product is expressed as mass fraction. The averaged composition of aerosols of various origins is given in the literature.[4–6] Data on the amount of dust annually emitted by natural sources into the atmosphere has wide variations: according to some it is 150–1500 million tonnes,[6] according to others it is 740–3400 million tonnes.[4] On the average wind erosion produces annually 500 million tonnes of dust (according to various authors from 200 to 1000);[4,7] volcanic eruptions produce 150 (10–200) million tonnes; forest fires 130 (20–50) million tonnes; the ocean 1000 million tonnes;[4] and vegetation from 75 to 1000 million tonnes.[7] It has been suggested that because of the rapid removal of sea salt from the

atmosphere only 10% of the amount emitted into the atmosphere is carried to the continents.[8,9] The estimates for cosmic dust are highly contradictory. On the one hand, even according to highest estimates, only the inflow of 'cosmic' nickel is comparable to the amount of this element brought into the atmosphere by soil dust.[4] On the other hand, some consider that it has been precisely the inflow of cosmic dust that has built up the trace element composition of the aerosols, the soil, the ocean, and the vegetation over many thousands of years.[10,11] In that case it is not meteoric matter but comet matter that would be the main source. This hypothesis raises some doubts because the concentrations of elements in the atmosphere over continents, over the ocean, and in polar regions differ widely. The emission of aerosols into the atmosphere by vegetation has been experimentally confirmed.[12–14] The fluxes of various elements from this source are as follows: Pb, 1.6; Cu, 2.5; Ni, 0.8–1.6; Cd, 0.2; As, 0.26; Se, 0.14; V, 0.2 thousand tonnes per year.[7,15,16] It is difficult to estimate the elemental composition of the emissions from the composition of the source itself because of fractionation. Thus, the amount of trace elements (Ag, Cu, Zn, As, Sb, etc.), compared to the amount of Fe, is considerably higher in the dust-forming soil particles than their average content in the surface layer of the soil.[17] Similar fractionation at the atmosphere–ocean[18–20] interface is due to the different degrees of enrichment (10–20 fold) of the ocean surface film with various elements. This is also due to different concentrations of these elements in the walls of bubbles formed in a rough sea.[8,21,22] Because of the high temperatures that develop in forest fires and volcanic eruptions it is mainly volatile elements that are emitted into the atmosphere.[4,8] Direct measurements of local concentrations of elements in the smoke produced by forest fires and in volcanic ashes show that these concentrations may differ by an order of magnitude or even more.[5,7]

A number of metals and metalloids may enter the atmosphere in gaseous phase. Thus, from 0.04[21] or 0.09[4] to 0.16 thousand tonnes of aerosol mercury is emitted into the atmosphere annually.[25] The source of gaseous selenium in the atmosphere are selenium-containing organic substances.[26–28] The gaseous fraction of elements (in relation to the total amount of each element) emitted in volcanic eruptions) is large: for Hg it is 64–78%; for Cd 25–40%; for Zn 22–36%; for Pb 4–7%; for As 33–49%; and for Sb 74–85%.[8]

The above data indicate that there is no single way of estimating the natural inflow of metals into the atmosphere. Of the values given by different authors only those for the trace elements brought into the atmosphere with soil dust are more or less in agreement. The greatest differences are in values obtained for elements introduced into the atmosphere in aerosol or vapour form; also for elements emitted in volcanic eruptions or forest fires.[5,7]

The most convenient way to estimate anthropogenic emissions of metals and metalloids into the atmosphere is by the amount of each element emitted per unit of it produced or per unit of fuel burnt (Table 1). Another method is used for aerosol emissions: it is based on the average concentration of metals in the dust of large cities all over the world and the global emission of industrial dust into the atmosphere. The anthropogenic emission of aerosols into the atmosphere obtained in this way is the product of these values.[4,6] The wide scatter of values for global anthropogenic emissions is due to several factors: different estimates of the total amount of emitted industrial dust and of the concentration of metals in it; different production technologies and different levels of waste purification; the difficulty of estimating emissions in vapour phase; the fact that the account emitted depends on the temperature of the source and volatility of the element.[4,5] Below we give a few examples of uncertainty in the initial data used for calculations. According to

Table 1. Emission of toxic metals per unit of production.[5,12,25,29,30]

Source of emissions	Units	As	Cd	Cr	Ni	Pb	Sb	V	Zn	Cu
Thermal power										
burning of coal	mg MWh^{-1}	42–170	18–54	310–1200	340–1470	240–2600	33–140	210–1000	216–1280	220–1000
burning of liquid fuel		87	44	155	3700	450		13 300	325	620
Industrial combustion of fuel										
coal	g $tonne^{-1}$	0.3–1.3	0.1–0.7	1.7–12	2.2–14.5	0.5–7.2	0.2–1.4	1.2–9.7	1.7–11.4	1.4–9.8
liquid fuel	g $klitre^{-1}$	1.2	0.4	7	52	6.4*		187	4.5	8.8
Refuse incineration	g $tonne^{-1}$	0.52	2.1	1.1	0.33	18–50	4.55	25	260	3.7
Burning of wood	g $tonne^{-1}$	0.3–0.5	0.2–0.3		3.1–4.7	4.7–7.0			39–58	12–19
Nonferrous metallurgy	kg $tonne^{-1}$	0.4–3.0	0.2–1.3			0.3–6.4				
Primary metal production	kg $tonne^{-1}$									
zinc, cadmium		0.6	0.1–0.5			1.2–25			15.7–17.6	0.14
copper, nickel		1–3	0.2–1.3		9	2.3–3.6	0.1		0.84–0.97	1.7–3.6
lead		0.18	0.002–0.005		0.09	3–7.7			0.11	0.06–0.07
Production from scrap metal	g $tonne^{-1}$									
copper			4.0			54–214	3		500–1630	150
zinc									9000	
lead			2.5			770			300	
Ferrous metallurgy		6–8	0.08–0.4	4–40	1.3–10	38–60			20–155	0.5–4.5
Mining of metal ores	g $tonne^{-1}$	0.1	0.5		9000	910			0.1**	100

*The emission of lead from the combustion of petrol containing tetraethyl lead is 0.37 g $litre^{-1}$.[25]

**Calculated per gramme of mined Zn + Cu + Pb.

Ostromogilskii et al.[4] the total emission of industrial dust is 80 million tonnes per year, whereas according to Izrael' et al.[6] it is between 60 and 600 million tonnes. Besides, the elemental composition of the ore or fuel (even the same type of ore or fuel) depends to a great degree on where it has been minded.[31] There is no reliable estimate of the fraction of the metals contained in raw materials and fuel that is emitted into the atmosphere as a result of industrial processes. According to Ostromogilskii et al.[4] when coal is burnt, about 10% of the Al, Co, Fe, Mn, and Sc that it contains is emitted into the atmosphere. For Cr, Cu, Ni, and V the amount is about 30%; for As, Br, Hg, Sb, and Se it is close to 100%. The gas-phase component for these elements in the emissions from metallurgical works is up to 30% for Cr, Se, Br, and Cd; up to 70% for As; and up to 100% for Hg. As a rule, the largest emissions of metals into the atmosphere come from iron-and-steel works and nonferrous metal works and by plants that burn fuel.[32] The Pb emissions come mainly from motor transport.[5]

Table 2 gives generalized data on the emission of metals and metalloids into the atmosphere from natural and anthropogenic sources. Our expert estimates of the emissions of elements into the

Table 2. Emission of elements from natural and anthropogenic sources into the atmosphere.

Element	Main sources of emission		Natural emissions,*1 1000 t year^{-1}	Anthropogenic emissions,*1 1000 t year^{-1}	Mobilization coefficient*2	Refs.

*1 The upper numbers give our estimate, the lower ones—the scatter of values obtained by other authors.

*2 The ratio of anthropogenic emissions to natural emissions.

*3 The values in parentheses take the gas fraction into account.

*4 The maximum estimate of the large emission of the element from the ocean into the atmosphere.[8] According to Ref. 22 this emission was even larger (170×10^8 t year^{-1}).

*5 The estimates in parentheses take into account the destruction of organic matter, especially in the oceans.[25] According to a similar estimate,[35] it is 48×10^3 t year^{-1}.

atmosphere that are listed in Table 1 were obtained by taking account of the density of distribution of values quoted by different authors.

These data apply to 1979–1980. Data are available in the literature on the emission of metals in certain European countries[7,29] and in certain regions of the USSR.[39] It should be noted that 77–87% of Pb, Cd, Hg, and As emissions occur at the latitude of 30°–70° north.[25,33,37]

Metals and metalloids with a mobilization coefficient over 1.0 can be arranged in the following sequence:

$$Sb > Ag > Pb > Se > Cd > Cu > Zn > As > Ni > V.$$

Metals with a mobilization coefficient under 1.0 can be arranged in the following sequence:

$$Fe, Al < Hg < Mn < Co < Cr.$$

There may, of course, be a much greater contribution of anthropogenic emissions on a regional and local level.

III. Physicochemical properties of aerosols

To get a correct picture of the scale and the pattern of distribution in the environment of metals and other elements that are emitted into the atmosphere and of the danger they pose to man and the biota we need data on a whole range of physicochemical properties of aerosols that contain these elements.

Vapour and aerosol-phases

Conventional air filters for aerosols (Petryanov filters, for instance) usually do not trap gaseous and fine submicrometer particles. Therefore if activated carbon[40] or a freezer set to −50 to −60 °C[41–43] is mounted behind the filter, it is possible to assess the fraction of metals and trace elements present in the atmosphere in the form of vapour or finely dispersed aerosols. Mercury has the highest fraction, from 70 to 99% of the total content.[44–46] This fraction increases as air temperature rises and decreases with growing dust content. In Japan seasonal changes have been noted in the concentration of mercury: the total concentration of mercury in the air and the fraction of it in the gas phase and in submicrometer particles is lower in winter than in summer.[47] Of the eighteen trace elements discussed in the literature,[40–42,48] Fe, Sc, Mn, V, Ba, occur mainly in the aerosol phase (over 70%). The fraction of As, Se, Br, Ag, Cd in the gas phase and submicrometer particles often exceeds 50% of their total content. The same is true for lead emitted by car engines, though its fraction fluctuates widely.[49] The aerosol fraction of Co, Cu, Zn, and Sb is low in some cases and very high in others. In the air of industrial towns the contribution of the aerosol fraction seems to be greater. Thus, in Frankfurt the aerosol fraction of Fe, Cd, Pb, Mn, and Cu is not less than 90%.[50] In the cities of the USA 96–98% of As occurs in the form of aerosols.[51] Near the ocean this value drops to 93.5%.

Density of aerosol particles

In most calculations and measurements the density of particles that contain metals and trace elements, is usually taken to be constant and equal to 1–2 g cm^{-3}. But in reality it does depend on the size of the particles. According to Watson et al.,[52] finely dispersed aerosols have a density of 1.7 g cm^{-3}, whereas that of coarsely dispersed aerosols is 2.6 g cm^{-3}. In a detailed study[53] it was noted that the density of the particles had a tendency to increase as they grew in size. Thus, if the particles are subdivided according to size into different ranges and the relationship between Fe, Mn, Zn and Cu content in the aerosol and the particle density is plotted for each range, in the range with larger particles the distribution maximum will shift to the region of denser particles. In that case the maximum will become broader. In some cases there may be two distribution maxima. Thus, one maximum for Fe, Mn, Zn and Cu occurs at a density of 2.5–2.7 g cm^{-3}, while another occurs at a density over 3.3 g cm^{-3}. As a rule the denser particles originate from the soil and consist mainly of oxides (the density of SiO_2 is 2.7 g cm^{-3}). Anthropogenic aerosols have a lower density, but they can coagulate with soil dust.

Similar results were obtained for the three-dimensional relationships between the Pb, Cd, Zn, Fe, Hg, Br, As, Cr, Co, and Mn content in road dust and the size and density of the particles of magnetic and non-magnetic aerosols.[54] Moreover, in some cases it was possible to determine the origin of the elements from the density and size of the particles (exhaust fumes, tyre rubber evaporation, soil dust, etc.). The major part of road dust consists of particles with a density of 2.2–2.9 g cm^{-3}.

Solubility of the aerosol

The fraction of water-soluble metal and metalloid compounds in the aerosol grows as the particle size decreases.[21,25] Thus, in rural areas the fraction of the soluble compounds of Cd, Pb, Mn and Zn in the aerosols for particles with a diameter $d \approx 0.1$ to 0.3 μm was 90%, and for $d \approx 5$ to 10 μm it was 80, 25, 75, and 55% respectively.

As a result, the fraction of water-soluble metal compounds in the precipitation grows with the distance from the source of emission.[56,57] In many cases this growth can be approximated by an exponential relationship. It has been found that the fractions of soluble Pb, Cd, and Cu compounds in the snow cover around a steel plant (USSR) increase linearly up to a distance of 30–40 km.[59] An increase in the fraction of soluble compounds was observed for 21 elements. However, there are isolated cases where the relationships between distance and the fraction of soluble forms is more complex; in a few cases this fraction may even decrease.[60]

The fraction of soluble Pb, Fe, Mn, and Zn compounds in aerosols over urban areas (19, 4, 33, 69%, respectively) is considerably lower than in aerosols over the ocean (84, 53, 74, 79%, respectively).[50] It has been also noted that the fraction of acid-soluble forms of metals and trace elements in aerosols tends to be smaller over continents than over oceans.[61] In rural and 'clean background' areas the fraction of soluble forms of the elements in the snow cover was (%): Pb, 21; Zn, 65–100; Cd, 65; Cu, 40–80; Co, 60; Cr, 80–85; Ni, 80; Sb, 60–70; Se, 80–100; V, 60%.[32,62] In contrast to this, near motorways the main fraction of Pb, Mn, and Ti is in a nonsoluble form.[63] In rural regions in Sweden the fraction of gaseous mercury in soluble state reaches its maximum in winter (up to 5–10%).[23]

The solubility of metal-containing compounds was found to depend on their origin. Thus, both in urban and rural areas metals and trace elements in aerosols of soil origin (e.g., Sc, La, Co, Fe) are mostly in nonsoluble form. In contrast to this, volatile trace elements of anthropogenic origin (As, Cd, Sb, Se, Cr, Cu) are found mainly in soluble form.[46] The fraction of soluble compounds is much greater in rainfalls than in dry precipitations. This is especially true for Cu (90 and 30% respectively) and Pb (83 and 5%). The fraction of soluble forms of these metals decreases with increasing pH and the concentration of insoluble Fe.[64]

Size of aerosol particles

Aerosol particles that contain metals and other elements range in size from 5×10^{-3} to 20–40 μm or more.[65] The content of dispersed elements in the aerosol is largely determined by the nature of its sources. Furthermore, it varies with the distance from the source of emission. This is due to the different residence times of particles of different sizes in the atmosphere. In aerosols emitted into the atmosphere as a result of refuse incineration 65 mass% consisted of 0.1–2 μm particles. In the emissions of iron and steel works 57% of the total amount of metals consisted of particles smaller than 2 μm.[65,66] The content of dispersed elements depends largely on the degree of purification: the better the purification, the higher the fraction of finely-dispersed aerosols that contain a large amount of volatile elements (Pb, Sb, Se, Cd, Zn, As, S).[67,68] The degree of purification has a much smaller effect on the mass fraction of such metals as Fe, Al, Ni, Mn, Co, Cu in the emissions from metallurgical works. The bulk of these metals is concentrated in particles with $d > 2$ μm.[67,69] In motorcar exhaust fumes, Pb, Br, and Cl are contained in small particles ($d < 0.5$ μm). But in the presence of large particles from road and soil dust these aerosols coagulate rapidly.[70,71] Table 3 lists the selective median (by mass) diameters of metal-containing aerosols. Two extremes are compared: the urban atmosphere and the atmosphere of the 'cleanest' and remote background areas. Aerosol particles containing most of the elements discussed earlier (except Fe, Mn, Co, Pb) have a tendency to have a smaller diameter in remote background areas than in urban or suburban regions. In the Antarctica, for instance, up to 90–95% of As, Se, Zn, Br, S, and up to 60–70% of Sc and Mn is contained in particles with $d \leqslant 0.6$ μm.[9,79] Similar estimates for the Arctic and the Antarctic are given in the literature.[66,80] However, no such relationship is observed in certain continental regions, for instance in Central Asia. This is due to the special features of the natural and anthropogenic sources in these regions.[40] According to Table 3, volatile elements (Pb, As, Cd, Zn, Cu, Se, Sb) are, as a rule, found in smaller particles than nonvolatile ones (Fe, Mn, Co, Al, etc.). This fact is corroborated by other evidence, not listed in the table: the median diameters of particles that contain Fe and Al are in the range of 2.5–7.0 μm, whereas particles containing Pb, Se, Cd, V, Zn, and Sn are characterised by $d < 1$ μm.[67]

As particles become larger, there is also a tendency for the mass fraction of nonvolatile metals in aerosols (for instance, in aerosols of soil origin) to increase. The reverse is true of volatile elements (and high-temperature sources).[71,75,78,81] The distribution of metals according to the size of aerosol particles is governed by the logarithmic normal law.[74,82] One can get not only unimodal distributions, but bimodal and trimodal distributions as well.[71,83,84]

Thus, 0.25 μm and 3 μm modes have been established for Se,[85] 0.5 and 2.5 μm modes for Pb and Br,[86] and 0.8 and 4 μm modes for Hg,[47] and so on. In many cases each distribution mode can be related to the presence of an aerosol of certain origin.[14,86] Thus, the mode in the coarsely dispersed part of the distribution is believed to be connected with soil dust.[14] The size of the aerosol particles (the metal carriers) has a different seasonal dependence in different cities.[74] It depends on precipitation[43] and on the direction of the wind with respect to the aerosol source.[70,87] In remote background areas (e.g. in polar regions) the size of the aerosol particles changes as different air masses arrive.[88,89] As a rule, with increasing altitude the aerosol particles become smaller.[81]

Enrichment of aerosols with metals

The enrichment factor

$$K_{en} = (X_i/q)_{atm}(X_i/q)_s,$$

is often used to estimate the degree of fractionation of metals and

trace elements in aerosols. X_i and q are the concentrations of the required and the reference (typical for a particular aerosol source) elements. The subscripts 'atm' and 's' refer to the atmospheric aerosol and the source respectively. Fe, Al, and Sc (their global abundance values) are usually chosen as reference elements for soil dust, and Na or Cl for oceanic dust (ocean water).[73,90,91] The values of K_{en} reported in the literature are largely based on global abundance values. In this way it is possible to achieve a certain universality which is needed for the comparison of data on a global level. K_{en} values referred to for Al and Sc are listed in the literature.[73,90] They mainly related to areas that are at some distance from industrial sources.

These data are presented in the diagram shown in Fig. 1 for the plotting of which 500 values of K_{en} for 42 elements have been used. The elements can be divided into three groups: highly enriched ($K_{en} > 25$), moderately enriched ($3.6 < K_{en} < 25$), and slightly enriched ($K_{en} < 3.6$). As a rule, the volatile elements (I, Pb, As, Cd, Se, Hg, and others) are characterised by the highest values of K_{en}. The moderately enriched group includes Cs and Na, while the slightly enriched group consists mainly of nonvolatile elements (Fe, Ni, Sc, Mn, etc.). There is a wide variation of K_{en} values. Incidently, the values of K_{en} may vary widely even when measurements are made at one and the same site.[92] As the particles become smaller, the enrichment factor, especially for volatile elements, becomes substantially larger.[77,78,93] The results of such measurements carried out in Accra (Ghana) could be fitted with an exponential function.[75] K_{en} for nonvolatile and lithogenic elements does not increase so markedly with decreasing particle size, or it may even not increase at all.[78,93]

In some cases there is a bimodal distribution of K_{en} according to particle size.[68,78] Distribution of K_{en} as a function of geographical position depends on the location of anthropogenic and natural sources of aerosols.[5,17,21,60,77] It is mainly small particles, the most highly enriched with volatile elements, that are carried to great distances.[67] Apparently that is why replacement of global abundance values by concentrations of the elements in local soils affects the value of K_{en} considerably.[77] Quite often the K_{en} values for one and the same element emitted into the atmosphere from different sources, even in the same region, differ quite widely.[94–96] In towns K_{en} values are largely determined by industrial and transport emissions. In emissions from metallurgical works and thermal power stations the order of magnitude of K_{en} for Cd, Zn, As, Pb, and Cu is 10^2-10^3, and for Fe $K_{en} \approx 1.0$.[60] In continental rural areas K_{en} is lower than over the oceans. In polar regions (especially over the Antarctic) it is higher than over the oceans; in the southern hemisphere it is higher than in the northern hemisphere.[73,97,98] However, no such relationship has been observed in other studies.[42,90,99,100] It is not clear why the evidence is so contradictory. Possibly the different values taken for K_{en} play some part in this. There are very few data as yet on K_{en} values in the troposphere and the stratosphere.[101]

Chemical compounds of metals and metalloids

The following compounds were found in the emissions and the ambient atmosphere around plants for smelting Pb, Zn, Cd, and Cu: PbS, $PbSO_4$, $PbO.PbSO_4$, ZnO, ZnS, metallic Pb, CdO, $Zn(PO_3)_2$, metallic Cd, $Cd(OH)_2$, metallic Cu, $CuSO_4$.[102–104] The aerosol matrices contained also SiO_2, S, graphite, K_2O, Na_2O, as well as compounds of major metallic constituents, Fe_2O_3, Al_2O_3, Al_2SiO_3. As a rule, the large particles contain oxides, and the small ones sulphates.[102,105] Fourteen lead compounds were detected near the highway in a rural area and in the exhaust fumes themselves.[102,106] The following gaseous tetraalkylated lead compounds were found near two petrol stations in the USA (% of total): $(CH_3)_4Pb$, 18–46; $(CH_3)_3C_2H_5Pb$, 12–31; $(CH_3)_2(C_2H_5)_2Pb$, 5 and 12; $CH_3(C_2H_5)_3Pb$, 2 and 7; $(C_2H_5)_4Pb$, 63 and 4. However, in the residential areas of large cities and in rural areas the amount of the first compound rose to 75 and 85% of total respectively, while the last three compounds were not detected at all. This implies that ethylated lead compounds degrade much faster than methylated ones.[102,107] Lead alkyls were found in the precipitations that came down in England[108] and Norway.[109] In this case tetraethyl lead is broken down in 48 hours and sometimes cannot be detected. Organometallic compounds of Pb, H, As, and Se, which are formed when these elements react with methane, were found in the atmosphere of several towns in Japan, for instance.[110] Gaseous mercury is present in the atmosphere mainly (up to 80% of total) in molecular form (Hg^0). Part of it gets oxidised and forms unidentified compounds of Hg(II). In that case the mercury is converted into soluble form.[23] Up to 30% of Hg over Europe is in the form of dimethyl mercury, whereas over the ocean only 5% is in this form.[111] The atmosphere of remote background regions contains 11–65% Hg^0, 12–25% divalent inorganic mercury, 21–34% methyl mercury, and 1–46% dimethyl mercury.[24]

The total amount of mercury in vapour state in the air over the Almadena mercury mine (in Spain) was made up of the following: Hg^0, 17–100%; methyl mercury, 0–66%; inorganic Hg(II), ~30%. There was also a small amount of dimethyl mercury.[112] As

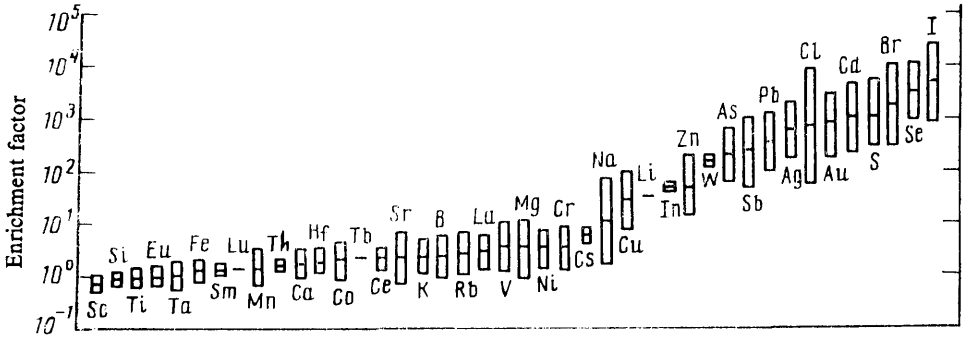

Figure 1. Enrichment factor, K_{en}, for elements in atmospheric aerosols in relation to global abundance ratio (with Al taken as the reference element).[90]

regards arsenic, in Japan up to 10% of it is found in aerosols in the form of organic compounds.[113] The organic particles consist mainly of dimethyl arsinic acid. In summer its concentration rises. Bromine compounds such as methylene bromide, methyl bromide, bromoform, and others were found in the atmosphere of Alaska, New Zealand and elsewhere.[114]

IV. Spatial distribution of concentrations of metals and some metalloids of anthropogenic origin in natural environment

The distance to which a pollutant may spread in the atmosphere largely depends on at least two factors: on how quickly it (a) disintegrates and (b) is transferred to the surface of land and ocean as 'dry' or wet precipitation. These processes have been discussed in detail in reviews,[115–118] and the respective theoretical calculation have also been performed.[119–122] The concentration of vapours of elements in atmospheric precipitations is governed by Henry's law. The Henry coefficient for Hg vapour is 0.48.[116] Dry precipitation of aerosols is connected with sedimentation due to gravity and turbulent air flow directed towards the surface of the Earth. It increases markedly with the height and density of vegetation.[119,123,124] The rate of dry precipitation falls as aerosol particles decrease in size to 1–2 μm, and then rises slightly again at $d < 0.1$ μm because of improved diffusion of very small particles towards the surface of vegetation in the boundary layer (near the Earth's surface where the wind velocity is zero).[15,119,124] The removal of the aerosol admixture from the atmosphere with precipitation is the result of two processes: capture of the aerosols by cloud drops inside the cloud (rainout) and by raindrops below the cloud (washout).[115–118] The mode of capture may vary widely: Brownian and convective diffusion, inertial capture, thermophoresis, etc.

Of the aerosols deposited by precipitation, 0.1–1 μm[116–119,124] particles have the smallest washout rate. In other size ranges the washout rate may be higher by one or several orders of magnitude. According to certain estimates, snow washes out aerosols much more effectively than rain.[117,125] The opposite applies to gases.[118] Snow flakes can capture aerosol particles of different sizes equally well and do so very effectively.[126] This contradicts the theory and needs to be confirmed. As a result, the total (dry and wet precipitation) rate of removal of aerosols from the atmosphere also falls at first as the particle size decreases approximately to 1 μm. In the 0.1–1 μm range the rate remains very small. Then for the even smaller (submicrometer) particles the rate rises once more. However, aerosol filters are unable to catch such particles effectively.[40,42,43] This should be taken into consideration when analysing the behaviour of the aerosol. Let us roughly assume that the rate of removal of aerosol particles from the atmosphere increases with particle size. There is experimental evidence that after precipitation the concentration in the air of the coarsely dispersed fraction of the aerosol drops more sharply than the concentration of the finely dispersed one.[43,127,128] In remote background areas the larger soil particles were also washed out more rapidly than the anthropogenic ones.[89]

The average residence time of atmospheric aerosol in the troposphere is believed to be 1–3 days. But when there is local precipitation of very large particles the residence time is no more than several hours. The residence time of gases in the troposphere is measured by months and years.[117,129]

Chronic exposure of metals and trace elements has the most serious effects. It is therefore important to know the mean monthly and annual concentrations of metals and trace elements in the atmosphere to allow us to assess the danger they pose. The highest concentrations, often in excess of maximum permissible concentrations (MPC), were observed in large cities and around emission sources, especially in the vicinity of metallurgical plants. Thus, in Mexico City cadmium concentrations were 10 times higher than MPC, Zn concentrations were 20 times higher, and Pb concentrations several times higher.[130] There is similar pollution in the cities of the FRG[131] and the USSR. In rural areas, in remote background terrestrial areas, over oceans and in polar regions the concentration of metals in the atmosphere is significantly lower. Thus, for Pb there is a difference of 4–5 orders of magnitude. In the centres of large cities concentrations of Pb in the air amount to $(1-10)\times10^{-6}$ g m^{-3}. In suburbs and rural areas it is lower by 1–2 orders of magnitude.[132] The average concentration of Pb in background areas is (g m^{-3}): for polar regions 0.1×10^{-9}; for 35°–65° N. lat., 10^{-9}; for 0–30° N. lat., 0.2×10^{-9}; for 0–30° S. lat., 0.3×10^{-10}; for 25°–55° S. lat., 15×10^{-10}; for Antarctica $10^{-11}-10^{-12}$.[133–135] In several cases a relationship was observed between lead concentration and the number of dwellers in the city.[136] Cadmium concentrations in the air of USA cities varies within the limits $(1-100)\times10^{-9}$ g m^{-3}. In British cities the average concentration of arsenic is 2.8×10^{-9} g m^{-3}. In rural areas in the USA it is $(4.0-0.3)\times10^{-9}$ g m^{-3}. In Antarctica it is 0.01×10^{-9} g m^{-3}.[21,135,137] The concentration of arsenic in the air of British cities is 6.4×10^{-9} g m^{-3}; at the South pole it is 6×10^{-12} g m^{-3}.[21]

It is interesting to note that the concentrations of Fe, Se, Co and of rare-earth elements, which are usually found in the larger particles, fall tens of times more rapidly with distance from the continent than the concentrations of Se, Sb, and other elements.[138] In the past decade a distinct tendency to lower the air pollution levels of Pb, Zn, Cu, Cd, V, and Mn has become evident in a number of foreign cities and remote background areas.[134,139–143]

There is much less difference between the concentrations of mercury, which is mostly present in vapour state. Thus, the Hg concentrations in USA cities is between 5 and 50 ng m^{-3}; in rural areas it varies from 3 to 9 ng m^{-3}; and over the waters of the Pacific and the Atlantic oceans it is 1–3 ng m^{-3}; in the Southern hemisphere it is only half that in the Northern hemisphere.[23,144] Around certain natural sources the Hg content may amount to 10^3 ng m^{-3}.[145] The vertical distribution of metals in the troposphere is complicated, with a general tendency for the concentration to decrease with height. There is an alternation of maxima, which reflects the fact that there are temperature inversions, advections of various air masses, and other factors.[101,146–148]

In Swiss cities in summer time the distribution of Cd, Cu, Mn, Pb, and Zn concentrations at 515–1500 m above sea level was found to be homogeneous.[149] In the USSR the maximum concentration of Hg in the lower troposphere was observed over the Urals.[150] There are very few experimental data on the amount of organic compounds of metals in the air and the precipitations. The concentration of tetraalkyl lead in European and American cities in 1978–1981 was 83 ng m^{-3}; on roads and in traffic tunnels it was up to 100–200 ng m^{-3}; in housing estates it was 20 ng m^{-3}; and in rural areas 1.7 ng m^{-3}.[151] In Norwegian cities it varied from 11 to 81 ng m^{-3}.[109] Earlier publications gave the concentration of tetraalkyl lead in city air as several micrograms per m^3.[49,132] Let us remember that MPC for a single exposure to tetraalkyl lead in a working zone is 75 g m^{-3}.[152] Most of the arsenic in atmospheric

precipitations is in the form of inorganic compounds.[153] The average concentrations of arsenites and arsenates in the region of the Hawaiian Islands were 0.007 and 0.012 parts per billion respectively; in the area around the Tacoma, WA, USA smelting works they were 1.06 parts per billion.

Soil and snow cover become polluted with metals brought from the atmosphere with 'dry' and wet precipitations. The spatial distribution of metals in these media around the source of emission follows the same pattern as in the surface layer of the Earth. The greatest danger of pollution is within the 10–20 km radius around the emission sources[154,155] and further.[68,72] The boundary of the polluted soil area is very arbitrary, because it is difficult to separate the natural (background) metal-content in the soil from the amount of metals derived from anthropogenic sources. The average levels of pollution of natural media by a local source are inversely proportional to the square of the height of the emission.[156] But the higher the emission takes place, the larger the amount of metals carried to great distances (regional and global pollution). The configuration of the local zone and the degree of its pollution also depend on the wind rose, the vigour and duration of the emissions, the particle size composition, and the frequency of precipitations when wind direction varies.[157,158] What is precipitated locally consists mainly of coarse particles (according to Izrael' et al.[6] global precipitations consist of particles with $d < 5$ μm). The relationship between the level of pollution of natural environment with metals and the distance from the source of emission is thought to follow approximately an exponential dependence in some cases, and a power dependence in others,[159,160–162] with the exponent close to -1.[72,163–166] The parameters of both the exponential and the power distributions are essentially determined by the velocity of the wind, how often it blows in a particular direction, by the height and vigour of the emissions, as well as by other factors. It is difficult to decide which of the above functions gives a more objective picture of the real situation. However, the theoretical dependence of aerosol concentration on the distance from the source becomes, after passing the maximum, close to a power dependence.[118] More complicated models of local precipitations, based on the theory of aerosol distribution in the atmosphere, are discussed in the literature.[119,167,168] From 10 to 40% of the respective emissions of Pb, Zn, Cu into the atmosphere were found to be precipitated in the local zone around a number of metallurgical works in the USSR.[169] By other estimates local precipitation of several metals around iron-and-steel works amounted to 15–37% of the emission of the respective element; around thermal power stations it amounted to 40–50% of the emission of the respective elements.[159]

Measurements taken in the region of the Sudbury copper works (in Canada)[69,72] showed that in a 40 km radius the following amounts of metals were precipitated from emissions from two chimneys 194 and 381 m high in the absence of natural precipitations: Fe, 15.2; Al, 8.9; Ni, 2.6%; finer aerosols Pb, Zn, and Cd, less than 2%. On days when there were natural precipitations the figures were: Fe, 68; Cu, 100; Ni, 36; Zn, 92; Al, 80; Cr, 14.2; Cd, 9.7%. On dry days the fraction of precipitations in the above zone for emissions from a chimney 93 m high was: Fe, 100; Ni, 29; Al, 58; Pb, 13; Cd, 1%. For Hg the respective indices were considerably lower: for operating chlorine-alkali plants the fraction of local mercury precipitations in a 10 km radius was from ~7%[170] to 10%;[23] in a 3 km radius it was 5%.[171]

It has been postulated that Hg can go through repeated precipitation and evaporation cycles,[46] finally accumulating in the polar regions in low-temperature conditions. But so far there has been no direct confirmation of this hypothesis.

Local zones with soil highly polluted with metals are often regarded as technogenic geochemical anomalies.[172,173] These zones are doubly dangerous because in such zones the fraction of metals in mobile and exchangeable state, and, consequently, easily assimilated by plants, is often significantly higher than in remote background areas.[154,165,174,175] In the zone of local precipitation the aerobic assimilation of metals by plants through their leaves and stalks plays a prominent role. This effect decreases with distance from the source of emission.[176,177] The combined effect of the extremely toxic compounds of sulphur and nitrogen with metals causes plant diseases and the destruction of forests and other vegatation, and reduces crop yields.[178–180]

Regional precipitations, and the more so global precipitations, usually do not lead to a significant increase of the amount of metals in the soil. However, it was established that in Norway the soil contained different amounts of lead: from 100 to 120 p.p.m. in the south to background levels of 10 p.p.m. in the north. This difference may be due to lead emission in Western Europe.[181] Areas of snow cover considerably polluted with metals extend over 10 to 13 thousand km^2 around Norilsk and Monchegorsk.[182]

Because car exhaust fumes are emitted close to the ground, soil and snow become polluted with lead and other metals in areas adjoining the highways to distances not greater than some tens and hundreds of metres.[86] Only 0.2–0.7% of Pb and 1.7–5.5% of Zn in this zone are in an exchangeable state.[183]

Technogenic toxic metals enter the oceans mainly from the atmosphere. Nearer the continental shelf river discharges start to play a greater role and both these factors become commensurate.[21] The maximum concentration of Pb in the surface layers of the Pacific ocean (up to 14–16 ng m^{-3}) is observed at mid-latitudes (20°–40° north lat.). Lead concentration is lower in the tropical zone (down to 6 ng m^{-3}), and in the southern hemisphere it is only 4–5 ng m^{-3}.[184,185] The natural level of lead in the surface layers of the northern Atlantic and Pacific oceans is exceeded by a factor of 8 to 20 and in the southern part of the Pacific ocean it is exceeded by a factor of 2. The vertical profile of Pb concentration has its maximum in the layer 0–2.5 km in depth. In deeper layers the concentration drops 6- to 7-fold.[21,184,185] The Cd, Zn, Cu, and Ni content in the ocean grows with depth down to 1000–1500 m, and in individual cases even to greater depths.[21,187] It is difficult to speak of the fraction of anthropogenic metals in this case. We can assume that deep in the oceans the concentrations are still at preindustrial levels, because vertical exchange takes a very long time.

It is interesting to trace how the anthropogenic emission of metals into the atmosphere increases the pollution of the environment on a global level on the example of polar regions, where biota is most sensitive to outside influences. In winter, when the polar front moves far down south, large masses of pollutants move into the arctic regions to form an aerosol haze there.[188–191] This haze contains sulphur and nitrogen compounds, polycyclic aromatic hydrocarbons, organic compounds, and soot, as well as metals and metalloids.[137,192–195] In winter, because precipitations are few and there is stagnation in the atmosphere, the lifespan of fine aerosol in these regions can last up to 2–3 weeks.[46] Plotting circulation paths in conjunction with the use of reference materials, together with other methods allows us to conclude that the polluted air masses move into the Arctic from Europe and to some extent from North America. Most of these masses settle in the European part of the USSR and in the Urals.[196,197] No similar phenomena have been

observed in the Antarctic. In spite of the presence of an anthropogenic polar 'haze', measurements of Hg, Cd, Zn, As, Cu, Sb, and Se concentrations in different layers of a glacier in Greenland gave no reliable proof of an increase in these concentrations in the industrial period.[133,198,199] This may be due to methodological difficulties (external pollution of the samples)[133,134] and to the wide scatter of data. It has been found that even in the pre-industrial period the concentrations of metals in the atmosphere were much higher during glaciation than in the interglacial ages.[134,200] The metals must have been of soil origin because the data correlate with Al. Pb is the exception: its content in the ice of Greenland in the period from 800 to 1950 AC increased 200 times (from 1.4×10^{-12} to 200×10^{-12}).[201] According to other evidence, by 1965 the content of Pb amounted to 230×10^{-12}; then by 1983 it decreased several times because a number of countries had prohibited the use of ethylated petrol.[134] In the Antarctic also no rise was observed in the concentrations of metals and metalloids (Hg, Cd, As, Fe, Zn etc.) in layers of ice dating from the industrial period.[133,199,202–204] Here too Pb was the only exception. However, estimates of the rise in its concentration in the industrial period are somewhat contradictory. In the ice of Antarctica lead concentrations increased 4- to 5-fold.[202–205]

There is also a different estimate.[133] According to it, the concentration of Pb in the ice layer increased to a somewhat lesser degree: from $(1-2)\times10^{-12}$ to $(2-5)\times10^{-12}$. Attempts were made[134] to assess the concentration of lead in the air of Antarctica in the preindustrial period on the basis of the current contents of lead in the glacier and in the atmosphere (7×10^{-12} and 1×10^{-12} g m^{-3}, respectively).

It is difficult to estimate the danger of regional and global pollution of the atmosphere with metals because there are no standards as yet. Such pollutions are relatively low-level, but they spread over large areas. Local pollutions are estimated by comparison with MPC, but this method has significant drawbacks. Every MPC refers to a specific metal or substance,[152,206,207] whereas in natural conditions there is a mixture of toxic substances. Some of them have a joint synergic effect on the Biota, whereas others have an antagonistic effect. Attempts to develop some standards for pollution of the environment by mixtures of toxic substances remain purely formal so far.[208] The concept of 'maximum permissible load' on the ecosystem has been proposed, but so far it has found no practical application.[209] It is still not clear what units should be used to measure this load. We believe that biomarkers characterizing the reaction of biological objects to pollution should be used to assess the danger of pollution of the environment by a combination of toxicants.[210] Suggestions have been made concerning the assessment of soil and air pollution with metals.[158,211,212] The concept of the maximum permissible emission (MPE) is widely used to safeguard against dangerous pollution levels. MPE is the emission after which the atmospheric concentration of a toxic substance does not exceed its MPC.[213] This concept has also been applied to the content of toxic metals in the soils around metallurgical works.[214] In general, it is necessary to set up such MPE values which would guarantee that the MPCs would not be exceeded in all natural environments. A serious drawback of MPCs for the atmosphere consists in these standards being determined with no regard for the dispersion properties of the aerosols, whereas it is mainly the finely dispersed aerosols that settle in the respiratory tract and the lungs. Most of Pb, Cd, Cu, Zn, Mn, and Fe from the atmospheric aerosols settle in the lungs (10–40% of the inhaled amount). If we consider the whole respiratory tract, including the nasopharynx, 50–90% of Fe, 30–42% of Pb, 40–70% of Cd, 28–62% of Zn inhaled are deposited there.[71]

V. Conclusion

Today there is a high level of air and soil pollution because of the emissions of metals into the atmosphere. In many cases the pollution exceeds the MPC. This is mainly true for large cities and centres of industry, especially if they contain nonferrous metal works or iron-and-steel works. Excessive amounts of toxic metals in the environment, especially if there are other toxicants as well, lead to diseases in man (including cancer). They also promote diseases of arboraceous vegetation and its destruction, and they reduce crops.[177,179,215–217]

A further rise in the pollution level is to be expected in the foreseeable future. This applies especially to soil, the surface layers of the oceans and the polar regions. It will be caused by a greater volume of emissions and by the accumulation of precipitations. Thus, the average annual global increase of emissions of metals into the atmosphere in 1950–1975 was for Pb, 3.1%; for Cd, 4%; and for Ni, 6.7%.[218] According to Ostromogil'skii et al.,[25] the worldwide emission of Pb will rise in the period 1980 to 2000 by 10%; for As and Cd this increase will amount to 20%. It takes from several months to several years to double the natural background amount of metals in a surface layer of soil 1 cm thick near a metallurgical plant.[165,219] In American cities it takes several tens of years to double the background amount of Pb, Cd, Zn in a 2.5 cm thick surface layer of soil; in residential areas it takes a hundred years or longer.[220] In rural and remote background areas the natural concentration of most metals in the 1 cm thick surface layer of soil also doubles in tens and hundreds of years.[165]

Calculations predicting the level of pollution of the environment with Pb, Cd, As, and Hg were carried out for 1980–2000 on the basis of the 'box' model.[25] One can expect the concentrations of Pb, Cd, and As in the air of nonindustrial terrestrial regions in the northern hemisphere to grow by several percent (up to 10%). In Antarctica they can be expected to grow by 25, 15, and 10% respectively. The Pb concentration in the surface layer of the northern part of the Atlantic ocean will almost double by 2010. In other parts of the ocean it will rise by tens of percent.

The maximal level of pollution of soil and ocean, which accumulate the metals emitted into the atmosphere, will be established after all the industrial reserves of these metals have been exhausted and they themselves have been dispersed over the globe. Even rough estimates[221] show that the amount of lead, mercury, cadmium, and arsenic in the soil will be tens and hundreds of times greater than at present. The migration of elements from the surface layer of soil into rivers and oceans is a very slow process. Because of that the achieved high levels of pollution of the soil with metals will be maintained for a long time (for hundreds or even thousands of years). This makes it so important to strive already today to reduce sharply the emissions of metals into the atmosphere and their dispersion in the environment by adopting progressive technologies and waste-free manufacturing processes.

Determination of polychlorinated dibenzo-*p*-dioxins, dibenzofurans, biphenyls and chlorine-containing pesticides in the environment

A K Prokof'ev
A N Severtsov Institute of Evolutionary Morphology and Animal Ecology, Academy of Sciences of the USSR, Moscow

ABSTRACT. Literature material has been correlated on methods of determining ecologically particularly dangerous polychlorinated compounds (dioxins, furans and biphenyls) and chlorine-containing pesticides and phenols in the environment, viz. in air, natural waters, soil, sludges and various tissues of biological organisms (including man). All stages of the analysis are reviewed, i.e. selection and storage of samples, methods of extraction and derivatisation, means of purification of organic extracts, gas chromatographic and gas chromatography-mass spectrometry methods of separating and estimating individual isomers and compounds and their detection limits.

The bibliography contains 164 references.

I. Introduction

Polychlorinated organic compounds (dioxins, furans, biphenyls) and chlorine-containing insecticides, herbicides and phenols have currently become a global ecological hazard because of their fairly high toxicity for mammals, including man, their persistence and their universal distribution both in the environment and in foodstuffs. Particular danger is presented by the 12 isomers of dioxin and furan containing 4–6 atoms of chlorine, of which 4 must be in positions 2, 3, 7 and 8 , and 13 isomers of biphenyl containing 4–7 chlorine atoms of which 4 must be in positions 4,4′ and/or 3,3′ and 5,5′. These isomers are very toxic compounds, they are synthesised by man and reliable methods have been developed for their quantitative determination at the ppt level (ng kg^{-1}). The limits of detection of chlorine-containing pesticides and their metabolites have been reduced significantly. The metabolites proved to be either precursors of xenobiotics of the dioxin type or synergistic with them.

The review is devoted to an analysis of the work of the last 5–7 years on the methods of determining quantitatively polychlorinated compounds of the types indicated. Special attention has been allotted to the isomer-specific determination of dioxins, furans and biphenyls.

II. Insecticides

Chlorine-containing insecticides are applied in the struggle against harmful insects. In this section most attention will be paid to the determination of 4,4′-dichlorodiphenyltrichloromethylmethane (DDT), its metabolites 4,4′-dichlorodiphenyldichloromethylmethane (DDD) and 4,4′-dichlorodiphenylchloroethylene (DDE) and also of the isomers of hexachlorocyclohexane (HCCH).

1. Selection and storage of test samples

Test samples of natural waters are taken with glass, teflon or metallic samplers, from vessels or bathometers. The volume of sample taken may vary from 4–25 litres depending on the assumed concentration of insectide.[1–4] It is not subjected to conservation and storage in view of the possible loss of insecticide as a result of adsorption onto vessel walls. Consequently it is necessary to extract the samples taken with an organic solvent, frequently hexane, within 2 hours. The organic extracts are stored in bottles with ground-glass stoppers. It is best to store them in the frozen state.[3] After storage at room temperature analysis must be carried out no later than 3 months after taking the sample.[1,2]

Sludges are selected with various hollow tubular samplers to avoid mixing when taking samples. Usually 10–15 cm upper layer of sediments is taken.[4–6] They are stored in glass jars at 4 °C or at −10 to −15 °C.[4,6] At room temperature samples may be preserved by acidification with hydrochloric acid to pH 2 and stored in that form for a month.[6]

Soils are sampled with an auger or a scoop and samples are mixed. They are air-dried in the laboratory or in the open air. They are stored in the dry state in small linen bags, and if naturally moist in the refrigerator.[7]

Test samples of air are always concentrated by passing them into liquid[8] or solid[9] adsorbents. The volumes of air may therefore amount to thousands of cubic metres.[9]

Biological samples are stored in the frozen state at −10 to −78 °C.[4,5,10–16] Only freshly taken samples must be frozen.

2. Extraction

Insecticides are usually extracted from test samples of natural waters with hexane[1–3,17,18] or dichloromethane.[4] The organic extract is dried with anhydrous sodium sulphate. The solid phase extraction of insecticides with microcolumns of charcoal and Tenax[19] and also with phases used for liquid chromatography[19–21] is extremely promising. The concentration factor may reach 1000 which permits the use of small volumes of water or eluates and excludes removal of solvent prior to gas chromatographic analysis (GC).

For soils an average test sample is first taken by quartering from the air-dried mixed specimen, roots and stones removed, and the sample then ground and screened through a sieve of pore diameter 0.5 mm. The efficiency of recovering insecticides from soils depends markedly on their type and their absorptive powers. Consequently it is suggested that the the optimum means of extraction of insecticides is selected for each test sample from three parallel subsamples.[7] After keeping the dry sample in distilled water the insecticide is extracted in the first extraction method with a mixture of hexane–acetone 4:1, in the second with a mixture of acetone–hexane 1:1 in the presence of 1% ammonium chloride solution and in the third with acetone with the same salt added.[7,17]

Preliminary deactivation of soils with ammonium chloride solution and subsequent extraction of insecticides in an ultrasonic bath with acetone and further re-extraction with hexane frequently enables analysis of extracts by GC with an electron capture detector (GC/ECD) without further purification.[22] It was shown that treatment of soils with 20% BF_3 in methanol prior to extraction increased the amount of HCCH isomers extracted by up to three times compared to any other extraction method.[23]

Insecticides are extracted from sludges, after homogenisation, with acetone[6] or with dichloromethane.[4]

Insecticides are often extracted from biological material with acetone–hexane mixtures in various proportions with simultaneous homogenisation of the biosample.[11,17] Acetonitrile or acetone is usually used for plant tissues.[24] Insecticides are then quantitatively transferred from water-soluble solvents to water-insoluble solvents, usually into hexane, cyclohexane or dichloromethane for purification.

Most frequently biosamples, after homogenisation, are dried with anhydrous sodium sulphate at a ratio of 1:4, the mixture is ground to a powder[5,10,14,25,26] and the insecticides extracted with an organic solvent in a chromatographic column or in a beaker.

Insecticides are usually extracted from milk with solvents,[16] however recently it has been suggested that extraction is carried out after adsorption of milk components on special cartridges,[27] silica gel[28] or Florisil.[29]

When it is important to know the lipid content of the biosample, extracts are evaporated to dryness, the mass of lipid determined in the dry residue, which is then dissolved in organic solvent for purification.

3. Purification of organic extracts

Removal of organic substances co-extracted with insecticides which interfere with analysis is achieved by treatment of hexane extracts with concentrated sulphuric acid until a colourless layer is obtained.[1–3,6,7,17,30] This method of purifying extracts is only used when acid-stable insecticides are being determined, for example DDT and its metabolites, HCCH isomers, hexachlorobenzene (HCB) and polychlorinated biphenyls (PCB). When analysing acid-unstable insecticides extracts are purified on adsorbents in chromatographic columns.

It should be mentioned that elemental sulphur and organosulphur compounds are often present in organic extracts of soils and sludges. These are not removed by acid treatment but interfere with the determination of HCCH isomers. Sulphur compounds are removed by adding to the hexane extracts solutions of tetrabutylammonium sulphate and sodium sulphate in the presence of isopropyl alcohol[6,7] or activated metallic copper.[4]

Insecticides of low stability in acid media, and they are the overwhelming majority, are separated from the interfering organic matrix usually on chromatographic columns of Florisil, silica gel or Al_2O_3,[5,8,11,13–16,18,21,24–27,29–32] or by high performance liquid chromatography (HPLC).[33] This purification may be automated.[34] A very efficient means of separating insecticides in extracts of animal and plant tissues is exclusion (gel-permeation) chromatography,[10,11,24,26,35] one of the variants of HPLC. Styrene-divinylbenzene gels, such as BioBeads SX2 or SX3, are used for this. Only 0.02% lipid remains in extracts after this treatment.[11]

4. Separation of insecticides in extracts

Extracts of insecticides (DDT, DDE, DDD and HCCH), purified from organic substances, may be analysed in gas chromatographs with packed columns only when contamination by PCB and many acids-unstable insecticides which interfere with the analysis is absent. In the majority of samples however, such contaminants are present and consequently extracts are usually fractionated.

Extracts of insecticides purified with sulphuric acid are subjected to alkaline dehydrochlorination with alcoholic alkali. In this case hydrochloric acid is split out from molecules of DDT, DDD, and HCCH while molecules of DDE, PCB and HCB are practically unchanged.[1,2,6,7,15] It should be mentioned that on Florisil, in addition to separating intefering organics from insecticides, it is possible to separate PCB from insecticides[13] and resolve insecticides into fractions[10,11] by changing the eluting solvents.

In the majority of cases extracts of insecticides purified on Florisil are resolved into fractions on silica gel,[5,8,26,30] after which they are analysed by gas chromatography.

The simultaneous purification and fractionation of insecticide extracts on one chromatographic column of aluminium oxide and silica gel[25,31] is of practical interest. This enables time and solvent volumes to be reduced.

5. Gas chromatographic separation and detection limits

Purified fractions of insecticides are analysed by GC/ECD usually on packed columns. If PCB are present in the extracts then fractions are analysed in the chromatograph prior to and after dehydrochlorination. The limit of detection of insecticides and PCB in sea and fresh water, depending on the sample volume taken, is equal to: for DDT and its metabolites 0.03 [3] and 0.2–3.8 ng litre^{-1},[1,2] α- β-, γ- and δ-HCCH 0.01 [3] and 0.2–1.3 ng litre^{-1},[1,2] PCB 0.2–20 ng litre^{-1};[1,2] in sludges: for DDT and its metabolites 0.3–0.5 [6] and 5 ng g^{-1} (SP-2250 or SP-2401 columns),[5] lindane and heptachlor 0.,1 [6] and 5 ng g^{-1},[5] α- and γ-HCCH, aldrin etc. (13 insecticides in all) 5 ng g^{-1},[5] PCB 30 [7] and 20 ng g^{-1};[5] in fish: for DDT and its metabolites 0.6 μg g^{-1} of fish fat,[17] 21 insecticides 10 ng g^{-1},[26] 19 insecticides 2–40 ng g^{-1},[10] PCB 0.6 μg g^{-1} fish fat[17] and 100 ng g^{-1};[26] in soils: for DDT and its metabolities 2–3 ng g^{-1}, α- and γ-HCCH 0.2 and PCB 30 ng g^{-1} dry weight.[7] Retention times for 28 insecticides on 9 different packed columns have been published.[36]

Recently insecticides and PCB have also been analysed on quartz capillary columns. This enables the simultaneous determination of significantly more insecticides from only two fractions.[11,26,31] Thus it is possible to determine 19 insecticides and 7 PCB isomers in biosamples on columns of length 25 m of CP-Sil 5 CB or CP-Sil 8 CB,[31] 37 insecticides in human adipose tissue on columns of length 15 m of DB-5 or DB-17 with a limit of detection of 0.9–14.3 ng g^{-1},[11] 28 insecticides in topsoil on columns of length 25 m of OV-1701, OV-17 and SE-52 [22] and 12 insecticides in water

on a column of length 30 m of SPB-608 with a limit of detection 10 ng litre^{-1} [by GC-mass spectrometry (GC-MS)].[19]

III. Biphenyls

1. Sample treatment

The PCB are a mixture of substances used as oils for transfomers, hydraulic fluids, dielectrics, etc. In different countries PCB have their own trade names, for example trichlorobiphenyls in the USSR, Sovols in France, Arochlors in USA and Chlophens in FRG. They are in turn divided into types reflecting the percentage chlorine content in the mixture and the number of chlorine atoms in the molecule. For example, Arochlor 1254 series 1200 contains 54% chlorine, it has an average of 4.9 chlorine atoms per molecule and an average molecular weight of 324, Chlophen A-50 contains 50% chlorine, and a pentachlorobiphenyl of the type of the electrochemical Sovol has 54%.[7] These are frequently used as standards in the determination of PCB.

Since PCB are met, as a rule, in the environment together with the various chlorine-containing insecticides, all these substances are usually determined in one sample. PCB are separated from acid-stable insecticides by alkaline dehydrochlorination and chromatograms are compared prior to and after dehydrochlorination. Insecticides are determined from the difference in peaks on the two chromatograms and PCB from the total peak heights in the second chromatogram. PCB are usually separated on silica gel (see above) when determining acid-stable insecticides. The limit of detection of total PCB content in natural water is 0.2–20 ng litre^{-1},[1,2] and in sea sludges and soils 2–5 ng g^{-1} dry weight respectively.[6,7] Chlophen A-50 is used as a standard for PCB.

When determining PCB the selection, storage and treatment of samples of environmental objects is generally the same as for insecticides (section II). Mention may also be made of the concentrating of PCB from contaminated natural waters with adsorbent C_{18},[37] the purification of extracts by HPLC with subsequent determination of PCB by GC/MS,[38] loss of the overall PCB content up to 56% and of each isomer separately when drying sludges at 60 °C for 48 h,[39] and also the possibility of combining purification and determination in one sequential system LC-GC/ECD,[40] which enables determination of PCB to be automated.

Methods have been described for determining many individual PCB isomers in various biological samples, such as whales,[41] penguins and their eggs,[42] molluscs,[43] sea mammals,[44] fish,[45–50] animal tissues,[51] milk [52] and human blood.[53] It is necessary to mention that PCB isomers from bound fats (phospholipids) must be separated quantitatively by saponification with subsequent extraction with polar solvents.[39]

2. Gas chromatographic separation and determination

The quantitative determination of PCB for individual types of PCB, such as Chlopen A-50 or Arochlor 1254, is difficult since different types of PCB or mixtures may be present in the environmental samples. Consequently several individual types of PCB or mixtures have come to be used as standards in recent years. For example, Arochlors 1242, 1248, 1254 and 1260 are used as standards for the determination of PCB in soil and grass with a limit of detection of 1 ng g^{-1} dry weight.[54] The same standards are used for lake deposits but with quartz columns,[55] and a mixed standard containing equal amounts of Arochlors 1242, 1254 and 1260 is used for soil with a limit of detection of 0.5 ng g^{-1}.[56]

Cross-calibration in the determination of actual amounts of Arochlors 1242 and 1254 and their sum in contaminated residues using seven individual standards containing Arochlors 1221, 1232, 1016, 1242, 1248, 1254 and 1260 showed that the relative standard error of the GC/ECD method using packed columns was 30% and of the GC/MS method using capillary columns was 38%.[57] Occasionally internal PCB standards, such as 2,4,5-trichloro- and 2,2′,3,4,5,6-hexachlorobiphenyl are added to test samples of sludges and entrapped water with subsequent determination by GC/ECD on capillary columns with 84–99% detection of standards.[58]

In view of the importance of Arochlors as standards the percentage of isomeric groups is determined in each of them by GC/MS. For example, Arochlor 1254 has Cl_4 16.0, Cl_5 59.9, Cl_6 23.8 and Cl_7 0.4% and Arochlor 1268 has Cl_7 4.0, Cl_8 36.3, Cl_9 52.3 and Cl_{10} 7.4%,[59] and a series of Arochlors may contain up to 60 individual isomers.[60]

The inadequacy of comparing concentrations in a test sample with that of determined Arochlor or Chlophen is reinforced by the change with time of the 'PCB picture' in the environment as a result, for example, of isomerically specific disintegration, biotransformation and bioaccumulation by living organisms. Furthermore the problem of quantitatively determining PCB will be aggravated by the removal by nature of individual PCB isomers in chemical and pyrolytic processes. In addition to the reasons mentioned above the precision of determination in environmental samples will also markedly depend on the variability and sensitivity of each isomer to the method being used.

In all 209 PCB isomers are known: Cl_1 (3), Cl_2 (12), Cl_3 (24), Cl_4 (42), Cl_5 (46), Cl_6 (42), Cl_7 (24), Cl_8 (12), Cl_9 (13), Cl_{10} (1), each has been given a number from 1 to 209.[60–62]

For more precise determination of PCB in samples the use of calibration mixtures of PCB isomers at various concentrations has been proposed. These include one isomer from each isomeric group, with a number of chlorine atoms from 1 to 10, and analysis by GC/MS.[63] Identification and quantitative determination of PCB isomers by the actual number of chlorine atoms is effected by their detection in a particular mass range in the mass spectrogram. For example all the Cl_4 isomers are in the mass range 288–294 and all the Cl_7 in 390–396. Using the same principle a further 21 polychlorinated insecticides may successfully be determined in one test sample in addition to PCB.[64] With the same set of standards it is possible to determine PCB in soils by GC/MS with positive chemical ionisation.[65]

For the precise determination of the total PCB content in a sample it is necessary to determine all the PCB isomers present in it. It is necessary that each isomer appears on the chromatogram as a single peak well separated from other PCB isomers or compounds. This makes it possible to avoid dubious results from the variable contribution of co-eluting isomers in an unresolved peak and also from differences in sensitivity coefficients in the ECD. Consequently the precise determination of the total PCB content in test samples must be carried out with a set of all the individual PCB isomers as standards and not with mixtures. This is impossible in practice although all 209 PCB isomers have recently been synthesised and their retention times determined.[66]

Determination of the total content of PCB or of separate isomers by high resolution gas chromatography (HRGC)/ECD is carried out at present on capillary columns of SE-54 phase (DB-5, CP Sil 8, HP-5) of length 25–60 m. However all isomers encountered in

natural test samples cannot be completely separated on just one column. Nonetheless the relative elution order of PCB isomers has been determined.[62,66] With a fixed substitution pattern in the first ring the retention of this family of isomers increases in the orders: 2 < 3 < 4; 2,6 < 2,5 < 2,4 < 2,3 < 3,5 < 3,4; 2,4,6 < 2,3,6 < 2,4,5 < 2,3,4 < 3,4,5; 2,3,5,6 < 2,3,4,6 < 2,3,4,5. The relative elution order of the PCB isomers remains the same for polar phases such as OV 1701 etc.[62] It should be mentioned that the separation of PCB isomers on columns with phases SE-30, SE-54 and OV-101 differ a little depending on the column manufacturer. This is linked with different methods of surface deactivation prior to coating with a film and immobilising the film itself.

Complete separation of all PCB isomers in complex mixtures was successfully achieved only in 1988 using two-dimensional GC [67,68] carried out on a Sichromat-2 (Siemens), fitted with two independent ovens and two ECD (main and monitor). A chromatogram of the mixture of PCB isomers being analysed is obtained with the first column (SE-54, 25 m × 0.32 mm) in the first oven. The main portion of the eluate, corresponding to the part of the chromatogram with complete separation of isomers, is then passed through the monitor detector and selected fractions of the eluate, corresponding to the unresolved isomers on the chromatogram, are directed to the second column (OV-210, 30 m × 0.32 mm) in the second oven with the main detector. The monitor detector on the first column shows the usual gas chromatogram of a mixture by ECD except for one or several breaks, corresponding to the eluate fractions directed to the second column. The main detector on the second column shows chromatograms of the separated isomers in the fractions of the eluate directed from the first column. The principle of the method and the technical details have been described previously.[69]

The chromatographic separation of isomers on the second column may be very efficient. For example, the cluster of three isomers Nos. 126 (3,3',4,4',5-), 129 (2,2',3,3',5-) and 178 (2,2',3,3',5',6-) have retention times on the first column of 26.81, 26.80 and 26.85 min respectively and on the second of 37.98, 37.13 and 36.48 min, i.e. the unresolved triplet was separated into three separate peaks.[67]

Extremely important problems are the criteria for selection of standard PCB isomers for analysis as a function of the range of chlorine numbers (the number of chlorine atoms in the PCB isomers) and their contribution to environmental test samples, the use for calculation of the total PCB content, the relative distribution between various phases of natural aqueous media such as the atmosphere, water, sludges and biological specimens, aqueous and lipid solvents, the tendency to bind to particles and lipids, persistency and finally toxicity.

The first criterion, considering only a number of isomers covering a wide range of physicochemical properties, may be used for specific purposes such as a comparison between types of sample and regions and also for directing analyses. However choosing isomers, based on a range of chlorine numbers together with a requirement for their significant content in mixtures of the Arochlor type, for precise determination leads to a more or less arbitrary selection of isomers, at least in an ecological sense. The limitation of data by isomer is probably not the most correct approach for an answer to many problems linked with the behaviour and effects of PCB in the environment. Examples are the set of the ICES [?International Commission for the Exploration of the Seas (Ed. of Translation)] consisting of six isomers with chlorine numbers 3–7: No. 28 (2,4,4'-), 52 (2,2',5,5'-), 101 (2,2,',4,5,5'-), 153 (2,2',4,4',5,5'-), 138 (2,2',3,4,4',5-) and 180 (2,2,',3,4,4',5,5'),[68] a mixture of Arochlors 1221, 1016, 1254, 1262 (20:10:7:6) for the analysis of environmental samples,[70] a set of fourteen isomers: Nos. 28, 52, 74 (2,4,4',5-), 66 (2,3',4,4'-), 101, 151 (2,2',3,5,5',6-), 118 (2,3',4,4',5-), 153, 105 (2,3,3',4,4'-), 138, 187 (2,2',3,4',5,5',6-), 183 (2,2',3,4,4',5',6-), 156 (2,3,3',4,4',5-) and 180, comprising about 70% total PCB content in human milk.[71,72]

The set of PCB isomers based on their toxicity is important. Quantitative structure–activity relationships show that the most toxic PCB isomers are isostereomeric with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.[51,73] It is proposed that their toxicity is explained by the presence of chlorine atoms in positions 4,4' and/or 3,3,',5,5' and also by the possibility of two benzene rings achieving a planar configuration when one or both *ortho* positions are not substituted by chlorine atoms. This condition is satisfied by 13 isomers: Nos. 37 (3,4,4'-), 77 (3,3',4,4'-), 81 (3,4,4',5-), 118, 123 (2',3,4,4',5,5'-), 114 (2,3,4,4',5-), 105, 126 (3,3',4,4',5-), 167 (2,3',4,4',5,5'-), 156, 157 (2,3,3',4,4',5-), 169 (3,3',4,4',5,5'-) and 189 (2,3,3',4,4',5,5'-). It has been proposed that the toxicity of PCB isomers be considered the most important criterion for determining them in evironmental samples. Only four toxic isomers (Nos. 81, 114, 169 and 189) may be determined on one column of phase SE-54 and the remaining isomers may only be determined by two-dimensional GC.[68]

Mention must be made of the influence of the quality of appropriate PCB standards used on the precision of determining PCB isomers. PCB isomers of inadequate or inapplicable purity are available for sale. This leads to the development of additional peaks in the spectrum when working with an ECD or flame-ionisation detector (FID) and to the splitting of peaks on various columns. Consequently the use of calibration standards of mixed PCB solutions consisting of such individually inadequately pure PCB isomer standards may lead to large qualitative and quantitative errors when determining separate isomers and overall PCB content.[68]

IV. Herbicides

Chlorine-containing herbicides are widely used in agriculture for the elimination of weeds and undesirable woody undergrowth and as defoliants. The most important of them are acidic in character and consequently they are determined, as a rule, as esters by GC/ECD. Their determination by HPLC has only been described in the form of free acids in the concentration range 20 ng litre^{-1} to 1 mg litre^{-1}.[74]

Usually test samples of water[74–77] or sludge[77] are acidified to pH < 2 and the herbicide extracted with organic solvent, then esterified and the ester purified on columns of silica gel or Florisil.[75–77] Diazomethane[75] and pentafluorobenzyl bromide[76,77] are used as derivatising agents. The limits of detection of the methods are 0.05 μg litre^{-1},[76] 0.5 μg litre^{-1},[75] and 10–25 μg kg^{-1}.[77] Determination is carried out on packed[75,77] and capillary columns. It was shown that the choice between pentafluorobenzyl and methyl esters for the determination of herbicides depends on the relative importance of the detection limits and the linear range of concentration.[78]

The determination of 18 (cyanoethyl)dimethylsilyl derivatives of herbicides by the GC/N–P detector made it possible to exclude purification of the sample, which had been required for GC/ECD, and to have a limit of detection of 0.1 μg litre^{-1}.[79] The same method has been proposed for the determination of herbicides in solid discharges.[80] Capillary columns of length 30 m with phases DB-5 [76,78,80] and SP-2250 [78] and of length 15 m with phase DB-1 [79] have been used. The retention times, linear range of concentration

and sensitivity coefficients for herbicide esters have been determined for the separate columns.

V. Phenols

Polychlorophenols are some of the main contaminating substances in the environment, particularly pentachlorophenol which is the most widespread wood preserving agent, and is also a disinfectant and pesticide. 2,4-Dichloro- and 2,4,5-trichlorophenols are formed on breakdown of the widespread herbicides 2,4-D and 2,4,5-T and accumulate in nature. Trace quantities of polychlorophenols are determined as a rule in environmental objects as esters which are freed more easily from the interfering influence of other compounds and are separated on chromatographic columns.

Polychlorophenols are usually extracted from test samples of natural waters with organic solvents and are acetylated at the same time with acetic anhydride.[74–84] The same procedure is applied to sludges,[82] or polychlorophenols are first extracted and then acetylated.[85,86] The degree of extraction of chlorophenols from residues, however, depends markedly on the method used and consequently serious difficulties are encountered in the interpretation of the results obtained. This was shown when comparing methods of isolating chloroguaiacols and chlorocatechols from contaminated test samples.[87] From biosamples (homogenised tissue) chlorophenols are separated by a mixture of solvents with anydrous sodium sulphate[88] or dilute sulphuric acid.[89]

Chlorophenoxyacetates isolated from natural waters are not purified before determination but from sludges and particularly from biosamples they are usually separated from interfering organics on silica gel for example.[86,88] Test samples of chlorophenols are stored under the same conditions before analysis as when determining organochlorine pesticides.

Chlorophenoxyacetates are determined by GC/ECD on capillary columns of length 12–30 m with phases OV-73,[81,82] OV-1701 and SE-54,[85,88] OV-1 [86] and DB-1,[84] and by GC/MS with phases DB-1 [84] and SPB-5.[86] The limits of detection are 1 ng litre^{-1} for natural waters[81] and 0.2 ng litre^{-1} for sludges.[86] The limit of detection for chloroanisoles and -veratroles from a wet mass of fish tissue is in the range 0.2–10 ng g^{-1}.[88]

It was shown that the determination of chlorophenols in water as acetates has significant advantages compared with determination as pentachlorobenzyl ethers because the acetylation can be carried out directly in the test sample, reducing matrix influences and improving detection. By GC/MS it is possible to determine up to 35 haloesters from one test sample, including phenol and monochlorophenols which are usually difficult to determine by GC/ECD.[84]

In recent years the chromatographic and mass spectrometric properties of upwards of 30 chlorophenols and various esters have been studied in detail. Absolute limits of detection, relative retention times and sensitivity coefficients have been determined for chlorophenols (GC/ECD),[90] (GC/FID),[91] acetates (GC/ECD),[90] (GC/ECD, GC/MS),[84] anisoles,[90] pentafluorobenzyl ethers (GC/ECD),[91–93] (GC/ECD, GC/MS) [84] (cyanoethyl)dimethylsilyl ethers (GC/N–P-detector, GC/MS).[94] These data will permit the improvement and simplification of effective methods of determining chlorophenols in environmental objects in the near future.

Chlorophenols are rarely determined by other methods without derivatisation. They are usually separated from water and concentrated on solid adsorbents, such as polydivinylstyrene,[95] graphite [96] and XAD resins,[97] and then determined by HPLC on columns with C_{18} phases [95,96] or GC/IR spectroscopy.[97] Limits of detection are 4–40 ng litre^{-1}.[96]

VI. Dioxins and furans

Polychlorinated dibenzo-*p*-dioxins (PCDD) and dibenzofurans (PCDF) are tricyclic aromatic compounds with similar physical, chemical and biological properties. They are the reason for the mass illness and poisoning of people in Seveso (Italy) in 1976, Japan and USA in 1971–1983, and particularly at the time of the war in South Vietnam in 1968–1973.

The number of chlorine atoms in these compounds varies from 1 to 8 and the total number of positional isomers in PCDD and PCDF is 75 and 135 respectively (Table 1), they have been numbered systematically with indices D and F. For example the most toxic isomers 2,3,7,8-TCDD and 2,3,7,8-TCDF have the symbols D 48 and F 83 respectively.[98] All these isomers differ significantly in acute toxicity and biological activity (up to 300 000 fold). The most toxic and bioactive are 12 isomers with 4–6 chlorine atoms, of which 4 must be in positions, 2,3,7 and 8 (Table 2). Several of these isomers have oral LD_{50} levels < 10 μg kg^{-1} for guinea pigs.[99]

Table 1. Number of positional isomers of PCDD and PCDF.

Level of chlorine substitution	Number of isomers	
	PCDD	PCDF
Cl (mono)	2	4
Cl_2 (di)	10	16
Cl_3 (tri)	14	28
Cl_4 (tetra)	22	38
Cl_5 (penta)	14	28
Cl_6 (hexa)	10	16
Cl_7 (hepta)	2	4
Cl_8 (octa)	1	1
Total	75	135

Table 2. The most toxic PCDD and PCDF isomers.

PCDD	PCDF
2,3,7,8-Tetra-CDD	2,3,7,8-Tetra-CDF
1,2,3,7,8-Penta-CDD	1,2,3,7,8-Penta-CDF
1,2,3,6,7,8-Hexa-CDD	2,3,4,7,8-Hexa-CDF
1,2,3,7,8,9-Hexa-CDD	1,2,3,6,7,8-Hexa-CDF
1,2,3,4,7,8-Hexa-CDD	1,2,3,7,8,9-Hexa-CDF
	1,2,3,4,7,8-Hexa-CDF
	2,3,4,6,7,8-Hexa-CDF

PCDD and PCDF are found in trace concentrations in industrial chemical products such as polychlorophenols and their derivatives, and herbicides based on phenoxyacids and diphenyl ethers.

They are found in combustion products of industrial and communal incineration furnaces, on pyrolysis of PCB, chlorophenols, chlorobenzenes and many other chlorine-containing organic compounds.[100,101]

Modern methods for the quantitative determination of the isomers of PCDD and PCDF in environmental objects at concentrations at the ppt level will be considered in this chapter. Principal attention will be paid to the most toxic isomer, viz. 2,3,7,8-TCDD. Some of this material has been correlated in reviews.[100-102]

In view of the extremely low hazardous concentrations of PCDD and PCDF the quantitative content of their separate isomers may only be determined by HRGC and MS, since the former is capable of separating all isomers but is insufficiently selective with a background of matrix interference and the second identifies isomers and is extremely sensitive in the whole mass range at a level of 10^{-13} g on using high or low resolution mass spectrometry. However without HRGC, mass spectrometry does not resolve the majority of isomers because many of them give very similar mass spectra.[101,102]

1. Selection and storage of samples

Test samples of air containing PCDD and PCDF are taken in equipment consisting of sequentially connected filters for the removal of aerosols and cartridges of various adsorbents for trapping gaseous products. Glass fibre,[103-105] quartz wadding,[106] and as adsorbents XAD-2 resin,[105,107] polyurethane foam,[103,108] silica gel [104] and ethyleneglycol [106] are used as filters. A 6-1000 m^3 volume of air is passed through the filters and adsorbents under vacuum at a rate of 1-14 $m^3\ h^{-1}$.

In order to concentrate PCDD and PCDF from drinking water it has been proposed to pass the latter (10-200 litre) through a cartridge of XAD-2 resin [109] or C_{18} phase [110] at a rate of 0.15 to 0.5 litre min^{-1}.

Soil samples up to 3 cm from the surface layer and deeper layers are taken with tubular samplers and stored before analysis in wide mouthed glass jars with teflon screw caps at 4 °C [111] or −30 °C.[112]

After taking and before analysis biosamples must be rapidly frozen if possible and stored in the frozen state down to −180 °C, as a rule, in aluminium foil. This was shown for fish,[112-115] seals,[116] rabbits and pheasants,[112] human tissue [117-119] and vegetable fruit.[112] Temporary storage in the cold state is possible in glass vessels for test samples of cows' cream and earthworms (after washing and homogenisation).[112]

2. Preparation of samples for analysis and extraction

Samples need to be carefully homogenised and often dried for the quantitative recovery of PCDD and PCDF isomers from environmental samples using organic solvents.

Test samples of soil and sludges are dried in air or in a desiccator to constant weight at 60-110 °C and moisture content is usually determined. They are then screened through a sieve to remove foreign bodies (stones, shells, roots, etc.).[111,120-122] Test samples are also dried by mixing with anhydrous sodium sulphate [123-125] or by lyophilisation.[126]

Biological test samples are homogenised by alkaline,[112,113,118,127-129] acidic [115,129-131] or enzymic [132] degradation, lyophilisation and subsequent crushing,[129,133] grinding in a meat grinder or homogeniser with subsequent powdering with anhydrous sodium sulphate.[114,117,123,129,134-138]

For the complete identification and precise quantitative determination of PCDD and PCDF isomers it is necessary to introduce precise amounts of a mixture of isotopically labelled PCDD and PCDF standards. These are added to the homogenised test sample (biological tissue, soil, sludges, etc.) and to samples taken from various filters and to cartridges (from air and various types of water) before extracting them with organic solvent. The standards have a definite number of chlorine atoms including tetra- (T), penta- (Pe), hexa-, hepta-, and octa- (O)-CDD and -CDF, 10 isomers in all (0.1-3 ng of each). All the standards in Table 2 are used for the quantitative determination of all the most toxic isomers. The isotopically labelled standards $^{13}C_{12}$-PCDD/PCDF and less frequently $^{37}Cl_{4-8}$-PCDD/PCDF are generally used.[100-102,139] It should be mentioned however that these standards are very expensive. Consequently the whole set are used in only a few laboratories in the world. The majority use only a few standards which positively reduces the precision of determining and identifying PCDD/PCDF.

In addition to using filters for aerosols and cartridges for air, PCDD and PCDF are extracted from samples in a Soxhlet apparatus usually with toluene,[103-105,108] and from soils and sludges with various organic solvents or solvent mixtures.[111,121,122,124,125,140,141] It should be mentioned that the degree of recovery of PCDD/PCDF is increased by previous treatment of samples of soil, sludges and aerosols with hydrochloric acid prior to extraction or carrying out extraction combined with ultrasonic treatment.[142]

PCDD/PCDF are extracted from water with dichloromethane[125,141] and, after concentrating them on a cartridge with adsorbents, with acetonitrile or mixtures containing it.[109,110] PCDD/PCDF are extracted from homogenised biological samples such as fish tissue,[112-115,121,123-129,131,133,135,138] adipose tissue,[116-118,123,134,137,143,144] blood plasma,[119,144] milk [130,132,136,145] or human tissue [139] most frequently of all with hexane or mixtures of it with other organic solvents.

3. Purification of organic extracts

In addition to PCDD and PCDF, many other co-extracted substances and compounds of biogenic (lipids, proteins, etc.) and anthropogenic occurrence are contained in organic extracts of samples from environmental objects, which it is necessary to separate before determining dioxins and furans by GC/MS.

A multistage and very laborious purification of extracts is required when determining PCDD and PCDF by low resolution GC/MS (on packed columns). For example, extracts of human milk are purified on four chromatographic columns containing as adsorbents: 1) silica gel/alkali on silica gel/acid on silica gel; 2) silica gel/acid on silica gel; 3) silver nitrate on silica gel; 4) aluminium oxide and two columns of reversed and normal phase HPLC.[130]

The requirement for purification of organic extracts is reduced with the introduction of HRGC on capillary glass and particularly quartz columns with bonded phases and of length 30-60 m. It should be mentioned that purification methods vary strongly in relation to matrix complexity and in the case of biological samples it is necessary to purify extracts from far larger quantities of interfering substances and compounds than in the case, for example, of samples of atmospheric air.

After purification all the PCDD/PCDF isomers are concentrated as a rule on a column of carbon of type PX-21 (Amoco) or Carbopak (Supelco) from which they are eluted usually with toluene for analysis by GC/MS.

Extracts of air samples require simpler methods of purification. Their purification has been proposed on two columns of modified silica gel/silica gel and carbon on celite 545 [105] or aluminium oxide,[108] on a column of Florisil and normal phase HPLC,[103] on three columns with basic and acidic aluminium oxide and with activated carbon.[104]

Extracts of water, sludge and particularly biological samples, are usually subjected to complex and careful purification for determining the large number of individual isomers of various groups of PCDD and PCDF. Often however only 2,3,7,8-TCDD or other individual isomers or groups of isomers are determined. In this event the purification of extracts is significantly simplified. It must also be emphasised that it it possible to determine all PCDD and PCDF isomers from one fraction when purifiying extracts by adsorption column chromatography.[123] When using purification by normal or reversed phase HPLC in the last stage of purification several fractions must be used. Consequently these methods are usually used for determining separate isomers or groups of isomers.

Organic extracts of water are purified with conc. H_2SO_4 prior to decolourisation and on columns of Florisil and carbon/celite 545,[109] on columns of silica gel/acid on silica gel, of acid aluminium oxide and carbon/celite 545.[125]

Extracts of sludges are purified on columns of carbon/celite 545 and of silica gel with subsequent normal and reversed phase HPLC,[122] after removal of sulphur on columns of acid on silica gel, alkali on silica gel, $AgNO_3$ on silica gel, basic Al_2O_3, reversed phase HPLC,[126] exclusion chromatography, sequential treatment with Na_3PO_4, H_2SO_4, on columns of Al_2O_3 and carbon,[131] on columns of silica gel/Na_2CO_3/alkali on silica gel/H_2SO_4 with $CaSO_4$/silica gel/alkali on silica gel, acid Al_2O_3, carbon/celite 545 and neutral Al_2O_3.[121] Soils were purified as for water,[125] on columns of CsOH/silica gel/acid on silica gel and on Al_2O_3,[111] contaminated soil on columns of CsOH/silica gel/acid on silica gel and $AgNO_3$/silica gel.[111]

It has been proposed to purify extracts of fish tissue on columns of MgO/celite 545/Al_2O_3 and Florisil/Al_2O_3,[133] on a column of acidic Al_2O_3/basic Al_2O_3 and then by normal and reversed phase HPLC,[128] on three columns of H_2SO_4/silica gel, NaOH/silica gel or $AgNO_3$, basic Al_2O_3 and reversed phase HPLC,[115] by exclusion chromatography and reversed phase HPLC on two different columns,[127] by exclusion chromatography and on columns of Al_2O_3 and Florisil,[138] on four columns with H_2SO_4 and NaOH with silica gel and by HPLC,[112] on three columns of celite 545/conc. H_2SO_4, Cs_2SiO_3 and carbon,[114] and on columns of silica gel/K_2SiO_3/H_2SO_4/celite 545, Al_2O_3, carbon/silica gel [135] as in the case of sludges.[121,131]

Extracts of human tissue samples are purified by treatment with H_2SO_4, on columns of Florisil and carbon/silica gel,[139] adipose tissue on three columns of silica gel/alkali on silica gel/acid on silica gel, $AgNO_3$/silica gel, basic Al_2O_3 and then normal and reverse phase HPLC,[146] on three columns of acid on silica gel, Al_2O_3, carbon/celite,[117] by exclusion chromatography on columns of Florisil and of carbon,[143] by exclusion chromatography on columns of Florisil, Al_2O_3 and carbon/celite 545,[116] by treatment with H_2SO_4, on columns of silica gel, carbon/silica gel, by GC,[118] human blood plasma on columns of acid on silica gel/silica gel and carbon/celite 545,[144] as for adipose tissue,[119] and human milk by a modified procedure [136] for adipose tissue.[146]

Among the contemporary methods of preparing samples and analysing by GC/MS a procedure has been evolved combining the extraction and purification of samples of soil, sludges and biological specimens into a two stage process and enabling determination of all the PCDD and PCDF isomers from one fraction.[123] In the first stage the mixture of homogenised test sample and Na_2SO_4 is extracted in the first column and the extract passed in the same column through K_2SiO_3/silica gel, and then through two columns of Cs_2SiO_3 or K_2SiO_3/silica gel and activated carbon. With the exception of *ortho*-PCB, the PCDD, PCDF, polychlorinated naphthalenes (PCN), biphenyls (PCBP) and a series of polyaromatic hydrocarbons remain on the carbon adsorbent. In the second stage the extract is passed through two columns of Cs_2SiO_3/acid on silica gel and aluminium oxide. Modifications of this procedure have been applied successfully to the determination of PCDD/PCDF isomers in human adipose tissue,[134,144] and also in human and cows' milk.[145,147]

It is evident from the material presented above that the purification of extracts for subsequent determination of PCDD and PCDF by GC/MS is a complex and prolonged process in the majority of cases. The main part of the time is consumed in this way, occasionally reaching 80% (10 h or more) of the time for carrying out the whole analysis. Consequently attempts have been made to reduce the time of purification of extracts for which a modified method of separation and identification by GC/MS/MS has been proposed.[109,148–150]

The method of tandem mass spectrometry is based on the separation of the components of a mixture according to their molecular weight in the first analyser of the mass spectrometer (low or high resolution) and obtaining structural information on the determined compounds in the second analyser at low resolution. It is impossible to use these separating capabilities of the MS/MS method for the direct analysis of extracts in view of the extremely low concentrations of PCDD and PCDF in comparison with the main interfering compounds. Consequently it is necessary first to remove the latter from the compounds to be determined on short capillary gas chromatographic columns of length 12 m. This method has been used successfully for determining PCDD and PCDF in drinking water and soil and has enabled the time required for purification of extracts of biological samples to be reduced significantly by shortening several stages.

4. Gas chromatographic separation of isomers

Purified extracts of PCDD and PCDF are most frequently analysed by gas chromatography-mass spectrometry with quartz and, far more rarely, with glass capillary columns, usually 50–60 m long with a strongly polar (3-cyanopropyl)polysiloxane phase, such as SP-2330,[135,138,145] SP-2331,[105,126,136,144] CP-Sil 88 [118,125] and Silar 10C,[151] and with non-polar phase DB-5.[116,124,143,145–147] Columns of length 25–30 m with DB-5 have also been used.[116,135,137,139] The columns lead directly into the ion source of the mass spectrometer operating in electron impact (EI) or negative chemical ionisation (NCI) modes.

It must be emphasised however that at the present time a single column does not exist in which it would be possible to separate all the 2,3,7,8-substituted PCDD/PCDF isomers in the presence of all the PCDD/PCDF isomers. It is possible to separate all the 2,3,7,8-substituted isomers of PCDD successfully on columns of SP-2330 [151] and Silar 10C,[152] but in the case of the 2,3,7,8-substituted isomers of PCDF this proved to be impossible even within the TCDF group.[153,154] In the latter case complete separation was achieved only when using two columns such as SP-2331 and DB-17,[155] or on a column of a new smectic liquid crystal phase.[156]

The use of sequential combined columns of DB-5 and CP-Sil 88 of length 50–60 m must be mentioned. The various chlorine groups of PCDD/PCDF with equal numbers of chlorine atoms are separated on the first column and the isomers in these groups in the second. Such a method enables large volumes of solvent, up to 10 μlitre, to be injected into the gas chromatograph and significantly reduces the level of detection.[137]

Gas chromatographic characteristics have been described for all TCDD-OCDD for a Silar 10C column,[152] all PCDF for a DB-5 column,[157] for 35 PCDF for SP-2330 and V-101 columns,[158] for all TCDF for DB-5 and SP-2331 [154] and SE-54 and SP-2330 columns,[153] all TCDD for SP-2330 and OV-1 columns[159] and for columns with modified (cyanopropyl)polysiloxane phase,[160] and for the toxic PCDD/PCDF for columns with the new OV-240-OH phase.[161]

5. Mass spectrometric determination

The mass spectrometry of PCDD and PCDF has been described in detail in reviews[100–102,151,162,163] and will be considered here only briefly and as applied to the quantitative determination of isomers of xenobiotics in the environment.

Table 3. Ions (m/z) used for monitoring PCDD and PCDF in test samples of environmental objects.[101]

Ions for monitoring		Tetra-	Penta-	Hexa-	Hepta-	Octa-
	PCDD					
EI	M^+	320	354	388	422	—
	$(M+2)^+$	322	356	390	424	458
	$(M+4)^+$	—	—	—	—	460
NCI	M^-	(320)	354	—	—	—
	$(M+2)^-$	(322)	356	—	—	—
	$(M-Cl)^-$	—	—	353	387	—
	$(M+2-Cl)^-$	—	—	355	389	423
	$(M+4-Cl)^-$	—	—	—	—	425
	PCDF					
EI	M^+	304	338	372	406	—
	$(M+2)^+$[a]	306	340	374	408	442
	$(M+4)^+$[a]	—	—	—	—	444
NCI	M^-	304	338	372	406	—
	$(M+2)^-$[a]	306	340	374	408	442
	$(M+4)^-$[a]	—	—	—	—	444

[a] PCN and PCT intefere a little, but interference from PCDPE is possible.

Low resolution quadrupole mass spectrometry is most frequently used for monitoring PCDD and PCDF. EI in the selective ion detection (SID) mode is used for the determination of TCDD/TCDF for which it has a high sensitivity (1–10 pg). However the sensitivity falls significantly for the more chlorinated isomers. On the other hand NCI in the SID mode is 1–2 orders of magnitude (10–100 fg) more sensitive, when using methane as carrier gas, for all the PeCDD-OCDD and TCDF-OCDF in comparison with EI but has a low sensitivity for all TCDD, only 20% of that for EI.

PCDD/PCDF ions used for monitoring in EI are M^+ (for tetra-, penta- and hexa-) and $(M+2)^+$ for hepta- and octachloro compounds, in NCI M^- for the less chlorinated isomers of PCDD and M^- and $(M+2-Cl)^-$ for the more chlorinated isomers. For PCDF M^- or $(M+2)^-$ (Table 3) are used.[101]

The use of high resolution mass spectrometry (5000–10 000) gives additional selectivity and the senstivity on EI in the SID mode may reach 10–200 fg for all TCDD(F)-OCDD(F). The use of high resolution mass spectrometry and of MS/MS for determining PCDD/PCDF isomers has been described in detail in a review.[102]

The quantitative determination of PCDD/PCDF isomers is based on measurements of peak area or height and comparison of them with calibration graphs of external standards and isotopically labelled internal standards. Introduction of the latter into test samples before extraction of PCDD/PCDF helps to explain their loss in the extraction process and in the purification of extracts. It also aids identification of isomers and their quantitative determination.

Table 4. Molecular ions of PCDD and PCDF.[101]

Molecular ions (m/z, M^+, M^-) (chlorination)	Compounds					
	PCDD	$^{13}C_{12}$-PCDD	^{37}Cl-PCDD	PCDF	$^{13}C_{12}$-PCDF	^{37}Cl-PCDF
Mono-	218	230	220	202	214	204
Di-	252	264	256	236	248	240
Tri-	286	298	292	270	282	276
Tetra-	320	332	328	304	316	312
Penta-	354	366	364	338	350	348
Hexa-	388	400	400	372	384	384
Hepta-	422	434	436	406	418	420
Octa-	456	468	472	440	452	456

The following are necessary[101] for proof of identity of PCDD/PCDF isomers. The retention time of the PCDD and PCDF isomers being determined must be within 3 sec to establish the isomeric specificity and must be confirmed daily. The signal to noise ratio must be at least 2.5:1. The chlorine cluster must be ±10% of the theoretical value and precise fragments, such as $(M-COCl)^+$ ions, must coincide with the precise chlorine cluster.

In spite of the use of fairly effective methods of purification of extracts the presence is occasionally encountered of other contaminating polychlorinated compounds interfering with analysis. These may be mainly non-*ortho*-substituted PCB, PCN, PCBF, polychlorinated terphenyls (PCT), diphenyl ethers (PCDPE), pyrenes (PCP) (Tables 4 and 5) and also occasionally polychlorinated anthracenes, phenanthrenes and fluorenes. These compounds however are usually readily distinguished by their intense M^+ or M^- ion and the number of chlorine atoms deduced from their ionic clusters. In rare cases polychlorinated benzenes, benzofurans and styrenes are observed, but they do not interfere with the analysis.[101]

Methods of analysis of trace quantities of PCDD/PCDF have improved markedly in recent years and this permits a significant reduction in their limits of detection. They are, for example (depending on the isomers), for samples of air 0.01–0.05 [105] and 0.1–1 pg m^{-3},[103] sludges (for TCDD) 0.1 ng kg^{-1},[126] drinking water 1 pg $litre^{-1}$,[109] blood plasma 0.003–0.02 [144] and 1.25 pg $litre^{-1}$ (for TCDD),[119] adipose tissue 2–10 ng kg^{-1},[139] milk 0.1–0.5 [147] and 0.2–0.4 ng $litre^{-1}$.[145]

Table 5. Molecular ions of polychlorinated compounds present in environmental test samples and possibly interfering in the mass spectrometric analysis of PCDD and PCDF.[101]

6. Safety techniques when carrying out analyses

It is necessary to take special safety measures when carrying out analyses because of the extreme toxicity of many isomers of PCDD and PCDF. These begin at sample taking and end with the decontamination of the waste water after carrying out analyses.[164]

When taking samples of environmental objects precautions depend strongly on the concentrations of PCDD/PCDF presumed to be present. In the case of strongly contaminated places of sampling and of the samples themselves special safety measures must be applied which are linked with the organisation of decontamination areas, special clothing, etc. In uncontaminated places test samples of PCDD/PCDF are collected with the same precautions as when taking samples of other highly toxic xenobiotics for analysis.

The selected samples are carefully packed and transferred to the station laboratory. Each test sample of soil and sludge in glass beakers with teflon screw lids is placed in a plastic container which is itself placed in a metal container with kieselguhr. Biological samples are wrapped 2–3 times in aluminium foil and transferred in the frozen state in foam-plastic containers. Water samples in glass bottles are first placed in a plastic container with kieselguhr which is then put into a metal container with kieselguhr.

All work must be carried out in the station laboratory in a fume cupboard. Liquid waste water must be mixed with methanol or ethanol and irradiated with UV light at a wavelength > 290 nm for several days. Residues of samples coming out of a chromatograph and GC/MS sample effluent must be passed through a column of activated charcoal or bubbled through a trap of oil or high boiling alcohol.

Working surfaces and equipment in a station laboratory are sampled periodically with pieces of filter paper to determine their cleanliness. This is considered satisfactory at a content of 1 μg 2,3,7,8-TCDD in the wipe sample. At >1 μg the location must be cleaned and at >10 μg there is a threat of contamination and consequently working places must be cleaned meticulously.

The problems arising after the accumulation in nature of a large number of highly toxic chlorine–containing xenobiotics oblige mankind to solve a most complex analytical problem, viz. to develop methods for the quantitative and qualitative determination at the ppt level of polycyclic mixtures in various natural objects. This requires highly pure, and frequently ultrapure, organic solvents, inorganic acids, adsorbents and other chemical reagents, expensive high purity standards for compounds and the isomers to be determined, chromatographs with capillary columns and gas chromatograph-mass spectrometers of high (6000–10 000) resolution with modern systems for processing the results obtained. For the safe determination of complex mixtures of dioxins and furans exceptional cleanliness of laboratory premises is required, to the level for carrying out genetic engineering work, there are very stiff requirements for safety techniques and high qualifications are needed for the scientific and service personnel. The combination of these necessary conditions has a strong influence on the cost of analysis of the first sample, from several tens for determining insecticides to SUS 3000 for the isomerically specific determination of dioxins and furans in biological samples.

Nonetheless the large material outlay in developed countries on the bulk analysis of polychlorinated compounds, particularly the most toxic isomers of dioxins, furans and biphenyls in environmental samples, and, which is very important, in human milk, adipose tissue and blood plasma is considered necessary since these xenobiotics are one of the main sources of progressing immunodeficiency of higher organisms, similar in character to the immunodeficiency caused by the AIDs virus.

In the last five years the industrially developed countries have joined in the need to increase the sensitivity of methods of determining analytically down to a level of 1 ppq (pg kg^{-1}) for 2,3,7,8-TCDD. Only in this case does it seem possible to assess admissible levels for these xenobiotics for the developing foetus and the newborn and to solve many practically important problems including a check on the purity of childrens' food. There is no doubt that the solution of this problem reduces in principle to new technology in ultramicroanalysis.

Dioxins: analytical chemical aspects of the problem

L A Fedorov, B F Myasoedov
V I Vernadsky Institute of Geochemistry and Analytical Chemistry, Academy of Sciences of the USSR, Moscow

ABSTRACT. The dioxins are a large set of polyhalogenated polycyclic compounds formed as impurities during many types of production using chlorine, bromine and their compounds. These xenobiotics have no equals among other contaminants in their danger to man and in global ecological effects. The current status of some aspects of the problem of dioxin and related compounds is considered using material from the foreign scientific press. Data are presented on the physicochemical and other properties of dioxins. Information is correlated on the main sources of dioxins and on the methods of determining them in the environment and the biosphere (air, soil, water, biological samples, etc.). Problems considered are the contamination of the environment, monitoring, ways of reducing the danger and the prevention of dioxin contamination.

The bibliography contains 563 references.

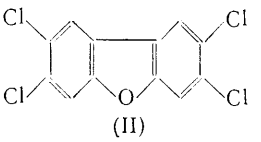
I. Introduction

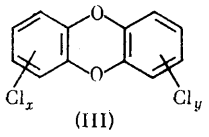
In the last 15–20 years, one more ecological hazard has been added to the vast total threatening civilisation, viz. the possibility of planetary poisoning of our habitation by dioxin and compounds related it.[1–114] Dioxin and the numerous group of dioxin-like substances are foreign to the living organism (xenobiotics) and enter the biosphere from the production or discharges of numerous technologies. In contrast to the mass of other xenobiotics such as organochlorine pesticides *dioxins are never the desired product* of human activity. They only accompany it as microimpurities.[50] Consequently the negative actions of dioxin microimpurities on the living matter of the planet remained unnoticed against the background of the action of thousands and millions of tons of other technogenic discharges for many decades. However this dioxin microimpurity, characterised by a complex of unusual physicochemical properties and unique biological activity, may become a source of the most dangerous lasting contamination of the biosphere, significantly more serious than its contamination by many other substances such as the organochlorine pesticides.[94]



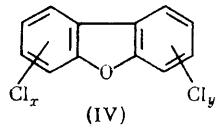
This is because in the last 50–60 years dioxins and related compounds have been generated continuously and on ever increasing scale by civilisation, discharged into nature and have accumulated there. The process of accumulation of these xenobiotics in the biosphere knows no saturation limits or national boundaries. At the present time the situation is such that the concentration of dioxins in the hydrosphere and lithosphere may reach critical values and disease of living matter may assume an irreversible character.

The history of the 'acquaintance' of mankind with dioxins arose in 1930 when the development of the manufacture and use of polychlorophenols led to an increase in the *occupational disease chloroacne* (relapsing inflammation of the sebaceous glands), although the illness itself had been known since 1899.[50,88–93] The geographical distribution of chloroacne spread significantly in 1940–1950 linked with the creation of large tonnage manufacture of 2,4,5-trichlorophenol and also of the manufacture of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) obtained from it, of the antibacterial preparation hexachlorophene, etc. Many cases of poisoning of personnel in this industry during operations have been described, some as a result of accidents.[17,38,88] It has recently been shown that recurrences of chloracne in many of those affected have developed even 20–35 years after the disease.[90]

The source of these diseases was established in 1957 by several groups of investigators simultaneously.[115–117] It turned out to be 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) (I) formed as a microcontaminant when making 2,4,5-trichlorophenol (TCP).[115–116] Passing with the latter into technological chains and then into the final product (herbicides, antibacterial preparations, etc.) dioxin (I) sets in motion, as clarified recently, not only the disease chloracne, but also others including acute poisoning.[93,118,119]



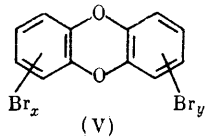
(I)



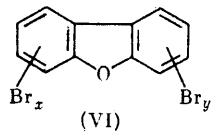
(II)

2,3,7,8-Tetrachlorodibenzofuran (2,3,7,8-TCDF) (II) was also postulated, simultaneously with dioxin (I), as a chloracnogenic factor.[117] However particular attention has been drawn to this xenobiotic itself as a microcontaminant in polychlorobiphenyls (PCB) used as liquid dielectrics, heat-transfer agents, hydraulic fluids, etc. The massive poisonings caused by xenobiotic (II) (in 1968 in Japan[120] and in 1979 in Taiwan[121]) were linked with the entry of PCB into rice oil which led to the so-called Yusho illness (acute liver poisoning acocmpanied by many side effects).[95,96]

It has been shown that xenobiotics (I) and (II), like many other examples of polychlorinated dibenzo-*p*-dioxins (PCDD) (III) and dibenzofurans (PCDF) (IV), have similar toxicological characteristics.[122]

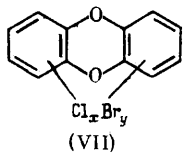


(III)

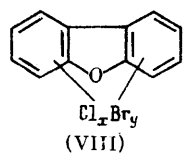


(IV)

$n = x + y = 1$ to 8



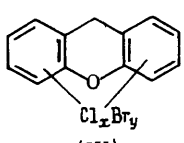
The presence of micro contamination by (III) and (IV) in the products of chloro-compound manufacture is the reason for many cases of poisoning in the sixties, seventies and even the eighties.[17,23,93,96,97] Their entry into chicken feed has repeatedly caused much damage to the broiler industry.[123] Poisoning of people and extended contamination of various objects by xenobiotics (III) and (IV) has been observed many times in the non-industrial sphere as well, for example in the inadvertent utilisation of effluent from chloro-compound manufacture,[66,67,70,71] in poisoning at electric power plants, where much polychlorovinyl insulation material is concentrated or there are transformers (capacitors) packed with PCB.[47,88,124,125]



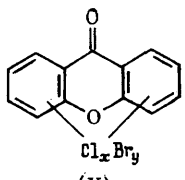
It has been established recently that polybromo-[126–129] and mixed polybromochloro-containing[130,131] dibenzo-*p*-dioxins and dibenzofurans of structure (V)–(VIII) are not less but in some cases more dangerous than the polychlorinated derivatives (III) and (IV). These are formed as byproducts in the manufacture of organic halides, on burning fuel in the presence of bromine compounds and also on processing or the destruction of industrial and domestic refuse.

(V)

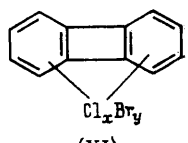
(VI)



$n = x + y = 1$ to 8

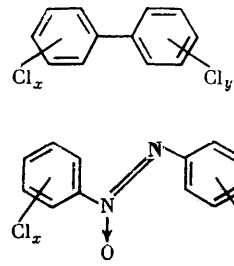


(VII)



(VIII)

$n = 1$ to 8



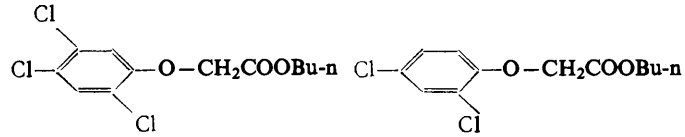
Many other organohalogen compounds possess the biological activity characteristic of dioxin (I). These include certain tricyclic compounds such as polychloro-, polybromo- or polychlorobromo-containing xanthenes (IX), xanthones (X) and biphenylenes (XI)[55,132,133] and also the structurally more complex polychlorinated quaterphenyls.[95,96,134]

(IX)

(X)

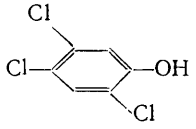
(XI)

Finally a series of bicyclic compounds such as polychlorobiphenyls,[95,96] polychloroazo- and polychloroazoxybenzenes[135] should also be included.



Many of the tri- and bicyclic compounds indicated accompany chemical production and are precursors of xenobiotics (III) and (IV) in nature.

In the industrially developed nations the attention of investigators was drawn long ago to the danger of permanent contamination of the biosphere with dioxin and related xenobiotics. This is evidenced by the appearance of numerous monographs, symposia, scientific conference proceedings,[1–43] reviews[44–114] and dissertations[136–145] devoted to individual aspects and to this problem as a whole. Since 1980 international cooperation has been effected within the framework of annual international scientific conferences devoted to the dioxin problem.[25–34] In several countries the problems linked with dioxins occupy one of the most important places in state ecological and ecologo-economic programmes.



In the last two decades the problems of contaminating the biosphere with dioxins have been widely discussed by the public, in political circles and in the press. This was made possible by the active exposure of the material from two massive events in the years 1960–1970.

One of these was the war of the *USA in Vietnam* in which ~57,000 tons of the herbicide 'Agent Orange' containing (according to official data) about 170 kg dioxin (I) was applied to the territory of South Vietnam during 1962–1970.[35–41,72] The numerous communications generated on the massive disease of the population of this region and the participants of the war,[39,50,66,72,146–149] the negative effects of the herbicide on the child-bearing function of the women, its teratogenic action[146,147] and the more remote consequences of the disease[11,18,24] could not fail to cause alarm since the components of herbicide 'Agent Orange' [a mixture of the butyl ester of 2,4,5-trichlorophenoxyacetic acid, 2,4,5-T (XII), containing (I) as a contaminant, and the butyl ester of 2,4-dichlorophenoxyacetic acid (XIII)] were widely used in agriculture.

(XII) (XIII)

The other occurrence proved to be an *industrial incident* happening in July 1976 *in Seveso* (Italy).[67,69,99,100,106,150–156] At the ICMESA works the discharge took place, as a result of an accident,

of hundreds of tons of 2,4,5-trichlorophenol (XIV) which was accompanied by the discharge of dioxin (I) and other xenobiotics of the type of (III) and (IV).

(XIV)

No less than 500 people suffered drastically from contamination by the noxious cloud in the neighbouring territory. Several thousand residents of neighbouring small villages were subjected to the action of dioxin, thousands of domestic animals perished. It was considered that from 2 to 3 kg, according to some assessments up to 5 kg, dioxin was dispersed as a result of the accident. It is difficult to know the amount more precisely since the procedures of the seventies did not permit complete recovery of dioxin from the samples analysed.[154]

Both these occurrences and also cases, less known to the wider public, of contamination of land such as in the state of Missouri (USA),[66,67,70,71,157,158] revealed the horrible perspective of remote consequences of global contamination of the biosphere by xenobiotics of the dioxin type. This could not fail to exert psychological pressure on mankind and led to increased attention to dioxin as the source of possible global ecological disaster, in principle more serious and immeasurably more dangerous than the multiton discharge of other contaminants.

The analytical chemical aspects of the problem of dioxin and related compounds are considered briefly (chiefly from foreign published material) in the present review. Problems of the physicochemical and medico-ecological characteristics of dioxins, some technological problems, etc. are also considered in part. Attention is mainly paid in the present review to the contaminants which are most widespread in nature, viz. chlorinated dibenzo-*p*-dioxin (III) and dibenzofuran (IV), from the sum total of xenobiotics (III)–(XI) and the corresponding bicyclic compounds.

II. Physicochemical properties of dioxin-type xenobiotics

Resolution of the practical problems of the organic analysis of xenobiotics (III)–(VIII) is complicated appreciably by the problem of their *isomer composition*. Thus the archetype of all the substances, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (I), is only one of the 22 possible isomeric tetrachlorodibenzo-*p*-dioxins. Equally 2,3,7,8-tetrachlorodibenzofuran (II) is only one of the 38 possible isomeric tetrachlorodibenzofurans. Altogether the total of uniformly substituted polychloro- or polybromodibenzo-*p*-dioxins and dibenzofurans comprises 420 individual substances. The isomer composition of mixed chlorobromo-containing xenobiotics (VII) and (VIII) is even more abundant.

Data on the complete isomeric composition of xenobiotics (III)–(VIII) are correlated in Table 1.[130] To complete the picture, data on compounds (IX)–(XI) are also included although the xanthenes and xanthones at present are not important for natural processes and the biphenylenes are converted into compounds (III) and (IV). As was shown in the last decade, practically all of the 5020 substances of classes (III)–(VIII) may form part of microdischarges of modern technology. Only tetra- to octa-substituted (III)–(VIII) containing halogen atoms in positions 2,3,7,8 are highly dangerous to man and nature. There is obviously an order of difficulty in the analytical chemistry connected with the need to identify and estimate the tens or hundreds of xenobiotics most dangerous to the environment among thousands of similar substances.

Table 1. Number of homologues and isomers in families of tricyclic halogen-containing xenobiotics (III)–(VIII) and in compounds (IX)–(XI) as a function of the number of chlorine and/or bromine atoms in the molecule.

$n=x+y$	Number of isomers								
	(III)	(IV)	(V)	(VI)	(VII)	(VIII)	(IX)	(X)	(XI)
1	2	4	2	4	0	0	8	8	4
2	10	16	10	16	14	28	60	60	34
3	14	28	14	28	84	168	224	224	112
4	22	38	22	38	254	496	572	572	298
5	14	28	14	28	420	840	896	896	448
6	10	16	10	16	452	880	912	912	472
7	2	4	2	4	252	504	512	512	256
8	1	1	1	1	74	134	136	136	76
Total	75	135	75	135	1550	3050	3320	3320	1700

Further complexity in the organisation of analysis may be explained by the presence in microdischarges from existing technology of functionally substituted xenobiotics (III)–(VIII) containing NO_2, NH_2, Alk and other groups in place of halogen. These are highly dangerous substances in several cases. Among them, and among (III)–(VIII), competitive antagonists of the highly toxic xenobiotics are encountered which reduce the effect of the latter.[132,159–161] This may also lead to an increase in the volume of analytical work and in its complexity as a result of a wider background and limitations on the use of biological methods of analysis.

Difficulties arising in connection with the broad isomeric composition of xenobiotics (III)–(VIII) are also caused by inadequate measurements of physical and chemical properties in series of regioisomers. The physical properties of the xenobiotics are determined mainly by their overall chemical nature, including the number of halogen atoms in the molecule, and the chemical properties also depend essentially on the positions of halogen atoms. Correspondingly regioisomers differ appreciably in biological activity and in their rate and route of metabolism in nature. Both bioactivation and biodegradation of compounds (III)–(VIII) are possible in nature.[162–164] Thus xenobiotics (III)–(VIII) constitute a system of contamination of nature which is not only complex but also changing constantly in direction and time.

Three groups of properties are particularly important for practical analytical chemistry. First there are properties determining the limiting content of xenobiotics in various phases (water, soil and air),

then properties governing the form of their existence and behaviour in these phases and finally properties controlling the behaviour of xenobiotics at phase boundaries (air–water, soil–water, water–octanol, phase–living organism).[44,45,73–75,165–195] Certain physicochemical characteristics of compounds of the (III) family, derived from published data,[45] are correlated in Table 2. These also permit opinions to be formed on the properties of xenobiotics (IV)–(VIII) [some properties of compounds (IV) are given[141]]. It follows from the data presented that such key properties of xenobiotics (III) as solubility in water, distribution coefficient in the octanol–water system (K_{OW}) and vapour pressure (P^S) do not change regularly with increasing number of chlorine atoms in the molecule.

Characteristically dioxin (I) and also the corresponding furan (II) are crystalline substances with melting points 305[45,49,196] and 227–228 °C[141] respectively. The other tetrachloro derivatives (III) and (IV) are also high melting. A lower melting point is characteristic for the less chlorinated compounds (III) and (IV).[45,141]

The good solubility of various (III) derivatives in organic solvents is determined by the *lipophilic* (hydrophobic) nature of these nonionic organohalogen compounds. In particular the solubility of dioxin (I) is (in g litre^{-1}) 0.57 in benzene, 0.37 in chloroform, 0.11 in acetone and 0.05 in octanol.[196] At the same time these xenobiotics are practically insoluble in water (2.10^{-7} g litre^{-1}).[196] It must however be stressed that, as recent measurements have shown, under practical conditions the solubility of dioxin (I) in water may be both less[169] and significantly greater[170] than that measured initially in double distilled water.[196] This is explained by the high capability of (I) towards complex formation with water-soluble polymers.[183] These latter substances, such as humic and fulvic acids, are absent from super-pure water,[170] however they are present under actual conditions of analysis. Derivatives of the (IV) series are just as poorly soluble in water as those of the (III) series.[197]

The *volatility* of the xenobiotics under consideration is usually insignificant.[45] For example the vapour pressure of dioxin (I) under ideal conditions is 1.7×10^{-6} mm Hg.[49,196] However even in 1973 it was reported that (I) may actually be present in air at a 'supersaturated' concentration,[198] which is caused by its effective adsorption on various aerosol particles.

It follows from these data that the actual concentrations of (I) determined by analysis in two most important phases, viz. air and water, may prove to be greater than the concentration determined by the physicochemical characteristics, volatility and solubility, obtained under ideal conditions. In addition the transport of xenobiotics in these media is not subject to such an extent to the rules of gas dynamics or true solutions. How much is determined by the behaviour of their carriers, aerosol particles in the air and molecular complexes in soil and water?

Two other physicochemical characteristics of the xenobiotics under consideration are analytically and toxicokinetically important. These are the *high adhesive ability* in relation to different types of evolved surface, including soil, ashes, residues, etc.[166,199,200] (this property depends appreciably on the presence of other organic substances in the material[166,179]) and the *high distribution coefficient in the octanol–water system* (Table 2).[178] In reality these two properties determine the special behaviour of xenobiotics in the environment and their entry into living matter.

It is known for example that in inanimate nature xenobiotics (III) and (IV) gradually transfer into the organic phase of soil or water migrating onwards as complexes with organic substances (they pass into the air, reservoirs, and are incorporated into food chains).[165–181] Having entered into living organisms xenobiotics accumulate in them (bioconcentration).[182–195] It has been proposed that the coefficient of *bioconcentration* (BCC) is linked with the distribution coefficient in the octanol–water system by a simple relationship[184,185] (value of BCC are given in Table 2 and were calculated with the aid of the

Table 2. Some physicochemical characteristics of polychlorobenzo-*p*-dioxins (III).

Compound	Mp, °C	Water solubility, ng litre^{-1}	lg K_{OW}	Vapour pressure P_L^S, Pa	Henry constant, Pa m^3 mol^{-1}	Molar volume, cm^3 mol^{-1}	Predicted log BCC
2-Cl-DD	105.5	278 000 (25° C)	4.94	$8.58 \cdot 10^{-2}$	14.82	212.9	3.52

proposed expression log BCC = 0.76 K_{OW} − 0.23[185]). However, the experimental values of BCC for xenobiotics (III) and (IV) in animals or in plants (for example in fish values of BCC vary from 2000 to 6000[188]) proved to be significantly lower than might have been expected[165] proceeding from data on the distribution coefficients of xenobiotics in the octanol–water system and on their water solubility. This is explained by the substantial influence of the biochemical special features of the accumulating organisms on the degree of absorption and the retaining ability for xenobiotics and also on the substantial difference of the properties of pure xenobiotics from the properties of their actual adducts with organic substances taking part in biotransfer.[181–183,186]

One of the analytically important characteristics of compounds (III) and (IV) is their extreme *chemical stability* in acid and alkaline solutions and also their stability towards oxidation under uncatalysed conditions.[201] This determines the high stability of xenobiotics (III) and (IV) in the environment. In particular the *half-decomposition time* of dioxin (I) in soil exceeds 8–10 years.[100,156,202]† The roles of photolysis on the surface[204] and of biodegradation[205] in their breakdown are insignificant. However it is necessary to consider the ability of highly chlorinated compounds (III) and (IV) with n = 7 and 8 to be converted photolytically on a soil surface into dioxin (I) and other xenobiotics with a lateral 2,3,7,8 disposition of chlorine atoms.[206] Their ability towards hydrolysis and nucleophilic substitution in strongly alkaline alcoholic solutions on heating is also known and may seriously distort analytical data.[207]

The irreversible thermal breakdown of organochlorine xenobiotics considered above occurs at temperatures somewhat exceeding 750 °C.[208] It was shown subsequently[209] that the thermal decomposition of xenobiotics (III) and (IV) is a reversible process at temperatures up to 1200 °C. Only maintaining the xenobiotics for 4–7 sec at a temperature of 1200 °C and above led to irreversible fragmentation. This circumstance produces specific requirements for the mode of operating incinerators (INC).[65] The organobromine xenobiotics (V) and (VI) are also thermally stable. Their formation and not their destruction occurs more effectively at 800 °C.[210] At the same time organochlorine xenobiotics and their organobromine analogues are comparatively readily decomposed in actual solution by UV irradiation.[211–214] Other means of non-thermal decomposition of xenobiotics are known.[211]

At the present time many of the 210 organochlorine compounds of the (III) and (IV) types of xenobiotics have been synthesised, isolated pure and studied.[198,215–220] The *danger* of such work for personnel has been reported[118] as has the need to observe the most strict precautions when working with these substances.[219] Recently there have been reports of the synthesis and investigation of a series of organobromine compounds of the (V) and (VI) type,[126–129,221] of mixed organochlorobromo compounds of the (VII) and (VIII) types,[126,127,130,131] and also of organohalo-xanthenes, xanthones and biphenyls (IX)–(XI).[132,222] The synthesis of analytically important compounds enriched with particular isotopes has been carried out.[223,224]

The *physicochemical investigation* of xenobiotics (III) and (IV) is accompanied by significant difficulties caused both by the diversity of their homology and isomeric composition and by the high toxicity of many of them. None the less fairly similar chromatographic and mass spectrometric data have been obtained for many individual isomers which is particularly important when organising their practical determination in various objects.[217–219,225–227] Spectroscopic investigations of these compounds have also been carried out in radiofrequency[216,218,220,228–231] and optical[215,232,233] ranges.

^{1}H NMR spectra have been described for many isomers of (III) and (IV)[218,220,228–230] and ^{13}C NMR spectra of certain isomers,[216] ^{1}H and ^{13}C relaxation times have been measured for individual isomers.[230,231] The possibility has been noted of using ^{1}H NMR spectroscopy in the identification and determination of individual isomers of (III) and (IV) in mixtures of them at the microgram level.[228–230] It must be stressed that ^{13}C NMR spectroscopy is an uncommon physical method of investigation, which allows spectra of previously unstudied substances to be predicted using already investigated substances as examples. A successful example of such type has been demonstrated[234] in which calculation of the ^{13}C NMR spectra was carried out for 69 isomers of the (III) series, including all those highly toxic, on the basis of known spectral data on 6 nontoxic isomers.[216]

When determining the *spatial structure* of dioxins (III) by diffraction methods it was found that the 1,2,3,7,8,9-hexachlorodibenzo-*p*-dioxin molecule (the source of the known epidemic in the broiler industry of the USA[123]) is non-planar (the angle between the two faces about the O–O axis is 4.8°).[235] The structure of 2,8-dichlorodibenzo-*p*-dioxin was analogous but the molecules of 2,7-dichloro-, 2,3,7,8-tetrachloro- and octachlorodibenzo-*p*-dioxin proved to be practically planar.[236] It should be mentioned that the actual planarity of the molecule (together with the lateral disposition of the halogen atoms in the aromatic rings) is one of the key properties determining the high toxicity of xenobiotics (III) and (IV).[237] It is also interesting that in the compound (III) series the C–Cl bond length is progressively reduced with an increase in the number of chlorine atoms in the molecule.[236]

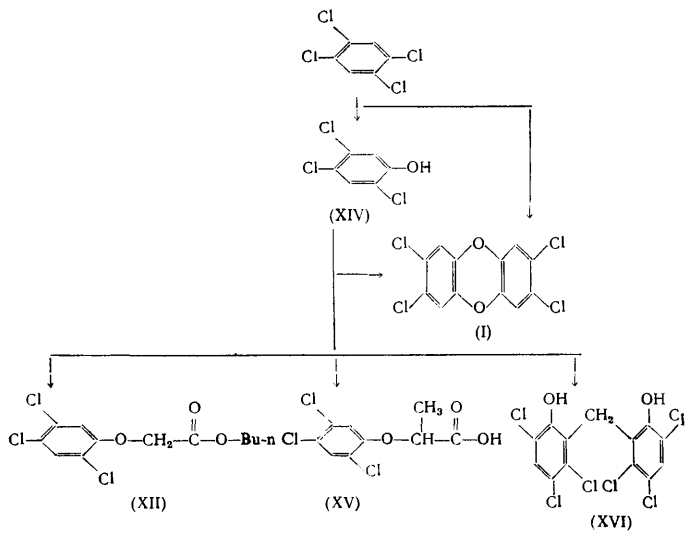
III. Sources

The known data on the sources and routes of formation of xenobiotics (III)–(VIII) have been published in a series of reviews.[48,56,58,59,61,238] Several mechanisms have been considered for the generation of these xenobiotics in relation to structure, properties of precursors and conditions of conversion. These may be nucleophilic substitution reactions, radical processes and pyrolysis. In addition an increase in the number of halogen atoms in preformed tricylic compounds occurs by electrophilic substitution of hydrogen by halogen.[58]

Sources of the xenobiotics under consideration have an exclusively *technogenic character*[239,240] although attempts are known to explain their appearance in the biosphere by forest and steppe fires.[241] The appearance of the xenobiotics in the environment beginning in the

† The half-decomposition time of dioxin (I) in soil has been reliably established for many years.[23,50] An outside report appeared more recently indicating it was from 0.5 to 1 year.[203] In the USA a similar sort of error had far reaching consequences. After inadvertent contamination of many parts of the state of Missouri in 1971–1972 by effluent from hexachlorophene manufacture containing significant admixture of dioxin (I) and the disclosure of this happening in 1974, decontamination of the territory was not carried out for many years in the hope of natural decomposition of dioxin in the soil. Only at the beginning of the eighties when it was revealed that the half-decomposition time of (I) was not 0.5 to 1 year but approximately 10 years did massive operations begin on the destruction of the consequences of the accident, including destroying the dioxin in dumps. This proved to be even more difficult to accomplish and incomparably more expensive.[67,70,71]

1940's was caused by the development of various technologies linked chiefly with the manufacture and use of organochlorine compounds. In any case proof has not been found of the accumulation of these xenobiotics in bottom sediments of rivers and lakes formed prior to 1940, i.e. before the beginning of manufacture of herbicides based on chlorophenoxyacetic acids.[239] The sources of xenobiotics (III)–(VIII) are subdivided according to economic-territorial criteria into local and diffuse (spatially distributed) and, according to the rate of accumulation in the environment and in living matter, into continuous or periodic.



Sources delivering xenobiotics (III)–(VIII) into the environment are divided chiefly into three groups.[63,238]

1) The operation of defective manufacturing technology and the application of chemical production (of aromatic and aliphatic organochlorine and -bromine compounds, inorganic chlorides, any chemical products with the intermediate use of chlorine, inorganic chlorides, organochlorine and -bromine compounds, including use as catalysts and solvents), which are characterised by a) the presence of waste water and effluent of such manufacture,[242] b) premeditated introduction into nature of chemical products containing admixture of xenobiotics or their precursors and c) imperfect safety measures when burying or recovering effluent of chemical manufacture containing admixture of (III)–(IV).

2) Discharges from undertakings of any type (cellulose-paper, metallurgical, etc. and also undertakings specialising in the combustion of industrial and domestic refuse).

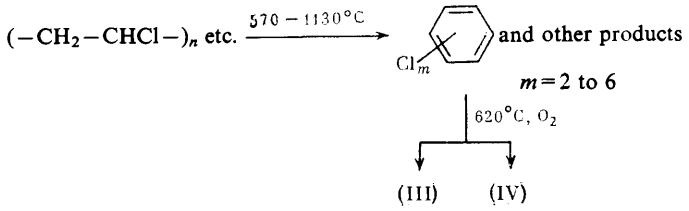
3) Automobile exhausts.

The most toxic xenobiotic (I) is formed in the manufacture of the phenoxy herbicides 2,4,5-T (XII) and Silvex 2,4,5-TP (XV), which are widely used in agriculture, and also of the antibacterial preparation hexachlorophene (XVI). Dioxin (I) arises as a side product under the actual conditions of manufacture of 2,4,5-trichlorophenol (XIV) which is the precursor of compounds (XII), (XV) and (XVI) [for example when the process is conducted at a temperature exceeding that (180°) required by the technological regulations[8,79,124]].

The content of dioxin (I) in 2,4,5-trichlorophenol (XIV) may reach 6.2 p.p.m depending on the special features of the technology‡.[243] In such final products as herbicides (XII) and (XV), the content of (I) proved to be subtantially greater [prior to 1970 the amount of (I) in products (XII) and (XV) reached 30 and even 100 p.p.m., later it was reduced to 0.01 p.p.m.[8,68]]. Considering that the greatest volume of production of 2,4,5-T occurred in 1960–1970 (its output during this period was 48.6 thousand tons) this means that the maximum quantity of dioxin (I) which was manufactured during this time may have reached 4800 kg. Significant quantities of hexa-, hepta- and octachlorodibenzo-*p*-dioxins (up to 1000 p.p.m.) have been detected in tri- and tetrachlorophenols[243] and in pentachlorophenol, widely used as a wood preservative.[243,244] In particular in the USA, the largest manufacturer of pentachlorophenol, several tons of xenobiotics (III) and (IV) were in fact 'discharged' in 1972–1977.[68]

Xenobiotics (III) and (IV) are formed in significant amounts in the *cellulose–paper industry* at the stage of bleaching the pulp with chlorine and compounds containing it.[56,133,144,245–251] This source of contamination of the environment with xenobiotics (III) and (IV) was first considered even in 1974.[245] However only investigations of recent years showed that xenobiotics are present not only in finished timber products[250] and in paper (at the p.p.t. level),[247] but also in all the technological chain, viz. the pulp itself, filtrate, the filtered off mass,[248–250] and in the solid and liquid effluent (up to 400 p.p.t.)[133,249] and the gases discharged from combustion. Up to 22 different isomers of (III) and (IV) were detected in the waste products from the cellulose–paper industry. These had 4 to 8 chlorine atoms and included 12 which are particularly toxic. The most toxic dioxin (I) was present in these mixtures in appreciable amounts.[248] Increased concentrations of xenobiotics (III) and (IV) were also found in fish, crabs and other representatives of aquafauna, inhabiting the vicinity of the drains of these undertakings.[133,249]

Incinerators (INC), which are widely used in industrially developed nations for the destruction of domestic and nontoxic industrial waste, and equipment for the destruction of toxic waste and effluent, are a steady source of xenobiotics (III) and (IV) and related substances. The first INC for the destruction of domestic waste was built in England in 1876 and at present such equipment operates for various purposes, including energy production, in great numbers in Western Europe, North America and Japan. The volumes of waste destroyed are very large. Japan burns 50 million tons waste in a year, the USA 28 million (7% total volume), FRG 8 million, Sweden 7 million, etc. Only in Canada is relatively little waste burned, viz. 1–2 million tons (in comparison it is reported that in Paris alone up to 3 million tons is burned in a year).[22]



Microadmixture of (III) was found in 1977 for the first time in light ashes and effluent gases from INC in the Netherlands.[252] Later an analogous admixture was detected and studied in discharges from INC in other industrially developed countries, viz. USA and Canada,[52,253–257] England,[258,259] Switzerland and Sweden,[260–264] Italy,[265–268] FRG,[269–271] France,[272] Belgium,[273] Japan,[274–279] Austria,[279] Denmark,[280,281] Norway[282] and other countries.[51,283,284]

One INC of average productive capacity (50–200 thousand tons per year) emits 1–100 ng m^{-3} or 1–100 g xenobiotics (III) and (IV)

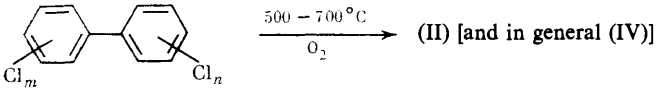
‡ Here and subsequently the units of measurement used will be those taken in analytical chemistry for trace amounts of organic substances, viz. p.p.m. (μg g^{-1}, mg kg^{-1}), p.p.b. (ng g^{-1}, μg kg^{-1}), p.p.t (pg g^{-1}, ng kg^{-1}), p.p.q (fg g^{-1}, pg kg^{-1}).

per year in comparable concentrations.[56,142] The amount of xenobiotics formed on burning depends on the mode of burning and the character of the refuse being destroyed. However on the whole none of the existing technologies for burning refuse is capable of preventing their formation.[48,51,63,239–240,274] Installations for destroying industrial refuse do not differ from INC in this respect.[261] Usually the attention of investigators is centred on xenobiotics passing out with effluent gases and light ash, however their presence in furnace scale transferred to burial is no less dangerous. Scales are highly toxic discharges as a result of their high xenobiotic content and their accumulation in small sized dumps.[274]

Xenobiotics (III) and (IV) are formed in particularly large amounts when burning waste containing compounds, such as polyvinyl chloride, which contain halogen atoms.[246,259,261]

Burning of bromine-containing contaminants, which are associated with many textile and other materials in amounts up to 10–20% as fire-repellants,[285] is accompanied by the formation of organobromine xenobiotics (V) and (VI).[128,129,210,286] Mixed organochlorine-organobromine compounds (VII) and (VIII) have been detected in discharges from INC.[287,288]

Routes for the accumulation of xenobiotics (III)–(VIII) have still not been finally clarified.[58,246,289] It was considered[51,246] that they are formed when processing refuse or remained undestroyed in the process for burning refuse containing these xenobiotics in trace amounts. For example representatives of these xenobiotics, chlorophenols, have been obtained on combustion of other organic materials in the presence of inorganic chlorine compounds. At the present time one is persuaded that xenobiotics (III)–(VIII) are formed in all high temperature processes involving carbon and any chlorine compound in any valency state,[270,290] but catalysts are always found in such complex heterogeneous systems. Both metallic surfaces and the surface of light ash have proved to act in this way.[289]



A new group of local sources has recently been revealed.[261] As it turned out xenobiotics (III) and (IV) are formed in *metallurgical plants* such as the electrochemical preparation of nickel and magnesium oxides,[291] in steel casting manufacture,[292] on smelting iron and copper scrap,[261] etc. Xenobiotics (III) and (IV) were everywhere, in waste water and discharges from these works, in the surrounding soil, in air tanks, etc.

Domestic stoves operating on coal and oil may also be local sources of the xenobiotics under consideration. The low content of (III) and (IV) in flue gases may not cause alarm[261] due to the low probability of the appearance of halogen sources in the fuel.[63] However recent data[293] showed that it is impossible to disregard this source, particularly due to its widespread distribution and uncontrolled nature.

The polychlorinated (PCB) and polybrominated biphenyls (PBB) are dangerous sources of xenobiotics of the type of (IV) and (VI). Thanks to their electrical and thermal characteristics, incombustibility and high chemical stability, these substances are widely used as liquid dielectrics and high temperature heat-transfer agents. Their worldwide manufacture exceeds 4 million tons per year.[55] Xenobiotics (IV) and (VI) are formed in the synthesis of PCB and PBB.[122,134,294] The content of (IV) in some PCB reaches 33 p.p.m.[295]

In addition xenobiotics (IV) and (VI) are also formed on overheating and burning PCB[296] and PBB.[128,137] Thus the content of compounds (IV) in rice oil contaminated with PBB proved to be two orders of magnitude greater after using it for food than in the initial PCB.[297] In conflagrations at transformer stations the concentrations of (IV) and related xenobiotics may prove to be so significant[48,59,295,298] that the restoration of damaged buildings becomes impossible.[125] In particular 8 fires in transformers containing PCB were recorded in the USA in 1981–1985 alone, including a fire at the White House in 1985. About 20 explosions and fires at capacitor installations containing PCB were known in Western European countries.[296]

The process of thermal formation of xenobiotics of the (IV) type is represented in general in the following manner.[137]

Several more detailed mechanisms of this reaction have been proposed which explain the isomeric composition of xenobiotics (IV) formed on combustion of PCB.[59]

The *exhaust gases of motor vehicles* may serve as an example of a diffuse source of xenobiotics (III)–(VI) and was described even in 1980.[241] An increase in the octane number of petrol is usually achieved by introducing dichloro- or dibromoethane or other organobromine substances together with $(C_2H_5)_4Pb$ or $(CH_3)_4Pb$. The former are precursors of harmful substances,[299] including xenobiotics (III)–(VIII).[300–303] The average output of xenobiotics by a motor vehicle using ethylated petrol is 30–540 pg km^{-1} (in dioxin equivalents, see below).[301] These amounts may be considered insignificant at first glance. The locations of heavy contamination by dioxins of motorways and regions adjacent to them are the fault of motor transport. These include poorly ventilated roadway tunnels,[142,304] soil alongside motorways with busy traffic, etc. It is also impossible to ignore the detection of xenobiotics in the exhausts of motor vehicles operating on unethylated petrol.[238]

The *water supply system* may prove to be a diffuse source of (III) and (IV). There were no communications for a long time on the detection of serious quantities of xenobiotics in drinking water after its chlorination, although the formation of (III) and (IV) in significant amounts is inevitable after introducing phenolic substances into chlorinated water after their discharge from industrial undertakings. Events which occurred in spring 1990 in Ufa, when chlorination of the water supply was obliged to be stopped due to the introduction of phenols into it by the Khimprom Industrial Combine, is direct confirmation of this.[305] It is possible

that in this case there was a direct dropping of dioxins (III) into the river and they then entered the water intake (*Arguments and Facts*, 1990, No. 33).

Industrial and other *waste products* eliminated from operations by their simple burial, storage or use may also prove to be dangerous. Such happenings were noted in Japan in places for the accumulation of large quantities of ash from INC containing (I) and (II) at 6.7 and 1.3 p.p.b. respectively.[274] Another example is the utilisation of output from PCB operations. In Japan for example after prohibition of PCB use residues (5000 tons) were burned[23] and led to the discharge of (IV). In the USA transformers and capacitors containing 600 thousand tons PCB derivatives scrapped in 1929–1977 were stored in dumps. The presence in them of only 1 p.p.b. xenobiotics implies the accumulation in the dumps of 0.6 kg dibenzofuran (II).[306] However it is known that the actual content of (IV) in PCB is significantly greater and reaches 33 p.p.m.[295]

Just how serious a problem is the storage of waste products from the manufacture of organochlorine pesticides may be judged from data of the USA,[61,307–310] FRG[311] and the Netherlands.[312–314] The quantity of dioxin (I) contained in waste products from 2,4,5-trichlorophenol (XIV) manufacture in dumps in New York state (USA) in the vicinity of Canada has been estimated at 45 kg.[61,307] In FRG in areas near Hamburg segregated for the storage of waste products from the manufacture of the herbicides 2,4,5-T (XII), Silvex (XV), lindane, etc., huge amounts (at the level of p.p.m.) of both dioxin (I) itself and many other xenobiotics (III) and (IV) were found in soil.[311] Close to Amsterdam 2000 tons organochlorine waste products, mainly from the manufacture of the herbicides 2,4,5-T and lindane, had been stored in steel drums during 1955–1970. By the beginning of the eighties the majority of the drums had disintegrated [at that time the actual waste products still contained large amounts of dioxin (I) (up to 21 p.p.m.) and (IV) isomers] and the contamination of soil layers close to the dump by dioxin (I) reached 8 p.p.b.[312,313]

The reason for the contamination of land in Missouri (USA) in 1971–1972 was the unjustified use of waste products of hexachlorophene (XVI) manufacture, which contained a large amount of dioxin (I) in vat residues. As a result in more than 40 populated localities, 5000 inhabitants proved to have been dusted with ~29 kg dioxin (from 22 to 68 kg according to different assessments). In 1974 when dioxin (I) was identified its concentration in soil in individual places reached 30 p.p.m. and even in 1983 when examination of the health of all the inhabitants living in the contaminated territory began localities were found with a contamination of up to 2.2 p.p.m.[70]

Finally the industrial manufacture of dioxin-containing herbicides itself may be converted from a local source to a diffuse source since the transportation of herbicides by the commercial route and then their spraying over agricultural or other land is practically uncontrollable. Thus the reserves of herbicides (XII) and (XV) accumulated in the USA, particularly abundant in dioxin (I), have entered many countries of the world, especially after the prohibition of their use in the USA in 1979. Several states have 'imported' dioxins from the industrially developed countries as contaminants in the herbicide 2,4-D (XIII). Although the content of the most toxic dioxin (I) in them is not large admixture of other mono-, di-, tri- and tetrachlorodibenzodioxins (III) is fairly considerable.[243]

As a consequence a huge amount of dioxin (I) and other substituted dioxins is circulating in the biosphere at present, and has been introduced over several decades together with numerous organochlorine herbicides. The herbicide 'Agent Orange' for military purposes is one of them. The average content of (I) in the latter is officially considered to be close to 2 p.p.m.§ and in previous samples (obtained from non-toxic isomers of hexachloran) it reached 47 p.p.m.[17] Overall, pesticides based on 2,4,5-trichlorophenol (XIV) are *one of the main sources of contamination of nature by dioxin (I)* and also by other less toxic but not less dangerous xenobiotics of the (III) and (IV) types.[214,315] In this context it is difficult to agree with the statement that 'the fraction of pesticides and other products of the chemical industry in the contamination of the environment is less than 5%.[64] This opinion does not rest on facts if the actual influence on the biosphere and not the volume of refuse discharged is considered.

In the middle of the eighties a first attempt was made by scientists of FRG, the Netherlands and USA at a *comparative analysis of the importance* for the active life of the biosphere of *various sources of xenobiotics* (III) and (IV).[68] This is a particularly complex problem since the known sources have differences in principle in quantitative and qualitative respects. As it turned out the considered sources may be arranged in decreasing order of danger as follows:

- –manufacture and use of the herbicide 2,4,5-T (XII),
- –pentachlorophenol,
- –tetrachlorophenol,
- –2,4,5-trichlorophenol (XIV),
- –polychlorodibenzofurans (IV) and PCB,
- –destruction of domestic refuse in INC,
- –fires in transformer installations containing PCB,
- –operations of chloro-compound manufacture,
- –combustion of chemical waste.

In conclusion it is emphasised that the available data on sources of xenobiotics (III)–(VIII) reveals only some of the most dangerous contaminated objects (or regions) with the aim of their analytical inspection for dioxin content. In future a large number of technologies will have to be studied from the point of view of the danger of generating dioxins. These will include the thermal reprocessing of carbon compounds in the presence of inorganic chlorine compounds, mild processes for the interaction of biomaterials with chlorine-containing oxidising agents, and also biotransformations of (III)–(VIII) from various products of organohalogen synthesis.

IV. Toxicity, medical effects and their consequences

After the discovery of the high acute toxicity of organochlorine xenobiotics (III) and (IV)[2–18,24,80,81,119,316] and their bromine-containing analogues (V) and (VI)[76,317] a large number of papers appeared devoted to the study of the toxicological features of these substances.[76–87,119,141,316–325] Data on the acute toxicity of

§ However some authors do not agree with the official point of view and suggest that the content of (I) in the military mixture of 'Agent Orange' was 5000 times greater than in herbicides used in agriculture. Turning in passing to the problem of the toxicity of the 'Agent Orange' mixture, which became widely known after the war in Vietnam, it should be mentioned that the presence in it of the highly toxic dioxin (I) became known to the scientific USA in 1963 and to the Presidential Scientific Consultative Committee in 1965. In 1970 the corresponding hearing took place in the US Congress after which use of the military mixture ceased.[23,148]

xenobiotics (III)–(VI) were obtained in animals and their chronic action has been studied both in animals and in man (including volunteers).[79]

Dioxin (I) possesses the maximal toxicity.[316] It is more toxic than cyanides, strychnine and curare.[326] Its toxicity is greater than, or at least comparable with, the toxicity of the antichlolinesterase poisons tabun, sarin, soman and VX gas.[326,327]

There is confirmation[91] that dioxin (I), the most toxic of substances synthesised by man, cannot in principle be regarded as a journalistic exaggeration. Dioxin is accepted as a standard for the toxicological assessment of all the xenobiotics of the (III)–(VIII) types. It must however be emphasised that the main danger of dioxin (I) and xenobiotics (III)–(VIII) in general resides in their cumulative action and the delayed consequences of chronic poisoning by extremely small doses.[49,86,93]

Table 3. Acute toxicity of some xenobiotics (III)–(VI), insecticides and toxic substances.[81,319,327–329]

Compound	LD_{50}, μg kg^{-1} (ppb)

Tabun		208		
Sarin		83		
Soman		156		
VX		20.1		

Information on the *acute toxicity of xenobiotics* (III)–(VI) is given in Table 3. Apart from dioxin (I), 1,2,3,7,8-Cl_5-DD possesses high toxicity. Some chlorinated derivatives of the (IV) series, particularly (II) and two of its Cl_5-isomers, viz. 1,2,3,7,8-Cl_5-DF and 2,3,4,7,8-Cl_5-DF, are also close in toxicity.[319,321] The toxicity of the xenobiotics indicated is many orders of magnitude greater than the toxicity of DDT and, which is very important, depends significantly on the species peculiarities of the experimental animals. The toxicities of the organobromine derivatives (V) and (VI) [organobromine analogues of (I) and (II)] and also 2,3,7-Br_3-DD[76,317] and of the mixed organobromine-chlorine compounds (VII) and (VIII) are just as high.[322]

The remaining compounds of types (III) and (IV) are less toxic than (I) and (II) although not all representatives of the (III) and (IV) series and even fewer of (V)–(VIII) have been studied in such detail.[81] In compounds of the (III) and (IV) series the xenobiotics containing from 4 to 6 chlorine atoms are particularly toxic while the presence of a lateral 2,3,7,8-Cl_4 fragment is an obligatory condition for high toxicity. In the organochlorine series there are 12 such isomers [5 in the (III) family and 7 in the (IV) family] but there are 568 if bromine and mixed chlorine–bromine compounds are considered.[130] On increasing or decreasing the number of halogen atoms the toxicity of compounds is sharply reduced.[81,319] However the danger of xenobiotics (III) and (IV) for man and nature is not just their acute toxicity. Almost all polyhalogenated compounds containing the 2,3,7,8-Hal_4 fragment, including the penta- and octa-substituted derivatives, are dangerous by various tests.[77–82,319]

The toxicological special features of the xenobiotics under consideration are linked primarily with their high lipophilicity and exceptional stability in the environment and in living organisms.[330] The lipophilic nature of the xenobiotics enables their accumulation in the organic phase of the biosphere and bioconcentration in living organisms. The xenobiotics accumulate efficiently in representatives of fauna, mainly in lipid tissue (approximately 90%[331]), liver, thymus and the blood-producing organs[142,151,331–335] and are eliminated very slowly (but from man they are practically not eliminated).[77,336,337] *Bioconcentration* is effected both by the food chain and by interphase transfer from other media, including air, water and soil (even in the case of their infinitesimal content in these media).[46,165,175,182–195,338] The high stability of these xenobiotics causes their extended retention in natural media and a long period for half-elimination from the organism of animals and man. Toxicokinetic investigations in recent years have shown that for man the *time for half-elimination of dioxin (I) from the organism reaches 6–7 years*[336,337] [for xenobiotics of the (IV) series it is somewhat lower at 1–2 years[339]].

In order to display high toxicity xenobiotics (III)–(VIII), in addition to hydrophobicity and high stability, must possess a high *affinity for their bioreceptor*,[24,77,82–85,317,329,340–343] which is known as the dioxin receptor[83–85,317,329] (although discussion on this problem still continues[344]). They must also have *high biological activity*, expressed as the concentration of substrate causing a 50% increase in the maximum possible cytochrome P-448 activity. All these requirements are possessed by those isomers of the (III)–(VIII) series of compounds containing four chlorine atoms in positions 2,3,7,8. These properties are expressed most clearly in (I) and homologues and analogues close to it in structure which fit into a rectangle of size 0.68 × 1.4 nm^2.

The rate of their *metabolism in vivo* shows an insignificant effect on the toxicity of (III)–(VIII). It was shown for (I) and (II) for example that the rate and direction of metabolism depend on the biological special features of the organism[162–164,195,345] and this process may lead to a less toxic substance.[346] In addition bioactivation in the organism by reductive dechlorination to more toxic substances may occur with Cl_5–Cl_8 derivatives (III).[164]

The diversity of mixtures of xenobiotics (III)–(VIII) actually existing in the environment and the non-equivalence of the toxic action of their individual components hinders assessment of the actual danger of these series to particular objects and regions. It has been proposed that the toxicity of each xenobiotic, chiefly of the (III)–(VI) series, should be cited in terms of a single standard, viz. dioxin (I).[347] For each compound there is a *toxicity coefficient* (TC) relative to dioxin which is determined either by the LD_{50} value,[348] characterising the acute toxicity, or by some more important quality [carcinogenic effect,[349] induction of aryl hydrocarbon hydroxylase (AHH),[350,351] a combination of several effects simultaneously,[352] etc.].[353–355] The TC system enables the toxicity characteristics of any actual mixture of xenobiotics to be reduced to a 'toxicity equivalent' ('*dioxin equivalent*', DE) if the content of each component has been previously determined. In other words, the toxicity of a complex mixture of xenobiotics (III) and (IV) may be expressed through the toxicity of dioxin (I), taken in an amount equivalent in toxicity (in overall dioxin units)¶.

Several TC systems have been proposed[33,347–355,359] and some of them are shown in Table 4 (see also Ref. 347). The complexity of the problem and the non-comparable nature of the initial toxicological packages do not permit the development of a single, generally acknowledged TC system. In the Scandinavian countries and the Netherlands for example a system[348] was used at one time which was proposed in 1982–1983 and revived in 1986 by one of the groups of investigators in the USA. It required the obligatory calculation of the contributions of isomers containing the 2,3,7,8-Cl_4 fragment. Other systems are known which were developed by specialists in the USA,[354] Canada,[352] Switzerland,[353] FRG,[359] by scientists in the northern countries of Europe (the NORDIC system in 1987[355]) and by others.[142,347] A TC system has been described[349] which operates with whole groups of isomers (Cl_4-, Cl_5-, Cl_6-compounds etc.) without separating individual isomers apart from the toxic. An international TC system has been proposed recently.[33] In the main the TC systems developed by various toxicological schools are fairly close (Table 4). Correspondingly assessments of the degree of contamination made using them (as DE) do not differ very much. However critical analysis of the actual approach to assessment of the relative toxicity of various xenobiotics (III)–(VIII) remains fruitful.[360]

Assessment of the degree of contamination of objects by actual mixtures of (III) and (IV) comprises two stages, an analytical and a toxicological. The analytical stage provides separate determination of each component of a mixture in the sample. The danger of the whole mixture (in DE) is assessed in the toxicological stage by summation of its components allowing for the TC of each. To sum up, the DE is found for an actual mixture of xenobiotics expressed in weight units of (I).

Turning to the *medical aspects of the problem* it is noted that the action of (I), (II) and in general any xenobiotic of the (III)–(VIII) series on a living organism (man or warm-blooded animals) is many-sided and depends significantly on the dose of poison, the means of its appearance in the organism, and the age and condition of the organism.[24] Even at insignificant concentrations they cause *suppression of the immune system* and disturb the ability of the organism to adapt to changing conditions of the environment which leads to a sharp suppression of mental and physical efficiency.[324,325] In somewhat higher concentrations they cause *mutagenic, teratogenic* (birth of child-monsters from affected parents) and *embryotoxic effects*, disturbance of the activity of the nervous system, diseases of the liver, digestive tract, etc.[2–18,24,49,86–95,361–364]

The clinical symptoms of disease by xenobiotics (III)–(VIII) are however not clearly expressed and the degree of poisoning by these xenobiotics is not always adequately marked. The appearance of the *disease chloracne* is frequently the first *symptom of heavy poisoning*[88–93,361,365] and in all cases there is porphyria (suppression of porphyrin metabolism). Rapid, progressing emaciation of those affected is observed with heavy poisoning.[24,49,93]

The *epidemiological consequences of disease* from xenobiotics (III) and (IV) have been correlated in a comparatively detailed manner.[49,88,93,95,158,361,365–397] Data were obtained on examination of cohorts of people involved in industrial accidents and other mass afflictions (FRG,[56,365–368] USA,[147,157,369–373] Italy,[99,152,153,155,374] France,[375] England,[361,395] Japan and Taiwan,[95,120,121,376,377] the Netherlands,[378] Sweden,[379,380] Denmark,[381] Finland,[382] New Zealand,[383,384] Hungary,[385] Czechoslovakia[386–388] and USSR[389–393]) including occupational contact with substances in industry and in agriculture.[158,394–397] For example data are shown in Table 5 on only one group of affected people who were employed in the industrial manufacture of the herbicide 2,4,5-T (XII) and its

¶ The DE system assumes additivity of the toxic action of individual xenobiotics in complex mixtures.[68,356,357] In reality this is not always so and the need to consider synergy (see[68,358] for example) or antagonistic effects already mentioned[132,159–161] remains a practical problem.

Table 5. Illnesses of people linked with the industrial manufacture of 2,4,5-trichlorophenol (TCP) and herbicide 2,4,5-T (XII).

technological precursor 2,4,5-trichlorophenol (XIV). Results of studies[35,37,79,88,389–393] were used. Altogether this group includes more than 1000 men having suffered from dioxin (I) in industrial incidents,[97] including at least 8 explosions†. The number of persons suffering from xenobiotics (IV) in connection with massive poisoning in Japan in 1968 and in Taiwan in 1979 exceeded 1850 and 2000 respectively.[95] A large volume of data on poisoning by dioxin (I) contained in herbicide 2,4,5-T (XII) was obtained by systematic examination of American and Australian veterans of the war in Vietnam and members of their families.[143,147–149] All these epidemiological data were obtained from observation of affected people over 10,[61,388,390,395] 15–20[143,373,377,397] and even 30[142,143,368] years after their contact with the xenobiotics and has enabled a more correct judgement to be made on the distant consequences of the effect on people by xenobiotics (III) and (IV).[87,90,93,396,397] As it turned out the symptoms of chloracne continued to be observed on average for 26 years.[394]

The epidemiological consequences of the contact of people with dioxins therefore have a *universal character*. They also occur in the USSR. This may be judged by the data on diseases linked with the manufacture of 2,4,5-trichlorophenol (XIV)[389,390] and herbicide 2,4,5-T (XII),[391–393] which occurred in our country in chemical works in Ufa within the framework of the usual dioxinogenic technology. The experimental output of 2,4,5-trichlorophenol began in 1961 and industrial output of 2,4,5-T in 1965.[393] Fifteen victims were recorded in the manufacture of 2,4,5-trichlorophenol.[389] The first examination of workers contacted in the process of 2,4,5-T manufacture was carried out shortly after its start by the Ufimsk Scientific-Research Institute for Hygiene and Occupational Diseases. Subsequently examinations became regular.[391,392] It became apparent that there were 128 persons with clearly expressed skin disease (serious forms of occupational acne in organochlorine manufacture), characteristic of groups affected in other countries, where there were similar industries, which amounted to 85% total number contacted. Apart from disease of the sebacious follicular apparatus of the skin, accompanying disease of the nervous system, liver, suppression of lipid metabolism, etc. was established.[391–393] Since reconstruction of the plant for the manufacture of herbicide 2,4,5-T from 2,4,5-trichlorophenol did not provide absolute protection for personnel from the development of serious forms of occupational acne and intoxication, the plant was reprofiled to 2,4-D in 1968.[393] Output of 2,4,5-trichlorophenol was stopped in 1987.

It should be mentioned however that there is extreme heterogeneity in the available epidemiological data and there are methodological errors in many investigations. The results obtained for the affected regions of South Vietnam must be considered to be the most objective. These were compared with the ecologically clean regions of North Vietnam. These data fortified by information on the quantitative content of (I) in human breast milk and lipid deposits of people[398] indicate the negative effects of xenobiotics (III)–(VIII) on the life span of the population, on its resistance towards various, especially viral, infections, towards the overall medical situation in the affected regions and towards the child-bearing function of the women. It may be considered that dioxins are one of the most important factors inducing deterioration of the racial stock of several human populations.[35–41]

Decisions have been made on the health and hygiene aspects of the problem of dioxins and related xenobiotics. The impact of these poisons and also the high probability of the appearance and accumulation in nature of dioxin synergists capable of enhancing

† The concentrations of dioxin (I) in vat residues, discovered when investigating the circumstances of these incidents, proved to be extremely significant. It was 2400 p.p.m. in Czechoslovakia, 2000 p.p.m. in USA (1964), 1000 p.p.m. in the Netherlands, 400 p.p.m. in England and 140 p.p.m. in Austria. For comparison it may be noted that the concentration of (I) in soil at the centre of the contaminated zone in Seveso (Italy) was 0.55 p.p.m.[79]

their toxic action,[358] has compelled the health and hygiene services of the industrially developed countries to conduct appropriate investigations. The appearance of dioxin-type xenobiotics in foodstuffs, drinking water and in the air of populated localities is recognised to be inadmissible. However to achieve this while vast quantities of these xenobiotics are circulating in the biosphere, while technology is operating and actually delivering these xenobiotics to the environment, is impossible. At present the problem of limiting the risk of affecting man and nature with dioxin (I) and related substances continues. For this purpose *standards* have been established for admissible *technogenic discharges of xenobiotics* by industry, limiting standards for their *content in the environment* and also standards for admissible '*consumption*' of these substances by *man*.[77,355,399–408]

The limiting standards for admissible weekly and daily consumption by man of dioxin and other xenobiotics of this type (WCD and DCD respectively) are expressed in so-called DE. These are in the form of the weight quantity of dioxin (I) the systematic consumption of which leads to an increase of one victim per million population. Values of WCD and DCD are determined in model experiments in animals by assessing the risk of a teratogenic or carcinogenic effect, immunosuppression, etc. Standards developed by a group of specialists in Sweden, Denmark, Norway, and Finland[355] for the risk of carcinogenicity are: DCD $\leqslant$ 5 pg kg^{-1} and WCD $\leqslant$ 35 pg kg^{-1} which means consumption of $\sim$2000–2500 pg DE in a week for a person of weight 60–70 kg. A similar standard (DCD $\leqslant$ 4 pg kg^{-1}) has been proposed in the Netherlands.[399] In Ontario (Canada) and FRG a DCD $\leqslant$ 10 pg kg^{-1} is considered admissible.[400,404] In USA sizes of DCD for various regions for the risk of carcinogenicity and immunosuppression vary from 10 to 0.1 pg kg^{-1}.[405] On the whole the standards for DCD adopted in the world vary within the limits 0.006 to 10 pg kg^{-1}.[33]

The developed standards for WCD and DCD are used to establish the limiting content of xenobiotics (III)–(VIII) in foodstuffs and in the water, soil and air of the environment. Proceeding from these standards the consumption of fish from internal reservoirs is prohibited, and the consumption of fish from individual farms and milk production from strongly affected regions is limited in some countries. According to the data of the Environmental Protection Agency (EPA) of the USA and of an international group of experts regions containing 1 p.p.b., i.e. 1 μg xenobiotic in 1 kg soil (in DE), are unsuitable for habitation by man. The concentration of xenobiotics in the land of stock farms must not exceed 10 p.p.t., i.e. 10 ng kg^{-1} soil (Netherlands).[402] In Sweden the standard for the limiting content of dioxins in effluent gas for INC under construction is 0.1 ng m^{-3} (for old furnaces a concentration of 0.5–2.0 ng m^{-3} is allowed).[401] In Italy[62] a content of 0.5 ng xenobiotics in 1 m^3 effluent gases is considered admissible, but investigators consider the requirements of the Swedish experts to be correct. In the USA the official standard of the EPA determining the content of dioxins in the air of work places is 0.13 pg m^{-3}.[403]

A general representation is given in Table 6 of the limiting admissible levels of xenobiotics (in DE) which must not be exceeded in the environment and in the surroundings of human habitation in general. This is composed from data of the Italian National Toxicological Committee.[21] More than 10 years study of the problem form the basis for these standards (after the events at Seveso in 1976). The set of standards for the maximum permitted concentration (MPC) of dioxin (I) in air, water, soil, etc. considered by the Minsitry of Health of the USSR has been mentioned[24] as a working alternative for the USSR. It is inconvenient to discuss them at present. However the tentative admissible level (TAL) for dioxin content in water has already been determined by the 'Health Rules and Standards for Preserving Water Surfaces from Contamination', of the USSR Ministry of Health No. 4630-88. This standard is extremely lenient at 0.000035 mg $litre^{-1}$. The fact that the document permits a standard such that the dioxin concentration in water in the USSR will exceed the Italian standard by a factor of 700 000 means that the official standard of the USSR Ministry of Health has no scientific basis at present. In particular it permits without punishment the dumping in only one year of more than 100 kg dioxin (I) in the Ufa river, an absurd amount when it is considered that US airmen sprayed 170 kg (I) in Vietnam in the course of 9 years ('Arguments and Facts', 1990, No. 33).

Table 6. Limiting levels of mixtures of xenobiotics (III) and (IV) permissible in the environment in Italy.[21]

Object	Type of material	Limiting permissible level
Air	Atmospheric air	0.04 pg m^{-3}
	Air in work places	0.12 pg m^{-3}
Water	Drinking, sea, ground water. Reservoir water	0.05 pg $litre^{-1}$
	Community sewer water after purification	0.5 pg $litre^{-1}$
	Community sewer water before purification	50 pg $litre^{-1}$
	Industrial waste water after purification	0.5 pg $litre^{-1}$
	Industrial vat residues	1 μg kg^{-1} (1 ppb)
Soil	Soil in agricultural regions	10 ng kg^{-1} (10 ppt)
	Non-agricultural soil	50 ppt
	Soil in industrial regions	250 ppt
Surfaces	Exterior walls of buildings	75 μg m^{-2}
	Internal walls and surfaces	25 μg m^{-2}

V. Determination of xenobiotics of the dioxin type

The determination of xenobiotics (III)–(VIII) in the environment and in biological samples is a most difficult analytical problem. This is primarily because the toxicological properties of these xenobiotics require that their detection limits in various materials should be substantially lower than those which are typical of many problems of organic analysis, including the determination of pesticides [for example less than 20 years ago the dose of dioxin (I) lethal for guinea pigs was less than the detection limit of the apparatus used for its determination[409]]. No less important is the structural diversity of both the actual substances being determined (see Table 1) and the compounds accompanying them. In other words there is a need to determine all the desired groups of xenobiotics (usually this is tens of substances simultaneously) the individual isomers of which differ principally in toxicity (see Table 3).

The high toxicity of dioxin (I) demanded development and introduction into analytical practice of isomer-selective methods providing detection of picogram (10^{-12} g) and even femtogram (10^{-15} g) quantities, i.e. the determination of compounds with concentrations in the p.p.t. and p.p.q. region.[143,410–436] Data on the dynamics of the reduction of detection limits for dioxin (I) during

the last 20–25 years indicate the important progress achieved in this area. Thus the detection limit of (I) in environmental samples was 1 000 000 p.p.t. in 1965, 50 000 in 1970, 10 in 1975, 0.2 in 1980 and 0.01 p.p.t. in 1983. Similar results have been obtained in the analysis of samples of herbicide 2,4,5-T (XII). The detection limit of (XII) was 1 000 000 p.p.t. in 1965 and 1000 p.p.t. in 1985. Equally significant progress has been achieved in the selectivity of the analytical methods. In 1966 20 isomers of tetrachlorodibenzo-*p*-dioxin, including (I), were determined in environmental samples as one chromatographic signal but already in 1979 it was possible to determine the most toxic isomer, viz. 2,3,7,8-Cl_4-DD, as an individual analytical signal.[105]

Thanks to wide international collaboration many procedures for determining trace amounts of xenobiotics (III) and (IV), including the most toxic, have been devised up to the present time [less for the (V) and (VI) groups as yet[418]]. The application of highly efficient purification of xenobiotics from the multitude of background substances has been proposed and includes their extraction recovery, chromatographic separation and mass spectrometric determination. This progress was provided both by improvements in analytical possibilities by instrumental technique and by the development and standardisation of methods of sample-taking and sample-preparation.

The known analytical procedures (see reviews[86,101–114] and a multitude of papers of recent years[227,414–478]) encompass practically all the important materials, viz. soil and sludges,[100,106,150,413,414,424–427,433,437–440] gaseous media including the air, smokes and exhaust gases and dust particles transported by them, ashes and fogs,[100,410,415,418,421,423,428,435,436,441–447] water,[106,417,424,429,430,432] various surfaces,[150,442,462] industrial goods and waste[413,422,425,429,430,432,441,447,448] and biological samples of vegetable[133,411,479] and animal[151,191,413,414,416,419,420,425,449–452] origin. The choice of actual procedure depends on the problems for the investigator, whether it is necessary to identify the source of discharge of xenobiotics or whether there is a need to assess an actual situation.

Two approaches have been formulated to determine xenobiotics:[102] 1) simultaneous determination of all homologues and isomers in one fraction by enrichment of the component to be measured (separation from the matrix), 2) determination of individual isomers, particularly (I) and (II) which are the most toxic. Both approaches are used for general orientation in ecological circumstances although the first is more useful for monitoring programmes. If the target is the assessment of the dioxin danger of samples and regions then the analytical procedure must be toxicologically oriented [i.e. aimed at the determination of the 12 most toxic isomers of (III) and (IV) out of the 210] and rapid (when biological methods of determination are particularly effective).[111,351,480–484]

Knowledge of the physicochemical, structural and toxicological special features of the xenobiotics under consideration, primarily (III) and (IV), enables the formulation of *general requirements* which any method of determining them in the environment and biological specimens must satisfy.[143] The procedure must provide:

1. high sensitivity, due to the exceptional toxicity of (I) and several other compounds,
2. high selectivity, for which it is necessary to separate the xenobiotics being determined from substances accompanying them in the material the concentration of which may be several orders greater,
3. high specificity providing differentiation of the desired substances within the limits of close mixtures of isomers, particularly the separate determination of the most toxic dioxin (I) in the presence of the remaining 21 Cl_4-isomers of dioxin, etc.,
4. high reproducibility of results on quantitative determination.

The first, second and fourth requirements are provided in a completely satisfactory manner by high resolution mass spectrometry. Differentiation of individual isomers in mixtures is achieved by high resolution gas chromatography.

At the present time only a limited number of analytical laboratories in the industrially developed nations are able to carry out analyses on xenobiotics (III) and (IV) of any degree of complexity, particularly to effect quantitative determination in samples of different types. The short account given below of the state of the analytical side of the problem rests mainly on the experiments of several groups working particularly effectively. They are in laboratories in Sweden and Switzerland,[102,109] USA,[101,103–105,412,413,416,441,458] Italy,[100,106] FRG,[107,108,463,464,466] Canada,[110,439,440,465] Japan,[448] France,[434] Norway[415] and other countries by whose efforts an entire methodology of determining dioxin (I) and related compounds in any sample has been built up.

Several obligatory stages are included in all the various procedures for determining xenobiotics (III) and (IV). These are the taking and preparation of samples, the isolation of the desired substances from the sample, their purification and concentration and finally the correct qualitative and quantitative determination of xenobiotics.

Techniques for *selecting a sample* must be suitable for the character of the specimen. This may be the selection of soil in a volume of fixed dimensions, selection of layers of sludge from two reservoirs, the selection and cutting of vegetables, the collection of atmospheric dust in special containers and large capacity test-samplers, wipes of dust or scraping of the upper layer of solid surfaces, the absorption of substances from water, the taking of test samples of ground or surface water and, finally, the specialised selection of biological specimens of animal origin (selection of fluids, organs and tissues). The *preparation of samples* also includes several operations, viz. sifting (soils), drying (soils and sludges), lyophilisation (biological substrates) and acid treatment (water, soils, sludges) and alkaline treatment (vegetation, residues, biological substrates).[106]

When selecting samples the problem of the amount required arises since the detection limit of the desired group of substances must be provided at the p.p.t. level and at the same time the possibility of erroneous results appearing must be avoided. In principle a detection limit of 1–10 p.p.t. of dioxin (I) may be successfully reached with a test sample of 1 g. This is particularly important for biological samples of animal origin, such as blood, milk, lipid tissue, etc. Otherwise one is obliged to deal not only with large amounts of sample but also with the hazard of the large effect of the matrix. The problem of volume is less pressing for samples of air, water and soil (discounting the role of the matrix). For the detection of femtogram quantities of (I) in air it is possible, for example, to take a sample from a volume of 1000 m^3.[415]

Recovery of xenobiotics and their subsequent purification is carried out in such a manner that the substances being determined are not lost in this process and not formed anew. This is provided by introducing into the test sample one or several internal standards from a number of compounds of types (III) and (IV) labelled with ^{13}C, ^{14}C, ^{3}H or ^{37}Cl.[106,141–143,413,485,486]

The mixture of xenobiotics is *recovered* from a sample, as a rule, by extraction with an organic solvent such as hexane, benzene, toluene, chloroform, dichloromethane, petroleum ether, etc. or solvent mixtures (hexane/acetone, chloroform/methanol, dichloromethane/cyclohexane etc.). Dimethyl sulphoxide has proved to be very effective.[425] Extraction is carried out with manual or mechanical shaking (suitable for substrates of all types) or in a Soxhlet apparatus (soil particles and air dust). The degree of recovery of the standard is usually 70–80%.[429] The more firmly the desired xenobiotic is bound to the matrix the worse is the recovery. The action of ultrasonic vibration on the sample (soil, water sludges),[106,487] absorption on polymeric resins (water, air)[106,417,423] and extraction using supercritical liquids[440] are used to increase the completeness of recovery of xenobiotics.

Various methods are used for the *purification of extracts* such as redistribution from one solvent system to another, and multistage purification using chromatographic techniques (columns, gel chromatography, high performance liquid chromatography, HPLC, etc.). The procedure for the purification of environmental samples calls for multiple chromatography (on pure silica, silica modified with sulphuric acid and on alumina), which provides recovery of all substances of types (III) and (IV) at a content of (I) at the level of 1–10 p.p.t.[100,141] Purification of biological and environmental samples is more effective using chromatography on activated carbon,[413,485] which preferentially retains planar polynuclear hydrocarbons. The effectiveness of the specific recovery of the latter by activated carbon is confirmed by comparison of the various methods of purifying (I) (on determining its content in fish)[486] and the other xenobiotics (III) and (IV).[103] Extracts of lipid tissue or samples of animal or vegetable origin are purified from readily decomposing organic substances by treatment with concentrated sulphuric acid. Generally the total process for purifying samples includes at least six procedures. These are purification on a column of the extrelut type (biological substrates), on silica gel (samples of soil and plants), on a column of Florisil (majority of substrates), on a column of aluminium oxide (majority of substrates), treatment with acid (majority of substrates) and with acetonitrile (samples with a high fat and oil content).[106]

When purifying extracts by a chromatographic technique their *concentration* and preliminary separation is effected simultaneously.

Analysis of a sample includes the determination in the purified extract of individual groups of xenobiotics (III) and (IV) (for example all 2,3,7,8-Cl_4-containing homologues and isomers, all Cl_4-isomers of DD or DF, all groups of isomers of Cl_4-, Cl_5- and Cl_6-DD, etc.) or the separate determination of each component of a mixture, especially the most toxic. This is achieved by the sequential use of chromatography and quantitative mass spectrometry, including high resolution. Occasionally their direct combination is used, for example by connecting the chromatographic column directly to the ion source of the mass spectrometer. Depending on the combination taken and the frequently fairly complex procedure each stage of the analysis (sample preparation, its introduction into the mass spectrometer, and finally the mass spectrometric determination proper) may be assigned to virtually one of three classes, viz. low, medium and high resolution. Correspondingly it is possible to effect in practice a very large number of independent procedures each of which provides resolution of an actual problem.[105]

High resolution chromatography is used for the *separation of individual isomers in mixtures*.[143] Separation of xenobiotics is carried out by temperature programming on capillary columns, prepared from glass or fused quartz, of length up to 60 m (internal diameter of the order of 0.25 mm). Silar 10C, OV-17 and OV-101, DB-5 or DB-225, SP-2330, SP-2331 and SP-2340, SE-54, CP Sil 88, SILOV, etc., are used as stationary phases.

A quadrupole mass spectrometer is used in the gas chromatographic-mass spectrometric determination of xenobiotics. Ionisation may be effected by two means, by electron impact (EI) and chemical ionisation. Ionisation by EI (ionisation conditions are up to 70 eV, 250 °C) is most suitable for Cl_4-derivatives of (III) and (IV).[137] The detection limits of 1–10 pg for Cl_4-xenobiotics (III) and (IV) and 10–50 pg for Cl_8-compounds are achieved using single and multi-ion detectors (SID and MID). To obtain a complete mass spectrum 0.1–1 ng substance is required.[109] Negative ion chemical ionisation (NCI) using methane as reagent (0.35 Torr, 180 °C) provides high sensitivity of determination of all furans (IV) with $x + y = 4$ to 8 and also of dioxins (III) with $x + y \geqslant 5$ [i.e. highly chlorinated dioxins except for (I)]. The sensitivity of this method using SID detection is 10–100 fg, i.e. 1–2 orders of magnitude greater than on using ionisation by EI.[143] The NCI technique using O_2 as reagent requires construction of a special ion source.

The use of high resolution mass spectrometry provides a further increase in selectivity and sensitivity. In particular at a resolution of 5000–10 000 using EI and SID techniques a sensitivity of 10–200 fg is achieved, which is improved for xenobiotics (III) and (IV) with the progressive transition from tetra- to octachloro derivatives.[109]

A mass spectrometric detector (mass fragmentography) is used for the *quantitative* mass spectrometric *determination* of xenobiotics (III) and (IV). The precision of determination is provided using isotopically labelled standards. This is particularly important in cases when the concentration of the desired substances in the sample is at the p.p.t. level or below.

A principal step in the determination of xenobiotics (III) and (IV) is the creation of *isomer-specific* methods of identifying and quantitatively determining individual isomers in mixtures.[102,143,216,225,276,298,448,463,465,467] The mass spectrometric method does not provide determination of individual isomers [the spectra of the majority of isomers in each of the mixtures of compounds of both types (III) and (IV) proved to be similar]. The need to determine individual isomers is dictated by the principal differences in toxicity of the individual xenobiotics forming the large series of isomers.

The possibility of separating individual isomers, such as the most toxic, is provided by a combination of high resolution gas chromatography with subsequent mass spectrometry for the quantitative determination of the separated isomers. High resolution GLC with a glass capillary column of Silar 10C (cyanosiloxane phase) is used for the separation of the most toxic isomer (I) from the remaining 21 Cl_4-DD isomers.[225] The separation of toxic dibenzofuran (II) from the remaining 37 Cl_4-DF isomers is achieved by several procedures, including capillary GC with a smectic liquid crystalline phase.[463,464] A procedure has been described for the identification of individual dioxin isomers (III) [in each of the series of (III) with $x + y = 4$ to 8] with Silar 10C[225] and SP-2330[298] columns and with activated alumina.[467] A method of identifying each of the 38 isomers of Cl_4-DF in mixtures of them has been described and was achieved using capillary columns of SP-2330 and SE-54.[217] Separation of the majority of isomers in mixtures of Cl_4-, Cl_5- and Cl_6-DF using SP-2330 columns has been reported.[298] This is particularly important when it is necessary to separate such pairs of isomers as the toxic 1,2,3,7,8-Cl_5-DF and the less toxic 1,2,3,4,8-Cl_5-DF and also the toxic 1,2,3,4,7,8-Cl_6-DF and the less toxic 1,2,3,4,7,9-Cl_6-DF which are usually eluted unseparated. Such a separation was achieved on OV-17 and DV-5 columns.[143]

The use of high resolution techniques is obligatory if xenobiotics (III) and (IV) are present in a sample at the background level. It has been shown in practice that at such low concentrations erroneous results may arise and to exclude this it is necessary to apply different methods simultaneously.[105]

Table 7. Limits of detection of dioxin (I) in various samples taken in the Seveso region.[106]

Sample type	Sensitivity, ppt	Chromatographic and mass spectrometric technique for determination
Water	≤0.01	Standard or high resolution
Air dust	60–200	High resolution
Vegetation	≤1	Ditto
Biological media	<100	"
Soil	≤1	"
Sludges	<100	Standard or high resolution
Solid surfaces	<10 ng m^{-2}	Ditto

Some successes in the determination of xenobiotics achieved in the last 10–15 years are reflected in Table 7. The detection limits of dioxin (I) given in it were obtained using standard analytical techniques when investigating samples selected in the Seveso (Italy) region after the accident in 1976.[106] Numerous correlations of that type pertaining to the whole range of possible analytical problems in the determination of xenobiotics (III)–(VIII) have been collated.[104,105]

There are definite differences in the set of procedures for determining (III)–(VI) in natural samples associated mainly with sample selection, sample preparation and the purification of extracts.[106]

Since xenobiotics are mainly in the absorbed state in *water* bound to colloids and soil particles and to a much lesser extent in the free state, their mobility is determined by the mobility of these particles. To extract xenobiotics from water samples a mixture of saturated hydrocarbons is used such as hexane–acetone (4:1) or hexane–dichloromethane. Later, samples to be analysed were passed through an absorbent material from which the samples enriched with xenobiotic were extracted with a suitable solvent such as ethyl ether. Most frequently chromatographic filtration through a column of alumina sometimes at low pressure is used for purification. Chromatography using a column with a multilayer packing or a column of Florisil remain the standard methods of purification.

Hundreds of milligrams of sample are collected when analysing *atmospheric dust* at low dioxin (I) concentrations. This is achieved using special vessels for the passive collection of dust (for a period of the order of 30 days) or high volume samplers. Attempts have been made to use electrostatic precipitators (their drawbacks were poor reproducibility of results, dependence on atmospheric moisture, a requirement for special positioning and maintenance). At the end of sample collection atmospheric moisture absorbed incidentally was separated by filtration and analysed by the specification for the analysis of water. The solid was dried for 24 h, after which xenobiotics and accompanying substances were extracted with a hexane–acetone mixture (4:1). Particles collected on the glass fibre filter of a high volume sampler were recovered in a similar manner. The extract was purified on a multilayer column and a column of alumina. Dioxin (I) and related compounds were determined in the extract by GC-MS.

In the analysis of *vegetation* it is assumed that dioxin (I) settles on the surface of samples and is there in a mobile form. Consequently in the seventies dioxin was simply extracted from grass without previous treatment and subsequent purification. More recently it has become clear that xenobiotics may also pass into plants from the soil and their level in plants may be comparable or greater than the levels in the environment. Since xenobiotics are bound to internal tissues of plants more firmly than to their surfaces after settling out of the atmosphere, samples are subjected to alkaline treatment with subsequent extraction. Three stages at least are used for the purification of (I). These are filtration through a multilayer column, through a column of Florisil (magnesium silicate) and finally through a column of alumina. In some procedures these three stages are preceded by filtration through silica gel which is required to retain highly polar compounds. The use of high resolution techniques increased the selectivity of determination. The procedures devised enable (I) to be determined in various plant organs.

When determining xenobiotics in domestic and wild *animals* data are obtained not only on their content but a correlation is found with the levels of their content in the environment (bioconcentration) as well. Previous treatment of biological samples includes alkaline hydrolysis with subsequent extraction with hexane. The extract is purified through a multilayer chromatographic column and through a column of the extrelut type. Xenobiotics have been identified and quantitatively determined in many samples using the usual GC-MS technique.

The analysis of *soil* for content of dioxin (I) and related xenobiotics was initially carried out by extraction with dichloromethane without preliminary treatment. Later an additional step has been introduced, viz. treatment with sulphuric acid and chromatographic filtration on a column of alumina, then an additional filtration on a column of Florisil. Purification with acetonitrile has also been applied. Solvents or mixtures containing no dichloromethane are used for extraction, the most effective being a hexane–acetone mixture (4:1). These preliminary purification stages enable an increase in the sensitivity and selectivity of the analysis particularly when using high resolution techniques.

As a rule the content of xenobiotics in water is below the detection limit. However they are found in *sludges*, mud and finely dispersed particles. Procedures for the analysis of sludges are similar to the procedures used for the analysis of soil. Usually sludges, mud and finely dispersed particles are first treated with acid or alkali to decompose mineral components and accompanying organic substances. This increases recovery of xenobiotics from the liquid extract. An alternative route is the drying of the sample and subsequent extraction of xenobiotics from the solid substrates.

Cotton pads moistened with a hexane–acetone (4:1) mixture are used for the collection of test samples containing dioxin (I) and related compounds from smooth, hard and non-absorbent *surfaces* (pottery, glass, tiles, plastic, varnished articles of metal and wood, etc.). To establish the degree of contamination of buildings wipes are taken of the walls, floors and windows (usually from areas of 0.5 × 0.5 m^2). The outer surfaces of buildings are examined by scraping

(1–2 mm) a square of surface 0.1–0.25 m^2 of the outer layer of the wall. Xenobiotics are extracted from cotton pads and scrapings with a mixture of hexane–acetone (4:1). Purification of the extract consists of acid treatment using a multilayer column and chromatographic filtration on alumina. Occasionally a column of Florisil is applied for intermediate purification. Detection and quantitative determination of xenobiotics is carried out by GC-MS.

Turning to the *overall organisation of analyses* of xenobiotics (III)–(VIII) it must be emphasised that this work is accompanied by considerable methodological and technical difficulties. Even within the framework of already established systems, i.e. essentially running, these analyses are extremely expensive, laborious and of long duration (as a rule they occupy many days). In addition the conduct of such analyses requires the use of special premises equipped with allowance for the very stiff requirements for accident prevention.[453–455] Because of the high toxicity of xenobiotics it is necessary that analytical samples separated for such analysis are not used for other purposes. It is also necessary that specially pure solvents, reagents and materials are used. In particular when taking air samples polyurethane or Teflon-coated glass-fibre filters are required together with polyurethane stoppers.[415,435,436] Finally the scale of carrying out analyses demands the organisation of the manufacture of standards. At present methods have been developed for the synthesis of each of the 210 xenobiotics of the (III) and (IV) series.[198,215–220,223,472]

Although many of the difficulties indicated have been overcome there are still often cases when analyses of a single specimen have been completed with serious deviations. To prevent similar errors interlaboratory comparative determinations are carried regularly in the industrially developed countries which enables comparison and standardisation of procedures.[150,419–422] The so-called 'method 8290' has been proposed for the same purpose, which enables, according to the ideas of its originators, the same results to be obtained in different laboratories by standardisation of the determination procedure.[478]

Work continues on the *improvement of techniques for the determination* of xenobiotics (III)–(VIII). Two main directions are planned. The first concerns the improvement of methods known already. Special extractors are being developed enabling the practically complete recovery of xenobiotics from soil, sludges and other materials.[426,440] Analyses are optimised both in the stages of separation of xenobiotics and in their determination. In particular computerised systems have been devised for the quantitative assessment of the results of gas chromatographic-mass spectrometric determination of xenobiotics.[468–470] Work is being conducted on the design of analytical techniques adapted for direct measurements under field conditions. For example a mobile mass spectrometer has been built in FRG which enables the direct determination under field conditions of dioxin (I) (in subnanogram quantities) and certain other highly toxic substances.[477]

The second direction concerns the development of new approaches to analysis brought into existence both by the laborious nature of the determination of xenobiotics (III)–(VI) within the framework of traditional methods and by the need to obtain express information on an actual epidemiological situation. Attempts have been made to develop *biological*, particularly immune, *methods of determining* and immediately *testing samples*.[111,351,480–484] Several biological substrates capable of specific and sensitive reaction with (I) and related xenobiotics have been proposed for biotesting (chick embryos, certain blood and sheep cells, etc.). The selective absorption of (III) and (IV) from the environment by certain flora[193] (leaves[488] and fir needles[194,489]) and fauna may be used for biotesting.[490] A radioimmunoassay has been developed for determining dioxins (III) in fish (Canada).[484]

The use of monoclonal antibodies for the immunodetermination of (III) and (IV) is particularly promising.[113,114,480] A set of antibodies has been isolated which provides a specific reaction with the highly toxic tetra- and pentachlorinated xenobiotics (III) and (IV) with lateral 2,3,7,8 disposition of chlorine atoms. These antibodies do not react with substances usually present (phenols, polychlorinated biphenyls, herbicides including 2,4,5-T, etc.). The determination of xenobiotics (III) and (IV) in material of various types, such as light ashes, motor oils, vat residues, etc., leads to satisfactory results (confirmed by correlation between data of immunodetermination and of normal GC-MS). The method provides detection of 0.5 ng dioxin (I). In our opinion this direction for analysis, in spite of several limitations, may provide a sharp drop in the consumption of time and money in the determination of samples of various types and forms a basis for effective monitoring in a practicable time scale.

VI. Environmental contamination by xenobiotics of the dioxin type. Monitoring

Problems of the chemistry of dioxin (I) in the environment[74] and the general global approach to the assessment of world-wide contamination of the biosphere by xenobiotics (III)–(VIII)[75,491,492] are still only being worked out. The previous attempt to solve this problem, accomplished in the study of the global contamination of nature by organochlorine insecticides, may only be used to a small extent. Thus xenobiotics (III)–(VIII), like the highly lipophilic organochlorine insecticides, accumulate readily in the organic phase of the biosphere and are redistricted along the food chain,[142,143] i.e. efficient participation in biotransfer is common to these two types of contaminant. At the same time the special features of the physical and chemical properties and the toxicological characteristics considered above determine the singularity of other routes of transfer of (III)–(VIII) in nature. Cases are already known at present of the efficient vertical migration of dioxin (I) in the lithosphere which determines the probability of contaminating water-bearing soil layers with it. The tendency to form stable molecular complexes in the organic phase of soils leads to an unusual, depending on soil-climate features, route for the horizontal migration of compounds (III) and (IV) in the lithosphere and to the effective conduct of transfer across boundaries. In this way modelling of the behaviour of (III)–(VIII) in nature is an incomparably more complex problem than for the organochlorine pesticides. It is made many times more complex by the extreme diversity of the homologues and isomers of (III)–(VIII).

It is known that monitoring is the most effective means of establishing the real situation for the contamination of the biosphere and is the basis for developing programmes for protecting regions, objects and populations. It is classified as chemical, biological and toxicological depending on the methods used. *Chemical monitoring* is effected by chemical, chiefly instrumental, methods. It has the purpose of recording territorial changes in xenobiotic concentration with time. *Biological monitoring* is aimed at the search for possible diseases of man and living organisms in general. *Toxicological monitoring* relates to the analysis of temporary effects of affected populations.[357,493]

The methodology of studying contamination of the biosphere by xenobiotics (III)–(VIII) comprises several parallel routes of investigation.

Firstly the methods of chemical and biological monitoring enable the *accumulation of information* on the distribution of these xenobiotics between various parts of the environment. Thus in recent years xenobiotics (III) and (IV) have been detected and determined in many new specimens such as reservoir sludges,[494] air and rain water,[172] sea and fresh-water life,[495] food products,[496] human tissue,[332,333] etc. At present there are data on the composition and content of xenobiotics (III)–(VI) in practically all parts of the biosphere: in water,[165,269,497–500] in soil and sludges,[253,304,500–506] air,[172,255,304,348,415,423,435,436,494,507–509] vegetation,[479,510] fish,[484,485,495,511] organs and tissues of warm-blooded animals,[142,143,191,332,333,495,512–518] human milk,[514,519–523] foodstuffs[141, 142,496,502,511,514,524–527] and technical products.[306,447,528] Several reports have been devoted to a study of the content and routes of migration of xenobiotics (III) and (IV) in animate and inanimate nature.[53,54,137,304]

Secondly the *geographical features* of the formation and distribution of (III) and (IV) in nature are assessed by monitoring methods. As already indicated above the composition has been studied and a quantitative assessment made of the discharge of xenobiotics when operating INC in practically all industrially developed countries of the world. The same applies also to the assessment of discharges from other sources and to the study of their content in the environment of various regions of human habitation. Such investigations have been conducted in USA,[348,453,507,521,529] Canada,[352,498,524] FRG,[300,500,501,514,519,527] Japan,[497,499,506,512,513,521] England,[63,505,510,520] Italy,[100,106,153,155,156] Sweden,[301,511,530] the Netherlands,[141] France,[531] New Zealand,[303] etc. The number of scientific laboratories occupied with this problem is growing continuously and is more than one hundred at present (47 in USA, 23 in FRG, 12 in Canada, 9 in Italy, 7 in England, 5 in the Netherlands, etc.).[33]

A particular approach to making contaminated regions apparent and clarifying the extent of their contamination is based upon the use of *data on sources* of xenobiotics (III)–(VIII). For example the total quantity of chlorophenols manufactured by the industrially developed nations is known (150 000 tons annually[63]) as is the territorial disposition of manufacture and the content of xenobiotics [predominantly of the (III) type] in each of the industrial products. In particular 99 places of manufacture of 2,4,5-trichlorophenol (XIV), of its use as a raw material in pesticide production and of the burial of poisonous waste are known and 17 of them are considered to be particularly dangerous.[532] The throughput and territorial distribution of INC are also known (2000 in Japan, 47 in FRG, 25 in Sweden,[22] 45 in Denmark,[280] 22 in northern Belgium,[273] etc.). The overall dimensions of the discharge of xenobiotics by these furnaces and the typical distribution in them of the most toxic homologues and isomers are also known. Finally the levels of consumption of ethylated petrol by the motor transport of various countries, their compositions and discharge volumes of (III)–(VIII) are known.

Allowing for these sources attempts have been made to assess the total volume of discharges and contamination by xenobiotics (III) and (IV) for actual territories and also the *dynamics of contamination* as a function of various factors. Existing experimental data on the similar ratio of homologues and isomers discharged by INC in industrially developed nations of various regions (Canada, Japan, France, Norway, etc.), regardless of the dependence on combustion regimen and the composition of the materials being destroyed,[283] was used as was data on the approximate similarity of the isomer–homologue composition of the xenobiotics discharged by various sources such as INC and motor transport.[304] However such approaches are not always reliable. In particular the hypothesis of the close relationship of homologues of (III) and (IV) present in the air in molecular form and absorbed onto aerosol particles has not been confirmed.[304] It turns out that particles transported by the air absorb the highly chlorinated (less volatile) homologues to a larger extent, thus effecting a forced separation which is not always favourable toxicologically.[172] It is also difficult to judge the quantities of xenobiotics (III)–(VIII) formed from their precursors in nature. For example the direction of the photodechlorination of the weakly toxic octachlorodibenzo-*p*-dioxin on a soil surface differs markedly from model conditions in solution. In nature a portion of the isomers of tetra-, penta- and hexachlorodibenzo-*p*-dioxin is formed by fission of *peri*-chlorine atoms, i.e. accumulation of highly toxic isomers with a 2,3,7,8-tetrachloro fragment occurs, while in solution chiefly lateral chlorine atoms are lost.[206]

It is important to know the detailed characteristics of individual suppliers of xenobiotics (III) and (IV) to bring about international cooperation on the problem of monitoring dioxins, since different sources may prove to predominate in individual countries.[63] Thus contamination of the English environment arose predominantly by the yearly inflow of xenobiotics from the manufacture and use of polychlorophenols [4.5 kg xenobiotics (in DE) from a yearly manufacture of 2000 tons chlorophenols].[63] The main sources of xenobiotics (2 kg) entering the environment in the Netherlands each year are INC.[533] In Norway the annual discharge of xenobiotics in waste water by only one metallurgical undertaking was 0.5 kg.[291]

The *integration of contributions to the contamination* of the environment by various sources of (III)–(VIII) enables assessment of the overall situation in any region and exposes the most dangerous technologies. For example assessment of the discharge of xenobiotics in Sweden in 1987 appeared as follows (in DE): combustion of domestic refuse 200–300 g, discharges from metallurgical undertakings 100–200 g, motor exhausts 10–150 g, etc. (about 1 kg in all).[534] In Canada, where discharges are more significant and contributions to the integrated contamination from individual sources are reduced year by year depending on industrial politics,[63] the following data were collected in 1986 (in Ontario province,[400] in DE): by combustion of rubbish in INC and the rendering harmless of waste water 8–10 kg, other forms of combustion 20–50 kg, impurities in polychlorobiphenyl > 4 kg, trans-border transfers (from USA) 2–20 kg, etc. Similar assessments have also been carried out for all Canada.[535] One further example of the integrated approach is the assessment by Swedish scientists of the overall content of xenobiotics in the sludges of the Baltic Sea accumulated from the whole industrial history of the region (the quantity of xenobiotics was 30 kg).[534]

When assessing *products of individual technologies* as sources of xenobiotics (III)–(VIII) it is important to know whether they are only carriers or carriers and precursors of contamination in nature. The degree of danger of a product of the first series is determined by the content in it of toxic microcontamination since the products themselves are usually effectively biodegraded in nature.[326,330] At the same time the danger of potential precursors of dioxins is not just their adequate microcontamination content since some routes for their metabolism, determined by the biological activity of the medium into which they enter, may lead to additional accumulation of dioxins in nature.

For instance paper is a product used by man in his way of living and is only a carrier of xenobiotics (III)–(VIII). Xenobiotics (III)–(VIII) are found in coffee filters, wrapping paper, paper napkins, childrens' napkins, etc.[247] Domestic use of paper is inevitably accompanied by transfer of xenobiotics directly into food (coffee, milk, butter, tea, etc.) and then into the organism.[247,536–538] The use of dioxin-containing paper is particularly dangerous for childrens' napkins, sanitary tampons, handkerchiefs, etc. since skin layers and mucous membranes extract the xenobiotics from paper.

Examples of products of the second series are polychlorophenols, polychloroanilines and their numerous derivatives, including azo and azoxy derivatives, certain polychlorobiphenyls, polychlorobenzenes, hexachlorane and other products. The manufacture and use of such products is inadmissible according to the concepts of the Environmental Protection Agency of the USA. Their danger for the contamination of nature may only be established experimentally by monitoring for dioxin.

Much attention has been paid in modern investigations to the process of transfering xenobiotics (III)–(VIII) in nature and their crossing from one phase to another. It has been shown that in air[539,540] and in water[541,542] various families of high molecular composition serve as carriers of xenobiotics. The main transport media for the transfer of xenobiotics are air and water and the atmosphere provides a more effective transport of xenobiotics from sources to an accumulating medium (or object).[174,175,494,539,540] The role of soil in the long-distance transport of xenobiotics is significantly less,[204] although our knowledge of the mechanism of the interaction of xenobiotics with the soil surface and sludges is hard to call exhaustive.[541]

When considering the problem of the *global transport of xenobiotics* it is necessary to pay attention to the principal differences between the three processes by which xenobiotics (III)–(VIII) cross from one phase to another, viz. the crossing of xenobiotics from their sources of manufacture to the environment, subsequent crossing from inanimate nature to flora and fauna, and finally, their return to inanimate nature from higher organisms. In the first case practically no changes occur in the composition of mixtures of xenobiotics. The ratios of homologues and isomers characteristic of their sources are mainly retained in inanimate nature. Only small changes are possible, explained by differences in the physicochemical properties of the xenobiotics.[283,300,543]

The picture changes sharply in the second process. Representatives of flora and fauna are particulary efficient in retaining xenobiotics with a 2,3,7,8-fragment by *bioconcentration*.[141,195,513,514] Within the homologues of this type as was made clear on analysis of the tissue of people living in different regions of the world, such as USA, Canada, Europe, and Japan,[332,333] no differences were observed in the ratio of xenobiotics. Selection is regulated in absorption concentration by the number of halogen atoms (it is most effective when $n = x + y = 8$) and accumulation during bioconcentration is effected with a toxicological orientation. It is also evidently impossible to ignore the special features of individual organisms with regard to efficient absorption of different types of xenobiotics. For example it was discovered recently[491] that the grampus concentrates xenobiotics mainly of the furan series (IV) and polychlorobiphenyls but compounds (III) are found in insignificant quantities.

When carrying out the third process, i.e. in the return *crossing of xenobiotics from higher organisms to inanimate nature*, the tendency is reversed. In biodeconcentration the most toxic xenobiotics with a 2,3,7,8-fragment effectively do not emerge from living organisms or only emerge from them as a final event.[141,544]

Precisely these features ensure that human disease by dioxins effectively occurs through the *food chain*. In this case only the most dangerous xenobiotics of the (III)–(VIII) series are consumed. The non-toxic isomers, many of which possess the properties of antagonists of (I) and (II), are selected out in the biotransfer process. Hence increased attention is being paid in practically all the industrially developed nations to the problem of analysing dioxins in foodstuffs, to the problem of manufacturing ecologically pure food and to the search for new safe foods.

Turning to biological monitoring for xenobiotics in the biosphere we note once again that the main source of their entry from the environment (soil, water and air) into man and animals is the food chain. Fish and dairy cows must receive a special mention of all the known concentrators of dioxins.[141,165,174,188,191] Xenobiotics transfer from fish to man (or to animals and birds eating them[141]) directly and from cows chiefly through milk.[175] It has been established[334] for example that xenobiotics accumulate efficiently in the milk of cows (in the lipid fraction[141]) grazing close to INC and in people using this milk (accumulation occurs more than 2 orders of magnitude more efficiently than on directly inhaling air from an INC[334]). The rate of absorbing xenobiotics from the oesophagus into animals[545] and later of transfering them into milk[338] is very high. Xenobiotics enter the offspring from the mother not so much through the placenta (natural protection operates) but more through the mothers' milk[321] and then through the oesophagus.[545] In this connection the World Health Organisation has developed an international programme on the dioxin problem in human breast milk in which practically all the industrially developed nations are involved.[141,514,520]

A detailed investigation by Swedish scientists[142] and by others[519–523] of the accumulation of dioxin in breast milk has shown that the content of xenobiotics (III) and (IV) in milk correlates with their concentration in the lipid tissue of the mother though they enter the lipid tissue from food, drinking water and the air. Direct transfer of dioxins into man through the integument from contaminated water and soil is also possible. The danger of infants being affected by dioxins is determined by the extent of the contamination of nature. Thus in 1970 there was a level of 0.8–1.45 p.p.b. of xenobiotics of type (III) in the milk of nursing mothers in South Vietnam. A large quantity of dioxins (16–30 p.p.t., in DE) was found in the maternal milk of women living in industrially more developed countries such as FRG, Belgium, Japan, the Netherlands, England, etc. The highest concentrations of dioxins (up to 30 p.p.t.) were observed in the milk of women living in huge industrial centres such as Hamburg (FRG). The first data on the dioxin content of maternal milk of inhabitants of the USSR have recently become known (obtained by scientists from USA and FRG).[546]

In conclusion it must be mentioned that monitoring of dioxin xenobiotics may be both universal and thematically or territorially oriented from the point of view of organising and financing the work.

Programmes accomplished in the USA[326,547] and Sweden[530] may be considered as examples of *universal monitoring*. The programme initiated in the USA in 1975[326] specified the carrying out of a huge series of determinations of xenobiotics in various samples in all regions of the country. Many state, industrial and university laboratories were involved. In 1983 the programme grew into a 'National Dioxin Strategy' conducted according to an assignment of

the US Congress[547] in seven main directions and emerging beyond the limits of just monitoring. In Sweden beginning in 1988 it is planned to carry out a 2.5 year universal monitoring consisting of 1000 analyses of various samples for content of xenobiotics (III) and (IV) and also of PCB, PBB and polychloronaphthalenes. The programme comprises a combination of chemical and biological methods of analysis and the samples include food, air, certain sediments, paper, INC discharges and biological specimens. The first 400 analyses were completed in 1988.[530]

Monitoring for xenobiotics (III) and (IV) is laborious and expensive (the cost of each determination including sample preparation comes to \$2000–2500[453]). In 1985 the cost of monitoring for these xenobiotics in the USA exceeded \$150 million.[63] The expenditure in Canada on monitoring up to 1985 reached \$6 million.[254] Large appropriations for similar purposes have been made in FRG[242] and Japan.[275]

Programmes for thematically and regionally oriented monitoring have been carried out regularly in the industrially developed nations. Examination of soil around Seveso (Italy) after the accident in 1976 is being continued,[156] the monitoring of regions near known 'dioxin dumps' is being carried out (Netherlands,[313,314] FRG,[311,501] USA[308–310]). In recent years vast programmes have been put into operation to study soil[505] and plants[510] in various regions of England, the 'supply baskets' of Canada,[524] FRG[527] and other countries are being examined. The toxicological monitoring of groups of people having, or having had in the past, 'contact' with xenobiotics (III) and (IV) is gradually beginning (USA[17,147,157,158,515] Japan,[95,96] Vietnam,[516,523] etc.).

Although the results of these programmes are considered to be satisfactory on the whole some alarming facts have been recorded. The analysis for xenobiotic content of fish caught in various Swedish waterways had led to the conclusion that the weekly consumption of Baltic Sea codfish in individual parts of the country exceeded the value of WCD taken as acceptable.[511] The weekly consumption of dioxins through food in West Berlin was 1.3 pg kg^{-1},[527] which is greater than the standard taken to be acceptable in some countries.[33]

VII. Prevention and destruction of dioxin contamination

Large scale measures to limit anthropogenic danger caused by xenobiotics (III)–(VIII) are being put into operation by the technically developed nations. These measures are effected in three main directions.

The first concerns the *improvement of the operating technology* whereby xenobiotics are no longer generated or their discharge is reduced to safe levels. In particular work is being carried out on modernising cellulose–paper industrial undertakings in Sweden,[548] USA[251] and other countries. New technology is being introduced for bleaching cellulose pulp which is accompanied by practically no formation of xenobiotics (III) and (IV),[548] and paper free from dioxins has already begun to be produced. Especially strict control has been established for paper for children.

Programmes have actively been put into operation for restricting the discharge of xenobiotics to the environment from the numerous INC in Sweden,[549] Japan,[275,278] Canada[254,255] and other countries. The introduction of technical improvements into the process of burning waste has provided minimum formation or even complete destruction of xenobiotics. This concerns the construction particularly of new INC.[255,259,289] An economical INC has been developed enabling elimination of xenobiotic formation in the process of burning domestic refuse.[550] A procedure has been found for destroying xenobiotics by passing the exhaust gases and light ash from the INC over a catalyst. In this case destruction of dioxins occurs almost completely even at 350–450 °C.[551] Equipment is widely used to remove xenobiotics from INC discharges and includes filters[272] and electrostatic precipitators.[552,553] In addition it is considered that the cardinal solution to the problem of destroying solid domestic waste requires prohibition of processing it without separation and use of components of the rubbish as secondary raw material.

The selection and manufacture of organochlorine compounds is being modernised in chemical undertakings. In the industrially developed nations the manufacture and application of chlorinated products, which are precursors of dioxins in nature, is prohibited. This primarily concerns 2,4,5-trichlorophenol and pesticides based on it.[49,142] In any case apparently only New Zealand manufactures and uses the herbicide 2,4,5-T in agriculture.[142] Some countries have also given up 2,4-D.[23] In some countries such as Japan the use of PCB is prohibited.[23] In others it is strictly controlled, ecologically safe replacements for these products are being developed.[142] Because of the change in composition of ethylated petrol the discharge of xenobiotics (III)–(VIII) when burning it in motor vehicles is reduced.[301] Ecologically safe methods (pyrolytic and others) of destroying chorine-containing vat residues are being developed.[532]

The second direction embraces *organisational measures* providing prevention and limitation of contamination of the environment by sudden discharges of xenobiotics. For example it is forbidden to use electric power equipment with PCB in large buildings in the USA to avoid contamination by PCB in fires,[23] which took place previously.[33,125]

The third direction of work concerns the *destruction of the results of dioxin contamination of territory*, the elimination of xenobiotics from the environment and from industrial waste and burial of the latter. Seemingly the first historically was the massive work on the decontamination of the vicinity of Seveso (Italy) from dioxin (I).[100] Similar measures were taken in the state of Missouri and in several other contaminated regions of the USA.[547,554] Expensive and very careful work has been accomplished in the industrially developed countries on the destruction of previously manufactured dioxin products such as residues of the herbicide 'Agent Orange' (USA),[310] PCB (Japan),[23] etc. Necessary measures are being applied in relation to the decontamination of large dumps which proved in fact to be sources of xenobiotics (III) and (IV) (Netherlands,[313,314] USA,[547,554] etc.).

Achievements in the area of low temperature and thermal methods of dehalogenation and destruction of xenobiotics (III)–(VIII) have been summarised.[211,532,554–556] The most effective are considered to be the destruction of dioxins by catalytic oxidation and by photodestruction, after preliminary recovery from soil with solvents and sublimation in solution at 500–600 °C. Recently biological methods of decomposing dioxins have been developed. For example fungi of certain species have been isolated which are capable of decomposing xenobiotics (III) and (IV) to nontoxic products.[557] They may find use for the partial decontamination of highly dangerous vat residues if the rate of biodestruction of dioxins by these organisms can be appreciably increased. It has been shown possible to decontaminate water contaminated with dioxins by ozonisation.[558]

Numerous procedures for the decontamination of soil and of chemical industry waste products from xenobiotics are being developed in the USA.[532,554,555] Mobile equipment has been devised for the thermal treatment of soil contaminated with xenobiotics and of solid and liquid waste at temperatures up to 4500 °C. Xenobiotics are more than 99.9999% destroyed by this.[554] A drawback of this procedure is the low throughput and high energy cost so preliminary recovery and destruction of dioxins by other methods is considered expedient. The dechlorination of xenobiotics found in waste and extracted from contaminated soil in laboratory and field conditions has been worked out by melting them with ethyleneglycol, with solid KOH or other alkalis.[559,560] Burial of soil contaminated with xenobiotics in abandoned mine workings has been proposed.[554] Special clays have been proposed for the efficient recovery of highly toxic xenobiotics (III) and (IV) from industrial waste.[532,561,562] Stabilisation procedures, including consolidation of xenobiotics in industrial waste products (such as by vitrification), have been developed.[532]

- - - o0o - - -

In any event the global attempt to study the problem is thriving. Some developed countries have learned from their technological errors, others have learned from abroad. Our society must not be out of the picture while experiencing a period of brisk ecologisation. First of all this must be directed towards acceptance of exhaustive measures for the exclusion of dioxins from the environment and particularly from foodstuffs. The organisation of All-Union chemical and toxicological monitoring for this technological danger and, which is very difficult, the fitting out of our existing analytical centres of various types with appropriate instruments are also important. Finally data on the content of dioxins in the discharges from all our undertakings and in their dumps must remain an obligatory element of their technological passports.[563]

Modelling of metal complexes by the method of molecular mechanics

D V Pozigun, V E Kuz'min, G L Kamalov
Bogatskii Physicochemical Institute, Academy of Sciences of the Ukrainian SSR, Odessa

ABSTRACT. The review considers various approaches to the conformational analysis of metal complexes within the framework of the method of molecular dynamics and analyses their possibilities and limitations. The limits of the applicability and usefulness of such calculations are outlined.

The bibliography includes 128 references.

I. Introduction

Molecular mechanics constitutes an empirical computational method in which the molecule is regarded as a system of interacting atoms. In this model, electronic ideas are involved implicitly or are absent altogether. The method is also known as the method of atom–atom potential functions, the additive model of interatomic interactions, the molecular force field method, the mechanical model of the molecule, etc.[1] We shall use the term "method of molecular mechanics" (MMM).

Molecular mechanics is one of the most powerful methods applied at the present time in the study of the steric structure of molecules and the estimation of the energies of intramolecular and intermolecular interactions and the properties associated with them. It is applied widely in organic chemistry for the solution of various structural and conformational problems, the calculation of the strain energy, thermochemical properties, and frequencies in vibrational spectra, for the prediction of the rates of chemical reactions and their stereochemical features, for the allowance of the packing effect in condensed media, etc.[2] However, the application of the MMM in the chemistry of metal complex compounds (particularly the compounds of transition metals) is significantly complicated, as a result of which the method has not so far been used very widely.

The main characteristic feature of the MMM applied to metal complexes is the necessity to model the coordination unit, because it is by no means always possible to establish *a priori* the type of coordination polyhedron for a metal with a specified atomic (ionic) radius and a specified coordination number. Here it is necessary to take into account the possibility of the occurrence of different oxidation states of the complex-forming metal and the different structural functions of the ligand.

Furthermore, like any empirical method, the MMM requires the use of a series of parameters, whose correct determination is difficult, particularly in the case of metal complexes, owing to the lack of a sufficient amount of the necessary experimental data. The problem of the selection of the initial approximations for the calculation, which is particularly important for polycyclic chelate compounds, also complicates the conformational analysis of complexes.

In this connection, in the conformational calculations for metal complexes it is necessary to introduce additional hypotheses about the structure of the coordination polyhedron, the nature of the interaction of the ligands with the metal, etc., which is the reason for the wide variety of the modifications of the MMM applied to the chemistry of coordination and organometallic compounds. The choice of a particular model is determined by the information possessed by the investigator and by the problems which he wishes to solve.

This review deals with various approaches to the conformational analysis of metal complexes within the framework of the MMM, their possibilities and limitations are analysed, and the limits of the applicability and usefulness of such calculations are outlined.

We decided not to describe in detail the MMM, its formal features and mathematical apparatus, the form of the potential functions, the technique of the calculation, etc. and also not to consider the advantages and disadvantages of the MMM compared with the experimental and other computational methods for the study of the steric structures and molecules. These questions have been dealt with in detail in numerous publications and in a series of fundamental monographs (see, for example, Refs. 2–4). Here we shall deal with the possibilities of the most "complete" or "correct" (i.e. with the minimum number of simplifications) version of the MMM. The widely used modifications of the MMM, differing mainly in the approach to the modelling of the coordination polyhedron, will be compared and the range of problems solved with their aid will be outlined. The methods for the conformational analysis of many-centre systems (cluster compounds) will be discussed separately.

We thought it desirable to consider also a series of simple mechanical models (strictly speaking not relevant to the MMM), which, on the one hand, are closely related to this method in their "ideology" and, on the other hand, may be useful in certain cases for the study of the steric structures of complex compounds.

Since the problems dealt with in this review have already been considered in a series of other reviews and monographs (see, for example, Refs. 5–7), we shall discuss mainly the results published in 1985–1988. Early studies containing descriptions of the models and

approaches used in subsequent publications as well as the necessary experimental data are an exception.

II. Complete allowance for the deformations of the coordination polyhedron

The MMM is most widely used in the study of the structures of coordination compounds: the prediction and reproduction of the geometry of the complexes, and comparison of the relative stabilities of isomers and structurally similar compounds. In certain branches of the chemistry of metal complexes, studies of this kind have already become fairly systematic. For example, the steric structures of chelate complexes of transition metals with nitrogen-containing ligands have been studied in detail. A review[8] summarises the results of structural and conformational studies of trisalkylenediamine complexes of transition metals with the aid of the MMM—this applies mainly to cobalt(III) complexes, which apparently have in general been studied most thoroughly by this method, and to chromium(III) complexes with five-, six-, and seven-membered chelate rings. The review presents data on the relative stabilities and geometries of the structural isomers and conformers of the above complexes.

An example of the uses of the MMM for the determination of the relative energy factors favouring the existence of particular isomers of complexes is provided by a study[9] of copper(II) complexes with unsubstituted, *N*-monomethyl-, and *N,N*-dimethyl-substituted (*R*)- and (*S*)-alanines. The calculation was performed in accordance with the MM2 program[10] using the parametrisation of Raos et al.[11] in terms of the approximation of the square planar configuration of copper(II). The calculation revealed that the energies of the *cis*- and *trans*-isomers of the $Cu(Ala)_2$ complex are similar and hence that there is a possibility of the presence of the *cis*-isomer in the equilibrium mixture. In complexes with mono- and di-methyl-substituted alanines, the differences between the energies of the *cis*- and *trans*-isomers increase and in the latter case the *cis*-isomers hardly occur. According to the calculation, the complexes containing ligands with the same configuration are more stable.

Similar problems were considered in a study[12] (see also Refs. 11 and 13) of copper(II) bis-*N,N*-dimethylisoleucinates CuL_2. A detailed conformational analysis of the isomers $Cu[(S)\text{-}L]_2$ and Cu[(*S*)-L][(*R*)-L] with the same *trans*-bonding of the aminoacid ligands was carried out. A characteristic of the stability of the isomer, taking into account the contributions of the possible conformations, is the quantity $<G>$†:

$$\langle G\rangle = \frac{\sum_{i=1}^{N} G_i \exp(-G_i/RT)}{\sum_{i=1}^{N} \exp(-G_i/RT)},$$

where G_i is the energy of the *i*th isomer calculated by the MMM. The authors[12] examined 16 conformers but only three of them make the dominant contribution to the quantity $<G>$ [72.4% in the case of the (*S,S*)-isomer ($<G>$ = −1.45 kJ mol^{-1}), which is consistent with experimental data,[16] although the difference between the energies of the diastereoisomers was not in fact reproduced quantitatively.

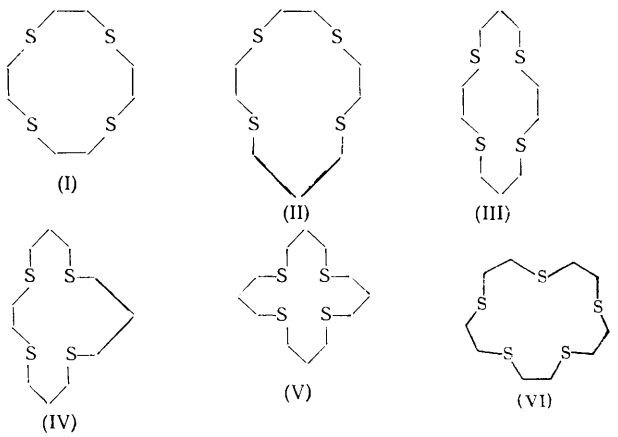
We may note that the use of the quantity $<G>$ as a characteristic of the relative stability of the complex undoubtedly leads to more correct results than the use of the energy of the steric strain of the most stable conformer frequently employed (see, for example, Timofeeva, et al.[9]) for such estimates.

The MMM can be applied also to the study of complex bioinorganic systems. For example, the possible structures of double-stranded oligonucleotides [*d*(G1−G2−C3−C4−G5−G6−C7−C8)−*d*(G9−G10−C11−C12−G13−G14−C15−C16)] and [*d*(T1−C2−T3−C4−G5−G6−T7−C8−T9−C10)−*d*(G11−A12−G13−A14−C15−C16−G17−A18−G19−A20)]‡ and their complexes with *cis*-diamminedichloroplatinum(II) (antitumour preparations) have been investigated.[17,18] The calculations were carried out by the AMBER program[19] using different force fields whose specific parameters as well as the procedures used to model the coordination polyhedron are unfortunately not indicated by the authors. In conformity with earlier data,[20,21] the addition of the *cis*-$[Pt(NH_3)_2]^{2+}$ fragment to the N atoms of two neighbouring guanosine G5−G6 fragments was considered. It was shown that platination leads to appreciable changes in the structure of the nucleotides: it disturbs the system of stacking interactions in the chain of nitrogen-containing bases, alters the conformation of the monosaccharide as well as the system of intrastrand and interstrand hydrogen bonds in the G5−G6 region, and is accompanied by the formation of a new P=O...H−N hydrogen bond involving a coordinated NH_3 molecule and the phosphate group of guanosine G5. According to the authors,[17,18] the presence of this hydrogen bond and the changes in the steric structure induced by it influence significantly the antitumour activity of platinated oligonucleotides, which in fact explains the observed[22] decrease in this activity in the series of ligands $NH_3 > NH_2R \geqslant NHR_2 \gg NR_3$.

Subsequently the same investigators showed[23] that platination of DNA can also lead to the bending of the axis of its helix. Two such "curved" structures have been investigated[23] with the aid of the MMM in relation to the decanucleotide [*d*(TCTCG*G*TCTC)−*d*(GAGACCGAGA)]§. According to the calculation, the stabilisation of both structures is caused by the appearance of yet another hydrogen bond between the second NH_3 ligand and the O atom of the guanosine G6.

The conclusion that both hydrogen bonds play a significant role in the complexes of DNA with various derivatives of diammine dichloroplatinum has been confirmed also by Hambley,[24] who investigated by the MMM the interaction of oligonucleotides with the (*R,R*)- and (*S-S*)-isomer of cyclohexylene-1,2-diammine platinum(II).

The MMM has been used[25] to elucidate the causes of the experimentally established[26,27] addition of diamminedichloroplatinum to the −A−G− sequence of nucleotides and the absence of adducts of this kind with the −G−A− nucleotides. The trinucleotides [*d*(GT*A*)−*d*(TCC)] and [*d*(GA*G*)−*d*(CTC)] were used as models of DNA and the calculations were performed using the force field specified by Weiner et al.[28]



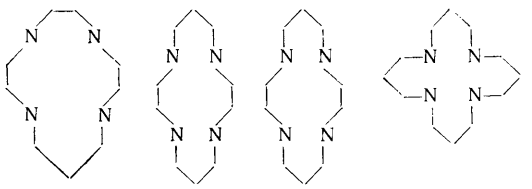
† The authors[12] refer to the quantity $<G>$ as the "Gibbs energy", although in fact it is none other than the enthalpy contribution to the steric component of the free energy of the molecule. For further details about the estimation of the latter with the aid of the MMM, see Kuz'min and co-workers.[14,15]

‡ A = adenosine, G = guanosine, T = thymidine, and C = cytidine.

§ Here and henceforth the asterisks denote the site of addition of *cis*-$[Pt(NH_3)_2]^{2+}$.

The MMM calculation showed that the formation of a complex with the second trinucleotide indicated is more favourable to the extent of 28.1 kJ mol^{-1}. This is explained by the fact that in the case of the $-A-G-$ sequence the complex is stabilised by the formation of the $-NH_3...O$ (guanosine) hydrogen bond (see above). On the other hand, in the case of the reverse sequence of nucleotides such bonding is impossible and the complex is destabilised as a result of the $-NH_3...N$ (adenosine) repulsion.

The MMM is so far used extremely rarely for the quantitative estimation of the influence of the steric factors on the reactivity of metal complexes. As one of the few available examples, one may quote a study[29] of the copper(II) complexes with the ligands (I)–(VI):



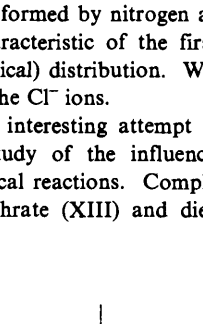
Boyd's program[30] was used for the calculations and the force field was analogous to that employed by Brubaker and Johnson.[6] The calculated structures are fully consistent with those found by X-ray diffraction (XRD).[31]

An attempt was made to subtract from the experimental[32] enthalpies and free energies of formation of the above complexes the calculated energy of the intramolecular strain in the ligands. It was found that the remaining part of the free energy, corresponding to the hypothetical complex free from intramolecular strain (ΔG_{int}), is virtually the same for complexes with the ligands (I)–(V) and amounts to 35.5 kJ mol^{-1}. At the same time, linear relations were observed between the intramolecular strain energy (ISE) calculated by the MMM and the free energy of formation of the complexes with the ligands (I)–(V) and also between the intramolecular strain energy and the logarithms of the rate constants for the dissociation of the complexes with the ligands (II)–(V) in aqueous solution.[33]

It has been concluded[29] that the enthalpies of formation of the above complexes and the enthalpies of activation for the complex formation reactions are predominantly influenced by the intramolecular strain in the ligand when the contribution of the Cu–S interactions is constant. The anomalous behaviour of the complex with the ligand (VI), which is inconsistent with the above relations, can apparently be explained, according to the authors, by the influence of the fifth Cu–S bond not only on the enthalpy components but also on the entropy components of the free energies of formation of the complexes.

The same authors investigated with the aid of the MMM the dissociation in aqueous solution of the complexes $[CoLCl_2]^+$, where L represents the nitrogen-containing macrocyclic ligands (VII)–(X) and their open-chain analogues—1,8-diamino-3,6-diazaoctane (XI) and 1,9-diamino-3,7-diazanonane (XII).

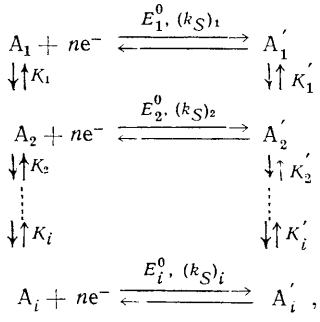
The calculations were performed using the force field of Brubaker and Johnson[6] and Boyd's program.[30]



Two model intermediates formed in the hydrolysis of the complexes $[CoLCl_2]^+$ as a result of the removal of one chlorine atom from the initial molecule have been considered.[34] It was assumed that in the first intermediate the geometry of the ligand environment of the cobalt atom remains unaltered, while in the second a new geometry was calculated by means of additional optimisation. The free energy ΔG_{int} was calculated for the second model of the intermediate as had been done by Brubaker and Johnson.[29] It was found that ΔG_{int} is constant for the group of open-chain ligands (~123 kJ mol^{-1}) and the group of tetraazamacrocycles (~137 kJ mol^{-1}). The authors do not explain the difference between these quantities. In our view, the difference is caused by the entropy component of the macrocyclic effect.[35] The authors[34] also analysed in terms of the optimised structure of the intermediate the possibility of the formation of various products of the hydrolysis of the isomeric complexes of (XII).

Continuing these investigations, an attempt was made[36] to model with the aid of the MMM the first hydration shell of the complex cation $[CoLCl_2]^+$, where L is the macrocycle (VIII).

According to the model proposed by the authors,[36] the other molecules (from 1 to 14 molecules) were placed in a random fashion at distances of ~5 Å from the complex and their relative disposition was then found by direct optimisation. Potential functions without an electrostatic component were used.



The calculations were performed for 80 different initial positions of the water molecules. The authors note that, as a result of the $-O...H-C-$ interactions, the distribution of H_2O molecules in the plane formed by nitrogen atoms outside the limits of the macrocycle is characteristic of the first hydration shell and not their random (spherical) distribution. Water molecules are more rarely distributed near the Cl^- ions.

An interesting attempt has been made[37] to apply the MMM to the study of the influence of conformational effects on electrochemical reactions. Complexes of divalent and trivalent cobalt with sepulchrate (XIII) and diethylenetriamine (XIV) were investigated.

Cobalt(III) complexes with nitrogen-containing ligands have been fairly frequently investigated by the MMM (see, for example, Brubaker and Johnson[6] and Saito[8]), but the analogous cobalt(II) complexes have been little studied. The force field proposed by Bond et al.,[37] which applies to both these and other complexes, is therefore of independent value. The results obtained reproduce satisfactorily the XRD data.[38,39]

It has been shown that the most stable conformers of complexes with divalent and trivalent cobalt are significantly different [both for the ligand (XIII) and for (XIV)] and the oxidation-reduction process is therefore accompanied by conformational transitions. Thus, according to Bond et al.,[37] the above electrochemical reaction can be represented by the following scheme:

where A_i and A'_i are conformers of complexes in different oxidation states, K_i and K'_i are the constants of the conformational equilibria, E°_i is the standard oxidation-reduction potential, and $(k_S)_i$ is the rate constant for electron transfer.

The authors compared the results of the calculation with the results of a polarographic experiment, but were unable to estimate quantitatively the nature and rates of the conformational transitions.

The calculated and experimental free energies of formation of three structural isomers of cobalt(II) and cobalt(III) complexes with the ligand (XIV) were compared. The results of the calculation did not agree with the experimental data (which is not surprising, since one is dealing with a heterogenous electrode process), but they undergo parallel changes on passing from cobalt(II) to cobalt(III).

The MMM was used similarly[40] to study the electrochemical oxidation-reduction of cobalt complexes with 1,2-propylenediamine. Four structural isomers of the above complexes were investigated. Their calculated enthalpies of formation are satisfactorily correlated with the experimental data. The oxidation-reduction potential of this system was calculated from the difference between the energies of the corresponding cobalt(III) and cobalt(II) isomers. It proved to be ~20 mV, which agrees with experimental polarographic data.

The steric factors governing the stabilities of mixed thiosemicarbazide–carboxylate complexes $CuL_n(TSC)_2$, where TSC = thiosemicarbazide and its phenyl derivatives and L = anions of monocarboxylic ($RCOO^-$, n = 2) and dicarboxylic [$R(COO^-)_2$, n = 1] acids and Cl^-, have been investigated[41] with the aid of the MMM. The calculations were performed using the CONCOORD program pack.[42]

In the series of bisthiosemicarbazide complexes (L = Cl^-), the *trans*-isomers with the diequatorial arrangement of the phenyl groups were found to be more stable. A satisfactory linear relation was observed between the conformational energies and the stability constants of the complexes in aqueous solutions. It was shown that the formation of heteroligand copper(II) thiosemicarbazide-carboxylate complexes is mainly determined by the greater or lesser steric strain in these complexes compared with the corresponding copper(II) bisthiosemicarbazide.

Thus it can be seen from the examples considered¶ that the MMM can be used successfully in the chemistry of metal complexes for the solution of different problems. It not only permits the calculations of the structures and relative stabilities of the complexes which have now come to be regarded as usual, but also it enables one to investigate their functioning and permits a quantitative estimation of the influence of steric factors on their reactivity.

However, we may note that the calculations considered above were performed for compounds with complex-forming metals which have been comparatively thoroughly investigated by the MMM [one may include among them perhaps only cobalt(III) and copper(II)], while in the case of cobalt(II) a preliminary parametrisation was required, which is impossible without an adequate set of experimental data which is difficult to obtain.

In order to perform such calculations for metal complex derivatives, various modifications of the MMM, based on the complete or partial neglect of the nature (type, dynamics) of the coordination polyhedron and on the introduction of additional *a priori* hypotheses about the specificity of the interaction of the metals with the ligands, were developed. Two models were mainly used.

The model of the first type is as follows: the form of the coordination polyhedron is not fixed, only metal–ligand bond lengths being fixed. The force constants of the L–M–L bond angles were close to zero.

In the model of the second type the coordination polyhedron is fixed and the force constants of the L–M–L angles are infinitely large.

Such assumptions naturally make the model more approximate but in many cases the use of approaches of this kind makes it possible to obtain useful information about the steric structure and properties of metal complexes.

III. The "floating point" model

An example of the most logical application of the model of the first type is the modification of the MMM, proposed by Dashevskii, Baranov, et al.,[43] which the authors called the "floating point" method or (on the basis of the mathematical procedure employed) the method of "penalty functions" (Fig. 1).

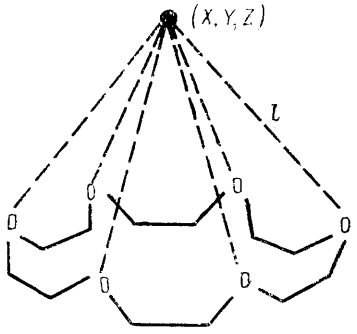
In this method, the complex forming atom is modelled by the so called "floating point".[43,44] Its interaction with the ligands is described by a penalty function of the type

$$U_{\text{pen}} = \sum_i K(l_i - l_0)^2,$$

where K is an empirical constant—the contribution of the penalty function to the overall target function (for further details, see Baranov et al.[44]), l_i is the distance from the donor atoms of the ligand to an arbitrary "floating" point with the coordinates X, Y,

¶We recall that we are dealing with the most "complete" version of the method, i.e. the calculations were performed taking into account both the deformations of the coordination unit and the non-valence L–M interactions.

and Z, and l_0 is the specified length of the coordinate bond. The summation is carried out over all the possible metal–ligand bonds and the resulting quantity U_{pen} is added to the energy of the intramolecular interactions calculated by the MMM. Next, the minimum in the overall target function is sought with respect to all the conformational parameters of the ligands and the coordinates of the point.



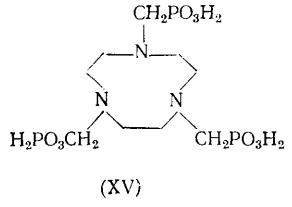


Figure 1. The "floating point" model.

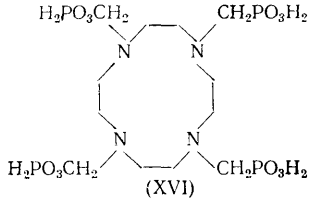
By repeating calculations of this kind for variable values of l_0, one determines the $\Delta E = f(l_0)$ relation, each point of which reflects the energy expended by the ligand on the rearrangement to the conformation characteristic of it in the complex with the cation i separated from the donor atoms by a distance l_{0i}. If the above relation has a deep minimum, then the position of the latter defines the optimum length of the coordinate bond, the geometry of the coordination unit, and the conformation of the chelate rings.



Thus in the method described account is taken only of characteristics such as the metal–donor atom bond lengths. The type of coordination polyhedron is not then fixed and non-valence interactions between the metal and the atoms of the ligand as well as the nature of the deformation of the metal–donor centre bonds are disregarded. An undoubted advantage of the method of penalty functions is the fact that the curves obtained for the variation of the conformational energy of the ligand with the length of the hypothetical coordinate bond can be interpreted in many instances as selectivity curves, using them for the analysis of the possibility of the adaptation of the given ligand to a particular metal cation.[45] We may also note that the above curves reflect to some extent not only the result but also the cause of the conformational rearrangement of the ligand during complex formation.

An example of the use of the "floating point" method may be provided by a study[44] (see also Refs. 43 and 46–48) of the complex-forming properties of tetraphenylmethylenediphosphine dioxide $(C_6H_5)_2P(O)CH_2P(O)(C_6H_5)_2$. The dependence of the conformational energy (taking into account the "penalty") of the complexes ML_3 on the metal–ligand donor atom distance was investigated in this study. It was shown how the structure of the coordination unit varies as a function of l_0: for l_0 = 3 Å, the coordination polyhedron is an almost regular octahedron with a twist-conformation of the chelate rings; for l_0 = 2.5 Å, it is a regular prism with the chelate rings in the chair conformation; for l = 2 Å, it is a distorted octahedron with two chelate rings in the boat conformation and the third one in the twisted chair conformation. It has been stated[44] that these results reproduce satisfactorily the experimental data[49,50] for the structure of the coordination polyhedron in complexes of this kind.

The method of penalty functions is usually employed to investigate the complex-forming capacity of macrocyclic polydentate ligands. Thus a theoretical conformational analysis of the macrocycles (XV) and (XVI) with exocyclic groups containing donor centres (cyclopendants) has been carried out[51] (see also another study by Kabachnik, et al.[52]).

(XV)

(XVI)

Analysis of the dependences of the conformational energy on l_0 (by a procedure similar to that described above) showed that the optimum length of the M–L bond for the ligand (XV) is 1.95 Å. The ligand is then in the hexadentate "twisted basket" conformation. The selectivity of the ligand (XV) in this conformation is significantly greater than that of (XVI) for which the most favourable lengths of the coordinate bonds are in the wide range 1.9–2.2 Å. The maximum denticity of the ligand (XVI) is not achieved. It exhibits a denticity of 5 or 6. According to the calculation, in certain cases [for example in the copper(II) complex[52]] the ligand (XV) is also in the pentadentate conformation, which indicates the possibility of a ready adjustment of the ligand contour of the cyclopendants with respect to the coordination polyhedron characteristic of the metal ion.

The results obtained agree with the experimental data[53,54] for the stability constants of the transition metal and group II metal complexes with the ligands (XV) and (XVI).

The method of penalty functions has also been used[55,56] to estimate the selectivity of the formation of crown-ether complexes. A study was made of the influence of the ring size and of the number and relative positions of the donor atoms on the capacity of macrocyclic complexones for adaptation. It was shown that both an increase in ring size and an increase in the number of donor centres increased the selectivity of macrocyclic ligands. In the first case, the length of the hypothetical coordinate bond corresponding to the optimum conformation of the complex diminishes under these conditions, while in the second it increases. The introduction of conformationally rigid fragments into the ligand diminishes its selectivity. It has been established that analysis of the selectivity curves obtained by the method of penalty functions permits a satisfactory prediction of the relative stabilities of the complexes of crown-ethers with alkali metal ions.

A model similar to the method of penalty functions, which the authors called[57,58] the "hinged model", has been used to investigate the structures of transition metal complexes $M(CO)_6$, $CpM(CO)_n$ (n = 3, 4), $(\eta^4\text{-}C_4H_6)M(CO)_3$, MCp_2, $M[C_5(CH_3)_5]_2$, Cp_2MX_2 (X = H, Cl, CO), and Cp_2MH_3. The calculations were performed in accordance with Boyd's program.[30]

In the model discussed, as in the method of penalty functions, the force constants for the deformation of the angles at the metal atom were assumed to be zero. Thus the form of the coordination polyhedron is not controlled and the ligands bound to the complex-forming agent can rotate freely around the centre ("hinge"). However, in contrast to the "floating point" model, in this modification of the MMM the M–L bond lengths are not varied and their values, taken from X-ray diffraction data, are fixed by specifying higher force constants (the analogue of the "penalty").

The optimum disposition of the ligands corresponds to the minimum in the energy of the non-valence interactions between them (as in the "points on a sphere" model[59]) and the non-valence interactions with the metal atom are not taken into account.

The calculations performed on the basis of the "hinged" model made it possible to reproduce qualitatively the relative disposition of the ligands in the structures most typical for organometallic compounds (half-sandwich, sandwich, and bent sandwich). A satisfactory agreement was achieved between the calculated and experimental ligand–metal–ligand angles (the discrepancies were 5–10°). Certain regular features observed in the structure of π-complexes were reproduced.

The "floating point" ("hinged") model described can apparently be used quite correctly to carry out calculations for complexes with isotropic spherical complex-forming metal cations (alkali and alkaline earth metals—see, for example, Trigub[55] and Kuz'min[56]). On the other hand, its application to transition metal complexes is significantly restricted (as has been justly noted by Slovokhotov, et al.[57]) to the range of compounds for which the principle of the uniform filling of the coordination sphere by the ligands holds. These include, for example, complexes in which the transition metal atom attains the 18-electron inert gas shell environment ("quasi-spherical" ligand environment[60]) and complexes in which "premature" dense filling of the coordination sphere by ligands takes place (for example, π-complexes[57]).

It is noteworthy that consideration of the legitimacy of the assumption of the elasticity of the bond angles (and hence of the applicability of the "hinged" model) is outside the framework of the MMM and should be based on experimental data or on the results obtained by more rigorous computational methods.

When applied correctly, such models, neglecting the elasticity of the bond angles and the metal atom, make it possible, as shown above, not only to estimate the conformational changes in the ligand occurring on complex formation but also to reproduce qualitatively the type of coordination polyhedron and also (using the procedure of "penalty functions") to investigate the process dynamics and the influence of steric factors on the selectivity of the complex formation.

We may note that in all the models examined above no account is taken of non-valence metal–ligand interactions, allowance for which (which naturally requires an additional parametrisation) increases significantly the reliability of the results obtained with the aid of these approaches. When no account is taken of non-valence interactions, a situation may arise, in particular, where the "floating point" coincides with one of the non-donating ligand atoms or is "superimposed" on one of the bonds (which lacks physical significance for understandable reasons).

An attempt to take into account non-valence interactions of the metal–ligand type was undertaken in a study[61] of β-diketonate (β-dik) lanthanide complexes $Ln(\beta\text{-dik})_3L$ (Ln = Eu, Yb; β-dik = acetylacetonate, dipivaloylmethanate; L = water, quinuclidine). The authors[61] consider these complexes as models for the study of the steric factors governing the functioning of lanthanide shift reagents in NMR spectroscopy. A modified[61] MM2 program[10] was used in the calculations. Here the force field was expanded by incorporating in it the force constants of the bonds and bond angles, the barriers to rotation, and the parameters of the van der Waals interactions with participation of Eu and Yb atoms (with the exception of the force constants of the bond angles at the metal atom). The calculated structures of the complexes agree well with those found by the X-ray diffraction method;[62,63] it was shown that the most favourable conformations correspond to the three-bladed propeller form.

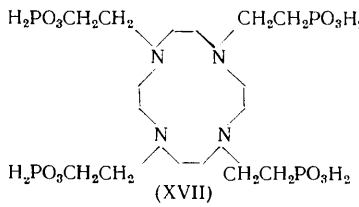
It has been suggested[64] that not only non-bonding interactions of the metal atom (without additional parametrisation) but also the form of the coordination polyhedron be taken into account within the framework of the "floating point" model. For this purpose, the penalty function is supplemented as follows:

(1) By quasi-non-valence interactions of the "floating point" with the ligand atoms which are not donor centres, in conformity with the hard sphere approach:

$$F_{r_i^*<r_0} = \begin{cases} 0, & r_i > r_0 \\ U_{\max}, & r_i \leqslant r_0 \end{cases},$$

where r_i is the distance from the "floating point" to the ith ligand atom, r_0 the van der Waals radius of the ith atom, and $U_{\max}$ an empirical constant—the "barrier" to the collision of atoms.

(2) By quasi-elastic angular deformations:



$$U_{\text{def}} = K_2 \sum_i (\alpha_i - \alpha_0)^2,$$

where K_2 is an empirical constant (the contribution of the deformation of bond angles to the overall target function), α_i are the angles formed in the ligand–"floating point"–ligand system, and α_0 are the bond angles characteristic of the donor atoms of the ligands and of the quasi-coordination polyhedron corresponding to the "floating point".

For comparison, the calculation was performed in terms of the approximation described[64] for 18-crown-6, the cryptand[2.2.2.], and the cyclopendant (XVI), which had been investigated previously[43,51] without the refinements indicated. It was shown that such correction of the penalty function influences significantly the form of the dependence of the energy of the molecule on the metal–ligand distance, particularly on the steepness of the walls of the "potential well". Some of the conformations of the ligands indicated, generated previously, proved to be artefacts.

However, one may note that the observed effects are in all probability not associated with the introduction of quasi-elastic angular deformations into the penalty functions; they depend to a large extent on the selection of the initial approximation for the conformational calculations.

Complexes with the cyclopendant (XVIII) have also been investigated:[64]

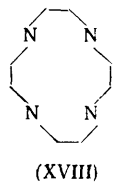
(XVII)

It was established that the ligand (XVII) [similarly to the ligand (XVI)] in the complex has a folded conformation of the macrocycle while the increase in the length of the exocyclic groups diminishes the selectivity of the complex formation with participation of the ligand (XVII).

There is no doubt that the additional features described increase the applicability of the method of penalty functions, although the "adjustable" character of the coefficients employed nevertheless reduces the correctness of this approach.

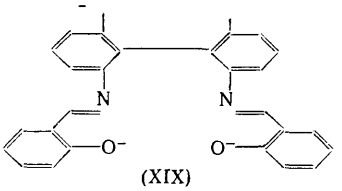
IV. The "rigid polyhedron" model

As an example of the use of the model of the second type (see above) we shall consider the approach[65–68] in which the complex-forming atom is modelled by an "ideal" polyhedron. Its configuration is specified on the basis of experimental data referring either to the complex itself or to its analogues and it does not change during the calculations (the lengths of the metal–ligand bonds and the ligand–metal–ligand angles are constant, as a result of which this approach can be referred to as the method of "rigid" or "ideal" polyhedra (the name is conventional because the authors themselves do not name their model). The non-valence interactions of the metal with the ligand atoms as well as the barriers to rotation about the metal–ligand bonds are ignored in this method.



An important component of the above method is the procedure used to search for the initial approximation for the optimisation of the geometry (it is of an especially great current interest for complexes with polydentate ligands forming several chelate rings with common edges). It consists in sorting through all the possible combinations of chelate rings having different conformations taking into account the "rigidity" of the coordination polyhedron. Referring to this process as "assembly on a templet", the authors[65–68] see in it some analogy with templet synthesis. The number of combinations is limited by the steric conditions governing the cross-linking of the chelate rings. A preliminary study is made of the conformational possibilities of the isolated chelate rings and the families of the most favourable conformations and the ways in which they can undergo interconversions are found (see, for example, Pletnev and co-workers[66,69]).

This method of selecting the initial approximation has undoubted advantages—it guarantees the selection of initial approximations which are known beforehand to correspond to the topology of the coordination unit and makes it possible to monitor the configuration of the complex.

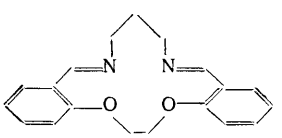


The approach described has been applied successfully to the calculation of the structures of various metal complexes using the specially developed FORCON program.[66]

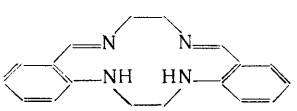
Thus the structure of the cobalt(III) complex of the macrocycle (XVIII) having the composition $[CoL(NO_2)_2]^+$ with the *cis*-octahedral (with respect to the nitro-groups) coordination of cobalt has been calculated[65] (see also Pletnev, et al.[66]). The calculation yielded two structures, one of which (less favourable) agrees well with X-ray diffraction data.[70]

Pletnev, et al.[65] investigated the steric structure and the stability factors of the cobalt complex with the ligand (XIX).

(XVIII)

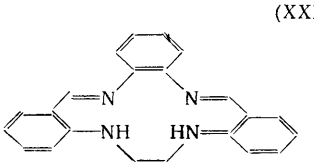


(XIX)



The conformational analysis of the salicylideneamine chelate ring showed that its optimum conformation is non-planar and the deformation of the bond angles is minimal. At the same time, the flattening of the ring does not require much energy expenditure (9.2 kJ mol^{-1}).

The structure of the above complex was calculated in terms of the approximation of the following coordination polyhedra: square, distorted square ("twisted" via the diagonal twist mechanism by 30°), distorted tetrahedron (square "twisted" by 67.6°, which is consistent with the experimental data[71]), and a tetrahedron. Although the results for the distorted tetrahedral structure agree well with experiment, this structure is not most favourable from the standpoint of steric strain in the ligand; the structure of the distorted square, twisted by 30°, is optimal. Evidently the occurrence in the complex of the distorted tetrahedral configuration is determined by the characteristic features of the crystal packing. The authors state that the changes in strain energy on formation of the polyhedron are comparable to the measured enthalpies of the square–tetrahedron interconversion (~20 kJ mol^{-1} [72]) and the contribution of the steric strain in the ligand to the stabilisation of a particular polyhedron should not be neglected.



Complexes of the following macrocyclic reagents have been investigated:[67]

(XX)

(XXI)

(XXII)

Calculations have been carried out for the structures (XX)–(XXII) and the conformations the optimum (from the standpoint of the possibility of coordination) directions of the lone pairs of the donor atoms of the ligands were discovered. The following versions of the geometry of the coordination unit were considered: square, tetrahedral and distorted tetrahedral, bisphenoidal, octahedral, trigonal-bipyramidal, tetragonal-pyramidal, and linear. The formation of square and bisphenoidal complexes is not favourable for the ligand (XX), whereas tetrahedral and distorted tetrahedral complexes cannot be formed for steric reasons. The "capped" (tetragonal-pyramidal) structure of the coordination unit proved to be optimal for complexes of the monoanions of the

tetraazamacrocycles (XXI) and (XXII), while the square structure proved to be optimal for the dianions. The results obtained are in the main consistent with X-ray diffraction data.[73,74] An attempt was made to justify certain extraction properties of the reagents (XX)–(XXII) on the basis of the probable structures of the complexes.[65–68]

The nickel complexes NiL_2 [L = *o*-hydroxyazobenzene (XXIII), *o*-mercaptoazobenzene (XXIV)] with a square-planar configuration of the coordination polyhedron have been examined.[68] The calculated structures of the complexes reproduce satisfactorily the experimental data.[75] The steric factors promoting the formation of six-membered [for the ligand (XXIII)] and five-membered [for the ligand (XXIV)] chelate rings are being interpreted.

Thus the "rigid polyhedron" approach described is entirely suitable for the calculation of the structures of structurally varied metal complexes. Its undoubted advantages include allowance for the configuration of the coordination unit and the corresponding steric organisation of the donor centres of the ligands ("the locus" of the macrocycle according to the authors terminology[65,68]). The method of selecting the initial approximations is also novel.

At the same time, although the approach described takes into account the geometry of the polyhedron it does not consider other characteristics of the complex-forming atom. No account is taken of either the distortions of the coordination polyhedron under the influence of the ligand environment or of the features of the conformational behaviour of the ligands in the field of the non-valence interactions with the central atom or ion. This is probably the explanation of certain inaccuracies in the results, which have been pointed out by the authors themselves.

Furthermore, the question of the selection of a particular type of coordination polyhedron in the absence of experimental data for the structure of the complex investigated remains open. The authors[67] suggest that various ideal polyhedra should be "sorted through" with comparison of their steric strains, but this approach is also only a palliative.

V. Characteristic features of the modelling of polynuclear complexes

In our view, the attempts to apply the MMM to the study of cluster compounds merit special consideration since allowance for the specific features of the structures of polynuclear complexes involves additional difficulties.

The main problem arising in the application of the MMM to calculations for complexes of this kind consists in the fact that the method requires an unambiguous determination of the orders of the bonds involving the atoms in the molecule, because the deformation of the valence bonds and the non-bonding interactions are described in the MMM by fundamentally different potential functions. Even when X-ray diffraction data are available, in the case of clusters it is frequently impossible to determine unambiguously the metal–metal and metal–ligand bond orders.[76] To overcome these difficulties, it has been suggested,[77] for example, that the interaction of the ligands with the metallic core as a whole and not with specific metal atoms be considered. The concept of an "equipotential surface of the cluster", formed on combining (for further details, see Lauher[77]) the spheres circumscribed around each metal atom (the radii of the spheres correspond to the metal–ligand donor atom bond lengths), has been introduced. Thus the cluster core is replaced by a kind of "superatom".

In the calculation of the energy of the steric strain within the framework of the MMM, additional terms are introduced, taking into account the distance of the ligand from the equipotential surface and the deviation of the ligand axis (for example the C–O bond for carbonyls) from the direction normal to this surface. These contributions are calculated in different ways for the regions corresponding to the bridging and terminal bonding of the ligands (the subdivision of the equipotential surface is based on X-ray diffraction data).

This approach was used to study a series of metal carbonyls with the compositions $Fe_2(CO)_9$, $Co_2(CO)_8$, $Fe_2(CO)_8^{2-}$, $CoFe(CO)_8^-$, $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$, $Co_4(CO)_{12}$, $Ir_4(CO)_{12}$, $Fe_4(CO)_{13}^{2-}$, $CoFe_3(CO)_3^{2-}$, $CrFe_3(CO)_{14}^{2-}$, and $Mn_4(CO)_{16}$. The results of the calculations for these complexes (in accordance with Allinger's program[10]) agree well with X-ray diffraction data.[78–82] Furthermore, in the study of these complexes a dependence of the metal–metal bond length on the steric strain energy was noted. Another relatively simple approach was used by Newson and co-workers[83,84]—"interactive molecular graphics"—in the study of the steric structures of clusters. In this model, the dependence of the energy of the steric strain of the molecule on one or two internal coordinates (usually torsional angles) is investigated. The geometry of the remaining part of the complex is then fixed on the basis of X-ray diffraction data. The intramolecular strain energy involved only non-bonding van der Waals interactions (with the parametrisation of DelRe, et al.[85]), while the contributions of metal atoms are disregarded. Despite the evident deficiencies associated with the neglect of a number of important factors, this approach can be used in some cases to estimate steric strain.

Thus the steric hindrance in the complex $Fe_4(CO)_{12}CR$ (R = CH_2, CH_3, CO_2CH_3) caused by the presence of the substituent R was investigated[83] with the aid of the "interactive molecular graphics" (X-ray diffraction data were used[86]). In the determination of the steric hindrance in the cluster, the variable parameter is the torsional angle around the C–R bond, whose magnitude in the optimised conformation agreed with experimental data[86] to within 5°. It was shown that the steric hindrance in the cluster increases significantly when the sp^2-hybridised hydrogen atom in the substituent R is replaced by a sp^3-hybridised hydrogen atom. The dinuclear complexes $[CpMoS(\mu\text{-}S)]_2$, $[C_5(CH_3)_5MoS(\mu\text{-}S)]_2$, and $[(C_2H_4S_2)MoS(\mu\text{-}S)]_2$ were investigated similarly.[84] Scanning with respect to the Mo–S–S–Mo torsional angle revealed the stable conformations of the complex, which proved to be consistent with the experimental ones.[87] It was shown that the stability of the *anti*-isomers of the above complexes is greater than that of the *syn*-isomers.

The interaction of the iron(III) complexes $[Fe_3O(H_2O)_3Piv_6]^+$ (A) and $Fe_6O_2(OH)_2Piv_{12}$ (B) (where Piv = pivaloyl) with the hydroperoxide of dibenzyl ether has also been examined.[88] In the calculation of the steric strain energy, X-ray diffraction data were used[89,90] and the variable parameter was the Fe...O–OR distance.

H

It was shown that the lower catalytic activity of the hexanuclear complex (B) compared with the tetranuclear complex (A) in the hydroperoxide decomposition reaction may be caused by the greatest steric hindrance occurring in the coordination of the latter to the catalytic centre of the complex.

The disadvantages of the models described above include, firstly, the neglect of the metal–metal interaction and also non-bonding metal–ligand interactions and, secondly, the impossibility of carrying out calculations of this kind without X-ray diffraction data.

The approaches described do not allow calculation for the intrinsic metallic core of the cluster although they do take into account the steric effect associated with the influence of the ligand environment.

We may note, however, that even such limited information can in many instances be useful for the elucidation of the causes of the formation of polynuclear complexes with a specific structure.

An attempt to take into account the above interactions in the calculations for polynuclear metal complexes (in the absence of a metal–metal bond) has been undertaken in studies[91,92] of copper complexes of 1,2-dicarboxylic acids with the composition $Cu_2L(OH)_2.2H_2O$ {L = anion of succinic, 4-cyclohexene-1,2-dicarboxylic, 3-methyl-4-cyclohexene-1,2-dicarboxylic, 4-methyl-4-cyclohexene-1,2-dicarboxylic, and *endo*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic acids}. It was shown that the complex $Cu_2L(OH)_2.2H_2O$ can be represented as a superposition of two isomeric structures with bond bidentate-cyclic and bidentate-bridged coordination of the carboxylate groups. With increase in the structural rigidity of the ligand, the contribution of the isomer with the bidentate-cyclic type of coordination increases.

The most correct method of applying the MMM to the study of cluster compounds involves undoubtedly the generation of force fields, including, among other parameters, the force constants for metal–metal bonds and the corresponding constants for the bond and torsional angles. This approach was in fact used by Boeyns and co-workers.[93,94]

Boeyns et al.[93] investigated the complexes $M_2(XYCCH_3)_4$ and $M_2(XYCCH_3)_4L_2$ [M = Rh, Pd, Cd, Cu; X, Y = S, O; L = H_2O, CH_3CSOH, $(CH_3)_2SO$, PPh_3]. A force field, calibrated on the basis of vibrational spectra[95] and including parameters for the above metals, was proposed. Calculations and experimental data led the authors[93] to the conclusion that the metal–metal distance in the above complexes is determined by steric factors both in the presence of the bond (Rh complex) and in its absence (Pd, Cu, and Cd complexes). A change in the nature of the steric influence can lead not only to a lengthening but also to a shortening of the metal–metal bonds.

However, in our view, such categorical conclusions concerning the predominant influence of the steric factor on the lengths of metal–metal bonds are not sufficiently justified. In the study of clusters, it is quite impermissible to neglect, as was done by Boeyns et al.,[93] the electronic factor and in the first place the orbital interactions of the metal atoms.

A similar approach was used in another study by Boeyns[94] to investigate high-order bonds in the complexes $Cr_2(CH_3)_8^{4-}$, $Mo_2(CH_3)_8^{4-}$, $W_2(CH_3)_8^{4-}$, and $Re_2(CH_3)_8^{2-}$. The force constants of the fourth-order metal–metal bonds as well as the parameters of the non-bonding van der Waals interactions were also calculated for the above atoms from experimental data.[96,97] The dependence of the energy of the steric strain of the complexes on the torsional angle of the metal–metal bond was examined. The stabilisation of the unfavourable eclipsed conformation is explained in this instance by the contribution of the δ-bonding component to the Cr–Cr bond (46 kJ mol^{-1}).[94] The properties of triple and quadruple W–W bonds were compared in relation to the complexes $W_2(O_2CC_2H_5)_4$ and $W_2(O_2CC_2H_5)_4(CH_2C_6H_5)_2$ and it was shown that, although the structures of these complexes are similar, the triple bond is significantly more mobile than the quadruple bond. The rotation about the Re–Re triple bond has been investigated[94] for the complex $Re_2Cl_4[P(C_2H_5)_3]_4$. It is claimed that in this case (in the absence of δ-bonding) the occurrence of the eclipsed conformation is caused by steric factors.

However, one cannot agree with all the conclusions reached by Boeyns,[94] because here too the role of orbital interactions has been clearly underestimated. In particular, one can hardly regard as correct the attempt to estimate (especially quantitatively) the effect of the δ-bond with the aid of the MMM.

VI. Simplified "mechanical" and geometrical models

Together with the MMM, simpler approaches based on "mechanical" ideas and geometrical models may be useful in the study of the steric structures of complexes. One of such approaches is the familiar Tolman method of conical angles θ (see, for example, Refs. 98 and 99) (Fig. 2). The method continues to be improved and has found extensive applications in quantitative estimations of steric factors in metal complexes.

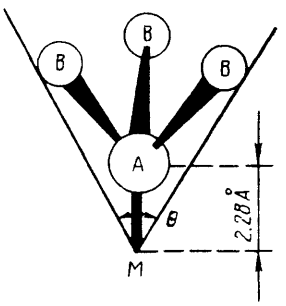


Figure 2. Tolman's conical angle model.

Thus a universal formula has been proposed[100] for the calculation of the conical angles of ligands of the type AB_n (A = atom coordinated to the metal; B = atom linked to A).

Similar formulae have been derived[101] for complex ligands of the type AB'_3, where B′ is a group of atoms. The effective covalent and van der Waals radii of the groups B′ and the conical angles of the ligands AB'_3 have been calculated from the available standardised data[99,102] for phosphorus-containing ligands PB'_3. The conical angles for 610 ligands of the type AB'_3 (A = N, P, As, Sb, Bi, C, Si, Ge, Sn, Pb; B′ = alkyl, cycloalkyl, aryl, alkylaryl, arylalkyl) have been published.[101,103] It was shown that the conical angles for Group IV and V elements are the same in the case of neighbouring elements A and decrease within the Group as the atomic number increases. It was noted that the conical angles depend little on the nature of the metal.

The attempt to extend to organic[104] and organoelement[105] compounds the above system for the description of the steric properties of substituents (ligands) in inorganic compounds is of interest. The attempt was based on the conical angles θ and derivatives of the "degrees of shielding" $\Lambda = \sin^2(\theta/4)$ with respect to these angles. The authors[104,105] derived simple formulae relating these parameters to the covalent radius of the central atom and published their values for various elements (H, B, C, Si, N, P, O, S, the halogens, and the transition metals). Thus a universal scale of steric constants for coordination, organic, and organoelement chemistry has been proposed.[104,105] Its undoubted advantages are

the uniqueness of the approach, a clear-cut geometrical significance of the parameters, and the ability in many instances to describe experimental data correctly.

However, one hardly agrees with the author's view that this system of constants is preferable to the familiar empirical scales of the E_s type, because both can be used only in those cases where the substituent is linked directly to the reaction centre (see, for example, Kuz'min and co-workers[14,15] and Gallo[106]).

Domrachev et al.[107] (see also Refs. 108 and 109) suggest that, not the conical angle, but the solid angle filled by the substituent R be used for the quantitative estimation of the degree of steric shielding of the metal atom in compounds of the type MR_n [R = PPh_3, CPh_3, η^1-Cp, η^5-Cp, CH_3, C_2H_5, CF_3, $C(CH_3)_3$, etc.]. Here the ligand atoms are specified as hard spheres with van der Waals radii. The sum of the solid angles of all the substituents (ligands) is used to estimate the steric strain in the complex. When it is exceeded (4π is the total solid angle), strain in the structure is indicated. The parameter described is satisfactorily correlated with data for the thermal stabilities of the compounds indicated.

In order to achieve a more correct estimation of the "non-valence interactions", it has been suggested[110] that these interactions be considered at the distance from the complex-forming atom where interligand contacts occur. The area S shielded by the ligand on the surface of a sphere with a radius r equal to the length of the metal–ligand bond is used as a steric characteristic of the ligand. The overall ligand environment of the metal is estimated by means of the expression $\sum_i S_i/4\pi r_i^2 \leqslant 1$. The closeness of this parameter to unity indicates, according to the author,[110] the existence of strain in the molecule (see also Refs. 107–109). The values of S calculated for a series of ligands have been published.[110]

Using, within the framework of the approach described, the parameters S, the same author analysed the structures of the metallocenes MCp_n (M = Be, Fe, Cr, V, Ti, Sc, Nd, Sm, Th, Zr, Hf, U; n = 2, 4) and discovered the factors determining whether the η^1- or the η^5-coordination of the cyclopentadienyl group is preferred.[111] This approach has been used[112] to estimate the relative stabilities of various isomers of the complex $Ca(BH_4)_2.2.(CH_3OCH_2CH_2OCH_2CH_2OCH_3)$.

The sum of the solid angles of the ligands (SAS), normalised with respect to 4π, has been used for the quantitative estimation of the steric factors governing the stabilities of uranium complexes with the general formula $U(Cp)X_3L_n$ {X = CNS; n = 1, L = $CH_3OCH_2.CH_2OCH_3$; n = 2, L = $CH_3CON(CH_3)_2$, tetrahydrofuran, $P[N(CH_3)_2]_3O$; X = Cl, Br; n = 1, L = $Ph_2(O)PCH_2P(O)Ph_2$; n = 2, L = $(CH_3)_2CCON(CH_3)_2$, $POPh_3$}.[113] The authors isolated the region of the optimum shielding (SAS = 0.81) of the metal atom (the optimum packing of the ligands in the coordination sphere). With decrease or increase in the degree of shielding, the complexes become unstable.

In the study of lanthanide complexes $LnCp_3(NCR)_2$ (Ln = La, Ce, Pr; R = CH_3, C_2H_5), an additional term taking into account the radius of the metal atom is introduced into the SAS parameter.[114] It was shown that the size of the central atom influences significantly the stability of the complex and that lanthanum compounds are the most stable. The most favourable configuration of the ligand environment, corresponding to the optimum value SAS = 0.72, was discovered.

An attempt has been made[115,116] to use similar ideas not only for the quantitative estimation of the steric effect but also for the prediction of the geometries of the complexes. A model based on the principle of closest packing of the ligands (represented by solid cones with the apex at the centre of the metal atom) in the coordination sphere has been proposed. In terms of mathematical procedures, this approach is a vector analogue of the SAS model (for further details, see Xing-Fu, et al.[115]). Using the conical model, the structures of more than 50 compounds of the type MA_4, MA_3B, MA_2B_2, MAB_2C, and MABCD were calculated (M = actinides, lanthanides, and Group IVB metals). The results agree well with X-ray diffraction data. It has been shown[116] for the formation and dissociation reactions of complexes (see above) that the conical model is applicable to the study of the influence of steric factors on the possible direction of the process. More than 160 lanthanide complexes have been studied with the aid of the conical model.[117]

However, the postulates of the conical model have been developed most fully in the concept of the "coordination site" described in a series of investigations.[118–122] According to this model, not only ligands but also the conical "sites" which they can occupy may be described with the aid of the solid (or conical) angle. A "diagram of levels" is constructed on the basis of the determination in the coordination sphere of the metal atom of "first-order, second-order, etc. 'coordination sites'" (by distributing the Tolman cones in the "holes" within the close packing of the coordination sites of the previous order). The degeneracy of the "levels" in the presence of molecular symmetry and their alteration following the deformation of typical coordination polyhedra have been considered.[118]

The concept of "pre-bonding molecular structure", calculated from the level diagram in terms of the approximation of spherical (the halogens) and disc (Cp) ligands, has been introduced.[19] In order to estimate the correspondence between the ligand and the coordination site, the seat function is introduced:

$$F = \sum_i^m K_i (S_i - \theta_i)^2, \quad F' = \sum_i^m K_i (S_i - \theta_i)^2/\theta_i^2,$$

where m is the number of ligands, K_i the rigidity coefficient, S_i the conical angle of the "site", and θ_i the conical angle of the ligand (K = 1, $S \geqslant \theta$, K = 5, $S < \theta$).

With the aid of the proposed model, it has been possible[118–122] to explain the occurrence of disproportionation reactions, the distribution of ligands between the anion and cation in complex salts, thermolysis, racemisation, and a series of other reactions characteristic of actinide complexes.

However, we may note that all the models described above are suitable only for mononuclear coordination compounds. An approach, similar to that of Lobkovskii[110] and Bagnall and Xing-Fu,[113] based on the construction of projections of the ligands onto a cylindrical surface with a unit radius whose axis coincides with the M–M bond, has been proposed[109] for dinuclear complexes.

A general approach, suitable for polynuclear complexes containing a metal chain or a metallocycle has been put forward.[123] A closed continuous surface covering the metal atoms is constructed in accordance with specific rules. Next, the total area S of this surface is determined as well as its component S_e shielded by the ligands. A characteristic of the degree of shielding of the metallic core is the ratio $K = S/S_e$. Polynuclear complexes of Ti, V, Hg, Ge, Pt, Fe, Mn, and Cr were investigated within the framework of this model. It was shown that, by selecting appropriate ligands, it is possible to achieve the stabilisation of the required structure of the core. It has been suggested that the approach described can be used to study clusters with two-dimensional and three-dimensional structures.

The "frontal steric effect" model has been used successfully[124] to estimate the steric factors governing the stability of complexes. According to this model,[125] the steric effect of the substituent is proportional to the area which it occupies on a spherical surface separating it from the reaction centre. A computational scale of steric constants has been introduced: $R_S = 30 \lg \left(1-\sum_i r_i^2/4L_i^2\right)$, where r_i is the atomic radius of the ith atom in a complex substituent and L_i is the distance from the ith atom to the reaction centre.

This model has been used to investigate the complexes $(R_2PSS)_2M$ (M = Ni, Cu; R = various cyclic and acyclic substituents).[124] Comparison of the calculated results with the stability constants of the complexes[126] showed that, within the framework of individual reaction series, their stability is controlled by the steric factors of the substituents (a satisfactory correlation with the parameter R_S is observed).

An attempt has been made[127] to create on the basis of molecular-mechanical ideas a so called general model of the coordinate bond. According to this model, the length of the metal–donor centre bond is determined by the energy balance of the coordinate bond proper (described by the Morse potential) and the van der Waals interactions in the ligand environment. On the basis of this approach, the authors were able to explain the observed differences between the "long" and "short" Ln–H_2O bonds in the complexes $Ln(C_2H_5SO_4)_3.9H_2O$ and also the variation of the length of these bonds in the La–Lu series.

Table 1. The force fields used in calculations for metal complexes.

Metal	Ligand atoms	Allowance for the contributions of different interactions to the conformational energy				Refs.
		val	angle	tors	nb

Rh	H, C, O, S, P	+	+	+	−	[93]
Pd	H, C, O, S, P	+	+	+	+	[93]
Cr	C	+	−	−	−	[94]
Mo	C	+	−	−	−	[94]
W	C	+	−	−	−	[94]
Re	H, C, P, Cl	+	−	−	−	[94]
Eu	H, C, N, O	+	+	+	+	[61]
Yb	H, C, N, O	+	+	+	+	[61]

Notation adopted: val—bond deformations: angle—bond angle deformations; tors—torsional strain; nb—non-bonding interactions; + parameters are present; −parameters are absent.

A novel mechanical model has been used[128] to investigate the elementary steps in the synthesis-decomposition reactions of diarenechromium compounds. The $Cr(\eta^6\text{-}C_6R_6)_2$ (R = H, CH_3) molecules were represented by three-particle systems in which the benzene rings were represented by toroids of rotation. The metal–ligand interactions were described by the Morse potentials and the non-valence interactions by functions of the Lennard-Jones type. In all probability, this approach can be applied in a qualitative analysis of the stabilities and structures of the given systems.

As can be seen from the examples examined, the simplified mechanical models of complexes can be employed only in those cases where the steric strain of the molecules is determined primarily by the non-valence interactions between the ligands. In all probability, such approaches cannot be used correctly if the behaviour of the complexes is influenced significantly also by the structures and conformational characteristics of the ligands which are modelled, as a rule, by hard cones or spheres in such approaches. The mechanical models described can be used only when the principle of uniform filling of the coordination sphere by the ligands holds.

Thus analysis of the literature on the application of the MMM to the study of steric factors regulating the structures and properties of transition metal complexes shows that calculations of this kind make it possible to obtain much useful information. The method of molecular mechanics is at present available for the study of a wide range of compounds with various metals (Table 1 presents data for the known force fields). It is important to emphasise that, when the method is used correctly, a satisfactory agreement is achieved with the experimental results and in many instances it becomes possible to predict the properties of complexes.

The use of Langmuir–Blodgett films as recording layers in optical information carriers

O V Chechel', E N Nikolaev
Institute of Energy Problems in Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The review deals with methods of recording and reproducing information for external computer memory devices in which Langmuir–Blodgett films are used as carriers and also with the physical effects occurring in these films, which may be used in the future for the creation of new superdense optical information carriers. Attention has concentrated on the photochromic reactions in the *J*-aggregates of Langmuir–Blodgett films, which permit the reversible recording of information. In many cases the preparation of the carrier and the technical characteristics of the corresponding memory devices are described in detail. The review considers the original studies and patents on this topic which have been published during the last 15 years.

The bibliography includes 55 references.

I. Introduction

The problem of creating information carriers for optical reversible memory devices (MD) on computers as well as improvement of the density of the recording in such devices are of extremely great current interest. The optical memory devices of the archive type widely used nowadays do not provide for the local deletion and re-recording of information. The first reversible optical memory devices which became commercially available are memory devices with thermomagnetic recording and magnetooptical reproduction based on the Kerr and Faraday effects[1].

Numerous procedures for the recording and reproduction of information based on new principles as well as information carriers with recording layers having a wide variety of compositions, in particular with film recording layers prepared by the Langmuir–Blodgett method[2], have been proposed recently.

The Langmuir–Blodgett films (LB films) consist of layers of amphiphilic molecules (i.e. molecules having hydrophilic and hydrophobic components), which are ordered at the molecular level. They are transferred successively from the surface of a liquid subphase onto a solid support.[3]

The apparatus for the preparation of LB films is illustrated in Fig. 1. The process involving the deposition of a LB film begins with the deposition onto the surface of a liquid which is a solution of an amphiphilic substance in a volatile inert solvent at a concentration of the order of 0.1%. After the solvent has been evaporated, a monomolecular film consisting of molecules oriented uniformly with respect to their hydrophilic and hydrophobic groups in relation to the surface of the liquid is produced. The film is then removed by a mobile barrier, whilst monitoring the surface tension.

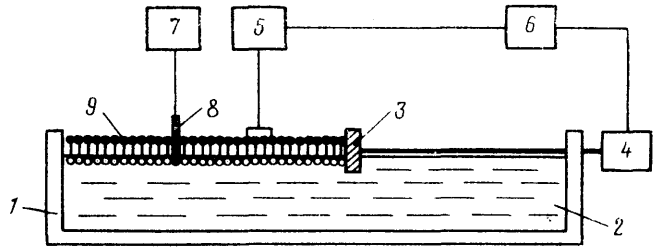

Figure 1. Schematic illustration of the apparatus for the deposition of Langmuir–Blodgett films on a solid support: *1*, bath; *2*, doubly distilled water; *3*, mobile barrier; *4*, motor driving the barrier for the compression of the monomolecular film; *5*, balance for the measurement of surface pressure; *6*, feedback device for monitoring the surface pressure; *7*, system for the lowering of the support; *8*, support; *9*, LB film.

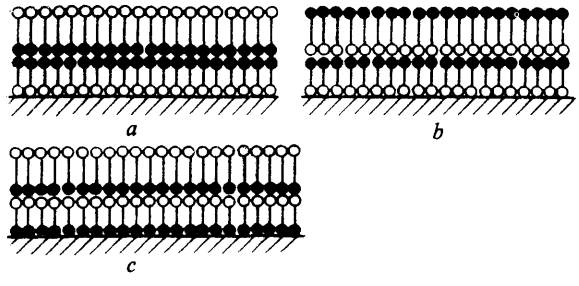

Figure 2. The structures of the Y-type (*a*), X-type (*b*), and Z-type (*c*) LB films

After the attainment of a certain film surface area, a sharp break appears on the plot of the surface pressure against the area per molecule, indicating the formation of a close-packed monolayer.

At the break point or at a somewhat lower surface pressure, the support is passed through the film and the amphiphilic molecules are deposited on the support with retention of their packing and orientation. If the support is hydrophobic, then the first layer of molecules is oriented with the hydrophobic ends towards the support and if it is hydrophilic the reverse orientation occurs. By repeating successively the procedure described, it is possible to deposit up to several hundred monolayers on the support. Depending on the deposition conditions, it is possible to obtain centrosymmetrical LB films of the Y type (Fig. 2*a*) with the opposite orientation of the molecules in neighbouring layers, or non-centrosymmetrical LB films of the X type (the hydrophobic ends of the molecules adjoin the support) (Fig. 2*b*), or such layers of the Z type (the hydrophilic ends adjoin the support) (Fig. 2*c*).

The constantly growing interest in the applications of LB films in a wide variety of engineering fields such as molecular electronics[4–7], optoelectronics[8–11], gas sensors[12–14], as lubricants for magnetic memory devices[15], in molecular engineering[16–18], etc. can be explained by a whole series of their unique properties such as an accurately specified thickness, which can be controlled to within a few angstroms, a high degree of homogeneity, and a constant mutual orientation of the molecules and their functional groups. It is then possible to create assemblies of molecular layers and individual molecules of any architecture.

The possibility of controlling the orientation of the molecules and the interaction between them at rigorously controlled distances makes it possible to achieve a reversible optical memory in LB films. The recording processes in such films can be of two types — chemical and orientational. The former are divided into intramolecular transformations (for example *cis–trans* isomerisation[19]) and chemical reactions of neighbouring molecules in one monolayer (for example, dimerisation[20] and polymerisation[21]) and in neighbouring monolayers, while the latter can be divided into *J*-aggregation processes[22,23] (i.e. rearrangements of an elementary two-dimensional cell of the LB film), degradations of *J*-aggregates[24,25], the reversible phase transitions of various kinds, including those involving the appearance of photodichroism under the influence of polarised light[26].

The recording processes based on chemical reactions make it possible to achieve a satisfactory permanence of the information and a high signal/noise ratio in the corresponding memory devices, but here it is difficult to achieve a reversible recording. Recording layers based on spiropyrans, in which a reversible structural rearrangement under the influence of UV and visible radiation can be readily achieved, are an exception[27].

The greatest stability of the recording layer can be attained if it is subjected to preliminary polymerisation by irradiation with UV light or low-energy electrons, which can be done also without the degradation of the LB film[28–31]. Information can be recorded in such layers also by means of the degradation of the polymer.

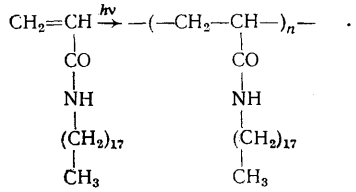
In recent years attempts have been made to create multilayer polyimide LB films which are thermally stable up to 700 K. These will be the most thermally stable thin organic films among those known to date.

With the aid of photochemical recording, it is possible to ensure also the replication of recorded information. Thus the photodimers formed in LB films under the influence of optical radiation have both optical and physicochemical properties different from those of the individual molecules. When the mixed layer is deposited by the Langmuir–Blodgett method onto a monolayer which has already been modified, the dimers are arranged on dimers and individual molecules are arranged on individual molecules. Thus the subsequent layer replicates the information recorded on the preceding layer. The upper layer can be separated from the lower layer by placing on its surface a film of poly(vinyl alcohol) and then splitting off both films[32,33]

The recording processes based on changes in the orientation and the relative positions of the molecules in the LB film make it possible to achieve the reversible recording of information, but the corresponding memory devices cannot at present compete with magnetooptical memory devices as regards the permanence of the recording, the signal/noise ratio, and a number of recording/re-recording cycles. Furthermore, when LB films consisting of two and more coaggregates are used (which is frequently necessary in recording procedures based on *J*-aggregation and *cis–trans* isomerisation processes), the problem of the formation of domains in the LB film owing to phase separation in the mixed monolayer arises[34]. The molecules in such island domains behave in many respects like a single assembly, as a result of which the recorded bit is blurred and the signal/noise ratio in the corresponding memory devices is therefore reduced. In an attempt to overcome these phenomena, use is made of special conditions in the deposition of films from a non-densely compressed monolayer whereupon the LB film consists of a "two-dimensional liquid" or various stabilising additives incorporated in the monolayer which diminish the size of the structured domains by becoming distributed along their boundaries.

Briefly, a vigorous search for reversible optical systems based on the LB technology and for ways of modifying thermoptically is being prosecuted at the present time, which will undoubtedly yield positive results in the future. The principal advantage of an optical memory with a carrier based on LB films over a magnetooptical memory will apparently become the achievement of multicolour recording on photochromic LB films containing either dyes of several types with absorption bands in different spectral ranges, located in successive layers, or one dye in one layer with various photochromic groups attached to one molecule, or coaggregate dyes. Multicolour optical recording makes it possible to create memory devices with a recording density several times greater than in the usual optical memory devices by recording several bits of information simultaneously at a single location of the laser spot.

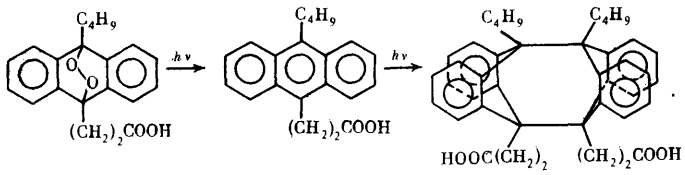
The review deals with the principal methods of recording and reproducing information on carriers prepared by the Langmuir–Blodgett method proposed recently, the specific compositions and methods of depositing recording layers, as well as the physicochemical processes occurring in LB layers. There is a prospect that these processes may be used to record information. The main bulk of the review is devoted to reversible systems, while among systems of the archive type only some are mentioned.



II. Archive recording

Archive memory devices do not allow the deletion and re-recording of information; they are designed for the long term storage of large amounts of information and belong to the so called "write once/read many" type in contrast to the reversible "write many/read many" memory devices. The principal requirements which must be met by archive devices is the greatest possible density of recording and the shortest possible access time to the data.

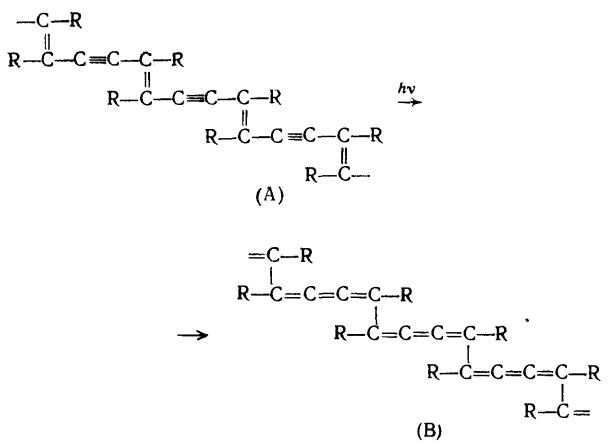
We shall consider certain physical principles on which information recording processes in these devices are based.



1. Photopolymerisation

Several systems have been proposed in which the local polymerisation under the influence of light is used to record information. An example of such a system has been examined in a study[21] where a stable polymer was formed under the influence of UV radiation in a LB film based on *N*-octadecylacrylamide as a result of the reaction

2. Photodimerisation



Intermolecular photodimerisation of neighbouring 9-anthryl-10-butyl-3-propanoic acid molecules has been used[20] to record information on a LB film:

This reaction proceeds in an arachidonic acid matrix with acid : matrix = 1 : 1 and 1 : 3 ratios under the influence of laser light with a wavelength of 420 ± 2.5 nm. The optical absorption spectrum of the film changes significantly under these conditions. The reverse reaction is not observed either in the dark or on irradiation with the light corresponding to the absorption band of the dimer over a period of 14 h.

3. Photoinduced transformation of the polymer

An optical information carrier has been described[35] in which the acetylenic form (A) of polydiacetylene is converted into the butadiene form (B) under the influence of UV radiation:

The rate of recording on such films is 10^8 bits s^{-1} and the required energy density for recording is less than 800 J m^{-2}.

The carrier is prepared as follows. The monomer, for example pentacosa-10,12-diynoic acid

is deposited on the surface of water, buffered with $CdCl_2$ (10^{-4} M, pH 6.1), at 15 ± 0.1 °C by the Langmuir–Blodgett method. Chloroform, in which the acid concentration is 0.7 kg m^{-3}, is used as the solvent. 40 Monolayers of a Y-type LB film are deposited on a sulphuric acid-treated quartz glass support at a surface pressure of 25×10^{-3} N m^{-1}. This results in the formation of a coating having a thickness of the order of 1000 Å. Under the influence of 5 W m^{-2} UV radiation (λ = 240–400 nm), the acid polymerises in 40 min. The spectrum of the polymer then corresponds to the (A) form [Fig. 3, curve (*A*)]. On further irradiation with UV light up to a total dose of 100 J m^{-2}, the absorption spectrum changes [Fig. 3, curve (*B*)], indicates the conversion of the polymer into the (B) form. The recording of information is thus achieved. The change in the relative amounts of the polymers in the (A) and (B) forms as a function of the absorbed energy is illustrated in Fig. 4. The shorter the irradiation wavelength, the higher the efficiency of the (A)→(B) transformation.

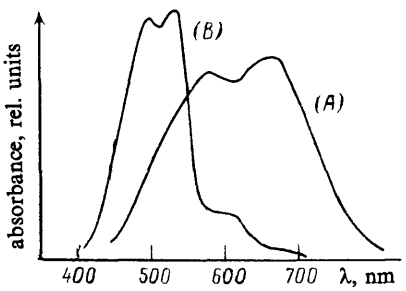


Figure 3. Absorption spectrum of a polydiacetylene LB film in the acetylene (A) and butadiene (B) forms.

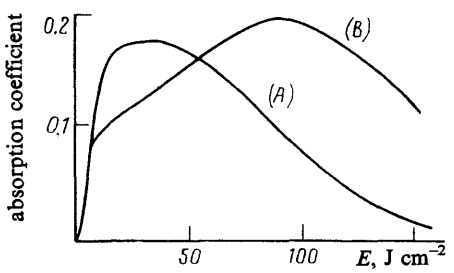

Figure 4. Variation of the relative amount of polyacetylene in the acetylene (A) (λ = 638 nm) and butadiene (B) (λ = 535 nm) forms as a function of the absorbed energy.

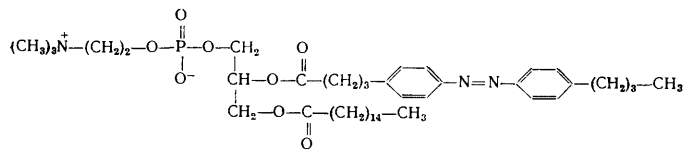
Archive devices with a carrier based on a LB film cannot as yet compete with the traditional optical discs, on which information is recorded by the photolithographic method, despite the simple

recording technology and the higher information density. The principal disadvantages of the recording procedures described above are the long photopolymerisation reaction and phototransformation times as well as the inadequate lifetime of the recorded information. Nevertheless studies are being conducted in order to reduce the photochemical reaction time in such systems[36] and also in order to stabilise the reaction products with the aid of different kinds of coaggregates.



III. Reversible recording

The reversible methods for the recording of information are designed for external computer memory devices in which it is necessary to be able to delete the previously recorded information and to record new information. The principal requirements which must be met by such devices is the attainment of the largest possible number of recording–re-recording cycles as well as the greatest possible permanence of the recorded data. Reversible memory devices are divided into locally reversible, in which it is possible to re-record selectively over part of the existing information on the carrier, and others in which information can be re-recorded only after deleting the previously recorded information from the entire carrier. As regards the locally reversible memory devices, the latter are used widely at the present time with the information carrier in the form of magnetic discs with a realistically attainable recording density of 10^{10} bits m^{-2} as well as magnetooptical devices already prepared for mass production[1] with a recording density reaching 10^{12} bits m^{-2}.

1. Reversible recording without local re-recording

(a) *Cis–trans* isomerisation

LB films of photochromic phopholipids containing azobenzene have been investigated[19], for example:

When they are irradiated with UV light, *cis–trans* isomerisation (of azobenzene) takes place, the *cis*-isomer predominating in the film; on irradiation with visible light (at the wavelength λ = 540 nm), the *trans*-isomer predominates. The refractive index of the film then changes. By recording the modulation of the refractive index, it is possible to reproduce the recorded information. However, thermal equalisation of the relative amounts of the *cis*- and *trans*-isomers as a result of the reverse reaction is observed in this system, so that the proposed carrier is as yet difficult to use in memory devices.

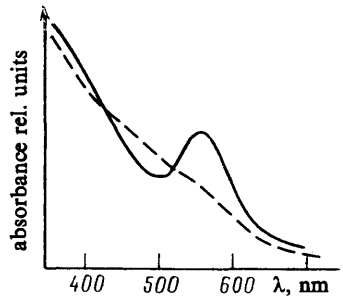
It has been suggested that photochromic reactions, i.e. reactions involving a reversible change in the structure of molecules or in their electronic state under the influence of light accompanied by a change in the colour of the substance, have been proposed for the optical recording of information. This also entails as a rule a change in the refractive index of the film. Photochromic materials comprise a broad class of compounds—spiropyrans, metal dithizonates and metal-phthalocyanines, polycyclic hydrocarbons, etc. Since photochromic materials do not form a stable LB film, they are introduced into a matrix consisting of the film-forming substance, which is usually an aliphatic acid containing between 10 and 25 atoms together with stabilising additives. Sometimes the resulting film is also polymerised.

A large class of optical carriers, prepared by the Langmuir–Blodgett method and capable of the undergoing *cis–trans* isomerisation under the influence of light, has been described[37]. It includes photochromic materials with a N=N bond (azobenzene derivatives) or a C=C bond (indigo and thioindigo derivatives into which a hydrocarbon group, such as alkyl, alkoxy-, alkylacyl, or alkylamino-groups containing at least 10 and preferably 14–25 carbon atoms, has been introduced). We shall now list some of these compounds; for example, we have 4-monostearylamino-azobenzene, *N,N'*-distearylindigo, 5-octadecyl-5'-t-butylthioindigo, and 5-octadecyl-1,8-naphthylthioindigo. Aliphatic acids and their derivatives (stearic and arachidonic acids, methyl stearate, stearyl alcohol), tripalmitin, phospholipids etc. can be used as the film forming components necessary for the formation of the LB film. The molar ratio of the film forming component to the photochromic substance is varied from 1:1 to 6:1, the 1:1 and 2:1 ratios being most preferred. The solvents employed are benzene, chloroform, n-hexane, cyclohexane, and ethyl ether. The concentrations of the photochromic and film-forming substances in these solvents vary from 0.1 to 10 g m^{-3} (concentrations in the range 0.1–1 g m^{-3} being most preferred). The aqueous subphase is buffered by barium, calcium, or lithium salts at concentrations in the range 10^{-3}–10^{-5} M (pH 4–9). Acrylic resin is deposited on the recording layer in order to improve the operating characteristics of the carrier.

Several patented carriers will be examined below as specific examples[37].

Example 1. One of two mixtures—10^{-3} M solution of 4-monostearylaminoazobenzene in toluene or 10^{-3} M solution of a mixture of monostearylaminoazobenzene and stearic acid (in molar proportions of 1:2) in benzene—is irradiated with light at a wavelength of 360 nm. The irradiated solution (2.5×10^{-7} m^3) is deposited on water (pH 7, T = 18 °C) and the resulting film is compressed at a rate of 10 mm min^{-1} to the surface pressure $P_0 = 20 \times 10^{-3}$ N m^{-1}. After that, 30 monolayers of the film (750 Å) are deposited in succession on the support by the LB method. Information is recorded by means of a laser beam at a wavelength of 440 nm, focussed to a diameter of 1 μm. Before recording, the medium absorbs at a wavelength of 440 nm, while after recording it is transparent in this region. Information is retained for a fairly long time (for 30 days in the case of the carrier prepared from 4-monostearylaminobenzene and stearic acid).

Example 2. One of two mixtures—10^{-3} M *N,N'*-distearylindigo (the method of preparation has been described in a patent) in benzene or 1.5×10^{-3} M solution of a mixture of *N,N'*-distearylindigo and tripalmitin (molar ratio 1:2) in benzene—is irrigated with light at λ = 580 nm. The irradiated solution (2×10^{-7} m^3) is deposited on water (pH 5.8; T - 18 °C) and the resulting film is compressed at a rate of 1.6×10^{-4} m s^{-1} to the surface pressure $P_0 = 25 \times 10^{-3}$ M m^{-1}. Next, 20 monolayers of the film are deposited by the LB method on a hydrophobic glass carrier (treated in cadmium arachidate) by the LB method. The recording is performed with a laser at a wavelength of 440 nm. Before recording, the medium is transparent in the region of 540 nm, but after irradiation it becomes absorbing. The absorption spectra of the carrier containing *N',N'*-distearylindigo and tripalmitin, before and after recording, are illustrated in Fig. 5.



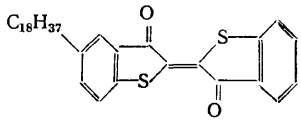


Figure 5. Absorption spectra of a carrier containing *N,N'*-distearylindigo and tripalmitin before recording (dashed line) and after recording (continuous line) with a laser operating at a wavelength of 440 nm.

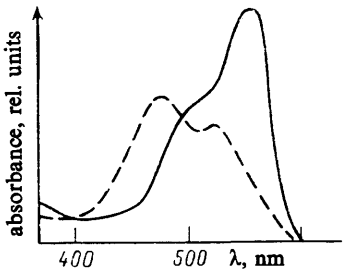
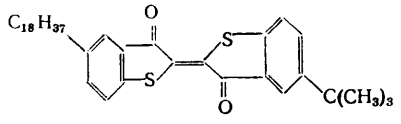
Example 3. A solution of 5-octadecylthioindigo (10^{-3} M) (the method of preparation has been described in a patent[37]), i.e.

in benzene is irrigated with light at λ = 560 nm. The irradiated solution (3×10^{-7} m^3) is deposited on the surface of water (pH 5.2; T = 18 °C) and the resulting film is compressed at a rate of 1.6×10^{-4} m s^{-1} to the surface pressure $P_0 = 20 \times 10^{-3}$ N m^{-1}. Next, 20 monolayers are deposited on a hydrophobic glass support (treated with cadmium arachidate) by the LB method. The recording is carried out at a wavelength of 560 nm. The absorption spectra before and after irradiation are presented in Fig. 6.





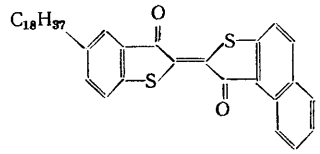


Figure 6. Absorption spectra of a carrier based on 5-octadecylthioindigo before recording (dashed line) and after recording (continuous line) at a wavelength of 560 nm.

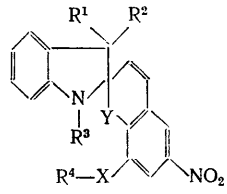
Example 4. A solution of a mixture of 5'-t-butyl-5-octadecylthioindigo (0.5×10^{-3} M) i.e.

and tripalmitin (molar ratio 1:2) in chloroform is irradiated with light at a wavelength of 550 nm and 20 monolayers of the film are deposited on a chromium-plated support treated with cadmium arachidate. The recording is carried out a wavelength of 450 nm. The medium is transparent at a wavelength of 450 nm before recording and absorbs in this region after recording.



Example 5. A solution of 5-octadecyl-1,8-naphthalthioindigo (0.5×10^{-3} M), i.e.

and tripalmitin (molar ratio 1:2) is irradiated with light at a wavelength of 600 nm and 30 monolayers of the film deposited by the LB method on a glass support treated with cadmium arachidate. The recording is performed at a wavelength of 480 nm. Before irradiation, the medium absorbs in the region of 480 nm and after irradiation it is transparent in this region.

(b) Photochemical reactions in *J*-aggregates of organic dyes

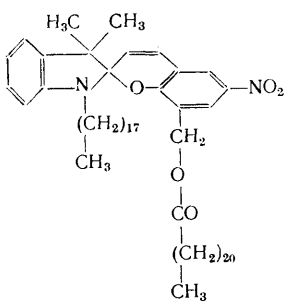
The optical carriers described in patents[38–40] contain *J*-aggregates of spiropyrans of the type

where R^1 and R^2 are long alkyl group, R^3 is an alkyl group containing at least 10 and preferably 14–24 carbon atoms (hexadecyl, octadecyl, etc.), X is a single bond or one of the groups $-C_nH_{2n}OCO-$, $-C_nH_{2n}COO-$, $-C_nH_{2n}NHCO-$, $-C_nH_{2n}-CONH-$, or $-C_nH_{2n}O-$, where $n \geqslant 0$ (the $-CH_2OCO-$ or $-O-$ groups are most preferred), R^4 is an alkyl group containing at least one carbon atom, and Y=O or S. Among spiropyrans, the following are more preferred: 8-methoxy-3,3'-dimethyl-6-nitro-1'-octadecyl[2*H*-1-benzopyra-2,2'-indoline] and 8-dodecasonyloxy-3,3'-dimethyl-6-nitro-1'-octadecylspiro[2*H*-1-benzopyran-2,2'-indoline].

These spiropyrans, deposited on a carrier by the LB method, give rise to *J*-aggregates on heating[27,41–43]. The aggregates have narrower absorption bands than the unreacted dye, which makes it possible to increase the sensitivity of the method. The absorption bands undergo a bathochromic shift on formation of the *J*-aggregates.

The carrier can consist of dyes of two and more types[39]. Information is then recorded by means of laser beams at different wavelengths focussed in one spot.

On exposure to UV radiation, the spiropyrans photomerise to the corresponding photomerocyanines having maximum absorption peaks in the range 400–700 nm. However, these photomerocyanines are unstable and are usually reconverted into the initial spiropyrans even in the dark. On the other hand, if the



photomerocyanines are converted into *J*-aggregates as a result of a thermal reaction, the latter become more sensitive.

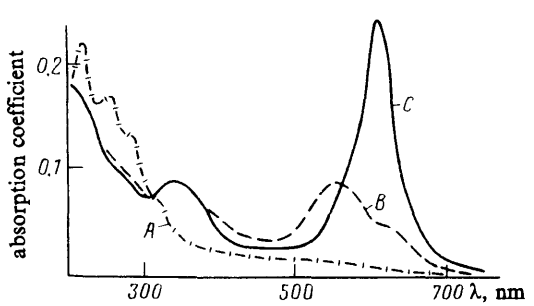
Aliphatic acids or their salts with polar groups are used to stabilise photomerocyanines in a LB film. One should use preferably acids with 14–24 carbon atoms (myristic, pentadecanoic, palmitic, heptadecanoic, stearic, nonadecanoic, behenic, etc.).

The solvents employed are chloroform, benzene, toluene tetrahydrofuran, acetonitrile, acetone, ethanol, etc. The solute concentrations are in the range 0.1–3 wt.%.

We shall now examine several specific examples.

Example 1. A solution of the spiropyran (3 M) (the method of preparation has been described in a patent[38])

and n-octadecane (in molar proportions of 1:2) is deposited on the surface of an aqueous subphase (pH 7.2; T = 18 °C). Next, 12 monolayers of a Y-type film are deposited on a hydrophobic glass [treated in a 10% (by volume) solution of chlorotrimethylsilane in toluene for 30 min] by the LB method. The absorption spectrum of the resulting film is illustrated in Fig. 7 (curve *A*). After the film has been irradiated with UV light for 10 min, a peak appears in the spectrum in the region of 583 nm, which is characteristic of photomerocyanine (curve *B*), while after heating by IR irradiation to 35–40 °C, *J*-aggregates appear (curve *C*). During the recording of information by means of a laser at a wavelength of 618 nm and an energy density of 5×10^3 J m^{-2}, there is a local reconversion of the photomerocyanine into the spiropyran (the absorption spectrum *A* is restored). Information is read by means of a laser beam with an energy density of 50 J m^{-2} and is deleted by UV light and heating. Information is not lost in the course of 5000 h and longer.



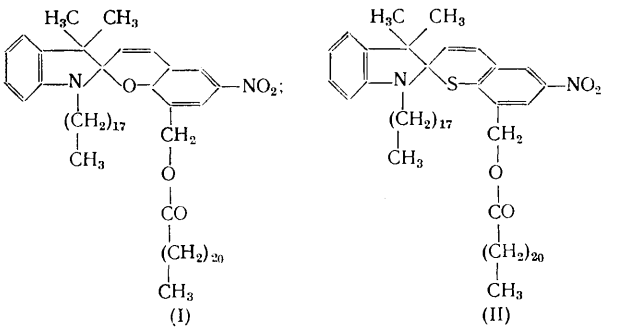


Figure 7. Absorption spectra of a LB film in a mixture of a spiropyran[39] and n-octadecane (molar ratio 1:2) before irradiation with UV light (*A*), after irradiation (*B*), and after additional heating by IR radiation to 35–40 °C (*C*). Heating results in the formation of *J*-aggregates of the corresponding photomerocyanine; (I) and (II)—dyes (see text).

It is also possible to record information by the conversion of the spiropyran into photomerocyanine[40].

Example 2. Two spiropyrans[39]

are deposited in succession on a carrier: 1 mmol of the spiropyran and 2 mmol of n-octadecane are dissolved in chloroform, 7×10^{-7} m^3 of the solution is deposited on the surface of an aqueous subphase buffered with sodium phosphate (pH 7.2; T = 18 °C), the resulting film is compressed to the pressure $P_0 = 20 \times 10^{-3}$ N m^{-1}, and 20 Y-type monolayers are deposited by the LB method on a hydrophobic glass support treated in 10% solution (by volume) of chlorotrimethylsilane in toluene for 30 min. The same procedure is gone through with the second spiropyran.

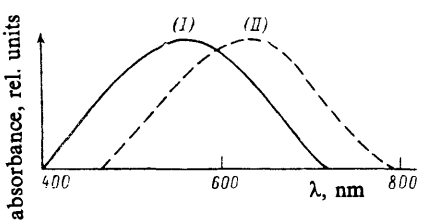

Figure 8. Absorption spectra of a carrier consisting of two spiropyrans[39] after their conversion into the corresponding photomerocyanines as a result of UV irradiation.

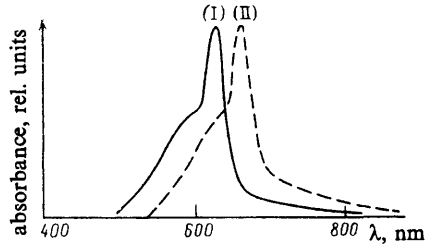
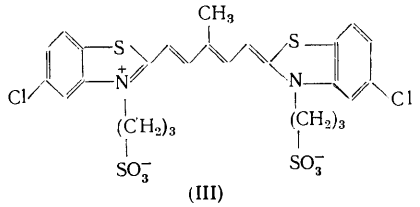
After this, the carrier is irradiated with the light from a UV lamp (at a wavelength of 350 nm) for 10 min. This results in the formation of photomerocyanines whose absorption spectra are illustrated in Fig. 8. (When two and more dyes are used, it is essential that their maxima should differ by at least the half-width of the absorption peak of the *J*-aggregates, i.e. by 20–30 nm.) The carrier is then heated by an IR lamp to 35–40 °C for 15 min. The spectra of the resulting *J*-aggregates are shown in Fig. 9. Evidently the peaks undergo a bathochromic shift by 35–50 nm and are narrowed to a half-width of about 30 nm.

The recording is carried out by means of two lasers operating at wavelengths of 618 and 653 nm and with an energy density of 5×10^3 J m^{-2}. Information is read by the same lasers at an intensity of 50 J m^{-2}.

Information is deleted by UV irradiation and by heating the carrier.

Yet another class of photochromic materials, whose complex molecule contains benzothiopyran, has been described[44]. A non-irradiated LB film with the photochromic substance has no absorption peaks in the range 500–900 nm, while the film irradiated with UV light absorbs strongly in the range 600–850 nm. The carrier consists of three layers—recording, refracting, and reflecting. A laser operating at a wavelength of 780 nm and with a power of 7.5 mW is used for recording. The sensitivity of the recording for a 20% change in the reflectance is 1.5×10^3 J m^{-2}. The signal/noise ratio in the reproduction of the information is 54 dB.





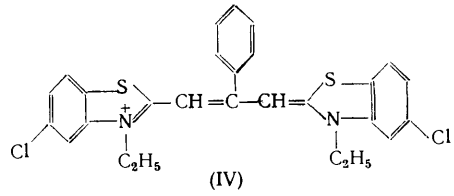


Figure 9. Spectra of photomerocyanines after the formation of *J*-aggregates; (I)–(II)—dyes (see text).

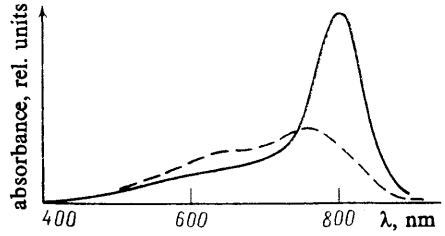
Multicolour carriers based on dyes containing *J*-aggregates have been proposed[24,45]. The following dyes are most preferred:

At least two of the following three substances are employed as the film-forming materials: dioctadecylammonium chloride (DODAC), stearylamine, and methyl stearate. It is possible to use arachidonic acid alone.

Example 1. The dye (III), stearylamine, and methyl stearate (molar ratios 1:1:3, overall concentration of stearylamine and methyl stearate 10^{-9} kg m^{-3}) in the 4:1 chloroform–methanol mixed solvent is deposited on the surface of water at 16 °C and the layer is compressed to surface pressure $P_0 = 35 \times 10^{-3}$ N m^{-1}. Next, 25 monolayers of the film (800 Å) are deposited by the LB method on a glass support coated by a layer of aluminium (2000 Å).

The recording is performed with a semiconductor laser operating at a wavelength of 780 nm, with a power of 6×10^{-3} W and with a pulse duration of 10^{-7} s. The *J*-aggregates undergo local decomposition under these conditions. The absorption spectra of such a mixture before and after recording are illustrated in Fig. 10.



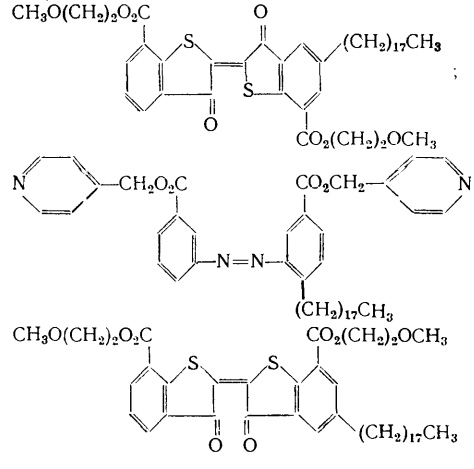


Figure 10. Absorption spectrum of the dye (III), stearylamine, and methyl stearate (molar ratio 1:1:3) in a LB film before recording (continuous line) and after recording (dashed line) with a laser operating at a wavelength of 780 nm. Irradiation results in the local decomposition of *J*-aggregates.

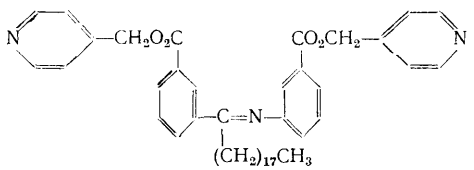
Example 2. A LB film of the dye (IV) and arachidonic acid (molar ratio 1:2) is deposited on top of the recording layer prepared as described in example 1. The film is compressed on the surface of water (T = 16 °C) to the surface pressure $P_0 = 30 \times 10^{-3}$ N m^{-1} and 6 monolayers of the film (200 Å) are deposited. The recording is performed with two lasers having a power of 3.5×10^{-3} W and operating at the wavelengths corresponding to the absorption peaks of the two dyes—at 670 and 780 nm.

(c) Photochemical liberation of the metal

The photochemical liberation of the metal in the LB film has been proposed in a number of studies[46–51] as reversible reaction.



Example 1. One of the substances below[46–48], i.e.

is dissolved in $CHCl_3$ and deposited on an aqueous subphase buffered with $AgNO_3$ (pH 5.2). After the evaporation of $CHCl_3$, between 1 and 25 monolayers of the film are deposited by the LB

method on a glass support, the film being simultaneously irradiated with light at a wavelength of 450 nm. The recording is carried out with a laser operating at a wavelength of 550 nm. The absorption peak at 620 nm changes under these conditions. The reading of information is also based on this peak. Information is deleted by laser light at a wavelength of 450 nm in the course of 3 min.

Example 2. The substance

is dissolved in $CHCl_3$ and is deposited on the surface of an aqueous subphase containing Cu^+ ions (pH 5.2). After the evaporation of $CHCl_3$, between 1 and 25 monolayers of the film are deposited by the LB method on a glass support, the film being simultaneously irradiated with light at λ = 313 nm. The recording is carried out by means of a laser beam at a wavelength of 450 nm and is read from the change in the peak in the region of 530 nm in the absorption spectrum of the film. Information is deleted by irradiation with light at λ = 313 nm for 3 min[49–51].

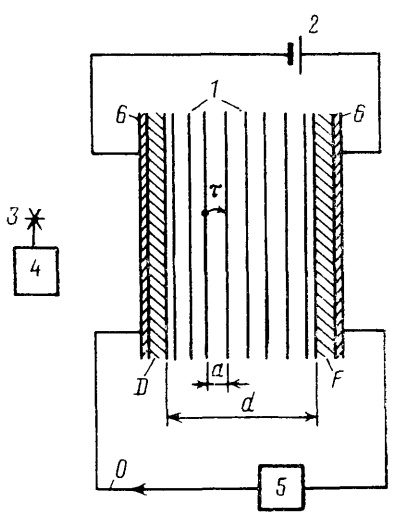


Figure 11. A multilayer carrier comprising polydiacetylene LB layers: *1*, carrier; *2*, source of supply; *3*, laser; *4*, modulator; *5*, optical amplifier; *6*, electrodes; *D*—photoinjection layer; *F*—fluorescent layer; *O*—optical loop.

In conclusion of this Section, we shall deal with a fundamentally new method of recording information on a multilayer carrier prepared by the LB technology, which can be employed in operating memory devices.

(d) Photoelectron recording on a multilayer carrier

A patent[52] describes how diacetylene LB films, polymerised to achieve stability by UV or electron irradiation, are placed between a photoinjection layer *D* and a fluorescent layer *F* (Fig. 11).

The recording is carried out with a laser fitted with a modulator. During recording, electrons are emitted from the layer *D* and are then caused by the electric field, generated in a source connected via electrodes to the carrier, to jump from layer to layer for as long as the field operates. The *F* and *D* layers can be connected by the optical loop O fitted with an optical or electrical amplifier. The loop is used to maintain the supply to the *D* layer and makes it possible to store the recorded information for a long time.

An 8-layer information carrier, possibly containing an even greater number of layers, has been described[52].

We shall consider the behaviour of an electron after its emission from the *D* layer. Suppose that τ is the time taken for the jump to the next polydiacetylene plane, whereupon

$$1/\tau = \nu \exp(-2ka),$$

where ν is the background frequency, a the distance between the layers, and $k^2 = 2mA/h^2$ (A is the electron affinity of the layer and m the mass of the electron).

If a potential $V > V(h) = n^2 k_B T/e$, where n is the number of layers, k_B the Boltzmann constant, T the absolute temperature, and e the charge of the electron, is applied to the carrier then the drift along the field exceeds the diffusion of the electron over the distance a. Under these conditions, the energy difference between the electrons in neighbouring layers is greater than $k_B T$ and the reverse jump against the field beomes unlikely. For a film made up of 8 layers at room temperature, $V(h) \simeq 0.2$ V. When $a = 10^{-9}$ m, $A = 1.6 \times 10^{-19}$ J, and $\nu = 10^{14}$ Hz, the time τ between the jumps is 8.8×10^{-6} s. Thus, when a potential of 0.2 V is applied to the carrier, the electron injected into the first layer emerges from the 8th layer after 70 μs.

The laser beam is modulated in such a way that the pulse has a width t and a period t/n. The set of light pulses corresponding, for example, to the 10011010 datum is transformed into the presence or absence of a charge in the corresponding layer after a time t. The closed optical loop *O* makes it possible to increase the storage time. It is also possible to use several layers carrying a charge q_m per bit. The criterion indicating that neighbouring bits will not diffuse into one another after N cycles as described by the expression

$$V/V(h) > N/M^2,$$

where M is the number of layers used to store one bit of information.

In reading the information, it is possible to employ the current differentiation method instead of detection with the aid of the fluorescent *F* layer. The maximum current change is $\Delta I = q_m/n\tau$.

Figs. 12 and 13 illustrate another carrier made up of polydiacetylene bilayers of two types, differing in the electron affinity by $\Delta A \simeq 10 k_B T$. For the electron jumps illustrated in the figures by arrows, we have

$1/\tau_{12}(s) = \nu \exp(-2ka) \exp(-\Delta A/k_B T)$ in a weak field $E < \Delta A/(e.a)$;

$1/\tau_{12}(l) = \nu \exp(-2ka)$ in a strong field $E \geqslant \Delta A/(e.a)$;

$$1/\tau_{11} = \nu \exp(-4ka),$$

where τ_{12} is the time taken for a jump from a type *1* layer to a neighbouring type *2* layer in weak (Fig. 12) and strong (Fig. 13) fields and τ_{11} is the time taken for a jump from a type *1* layer to the nearest type *1* layer.

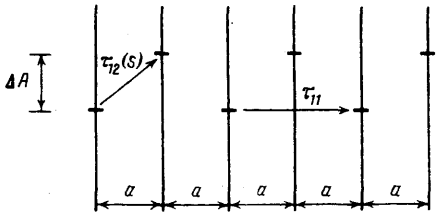

Figure 12. Schematic illustration of the energy levels of a carrier consisting of bilayers of polydiacetylene of two types differing in electron affinity ΔA by $\sim 10k_BT$ in a weak electric field ($E < \Delta A/ea$).

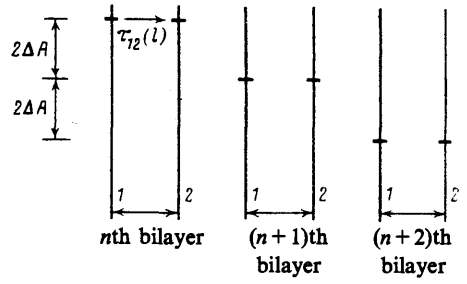

Figure 13. Schematic illustration of the energy levels of a carrier made up of polydiacetylene bilayers in a strong electric field ($E > \Delta A/ea$).

Thus $\tau_{12}(l) \ll \tau_{12}(s) \ll \tau_{11}$.

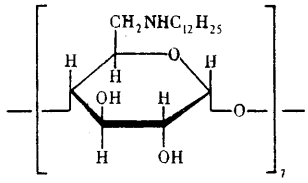
In the carrier described, one bit occupies one bilayer. For T = 300 K and $A = 10k_BT$, we have $\tau_{12}(l) = 8.8 \times 10^{-6}$ s, $\tau_{12}(s) = 0.19$ s, and $\tau_{11} = 2.17$ h.

The recording is carried out in a strong field $E = A/ea = 2.5 \times 10^8$ W m^{-1} for $A = 10k_BT$ at T = 300 K. It is stored in a weak or zero field for a time $\tau_{12}(s)$ and is read in a strong field. The storage time can be increased by using three layers for the recording of one bit (two layers of type *2* between insulated layers of type *1*). In this case, we obtain $\tau_{11} \simeq 20000$ years and $\tau_{12}(s) = 6000$ years at τ = 77 K.

2. Locally reversible recording

The creation of photochemical carriers with the possibility of local re-recording of information has been reported[53]. The carrier was made from 4-$RC_6H_4CH{=}CH{-}CH{=}CHCO_2H$ (V) (R = alkyl or alkoxy-group with 6–20 carbon atoms). For example, a quartz support coated by the LB method with 162 layers of the 2-*trans*, 4-*trans*-(V) mixture (R = n-octyloxy-group) produces a carrier with an absorption peak in the region of 300 nm. Irradiation with light at a wavelength of 300 nm diminishes the intensity of this peak and at the same time a new peak appears in the region of 270 nm. On the other hand, irradiation with light at a wavelength of 270 nm restores the peak in the region of 300 nm. Thus, using two lasers, it is possible to ensure the local re-recording of information.

As stated above, in reversible information carriers based on azobenzene derivatives[37] the reverse *trans*-isomerisation reaction is hindered because of the high energy of the re-packing of molecules in the monolayer. In order to overcome this difficulty and ensure the local re-recording of information, it has recently been suggested[54] that molecules of azobenzene derivatives, i.e.



(a) X = H, Y = COOH;

(b) X = $(CH_3)_2N$, Y = COOH;

(c) X = $(CH_3)_2N$, Y = SO_3Na;

be incorporated within the cavity of the β-cyclodextrin molecule:

This seven-membered cyclic β-dextrin molecule is barrel-shaped and has an inner cavity approximately 50 nm in diameter. The *trans*-isomer of the azobenzene derivative and β-cyclodextrin (molar ratio 1:1) are deposited in the form of a LB film comprising 50 monolayers. The azobenzene molecule is then located within the β-cyclodextrin cavity in such a way that its long axis coincides with the axes of the aliphatic substituents in the β-cyclodextrin and the *cis–trans* isomerisation of azobenzene can be readily achieved on treatment with light in the visible or near UV regions.

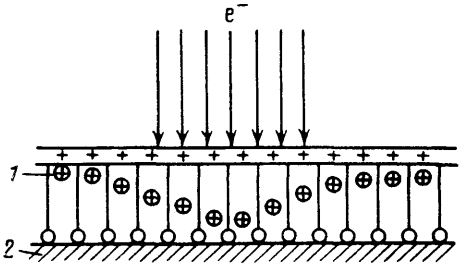


Figure 14. Carrier comprising a barium stearate LB film with mobile barium ions: *1*, barium ions; *2*, carbon base.

IV. Recording of information by an electron beam on a LB film with mobile ions

It has been proposed in a patent[55] that a LB film of barium stearate (Fig. 14) with mobile barium ions, deposited on a carbon base, be used as the information carrier. The LB film has an electrical surface potential of 100 mV relative to the base. If a

potential of +2.5 V is applied to the latter, then the excess barium ions migrate to the surface of the film.

Recording is achieved by means of an electron beam ($I = 10^{-10}$ A, $E = 1.6 \times 10^{-17}$ J, $d = 10^{-8}$ m). When it reaches the site where the information bit should be recorded (for example "1"), the potential of the support is reduced to zero by means of a synchronised potential source. A negative field gradient relative to the support is generated. However, it is insufficient for the migration of the ions to the support. Under the influence of the electron beam, the ions migrate into the bulk of the film. After the information bit has been recorded, the surface potential is reduced at this site by 0.1 V and the surface has a higher secondary emission coefficient. The information is read by secondary electron spectroscopic methods or by the diffraction of low-energy electrons using an electron beam with a current of $10^{-11}-10^{-12}$ A. The density of the recording reaches 10^{16} bits m^{-2}. Local deletion of information in this method has not so far been attained.

Activation of C–C bonds in unsaturated hydrocarbons by metal complexes

I S Akhrem, M E Vol'pin
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The current position of the problem of the activation of C–C bonds in alkanes and cycloalkanes is examined. The two main routes for the cleavage of unactivated single C–C bonds—metal-complex cleavage on an unsaturated coordinate metal site and electrophilic cleavage—are discussed. The literature data on the development of catalysts for the "low-temperature" cleavage of C–C bonds in alkanes are correlated.

The bibliography includes 158 references

I. Introduction

A new stage in the chemistry of alkanes that could be called "the low-temperature chemistry of paraffins" began in the 1970s.

Activation of the C–H bonds of saturated hydrocarbons by transition metal complexes in solution[1] was discovered in 1969 and thus new possibilities for selective conversions of alkanes, including methane, under mild conditions were demonstrated. This area is undergoing rapid development at the present time.[2–15] In his introduction to the recently published issue of *New Journal of Chemistry* that is devoted to problems concerning the activation and functionalisation of alkanes, Hill writes that there are few problems in chemistry which would have stimulated greater interest during the last ten years than the selective conversions of alkanes. The reasons for this are clear. Alkanes constitute "the ultimate feedstocks for production of a myriad of organic products from pharmaceuticals and fibres to new and innovative materials".[15]

The second important milestone in the development of the low-temperature chemistry of alkanes is mainly connected with the discovery of new proton superacids whose acidity is greater than that of sulphuric acid by a factor of 10^7-10^{19}.[16–20] Because of the exceptionally high electrophilicity of the unsolvated proton in superacid media it was possible for the first time to carry out conversions of alkanes effectively at room temperature and lower temperatures.[16–26] Until recently proton superacids were the only reagents capable of cleaving not only the C–H bonds but also the more inert C–C bonds in alkanes under mild conditions.[27,28] By using superacid media it was possible to observe experimentally for the first time alkyl cations formed from alkanes,[16,21,22] which had previously been postulated as intermediates in organic reactions.

Another important contribution to the problem of the activation of alkanes has been made by the concept of the "pentacoordinate carbonium ion", which plays a key role in electrophilic attack on C–H and C–C σ-bonds.[19] Superacid activation of alkanes, to which a large number of publications have been devoted, will not be specifically examined in this review. We should only mention that the use of proton superacids is severely restricted by their limited availability, toxicity, and corrosive nature, and the difficulties in using them.

We also do not have the opportunity to dwell on the impressive progress achieved in a traditional area such as the gas-phase reactions of alkanes on heterogeneous metal and oxide catalysts, which as usual has played a leading role in industrial processes (see, for example, several studies).[29–40]

* Calculated from the results of Zhorov.[45]
** Alkene-1.

The aim of this review is to cover the recent progress in the low-temperature activation of the C–C bonds of alkanes by metal complexes.

It is well known that the carbon–carbon bond of paraffins is amongst the most passive of bonds of one of the most inert classes of organic compounds. Not long before the discovery of the metal-complex activation of the C–H bonds of alkanes, Halpern wrote that this problem presents a challenge to chemists.[41,42] This can apply even more to the activation of C–C bonds.

The ever increasing interest in a solution to this problem is governed by the key role of reactions involving cleavage of C–C bonds in industrial processes for the treatment of hydrocarbon raw materials (isomerisation, cracking, hydrocracking, etc.).

Cleavage of the thermodynamically stable non-polar C–C σ-bonds in paraffins, which do not have either free electron pairs or low-lying vacant orbitals, usually takes place effectively at high temperatures (300–1000 °C) in the gas phase.[43,44]

It follows from Table 1 that the cracking of alkanes at a low temperature is thermodynamically unfavourable. Only at elevated temperatures is the thermodynamic restriction lifted, but high-temperature processes consume considerable energy and are generally not very selective.

On the other hand the oligomerisation of olefins at low temperatures is accompanied by the liberation of sufficient heat to compensate the energy of cleaving the C–C bonds. Therefore the low-temperature cracking of alkanes is thermodynamically possible if it occurs with the formation of lower alkanes and oligomers.

At the present time it would appear that two routes for the activation of C–C bonds in alkanes resulting in their cleavage are of the greatest significance. The first is an electrophilic route which either involves the direct cleavage of C–C bonds by treatment with an electrophile E^+

$$R_3C{-}CR_3 + E^+ \rightarrow R_3CE + \overset{+}{C}R_3 \qquad (1a)$$

or the initial cleavage of C–H bonds to form carbocations or cation-like intermediates, which subsequently undergo intramolecular reactions with cleavage of C–C bonds:†

$$RH \xrightarrow[-EH]{E^+} R^+ \rightleftarrows (R')^+ + \quad \diagup C{=}C \diagdown \qquad (1b)$$

The second route for activating C–C bonds involves their interaction with unsaturated coordinate transition metal complexes, which can formally be represented as occurring via the insertion (oxidative addition) of complex M into the C–C bond:

$$\diagup C{-}C \diagdown + M \rightarrow \diagup C{-}M{-}C \diagdown \rightarrow \text{products.} \qquad (2a)$$

In this case as in the electrophilic cleavage of C–C bonds, 2 routes are actually possible. The first involves the direct insertion of the metal complex into the C–C bond [scheme (2a)], similar to that which occurs with the covalent bonds: H–H,[48–50] R–X,[48] Si–H,[51–53] and C–H.[2,5–7,9,10,54–62]

The second route involves the oxidative addition of C–H bonds to the metal complex followed by cleavage of the C–C bond in the resulting σ-alkylhydride complex:

$$R{-}CH_2{-}CH_3 + M \rightleftarrows RCH_2CH_2{-}M{-}H \qquad (2b)$$

α-elimination | β-elimination

$$\begin{array}{ll} H & CH_2{=}CH_2 \\ | & | \\ CH_2{=}M{-}CH_2R & R{-}M{-}H \\ \downarrow\uparrow & \uparrow\downarrow \\ CH_3{-}M{-}CH_2R & CH_3CH_2{-}M{-}R \end{array}$$

As will be demonstrated below, scheme (2b) is not just speculative.

† The formation of carbocations from hydrocarbons may possible occur in stages. Initially one electron is transferred to the electrophile to form E, then the transfer of $H^{\cdot}$ occurs.[46,47]

II. Cleavage of C–C bonds in alkanes on a metal site

During the last thirty years significant progress has been made in the use of transition metal complexes for activating inert covalent bonds,[48–64] and C–H bonds in paraffins. However, all of the known catalytic conversions of unactivated alkanes and cycloalkanes by transition metal complexes in the liquid phase relate only to C–H bonds and not C–C bonds. Cleavage of C–C bonds only occurs in strained cycloalkanes and in energy-rich polyhedranes (see the review of Crabtree).[6]

What is the reason for the high degree of inertness of C–C bonds compared to C–H bonds in alkanes? The energies of σ-bonds (in kcal mol^{-1}) are given below:[65,66]

H–H	C–H	C–C
104	96–105	87–90

It follows from this that the C–C bond is appreciably less stable than the C–H and H–H bonds. However, their reactivity increases in reverse order. Thus, molecular hydrogen is fairly readily activated by a large number of metal complexes while examples of the activation of C–H bonds in alkanes and cycloalkanes are quite well known although comparatively rare. On the other hand the catalytic cleavage of C–C bonds in paraffins by metal complexes in the liquid phase has until recently not been reported at all:

Increase in reactivity ←

H–H C–H C–C

→ Decrease in bond strength

The theory that the metal-complex cleavage of a C–C bond to form two weak C–M bonds, the energy of which does not compensate the energy of cleavage of the C–C bond, is thermodynamically unfavourable has been made widely known.[5,6] Thus, it follows from the experimental results of Halpern[5] that the energy of the Co–R bond in dimethylglyoximate complexes $RCo(dmg)_2$ and the R–Mn bond in the complexes $RMn(CO)_5$ and $RMn(CO)_4(PPh_3)$ is in the range 18–25 kcal mol^{-1}. Halpern assumes that for other metals of the 3*d* series (end of the period) the same order of magnitude of M–C bond energy is typical. At the same time the energies of the corresponding M–H bonds are 52–80 kcal mol^{-1}. It was concluded from this that the oxidative addition of the H–H bond to the metal site of a complex is exothermic while addition of C–H bonds is an endothermic process. The oxidative addition of C–C bonds to a metal complex is thought to be even more thermodynamically unfavourable. However, this does not appear to be a general conclusion. Judging by the small amount of data on the M–C bond energies in solution for certain transition metals of the 3*d* series (beginning of the period), 4*d* and 5*d* series, lanthanides, and actinides, these values are considerably higher than those quoted (see Tables 2 and 3). We should note that the energies of M–C bonds in cationic complexes is higher than in neutral complexes and is approximately equal to the energies of M–H bonds (Table 3). As will be demonstrated below, the energies of $M^+{-}CH_3$ bonds in the gas phase are higher than the energies of the corresponding $M^+{-}H$ bonds. Thus, the thermodynamic restrictions on the cleavage of C–C bonds with metal complexes are not obligatory. The thermodynamics of these reactions also depend to a large extent on the characteristics of the metal complex and in certain cases they can be exothermic.[74]

Table 2. Energies of M–Alk bonds.

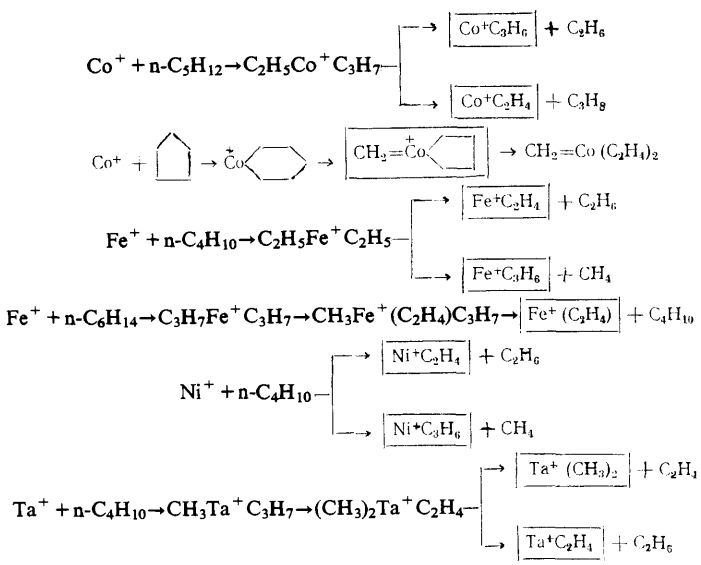
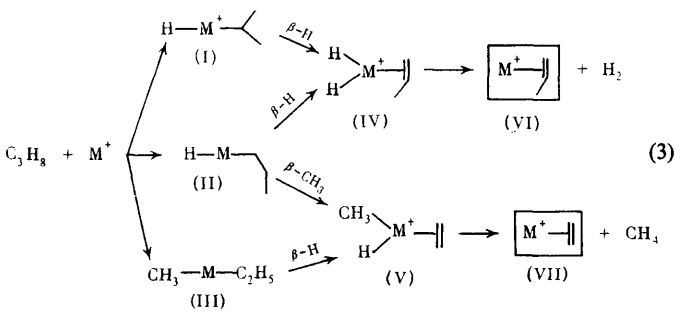
Table 3. Calculated energies of the M–C and M–H bonds in transition metal carbonyl complexes[73].



Complex	Energy of M–X bond, kcal mol^{-1}		Complex	Energy of M–X bond, kcal mol^{-1}	
	X=CH_3	X=H		X=CH_3	X=H
$XMn(CO)_5$	37	54	$XIr(CO)_4$	51	68
$XRe(CO)_5$	48	67	$XRe(CO)_5^+$	57	60
$XCo(CO)_4$	38	55	$XNi(CO)_4^+$	60	62
$XRh(CO)_4$	45	61			

These conclusions are supported by the literature data on the cleavage of C–C bonds in alkanes and cycloalkanes on a "ligand-free" metal site. These data will be examined below. On the other hand, all of the experimentally obtained material indicates the outstanding importance of steric factors in the attack by a metal complex or metal on a C–C bond.

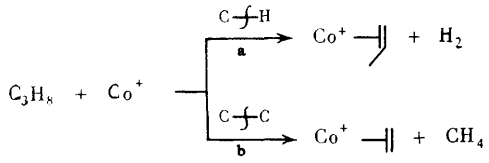


1. Cleavage of C–C bonds by metal ions in the gas phase

Alkanes and cycloalkanes can react with Fe^+, Ni^+, Co^+, Ta^+ and other ions in the gas phase.[75–92] The reactions are accompanied by cleavage of not only C–H but also C–C bonds. Furthermore, the cleavage of C–C bonds is frequently an exothermic process and constitutes the predominant conversion route of paraffins.

Examples of the cleavage of C–C bonds in alkanes and cycloalkanes by metal ions in the gas phase are given below (the observed reaction products are enclosed in boxes):

The proposed mechanism for the interaction of alkanes with Co^+, Ni^+, Fe^+, and other ions (for the reaction with propane) is shown in scheme (3):[86–89]



(3)

Scheme (3) involves the oxidative addition of C–H and C–C bonds of the alkane to M^+ to form intermediates (I), (II), and (III), the intramolecular transfer of β-H and β-CH_3 groups to the metal, resulting in the formation of dihydride (IV) and alkylhydride (V) olefin complexes, and elimination of H_2 from intermediate (IV) and CH_4 from intermediate (V) to give the observed olefin complexes (VI) and (VII).

Recently the reaction of alkanes with Co^+ and Ni^+ ions was made the subject of a more thorough investigation.[89] In this case an unusual feature of the reaction between propane and Co^+ was detected, which lay in the fact that of the two parallel reactions for cleavage of a C–H bond (4a) and a C–C bond (4b), the first predominates at low energies (0.1 eV) and the second predominates

at high energies (1 eV). The ratio of yields of $Co^+C_2H_4$:$Co^+C_3H_6$ was 1:2 in the first case and 3:1 in the second case.

(4)

Georgiadis et al.[89] assumes that cleavage of the C–C bond (4b) at a low energy occurs to a lesser degree because the overall reaction (4b) includes the endothermic elimination of methane from intermediate (V) [(V)→(VII) in scheme 3)], the energy barrier of which is 1.6 ± 0.7 kcal mol^{-1}. According to estimates, on going from methane to heavier homologues with the number of carbon atoms not less than 3, this barrier decreases from 19 to only a few kcal mol^{-1}. Since there is an endothermic stage, the overall exothermic‡ reaction (4b) [(II) or (III)→(V)→(VI) in scheme (3)] occurs with greater difficulty than reaction (4a), in which there is no endothermic stage [(I) or (II)→(IV)→(VI) in scheme (3)].

The two alternative mechanisms given in scheme (3) were examined[89] in order to explain why the C–C bond is preferentially cleaved as a result of the reaction between propane and Co^+ at high energies and also as a result of a wide range of reactions between alkanes and Ni^+, Fe^+, and Co^+ at all energies.

In accordance with the first mechanism, cleavage of the C–C bond occurs solely as a result of the insertion of M^+ into this bond [via intermediate (III)]. On the other hand, the transfer of the β-CH_3 group (III)→(V) does not occur. In this case the ratio of yields of products $M^+C_2H_4$:$M^+C_3H_6$ is determined completely by the ratio of probabilities of the oxidative addition of M^+ to the C–C and C–H bonds. The predominance of C–C clevage is due to thermodynamic factors—a weaker bond (compared to C–H) is broken and a stronger M^+–C bond (compared to M^+–H) is formed (Table 4).

The alternative mechanism is based on the assumption that both reactions for cleavage of the C–H and C–C bonds start with a common stage involving insertion of M^+ into C–H bonds. Insertion of M^+ into the C–C bond does not occur because of steric hindrance. The cleavage of the C–C bond occurs through the successive reactions (II)→(V)→(VII) [scheme (3)]. In this case preferential cleavage of the C–C bond may occur because transfer of the β-CH_3 group [(II)→(V)] predominates over transfer of β-H [(I) or (II)→(IV)] since formation of a stronger $M-CH_3$ bond is more favourable. In this case the ratio of $M^+C_2H_4$:$M^+C_3H_6$ or

$$C\text{–}C \,/\, C\text{–}H$$

must be equal to the ratio of the number of primary to secondary C–H bonds in propane, i.e., 3:1. This ratio actually occurs in the reaction of propane with Fe^+.[90] In the reaction of propane with Ni^+ the ratio of

$$C\text{–}C \,/\, C\text{–}H$$

increases to 3.5–4.0:1, which in the opinion of Schultz et al.,[90] could indicate a certain contribution from the mechanism for insertion of Ni^+ into a C–C bond. This reaction is exothermic, in contrast to the competing reaction for insertion of Ni^+ into a C–H bond (Table 4). Houriet et al.[91] have also shown that Ni^+ is mainly inserted into a C–C bond in reactions with linear alkanes.

Table 4. Energies of $M-CH_3$ and M–H bonds in the gas phase (kcal mol^{-1})*.

*The results of different authors cited in two studies[88,89] are summarised.

The ease of cleavage of the C–C bonds of alkanes by Fe^+, Ni^+, and Co^+ ions is due to the high energy of the M^+-CH_3 and $M-CH_3$ bonds in the gas phase. These energies are similar to the corresponding values of M^+–H and M–H and even exceed them (Table 4). Thus, the ratio of energies of these bonds in the gas phase is the opposite of what appears in solution. The difference in the strength of the bonds in the gas and condensed phases is attributed to the effect of steric factors in saturated systems (solution), resulting in a weakening of M–C bonds,[93] and also to the possibility of stabilisation of charge by the more polarisable alkyl group compared to H in ionic species in the gas phase.[83,86,89]

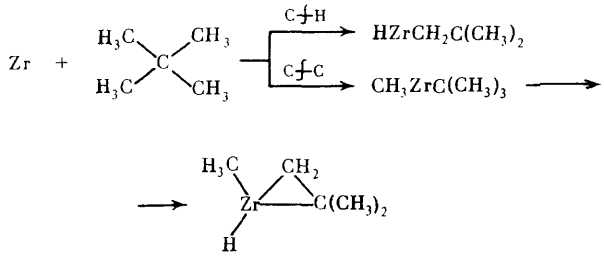
It should be emphasised that in all cases addition of a ligand to the metal inhibits cleavage of C–C bonds even in the gas phase. For example, replacement of Fe^+ by $Fe(CO)^+$ [77] and $Fe(CH_2)^+$ [84] is accompanied by a decrease in the proportion of C–C cleavage. The more shielded $Fe(CH_3)^+$ ion is completely inactive towards

‡ The energy of the $Co^+-C_2H_4$ bond (46 ± 8 kcal mol^{-1}) is 26 ± 8 kcal mol^{-1} greater than that needed for cleavage of the C–C bond.

aliphatic hydrocarbons.[85] In reactions of FeH^+, CoH^+, NiH^+, and $Co(CH_3)^+$ ions with alkanes only C–H bonds participate.[85,92] In contrast to the Ni^+ ion, the 14-electron complex $(\eta^5\text{-}C_5H_5)Ni^+$ does not cleave C–C bonds in hydrocarbons.[86]

Thus, the greater the steric hindrance, the lesser is the ability of the attacking species to cleave C–C bonds.

2. Cleavage of C–C bonds with small metal clusters

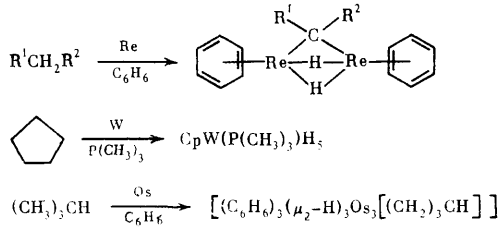


It was first shown in a study by Davis and Klabunde[91] that when atomic Ni and pentane are co-condensed at a low temperature very active small Ni clusters are formed, reacting with pentane even at −130 °C. In this case oxidative addition of the C–H and C–C bonds of the alkane to the Ni atoms occurs:

$$m\ Ni + n\ C_5H_{12} \xrightarrow{-196\,^\circ C} Ni_m(C_5H_{12})_n \xrightarrow[C\not\leftarrow H,\ C\not\leftarrow C]{-130\,^\circ C} \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!\diagdown\!\!(Ni)_m\!\!\diagup\!\!\begin{matrix} R^3 \\ R^4 \end{matrix}$$

R^1, R^2, R^3, R^4 = Alk, H.

The organic groups on the Ni atom inhibit the further agglomeration of clusters.



A similar pattern was observed in the co-condensation of Zr atoms with neopentane or isobutane.[95] Reaction of Zr with the alkane resulted in the formation of heterogeneous organozirconium surface complexes, to which Remick et al.[95] have attributed the following structure:

At the present time quite a few different examples of the vapour-phase synthesis of systems of a similar type are known.[96–101] They have various names in the literature: SMAD (Solvated Metal Atom Dispersion), obtained by dispersion of solvated metal atoms;[33,99–102] pseudo-organometallic powders;[33] ultradispersed metals;[103] ligand-free clusters;[103] metal microcrystals;[104] and others. In our opinion the most apt name is "low-ligand clusters",[105] reflecting the main characteristic of these systems.

Low-ligand clusters (LLCs) are intermediate between a compact metal and molecular clusters, being distinguished from both by the high percentage of surface atoms with low coordination numbers. In a bulk metal there are no ligand but the proportion of surface atoms is small while in molecular clusters all of the metal atoms are essentially saturated with ligands. The high percentage of surface atoms with low coordination numbers also governs the potentialities for using LLCs in catalysts, in particular for the cleavage of C–C bonds. The LLCs of nickel obtained by vapour-phase synthesis at normal temperatures are particles with a diameter of 25–36 Å or more (depending on the conditions of synthesis).[96] In terms of their catalytic activity they are superior to traditional Ni hydrocracking catalysts.[99,101] These systems can be used both in a pure form and in the form of particles deposited LLCs being the absence of a deactivating effect from the support.[102] The reasons for the increased activity of LLCs are discussed by Matsuo and Klabunde.[99] Bimetallic LLCs exhibit a particularly high activity.[100,101,106] For example, the presence in Co/SiO_2 of 2.5 at.% Mn–metal, which in itself is inactive in the hydrocracking of saturated hydrocarbons, increases the activity of the catalyst by a factor of 10^2.[100] It should be noted that the promotion of heterogeneous platinum catalyst with rhenium is widely used in industry.[107]

If the co-condensation of an atomic metal with an alkane takes place in the presence of a ligand [$P(CH_3)_3$, benzene], the reaction route changes considerably. In this case the conversions of alkanes take place solely with the participation of C–H bonds. On the other hand, the stabilising effect of the ligand hinders the agglomeration of the organometallic particle being formed. This method has been used for the synthesis of organometallic compounds:[108,109]

A serious disadvantage of the vapour-phase method for synthesising LLCs (in particular heavy metals, which are the most promising as catalysts) is the necessity to use special high-vacuum equipment. Therefore an attempt was made to synthesise catalysts for the cleavage of C–C bonds of alkanes based on LLCs by the conventional reduction of a transition metal compound in solution under conditions that excluded the deactivation of the LLC being formed.[105] It was shown that the reduction of OsO_4 in an alkane or arene with molecular hydrogen at 100–150 °C for 3–15 h or at 20 °C for 3 days resulted in the formation of active catalysts for the hydrocracking of paraffins:

$$OsO_4 + 4\,H_2 \xrightarrow[-4H_2O]{} \ll Os \gg \xrightarrow{RH} Os_{2.5-1.5}C_1H_{2-0}$$

An analysis of the EXAFS spectra showed that the pyrophoric osmium catalysts obtained in this way are actually Os LLCs with a particle diameter of 7–12 Å (if the synthesis is carried out at 20 °C) or 12–20 Å (at 150 °C). The combined data on hydrogenation and deuteration of the dry catalyst and other material suggest that the clusters are stabilised by carbon-containing ligands (probably CH_3, CH_2, CH, and C≡). It was established using EXAFS and XANES§ that for every surface Os atom there were 0.39–0.64 C atoms and the Os–C distance was 2.11–2.19 Å.[110]

The LLCs of Os obtained by a chemical method have similar properties to the LLCs of Ni and Co that are synthesised by a vapour-phase method (Table 5). The main product of the hydrogenation of all of these LLCs is methane.

Osmium LLCs have considerably higher activity than that of both cellular osmium and osmium black. The latter even at 180 °C is appreciably less active than osmium LLCs at 100 °C. At the same time fine LLCs (10 Å) exhibit higher activity than the coarser forms.[105] Hydrocracking of alkanes and cycloalkanes in the

§ X-Ray Absorption Near-Edge Structure.

presence of osmium LLCs takes place effectively at 100–150 °C at an initial H_2 pressure of 50 atm. Under these conditions 1 mole of catalyst has converted hundreds of moles of hydrocarbon after 5–15 h, and the catalyst can be used repeatedly without loss of activity.

Table 5. Certain properties of LLCs of osmium,[105] nickel, and cobalt[96].

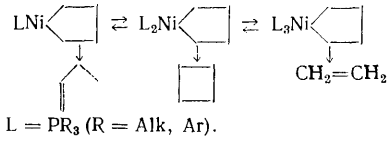
LLC	Overall composition	Specific surface $m^2 g^{-1}$	Particle size, Å
Os (20° C)*	$Os_{1,5}CH_{0-2}$	34	7–12
Os (150° C)*	$Os_{2,3-2,5}CH_{0-2}$	46	12–20
Ni**	$Ni_{2-9}CH_{2-3}$	37–40	25–36
Co**	Co_4CH_2	—	18–21

* Obtained by chemical synthesis.
** Obtained by gas-phase synthesis.

We can illustrate the composition of the products from the hydrocracking of certain alkanes and cycloalkanes (in moles per mole of converted RH) on osmium (LLCs) with a particle size of 10 Å (Os-I) and 20 Å (Os-II) (initial H_2 pressure 50 atm., reaction time 15 h):[105]

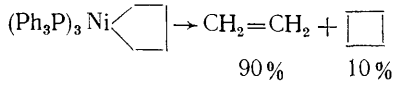
$$n\text{-}C_5H_{12} + H_2 \xrightarrow[89\%\ \text{conversion of RH}]{\text{Os-I, 120° C}} \underset{0.06}{C_4} + \underset{0.31}{C_3} + \underset{0.71}{C_2} + \underset{2.20}{C_1}$$

$$n\text{-}C_6H_{14} + H_2 \xrightarrow[60\%]{\text{Os-II, 150°}} \underset{0.10}{C_5} + \underset{0.04}{C_4} + \underset{0.11}{C_3} + \underset{0.50}{C_2} + \underset{3.29}{C_1}$$



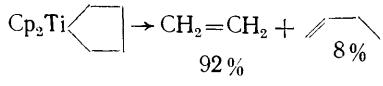
$$cyclo\text{-}C_5H_{10} + H_2 \xrightarrow[94\%]{\text{Os-II, 120° C}} \underset{0.88}{C_5} + \underset{0.04}{C_4} + \underset{0.07}{C_3} + \underset{0.09}{C_2} + \underset{0.22}{C_1}$$

$$cyclo\text{-}C_6H_{12} + H_2 \xrightarrow[89\%]{\text{Os-II, 150°C}} \underset{0.25}{C_6} + \underset{0.10}{C_5} + \underset{0.11}{C_4} + \underset{0.14}{C_3} + \underset{0.24}{C_2} + \underset{0.44}{C_1}$$

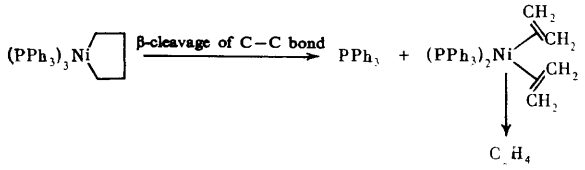


The conversion products of n-alkanes containing 5, 6, 8, or 18 carbon atoms (120–150 °C, 15 h) are represented by the complete range of lower alkanes from C_1 to C_{n-1}, with 80–97% of this being made up as a rule by methane, ethane, and propane. All of the products of cracking of n-alkanes have a linear structure. Cyclopentane and methylcyclopentane undergo hydrogenolysis to an appreciable extent at 100 °C. At 100–120 °C the hydrogenolysis of cyclopentane is effective and takes place selectivity to give n-pentane—a product of ring-opening. Selective opening of the ring also occurs in methylcyclopentane with cleavage of the least shielded bonds and formation of 2- and 3-methylpentanes.

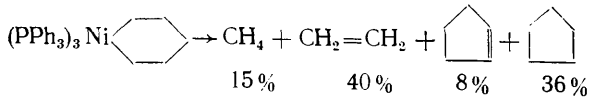
3. Cleavage of C–C bonds in alkyl complexes of transition metals



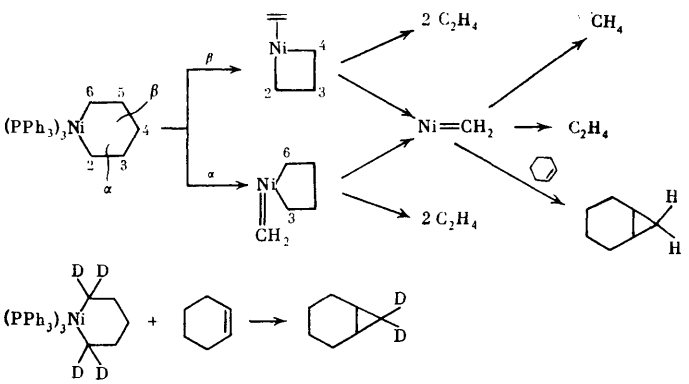
By assuming that C–C bonds are cleaved in intermediate alkyl complexes of transition metals in the gas phase (see Section II), it is possible effectively to elucidate the large quantity of experimental material on the reactions of alkanes and cycloalkanes with metal ions. The reactions of this type could be observed directly in solution. Thus, phosphine complexes of nickel metallocyclopentanes undergo reductive elimination, β-hydride elimination, and C–C cleavage.[111] The contribution of each of these processes depends on the coordination number of the Ni atom:



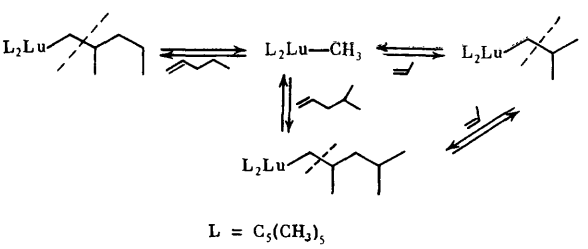
The Ni triphenylphosphine complex with the highest coordination number decomposes to form ethylene and cyclobutane;



Ethylene is also formed as the main product from a titanocyclopentane complex:

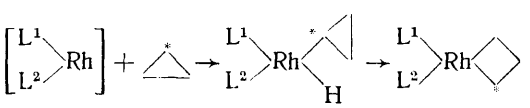


In both cases reaction takes place with the formation of intermediate bis(ethylene) complexes:[112]



Cleavage of C–C bonds also occurred in Ni-cyclohexane:[111]

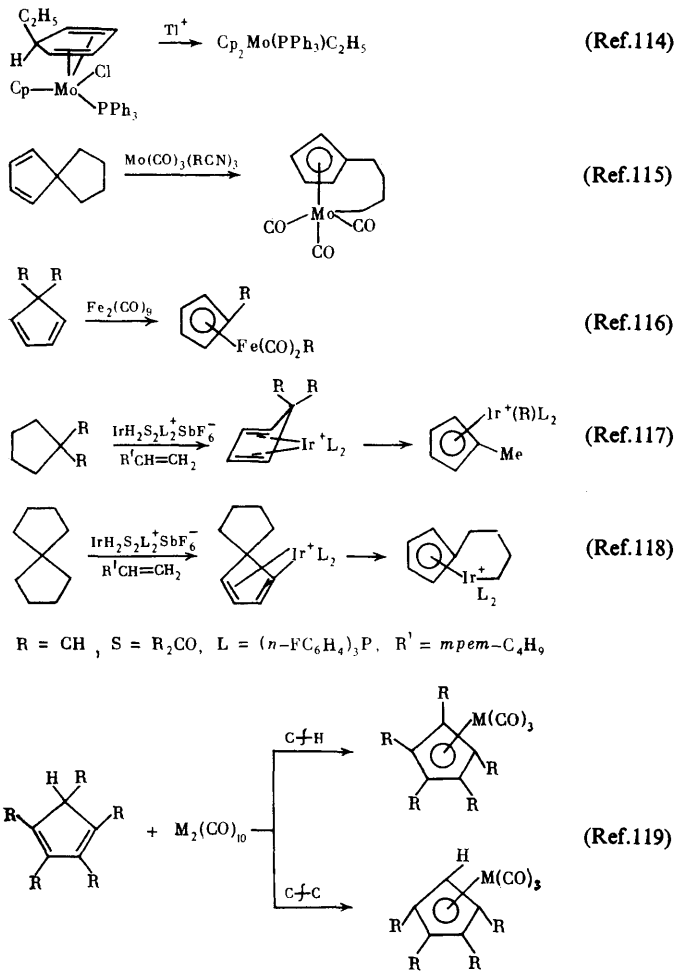
It was possible to demonstrate using complexes labelled with deuterium and with the use of traps (cyclohexene) that of the two possible routes for cleavage of C–C bonds α-elimination predominates.



The β-cleavage [sic] of C–C bonds was observed in lutetium alkyl complexes.[113] In this case the cleavage and formation of C–C bonds are reversible:

These reactions, which take place in solution, represent the α- and β-cleavage of C–C bonds in alkyl complexes of transition metals. The proposed cleavage of C–C bonds according to scheme (2b) is thus confirmed experimentally.

Another form of cleavage of a C–C bond in a Rh cyclopropyl derivative has also been reported:[56]



$L^1 = C_5(CH_3)_5$, $L^2 = P(CH_3)_3$.

4. Stoichiometric cleavage of C–C σ-bonds in hydrocarbons by transition metal complexes in solution

Because the cleavage of C–C bonds in alkanes by an attacking species is severely inhibited when steric hindrance increases, cases of the cleavage of single C–C bonds by transition metal complexes (even stoichiometric reactions) are extemely rare.

Examples of such reactions[114–119] are given below:

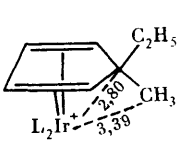
(Ref.114)

(Ref.115)

(Ref.116)

(Ref.117)

(Ref.118)



R = CH, S = R_2CO, L = $(n\text{-}FC_6H_4)_3P$, R' = *mpem*-C_4H_9

(Ref.119)

R = CH_3, when M = Mn
when M = Re the C–C bond is not cleaved.

In these examples, as in other similar reactions, the driving force of the reaction is formation of the π-complex of a cyclopentadienyl aromatic system, which provides an additional energy gain of 25 kcal mol^{-1}.

It is interesting that an agostic C–C bond was first detected[18] in the complex

The reactions of alkanes and cycloalkanes with carbonyl and carbonylhydride clusters of osmium and iridium, "bare" clusters of bismuth, and other clusters[120] have also been studied. In all cases

cleavage of a C–C bond in RH ny ML_n at 180 °C was found not to occur

$$RH \xrightarrow{ML_n,\ 180^\circ C} \gtrless C\text{–}C \lesssim \quad \text{does not occur}$$

RH = n-C_6H_{14}, cyclo-C_5H_{10}, cyclo-C_5H_9R, cyclo-C_6H_{12} etc.,

ML_n = $Ir_4(CO)_{12}$, $Os_3(CO)_{12}$, $H_2Os_3(CO)_{12}$, Bi_4^{2-}, Bi_5^{3-} etc.

Muetterties came to the conclusion that the use of metal carbonyl clusters in reactions involving aliphatic hydrocarbons had no future potential.[120]

Table 6. Logarithms of equilibrium constants of the hydrocracking reactions of alkanes and cycloalkanes calculated from the data of Zhorov[45].

Reaction	K_p, at T, K		
	300	500	700
$C_6H_6+H_2 \rightleftarrows 2CH_4$	11.971	7.472	4.359

$C_8H_{18}+H_2 \rightleftarrows C_2H_6+C_6H_{14}$	8.637	5.483	4.008
cyclo-$C_5H_{10}+H_2 \rightleftarrows C_5H_{12}$	7.157	3.374	1.341
cyclo-$C_6H_{12}+H_2 \rightleftarrows C_6H_{14}$	5.560	2.520	1.207

One report[121] states that the fragmentation of alkanes on exposure to γ-radiation is inhibited in the presence of $Co_2(CO)_8$ and at the same time there is the formation of $Co_3(CO)_9CR$ complexes, where R = CH_3, C_2H_5, and $CH(CH_3)_3$.

5. Catalytic cleavage of C–C bonds in alkanes and cycloalkanes by Ziegler-type systems

By taking into account the considerably steric shielding of the carbon atoms of a C–C bond, Akhrem et al.[122,123] formulated the requirements which must be satisfied by transition metal complexes that are capable of activating and cleaving such bonds:

a) the transition metal–carbon bond energy must be fairly high, which on the whole is typical for metals of the higher periods;

b) the degree of oxidation of the metal must be low, in other words, the metal must be capable of undergoing oxidative addition with ease;

c) the complex must have a low coordination number, which ensures the minimum steric hindrance in attack on the C–C bond;

d) ligands of a small size must be present on the metal atom, giving rise to the minimum steric hindrance (for example, H and CO).

Since conditions a–d will be conductive to activation of not only C–C bonds but also the more reactive C–H bonds, a shift in the equilibrium towards cleavage of C–C bonds according to scheme (5) could be assisted by inclusion into the reaction sphere of an additional reagent that reacts irreversible with the product of

Table 7. Hydrogenolysis of saturated hydrocarbons by systems based on rhenium carbonyl complexes and organoaluminium compounds[122].

[a] A = iso-$(C_4H_9)_2AlH$, B = $(C_2H_5)_3Al$; [b] n-alkanes in every case except those marked with an asterisk; [c] $(C_2H_5)_3Al$ is a source of ethane in addition to the hydrocarbon; [d] C_8 (0.06), C_9 (0.14), and C_{10} (0.14) alkanes are also formed.

insertion of the metal complex into this bond. This type of reagent could be, for example, hydrogen:

$$\begin{array}{c} RCH_2CH_2{-}M{-}H \rightleftarrows RCH_2CH_3 + M \rightleftarrows RCH_2{-}M{-}CH_3 \\ \downarrow H_2 \qquad\qquad\qquad\qquad\qquad\qquad \downarrow H_2 \\ RCH_2{-}CH_3 + MH_2 \rightleftarrows M + H_2 + RC_2H_5 \; RCH_3 + CH_4 + MH_2 \end{array} \quad (5)$$

It is significant also that the hydrocracking of saturated hydrocarbons is a thermodynamically favourable reaction (especially at lower temperatures, see Table 6).

Thus, the problem could be stated as follows: to study the possibility of cracking paraffins with H_2 on catalysts which meet conditions a–d.

An experiment with a number of compounds of different transition metals, mainly from Groups VI–VIII (carbonyls, carbonylhydrides, oxides, halides) and systems based on them, showed that the rhenium carbonyl and carbonylhydride complexes $Re_2(CO)_{10}$, $Re_3H_3(CO)_{12}$, $Re_4H_4(CO)_{12}$ in combination with organoaluminium compounds [$Al(C_2H_5)_3$, $(iso\text{-}C_4H_9)_2AlH$] are actually capable of activating C–C bonds in alkanes and cycloalkanes such as hexane, octane, cyclopentane, methylcyclopentane, cyclohexane, and others, and of catalysing their hydrogenolysis. The reactions occur in the respective hydrocarbon at 150–180 °C and at an initial H_2 pressure of 50 atm. At 180 °C after several hours a conversion close to quantitative is achieved, 1 mole of rhenium compound catalysing the conversion of hundreds of moles of hydrocarbons (Table 7).

The activity of the catalytic system depends to a considerable extent on the ratio of the components. Thus, the activity of the catalyst formed by interaction of $Re_2(CO)_{10}$ with $(iso\text{-}C_4H_9)_2AlH$ reaches a maximum at an atomic ratio of Al : Re = 3 : 1, with an increase of this ratio to 5.5 : 1 or a decrease to 1.5 : 1 leading to complete loss of activity.

The catalyst remaining after removal of the gaseous and liquid reaction products retains its activity and can cause subsequent batches of hydrocarbon to undergo hydrogenolysis. Organoaluminium compounds used separately, in the same way as rhenium complexes [$Re_2(CO)_{10}$, $Re_3H_3(CO)_{12}$, $Re_4H_4(CO)_{12}$, $CpRe(CO)_3$, Na_2ReH_9, Na_2ReH_9 + 18-crown-6] in the absence of organoaluminium compounds, do not have any hydrocracking activity towards alkanes (the reaction was carried out at 180 °C for 40 h.[122,123]

The main conversion products of n-alkanes at the early stages of the reaction are methane and linear hydrocarbons that contain one carbon atom less than in the original paraffin. Thus, in paraffins initially it is mainly the terminal CH_2-CH_3 bonds that are cleaved:

$$R{-}CH_2CH_3 + H_2 \xrightarrow{[Re]} RCH_3 + CH_4$$
$$\downarrow [Re]H_2$$
$$C_1 + C_2 + C_3 + \text{etc.}$$

The primary products of the hydrocracking of unsubstituted cycloalkanes are mainly linear alkanes with the same number of carbon atoms:

$$\underset{(CH_2)_n}{\bigcirc} + H_2 \xrightarrow{[Re]} H{-}(CH_2)_n{-}H$$
$$\downarrow [Re]H_2$$
$$C_1 + C_2 + C_3 + \ldots \text{ etc.}$$

Also, in the conversion products of alkanes and cycloalkanes lower hydrocarbons formed through subsequent multistage hydrogenolysis are always present. The proportion of these increases with an increase in conversion of the initial paraffin.

The catalysts are X-ray-amorphous insoluble pyrophoric powders containing Re (70%), Al (16%), C (4–9%), and H (1–2%). Hydrogenation of the catalysts with hydrogen at 100–200 °C or protolysis of them (using aqueous H_2SO_4 and CH_3COOH) leads to the isolation of C_1-C_5 alkanes (mainly C_4-C_5).

In the IR spectra of the catalysts two weak absorption bands occur at 1900 and 2025 cm^{-1}, which are attributed to Re–H bond vibrations. Analysis of the EXAFS spectra of the L_{III} region of rhenium showed that each rhenium atom is bound to 2–3 carbon atoms (Re–C distance is equal to 2.18 Å) and to 1–2 metal atoms (Re–M bond length is 2.6–2.7 Å, M = Re or Al). Thus, there is reason to believe that the catalytic systems obtained are organometallic rhenium hydride complexes.[122,123]

III. Novel superacid complexes — effective reagents and catalysts of low-temperature conversions of alkanes and cycloalkanes

The basicity of alkanes is low and therefore the rate of their conversions by even strong proton and aprotic acids at 20 °C is extremely slow.[43,44,124–126]

In our research into effective electrophilic catalysts for conversions of paraffins we turned our attention to the well-known Friedel–Crafts complexes $RCOX.AlX_3$.[127–132] At room temperature, in the same way as aluminium halides, they are inactive in reactions with alkanes.[124] However, a molecule of acid chloride contains two potentially nucleophilic sites X–C(R)=O and only one of these participates in the formation of an $RCOX.AlX_3$ complex. It has transpired that addition of a further mole of AlX_3 to traditional $RCOX.AlX_3$ systems causes a rapid change in their properties, converting complexes that are inert towards paraffins into very active reagents which have higher reactivity than not only Lewis acids and systems based on them but also, as a rule, the strongest proton superacids. Complexes of this type have been called aprotic organic superacids (AOS).[27,28,133]

1. Cracking of n-alkanes

$RCOX.2AlX_2$ complexes (R = CH_3, R = C_3H_7, X = Br, Cl) react extremely readily with C_5-C_{18} n-alkanes. In this case the latter undergo cracking to form the same principal products.[133,134]

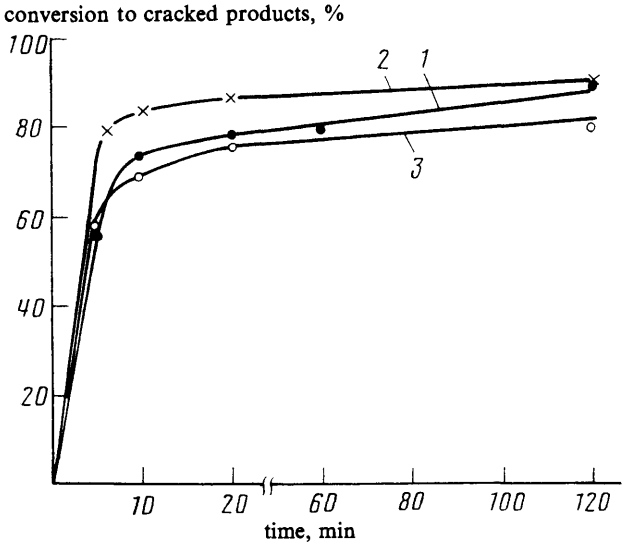
$$C_nH_{2n+2} \xrightarrow{RCOX_2AlX_2} iso\text{-}C_4H_{10} + iso\text{-}C_5H_{12} + iso\text{-}C_4H_9COR +$$
$$+ iso\text{-}C_4H_7COR + \text{oligomer}$$

For alkanes with *n* ranging from 5 to 18 conversion reaches 100% after 30 min at 20 °C. The resulting oligomers are branched polyunsaturated hydrocarbons with a molecular weight of 700–800.

Isobutane, isopentane, and oligomeric products are also formed when alkanes are treated with other catalysts based on aluminium halides, but these reactions occur under quite different conditions.[124–126]

The rate of catalytic cracking of n-alkanes in solution is especially high. Thus, in the presence of the complex $CH_3COBr.2AlBr_3$ (VIII) in CH_2Br_2 the conversions of C_8-C_{18} alkanes to cracked products

at room temperature reach 70–85% after only 10 min, and in the presence of the complex $CH_3COX.2AlCl_3$ (IX) there is 57–70% conversion after 20 min (Figs. 1 and 2). Such high rates of cracking do not occur even when the most active proton superacid systems are used, so that AOS, and primarily (VIII), can be classed as one of the most active catalysts for the fragmentation of n-alkanes. However, the number of catalytic cycles does not exceed 15 and decreases with an increase in length of the carbon chain of the alkane. Cyclododecane behaves similarly towards $RCOX.2AlX_3$ complexes. At room temperature it is cracked very readily to give the same principal products.



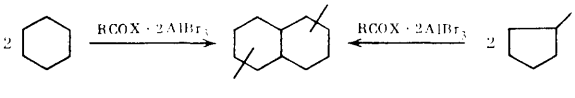


Figure 1. Cracking of C_8–C_{18} n-alkanes by the complex $CH_3COBr.2AlBr_3$ in CH_2Br_2 solution (20 °C, $[CH_3COBr]$ = 0.20 mol litre^{-1}) at the following ratios: *1*, $C_8H_{18}:CH_3COBr.2AlBr_3$ = 10:1; *2*, $C_{12}H_{26}:CH_3COBr.2AlBr_3$ = 5:1; *3*, $C_{18}H_{38}:CH_3COBr.2AlBr_3$ = 3:1.[133]

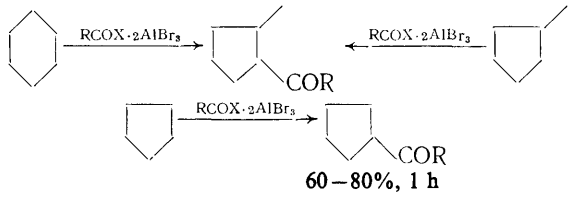
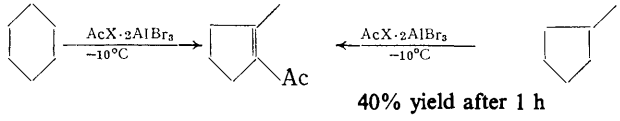


2. Oxidative combination and acylation of C_5–C_6 cycloalkanes

Aprotic organic superacids readily react with five- and six-membered cycloalkanes at 20 °C and lower temperatures.[27] The reactions occur by one of the three routes indicated below, and in certain cases the product yields are quite high. When there is excess cycloalkanes and in the absence of a solvent, cyclohexane or methylcyclopentane undergo oxidative coupling to form dimethyldecalins (mainly the 2,6- and 2,7-isomers):



[the ratio of RH:(VIII) = 12:1; at 20 °C conversion is 100% after 1 h]. An increase in the concentration of electrophilic reagent suppresses this process and favours the acylation of cycloalkanes.

Acylation is the sole route for cyclopentane under all conditions.

On increasing further the concentration of acylating agent, namely, when it is in excess, when the temperature is lowered dehydroacylation of cyclohexane or methylcyclopentane can be achieved:

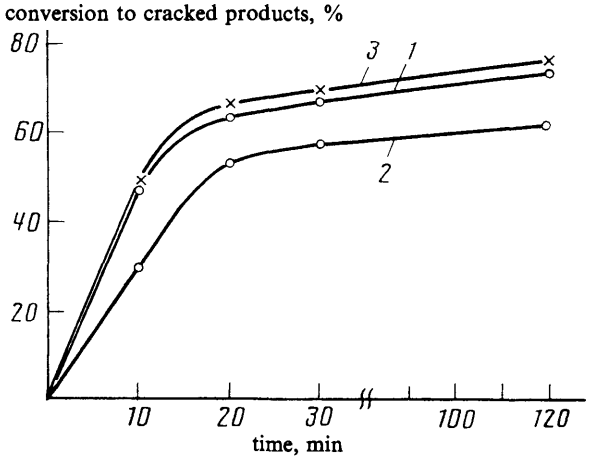


Figure 2. Cracking of C_8–C_{18} n-alkanes by the complex $CH_3COBr.2AlBr_3$ in CH_2Br_2 solution (20 °C, $[CH_3COBr]$ = 0.43 mol litre^{-1}) at the following ratios: *1*, $C_8H_{18}:CH_3COBr.2AlBr_3$ = 10:1; *2*, $C_{12}H_{26}:CH_3COBr.2AlBr_3$ = 5:1; *3*, $C_{18}H_{38}:CH_3COBr.2AlBr_3$ = 3:1.[133]

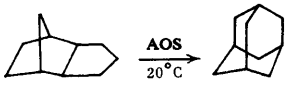
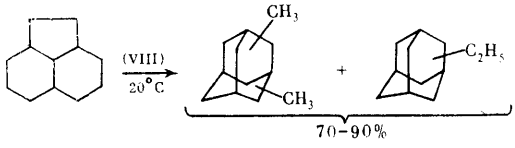


3. Isomerisation of C_4–C_6 n-alkanes to isoalkanes and saturated tricyclanes to adamantane and its homologues

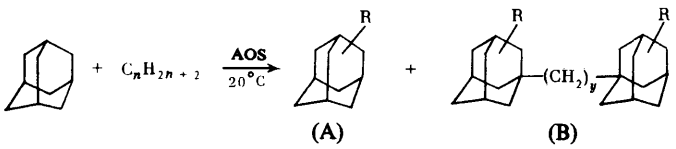
Complex (VIII) catalyses the isomerisation of n-butane to isobutane at 20 °C.[134,135] At a ratio of n-C_4H_{10}:(VIII) = 11:1 the equilibrium concentration of isobutane is reached within 3 h, the selectivity of isomerisation being 90% (at the earlier stages it is about 100%). In terms of activity complex (VIII) has no equal amongst all of the known catalysts for the isomerisation of n-butane, including the strongest proton superacids. Complex (IX), although less active than (VIII), is also more active than known catalysts based on AlX_3.



In contrast to higher alkanes, the cracking of n-pentane and n-hexane by aprotic organic superacids in CH_2Br_2 has an induction period during which there is a rapid and selective isomerisation of

n-pentane to 2-methylbutane, while n-hexane is isomerised to a mixture of all four possible isohexanes.[136] The yields of isoalkanes in the presence of (VIII) and (IX) reach 55–75% after 15–60 min and 50–60% after 90–120 min respectively with an almost complete absence of fragmentation.

Aprotic organic superacids effectively catalyse the synthesis of adamantane and its derivatives from isomeric saturated tricyclanes. Thus, they initiate the isomerisation of trimethylenenorbornane to adamantane:[13]



Complex (VIII) is also the most effective of all the known catalysts for isomerisation of perhydroacenaphthene or its isomeric $C_{12}H_{20}$ tricyclanes to a mixture of dimethyl- and ethyl-adamantanes in which 1-ethyladamantane predominates.[137] At 20 °C the initial hydrocarbons have already undergone quantitative conversion after only 5–12 min.

4. Alkylation of adamantane with n-alkanes

Alkylation of adamantane (AdH) with n-alkanes is a promising method for obtaining alkyladamantanes (AdAlk), whose use in the form of individual compounds or mixtures is of considerable interest.[138] The known methods for the alkylation of AdH are not very effective and are not at all suitable for the synthesis of higher AdAlk.[138–141] It was recently found that n-alkanes very readily alkylate AdH in the presence of AOS at 20 °C.[134,142] When stoichiometric quantities of complexes are used the conversion of AdH has reached 90–100% after 20 min. Under catalytic conditions [(AdH : (VIII)] = 8 : 1] the reactions with C_8–C_{18} alkanes are complete within 3 h, the total yield of AdAlk being 110–220 wt.% based on adamantane. The reaction products mainly comprise two types of compound—(A), which has a single adamantane ring with a total number of carbon atoms m ranging from 11 to 33, and (B) from m ranging from 23 to 51.

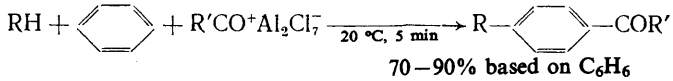
$n = 6–18$; R—one or more groups

In addition to the high rates of alkylation and yields of AdAlk, the possibility of regulating the composition of the resulting mixture with respect to the content of higher and lower homologues and the ratio of mono- to poly-AdAlk should also be included amongst the merits of this method.

5. Functionalisation of alkanes and cycloalkanes

The single-state functionalisation of paraffins is a promising method for the direct synthesis of organic compounds based on readily available hydrocarbon feedstocks.[14,15] Complexes (VIII) and (IX) effectively catalyse the ionic bromination of C_4–C_7 n-alkanes, cyclopentane, cyclohexane, trimethylenenorbornane, and other compounds at −20 and +20 °C to give exclusively or principally monobromides in high yield—55–370 wt.% based on complex (IX) and 110–910 wt.% based on (VIII).[143]

$$RH + Br_2 \rightarrow RBr + HBr.$$



The maximum yield of RBr based on Br_2 is 75%, bromination is not complicated by fragmentation. The monobromides that are formed from alkanes comprise mixtures of isomers; pure alkylcyclobromides are formed from cyclohexane and cyclopentane, which may be of interest synthetically. Until the study of Akhrem et al. was published,[143] the ionic bromination of n-alkanes had not been reported, while for simple iso- and cyclo-alkanes it was ineffective.[144,145]

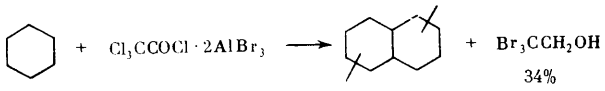
The considerable potentialities of AOS are indicated by other reactions for the functionalisation of alkanes which take place in their presence. One of these is the single-stage synthesis of organosulphur compounds from alkanes (or cycloalkanes) and elemental sulphur:

$$RH + S + R'CO^+Al_2X_7^- \xrightarrow[0-20\ ^\circ C]{} \underset{25-60\,\%}{\text{sec-RSCOR'}}$$

$RH = C_3H_8$, n-C_4H_{10}, n-C_5H_{12}, cyclo-C_5H_{10}, cyclo-C_6H_{12};
$R' = CH_3$, C_3H_7, Ph.

Another example is the alkylation and acylation of benzene in a single stage to form alkylated aromatic ketones. Isoalkanes and cycloalkanes with a tertiary carbon atom act as alkylating agents:

70–90% based on C_6H_6



RH = iso-C_4H_{10}, iso-C_5H_{12}, iso-C_6H_{14}, cyclo-$C_6H_{11}CH_3$.

6. Saturated hydrocarbons as reducing agents of acyl halides in the presence of $AlBr_3$

In the reactions between $RCOX.2AlX_3$ complexes and saturated hydrocarbons the latter act as reducing agents, initially converting the acyl halides which form part of these complexes into aldehydes:

$$RH + R'COX \cdot 2\,AlX_3 \rightarrow R^+ \ldots\ Al_2X_7^- + R'COH.$$

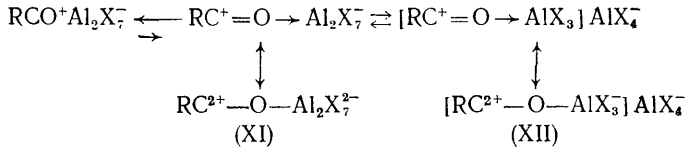
Examples of the reduction of acyl halides by saturated hydrocarbons in the presence of aluminium halides (20 °C, 1 h) are given below. In certain cases halogen exchange occurs in parallel with reduction.[134,146]

$$AdH + PhCOCl \cdot 2\,AlBr_3 \rightarrow \underset{70\,\%}{1\text{-Br-Ad}} + \underset{82\,\%}{PhCHO} + 2\,AlBr_3,$$

$$ClCO(CH_2)_3COCl + RH \xrightarrow[2)\ H_2O/H^+]{1)\ AlBr_3} \underset{40\,\%}{BrCH_2CH(Br)CH_2CH_2COH}.$$

7. Nature of the superacidic properties of $RCOX.2AlX_3$ complexes

With the aim of trying to account for the unusually high activity of $RCOX.2AlX_3$ complexes, which clearly distinguishes them from the well established $RCOX.AlX_3$ complexes, the structure of $RCOX.2AlX_3$ complexes (VIII) and (IX) and $RCOX.AlX_3$ complexes (X) were studied in the solid state and solution using NQR, ^1H, ^{13}C, ^{27}Al, and ^{17}O NMR and vibrational spectroscopy.[134,147,148] It was established that in the solid state they all comprise ionic acylium salts which differ only according to the structure of the anion: $RCO^+Al_2X_7^-$ for (VIII) and $RCO^+AlX_4^-$ for (X). In solution (CH_2X_2) (VIII) and (IX) consist of equilibrium mixtures of acylium salts $RCO^+Al_2X_7^-$ and donor-acceptor complexes $RC(X)=O\rightarrow Al_2X_6$, while complexes (X) exist solely in the form of coordination complexes $RC(X)=O\rightarrow AlX_3$:



$$RCOX + 2\,AlX_3 \rightarrow \underset{\text{in } CH_2X_2 \text{ solution}}{RC(X)=O\rightarrow Al_2X_6} \rightleftarrows RCO^+Al_2X_7^-,$$

$$RCOX + AlX_3 \rightarrow RC(X)=O\rightarrow AlX_3 \rightleftarrows RCO^+AlX_4^-.$$

In order to answer the question as to whether any acylium salt being generated in solution is capable of reacting at 20 °C with paraffins or whether the activity of the $RCO^+Al_2X_7^-$ acylium complexes is due to the presence of the dimeric anion forming part of its structure, it was necessary to synthesise two acylium salts that differed only according to the anion (one with a monomeric anion and the other with a dimeric anion) and to compare their reactivity. This problem was resolved in the case of two pairs of complexes: 1) $AcF.SbF_5$ and $AcF.2SbF_5$ (forming the acylium salts $Ac^+ScF_6^-$ and $Ac^+Sb_2F_{11}^-$ respectively in SO_2 solution); and 2) $MesCOBr.AlBr_3$ and $MesCOBr.2AlBr_3$ [which exist in CH_2Br_2 exclusively in the form of the ionic salts $MesCO^+AlBr_4^-$ and $MesCO^+Al_2Br_7^-$ respectively, Mes = 2,4,6-$(CH_3)_3C_6H_2$].[134,149] Only acylium salts containing a dimeric anion exhibited superacidic properties in reactions with alkanes and cycloalkanes while acylium salts with a monomeric anion were inactive at 20 °C.

Is it possible to relate such a marked difference in activity of $RCO^+AlBr_4^-$ and $RCO^+Al_2Br_7^-$ salts with the different degree of electrophilicity of the acylium cations in them? On the one hand it is true that the nucleophilicity of the $AlBr_4^-$ anion is greater than that of the $Al_2Br_7^-$ anion.[150] On the other hand, a substantial difference in the reactivity of these salts should be accompanied by an appreciable difference in the ^{13}C NMR spectra, which are very sensitive to a change in electron density. However, the ^{13}C NMR spectra of these salts are virtually identical, which raises doubts about the theory of the different electrophilicity of the acylium cations bound to monomeric and dimeric anions.[134,149]

The idea that in solutions of $RCO^+Al_2X_7^-$ complexes an equilibrium that is very much shifted to the left exists between the acylium salts and more electrophilic complexes in which the RCO^+ cations are coordinated with a Lewis acid deserves serious consideration.[149] It is clear that this type of coordination should lead to the formation of more electrophilic cations, which in the limiting case can be represented as acylium dications with the structures (XI) or (XII):

The latter probably exist in very low concentrations and cannot be identified by conventional spectroscopic methods, but it is they that are very likely to be responsible for the unusually high activity of $RCO.2AlX_3$ complexes—aprotic organic superacids.[149]

The idea that acyl halide complexes with two moles of AlX_3 of the type $RC(X\rightarrow AlX_3)=O\rightarrow AlX_3$ played an important part in the acylation of arenes was first suggested in 1962.[151] A report was recently published[152] stating that it was possible to detect the formation of the complex $CH_3C(Cl\rightarrow AlCl_3)=O\rightarrow AlCl_3$ in the system $AcCl-n$ moles of $AlCl_3$ in SO_2 solution using NMR. However, the interpretation of the spectroscopic data made in this study is at variance with that generally accepted and appears to be erroneous. Thus is has so far not been possible to observe complexes of the type (XI) or (XII) experimentally.

There would appear to be a direct analogy between complexes of the type (XI) or (XII) and the protosolvated form of the acylium cation (XIII), which was postulated by Olah et al.[153] as being formed in a proton superacid. Olah et al. assume that it is the protosolvated acylium cations (XIII) which are responsible for the transfer of a hydride ion from isobutane to the acylium cation that occurs in a proton superacid. In an aprotic solvent (SO_2) where ion (XIII) cannot be formed, the transfer of hydride ion from isobutane does not occur:

$$\underset{\text{(XIII)}}{CH_3C^+=O + H^+ \rightarrow CH_3C^+=O^+H},$$

$$\text{iso-}RH + CH_3C^+=O^+H \rightarrow \text{iso-}R^+ + CH_3CH=O^+H,$$

$$\text{iso-}RH + CH_3C^+=O \xrightarrow{SO_2} \text{iso-}R^+ + CH_3CHO.$$

Proton solvation of cations which contain atoms with a free electron pair is quite a general phenomenon.[154–156] The formation of the dications H_4O^{2+} and H_4S^{2+} was recently reported.[155,156]

In mentioning the similarity between postulated complexes of the type (XI) or (XII) and the protosolvated form of the acetylium cation (XIII), we should draw attention to the considerably greater activity of the former. Complexes of the type (XIII) are inert towards n-alkanes,[157,158] whereas $RCOX.2AlX_3$ systems react with them at high rates. Therefore, the possible presence of small quantities of protonated compounds in $RCOX.2AlX_3$ systems (from

traces of water or the destruction of complexes) cannot be the reason for the high activity of these systems, i.e., they should actually be regarded as aprotic organic superacids.

- - - o 0 o - - -

During the last 20 years the term "paraffins" has progressively lost its original meaning.

Metal-complex activation of inert σ-bonds (H−H, Si−H, Si−C, C−H) has provided a powerful stimulus for the development of the chemistry of inert molecules. At the present time there is the problem of the metal-complex activity of C−C bonds in alkanes. Although up to the present time there has been no single example of the cleavage of such bonds on well-characterised transition metal complexes, the data given in this review in conjunction with the preliminary results obtained on Ziegler-type systems would appear to suggest the possible occurrence of such reactions.

The development of "low-temperature" reagents and catalysts for the conversion of unactivated saturated hydrocarbons seems to indicate the considerable unexhausted possibilities in this area. There is future potential in the development of chemical methods for the synthesis of active catalysts for the cleavage of C−C bonds based on low-ligand clusters, and primarily heteronuclear LLCs on supports which retain all the advantages of Klabunde systems obtained by vapour-phase synthesis.

On the other hand, the availability of $RCOX.2AlX_3$ systems, the ease in working with them, and the possibility of carrying out a wide range of selective conversions of alkanes and cycloalkanes at room temperature in their presence give grounds for regarding the discovery of superacids of this type as a fundamentally new stage in the low-temperature chemistry of paraffins.

Metal complex catalysis of oxidation reactions: principles and problems

I I Moiseev, M N Vargaftik
Kurnakov Institute of General and Inorganic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The mechanisms of the oxidation of organic substrates, mainly alkenes, in the presence of mononuclear and polynuclear transition metal complexes, including cluster complexes, are examined.

The bibliography includes 121 references.

I. Introduction

Metal complex-catalysed liquid-phase oxidation constitutes an extensive field of chemical reactions embracing reactions occurring both in living nature and under the conditions of industrial manufacture. Industrially important reactions of this type include liquid-phase oxidation of paraffins and alkylarenes, the oxidation of alkenes to carbonyl compounds and vinyl and allyl esters, numerous alkene epoxidation processes, etc.[1]

The study of oxidation reactions has played an important role in the establishment of metal complex catalysis and in the formulation of its principles. Thus the oxidation of alkenes in the presence of palladium salts has become the first example in metal complex catalysis where it has been possible to characterise reliably all the stages and to discover the role of the catalyst components in this important multi-stage reaction. Despite the fact that the individual details remain controversial,[2] this process is probably the most thoroughly investigated also nowadays.

The authors' aim is not a laborious and exhaustive survey of oxidation reactions occurring under the influence of coordination compounds. Attention is concentrated on the reactions of unsaturated substrates. In contrast to, for example, the reactions of alkanes, in these reactions both participants in the oxidation process—the unsaturated hydrocarbon and the oxidant—are capable of interacting jointly or separately with the catalyst. This not only introduces a great variety into the mechanisms of the processes but also makes the above reaction a convenient object for the study of the principal ideas and methods of metal complex catalysis.

II. Mechanisms of the oxidation of alkenes

The functions of coordination compounds in the kinetics of oxidative homogeneous catalysis can be roughly reduced to the following schemes:

$$\begin{aligned} &M^n + Ox = A + M^m, \\ &A + Ol = P + Red; \end{aligned} \quad (1)$$

$$\begin{aligned} &M^n + Ox = M^m(A), \\ &M^m + Ol = P + M^n; \end{aligned} \quad (2)$$

$$\begin{aligned} &M^n + Ox = M^n(Ox), \\ &M^n(Ox) + Ol = P + M^n + Red; \end{aligned} \quad (3)$$

$$\begin{aligned} &M^n + Ol + Ox = Ol \cdot M^n \cdot Ox, \\ &Ol \cdot M^n \cdot Ox = P + M^n + Red; \end{aligned} \quad (4)$$

$$\begin{aligned} &M^m + Ol = M^n + P, \\ &M^n + Ox = M^m + Red, \end{aligned} \quad (5)$$

where M is the catalyst ($m > n$), Ox the oxidant, A the active form of the oxidant, Red its reduced form, Ol the substrate oxidised, and P the oxidation products.

In the first three schemes, the reaction product or its precursor arises as a consequence of the substrate being acted upon by the free (A) or bound in a complex [M^n(A)] active form of the oxidant or the complex of the catalyst and the oxidant [M^n(Ox)]. In scheme (4), the catalyst activates both the substrate and the oxidant, while in scheme (5) only the substrate is activated. Examples of olefin oxidation reactions via all the schemes indicated are known.[3,4]

III. Catalysis with participation of mononuclear complexes

A typical example of the oxidation of alkenes with participation of mononuclear transition complexes may be provided by the reaction of substituted alkenes on treatment with Fenton's reagent ($Fe^{2+}/Fe^{3+} + H_2O_2$). According to scheme (1), an iron(+3) compound acts as a reactant in the stage involving the formation of active intermediate species (free radicals). Admittedly, the aquo-complexes of iron do not merely generate free radicals [the active form of the oxidant in terms of scheme (1)] in these systems, i.e.

$$\begin{aligned} &Fe^{2+} + H_2O_2 + H^+ = Fe^{3+} + HO^\cdot + H_2O, \\ &Fe^{3+} + H_2O_2 = Fe^{2+} + HO_2^\cdot + H^+, \end{aligned}$$

but can also influence the nature of the product formed[6] by participating in the chain propagation and termination stages.[5]

Furthermore, in the interaction of iron compounds and hydrogen peroxide there is a possibility of the appearance of species which can be regarded as iron complexes containing the coordinated radical-anion $O^{\cdot}$ or as oxygen compounds of iron(+4). It has been suggested[3,7] that the oxygenyl complexes of iron(+5) or iron(+4) are responsible for the epoxidation of alkenes in the presence of haem-containing monoxidases, for example cytochrome P-450. Porphyrin complexes of iron, chromium, and manganese, modelling this enzyme, are known.[3,4,7,8] In all these systems, the catalyst interacts with the oxidant (which may be not only an inorganic or organic peroxide but also iodosobenzene,[9] the hypochlorite ion,[10] an amine *N*-oxide,[11] or 2-sulphonyloxyaziridine[12]) and abstracts from the latter an oxygen atom, which is coordinated to the catalyst and is then transferred to the substrate. Thus the main function of the catalyst in these processes is, according to scheme (2), the formation and stabilisation of the active form of the oxidant A (the oxygen atom) and also its transfer to the substrate undergoing oxidation. Direct interaction between the substrate and the catalyst is either very weak or does not occur at all. Thus analogues of cytochrome P-450 are capable of oxidising not only alkenes but also saturated hydrocarbons whose direct interaction with catalysts of this type is unlikely. Chromium complexes of Schiff bases,[13] copper nitrate,[14] and iron(+3) chloride and acetylacetonate[15] act similarly to metalloporphyrins.

In a number of instances, when O_2 interacts with the metal complex, its activation apparently reduces to its conversion into a coordinated superoxide ion.[8,16] Thus, in the epoxidation of ethylene in the gas phase, the interaction of O_2 with a silver atom or cluster can be completed by the transfer of an *s* electron from the silver atom to a molecule of dioxygen and the formation of a coordinated superoxide ion. The attack by the "free" valence of such a complex on the ethylene molecule and the subsequent intramolecular free-radical substitution should lead to an oxide form of the silver cluster [in the simplest case to silver(+2) oxide] and epoxyethane. After the reduction of silver oxide, the active form of the catalyst is regenerated and the catalytic cycle is closed. A palladium(+2) complex of the superoxide ion was obtained recently.[17] Modelling the reaction of the silver(+1) complex with the superoxide ion, it epoxidises alkenes smoothly.

The majority of the known catalysts of epoxidation by molecular oxygen actually effect the co-oxidation of the alkene when some kind of reductant, for example, ethylene and the products of its incomplete oxidation (in the gas-phase epoxidation of ethylene on a silver catalyst), of an alkene and an alkylarene (epoxidation of propene in the chalcone process), and of an alkene and H_2 or sodium tetrahydroborate (epoxidation catalysed by porphyrin complexes of manganese).

The first system in which both oxygen atoms are used to oxidise the alkene was discovered recently.[18] It was found that the interaction of dioxygen with tetramesitylporphyrinatoruthenium(II) involves the cleavage of the O=O bond and the formation of a ruthenium(+6) complex which contains two oxo-groups. This complex attacks the alkene and converts it into an epoxide. The ruthenium(+4) complex, arising under these conditions, disproportionates, regenerating the dioxide derivative of ruthenium(+6) and a ruthenium(+2) complex which on reaction with O_2 is also converted into the porphyrin complex of dioxoruthenium(+6).

A typical example of oxidation in accordance with scheme (3) is the epoxidation of alkenes by organic peroxides in the presence of molybdenum(+6) compounds.[19] A molybdenum(+6) atom with the non-bonding d^0 configuration is incapable of forming more or less stable π-complexes with alkenes.[20] Because of this, alkenes cannot compete with rigid oxo-ligands for a site in the coordination sphere of molybdenum(+6). The kinetic data[21–23] showing that, in the oxidation of propene by ethylphenyl hydroperoxide the alkene molecule not bound in a complex is attacked by the coordinated hydroperoxide molecule, are consistent with this finding. One of the mechanisms presupposes that the molybdenum(+6) complex of the hydroperoxide acts in the same way as an organic peracid in the Prilezhaev reaction.[19,23] However, the study of the stereochemistry of the oxidation of allyl alcohols led to the conclusion[4,24,25] that an oxygen atom bound directly to the metal is transferred to the alkene. In the transition state, this atom migrates to a neighbouring O atom of the coordinated alkyl peroxide ligand. To reach final conclusions, it is essential to investigate further this industrially important reaction. However, it is significant that in all these versions of the mechanism, the role of only the activator of the oxidant is attributed to the catalyst.

The reactions in which the catalyst activates simultaneously both the oxidant and the alkene [scheme (4)] are in the first place those catalysed by rhodium[26] and palladium[27–30] compounds.

In these reactions either the alkene is inserted between the catalyst metal atom and the oxidant molecule or the oxidant, interacting with the catalyst, influences the direction of the oxidation reaction. It is possible to obtain in this way, for example, glycol ethers instead of the aldehydes and ketones formed in the absence of an oxidant.[29] In addition, there also exists routes leading to the occurrence of scheme (4), in which both the oxidant and the alkene are coordinated to the catalyst, which effects the electron transfer between them.

Evidently, for the occurrence of such mediator[31] mechanism in the case of metals with the non-bonding d^0 configuration, special requirements must be met by the alkene structure. Since the double bond in the alkene cannot be used for its coordination to a metal atom with such electronic configuration, it is essential that the alkene should contain groups directly attached to the double bond, conjugated with the latter, and capable of coordination to the metal atom. All these conditions are satisfied, for example, by pentane-2,4-dione and its analogues in the enolic form.

In solutions of molybdates or tungstates, β-dicarbonyl compounds containing at least one hydrogen atom at the central carbon atom and hence capable of enolisation are smoothly oxidised by hydrogen peroxide.[32]

A ^{1}H NMR study of this reaction[33] showed that, even after the addition of only 0.5 mol of hydrogen peroxide per mole of acetylacetone (Hacac) under conditions where the reaction products (acetic acid and CO_2) are still absent, the signal due to the CH_3 groups of the coordinated $acac^-$ vanishes, the integral intensity of the signals of both forms of free Hacac diminishes, and a broadened singlet appears at 1.96 p.p.m., whose intensity increases as H_2O_2 is added, reaching a maximum for the ratio $[H_2O_2]:[Hacac] = 2$. Analysis of these data as well as comparison of the rates of oxidation of Hacac and a hypothetical intermediate which should have arisen in the oxidation of Hacac in accordance with the Baeyer–Villiger mechanism (formaldehyde and formic acid) showed that neither the free Hacac nor the coordinated $acac^-$ undergo oxidation in accordance with the Baeyer–Villiger mechanism under the experimental conditions. A complex containing the dianion of 2,2,4,4-tetrahydroxy-3-pentanone is the observed primary oxidation product. This complex was also synthesised independently from 3,3-dihydroxypentane-2,4-dione and sodium molybdate. The study of its IR and ^{1}H NMR spectra showed that the above ligand

forms in the coordination sphere a six-membered metallocycle incorporating the central metal atom.

The oxidation of Hacac by hydrogen peroxide takes place in the coordination sphere of molybdenum(+6) .[32] The key stage of this reaction includes the transfer of electrons from the coordinated $acac^-$ to the coordinated O_2^{2-} in the inner coordination sphere of the complex. The absence of signals due to paramagnetic species in the EPR spectra at 77 and 300 K indicates the occurrence of the two-electron transfer.[33] Nevertheless, one cannot fully exclude the possibility of the occurrence of two successive one-electron processes, because the absence of the EPR signals may be associated with the exchange interaction between the paramagnetic ligands formed in the coordination sphere of the molybdenum atom. Regardless of these details of the mechanism, the resulting transfer of two electrons from the pseudo-aromatic (acac.Mo) system to the σ orbital of the O_2^{2-} fragment destabilises the latter and leads to the appearance of the O^{2-} ligand linked by multiple bonds to the central atom, which is promoted by the tendency of Mo atoms to form multiple bonds with π-donor ligands. In the coordinated $acac^+$, the positive charge is located predominantly at the C(3) atom to which the nucleophilic attack by the H_2O molecule is directed. A short-lived molybdenum complex of 3-hydroxypentane-2,4-dione is apparently formed as a result of this attack. The repeated transfer of two electrons leads to the oxidation of this intermediate, which entails also the formation of the molybdenum complex of 3,3-dihydroxypentane-2,4-dione detected in the EPR spectrum. The subsequent oxidation of the organic ligand by hydrogen peroxide apparently proceeds via the mechanism of the Baeyer–Villiger reaction with or without the participation of MoO_4^{2-}.

One cannot rule out the possibility that inner-sphere electron transfer plays a much more important role in the catalysis by metal complexes having the non-bonding d^0 configuration than has been assumed until recently. In this connection, we may note kinetic data[34,35] showing that peroxides decompose in solutions of molybdenum(+6) compounds in water and of vanadium(+5) compounds in acetic acid via the intermediate formation of complexes containing at least two peroxide molecules at the metal atom.

If the peroxide disproportionates within the coordination sphere via the transfer of two electrons in one or two rapidly succeeding elementary steps, the primary product of such decomposition should be singlet oxygen or its complex with the metal atom. Indeed, the formation of $^1O_2$ has been detected in the oxidation of aromatic compounds by peroxides in the presence of molybdenum and vanadium compounds.[36,37] In the oxidation of anthracene by hydrogen peroxide in the presence of vanadium(+5) in acetic acid solutions, the product of the addition of $^1O_2$ to the substrate is also formed.[38] In addition, anthracene fully blocks the decomposition of H_2O_2 with formation of O_2. This fact as well as comparison of the rate constants for the physical quenching of $^1O_2$ and for the reaction of $^1O_2$ with anthracene demonstrate unambiguously that anthracene is oxidised not by the free singlet oxygen but by its precursor. Kinetic data and ^{51}V NMR spectra have led to the conclusion that the active intermediate—the agent transferring $^1O_2$ to the substrate molecule—is either the peroxo-complex V(+5) $(O_2^{2-})_3$ or a complex of the type V(+5)($^1O_2$).

Another active form of oxygen, also formed via a molecular pathway on decomposition of H_2O_2 in solutions of V(+5) in acetic and trifluoroacetic acids, is ozone, whose yield is 1 and 10% respectively.[39] The oxidative hydroxylation of cyclohexane[40,41] and methane[42] and the oxidative degradation of the multiple bonds of the electron-deficient perfluorobenzene[43] and perfluoroalkenes[44,45] with formation of perfluorocarboxylic acid fluorides also occur in the same systems under mild conditions. However, it has been found[46] that the rates of oxidation of all these substrates by ozone are much lower than the rates of oxidation of the same substrates by hydrogen peroxide. Thus, despite the fact that ozone is formed in the given system, it cannot be regarded as an active intermediate in the oxidation of the substrates indicated.

The involvement in the reaction of extremely unreactive electron-deficient perfluoroalkenes, which are incapable of reacting with free singlet oxygen, as well as the low yield of epoxides show that unsaturated perfluorohydrocarbons are oxidised with participation of oxygenyl complexes of vanadium as donors of $^1O_2$.

The mechanism of the formation of the active intermediates responsible for the evolution of O_3 and the oxidation of the substrates is apparently fairly complex. This is indicated by the following facts:

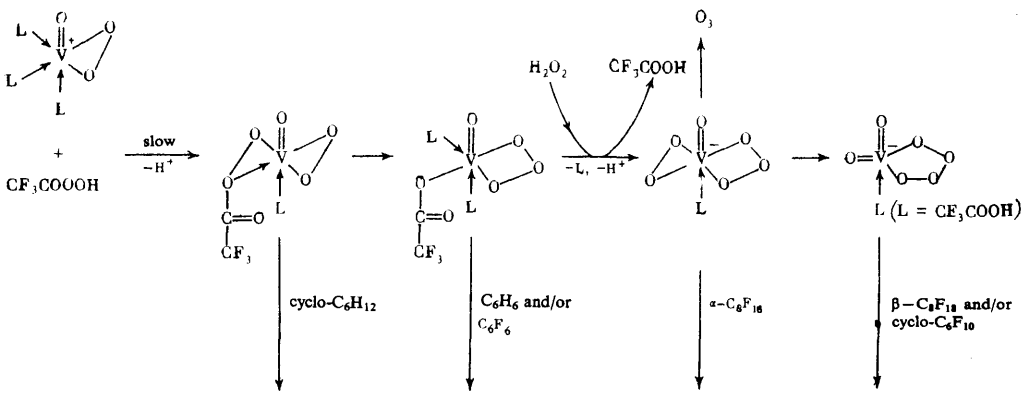
1. Cyclohexane, arenes, and perfluoroarenes completely block the evolution of ozone; α-perfluoroalkenes reduce by a factor of 3–5 the yield of O_3 while β-perfluoroalkenes do not affect the yield of ozone.

2. In the joint oxidation of substrates of different nature, each preceding member of the series—cyclohexane, arene, α-perfluoroarene, and β-perfluoroalkene—completely blocks the oxidation of any subsequent member, although in their separate oxidation the rates of consumption of all these substrates are comparable.[47]

All these facts can be reasonably explained within the framework of Scheme 1 according to which several (at least four) types of active intermediates are formed in the V(+5)–H_2O_2–RCOOH system, their concentrations being stationary and each of these species being responsible for the oxidation of a substrate of only one particular type.[48]

Exactly 30 years ago, the liquid-phase alkene oxidation reactions catalysed by palladium(+2) compounds were discovered:[49–51]

$$\begin{aligned} &C_2H_4 + {}^1/_2 O_2 = CH_3CHO, \\ &C_2H_4 + {}^1/_2 O_2 + AcOH = CH_2{=}CHOAc + H_2O, \\ &C_2H_4 + {}^1/_2 O_2 + 2ROH = CH_3CH(OR)_2 + H_2O. \end{aligned} \quad (6)$$



An important feature of these reactions, proceeding in accordance with scheme (5), is that the substrate activation (the key stage in which the alkene molecule is converted into a precursor of the final product) proceeds in the inner coordination sphere of the mononuclear palladium(+2) complex:[20]

$$\begin{aligned} &PdCl_4^{2-} + C_2H_4 = PdCl_3(\pi\text{-}C_2H_4)^- + Cl^-, \\ &PdCl_3(\pi\text{-}C_2H_4)^- + H_2O = PdCl_2(H_2O)(\pi\text{-}C_2H_4) + Cl^-, \\ &PdCl_2(H_2O)(\pi\text{-}C_2H_4) = PdCl_2(OH)(\pi\text{-}C_2H_4)^- + H^+, \\ &PdCl_2(OH)(\pi\text{-}C_2H_4)^- \rightarrow \sigma\text{-}Cl_2Pd{-}CH_2CH_2OH^-, \\ &\sigma\text{-}Cl_2Pd{-}CH_2CH_2OH^- \rightarrow Pd^0 + 2Cl^- + CH_3CHO, \\ &Pd^0 + Ox + 4Cl^- \rightarrow PdCl_4^{2-} + Red. \end{aligned} \quad (7)$$

At high palladium(+2) concentrations, dinuclear palladium(+2) complexes of the type $Pd_2Cl_6^{2-}$ also participate in these reactions, but the mechanism of their action differs fundamentally from that presented in scheme (7) for mononuclear complexes.[52]

Since the discovery by Shilov and Shteinman[53,54] of deuterium exchange between methane and D_2O in the presence of platinum salts, a vigorous search is being prosecuted throughout the world for transition metal complexes capable of catalysing reactions involving the oxidative functionalisation of alkanes. The recently published

Scheme 1

oxidation products

communications[55,56] about the oxidation of methane and certain other hydrocarbons by palladium(+2) salts may be included among the number of recent attempts to achieve the oxidation of an alkane in accordance with scheme (5). Palladium(+2) is usually introduced in the form of the trimeric acetate $Pd_3(OAc)_6$ into the trifluoroacetic acid solution where it is in all probability converted into the monomeric $Pd(OCOCF_3)_2$. Under fairly mild conditions, at 80 °C and 60–70 atm, methyl trifluoroacetate was obtained from methane in 60% yield:

$$CH_4 + Pd(OCOCF_3)_2 = CH_3OCOCF_3 + Pd^0 + CF_3COOH. \quad (8)$$

If this reaction is combined with the reoxidation of zerovalent palladium to palladium(+2), as had been done earlier in the oxidation of alkenes via reaction (6), it might be possible, in principle, to achieve the liquid-phase catalytic oxidation of methane by oxygen. Unfortunately, so far it has not been possible to reproduce in our laboratories the results obtained in the above studies.[55,56]

In the search for complexes of other transition metals capable of reacting with methane, it has recently been observed[57,58] that cobalt(+3) trifluoroacetate is reduced by methane under comparatively mild conditions (CF_3COOH solution, 150–180 °C, 10–40 atm), converting it into methyl trifluoroacetate in a nearly quantitative yield [90 ± 10% with respect to Co(+3)]:

$$CH_4 + 2Co(OCOCF_3)_3 = CH_3OCOCF_3 + 2Co(OCOCF_3)_2 + CF_3COOH. \quad (9)$$

In the presence of oxygen, the cobalt(+2) formed is oxidised to cobalt(+3):

$$Co(OCOCF_3)_2 + {}^1/_2 O_2 + CF_3COOH = Co(OCOCF_3)_3 + H_2O,$$

which made it possible to achieve for the first time the highly selective catalytic conversion of methane into methyl trifluoroacetate:[58]

$$CH_4 + {}^1/_2 O_2 + CF_3COOH = CH_3OCOCF_3 + H_2O. \quad (10)$$

The state of cobalt(+3) and cobalt(+2) in these solutions has not so far been investigated. There is no complete certainty that the cobalt(+3) complex is in fact the electrophile which attacks the methane molecule. One cannot rule out the possibility that reaction (10) proceeds as a result of the participation of the oxygenyl complexes of cobalt(+4), which may have a polynuclear structure.

IV. Catalysis with participation of clusters

A considerable amount of data indicating the existence of a specific field of catalysis in which the substrate is activated by polynuclear, mainly cluster, compounds of transition metals has accumulated recently. Among such palladium cluster-catalysed reactions, one may include, for example:

positional and geometrical isomerisation of alkenes;[59]
dimerisation and oligomerisation of alkenes;[60]
hydrogenation of acetylenes, dienes, nitro-compounds, quinones, and other unsaturated compounds;[61,62]
oxidative dehydrogenation of cyclohexene;[59]
oxidative acetoxylation of alkenes[63] and alkylarenes;[64]
alkoxycarbonylation of acetylene.[65]

The oxidative substitution of a hydrogen atom in alkenes (ethylene, propene) by the acetoxy-group, which has been achieved industrially, occupies a special place among these reactions:

$$C_nH_{2n} + {}^1/_2 O_2 + AcOH \xrightarrow[180\,^\circ C]{Pd/SiO_2} C_nH_{2n-1}OAc + H_2O. \quad (11)$$

This process is carried out in the vapour phase using metallic palladium with added alkali metal acetates on the surface of a porous carrier as the catalyst.[66]

It was initially postulated that the heterogeneous version of reaction (11) also proceeds via the mechanism characteristic of reactions (6) mentioned above, with participation of the mononuclear palladium(+2) complexes, via alternating stages in which palladium(+2) is reduced and zerovalent palladium is oxidised:

$$Pd(+2) + C_nH_{2n} + AcOH \rightarrow Pd(0) + C_nH_{2n-1}OAc + H_2O,$$
$$Pd(0) + {}^1/_2 O_2 \rightarrow Pd(+2) + H_2O.$$

However, the hypothesis of the involvement of palladium(+2) in reaction (11) agrees poorly with data concerning the selectivity of the oxidative acetoxylation of propene and ethylene.[67] Thus, in the

oxidation of propene by palladium(+2) acetate in solution in acetic acid, the yield of allyl acetate, which is high in the absence of water and at low temperatures (94% at 25 °C), falls sharply on raising the temperature and on increasing the water content (4% at 118 °C; the remainder consists of acetone and other side products).[68] On the other hand, in the presence of a heterogeneous palladium catalyst, the selectivity with respect to allyl acetate remains constantly high (~90%) even on raising the temperature to 180 °C and the water content to 10%.[69]

On interaction of $Pd(OAc)_2$ with the $C_3H_6-O_2$ mixture in solution in acetic acid containing NaOAc, propene is oxidised without the consumption of oxygen solely as a result of the reduction of palladium(+2). Under these conditions, a mixture of products is formed (isopropenyl acetate, n-propenyl acetate, allyl acetate, and acetone) with the same quantitative composition as in the absence of O_2.[70] However, after the complete reduction of palladium(+2), a slower catalytic reaction begins in which O_2 is consumed and the product of the allylic oxidation of propene (allyl acetate) is formed in a high yield.[67]

Significant differences between the selectivities of the action of palladium(+2) and heterogeneous palladium catalysts have been observed also in the oxidation of alkylarenes in the presence of carboxylic acids.[71,72] On treatment with palladium(+2) in solution in acetic or trifluoroacetic acid, toluene undergoes mainly oxidative coupling via the benzene rings with formation of a mixture of isomeric (*o*-, *m*-, and *p*-) bitolyls:

$$2C_6H_5CH_3 + Pd(+2) = CH_3C_6H_4-C_6H_4CH_3 + Pd(0) + 2H^+.$$

The reoxidation of the reduced form of palladium with oxygen makes it possible to carry out the process under catalytic conditions (with respect to palladium):

$$2C_6H_5CH_3 + {}^1/_2\,O_2 = CH_3C_6H_4-C_6H_4CH_3 + H_2O.$$

So long as an appreciable amount of reduced palladium does not accumulate in the system, the above toluene oxidation pathway remains unchanged. However, the accumulation of metallic palladium or the introduction of freshly prepared palladium black leads to a sharp alteration of the composition of the products. The main reaction pathway becomes the benzyl oxidation—the oxidative acetoxylation of toluene in the side chain: $C_6H_5CH_3 + \frac{1}{2}O_2 + AcOH = C_6H_5CH_2OAc = H_2O$.

Finally, the thermal instability of palladium(+2) carboxylates at temperatures above 100 °C, where the oxidative acetoxylation of alkenes and alkylarenes in the presence of a heterogeneous catalyst proceeds most readily at 150–200 °C, constitutes evidence against the participation of palladium(+2) in the heterogeneous-catalytic oxidation of alkenes.[63] All these data suggest that the active centres of the heterogeneous palladium catalysts, responsible for the oxidative acetoxylation of alkenes and alkylarenes, contain not palladium(+2) but palladium in a lower oxidation state.

As for other platinum metals, the lower oxidation state of palladium is represented, with few exceptions, by cluster compounds. However, stable coordinatively unsaturated clusters are as a rule catalytically inactive. Under the conditions of the catalytic reaction, it is also not possible to rule out the possibility of the decomposition of the cluster complex with formation of the catalytically active metal phase. Therefore, in order to elucidate the principal features of cluster catalysis, it is essential not only to synthesise a cluster suitable for the occurrence of the catalytic reaction but also it is necessary to make sure that the cluster and not its decomposition product is responsible for the catalysis of the given reaction.

V. Synthesis of catalytically active palladium clusters

One of the most effective methods of synthesis of transition metal clusters is based on the monocarbonyls and polycarbonyls of these metals.[73] Unfortunately, palladium does not form binary carbonyls stable under the usual conditions.[74] Palladium complexes containing other ligands in addition to CO are therefore used as the initial compounds.

When solutions of palladium(+2) salts are treated with CO, palladium(+2) is usually reduced to the metal. Thus the reduction of $Pd(OAc)_2$ by carbon monoxide in glacial acetic acid containing alkali metal acetates leads to the formation of metallic palladium, acetic anhydride, and CO_2:[21]

$$Pd(OAc)_2 + CO \rightarrow Pd^0 + Ac_2O + CO_2.$$

In carboxylic acids or carboxylic acid + benzene mixtures in the absence of alkali metal acetates, fairly stable complexes [(RCOO).Pd(CO)].*n*RCOOH, where n = 0.5 or 0, were obtained. Thus carbonylation of palladium(+2) acetate in glacial acetic acid at 50 °C leads to the compound $Pd_4(CO)_4(OAc)_4.2AcOH$. According to X-ray diffraction data,[76] the main structural unit of these crystals consists of the tetranuclear clusters $Pd_4(CO)_4(OAc)_4$ (PCA) with a rectangular metallic core (Fig. 1). The sides of the rectangle spanned by acetate bridges are longer (2.909 Å), while those linked by carbonyl bridges are shorter (2.603 Å) than the Pd–Pd distance in metallic palladium (2.751 Å).

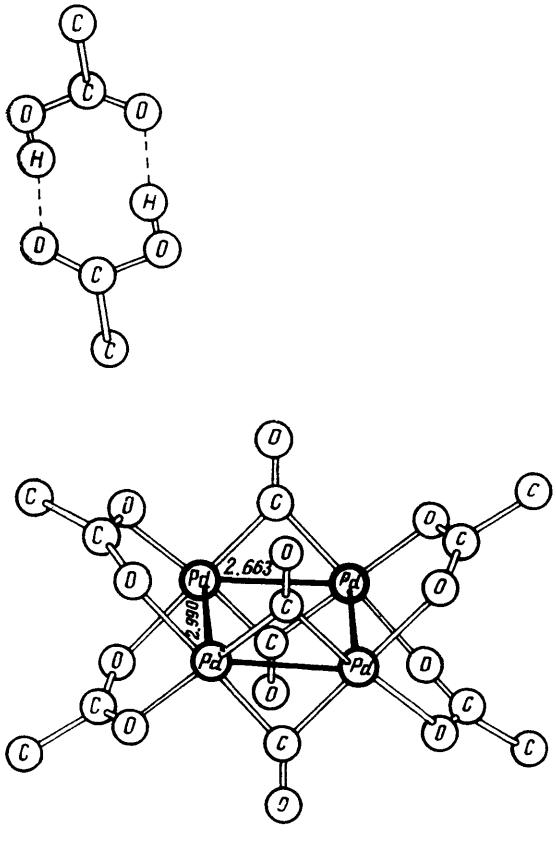


Figure 1. The structure of the cluster $Pd_4(CO)_4(OAc)_4.2AcOH$.

The reactions of $Pd(OCOEt)_2$ and $Pd(OCOPh)_2$ with CO afford the analogous clusters $Pd_4(CO)_4(OCOEt)_4$ and $Pd_4(CO)_4(OCOPh)_4$.[77] The similarity of the chemical properties and spectroscopic characteristics of these compounds suggested that they are all constructed similarly to PCA. Thus the synthesis of PCA, described by the equation

$$4Pd(OAc)_2+8CO=Pd_4(CO)_4(OAc)_4+2Ac_2O+4CO_2, \quad (12)$$

represents a general route to palladium(+1) carbonyl carboxylates.[77]

Studies on the kinetics and intermediates of reaction (12) led to the conclusion[78] that the formation of PCA from the trimeric palladium(+2) acetate is a reaction of the type of reductive condensation and involves the following stages:

(1) insertion of CO in the Pd–OAc bond;

(2) elimination of CO_2 with formation of the acyl fragment $Pd-C(O)-CH_3$;

(3) liberation of a molecule of acetic anhydride Ac_2O and the formation of the Pd–Pd bond.

The coordinated acetate groups in PCA are readily substituted by other carboxylates on interaction of the corresponding acids with PCA:

$$Pd_4(CO)_4(OAc)_4 \xrightarrow[-AcOH]{RCOOH} [Pd(CO)(OCOR)]_4, \quad R = CD_3,\ Et,\ Ph,\ CF_3,\ CCl_3,\ CH_2Cl. \quad (13)$$

The similarity of the IR spectra, chemical behaviour, and stoichiometry of these compounds with the data for PCA suggests that all these complexes are analogues of PCA.[77]

Treatment of PCA with inorganic acids, for example, hydrochloric acid, also leads to the substitution of the acetate groups by Cl^-, but the carbonyl chloride complexes formed are unstable. It might have been supposed that the substitution of the acetate groups in PCA by an involved metal complex anion, for example, carbonyl metallate, does not lead to the decomposition of the metallic core and would make it possible to obtain a heteronuclear palladium-containing cluster.

Indeed, the interaction of PCA with $Na[CpMo(CO)_3]$ yielded the anionic octanuclear cluster $Na_2\{Pd[Mo(CO)_3Cp]\}_4.2THF$.[79] According to X-ray diffraction data, the principal structural units of crystals of this compound are the centrosymmetric anion $\{Pd[Mo(CO)_3Cp]\}_4^{2-}$, two Na^+ cations, and two THF molecules. The Pd atoms are arranged at the vertices of the square (Pd–Pd = 2.675–2.691 Å) (Fig. 2). Each Mo atom forms an almost regular triangle with two Pd atoms (Pd–Mo = 2.723–2.741 Å) and all the metal atoms lie in the same plane.

The formation of the octanuclear cluster involves not only the substitution of the acetate ligands by the anions $CpMo(CO)_3^-$ but also the displacement of the neutral CO molecules. The liberated vacancies in the coordination sphere of palladium are occupied by the CO molecules coordinated to Mo, which are converted into bridges linking atoms of different metals. Apparently the process is not restricted to the substitution of ligands: during the reaction, Pd(+1) atoms are reduced, probably as a result of the one-electron oxidation of the $CpMo(CO)_3^-$ anions. If it is assumed that the Mo atoms forming part of this complex have a zero oxidation state, which obtains in the initial compound, then the observed reaction can be regarded as the reduction of Pd(+1) to Pd(+5):

$$Pd_4(CO)_4(OAc)_4+6Na[CpMo(CO)_3]=Na_2[Pd_4Mo_4Cp_4(CO)_{12}]+4CO+[CpMo(CO)_3]_2+4NaOAc. \quad (14)$$

Reactions (13) and (14) are examples of the substitution of the acido-ligands in PCA by other acido-groups. The substitution of the neutral carbonyl ligand is observed on interaction of PCA with diphenyldiazomethane.[80] The interaction of PCA with Ph_2CN_2 in benzene leads to the displacement of the CO groups and the formation of a complex containing diphenylcarbene as the ligand:

$$Pd_4(CO)_4(OAc)_4+Ph_2CN_2\rightarrow Pd_4(CPh_2)_4(OAc)_4+CO+4N_2.$$

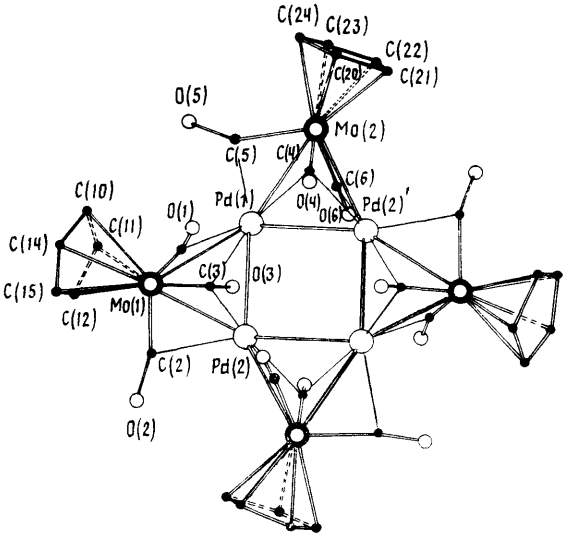

Figure 2. The structure of the cluster dianion $\{Pd_4[CpMo(CO)_3]_4\}^{2-}$.

The composition of the resulting complex as well as the results of physicochemical studies (elemental analysis, IR and ^1H NMR spectra, molecular weight measurements) can be equally attributed both to the formation of a complex with carbene ligands and a π-complex with tetraphenylethylene. However, the presence of carbene ligands in the complex is indicated by reactions leading to products characteristic of the free carbenes. Thus hydrogenation of the complex in benzene at 20 °C and 1 atm H_2 pressure leads to the dissociation of the Pd–C bonds and the formation of diphenylmethane:[81]

$$...Pd=CPh_2+H_2\rightarrow ...Pd+Ph_2CH_2.$$

Alkaline hydrolysis of the complex affords diphenylmethanol together with diphenylmethane and benzophenone:

$$...Pd=CPh_2+H_2O \xrightarrow{EtOH,\ KOH} ...Pd+Ph_2CHOH.$$

Interaction with alkenes results in the formation of the products of the cycloaddition of the carbene to the alkene, which is characteristic of both the free carbenes and of their complexes. For example, the reaction of the complex with hex-1-ene leads to 2-butyl-1,1-diphenyl-cyclopropane:

$$...Pd=CPh_2+CH_3(CH_2)_3CH=CH_2 \rightarrow ...Pd+CH_3(CH_2)_3CH(CPh_2)CH_2.$$

The structure of the carbene complex was investigated by the EXAFS method.[82] The results confirmed the hypothesis that a rectangular metallic core is present (Fig. 3).

PCA reacts in a very complex manner with ligands such as PPh_3, pyridine (Py), phenanthroline (Phen), diphosphine (Diphos), and bipyridyl (Bipy). Depending on the initial Pd:ligand concentration ratio, complexes of different composition are formed.[83] The palladium compounds produced for the ratio $[Pd]_\Sigma:[L]_\Sigma \geqslant 2$ (L = ligand) are fairly unstable. As $[Pd]_\Sigma:[L]_\Sigma$ diminishes, more stable complexes are formed.

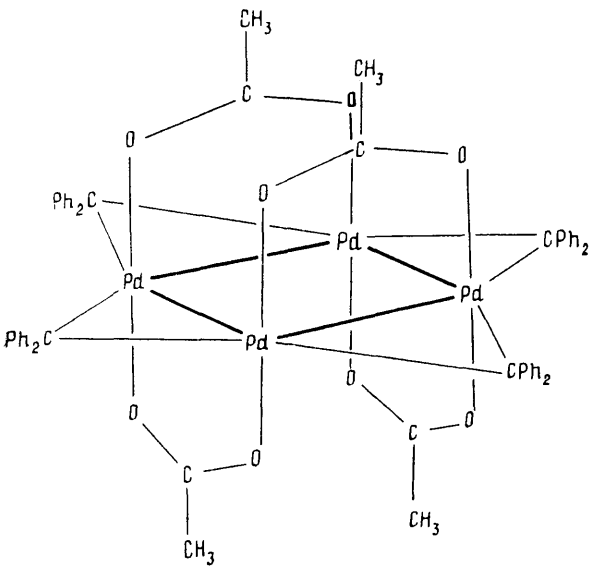

Figure 3. The structure of the carbene cluster $Pd_4(CPh_2)_4(OAc)_4$ according to EXAFS data.

The interaction of PCA with pyridine and its alkyl derivatives, using the ratio $[Pd]_\Sigma:[L]_\Sigma = 1:1$, involves the disproportionation of the Pd(+1) to Pd(+2) and Pd(0):

$$Pd_4(CO)_4(OAc)_4+4Py=2Pd^0+2PdPy_2(OAc)_2+4CO.$$

The reaction of PCA with diphosphine in benzene makes it possible to obtain the complex $Pd_2(Diphos)_2(CO)(OAc)_2.C_6H_6$:[84]

$$Pd_4(CO)_4(OAc)_4+4Diphos=2Pd_2(Diphos)_2(CO)(OAc)_2+2CO.$$

The interaction of PCA with a (5–10)-fold excess of diphosphine in tetrahydrofuran (THF) leads to the cationic complex $[Pd_2(\mu\text{-}CO)(Diphos)_4]^{2+}(OAc)_2$ with a different coordination of the diphosphine ligands:

$$Pd_4(CO)_4(OAc)_4+8Diphos=2Pd_2(CO)(Diphos)_4(OAc)_2+2CO.$$

When PCA is treated with PPh_3, the complex $Pd_2(CO).(PPh_3)_2(OAc)_2$ is formed:

$$Pd_4(CO)_4(OAc)_4+4PPh_3=2Pd_2(CO)(PPh_3)_2(OAc)_2+2CO.$$

This complex contains a CO bridging group [ν(CO) = 1800 cm^{-1}]. Depending on the conditions of the synthesis, compounds differing in the mode of coordination of the acetate groups are produced. Thus, when the reaction was carried out in solution in THF, a complex with acetate bridges was obtained [ν_s(COO) = 1530 cm^{-1}, ν_{as}(COO) = 1400 cm^{-1}, and $\Delta\nu$ = 130 cm^{-1}], while the reaction of PCA with PPh_3 in benzene leads to a compound with terminal OAc groups [ν_s(COO) = 1610 cm^{-1}, ν_{as}(COO) = 1350 cm^{-1}, $\Delta\nu$ = 260 cm^{-1}]. The complex is unstable in solution and gradually disproportionates to Pd(+2) and Pd(0). The latter was isolated in the form of the mononuclear complex $Pd(PPh_3)_3$.[84]

In the case of bipyridyl at an initial concentration of 0.5 M and a PCA concentration of 5×10^{-3} M, all the coordinated CO molecules are displaced:[83]

$$Pd_4(CO)_4(OAc)_4+2Bipy=2Pd_2(Bipy)(OAc)_2+4CO.$$

At low bipyridyl concentrations ($\leqslant 5 \times 10^{-3}$ M), only half of the coordinated CO molecules are displaced from PCA:

$$Pd_4(CO)_4(OAc)_4+2Bipy=2Pd_2(Bipy)(CO)(OAc)_2+2CO.$$

In contrast to bipyridyl, *o*-phenanthroline at 20 °C displaces from PCA only half of the coordinated CO molecules at the highest ligand concentrations:

$$Pd_4(CO)_4(OAc)_4+4Phen=2Pd_2(CO)(Phen)_2(OAc)_2+2CO.$$

The last two complexes were also obtained directly by reducing with carbon monoxide a solution in acetic acid containing $Pd(OAc)_2$ and L.[84]

The interaction of PCA with *o*-phenanthroline in the proportions $[Pd]_\Sigma:[Phen]_\Sigma = 1:1$ in solution in acetic acid affords the complex $Pd_4(CO)_2(Phen)_4(OAc)_4$:[85]

$$Pd_4(CO)_4(OAc)_4+4Phen=Pd_4(CO)_2(Phen)_4(OAc)_4+2CO.$$

The same complex was obtained by reducing with carbon monoxide palladium(+2) acetate in solution in acetic acid containing *o*-phenanthroline. According to X-ray diffraction data, the crystals of the complex contain as the main structural unit the tetrahedral cluster cation $[Pd_4(CO)_2(Phen)_4]^{4+}$ (Fig. 4). The OAc^- ligands are not linked directly to the palladium atoms but are located in the outer sphere. On formation of this complex from PCA, all the metal–metal distances change significantly: the lengths of the Pd–Pd bonds in the Pd(μ-CO)Pd fragments increase to 2.890 Å (in PCA this distance is 2.663 Å). None of the acetate groups in $[Pd_4(CO)_2(Phen)_4]^{4+}$ are coordinated to the palladium atoms, as in PCA, but are located in the outer sphere as the OAc^- anions.

The complexes obtained behave as moderately strong electrolytes in aqueous solution. They undergo a reversible substitution of OAc^- by X^- anions:

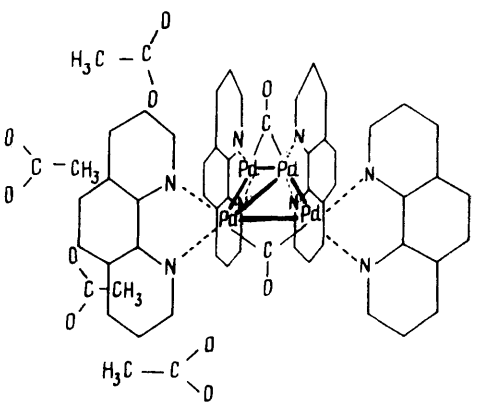
$$Pd_2(CO)Phen_2(OAc)_2 \underset{OAc}{\overset{X^-}{\rightleftarrows}} Pd_2(CO)Phen_2X_2,$$

$$X^- = ClO_4^-,\ Cl^-,\ HSO_4^-,\ Cl_3CCOO^-,\ F_3CCOO^-,\ CNS^-.$$

Such complexes have been isolated and characterised by elemental analysis and IR spectroscopy.[83]

The study of PCA and its derivatives showed that none of these complexes react with ethylene, propene, and toluene in carboxylic acids and do not exhibit a catalytic activity in the oxidation of these

hydrocarbons by molecular O_2. A low catalytic activity in the oxidation of propene to allyl acetate and of toluene to benzyl acetate [~0.1 mol (mol Pd)$^{-1}$ h^{-1} at 90 °C and 1 atm O_2] was observed only in the case of PCA after the latter had been kept in acetic acid solution containing 1 M sodium acetate for 0.5–1 h at 60–90 °C under a O_2 atmosphere. During this operation, PCA decomposes with formation of palladium black: $Pd_4(CO)_4(OAc)_4 = 4\,Pd + 2CO + 2CO_2 + 2Ac_2O$, while the CO, evolved as a result of this reaction and sorbed on the surface of metallic palladium, is oxidised by oxygen to CO_2, which makes the surface of the metal accessible to hydrocarbons.



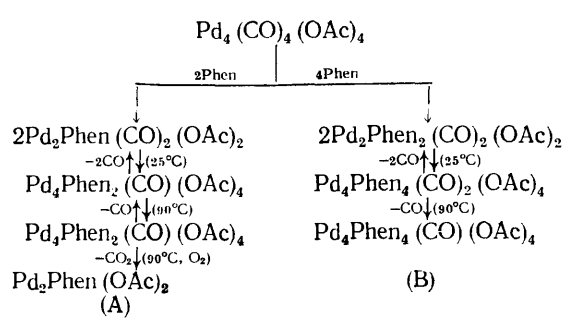


Figure 4. The structure of the cluster $[Pd_4(CO)_2Phen_4](OAc)_4$.

None of the remaining carbonyl carboxylate clusters described in this section exhibits a catalytic activity either because of their coordinative unsaturation and a low tendency towards the formation of intermediate complexes with an alkene or alkylarene molecule or as a consequence of their decomposition to other relatively inactive and also coordinatively unsaturated palladium complexes.

In contrast to this, the more labile palladium complexes formed in the reaction of PCA with *o*-phenanthroline or bipyridyl in solution in acetic acid using a concentration ratio $[Pd]_\Sigma:[L]_\Sigma \geqslant 1:1$ proved to be catalytically active.[64]

Studies on the reactions occurring between PCA and *o*-phenanthroline at different concentrations in solution in acetic acid led to the conclusion that the reactions in this system can be represented by the following scheme.[64]

The complexes of the (B) series, formed at comparatively high *o*-phenanthroline concentrations, lead at 25 °C to the stable cationic cluster $Pd_4Phen_4(CO)_2(OAc)_4$ with a tetrahedral metallic core (see above). The more labile series (A) complexes, formed at a concentration [Phen] $\leqslant 10^{-2}$ M are catalytically inactive so long as their composition includes even one coordinated CO molecule. The removal of the latter is achieved only in an O_2 atmosphere at $T \geqslant 90$ °C, which leads to the formation of a catalytically active substance whose elemental composition corresponds approximately to the formula $Pd_2(Phen)(OAc)_2$.[64]

A more exact chemical composition of the palladium-containing complex responsible for the catalytic activity in this system was not determined. Nevertheless the study of its catalytic properties permitted the conclusion that the catalytic reactions proceed in this instance without the involvement of divalent palladium. This is indicated by the following data:[67]

1. The reduction of palladium(+2) in acetic acid containing alkenes and toluene is sharply inhibited after the introduction of 0.1–0.5 M mol of *o*-phenanthroline, bipyridyl, or PPh_3 per mole of palladium. The addition of these ligands to a system based on PCA + Phen which has passed the catalyst formation stage [in accordance with scheme (A)] hardly affects the rate of the oxidative acetoxylation of propene and toluene even at an added ligand concentration exceeding by a factor of 2–5 the overall palladium concentration.

2. In the oxidation of propene in the catalytic system indicated, allyl acetate is formed in 100 ± 5% yield relative to the propene which has reacted and even traces of acetone, propenyl acetate, or isopropenyl acetate are absent; in the oxidation of toluene, there are no oxidative coupling and ring-acetoxylation products, only the products of the oxidative acetoxylation of the side chain being formed—benzyl acetate (⩾90%) and benzylidene diacetate (⩽10%).

3. The addition of 10–15% of water to a solution of the catalyst based on PCA + Phen does not lead to the appearance of acetaldehyde on oxidation of ethylene and acetone accompanying the oxidation of propene, which is not characteristic of catalytic systems based on palladium(+2).

4. When $Pd(OAc)_2$ is added to the catalytic system indicated, the selectivity of the oxidation of ethylene and toluene falls as a consequence of the formation of vinyl ethers and bitolyl respectively; acetone appears in the propene oxidation products.

Catalytic systems based on PCA + Phen (or Bipy, PPh_3) exhibit a comparatively high activity in the oxidative acetoxylation of ethylene, propene, and toluene under mild conditions (60–100 °C, 1 atm, 5–10 mol of the ester per mole of palladium per hour), which exceeds the activity of palladium black by a factor of 2–10. A deficiency of these catalytic systems is their low stability as a function of time: after continuous operation for 3–10 h at 60–90 °C, a deposit of palladium black is produced and the activity falls by a factor of 3–5.[64]

Apart from the oxidative acetoxylation reactions, the system based on PCA + Phen makes it possible to achieve the catalytic oxidative acetoxylation reaction. Thus, in solution in methanol propene is oxidised to allyl methyl ether:[86]

$$CH_2{=}CHMe + MeOH + {}^1/_2O_2 = CH_2{=}CHCH_2OMe + H_2O,$$

whereas isobutene is oxidised to methallyl methyl ether:

$$CH_2{=}CMe_2 + MeOH + {}^1/_2O_2 = CH_2{=}CMeCH_2OMe + H_2O.$$

Since catalytic activity is shown by products of the reaction of palladium(+1) carbonyl acetate not containing coordinated CO, it is useful to obtain a catalytically active palladium cluster by another procedure, bypassing the carbonyl complex formation stage.

It was observed[88] that solutions catalytically active in oxidative alkene acetoxylation reactions are formed when $Pd(OAc)_2$ is reduced in acetic acid containing *o*-phenanthroline, bipyridyl, and their analogues by various reductants, among which H_2 is the most convenient. The dependence of the catalytic activity on the overall content of the ligand L passes through a maximum in the region of ratios $[Pd]_\Sigma:[L]_\Sigma$ from 2:1 to 4:1.[63,88]

If it is postulated that the ratio $\{[Pd]_\Sigma:[L]_\Sigma\}_{max}$ indicates the composition of the compound responsible for the catalysis, one may conclude that the oxidation of alkenes is catalysed by ligand-deficient cluster compounds. In order to elucidate the nature of these compounds, their compositions and structures as well as the stoichiometry of the stages leading to the formation of catalytically active compounds were investigated.

The product of the reduction of palladium(+2) acetate by hydrogen in solution in acetic acid containing 0.5 mol of *o*-phenanthroline per palladium atom was isolated. It is an X-ray-amorphous substance whose composition corresponds to the very simple formula $Pd_4(Phen)(OAc)_2$.[89] It has been shown by volumetric measurements that 1.3 ± 0.05 mol of H_2 is consumed per mole of palladium(+2) in the formation of this substance, which could correspond to the following reaction stoichiometry:

$$4Pd_3(OAc)_6+3Phen+15H_2=3Pd_4Phen(OAc)_2H_4+6AcOH.$$

In order to confirm the conclusion that the complex is of the hydride type, its ^1H NMR spectra were investigated. In the range of chemical shifts δ = 0 to −80 p.p.m., no signals due to hydride atoms were detected in the high-resolution spectra (25 kHz frequency range) of solutions of the complex in CD_3OD, although a broad band with a maximum in the range δ = −30 to −50 p.p.m. (width 5 kHz) was found in the broad-band spectrum (250 kHz frequency range). Similar data have been obtained for the analogue of this complex containing bipyridyl instead of *o*-phenanthroline. The spectrum of the solid specimen, recorded with rotation at the "magic angle", contains three somewhat narrower (~2 kHz) bands in the range of δ from −35 to −50 p.p.m. These data confirm the hypothesis that the complexes obtained are of the hydride type.

The appreciable broadening of the hydride signal can be explained by the fact that the Pd atoms in these complexes form a polynuclear structure with a system of metal−metal bonds similar to that in the lattice of metallic palladium or its hydride phases. The protons of the $OCOCH_3$ groups are observed in the ^1H NMR spectrum as a narrow signal at δ = 2.0 p.p.m., while the signal of the *o*-phenanthroline protons consists of a complex unresolved multiplet in the range of δ from 6 to 9 p.p.m. The broadening of the usually resolved multiplet of the *o*-phenanthroline protons can be explained by the coordination of this ligand to the palladium atoms of the paramagnetic metallopolymer. This was confirmed by the weak temperature-independent paramagnetism found for the complex ($\chi_g^{300} = 0.5 \times 10^{-6}$ CGSU).[90]

The study of this complex by high-resolution transmission electron microscopy showed that its particles contain an approximately spherical metallic core 20 ± 5 Å in diameter.[89] The observed value agrees well with the average diameter of the particles obtained by the small angle X-ray scattering method (18 ± 5 Å).

The study of solid specimens of the hydrido-complex by the EXAFS method yielded the radial distribution curve for the atoms (RDA) on which there is one maximum corresponding to the Pd−N = 2.1 ± 0.1 Å interatomic distance and a signle peak corresponding to the Pd−Pd = 2.62 ± 0.05 Å distance. Maxima corresponding to more remote palladium atoms were not detected, which may be explained by the absence of long-range order in their arrangements as a consequence of the not completely regular incorporation of the H atoms in the core of the complex.[89]

The observed dimensions of the metallic core of the hydrido-complex molecule make it possible to estimate the value of *n* in the idealised formula $[Pd_4Phen(OAc)_2H_4]_n$ as approximately 100 on the assumption that the packing density of the palladium atoms in the core of this cluster is the same as in the metallic palladium lattice.

The chemical properties of the hydrido-complex indicate its high reactivity. Table 1 shows that treatment of the polynuclear hydrido-complex with various reagents leads as a rule to unstable products which decompose into mononuclear or oligonuclear palladium complexes. In contrast to this, the reaction with O_2 leads to the formation of clusters in which a massive metallic core is retained. These clusters proved to be effective catalysts of many oxidation reactions.

Table 1. The principal palladium-containing products of the reaction of a polynuclear hydrido-complex with various reagents at 293 K.

Reagent	Solvent, reaction time	Reaction products
Hg	AcOH, 2 h	H_2, Pd amalgam
PPh_3	DMF, 3 h	H_2, $Pd(PPh_3)_3$
CO	RCOOH (R=Me, Et, t-Bu), 1−3 h	$[Pd_4Phen_3(CO)_3H_2(OCOR)_3]_n$*
NO	AcOH, 1 h	$Pd_4(NO)_2(OAc)_6$
$H_2NCON(Me)NO$	DMF, 24 h	PdPhen$(NCO)_2$ (Ref.92)
Tetrachloro-*o*-benzoquinone	DMF, 3 h	$(C_6O_2Cl_4)Pd(DmPhen)$**
$PhenH^+X$, where X=BPh_4, PF_6, AsF_6	AcOH, 1−3 h	$PdPhen_2X$
O_2	AcOH, 10−30 min	$[Pd_9Phen(OAc)_3]_{60}$

*Polynuclear hydride complex with $n \simeq 2.3$.[93]

**DmPhen = 2,9-dimethyl-1,10-phenthroline was used instead of Phen in the synthesis of the hydrido-complex.

VI. Giant palladium clusters

In the reaction with O_2 the polynuclear hydrido-complex loses the hydride atoms forming part of its composition, which are bound in H_2O. A small proportion of the palladium atoms are then oxidised to palladium(+2) complexes, while the main bulk of them are converted into a cluster type substance whose simplest formula is $Pd_9(Phen)(OAc)_3$ (I) and which is stable in air and is soluble, like the hydrido-complex, in water and polar organic solvents.[94]

1. The structure of giant palladium clusters

The rate of sedimentation of compound (I) in aqueous solution obtained with the aid of an ultracentrifuge made it possible to estimate the molecular weight as (1.0 ± 0.05) × 10^5. More definite

information about the size of the molecules of compound (I) was obtained with the aid of the small angle X-ray diffraction method, high-resolution transmission electron microscopy, and electron diffraction.[90,91,94,95]

On the electron photomicrographs, the metallic cores of the molecules of compound (I) appear as almost regular spherical particles 26 ± 3.5 Å in diameter. The electron diffraction patterns, recorded for the same specimens of compound (I), contain 5–6 diffuse rings whose positions are close to those for metallic palladium.

The similarity between the sets of interplanar spacings for compound (I) and metallic palladium might indicate the identity of the principal parameters of the structures of the metallic core of compound (I) and the space-centred cubic lattice of metallic palladium. However, this hypothesis conflicts with EXAFS data, which definitely indicate eicosahedral packing of the palladium atoms in the molecules of compound (I) (see below). It is reasonable to postulate that the cause of the similarity between the electron diffraction patterns of compound (I) and metallic palladium is the degradation of the molecules of compound (I) leading to the formation of metallic particles on exposure to the electron beam.

The destructive effect of the electron beam on the cluster molecules was observed in electron microscope studies on the $Au_{55}(PPh_3)_{12}Cl_6$ [96,97] and $[Ni_{38}Pt_6(CO)_{48}H](Me_3NCH_2Ph)_5$ [98] clusters. As a result of the loss of ligands, the initial eicosahedral skeleton of the cluster can relax to a crystallite with a cubic face-centred lattice (for example in the form of a cubo-octahedron). It may be that similar processes occurred also in the electron microscope study of the recently synthesised platinum cluster $Pt_{309}L_{36}O_{30\pm10}$ (L = bis-sulphophenyl-1,10-phenanthroline) for which a cubo-octahedral structure of the cluster core was found by transmission electron microscopy.[99]

Apparently the conclusions about the structure of the clusters reached on the basis of electron microscope studies should be treated with much caution. However, if the agglomeration or breakdown of metallic particles are not observed in the course of the electron microscope study, as happened in the case of the palladium cluster, then electron diffraction patterns can be used for the independent estimation of the particle sizes.

The size of the particles responsible for diffraction, estimated from the half-widths of the diffraction rings, is approximately 25 Å for the cluster (I), which agrees with electron microscope and small angle X-ray diffraction data (Fig. 5):

Method	d, Å
Electron microscopy	26±3.5
Electron diffraction	25
Small angle X-ray diffraction	20

The small angle X-ray diffraction data also indicate the virtually unimodal nature of the size distribution of the particles.

The packing of the palladium atoms in the metallic core of compound (I) was determined with the aid of EXAFS spectra.[94] The RDA curve obtained on the basis of these spectra has a peak which corresponds to a Pd–O (or Pd–N) distance of 2.1 ± 0.1 Å. Four intense peaks correspond to the shortest Pd–Pd distances (Table 2). The observed set of interatomic Pd–Pd distances agrees best with the eicosahedral packing of the palladium atoms in the metallic core of the cluster (I) (the expected interatomic distances between the nearest neighbouring atoms in the eicosahedron are in the proportions 1:1.2:1.4:1.6) and differs appreciably from the expected set of distances for the face-centred cubic and hexagonal close packing.

The average atomic volume of palladium in the eicosahedral metallic core of compound (I), calculated using the interatomic distances from Table 2, is approximately 16 Å^3, which exceeds only slightly the atomic volume for metallic palladium (14.7 Å^3). This result rules out the possibility of the coordination of the Phen and OAc ligands to the inner palladium atoms in the cluster. Consequently the Phen and OAc groups are arranged on the periphery of the metallic core of the cluster (I).

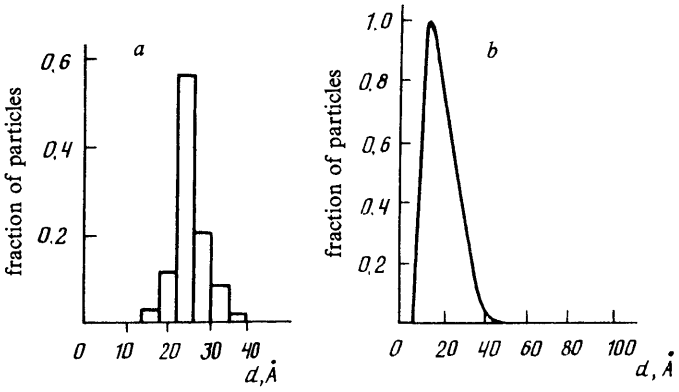

Figure 5. The size distribution of the metallic cores of the giant clusters (I) according to electron microscope (*a*) and small angle X-ray diffraction (*b*) data.

Table 2. Experimental (based on EXAFS data) shortest interatomic Pd–Pd distances in the metallic core of the cluster (I) and the values expected for different types of packing.

Type of data	Pd–Pd distance, Å				
Experimental	2.60±0.004	3.10±0.1	3.66±0.1	4.08±0.1	
Calculated for different types of packing:					
face-centred cubic	2.60		3.66		
hexagonal	2.60		3.66		4.50
eicosahedral	2.60	3.10	3.66	4.10	

Note. The smallest of the shortest distances was assumed to be 2.60 Å in the calculations for all types of packing.

Knowing the nature of the packing of the palladium atoms and the distances between the nearest neighbouring palladium atoms, it is possible to estimate the number of palladium atoms in the cluster molecule. For a sphere approximately 25 Å in diameter, this number N_Σ approximately equals 570. On the basis of this value and the chemical composition obtained from the results of elemental analysis, the molecule of compound (I) can be represented approximately by the formula $Pd_{570\pm30}Phen_{63\pm3}(OAc)_{190\pm10}$. The molecular weight corresponding to this formula (N = 83200) agrees with the result of the direct determination from the rate of sedimentation from aqueous solution.

The observed value $n = 570$ agrees well with the value of N_Σ for the idealised model comprising a 5-layer eicosahedron containing 561 metal atoms in conformity with the formula

$$N_\Sigma = {}^1/_3(10m^3+15m^2+11m+3) = 561 \quad [100],$$

where m is the number of eicosahedral layers ($m = 5$). Taking into account the chemical composition, the idealised formula $Pd_{561}Phen_{60}(OAc)_{180}$ was proposed for the eicosahedral cluster (I). This idealised formula apparently corresponds to the average size and composition of the cluster and not to definite fixed dimensions and chemical composition. In other words, the distribution of the particles of compound (I) about an average size $d \simeq 25$ Å and the idealised composition $Pd_{561}Phen_{60}(OAc)_{180}$.

This situation resembles to some extent organic polymers in which different molecules contain different numbers of monomeric units. Bearing in mind that the average Pd–Pd bond energy is fairly small (40–60 kJ mol^{-1}), one may expect that such giant clusters have certain defects ("apices", "niches", etc.) which are difficult to detect by electron microscopy.

Analysis of molecular models showed that the Phen ligands coordinated as bidentate species can be coordinated only at the apices and edges of the eicosahedron because of the steric hindrance generated by the H atoms in the 2- and 2'-positions in the *o*-phenanthroline molecule. As a result of this, out of the 252 metal atoms in the outer layer of the idealised eicosahedron only about 60 can be linked to the *o*-phenanthroline ligands involved in the bidentate coordination. The complete formal charge on the metallic core together with the electrically neutral Phen ligands is 180+ and is balanced by 180 anionic OAc^- ligands.

In this arrangement, almost the entire surface of the metallic core is sterically shielded by the bulky *o*-phenanthroline groups. The acetate anions can therefore be arranged only in the outer sphere of the cluster cation (I) (Fig. 6). We may note that a similar outer-sphere disposition of acetate anions was observed by X-ray diffraction in the tetranuclear cluster $[Pd_4Phen_4(CO)_2](OAc)_4$ [34] (Fig. 4).

The conclusion that the ligands OAc^- are involved in outer-sphere coordination was also confirmed by IR spectroscopic data [the frequency difference is $\nu_{as}(OCO)-\nu_s(OCO) = 165$ cm^{-1}, as in solid CH_3COONa] and ^1H NMR data (the line due to the protons of the OAc^- groups is observed as a narrow singlet at $\delta = 2.0$ p.p.m., in contrast to the appreciably broadened Phen multiplet).

The cluster (I) can be precipitated from aqueous solution by adding salts such as NaX or KX ($X^- = Cl^-$, Br^-, ClO_4^-, HSO_4^-, PF_6^-, AsF_6^-) with substitution of the OAc^- anions by X^-. Treatment of compound (I) with the salt KPF_6 yielded a cluster with the idealised formula $Pd_{561}Phen_{60}O_{60}(PF_6)_{60}$ (II), which is soluble in acetonitrile.[90,91]

Electron microscope data showed[91] that the metallic core of this cluster is almost spherical and has a diameter of 28 ± 5 Å, which agrees with small angle scattering data.

The results of chemical analysis and the stoichiometry of the conversion of the cluster (I) into (II) showed that the substitution of the outer-sphere OAc^- ligands in aqueous solution is accompanied by the partial hydrolysis of the cluster, as a result of which only 60 out of the 180 OAc^- anions are substituted by the PF_6^- anions, while the remaining 120 OAc^- anions are substituted by O^{2-}:[90]

$$Pd_{561}Phen_{60}(OAc)_{180}+60\,PF_6^-+60\,H_2O = Pd_{561}Phen_{60}(PF_6)_{60}O_{60}+ +120\,AcOH+60\,AcO^-.$$

Molecular clusters containing between 4 and 38 palladium atoms are known to be diamagnetic.[85,101] In contrast to this, the clusters (I) and (II), containing several hundreds of palladium atoms in the metallic core, possess metal-like properties, such as temperature-independent paramagnetism. The specific magnetic susceptibility at 300 K [$\chi_g^{300} = 1.0 \times 10^{-6}$ CGSU for (I) and 0.8×10^{-6} CGSU for (II)[90]] is close to that for metallic palladium particles deposited on SiO_2 [degree of dispersion 0.2–0.5; $\chi_g^{300} = (0.8 \pm 0.2) \times 10^{-6}$ CGSU[102]].

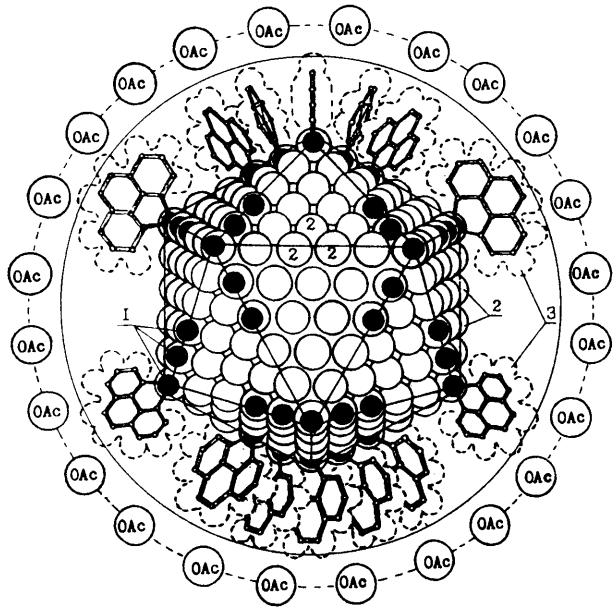

Figure 6. Idealised model of the giant cluster (I): *1*, palladium atoms coordinated to the phenanthroline ligand; *2*, palladium atoms available for coordination to the OAc^- anions or substrate molecules; *3*, van der Waals limits of the coordinated phenanthroline molecules.

The metallic core of the cluster (II) was also investigated by the EXAFS method.[90] The RDA curve for freshly prepared specimens of the cluster indicates the presence of Pd–Pd distances characteristic of both eicosahedral and cubo-octahedral cores. However, 30–100 days after the preparation of the specimen, only the peaks corresponding to a face-centred cubic lattice (cubo-octahedron) remain on the RDA curve. Similar changes in the structure of the metallic core were observed also after the replacement of the outer-sphere OAc^- anions by the BF_4^-, HSO_4^-, ClO_4^-, etc. anions. These data indicate the ease with which the eicosahedral packing of the metal atoms in the skeleton of the giant cluster relaxes to the cubo-octahedral packing as a result of the substitution of the ligands and standing for a long time even at room temperature.

Analysis of our molecular models showed that 60 oxygen atoms can be accommodated as bridging groups between the surface palladium atoms of the metallic core on the faces of a cubo-octahedron with a diameter of 28 Å without steric hindrance due to the 60 coordinated *o*-phenanthroline molecules.

The possibility of the coordination of oxygen atoms to the surface atoms of the metallic core in giant clusters was recently confirmed by the synthesis of a platinum cluster with the idealised formula $Pt_{309}L_{36}O_{30\pm10}$ (L = bis-sulphophenylphenanthroline),[99] which was obtained by the same method as the cluster (II) using platinum(+2) acetate instead of palladium(+2) acetate and a phenanthroline derivative in the form of the sodium salt of the corresponding sulphonic acid (see above). In the case of palladium, these investigators obtained a giant cluster with 561 palladium atoms in the idealised formula and a somewhat different composition of the coordination shell.[103]

The giant clusters obtained apparently serve as a bridge between the usual molecular clusters and colloidal metals. The size of the metallic core in giant clusters exceeds appreciably the size of the usual molecular clusters such as $Pd_{38}(CO)_{28}(PEt_3)_{12}$ [101] and $Au_{55}(PPh_3)_{12}Cl_6$,[104] approaching the lower limit of the sizes of colloidal metal particles. In contrast to the latter, giant clusters have a distinct ligand environment with a definite stoichiometry of the type characteristic of molecular clusters. However, in both cases when the number of metal atoms approaches several hundreds, a set of more or less imperfect metallopolyhedra is formed with a certain distribution with respect to size and chemical composition.

In principle, the metallic cores of such clusters need not necessarily contain the "magic number" of metal atoms.[100,105] Nevertheless large and giant clusters with metallic cores in the form of two-layer (M_{55}),[96] four-layer (M_{309}),[99] and five-layer (M_{561})[91] 12-vertex particles are now known.

Since the relaxation energy of the close packing is extremely small, such metallopolyhedra can readily undergo interconversions and, depending on the ligand environment, temperature, and other factors, can be stabilised as isomeric cubo-octahedra, eicosahedra, and anticubo-octahedra.[105] The solution of the problem of their true geometry requires the application of experimental methods, for example EXAFS, which do not have a destructive or some other strong effect on the substance.

The use of idealised formulae based on data obtained by the above methods is useful for the construction of models characterising the average size and composition of the giant clusters and suitable for the examination of their catalytic properties.

2. Catalytic properties of the giant clusters (I) and (II)

(a) Oxidative acetoxylation. In the presence of acetic acid in solutions of the clusters (I) and (II), oxidative acetoxylation reactions take place, involving the conversion of ethylene into vinyl acetate:

$$C_2H_4+{}^1/_2O_2+AcOH = CH_2{=}CHOAc+H_2O,$$

of propene into allyl acetate:

$$C_3H_6+{}^1/_2O_2+AcOH = CH_2{=}CHCH_2OAc+H_2O,$$

and of toluene into benzyl acetate:

$$PhCH_3+{}^1/_2O_2+AcOH = PhCH_2OAc+H_2O.$$

Their selectivity is 95–98%.[91] The only side reaction observed in the presence of these catalysts is further oxidation of the alkenyl and benzyl esters, as they accumulate, to ethylidene, allylidene, and benzylidene acetates respectively. Compared with metallic palladium catalysts, whose activity is manifested at higher temperatures,[106,107] the clusters (I) and (II) facilitate side reactions to a lesser extent.

(b) Oxidation of alcohols. The clusters (I) and (II) effectively catalyse the oxidation by molecular O_2 of primary aliphatic alcohols to esters in which the alcoholic and acid components have the same carbon skeleton as the initial alcohol:[108]

$$2RCH_2OH+O_2 = RCOOCH_2R+2H_2O.$$

Together with esters, the oxidation of primary alcohols leads to the formation of the aldehydes and the corresponding acetals (Table 3).

Secondary alcohols are smoothly oxidised to ketones:

$$(CH_3)_2CHOH+{}^1/_2O_2=(CH_3)_2CO+H_2O.$$

Table 3. Oxidation of alcohols by oxygen (1 atm) in the presence of the cluster (II) (suspension of 0.1 g of the cluster in 2.5 ml of the alcohol).

Alcohol	Temperature, °C	$10^3 W_0$, mol litre^{-1} h^{-1}	Composition of products	Yield, %
C_2H_5OH	60	2.3	$CH_3COOC_2H_5$	27
			$CH_3CH(OC_2H_5)_2$	55
			CH_3CHO	18
n-C_3H_7OH	60	2.0	$C_2H_5COOC_3H_7$	7
			$C_2H_5CH(OC_3H_7)_2$	16
			C_2H_5CHO	77
iso-C_3H_7OH	20	2.1	$(CH_3)_2CO$	100
n-C_4H_9OH	60	1.3	$C_3H_7COOC_4H_9$	59
			$C_3H_7CH(OC_4H_9)_2$	38
			C_3H_7CHO	3

(c) The formation of acetals from carbonyl compounds and alcohols. Presumably the oxidation of primary alcohols proceeds via the intermediate formation of aldehydes. This hypothesis is supported by the finding that, in the absence of O_2, acetaldehyde introduced into an alcoholic suspension of a cluster (II) is converted into the acetal:[109]

$$CH_3CHO+2EtOH=CH_3CH(OEt)_2+H_2O.$$

This reaction is of a general character and is catalysed not only by the clusters (I) and (II) but also by different types of palladium black.

(d) Oxidation of formic acid. The gas-phase decomposition of HCOOH into CO_2 and H_2 takes place at an appreciable rate on deposited palladium catalysts even at 50 °C.[110] The clusters (I) and (II) as well as palladium black catalyse the decomposition of HCOOH in the gas phase in the absence of O_2 at 50 °C. However, in the liquid phase at the same temperature the decomposition of HCOOH is not observed. In the presence of O_2 in solutions containing the clusters (I) and (II), formic acid is oxidised at 20–70 °C:[111]

$$HCOOH+{}^1/_2O_2=CO_2+H_2O.$$

In solutions of the clusters (I) and (II) in acetonitrile, the reaction kinetics are described by an equation of the Michaelis–Menten type:

$$W = k[\text{Clust}][\text{HCOOH}]\frac{[O_2]}{K + [O_2]}.$$

The observed isotope kinetic effects $k_{HCOOH}/k_{HCOOD} = 1.1 \pm 0.1$ and $k_{HCOOH}/k_{DCOOD} = 1.0 \pm 0.1$ show that the C–H and O–H bonds are not ruptured in either the rate-limiting or the preceding stages. A reaction mechanism was proposed on the basis of these data[111] in which the rate-limiting stage is the coordination of the undissociated HCOOH molecule to the palladium atoms on the surface of the metallic core. The subsequent stages—the dissociation of the coordinated HCOOH, the transfer of an H atom to the coordinated O_2, and the removal of the products from the surface of the metallic core of the cluster—are rapid and are not reflected in the reaction kinetics.

Thus giant palladium clusters exhibit a varied catalytic activity in both oxidation reactions and in the reactions which traditionally belong to the field of acid–basis catalysis. The mechanism of these reactions has been studied in greatest detail in relation to the oxidative acetoxylation of ethylene and propene.

VII. Kinetics and mechanisms of oxidation reactions in solutions of giant palladium clusters

The kinetics of the oxidation of ethylene in solutions of the cluster (II) in acetic acid–acetonitrile mixtures obey the following kinetic equation:[112]

$$r_0 = k[\text{Clust}]\frac{[C_2H_4]\cdot[O_2]\cdot[\text{AcOH}]}{(K_I + [C_2H_4])(K_{II} + [O_2])(K_{III} + [\text{AcOH}])},$$

where r_0 is the rate of formation of vinyl acetate from ethylene and K_I, K_{II}, and K_{III} are Michaelis constants.

The rate of accumulation of allyl acetate in the oxidation of propene in solutions of the clusters (I) and (II) is also directly proportional to the cluster concentration. In contrast to ethylene, deviations from linearity are not observed in the relation between r_0 and the propene concentration. However, when the O_2 concentration is varied, the rate of reaction changes in a more complex manner than was observed in the oxidation of ethylene. At a propene partial pressure greater than 0.9 atm, this variation is represented by a curve with a plateau, but, as the propene partial pressure is reduced to 0.5 atm, a maximum characteristic of the inhibition of the reaction by the initial reactant (in the given case oxygen) appears on the $r_0 = f(P_{O_2})$ curve. For $P_{C_3H_6} > 0.7$ atm, i.e. under conditions where the reaction is not inhibited by oxygen, the rate is described by an equation analogous to the kinetic equation for ethylene with the sole difference that the Michaelis constant for propene is much greater than that for ethylene (Table 4).[113] Comparison shows that the rate constants for the oxidation of ethylene and propene in the presence of both clusters differ by less than a factor of three. The range of variation of the Michaelis constants K_{II} and K_{III} on passing from one alkene to another and on replacing the cluster (I) by (II) is also not very great.

The greatest difference between the kinetic characteristics of the ethylene and propene oxidation reactions involves the appreciable alteration of the constant K_I.

The Michaelis nature of the kinetics of these reactions suggests that the oxidation-reduction reactions are preceded by stages involving the reversible coordination of the alkene, O_2, and AcOH to the cluster and that propene is coordinated much more weakly than ethylene, O_2, and AcOH.

In homogeneous alkene oxidation reactions with participation of mononuclear and dinuclear palladium(+2) complexes, the oxidation product is formed in the absence of O_2 in stoichiometric amounts relative to the palladium(+2) which has reacted. In contrast to this, in solutions of the clusters (I) and (II) the oxidation of alkenes in the absence of O_2 is not observed. This fact also indicates that the reactions of ethylene and propene in solutions of giant clusters cannot be explained by the alternation of oxidation-reduction reactions of the cluster with the substrate and the oxidant. The lower formation constants of the π-complexes of propene compared with ethylene can be accounted for by the greater size of the molecule of this substrate.

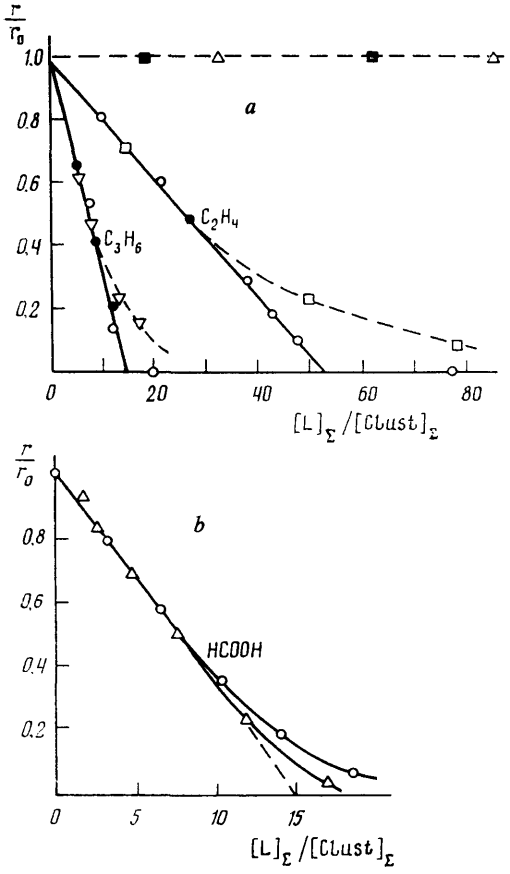
Table 4. Constants of the kinetic equation for the oxidation of ethylene and propene in solutions of the clusters (I) and (II) at 60 °C.

Substrate	Cluster	k, min^{-1}	K, mol $litre^{-1}$		
			$10^3 K_I$	$10^4 K_{II}$	K_{III}
Ethylene	(II)	8.2±0.7	5.8±0.3	3.0±0.2	1.3±0.1
Propene	(I)	3.3±0.3	30	5.2±0.3	0.67±0.05
Propene	(II)	5.6±0.5	30	1.2±0.1	4.8±0.5

Indeed, the surface of the metallic core of the cluster is sterically blocked by the bulky phenanthroline ligands. Analysis of the idealised molecular model showed that, on the surface of the metallic core of the cluster (I), there are approximately 20 palladium atoms sterically available for the coordination of the solvent or reactant molecules. However, the smaller C_2H_4 molecules are presumably coordinated more strongly at these sites than the C_3H_6 molecules whose steric requirements are more stringent. For the real molecules of a giant cluster, which probably differ to a greater or lesser extent from an ideal polyhedron, the number of accessible sites differs from that for the idealised model. This number can be determined experimentally by introducing into the solution of the cluster some kind of ligand (catalytic poison) which is strongly bound to the accessible palladium atoms on the surface of the metallic core. The results obtained for the influence of different poisons (Fig. 7) showed that ligands which are bulky (PPh_3, phenanthroline) but are effectively coordinated to palladium hardly affect the rate of oxidation of alkenes, since they do not apparently find on the surface of the cluster sites available for their coordination. Smaller ligands (mercaptans, thiocyanate, etc.) effectively block the cluster.

A similar picture has been observed also for the HCOOH oxidation reaction.[111] The complete inhibition of the ethylene oxidation reaction requires the blocking of approximately 50 palladium atoms, whereas for propene it is sufficient to bind only 15 metal atoms in the cluster to the poison ligand for the cluster to lose its catalytic activity.[112,113] These data confirm the above hypothesis that the steric factor plays a decisive role in the formation of complexes between the substrate and the cluster.

Oxidative alkene acetoxylation reactions reduce to the dissociation of the C–H bonds in the initial alkene and the substitution of the H atom by the OAc group. The kinetic data obtained have shown, however, that in solutions of the giant clusters both reactions take place at similar rates despite the considerable differences between the strengths of the C–H bonds in ethylene (the strength of the vinyl–H bond is 106 ± 2 kcal) and in propene (the strength of the allyl–H bond is 86.2 ± 2 kcal) (see Ref. 114, p. 39). This finding shows that, despite the common form of the kinetic equation, the rate-limiting states in the ethylene and propene reactions are significantly different. This hypothesis is supported by the kinetic isotope effects obtained (Table 5).[91]



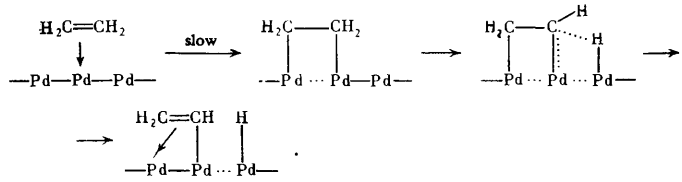


Figure 7. Dependence of the relative rates of oxidation of alkenes (*a*) and formic acid (*b*) by oxygen in solutions of the giant cluster (II) on the concentration of ligand-inhibitors: *a*, ○—$(C_2H_5)_2NCS_2Na$; ●—C_2H_5SH; ▽—I_2; □—KSCN; Δ—Phen; ■—PPh_3. *b*, ○—NaSCN; Δ—$(C_2H_5)_2NCS_2Na$.

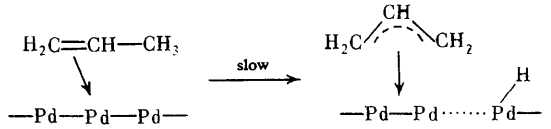
In the ethylene molecule, the C=C π-bond is weakest (~60 kcal). The data in Table 5 are consistent with the fact that hydrogen atoms are transferred from the coordinated C_2H_4 and CH_3COOH molecules in rapid stages following the rate-limiting stage. The closeness of the isotope effect H/D for ethylene to unity can be explained by the fact that in the slow stage the π-coordinated C_2H_4 molecule undergoes oxidative addition (with opening of the C=C π-bond) to the Pd–Pd group of the cluster with formation of the σ,σ-coordinated group...Pd–CH_2CH_2–Pd...:

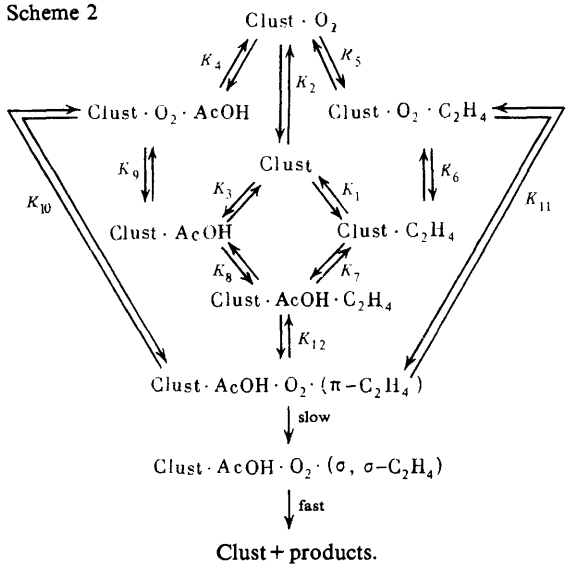


One cannot rule out the possibility that the subsequent dissociation of the C–H bond in this group is facilitated because of the possibility of the formation of a Pd–C multiple bond in the transition state.[115]

Analogous forms of adsorption had been postulated earlier for the hydrogenation and dehydrogenation of ethylene and the H/D exchange involving it on the surfaces of metallic catalysts.[116] Reliable evidence for the formation of σ,σ-coordinated ethylene and a π,σ-coordinated vinyl group on the surface of Pd(100) was obtained recently by means of a combination of thermoprogrammed reaction spectroscopy (TPRS) and high-resolution electron energy loss spectroscopy (HREELS).[117]

The intermediate formation of σ-bound organopalladium compounds $XPdCH_2CH_2OR$ had been established earlier in reactions involving the oxidation of ethylene by palladium(+2) salts.[118] In the case of the giant clusters (I) and (II), the palladium atoms at the metallic core of the cluster in an oxidation state close to zero participate in the reaction; as a result of the formation of the σ,σ-complex, the formal oxidation state of each of these atoms increases by unity, returning to the initial oxidation state after the completion of the catalytic cycle.

In the case of propene, the difference between the strengths of the π-C=C and allyl–H bonds is much smaller than the difference between the energies of the π-C=C and vinyl–H bonds in ethylene. The insertion of propene in the Pd–Pd bond of the cluster with dissociation of the allyl–H bond probably leads to a π-allyl complex and a coordinated hydride:

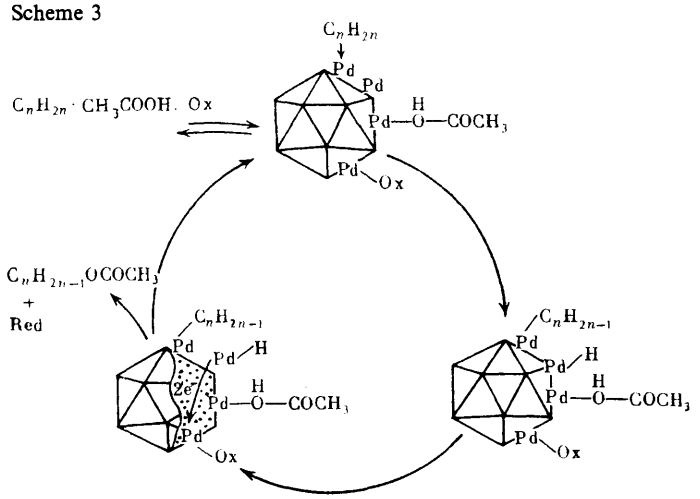


The stabilisation of the π-allyl complex as a result of the formation of a surface π-allyl group probably favours the situation where the competition between the vinyl and allyl reaction pathways is won by the latter and the oxidative acetoxylation of propene on clusters (I) and (II) proceeds only via the allyl pathway. The experimental kinetic isotope effects are consistent with the scheme (Table 5).

Table 5. Kinetic isotope effects in the oxidation of ethylene and propene by oxygen in solutions of the clusters (I) and (II) at 60 °C.

Substrate	Cluster	$k_{C_nH_{2n}}/k_{C_nD_{2n}}$	$k_{CH_3COOH}/k_{CD_3COOD}$
Ethylene	(II)	1.1±0.1	1.1±0.1
Propene	(I)	2.2±0.2	1.0±0.05
Propene	(II)	3.6±0.2	1.0±0.05

The subsequent reactions of the coordinated vinyl and allyl groups and H atoms on the surface of the metallic core of the cluster are apparently rapid and are not reflected in the rates of the overall reactions (see Scheme 2).



Scheme 2

The data for the inhibition of the alkene and HCOOH oxidation reactions by ligands[91,111] showed that only about 20% of the surface palladium atoms are accessible to the reactant molecules in the oxidation of ethylene and only about 5–6% of the total number of these atoms are accessible in the oxidation of propene and formic acid. It is unlikely that on the surface of the metallic core of the cluster shielded to such an extent all three molecules—O_2, the substrate undergoing oxidation, and AcOH—would be coordinated to neighbouring palladium atoms of the same section of the cluster. Apparently there are better grounds for the expectation that the alkene or HCOOH molecule is bound to one section of the cluster, the O_2 molecule is coordinated to another, not necessarily neighbouring, section, and electron transfer from the Pd–alkenyl, Pd–formyl, or Pd–H fragment to the coordinated O_2 molecule proceeds via the metallic core of the cluster, which plays the role of an "electronic mediator".[31]

The overall reaction scheme can be represented as follows:

Scheme 3

Not only O_2 but also palladium(+2) salts can function as electron acceptors in cluster catalytic systems. Thus propene is oxidised to allyl acetate in the stoichiometric reaction of C_3H_6 with $Pd(OCOCH_3)_2$ in CH_3COOH. The particles of dispersed metallic palladium, formed in the initial period of this reaction, can then play the role of the cluster catalysing the allyl oxidation of propene.[119] This approach makes it possible to explain the previously observed[68,120] change in the selectivity of the reaction of palladium(+2) with propene in acetic acid. For a comparatively small change in conditions (temperature, AcONa concentration, H_2O, added oxidants), the yield of allyl acetate varies from 4 to approximately 90%.

In the presence of the clusters (I) and (II), benzoyl peroxide can also serve as the electron acceptor. Thus in solution in acetic acid containing the clusters (I) and (II), the reaction

$$C_3H_6 + (C_6H_5COO)_2 + CH_3COOH = CH_2{=}CHCH_2OCOCH_3 + 2C_6H_5COOH,$$

takes place at 20 °C with a selectivity of 98–100% with respect to allyl acetate.[121]

Although outwardly this reaction looks like peroxide oxidation, it proceeds fundamentally via the same mechanism as the oxidation by oxygen or palladium(+2) on clusters, in the absence of which the reaction does not occur under the conditions indicated.

VIII. Conclusion

Thirty years ago, the oxidative metal complex catalysis was represented by mainly free-radical processes. Against the background of this extensive class of reactions, the molecular oxidation of alkenes in solutions of palladium salts, where the unsaturated substrate encounters neither oxygen nor its partial reduction products, appeared to be a glaring exception. Nowadays oxidation reactions without the participation of free radicals occupy a due place both in the arsenal of industrial chemistry and in laboratory practice.

The field of molecular oxidative catalysis has been continuously developing. Together with complexes containing metal atoms in stable oxidation states, cluster compounds containing metal atoms in unusual oxidation states begin to be used in catalytic practice. The application of metal complexes made it possible to generate singlet oxygen and ozone from hydrogen peroxide. The coordination compounds responsible for these reactions contain ligands in which the oxygen atoms have unusually low fractional oxidation states. Apparently, as metal complex catalysis develops, chemists will encounter increasingly new examples of unusual oxidation states of both the central atoms and the ligand atoms. We suggest that the advances in metal complex catalysis and in coordination chemistry are in many respects inter-related and depend on the interaction of these two branches of chemical science.

Metal complexes of macrocycles in catalysis

K B Yatsimirskii
Pisarzhevskii Institute of Physical Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. The reactions catalysed by metal complexes with synthetic macrocyclic ligands and, in particular, the hydrolysis reactions of esters, peptides, and other substrates are examined. Many macrocyclic coordination compounds of transition metals are active catalysts of reactions occurring at electrodes (electrocatalysis). The catalysis by macrocyclic transition metal compounds of reactions involving the oxidation of various organic substances by molecular oxygen and other oxidants, in particular, the oxygen compounds of the halogens, is described. Examples of photocatalysis with participation of macrocyclic transition metal complexes as catalysts are presented. Certain features of the electronic structure of transition metal complexes with macrocyclic ligands are considered and routes leading to further development of catalysis using such compounds are outlined.

The bibliography includes 90 references.

I. Introduction

Although the first systematic studies on the synthesis and properties of metal complexes of macrocyclic compounds were not carried out until the 1960s, the number of compounds of this kind described at the present time runs to several thousand. Studies on the synthesis and physicochemical characteristic of macrocyclic complexes have been surveyed in a number of monographs.[1–4]

Comparatively few studies have been devoted to the catalytic acceleration of various reactions by macrocyclic compounds but their number has increased sharply during the last decade. A general feature is manifested here: after the discovery and study of a new class of chemical compounds, their application begins to develop vigorously. This was the case, for example, with complexones and metal complexonates, which are now finding extensive applications in various branches of the national economy.

It is noteworthy that, as early as the 1970s, catalytic reactions with participation of natural macrocyclic compounds such as the porphyrins and phthalocyanines, a kind of analogue of the former, were investigated vigorously. Since a number of monographs and reviews have been devoted to this question,[5–7] the reactions catalysed by metalloporphyrins and metallophthalocyanines will not be considered as a rule in the present review. Nor will the extremely specific field of the so called phase transfer catalysis be considered. In it macrocyclic compounds (mainly crown-ethers) play the role of an agent transferring the reactive substance from one phase to another (for further details, see Hiraoka[2]).

II. Characteristic features of metal complexes of macrocycles important for catalysis

Solvated (including hydrated) metal ions can participate in many catalytic processes by themselves. Nevertheless, the incorporation of a metal ion in the cavity of a macrocycle alters its properties extremely significantly. A metal ion in a macrocyclic environment is in the first place fully or partly desolvated (dehydrated). On partial desolvation, the possibility of a fairly easy replacement of the remaining solvent molecules by the ions or molecules of the catalytic reaction substrate appears. In this case, the metal ion can function as an acid centre ("Lewis acid") and can also catalyse hydrolytic reactions such as hydrolysis, solvolysis, etc. Here one may see a certain analogy with hydrolytic enzymes such as carboxypeptidase and carbonic anhydrase, which contain in their active centres a zinc ion surrounded by electron-donating oxygen atoms of carboxylic acids or nitrogen atoms of imidazole groups. Zinc, copper, cobalt (II) and (III), and many other metal ions characterised by a marked tendency to combine with nucleophilic species can play the role of acid centres.

The electron-donating atoms of the macrocyclic ligand, coordinated in a specific way around the central metal atom, create a ligand field characterised by a definite "strength", expressed, for example, by the spectrochemical parameter $10Dg$ in an octahedral complex. Several electron-donating ligand atoms are fairly frequently arranged in approximately the same equatorial plane, leaving the axial positions relatively free for the substrate molecules or ions and one may therefore speak of the axial coordination of the substrate molecule or ion.

The possibility of such coordination is determined by the electronic structure of the central ion. For example, in the case of low-spin nickel(II) complexes the axial coordination of the substrate is difficult owing to the presence of the electron pair in the axially oriented d_{z^2} orbital and, conversely, in complexes with an unoccupied d_{z^2} orbital the σ-type axial coordination of a substrate species is entirely possible [low-spin macrocyclic iron(II), cobalt(III), etc. complexes]. The appearance of a dative π-bond of the type

LM(II)→S may play a major role in the formation of intermediate compounds of the substrate and the macrocyclic complex.

The oxidation-reduction potential of the M(n+1)L/M(n)L couple depends on the nature of the electron-donating atoms and other characteristics of the macrocyclic ligand (L). [8] The redox potential is determined by the potential of the simple solvated ions M(n+1) and M(n) and by the ratio of the stability constants of the complexes M(n)L and M(n+1)L. The greater this ratio (we shall designate it by η), the higher the redox potential of the given pair of complexes and conversely.

Among the factors which determine the ratio η, the following may be specified.

1. The nature of the electron-donating atoms in the macrocycle: the highest η is characteristic of ligands with sulphide sulphur atoms and the lowest of ligands with ether oxygen. Ligands with electron-donating amine nitrogen atoms have intermediate values of η.

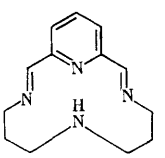
2. The charge on the ligands: the ratio η diminishes with increase in the negative charge of L.

3. The size of the cavity within the macrocycle: η also increases with increase in the size of the cavity.

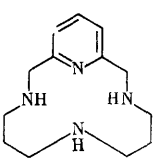
4. The possibility of the formation of dative π-bonds from the metal to the macrocycle leads as a rule to an increase in η.

Apart from these factors, it is essential to take into account the change in the spin state on oxidation-reduction of the complex, the difference between the effects of the ligand field on the M(n) and M(n+1) ions, the presence of alkyl substituents in the macrocycle, the change in the symmetry of the field on passing from M(n)L to M(n+1)L, etc.

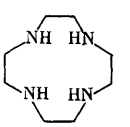
By selecting the macrocyclic environment, it is possible to regulate the redox potential of the M(n+1)L/M(n)L couple which catalyses the oxidation-reduction process at a particular stage of the latter.



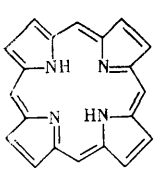
The possibility of the axial coordination of a nucleophilic molecule in the presence of an equatorial ligand and an unoccupied d_{z^2} orbital was noted above. If this orbital is occupied by a pair of electrons, the corresponding macrocyclic complex is itself converted into a nucleophile capable of combining with a proton, carbonium ions (for example, CH_3^+), and other "electrophiles". Such addition must not be hindered by a high positive charge on the complex and the nucleophiles are therefore usually macrocyclic cobalt(I) and nickel(I) complexes bearing low charges and having an unshared electron pair in the d_{z^2} orbital.



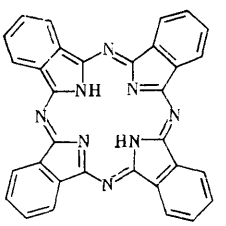
When the d_{z^2} orbital, oriented at right angles to the xy plane in which the electron-donating atoms of the macrocyclic ligand are located, is half-filled and six electrons are present in the d_{xz}, d_{yz} and d_{xy} orbitals (d^7 configuration), a kind of inorganic free radical species are produced [Co(II)L, Ni(III)L], which are capable of reacting with free radicals or generating them as a result of the homologous bond dissociation in the organic molecule.



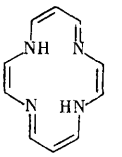
The characteristic features of the macrocyclic complexes of metal ions considered here make it possible not only to explain the mechanism of many catalytic processes but also to predict new ones. Even greater possibilities for the prediction of catalytic reactions with participation of macrocyclic complexes have arisen from the far-reaching analysis of processes in enzyme catalysis[9] and the construction on this basis of the corresponding models of the active centres of the enzymes. [10,11]



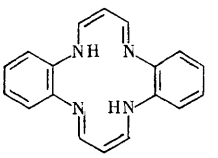
The use of the analogy between the active centres of metalloenzymes and a metal ion with its immediate environment in a complex ML, where L is a macrocyclic ligand, made it possible to discover many catalytically active compounds. In particular, using metalloporphyrins as analogues of haems and metallocorrins, it has been possible to achieve numerous catalytic processes in which metalloporphyrins and metallophthalocyanines are used. [5,6]



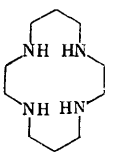
Despite the fact that several thousands of macrocyclic compounds are known nowadays, complexes with an extremely limited number of ligands (several tens) are used in catalytic reactions. In the further exposition in this review, we shall use structural formulae and the corresponding numbering of the ligands in considering the latter:



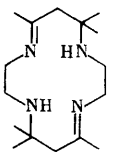
L1 (CR)



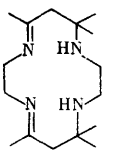
L2 (CRH)



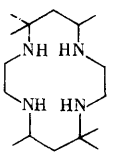
L3 (cyclene)



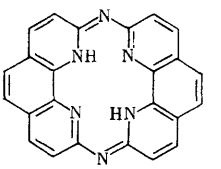
L4 (H_2P)



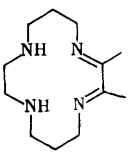
L5 (H_2Pc)



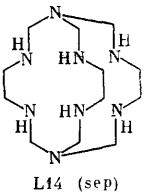
L6 (H_2TAA)



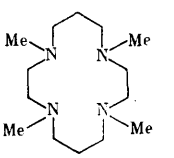
L7 (H_2DBTAA)



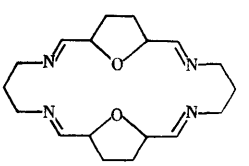
L8 (cyclam)



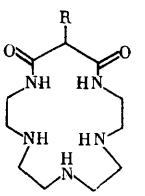
L9 (td)



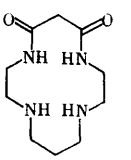
L10 (cd)



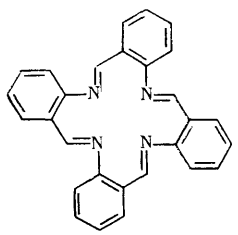
L11 (teta)



H_2L12

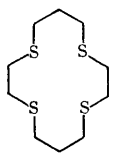


L13



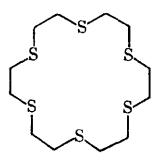
L14 (sep)

L15 (TMC)

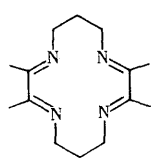


L16

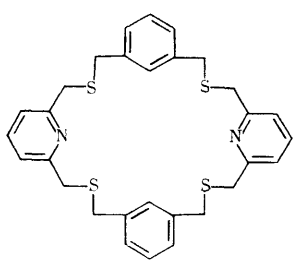
H_2L17



H_2L18



L19 (TAAB)



L20 (Ref.12 an S_4)

L21 (Ref.18 an S_6)

L22 (TIM)

L23

At the same time, use will be made of the conventional abbreviations for many ligands used widely in Soviet and foreign scientific literature. The ligands not illustrated here will be named in accordance with the Melson-Bush nomenclature,[1,3] which has come to be widely employed in the Soviet and foreign literature.

III. Catalysis of hydrolytic reactions by macrocyclic metal complexes

Many hydrolytic reactions (hydrolysis of peptides, esters, etc.) are catalysed by zinc-containing enzymes (for example, carboxypeptidase). The active centres of such enzymes contain a zinc ion linked to the electron-donating nitrogen atoms of the imidazole groups of histidine or the electron-donating oxygen atoms of the carboxy-groups of the glutamic acid residues. The complex $Zn(CR)^{2+}$ or ZnL1,[12] which accelerates the hydrolysis of methyl trifluoroacetate according to the scheme

$$CF_3COOMe+OH^- = CF_3COO^- + MeOH\ ,$$

by a factor of 6, can be considered as a model of this active centre.

The acceleration can be explained by the formation of a bond between the hydroxide ion and the zinc ion in the macrocyclic complex, as a result of which OH^- acquires the ability to add to the carbon atom of the ester group. The same complex $Zn(CR)^{2+}$ catalyses the hydration of acetaldehyde, i.e.

$$MeCHO+H_2O = MeCH(OH)_2\ ,$$

and the analogous CO_2 hydration reaction catalysed by carbonic anhydrase.[13] The substitution of zinc by copper(II) in the complex $M(CR)^{2+}$ increases its catalytic activity, in contrast to carbonic anhydrase. The catalytic activity of $M(CR)^{2+}$ [13] is due to the fact that it ensures the addition of the metal-coordinated hydroxide ion to the carbon atom in CO_2 or MeCHO at pH close to the physiological values.

The complexes $Zn(CR)^{2+}$ also catalyse the hydrolytic reactions of many phosphate esters, which is important as a detoxification procedure.[14] The catalytic reactions

$$(PhO)_2P(O)OC_6H_4NO_2+H_2O = (PhO)_2P(O)OH+NO_2C_6H_4OH,$$

and

$$(PhO)_2P(O)OC_6H_4NO_2+H_2O =$$

$$= (PhO)P(O)(OC_6H_4NO_2)OH+PhOH,$$

which proceed in a mixture of water and acetonitrile, have been described. The proposed mechanism of these reactions is analogous to that described above.

Similar hydrolytic reactions are catalysed not only by the complexes $Zn(CR)^{2+}$ but also by $Zn(cyclene)^{2+}$ (cyclene = L3).[15] $Zn(cyclene)^{2+}$ is even more effective than $Zn(CR)^{2+}$ in the hydrolysis of the ester $(NO_2)_2C_6H_3OP(X)(O)OEt$ (where X = Me or OEt).

The macrocyclic zinc complex $Zn([15]anN_4)^{2+}$ catalyses the hydrolysis of 4-nitrophenyl acetate.[16]

The cobalt(III) complex $[Co(cyclene)(H_2O)_2]^{3+}$ accelerates the hydrolysis of ATP with formation of ADP and phosphate.[17] The catalytic activity of this complex is manifested particularly strikingly at pH 8.6 (acceleration by a factor of 117), at pH 8.0 the ratio of the rate constants for the catalytic and non-catalytic reactions is 13.2, while at pH 7.0 it is only 2.2.

It has been suggested that cobalt(II) complexes with a chiral macrocycle containing the cyclene skeleton be used for the selective hydrolysis of specific N-terminal groups of peptides and for the conversion of L-alanine.[18]

IV. Electrocatalytic reactions with participation of macrocyclic metal complexes

Numerous studies devoted to the application of macrocyclic compounds in electrocatalysis are known. The earliest investigations concern the use of metalloporphyrins and metallophthalocyanines for the reduction of molecular oxygen at the cathode of a fuel cell.[19] Reviews of studies on this question are available in a number of monographs[5,6,20] and in a communication.[21]

The reduction of molecular oxygen at the cathode of a fuel cell is described by the overall equation[22]

$$O_2+4H^+ + 4e = 2H_2O,\ E^0 = 1.229\ V.$$

However, the process is complicated by intermediate reactions and, in particular, by the reduction of oxygen to hydrogen peroxide, which is characterised by a lower redox potential:[22]

$$O_2+2H^+ + 2e = H_2O_2,\ E^0 = 0.695\ V.$$

Other intermediate reactions in the reduction of O_2 to H_2O are also possible. Catalysis of the above overall reaction and of its individual stages is therefore necessary. The salts MPc and the salts of substituted porphyrins MP, especially cobalt(II), iron(II), and iron(III) salts, are used as catalysts. This is apparently associated with the ease of the formation of superoxide radical-anions O_2^- in the presence of the above complexes and their subsequent conversion into H_2O_2. It was subsequently observed that the salts of tetraazaannulenes (MTAA and MDBTAA) also exhibit a catalytic activity[23,24] these compounds being actually more active than the porphyrin and phthalocyanine salts. It may be that the salts of porphyrins, phthalocyanine and tetraazaannulenes also possess catalase activity, i.e. they accelerate the conversion of H_2O_2 into H_2O and O_2.

Studies on cobalt salts of different substituted tetraazannulenes[25] showed that the presence of various alkyl substituents in these compounds does not have a significant effect on the electrocatalytic activity of CoTAA.

Other cobalt salts of tetraaazamacrocyclic ligands [$Co(cyclam)^{3+}$, $Co(td)^{2+}$], forming intermediate dinuclear complexes with oxygen, have also been investigated as electrochemical reduction catalysts.[26] The cobalt complex with the hexaazamacrocyclic ligand L12 likewise proved to be a catalyst of the electrochemical reduction of molecular oxygen.[27]

Carbon electrodes modified by cobalt and iron salts with natural and synthetic polyazamacrocyclic ligands do not lose their activity on pyrolysis (600–800 °C). The latter actually increases.[27–33] It is naturally unlikely that the initial cobalt complexes were retained at the electrode.

The electrochemical reduction of oxygen to hydrogen peroxide at a rotating disc electrode is catalysed by the tetraazamacrocyclic cobalt complexes of cyclam (L8) or td (L9).[26] The ions $Co(cyclam)^{2+}$ also accelerate the subsequent reduction of H_2O_2 to H_2O when the conditions are altered.[34]

The electrochemical CO_2 reduction reactions, catalysed by macrocyclic coordination compounds, are of great theoretical and practical interest. Carbon dioxide is the main participant in photosynthetic reactions and in the future it may become the starting material for organic synthesis. Finally, the utilisation of CO_2 constitutes an extremely important aspect of the solution of ecological problems.

The most important electrochemical CO_2 reduction reactions are listed below with an indication of the corresponding standard potentials in an acid medium[22]:

$$CO_2 + 2H^+ + 2e = CO + H_2O,\ E^0 = -0.106\ V,$$

$$H_2CO_3 + 2H^+ + 2e = HCOOH + H_2O,\ E^0 = -0.166\ V,$$

$$2H_2CO_3 + 2H^+ + 2e = H_2C_2O_4 + 2H_2O,\ E^0 = -0.391\ V,$$

$$H_2CO_3 + 4H^+ + 4e = HCHO + 2H_2O,\ E^0 = -0.050\ V.$$

In an alkaline medium, the same reactions are characterised by different standard potentials[22]:

$$CO_3^{2-} + 3H^+ + 2e = HCO_2^- + H_2O,\ E^0 = 0.310\ V,$$

$$2CO_3^{2-} + 4H^+ + 2e = C_2O_4^{2-} + 2H_2O,\ E^0 = 0.478\ V,$$

$$CO_3^{2-} + 6H^+ + 4e = HCHO + 2H_2O,\ E^0 = 0.197\ V.$$

It is seen from the data presented that the electrochemical reduction of CO_2 can lead to the formation of a set of different products (CO, HCOOH, $H_2C_2O_4$, etc.).

Electrochemical CO_2 reduction reactions are accelerated by cobalt and nickel complexes of porphyrin and phthalocyanine[5,6,20] and also by cobalt complexes with comparatively simple tetraazamacrocyclic ligands.[35] Cobalt complexes with the "transdiene" (L9), the dimethyl-*cis*-diene (L13), and CR (L1), as well as nickel (II) complexes of CR (L1) have been investigated as catalysts of this chemical process.[36] A mechanism was proposed for the reduction of CO_2 to the final products (CO, HCOOH, $H_2C_2O_4$) and for the formation of hydrogen as a result of the reduction of the water protons (in all cases, cobalt is linked to the macrocyclic ligand):

$$\begin{array}{ccccc} Co\,(II) & \overset{+e}{\rightarrow} & Co^{-}(I) & \xrightarrow{+H^+} & Co\,(III)\,(H^-) \xrightarrow{+H^+} Co\,(III) + H_2 \\ & & \uparrow\downarrow{\scriptstyle +CO_2} & & \uparrow\downarrow{\scriptstyle +CO_2} \\ & & Co\,(I)\,CO_2 & & Co\,(III)\,(HCO_2^-) \overset{+H^+}{\rightleftarrows} Co\,(III) + CO + H_2O \\ & & \uparrow\downarrow & & \uparrow\downarrow{\scriptstyle +H^+} \\ & & Co\,(III) + C_2O_4^{2-} & & Co\,(III) + HCOOH\ . \end{array}$$

The electrocatalysis was carried out at a mercury cathode.

Further studies showed that nickel(II) complexes of cyclam (L8) exhibit an especially high effectiveness and selectivity in the reduction of CO_2.[37] Subsequently the mechanism of the electrochemical reduction of CO_2 was investigated in fair detail.[38]

It was established that the complex $Ni(cyclam)CO^+$ as well as the compounds $LNi(III)CO_2$ and LNi(II)CO may be formed as intermediates in the electrocatalytic reduction of CO_2.[39] The electrochemical reduction of carbon dioxide has also been observed at electrodes with a polymeric coating containing nickel complexes of tetraazaannulenes (L6, L7, etc.).[40]

The study of CO_2 as a ligand is of special interest.[41] Certain coordination compounds of cobalt(I), containing tetraazamacrocyclic compounds and carbon dioxide as ligands, have been described and characterised quantitatively.[42,43]

The bimacrocyclic cobalt complex $Co(sep)^{3+}$ (CoL14) [44] and the nickel complex $Ni(teta)^{2+}$ (NiL11) are used in electrocatalytic hydrogen evolution reactions.[45]

The electrocatalytic reduction of nitrate at a mercury electrode with formation of hydroxylamine, proceeding in accordance with the equation

$$NO_3^- + 7H^+ + 6e = NH_2OH + 2H_2O,$$

has been described.[46] The reaction is catalysed by nickel(II) and cobalt(III) complexes of cyclam (L8). The complexes of other transition metals with this ligand have a low activity.

Transition metal complexes with macrocyclic ligands also catalyse many electrochemical (anodic) oxidation processes. For example, cobalt complexes of porphyrins, phthalocyanine, and tetraaza-annulenes (L6, L7) catalyse the anodic oxidation of $SO_2(H_2SO_3)$, whereas copper, nickel, and palladium complexes are catalytically inactive.[47] The catalytic activity of the tetraazamacrocyclic complexes diminishes in the sequence CoTAA ≫ CoTPhP > CoPc. The catalytic activity of carbon electrodes modified by CoTAA persists also after their pyrolysis at 800 °C.[48]

The tetraazamacrocyclic nickel complex NiL18 catalyses the anodic oxidation of benzyl alcohol to benzaldehyde; the formation of the compound Ni(III)L as an intermediate is then postulated.[49] The same reaction is catalysed by the ruthenium(IV) and ruthenium(V) complexes of tetramethylcyclam (L15).[50]

Finally, the anodic oxidation of $PhSCH_2Si(Me)_3$ in the presence of an alcohol ROH leads to the formation of $PhSCH_2OR$ and the $Si(Me)_3^+$ cations:[51]

$$PhSCH_2Si\,(Me)_3 \xrightarrow{ROH} PhSCH_2OR + Si\,(Me)_3^+ + H^+ + 2e.$$

V. Reactions involving oxidation by oxygen catalysed by macrocyclic metal complexes

Catalysis by tetraazamacrocyclic transition metal complexes M(teta) and M(td) of the reactions involving the oxidation of various substrates, in particular cyclohexene, by molecular oxygen

has long been known.[52] The oxidation reactions of hydrogen sulphide and various mercaptans, catalysed by porphyrin complexes of cobalt, iron, copper, nickel, and a number of other transition metals, have been described.[5,6] To some extent, a similar catalytic activity of macrocyclic dinuclear complexes of copper(I) and copper(II) of the type Cu_2L (L = L16) is manifested in the reactions[53,54]

$$2\,PhSH + {}^1/_2\,O_2 = PhSSPh + H_2O,$$
$$2\,PhC{\equiv}CH + {}^1/_2\,O_2 = PhC{\equiv}C{-}C{\equiv}Ph + H_2O,$$
$$PhNHNHPh + {}^1/_2\,O_2 = PhN{=}NPh + H_2O.$$

Dinuclear complexes of the type Cu_2L16 can be regarded as models of the active centres of certain copper oxidases containing the so called EPR-undetectable copper(III).

Nickel complexes with a kind of tetraazamacrocyclic ligand-anions, each containing two amide (peptide) groups (L17, L18), exhibit a high catalytic activity in reactions involving the oxidation of various substrates by molecular oxygen. These nickel complexes catalyse the oxidation of benzene to phenol, of toluene to cresol, etc.[55,56] and also the oxidation of styrene by oxygen in the presence of tetrahydroborate.[57]

The catalytic acceleration of the oxidation of 1,3-bicyclooxolan to ethylene glycol monoformate by cobalt(II) complexes of dibenzo-18-crown-6 [58] appears fairly unexpected since cobalt(II) complexes do not form any kind of stable complexes with crown-ethers.

The copper(I) and copper(II) complexes with the tetraazamacrocyclic ligand TAAB (L19) catalyse the oxidation of ascorbic acid by molecular oxygen.[59,60] Ascorbic acid free radicals and superoxide radical-anions are then formed. Under certain conditions, this reaction can proceed in the vibrational regime.[61] Tetraazaannulene complexes of iron catalyse the oxidation of hydroquinone to quinone in solution in pyridine.[62]

Finally, the oxidation of a number of alcohols to aldehydes and ketones is catalysed by thiamacrocyclic complexes of copper(II) (L20 and L21). The copper compounds of the type $CuL20^{2+}$ and $CuL21^{2+}$ can be regarded as analogues of the active centres of the so called "blue proteins".[63]

Macrocyclic complexes of transition metals catalyse the photochemical oxidation of methanol to formaldehyde. Iron(II) complexes with the tetraazamacrocyclic ligand TIM (L22)[64] as well as the cobalt(III) complexes with the ligands L9 (td) and L14 (sep) [65,66] can be used as catalysts.

VI. Other reactions catalysed by macrocyclic metal complexes

The analogy between haem-containing proteins—catalase and peroxidases—and tetraazamacrocyclic transition metal complexes suggested that the latter might exhibit catalase or peroxidase activity. Such activity has been observed in iron(III)-, cobalt(III)-, ruthenium(III)-, and osmium(IV)-pthalocyanines.[67] Somewhat later, it was established that the complex $[Fe(CRH)Cl_2]^+$ (CRH = L2) possesses catalase activity.[68] The activity of $[Fe(CRH)Cl_2]^+$ is an order of magnitude smaller than that of catalase but an order of magnitude higher than that of the iron(III) aquo-ion. Subsequently it was discovered that this iron complex exhibits a peroxidase activity in the oxidation of benzene and its substituted derivatives by hydrogen peroxide.[69] The iron(II) complex of TAAB (L19) does not exhibit an appreciable catalase activity but it does possess a pronounced peroxidase activity: in its presence, hydrogen peroxide oxidises a number of substrates. The oxidation of the dye Eriochrome Black has been characterised quantitatively.[70]

Cobalt(II) complexes of sepulchrates (sep = L14) reduce oxygen quantitatively to H_2O_2, being oxidised at the same time to $Co(sep)^{3+}$, which subsequently readily returns to the initial state $Co(sep)^{2+}$.[71]

The complexes NiL17 and NiL18 exhibit a superoxide dismutase activity.[72]

A number of reactions with participation of NaClO and PhIO as oxidants are accelerated by nickel(II) complexes of cyclam (L8) and chelating ligands (salen).[73] If $NaClO_4$ is used for the oxidation of alkenes, the catalytic activity of the macrocyclic complex is then found to be lower than that of the complexes of Schiff bases, while in the case where PhIO is employed the nickel complex of cyclam is found to be a more effective catalyst. The PhIO oxidant converts styrene and *trans*-stilbene into benzaldehyde and styrene epoxide in the presence of the dinuclear copper complex Cu_2L_{23}.[74]

The epoxidation reaction is also catalysed by nickel complexes of cyclam and its substituted derivatives, especially TMC (L15).[75] The proposed mechanism of the catalysis of the epoxidation of alkenes in the presence of nickel complexes of cyclam postulates the formation of intermediate nickel(III) or even nickel(IV) compounds. Cobalt(II) complexes of cyclam exhibit a weak catalytic activity and the $Cu(cyclam)^{2+}$ complex is altogether inactive.[76] Nickel complexes of the tetraazamacrocycles CR (L1) and TIM (L22) also possess a high catalytic activity in epoxidation reactions.[77] The catalytic acceleration of the oxidation of styrene with formation of the epoxide and benzaldehyde by the iron(III) complex of a 21-membered chiral macrocyclic ligand, containing four amide and one bipyridyl group, has been observed.[78]

A characteristic feature of the vast majority of vibrational chemical reactions is the involvement in the oxidation of the substrate (for example, malonic acid) by an oxidant (for example, bromate) of a transition metal compound as catalyst in which the metal undergoes a periodic change in the oxidation state. Such a compound may be, in particular, a macrocyclic complex.[79]

It has been observed that tetraazamacrocyclic copper(II) complexes catalyse the oxidation of malonic acid by bromate in an oscillating reaction. The oxidation state of the copper then changes from 2 to 3 and back again. The use of copper(II) complexes with teta, td, and cd (L11, L9, and L10 respectively) as catalysts has been examined.[80–83] The copper complexes with unsaturated ligands (td and cd) can, in contrast to the complex with the saturated ligand (teta), function not only as catalysts but also as substrates, i.e. the ligands cd and td can be oxidised by bromate in the vibrational mode. A similar picture is also observed when nickel complexes of the *cis*-diene cd (L10) are used as catalysts.[81–83]

The use of metal complexes with macrocyclic ligands for the catalytic acceleration of chain transfer from polymers to the monomer in radical polymerisation reactions has been examined in a number of studies. Low-spin cobalt(II) complexes with tetraazamacrocyclic ligands, in particular, with porphyrin and derivatives of tetraazaannulenes (L4, L6, L7), exhibit a catalytic activity, while cobalt complexes of td, teta, and TAAB (L9, L11, and L19 respectively) are inactive.[5,7,84] In the key stage, the radical-like compound Co(II)L reacts with hydrogen atom of the substrate and forms a radical and a cobalt hydride of the type $(H^-)Co(III)L$. This hydride then decomposes with elimination of hydrogen, while the cobalt returns to the initial state cobalt(II).

Photocatalytic reactions involving the evolution of hydrogen from water on treatment with various electron donors, photosensitisers,

and photocatalysts have been described. Cobalt(II) sepulchrates (the L14 ligand) can be used as photocatalysts.[44,85] The use of the complex $Ni(cyclam)^{2+}$ in the photocatalytic evolution of H_2 from water in a system containing a bipyridylruthenium complex (sensitiser) and ascorbic acid (electron donor) has been described.[86] It is suggested that the nickel(II) in the macrocyclic complex is reduced to Ni(I)L; this nickel(I) compound, which possesses nucleophilic properties, reacts with a proton to form the complex $(H^-)Ni(III)L$, which evolves H_2 on reaction with protons and is reduced by ascorbic acid to Ni(II)L (L = cyclam).

Even earlier, it was shown that the photocatalyst of the water reduction reaction in solutions containing bipyridylruthenium complexes as the sensitiser and europium(II) salts as the electron donor may be the cobalt complex of TIM (L22).[87]

Coordination compounds of nickel(II) with chiral macrocyclic ligands, containing sulphide sulphur in the macrocycle or amine nitrogen as well as sulphur, catalyse Grignard reactions[88,89] and, in particular, the reaction between RMgCl and vinyl bromide.

VII. Conclusion

Catalysis by metal complexes with macrocyclic ligands constitutes a new chapter in chemical science, more than 90% of the studies quoted in the literature referring to the last decade. The considerable unutilised possibilities of this field of study are indicated by the fact that, out of the several thousand macrocyclic ligands described, only a few tens, most thoroughly investigated and readily synthesised, have so far found applications in catalysis. The possibility of using macrocyclic coordination compounds to model the activity of many metalloenzymes opens the way to good future prospects. Studies of this kind are associated with the development of a new promising scientific field — biomimetic chemistry ("biomimetics"),[90] particularly that aspect of it which deals with the creation of "synzymes" (synthetic enzymes).

Macrocyclic coordination compounds are used mainly in the catalysis of oxidation-reduction processes, although a certain number of hydrolytic reactions catalysed by metal complexes of macrocycles are known. In the case of oxidation-reduction processes, the possibility of regulating the redox potentials of catalysts within wide limits by varying the parameters of the macrocyclic ligand (the size of the cavity, the number and nature of electron-donating atoms, their positions, etc.) plays an extremely significant role. The possibility of detecting "unusual" electronic states of metal ions, including radical forms [low-spin cobalt(II) and nickel(III) complexes] and nucleophiles with an unshared electron pair located on the metal atom is of great importance. Finally, the possibility of varying the geometry and the electronic structure of the ligand itself from the "usual" macroheterocyclic cyclam (L8) to a complex system with a large number of π-bonds of the type of porphyrin or phthalocyanine gives rise to good future prospects.

Studies in the field of catalysis by metal complexes of macrocycles have so far been limited to a comparatively small number of metals. The extension of the range of metals incorporated in the macrocycle for the preparation of catalytically active species can lead to new results.

Finally, we may note that the application of metal complexes of macrocycles in catalysis is associated with the solution of a series of scientific-technical problems of very great current interest, such as the creation of fuel cells, the use of solar energy, the utilisation of CO_2, etc.

Catalysis by metal complexes in organoaluminium synthesis

U M Dzhemilev, O S Vostrikova, G A Tolstikov

ABSTRACT. In this review a summary is given of studies conducted both within and outside the Soviet Union on the synthesis and conversions of organoaluminium compounds (OACs) in the presence of metal complexes as catalysts. The following reactions have been examined: catalytic hydro-, carbo- and cyclo-alumination of unsaturated compounds, cross-coupling and conjugate addition of OACs to enones, and certain other conversions of OACs in the presence of metal complexes as catalysts.

The bibliography includes 211 references.

I. Introduction

In contrast with organomagnesium compounds, which have been widely used in organic synthesis since their discovery by Grignard, organoaluminium compounds (OACs) were almost unknown up to the 1950s. Since then, in spite of their cheapness and the availability of simple derivatives, they have been used mainly as components in catalytic systems for oligo- and poly-merisation of olefins.

In recent years the position has changed as many OACs have been elevated to a position of importance in organic synthesis and laboratory practise, in spite of the fairly high risks associated with their handling. Thus, *i*-Bu_2AlH is now one of the most widely used reducing agents in organic synthesis; the effective use of OACs as selective alkylating agents also deserves a special mention.

The new opportunities for using OACs in organic synthesis are now more and more associated with catalysis by metal complexes. Their selectivity has led to the discovery of many hitherto unknown reactions of practical value, and the mild conditions under which they can be conducted have minimised handling risks. Some reactions uncharacteristic of OACs have also led to the preparation of novel reagents considered previously as 'exotic'. During the last 10–15 years, a significant growth in publications in this area has been recorded.

In this review there is a survey of the results obtained by using homogeneous metal complexes as catalysts in the synthesis of varied OACs and their subsequent reactions; information has been excluded on the use of OACs as components of catalytic systems for the oligo- and poly-merisation of unsaturated compounds.

II. Hydroalumination

Hydroalumination of unsaturated compounds is one of the most characteristic reactions of OACs and frequently applied[1]. It is more than 25 years ago that the first experiments in hydroalumination with complex metal catalysts were undertaken with a view to broadening the scope of the reaction.[2,3] Since then, a large number of publications and patents have appeared in which many transition metals have been proposed as hydroalumination catalysts. However, as a result of exhaustive studies in this area by Ashby et al.[4–6], it has been established that both hydrometallation and hydrogenation of the unsaturation can take place in the presence of low-valent transition metal complexes, the latter course arising by hydride transfer from the medium. Thus, at the present time, any report on catalytic hydrometallation is greeted with much scepticism if there is no supporting evidence over and above analytical data on the products of hydrolysis of the reaction mass. It is our opinion that, nowadays, only titanium and zirconium compounds are 'beyond reproach' as hydroalumination catalysts. However, in this review there will be an examination of several interesting conversions in the presence of other transition metal complexes where the formation of OACs has been reliably confirmed.

1. Hydroalumination of acetylenes

Hydroalumination of disubstituted acetylenes is relatively facile, and can be achieved under fairly mild conditions with the aid of *i*-Bu_3Al or *i*-Bu_2AlH in the absence of any catalyst; however, it is not possible to avoid unwanted side reactions or subsequent conversions of the formed vinylalanes.[1,7]

A catalytic amount of $Ni(acac)_2$ enhances the reaction of OACs with 4-octyne, phenylpropyne and certain other disubstituted acetylenes at 25 °C.[8] At the same time, titanium or zirconium complexes have no effect on this reaction.[9,10]

However, in the presence of Cp_2TiCl_2, complexes of *i*-Bu_3Al with organomagnesium compounds (*i*-BuMgBr, EtMgBr) hydroaluminate the majority of disubstituted acetylenes readily under mild conditions, thereby avoiding unwanted reactions.[9–11]

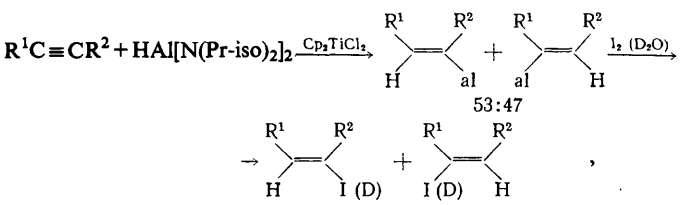
$$R^1C{\equiv}CR^2 + n\ i\text{-}Bu_3Al.RMgBr \xrightarrow[0-20\ ^\circ C,\ 20\ min]{Cp_2TiCl_2(2\%),\ Et_2O}$$

$$\rightarrow \underset{95-98\%}{\overset{M}{\underset{R^1}{\overset{|}{\diagup}}\!\!=\!\!\underset{R^2}{\diagdown}}} \xrightarrow{D_2O} \underset{100\%\ (Z\text{-isomer})}{\overset{D}{\underset{R^1}{\overset{|}{\diagup}}\!\!=\!\!\underset{R^2}{\diagdown}}}$$

R^1, R^2 = Alk, Ar, OR^3, $SiMe_3$; $n = 3-10$;

M = organomagnesium or organoaluminium compound.

The stereoselectivity with this reagent is as high as that with 9-borabicyclo[3.3.1]nonane, and there is no difference in regioselectivity for the hydrometallation of unsymmetrically disubstituted acetylenes.

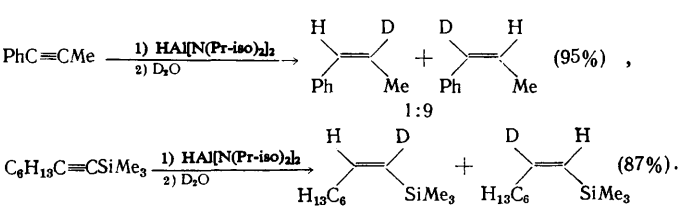


In the carboalumination of monosubstituted acetylenes with triethyl- and tripropyl-aluminium,[12-13] there is little mention of catalytic hydroalumination as a side reaction, and no indication on the possibility of achieving selective hydroalumination.

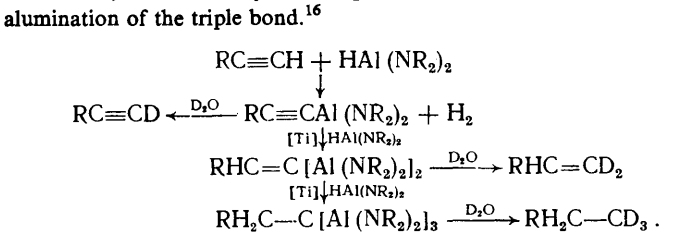
There are numerous examples of hydroalumination of acetylenes with a variety of complex hydrides. For this purpose, Ashby[14] recommended the novel bis(dialkylamino)alanes, being prepared in quantitative yield by interaction of aluminium with *sec*-amines under hydrogen pressure:

$$Al + H_2 + 2\,R_2NH \xrightarrow[\text{benzene}]{140\ ^\circ C,\ \sim 140\ atm\ H_2} HAl(NR_2)_2, \quad 100\%$$

R = Pr, Bu, Am.



In the presence of 5 mol% Cp_2TiCl_2, these hydrides readily add to mono- and di-substituted acetylenes in benzene (in which they are very soluble) at 0 °C to room temperature.[15] The conversion of the acetylenes is nearly quantitative. (*Z*)-Alkenylalanes (90–96%) are the main products, the corresponding (*E*)-isomers being formed in no more 1–4% yield.



R^1 = Me, R^2 = n-Pr, al – organoaluminium compound.

Subsequent treatment with D_2O led to 96–97% incorporation of deuterium into the derived alkenes. The corresponding alkanes are formed simultaneously in up to 10% yield[16].

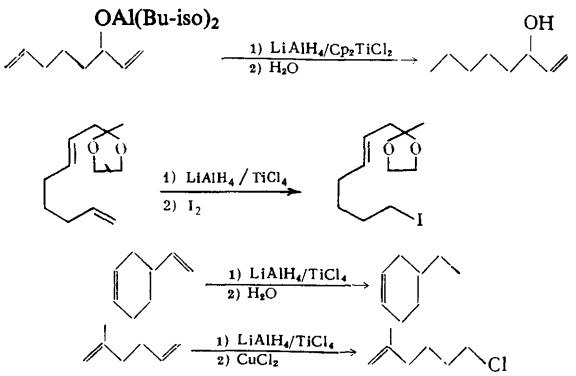
High regioselectivity is recorded only for the hydrometallation of 1-phenylprop-1-yne and 1-(trimethylsilyl)oct-1-yne:

For monosubstituted alkynes, deuterolysis of the products of hydroalumination affords, principally, a mixture of alkenes and alkanes in approximately equal amount with varying levels of D-incorporation; this confirms the complex nature of the metallation, and notably the aspect of mono- and di-hydroalumination of the triple bond.[16]

Hydroalumination of disubstituted acetylenes with other complex hydrides ($LiAlH_4$, $LiAlH_2[N(Pr\text{-}i)_2]_2$, $NaAlH_2(NEt_2)_2$, $NaAlH_2[N(Pr\text{-}i)_2]_2$, $LiAlMe_3H$) in the presence of Cp_2TiCl_2 or other titanium reagents proceeds in much the same way, the only difference being that stereoselectivity is higher (in some cases up to 100%) than with bis(dialkylamino)alanes and that side reactions are less.[5,6,16-19]

Mono- and di-phenyl-substituted acetylenes undergo hydroalumination non-selectivity, a significant amount of (*E*)-alkenylalanes being formed.[19]

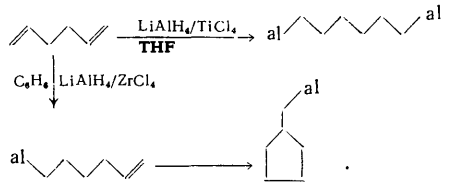
2. Hydroalumination of olefins



Catalytic hydroalumination of olefins is widely used in organic synthesis for a variety of purposes: for selective reduction of double bonds or their functionalisation, as well as for the preparation of higher OACs of defined structure for subsequent conversions.[20] Almost all of the readily available aluminium hydrides and simple alkylalanes have been used as hydroaluminating agents. For such purposes, $LiAlH_4$ has been most frequently used. Since Sato discovered that titanium and zirconium compounds may be used as catalysts for hydroalumination of olefins under mild conditions,[21,22] this reaction has found widespread application.

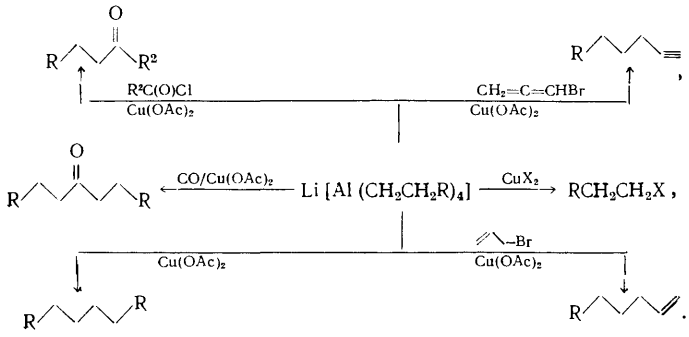
A variety of titanium complexes, among which those immobilised on inorganic[23] or polymeric[23,24] supports, is currently available for catalysed hydroalumination. The preliminary report[25] on the successful application of V and Cr salts as catalysts has not been subsequently confirmed. Recently, there was a communication[26] on the use of exotic catalysts, such as uranium salts (UCl_3 and UCl_4), for the hydroalumination of C_2–C_8 α-olefins. Zirconium complexes are no less effective than titanium complexes as catalysts; they are used preferably for the hydroalumination of allylic alcohols and ethers[27] since deoxygenation of these substrates takes place in the presence of titanium complexes.

It is reported[7,23,28] that reaction proceeds via intermediate formation of titanium or zirconium hydride complexes, which initially hydrometallate the olefin and are regenerated by subsequent transmetallation of the formed transition metal alkyl derivatives.



$$LiAlH_4 + ML_m \rightarrow L_nM{-}H,$$
$$L_nM{-}H + CH_2{=}CH{-}R \rightarrow L_nMCH_2{-}CH_2{-}R,$$
$$L_nMCH_2{-}CH_2{-}R + LiAlH_4 \rightarrow L_nM{-}H + al{-}CH_2{-}CH_2{-}R,$$
$$M = Ti, Zr;\ al = LiAl/4.$$

The relative reactivity of the alkenes in these reactions depends largely on steric factors. Disubstituted alkenes react far more slowly than monosubstituted alkenes, which in certain cases facilitates selective hydroalumination of the less substituted double bond:



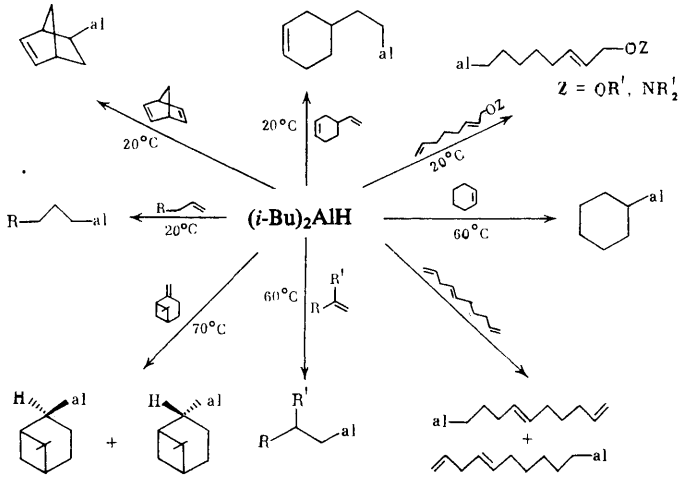
The course of the reaction with unconjugated α,ω-dienes, notably with 1,5-hexadiene, depends on the nature of the catalyst and the

reaction conditions. Thus, by using $TiCl_4$ in THF, 1,5-hexadiene was converted into acyclic bis-OACs; however, on replacement of THF by benzene, or of $TiCl_4$ by $ZrCl_4$, intramolecular cyclisation takes place:[9,15]

By catalytic hydroalumination a variety of highly reactive lithium tetralkylaluminates can be obtained, including derivatives with *O*- and *N*-functional groups.[27,30,33] Scheme 1 illustrates certain of their conversions in the presence of copper salts.[34–41]

Scheme 1

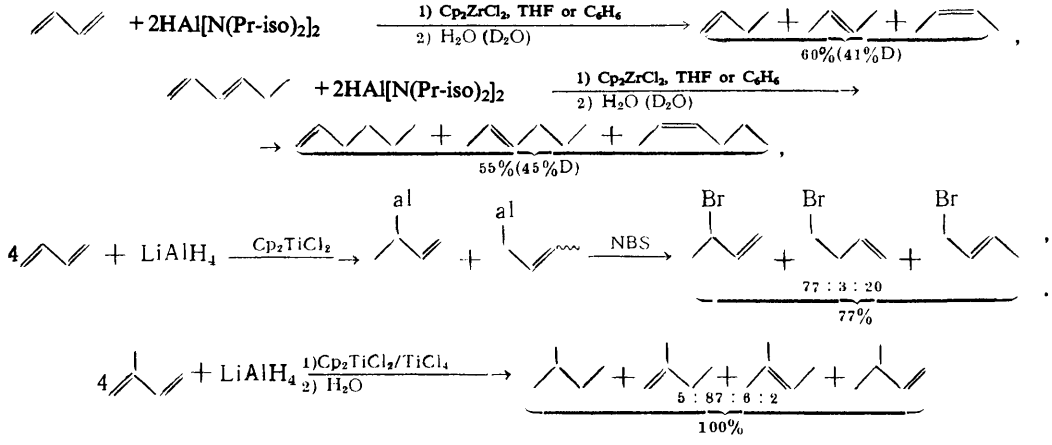
Such complex hydrides as $NaAlH_4$, $LiAlMe_3H$, $NaAlMe_3H$, and $NaAl(OCH_2CH_2OCH_3)_2H_2$ are no less active than $LiAlH_4$ in this respect.[6]



At the same time, other hydrides which Ashby studied, e.g. $HAl[N(Pr\text{-}i)_2]_2$, $HAl(NEt_2)_2$, $HAl[N(SiMe_3)_2]_2$, H_2AlCl, and $HAlCl_2$, displayed somewhat lower activity on hydroalumination of α-olefins in the presence of titanium complexes. As indicated above, the corresponding zirconium complexes exert almost no catalytic effect on the reaction.[4]

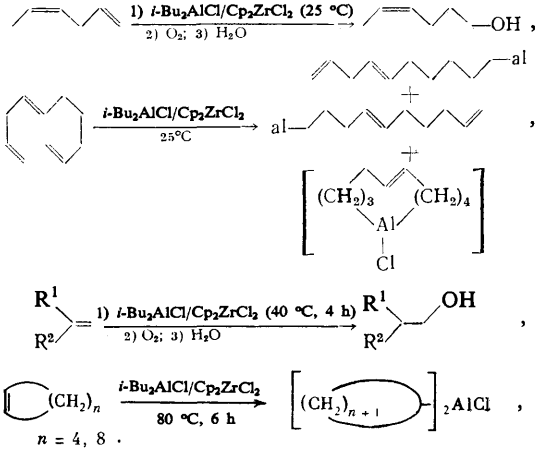
It has been reported that catalytic hydroalumination of conjugated dienes, e.g. isoprene, butadiene, and 1,3-hexadiene, can be achieved with $HAl[N(Pr\text{-}i)_2]_2$. However, selectivity in these reactions is not high.[4,23]

The more accessible and inexpensive alkylalanes may be used in place of complex hydrides for synthetically viable hydroaluminations. For hydroalumination of olefins with $(i\text{-}Bu)_2AlH$ under mild conditions, the most effective catalysts are zirconium salts;[42] with titanium catalysts, however, isomerisation and oligomerisation of the olefins are noted side reactions.



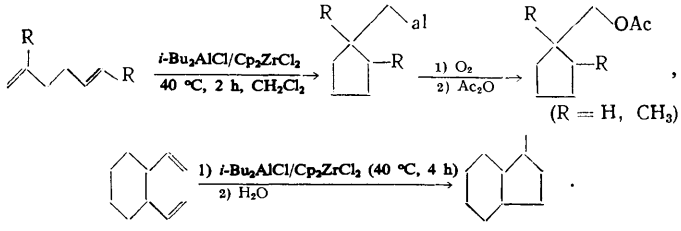
Thus, hydroalumination of α-olefins and norbornene derivatives with $(i\text{-}Bu)_2AlH$ can be effected almost quantitatively in the presence of $ZrCl_4$ at 20 °C during 3–6 h; the same reaction with α,β- and β,β′-disubstituted olefin requires a higher temperature (*ca.* 60 °C), thereby facilitating selective hydroalumination of polyene hydrocarbons possessing double bonds with different degrees of unsaturation (Scheme 2).[43–46]

Scheme 2



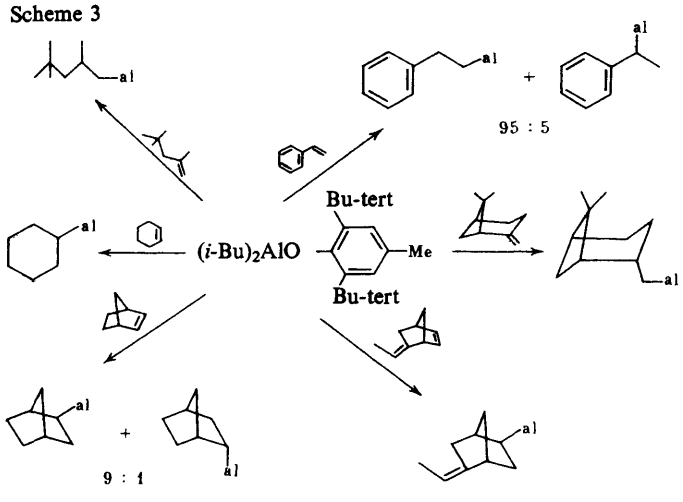
Chlorozirconium alkoxides have proved to be the most effective catalysts for hydroalumination of cyclic olefins.[44] The rate of hydroalumination of cyclic olefins depends on the ring size and decreases in the order: $C_5 > C_6 > C_7 > C_{12} > C_8$.

$i\text{-}Bu_3Al$ and $i\text{-}Bu_2AlCl$ are effective for the hydroalumination of a variety of olefins in the presence of a catalytic amount of Cp_2ZrCl_2.[47–50] $i\text{-}Bu_3Al$ adds to α-olefins even at 0–20 °C, which permits the synthesis of higher OACs under mild conditions; these include derivatives with functional groups (OH, SPh, Br) [47].

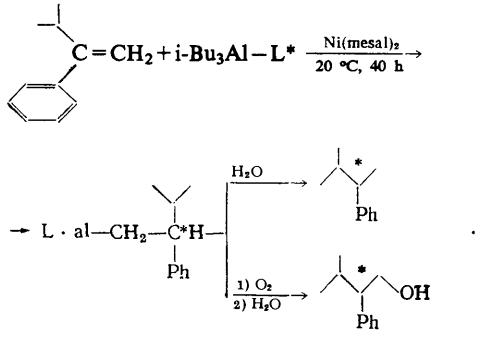


The interaction of *i*-Bu_3Al with cyclic olefins takes place at > 80 °C, although it is not possible to introduce more than two of the three isobutyl groups.[50]

Catalytic hydroalumination with *i*-Bu_2AlCl affords higher dialkylaluminium chlorides which cannot be obtained by classical routes, i.e. by non-catalytic hydroalumination.[48,50,51] For this reaction a general rule has been established: for hydroalumination with *i*-Bu_2AlH, α-olefins react most readily (at 25 °C), the disubstituted unsaturation in linear olefins reacts at 40 °C, and cyclic olefins only participate in reaction at 80 °C and above.

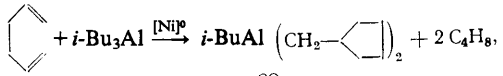


The interaction of 1,5-dienes with *i*-Bu_2AlCl under these same conditions leads to the formation of cyclic products:



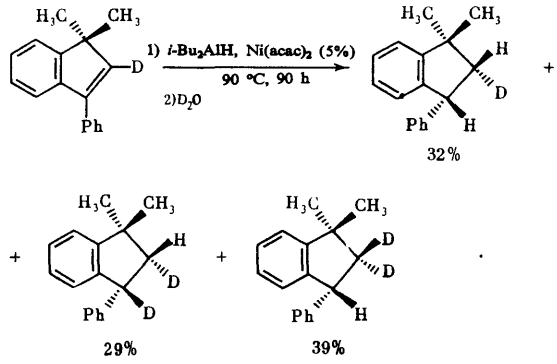
The organoaluminium monoaroxide obtained by interaction of *i*-Bu_2AlH with 2,6-di-tert-butyl-4-methylphenol regioselectively hydroaluminates mono- and di-substituted olefins (among which certain norbornene derivatives) at > 140 °C in xylene in the presence of *i*-Bu_2AlH/Cp_2ZrCl_2 as catalyst (Scheme 3).[52]

Scheme 3



The asymmetric hydroalumination of prochiral alkenes with complexes of the type *i*-Bu_3Al-L^* (where L^* is an optically active amine, such as (–)-N,N-dimenthylmethylamine) is catalysed by $Ni(mesal)_2$ (where mesal is methyl salicylate):

Hydrolysis or oxidation of the formed alane yields the corresponding optically active hydrocarbon or alcohol with a maximum optical yield of 27% [53] and 67% [54], respectively. The possibility of regenerating the chiral base affords this method real potential in synthetic chemistry.



The use of zero-valent nickel complexes as catalysts for the hydroalumination of α-olefins with *i*-Bu_3Al permits the removal of the nickel catalyst as volatile $Ni(CO)_4$ at the end of the reaction; the higher OACs thus obtained do not contain catalytic impurities.[54]

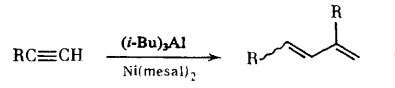
$$[Ni]_0 \xrightarrow{CO} Ni(CO)_4,$$

$[Ni]^0 = (C_2H_4)_3Ni,\ (COD)_2Ni,\ (PhCH{=}CHPh)_3Ni.$

A recent systematic study of the mechanism of nickel-catalysed hydroalumination has revealed that there are general features in common with a mechanism involving hydride transfer. Experimental data confirms the fact that there are catalytically active intermediates, most notably bimetallic nickel-aluminium hydrides[55].

As a rule a significant amount of saturated products is formed in addition to OACs.

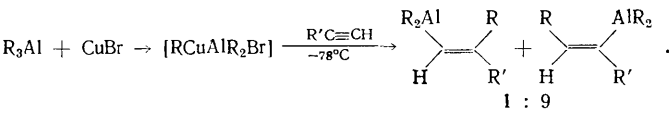
III. Carbo- and cyclo-alumination



Stereo- and regio-selective single-step addition (i.e. monocarbometallation) of organometallic compounds to olefins and acetylenes is extremely important in synthetic planning since it leads to the

simultaneous formation of a metal–carbon and carbon–carbon bond. Although various metals are known to participate in the carbometallation of multiple bonds, only zirconium-catalysed carboalumination and cuprate synthesis by the Normant procedure permits the desired addition with high regio- and stereo-selectivity.

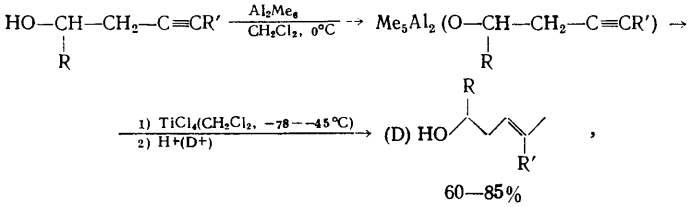
1. Carboalumination of acetylenes



Non-catalytic carboalumination of mono- and di-substituted acetylenes is rarely applied in synthetic chemistry because of the low selectivity[7]. However, the number of transition metals which have been used as catalysts for this reaction is extremely large.

Attempts at selective carbometallation of monosubstituted acetylenes in the presence of Ni and Mn have proved to be effectively negative. Thus, treatment of mono-substituted acetylenes with i-Bu_3Al in the presence of $Ni(mesal)_2$ led to the formation of dimers:

Under the same conditions enynes gave a more complex mixture containing a small amount of product derived by hydro- and carbometallation, in addition to di- and tri-mers.[56–59]

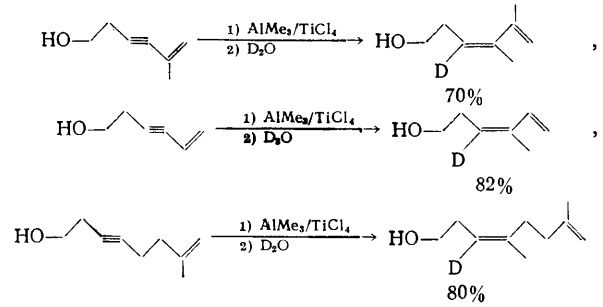


Carboalumination of 1-alkynes with trialkylalanes in the presence of $Cu(acac)_2$ and Ph_3P (Al : Cu : P = 2 : 1 : 1) is accompanied by their polymerisation, which leads to a reduction in the yield of desired product. High yields (up to 80%) and ⩾90% selectivity were found only by interaction of 1-alkynes with bimetallic aluminocuprate reagents, $R_3Al-CuBr$.[60,61]

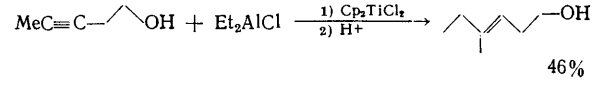
1 : 9

Disubstituted acetylenes, propargyl and homopropargyl alcohol, as well as ether derivatives thereof, were shown to be inactive under these reaction conditions.

More promising results were obtained by using titanium-containing catalysts which in certain cases lead to high regio- and stereo-selectivity. However, this reaction also has a number of limitations. The best results are obtained for the carbometallation of the relatively accessible homopropargyl alcohols on treatment with Me_3Al in the presence of $TiCl_4$.[62,63]

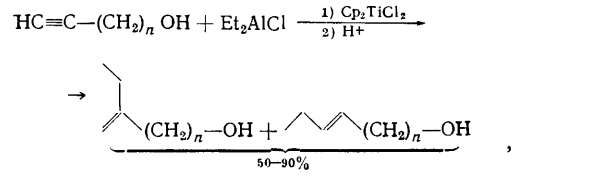


60–85%



R = H, Me, Et, Ph; R′ = H, Me, Et, n-Pr, i-Pr, n-Bu, n-Am, Ph.

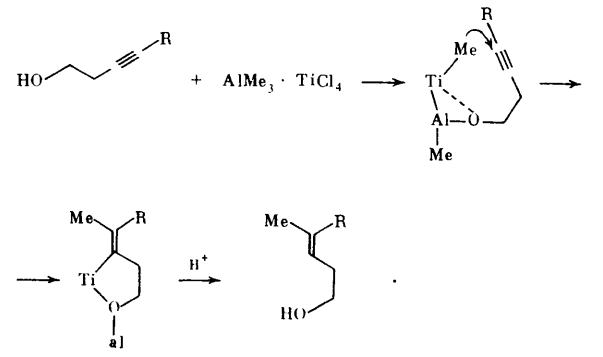
All the homopropargyl alcohols shown in the above scheme are selectively methylated at the triply-bonded carbon atom which is furthest from the OH-group.



In the case of 5-en-3-yn-1-ols, reaction affords (3Z)-4-methylalka-3,5-dien-1-ols in high yield and with complete selectivity; here also the methyl group is exclusively on the C_4 atom.[64]

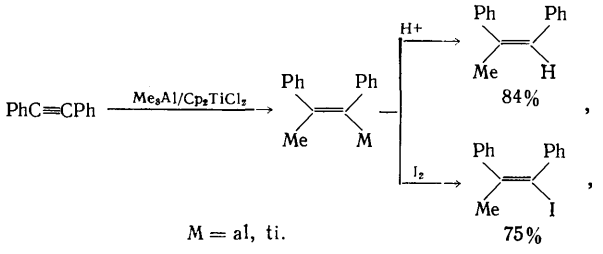
By replacement of Me_3Al by Et_2AlCl or $EtAlCl_2$, the level of regioselectivity is the same only in the case of disubstituted alkynes[65,66], the stereoselectivity remaining unchanged.

46%



50–90%

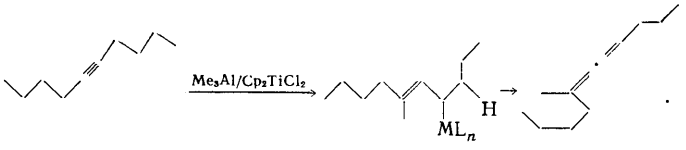
n = 2–4.



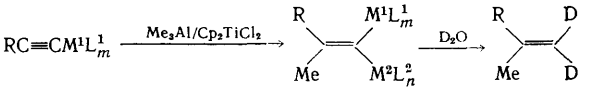
In this case Cp_2TiCl_2 has proved to be the best catalyst on conducting the reaction at 0 °C in methylene chloride during 4–6 h.

Evidently, reaction takes place via carbotitanation followed by transalkylation, although in isolated cases[66] it can be achieved easily in the presence of a catalytic amount (*ca.* 10 mol%) of the titanium reagent. However, as a rule, in order to obtain suitable yields, an equimolar amount of $TiCl_4$ or Cp_2TiCl_2 (relative to the starting alkyne) and twice the amount of OAC is required. According to certain authors,[67] the effective catalysts are four-valent titanium compounds which require activation by reduction to the three-valent state.

The regio- and stereo-selectivity of the reaction is determined by intramolecular formation of cyclic alkynyloxymetallic intermediates which are not disposed to β-hydride elimination or any other side reaction[62].



On the other hand, carboalumination of mono- and di-substituted alkynes which do not possess a hydroxyl group proceeds, as a rule, with low selectivity. Diphenylacetylene is an exception since it is readily carboaluminated under mild conditions with Me_3Al/Cp_2TiCl_2. The obtained OAC is converted on hydrolysis to (*Z*)-1,2-diphenylpropene (84%), while treatment with iodine affords 1-iodo-1,2-diphenylpropene (75%).[68]

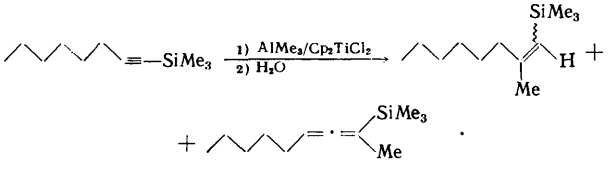


M = al, ti.

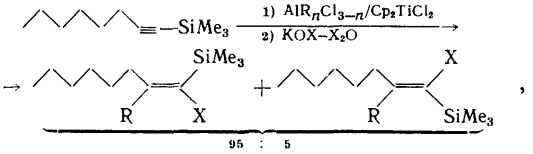
At the same time, reaction of dialkyl-substituted alkynes, e.g. 5-decyne, affords predominantly allenes:[68]

The yield of the products derived by carbometallation of monoalkyl-substituted acetylenes does not exceed 30%; unidentified oligomeric products are formed in the main.

For acetylenes functionalized at one of the unsaturated C-atoms by heteroatomic substituents (ZnCl, BR'_2, AlR'_2), the most selective system for carbometallation is Me_3Al/Cp_2TiCl_2.



$M^1L^1_m$ = ZnCl, BR'_2, AlR'_2;

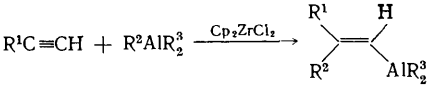


$M^2L^2_n$ = Al- and (or) Ti-containing group.

The heterobimetallic intermediates thus formed are converted on deuterolysis to 1,1-dideuterio-2-methylalkenes in 75–85% yield.[12]

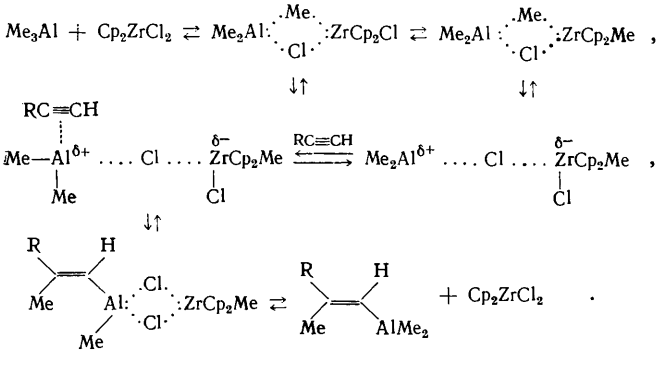
In the case of carbometallation of 1-trimethylsilyl-1-alkynes, the yield and composition of the product is largely dependent on the reaction conditions and on the subsequent treatment of the intermediate alkenyl complexes. Thus, a mixture of vinyl- and allenyl-silanes was obtained in approximately 80% yield by carbometallation of 1-trimethylsilyl-1-octyne with trimethylaluminium.

Higher selectivity can be achieved by using halogen-containing alanes. In view of the marked increase in rate of the key step, the formation of side-products is kept to a minimum.[69]



R = Me, Et; X = H, D.

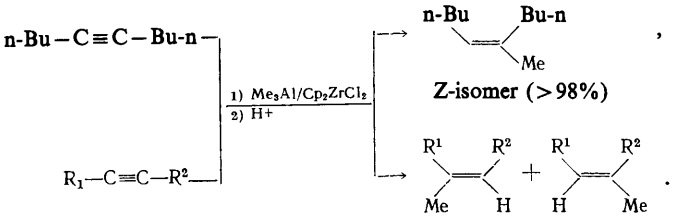
The decomposition of the carbometallation product with aqueous KOH (or KOD in D_2O) is a critical stage which determines the reproducibility of the results; if an equimolar amount of triethylamine or another Lewis base is added before decomposition, then non-deuteriated isomeric vinylsilanes are formed, the *trans*-isomer predominating.[70] This effect is explained by the destabilising effect of the Lewis base on the intermediate alkenylaluminium complexes, which facilitates their protonolysis by the reaction medium.[71,72]



The problems normally associated with catalytic carboalumination of acetylenes have been overcome most effectively by using zirconium-containing catalysts. Discovered in 1978 by Negishi and Van Horn[69], the zirconium-mediated route has been studied in detail and found a place in synthetic organic chemistry for selective carboalumination of acetylenes; it is especially useful for the selective formation of isoprenoid residues, which are constituents of a large number of natural products. Because various aspects of this reaction have been discussed repeatedly in previous reviews,[12,72–77] only the fundamental characteristics of the reaction will be briefly touched on here.

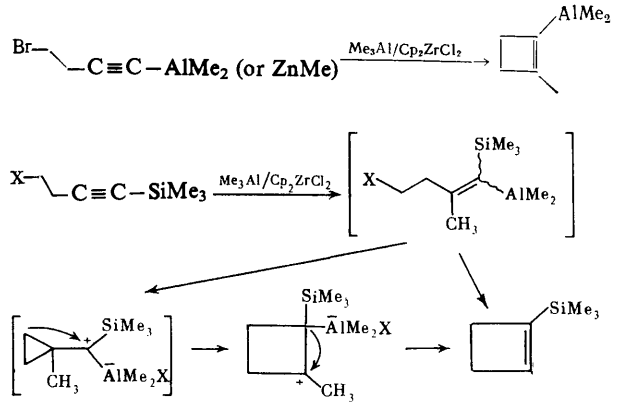
As a rule the interaction of mono- or di-substituted acetylenes with alkylalanes affords the corresponding *cis*-adducts (*ca.* 98% stereochemical purity) in approaching quantitative yields.

Reaction with trimethylalane is the most selective and that most often used; normally it is carried out in the presence of a catalytic amount (10 mol%) of Cp_2ZrCl_2. However, in certain cases, an equimolar amount of Cp_2ZrCl_2 and Me_3Al can be used to maximise the yield of desired product.

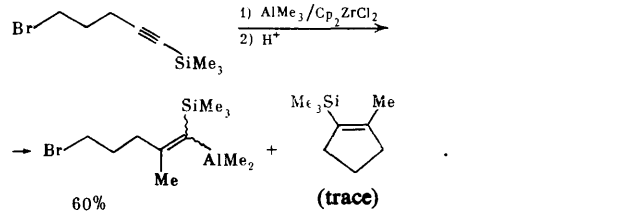


The mechanism of the reaction still requires clarification; however, current data would suggest that, in contrast with the corresponding titanium-catalysed process, it involves a direct interaction of the aluminium–carbon bond with the acetylene group.

Reaction of mono-substituted acetylenes with Me_3Al is not only stereoselective, but also regioselective.[79,80] Thus, 1-octyne, after appropriate treatment and hydrolysis, was converted into a 95:2 mixture of 2-methyl-1-octene and 2-nonene in a total yield of 97%:

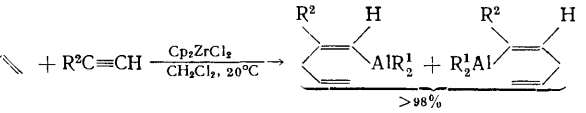


Symmetrically di-substituted acetylenes react with Me_3Al with the same stereoselectivity;[73] however for unsymmetrical substrates regioselectivity depends on the nature of the substituents.[12,78]



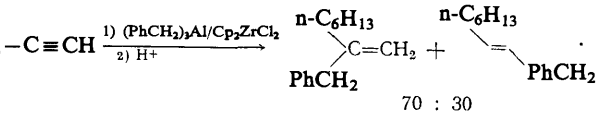
The overall yield is 89%. As well as alkyl groups, the alkyne component can contain such substituents as alkenyl, aryl, halogens, OH, OR', SPh, and $OSiR'_3$; alkadiynes are also reactive, but only one of the two multiple bonds is affected, even in the presence of an excess of $AlMe_3$.[81,82]

ω-Halogen-substituted acetylenes with trimethylsilyl, dialkylaluminium, or alkylzinc groups on the terminal carbon of the unsaturation are exceptions to the rule; here, functionalised cyclobutenes are formed instead of the expected adducts.[83,84]



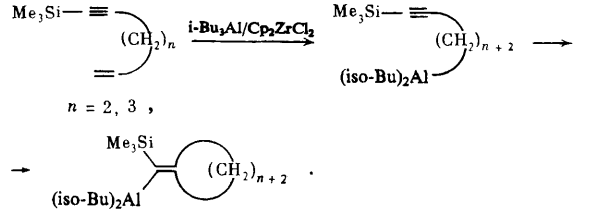
According to one report,[85] a π-type cyclisation is operative, in which the alkenyl fragment plays the role of nucleophile. The primary role of the σ-donor groups ($SiMe_3$, $AlMe_2$, ZnR) is to increase the nucleophilicity of the alkene. 5-Bromo-1-trimethylsilylalkynes are the least disposed to cyclisation, the principal products of reaction being acyclic.[85]

Unfortunately, the high (not less than 95%) regioselectivity associated with 'methylalumination' of terminal acetylenes falls to 75–85% on replacing the Me_3Al by other trialkylalanes.[12]



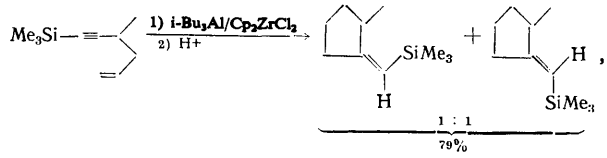
In addition to this, catalytic hydroalumination is a serious complication with those alkylalanes which are inclined to undergo β-hydride elimination. However, such hydroalumination can be successfully suppressed by using such reagent/catalyst combinations as $R_2AlCl-Cp_2ZrCl_2$ and $R_3Al-Cp_2Zr(R')Cl$.[12,86]

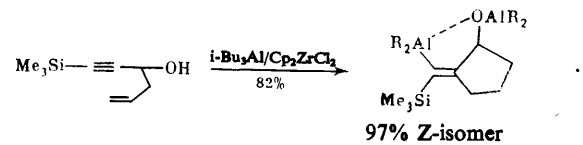
On account of the reduced regioselectivity, carboalumination with $AlEt_3$, $AlPr_3$ and other simple trialkylalanes has little synthetic value. The reactions of allyl- and benzyl-alanes with mono- and di-substituted acetylenes are no exception to this generalisation.[87,88]



Here, stereoselectivity is almost 100%, but high regioselectivity is found only in the case of phenyl-substituted acetylenes. Reaction is impeded if a Me_3Si group is situated on the triple bond and in the presence of more than one equivalent of an ethereal solvent. Dimethyl- and diisobutyl-allylalanes have both been used as allylating agents; however in the latter case simultaneous hydroalumination may take place with the participation of the isobutyl group. Allylaluminium sesquibromide was shown to be inactive.

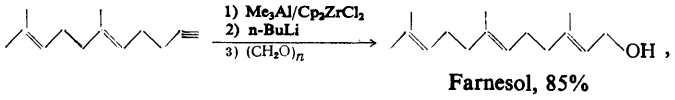
By comparison with allylalanes, benzylalanes are less active; reaction of $(PhCH_2)_3Al$ with 1-octyne takes place only at elevated temperatures (from 60 °C), affording a mixture of regioisomers in 90% total yield after 48 h.



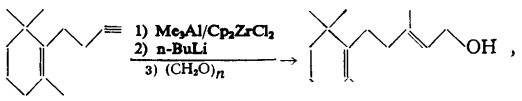


By replacing $(PhCH_2)_3Al$ with $(PhCH_2)_2AlMe$, products are formed via both benzyl- and methyl-alumination in approximately equal proportion, but $i\text{-}Bu_2AlCH_2Ph$ reacts only by cleavage of the isobutyl group.

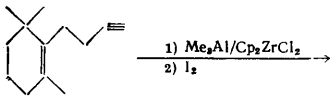
Finally, as one further example of zirconium-catalysed carboalumination, the intramolecular variant leads to the formation of exocyclic alkenylalanes. In this case, the carbometallating agent is regenerated *in situ* as a result of interaction of $i\text{-}Bu_3Al$ with the double bond of the starting enyne.[88,89]



In almost all examples, reaction is non-stereoselective.



In all of the above-mentioned examples of Cp_2ZrCl_2-catalysed carbometallation of terminal acetylenes with Me_3Al, the most useful synthetic aspect is the generation of key intermediates with high stereo- and regio-selectivity, as well as the high reactivity of the formed vinylalanes. The latter can be readily converted into other metallo-derivatives, e. g. boron, zirconium and mercury analogues, as well as into halogeno- or deuterium-containing hydrocarbons and compounds containing a variety of functional groups.[76]



The reaction has been used in the synthesis of an entire series of natural and biologically active compounds containing an isoprenoid residue, e. g. farnesol, geraniol. monocyclofarnesol, ocimene, α-farnesene (see p. 1167), vitamin A, mokupalide, brassinolide, dendrolasin, milbemycin, verrucarin, zoapatanol and others.[75,76,90–102]

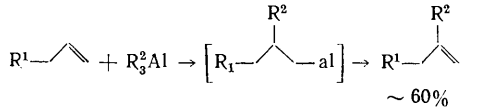
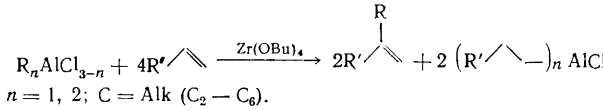
No doubt the more widespread application if this reaction has been restricted by the difficulties associated with handling concentrated solutions of trimethylaluminium.

2. Carboalumination of α-olefins

A significantly fewer number of publications have been devoted to the catalytic carboalumination of olefins. Thus, in contrast with homopropargyl alcohols,[63,67] homoallylic analogues are carboaluminated with very low selectivity on reaction with trialkylalanes or dialkylaluminium halides in the presence of titanium reagents ($TiCl_4$, $TiCl_2(acac)_2$, Cp_2TiCl_2).[63,67,103–105] Because of associated hydrometallation, hydrogenation, isomerisation and β-hydride elimination (in varying proportions), the yield of the regioisomeric mixture of OACs does not exceed 10–30%.

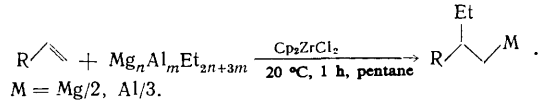


There are references to the selective carboalumination of α-olefins (C_6 to C_{12}) with diethylaluminium chloride in the presence of small amounts (0.5 to 3 mol%) of $TiCl_4$ or $Ti(OBu)_4$ at 20 °C in toluene over the course of 3 h.[106,107]

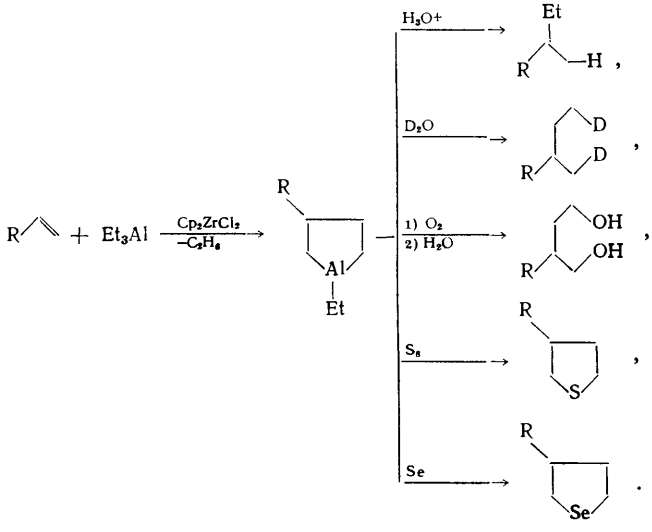


86–96%

Carboalumination of α-olefins with trialkylalanes in the presence of a stoichiometric amount of Cp_2TiCl_2 leads predominantly to the formation of products derived by β-hydride elimination, in addition to high molecular weight oligomers.[108]

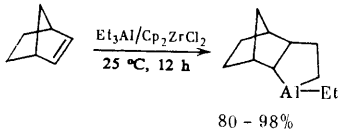


In the presence of a catalytic amount of $Zr(OBu)_4$, the analogous reaction with halogenalanes proceeds far more selectively, affording, in varying yield, products derived by β-alkylation of the starting olefins, in addition to the corresponding higher di-*n*-alkylaluminium halides.[51,109–112]

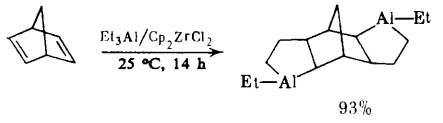


It is not possible to interrupt the process at the stage of carbometallation, even by varying reaction conditions and the proportion of starting materials; evidently, all stages proceed in one and the same catalytic matrix. The best yields were obtained by using dialkylaluminium halides, the activity of which was somewhat reduced with increase in the size of the hydrocarbon radical.[109] α-Olefins have been used as the unsaturated substrate; these may contain aryl substituents (but not OR or OH), as well as disubstituted double bonds. The latter do not react with alkylaluminium halides, but may undergo isomerisation.

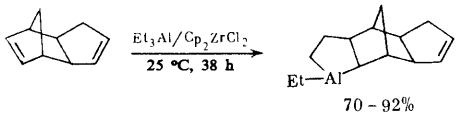
It has been shown that, contrary to earlier reports,[51,97,111] triethylaluminium selectively carboaluminates α-olefins under the action of zirconium-containing catalysts, but only as complexes with Et_2Mg[106]



By interaction of an excess of Et_3Al with olefins in the presence of a catalytic amount of Cp_2ZrCl_2, β-substituted aluminacyclopentanes are formed along with evolved ethane; carboalumination does not take place under these conditions:[112,113]

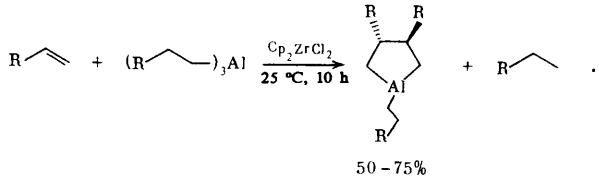


The described reaction is the first example of a catalytic cyclometallation. Although analogous catalytic reactions of organomagnesium and -lithium compounds are known,[116–118] this reaction type is normally found only in transition metal chemistry (as the non-catalytic variant).[114,115] The formation of intermediate zirconacyclopentane complexes has been proposed as the key step in the above reaction.[119–120]

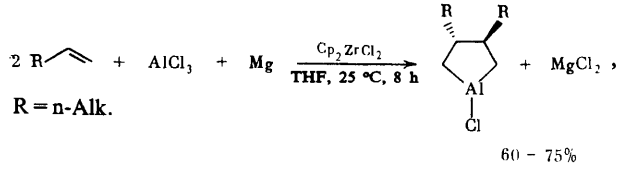


Not only α-olefins (including those with aryl and alkenyl substituents[121]) but also norbornene and some of its derivatives[122–124] may participate in the reaction with Et_3Al.

(Ref.122)



(Ref.123)

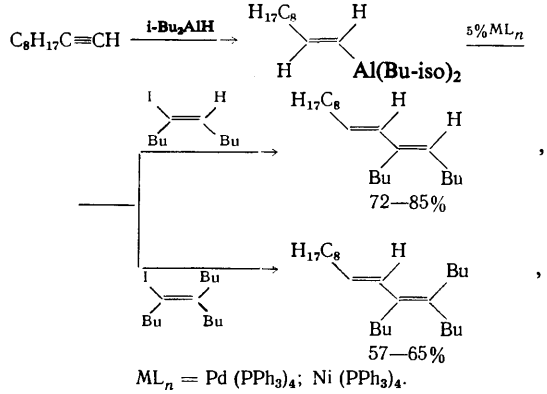


(Ref.124)

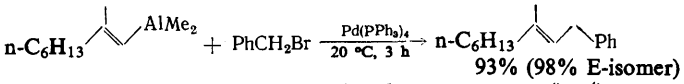
It is interesting to note that, on cyclometallation of norbornadiene, there is no formation of nortricyclene derivatives as observed with catalytic carbomagnesation[125] and hydroalumination.[46]

On replacement of $AlEt_3$ by higher trialkylalanes, their activity in the cyclometallation of α-olefins decreases.[126]

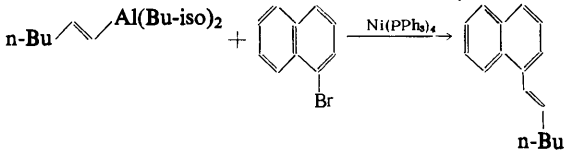
1-Chloroaluminacyclopentanes are formed by interaction of 2 equivalents of the α-olefin with $AlCl_3$ in the presence of Mg-powder and a catalytic amount of Cp_2ZrCl_2:



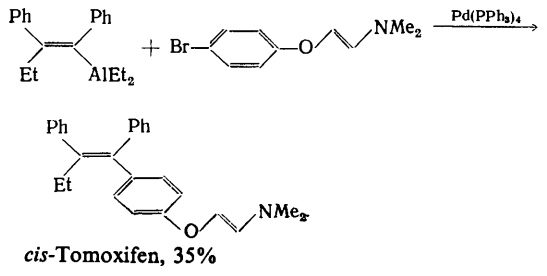
With the discovery of catalytic cyclometallation, there are wide possibilities for pursuing studies in a new field of organometallic chemistry: the chemistry of metallocycles of non-transition metals, the properties of which have, up to this time, remained almost unexplored. Thus, the obtained aluminacyclopentanes are extremely interesting synthetically, their reactivity differing from that of acyclic alkylalanes. In particular, they have proved to be suitable synthons



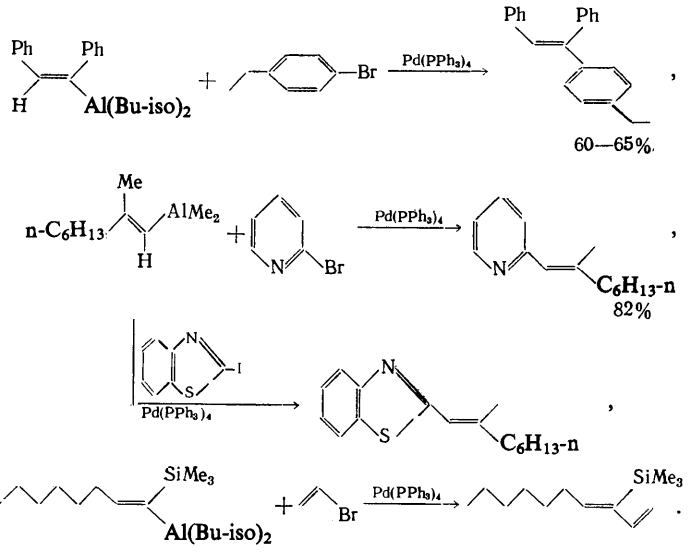
for the preparation of a variety of heterocyclic compounds,[127–131] and have found a use in natural product synthesis.[132–135] At the present time, much research is being performed on the reactions of alumina- and magnesia-cyclopentanes; some of their catalytic conversions will be examined below.



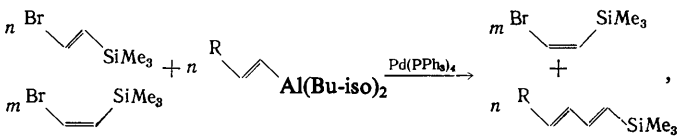
IV. Catalytic cross-coupling with organoaluminium compounds

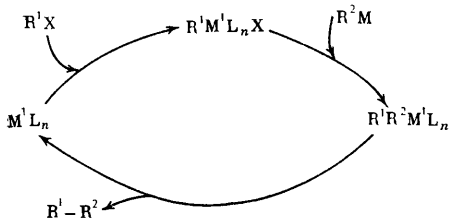


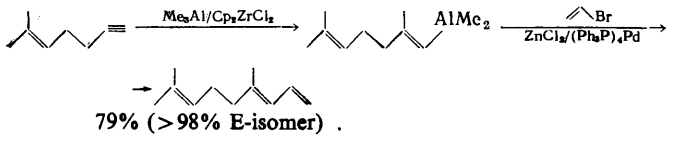
Discovered less than twenty years ago, catalytic cross-coupling is now one of the most generally applicable and far-reaching methods of forming the carbon–carbon bond from organometallic compounds. Among organoaluminium compounds which participate in cross-coupling, alkyl- and vinyl-alanes are most frequently used. This is, in part, because of their availability (via the above-described hydro- and carbo-metallation) and, in part, because of their ability to react selectively with a variety of electrophiles in the presence of a catalytic amount of transition metal complexes, notably Ni, Pd or Cu complexes.



Negishi et al.[136,137] have developed an excellent method of preparing conjugated dienes and arylalkenes of defined configuration via Ni- or Pd-catalysed coupling of vinylalanes with alkenyl, aryl or benzyl halides. The method has been applied to the synthesis of a number of biologically active compounds or synthons for their preparation.[138–142]

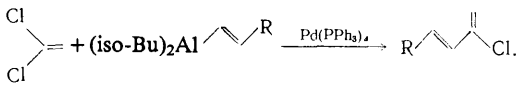




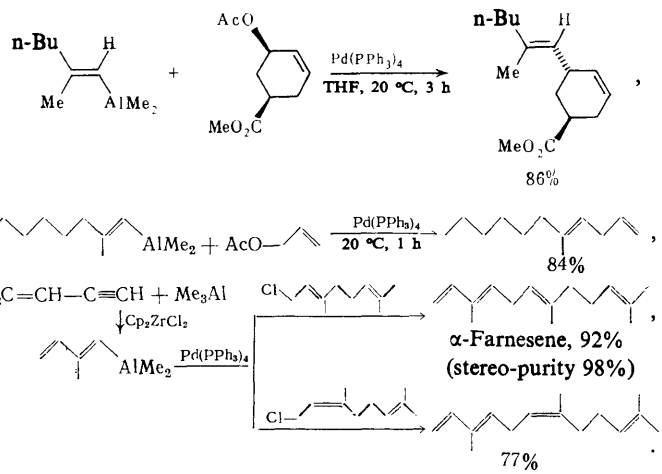


In all variants of the above cross-coupling, almost 100% stereospecificity results by using Pd-catalysts; however, there is some loss of stereoselectivity in the synthesis of conjugated dienes with Ni-complexes. Cross-coupling of (*E*)-1-alkenylalanes with a stereoisomeric mixture of (2-bromovinyl)trimethylsilanes proceeds stereoselectively in the presence of $Pd(PPh_3)_4$ (in THF–hexane at 40 °C for 16 h) with the formation of 4-alkyl-substituted (1*E*, 3*E*)-1-tri-methylsilyl-1,3-dienes, the stereo-purity of which exceeds 99%.[143]

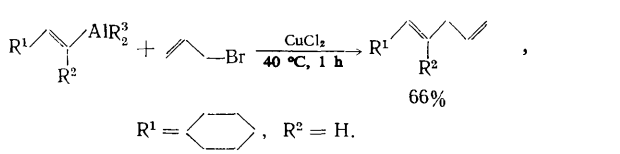
According to a specifically mechanistic study, it was established that cross-coupling proceeds through an initial oxidative addition of a Pd(0)-complex, followed by a rate-determining transmetallation with participation of an organopalladium(II) complex, and rapid decomposition of the diorganopalladium complex formed to give the cross-coupling product.[144]



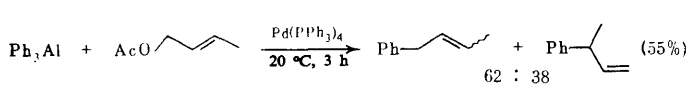
For cross-coupling of sterically hindered vinylalanes (notably those obtained by Zr-catalysed carboalumination) with vinyl halides it is necessary to use the bimetallic catalyst, $Pd(PPh_3)_4/ZnCl_2$.[145]



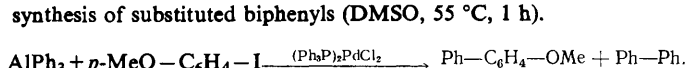
Without $ZnCl_2$ the yield remains below 1%. Dienylalanes may also undergo cross-coupling, although the products are obtained in high yield without $ZnCl_2$.[146]



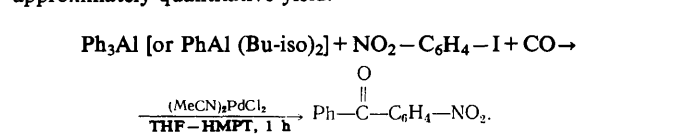
In the case of 1,1-dihalogenoalkenes, it is possible to replace selectively one of the chlorine atoms.[147]



Allyl halides and acetate also afford excellent yields of cross-coupling products with vinylalanes in the presence of Pd-complexes.[148–149]



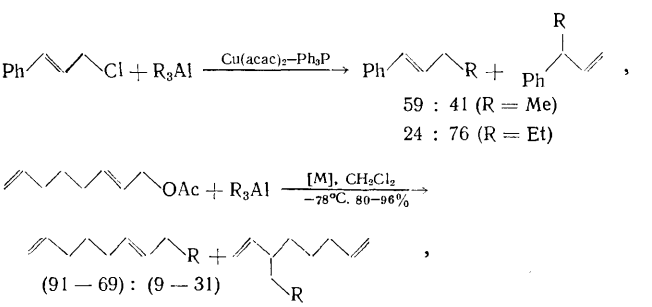
The reaction of allyl halides with vinylalanes is also catalysed by copper salts.[150]



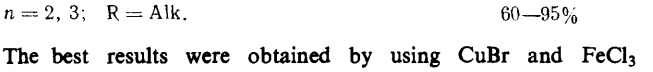
Examples of Pd-catalysed cross-coupling of arylalanes with allylic and aryl electrophiles are known:[151]

The coupling of arylalanes with aryl halides proceeds more selectively.[152,153] The reaction is of preparative value for the synthesis of substituted biphenyls (DMSO, 55 °C, 1 h).

By conducting this reaction in the presence of carbon monoxide, substituted aromatic ketones were obtained, sometimes in approximately quantitative yield:[154]

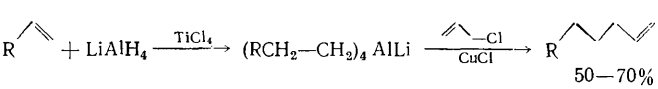


Cross-coupling of alkynylalanes normally proceeds non-selectively due to the formation of a large amount of product derived by homo-coupling.

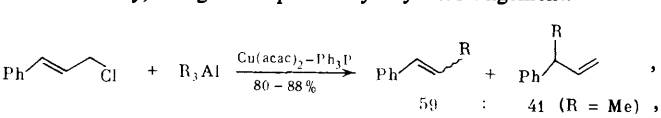


The maximum yield (42%) was achieved by using a catalyst containing diphenylphosphinoferrocene (dppf).[153]

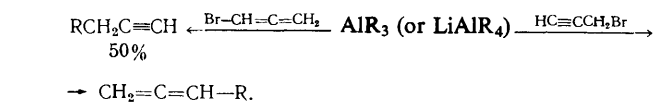
The reaction of alkylalanes and lithium tetraalkylaluminates with allylic electrophiles can, in principle, be conducted in the absence of catalyst; however, the selectivity and yield of coupling products are not high. Reaction is favoured by using copper-containing catalysts, and in a number of cases there is an effect on selectivity.[155–159]



R = n-C_6H_{13}, *i*-Bu, Et; [M] = CuBr, CuCl, $FeCl_3$.

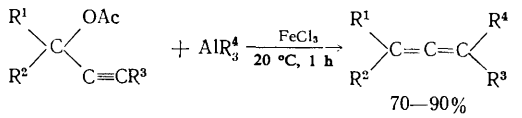


The best results were obtained by using CuBr and $FeCl_3$ as catalysts; with Pd-containing catalysts the selectivity is worse, although they have been successfully used in the cross-coupling of alkylalanes with certain halogenonucleosides (8-bromoadenosine and 5-bromouridine).[160]



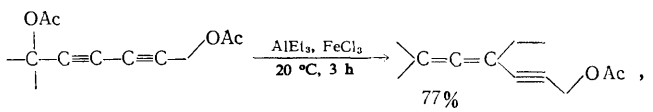
Lithium tetraalkylaluminates react in a similar manner with allyl halides in the presence of mono- and di-valent copper salts [CuCl, CuBr, CuI, CuCN, $CuCl_2$ and $Cu(OAc)_2$]. Contrasting with trialkylalanes, which participate by donating only one alkyl group, tetralkylaluminates transfer all four ligands.[34]

In the case of substituted allyl halides, reaction takes place as a rule non-selectively, being accompanied by allyl rearrangement:[161,162]

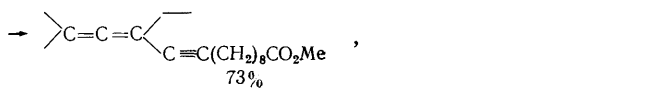


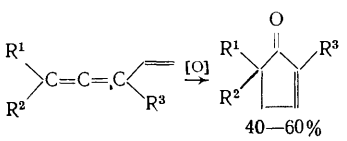
At the same time, products of rearrangement predominate on reaction of propargyl and allenyl halides with alkylalanes and alkylaluminates in the presence of CuCl at 0 °C during 5 h; the result is an original preparative route to primary allenes and acetylenes.[163–166]

The reaction of substituted propargyl acetates with trialkylalanes and



alkenyldialkylalanes proceeds readily in the presence of $FeCl_3$ (in this case being a more active catalyst than Pd or Cu salts), thereby providing a suitable method for preparing substituted allenes, including functionalised vinylallenes, diallenes and allenynes. A variety of different OACs may participate in the reaction. The obtained vinylallenes are of practical value as synthons for the preparation of a number of natural products with a cyclopentanone residue.[167–171]

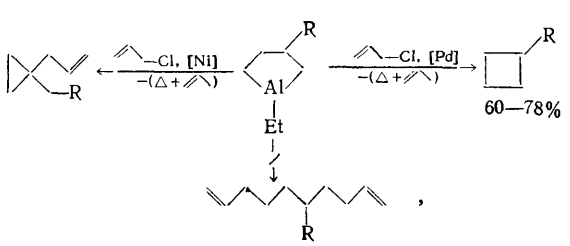




70—90%

R^1, R^2 = Me, Et, $CH{=}CH_2$; R^3 = H, $CH{=}CH_2$;

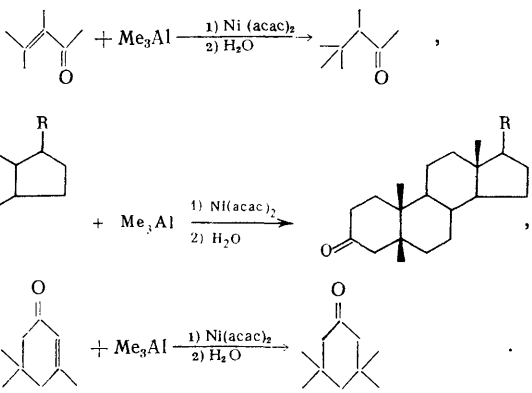
R^4 = Et, Me, *i*-Bu, n-C_6H_{13};



R^1, R^2, R^3 = H, Alk.

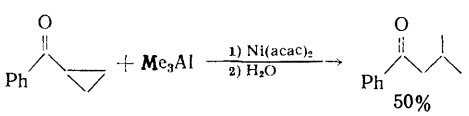
It is worth noting that reaction takes place preferably at the electrophilic centre of the propargyl group even in the presence of an allyl group (when R′ = $-CH{=}CH_2$).

Allyl halides react in an unusual manner with aluminacyclopentanes, the formation of which has been mentioned in the previous section under cyclometallation.[12,113] Thus, interaction of substituted aluminacyclopentanes with allyl chloride in the presence of palladium complexes affords mono-substituted cyclobutanes,[172] while allylcyclopropanes are obtained in the presence of nickel catalysts.[173]



R = Alk.

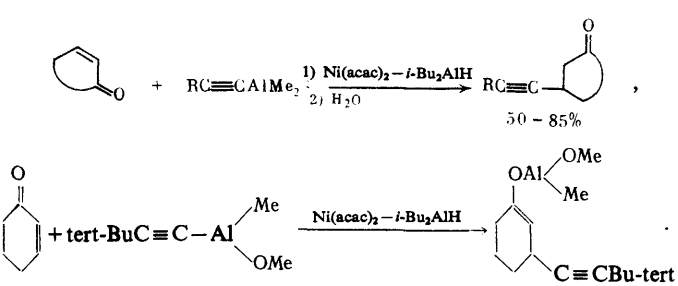
Reaction is accompanied by the evolution of a mixture of propylene and cyclopropane.



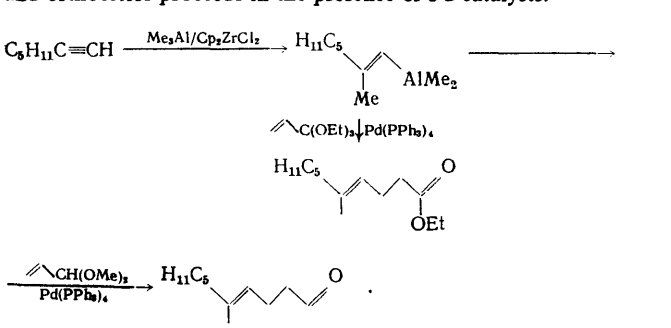
V. Catalytic reactions of organoaluminium compounds with carbonyl-containing compounds

1. Conjugate addition

It is known that reduction and alkylation of enones can proceed by both 1,2- and 1,4-addition. Both types of reaction are known with organoaluminium reagents. Selective 1,4-addition of Me_3Al to enones can be achieved in the presence of $Ni(acac)_2$.[174–176]

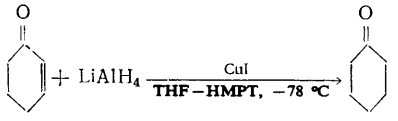


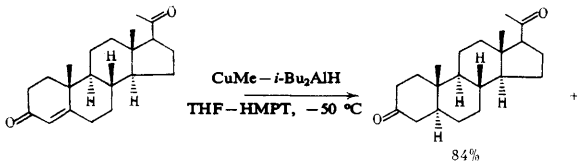
Cyclopropyl ketones react in a similar manner under these conditions:[175]



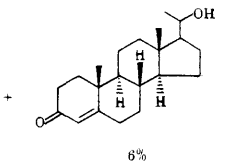
All such additions are normally complicated by the formation of high molecular-weight products derived by aldol condensation.

Dialkylalkynylalanes react with α,β-enones by donating only an alkyl group.[177,178] In order to obtain high yields of the alkynyl adduct, the catalyst must be preliminarily reduced by *i*-Bu_2AlH:

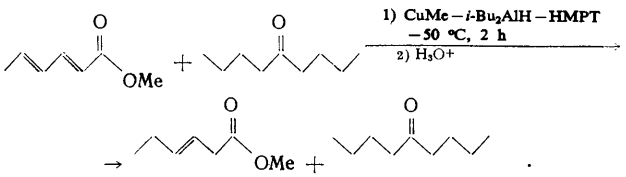




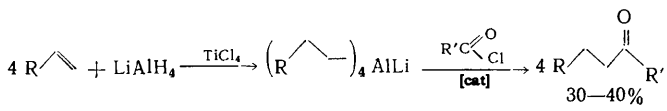
The analogous reaction of vinylalanes with α,β-unsaturated acetals and orthoesters proceeds in the presence of Pd-catalysts.[174]



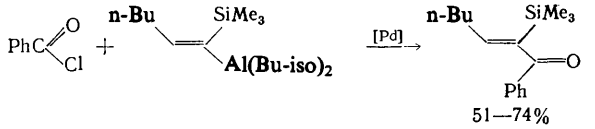
2. Conjugate reduction of enones



Conjugate reduction of α,β-unsaturated carbonyl compounds with *i*-Bu_2AlH [179] or $LiAlH_4$ [180] is catalysed by Cu(I) compounds, and proceeds in the presence of hexamethylphosphoramide (HMPT):

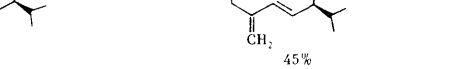


In the case of dienones, selective 1,6-reduction takes place even in the presence of an equivalent amount of saturated carbonyl compound:[180]



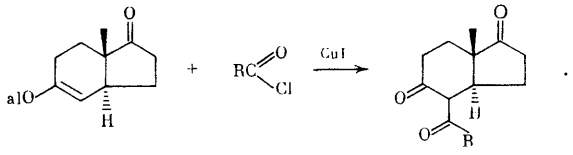
Triisobutylaluminium reacts with α,β-unsaturated ketones in the same way, but in the presence of nickel complexes.[181]

3. Synthesis of ketones

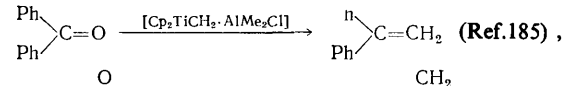


The interaction of OACs with acyl chlorides in the presence of transition metal salts may be applied as an effective method of preparing ketones:[35,182,183]

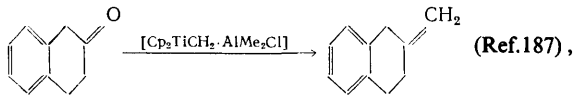
Palladium complexes [$Pd(PPh_3)_4$ and $Pd(OAc)_2.2PPh_3$] are the best catalysts for the selective synthesis of ketones from OACs containing alkenyl or alkynyl groups, whereas Ru-, Rh- and Ni-complexes were ineffective.[183]



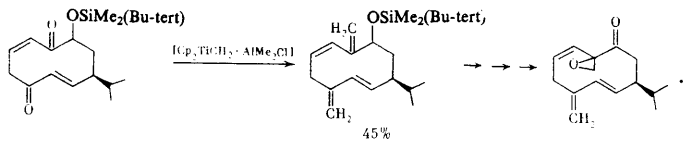
Trialkylalanes afford a better yield of ketones than tetraalkylaluminates,[182] and react not only with acyl chlorides but also with thiolocarboxylic acid esters:



X = Cl, SPh; R^1 = Ph, $CH_2=CH-(CH_2)_8-$; R^2 = Me, Et, *i*-Bu.

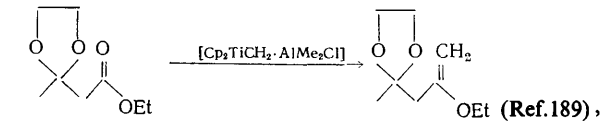


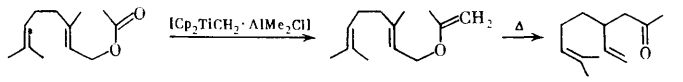
In addition, copper(I) salts catalyse the formation of 1,3-diketones from acyl chlorides and aluminium enolates:[184]



4. Methylenation of carbonyl compounds

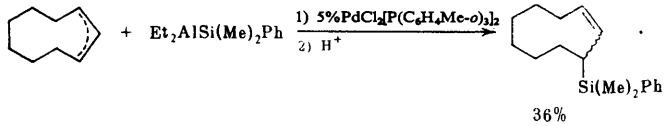
Tebbe's reagent ($Cp_2TiCH_2.AlMe_2Cl$), prepared *in situ* by treatment of Cp_2TiCl_2 with Me_3Al,[185,186] has proved to be useful for the methylenation of a variety of carbonyl compounds. It can serve as an alternative to the traditional Wittig reagent, notably for the methylenation of readily enolisable ketones which are unstable under the strongly basic conditions of the Wittig synthesis.



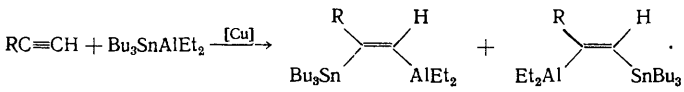


(Ref.188)

Esters and lactones are simply converted to the corresponding enolethers which may then react further:[189,190]



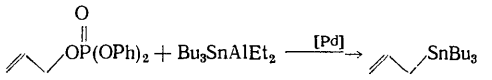
(Ref.190).



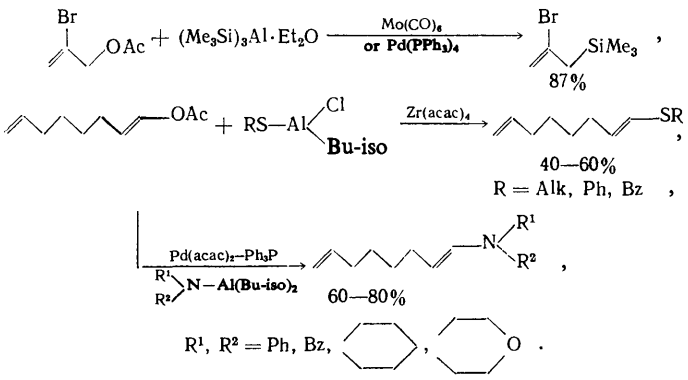
VI. Catalytic reactions across the aluminium-heteroatom bond

This section will be devoted to some interesting reactions related to carbometallation and cross-coupling which were discussed earlier; however, we shall be considering here reaction across the aluminium-heteroatom bond, rather than the aluminium-carbon bond (even in cases where the OAC contains both aluminium-heteroatom and aluminium-carbon bonds). In this way, a variety of hetero-functions

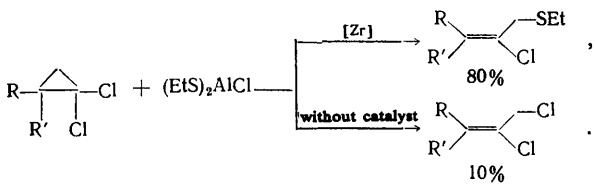
can be introduced into an organic compound. Thus, silylalumination of the allene group of 1,2-cyclononadiene with dimethyl(phenyl)silyldiethylalane in the presence of a Pd-catalyst affords a 3-dimethyl(phenyl)silyl-1-cyclononene:[191]



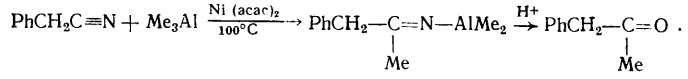
By interaction of mono-substituted acetylenes with dialkyl(stannyl)-alanes in the presence of Cu(I) salts (CuCN, CuI) or Pd(O)-complexes, stannylalumination of the triple bond takes place rather than carboalumination:[192–195]



Reaction is noteworthy for its high regio- and stereo-selectivity (80–92%). Contrasting with carbometallation, stannylalumination can be performed on acetylenes which possess tetrahydro-2-pyranyloxy-, hydroxy-, acetoxy-, and benzyloxy-groups.

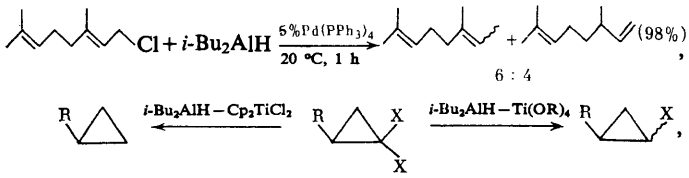


By interaction of (tributylstannyl)diethylalane with allyl phosphates, cross-coupling takes place with the formation of allylstannanes:[196]



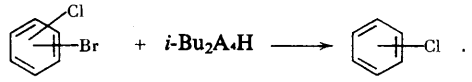
Similar reactions can also be achieved by fission of Al–Si [197], Al–N and Al–S bonds.[198,199]

Finally, by interaction of *gem*-dichlorocyclopropanes with bis(ethylthio)aluminium chloride in the presence of Zr-catalysts, a high yield of the corresponding allyl thioethers was obtained, i.e. the chlorocyclopropane here performs the function of an allyl halide equivalent.[200]



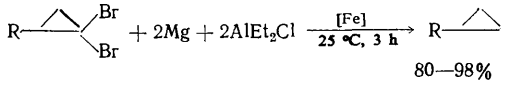
Addition of Me_3Al to the nitrile bond of alkyl, aryl and benzyl cyanides is analogous to carboalumination of acetylenes.

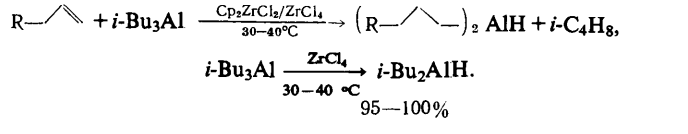
Reaction is more selective and milder in the presence of Ni-complexes[201] than without catalyst.



VII. Other catalytic reactions involving organoaluminium compounds

In the presence of palladium complexes,[202] as well as those of Ti, Zr and Hf,[202–207] *i*-Bu_2AlH effectively dehalogenates various types of halogenated hydrocarbon under mild conditions. These include allyl,[202] alkyl,[204] aryl[204] and cyclopropyl halides:[203–207]





In the case of aryl bromides containing aromatic chlorine, it is possible to replace the bromine with retention of the C–Cl bond.[204]

Complete dehalogenation of dibromocyclopropanes can be achieved with a mixture of Et_2AlCl and powdered magnesium in the presence of $FeCl_3$ as catalyst.[208]

The synthesis of *i*-Bu_2AlH and certain higher dialkylaluminium hydrides was carried out under mild conditions with the aid of zirconium catalysts:[209,210]

Higher alkylaluminium chlorides have been obtained by catalytic telomerisation of ethylene with diethylaluminium or sesquiethylaluminium chloride, also in the presence of zirconium catalysts.[211]

Key steps in the cross-coupling of organometallic compounds with organic halides, catalysed by nickel and palladium compounds

N A Bumagin, I P Beletskaya
M V Lomonosov State University, Moscow

ABSTRACT. The mechanism of cross-coupling of organometallic compounds with organic halides, catalysed by nickel and palladium complexes, has been examined. The key steps are discussed: oxidative addition, transmetallation, and reductive elimination. There is an analysis of the problems associated with the choice of the most effective ligands for the nickel and palladium complexes.

The bibliography contains 100 references.

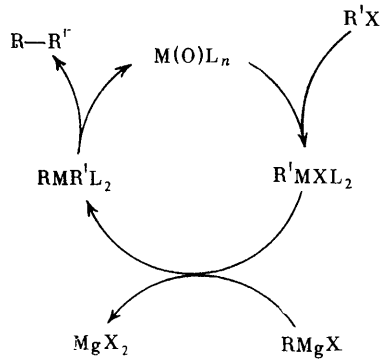
I. Introduction

A major problem in organic chemistry is the development of highly selective reactions in which carbon–carbon bond formation takes place. One such reaction is cross-coupling wherein organometallic compounds (notably of lithium and magnesium) interact with organic halides.



$$RM + R'X \rightarrow R{-}R' + MX. \quad (1)$$

However, cross-coupling has found a limited application in organic synthesis for two reasons: firstly, on account of concurrent elimination and exchange which leads to decrease in selectivity; and, secondly, on account of the inertness of organic halides possessing a halogen on an sp^2 atom. These limitations and associated practical difficulties can be overcome to a large extent by using organocopper compounds (in particular organocuprates) in place of organo-lithium or -magnesium reagents.[1,2] However, many problems remain unsolved. For example, cross-coupling with the formation of a carbon–carbon bond between sp^2 atoms proceeds with low selectivity; organic halides with reactive functional groups cannot always be used; and reactions with copper acetylides require fairly harsh conditions.

A new impulse to cross-coupling was given in the early 1970s when Kumada and Corrius et al.[3,4] demonstrated independently that cross-coupling of Grignard and organolithium compounds with alkenyl and aryl halides proceeds readily in the presence of nickel complexes. In 1975, it was shown[5] that the palladium complex, $Pd(PPh_3)_4$, is an effective catalyst for the reaction. Cross-coupling with more active organometallic compounds of (zinc,[6] aluminium,[7] zirconium,[8], boron,[9] tin [10] and mercury [11]) has significantly broadened the scope of the method, permitting the synthesis of various types of organic compound containing almost any functional group.

Since palladium- and nickel-catalysed cross-coupling proceeds under mild conditions in high yield and with high selectivity, the method has been widely applied in organic synthesis. Synthetic aspects of cross-coupling have been examined in earlier reviews.[12–17] This review is devoted to a detailed study of the mechanism of cross-coupling; a comparison is made of various organometallic compounds, RM in Eqn. (1), by considering the nature of the organic residues, R and R', and the metal, M; and the effect of the particular nickel of palladium catalyst has been studied.

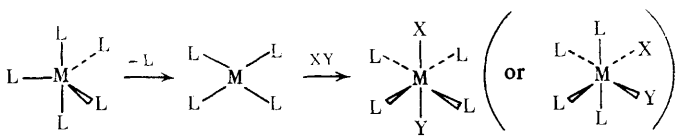
For nickel- and palladium catalysed cross-coupling of Grignard reagents with organic halides, it is generally accepted that the mechanism of the reaction involves an initial oxidative addition of R'X to the zero-valent metal complex, M(0) followed by transmetallation with formation of a complex, $RMR'L_2$, having two σ-bonded organic residues; reductive elimination of R–R' completes the cycle with regeneration of M(0) [3,18] (scheme 2):

(2)

Nickel and palladium complexes are known to participate in the individual stages of this catalytic cycle. Thus, oxidative addition of aryl halides to PdL_4 leads to the formation of palladium σ-complexes, *trans*-$ArPdXL_2$.[19] By interaction of such complexes with RMgX, diorganopalladium complexes, *trans*-$ArPdRL_2$, are obtained. Some of these complexes have been isolated in pure form, e.g. where R = Me, Ph; Ar = *p*-FC_6H_4; L = PEt_3. In solution complexes $ArPdRL_2$ gradually cleave with the formation of cross-coupling product.[20] However, scheme (2) reflects only the most characteristic features of catalytic cross-coupling. There is no indication, for example, of the configuration of the mono- and di-organo-complexes, and no indication of the precise mechanism of the ligand exchange, etc. There is a detailed discussion below of

oxidative addition, reductive elimination, and transmetallation. Although cross-coupling is performed primarily in the presence of palladium and nickel catalysts, other transition metals will be considered with a view to elucidating general trends.

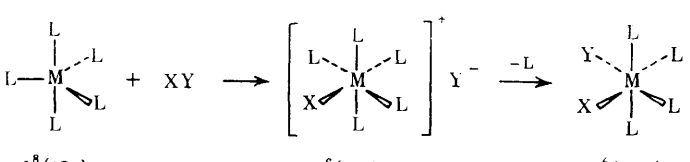
II. Oxidative addition



Oxidative addition is defined as the reaction of a transition metal complex with a substrate X–Y (H_2, O_2, RX, RH, etc.) wherein a covalent bond in the latter is cleaved with an associated one- or two-electron oxidation of the metal.[21]

$$X-Y+2M\rightarrow M-X+M-Y \text{ (or } X-M-M-Y) \quad (3)$$

$$X-Y+M\rightarrow X-M-Y \text{ (or } X-M^{+}Y^{-}) \quad (4)$$

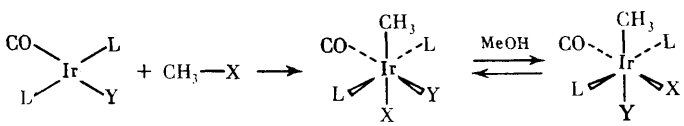


This reaction is characteristic of transition metal complexes in low oxidation states, especially complexes of Group VIII metals having a d^8- and d^{10}-electronic configuration. Oxidative addition is accompanied by a shift in the *d*-configuration from d^n to d^{n-1} or d^{n-2} with an increase in the coordination number. The reverse process, known as reductive elimination, is characterised by a decrease in the oxidation state of the transition metal. Clearly, it is because transition metals are able to exist in a number of oxidation states and are able to transfer easily from one oxidation state to another that they catalyse many reactions. On the contrary, oxidative addition and reductive elimination are quite uncharacteristic of non-transition metals. Thus, the latter do not catalyse cross-coupling. It should be pointed out that the term, oxidative addition, describes only the result of reacting X–Y with a transition metal complex, and is not a mechanistic definition.

In order to participate in oxidative addition, the transition metal complex may be either coordinatively saturated or unsaturated. The reactivity of coordinatively unsaturated complexes is, as a rule, significantly higher. There is an initial ligand dissociation on interaction of substrates, XY, with 5-coordinate 18-electron metal complexes with a d^8-configuration.

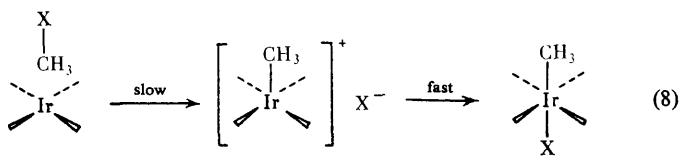
(5)

Coordinatively saturated d^8-complexes interact only with reagents having powerful oxidising properties. Reaction proceeds via intermediate formation of an octahedral cationic d^6-complex.



(6)

For substrates, XY, participating in oxidative addition one can designate three classes: class A are polar, electrophilic reagents; class B are reagents in which the bond between X and Y remains intact after oxidative addition; and class C are non-polar reagents.[21] Halogens (X_2), acids (HY), RSCl, RSO_2Cl, RX, RCOX, R_FI, RCN, $SnCl_4$, and HgX_2, for example, belong to class A; O_2, S_2, Se_2, *o*-quinones, RC≡CR, RN=NR, RCH=CHR, CS_2, CH_2O, cyclopropanes, $RCON_3$ and RN_3 are in class B; and H_2, R_3SiH, R_3GeH, R_3SnH, RSH, RCHO, ArH and RH are in class C. Of the multitude of oxidative oxidations,[21] we shall examine below only reactions involving organic halides (class A) in the presence of transition metal complexes.



As low-valent transition metal complexes are basically nucleophilic, they readily react with alkylating agents. However, in contrast with familiar nucleophilic reagents, zero-valent metal complexes do interact with aryl and alkenyl halides. In mechanistic terms, reaction may involve an S_N2-process, a radical chain process, or a single-electron transfer (SET), depending on the formal charge on the metal complex, the nature of the metal, the ligand environment, the structure of the organic halide, and on the conditions under which oxidative addition is performed.

The oxidative addition of methyl halides to an iridium(I) complex is representative.

(7)

A kinetic study has shown that the reaction is of the second order (first order in each reactant).[22] The rate of the reaction increases with solvent polarity, being in the order: DMF > MeCN > THF > C_6H_5Cl > C_6H_6; and the large negative entropy of activation accords with an S_N2 mechanism for nucleophilic substitution of a carbon atom. It should be pointed out that it was not possible to intercept the 5-coordinate cationic iridium(III) intermediate (scheme 8) with an external nucleophile.[23]

(8)

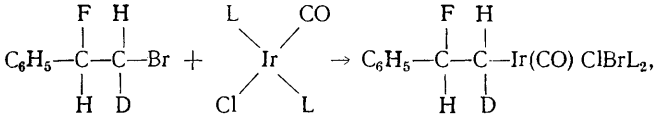
A *trans*-methyliridium(III) complex is formed in non-polar solvents as a result of oxidative addition. In methanol the *trans*-complex isomerises to the thermodynamically more stable *cis*-complex.[24] A radical chain mechanism was excluded since the rate of oxidative addition is unaffected in the presence of radical traps.

The rate of reaction (7) increases with the basicity of the phosphine ligand L:

$$PEt_3 > PEt_2Ph > PEtPh_2 > P(p\text{-Tol})_3 > PPh_3.$$

However, in a number of cases, a steric effect can be the dominant factor.[25] For example, complexes where L = $PPhMe_2$ are more active than those where L = PEt_3. Evidently, this would also explain the higher rate of oxidative addition of CH_3X to the complex $FIrCOL_2$ than to $IIrCOL_2$.

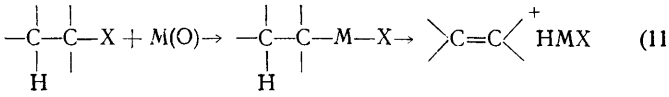
Ethyl iodide is significantly less reactive than methyl iodide, and secondary alkyl halides in general do not participate in reaction (7) in the absence of a radical initiator. These results are also consistent with an S_N2 process.



Secondary, and even primary, alkyl halides which are inactive in S_N2 reactions readily react with Ir(I) complexes by a radical chain

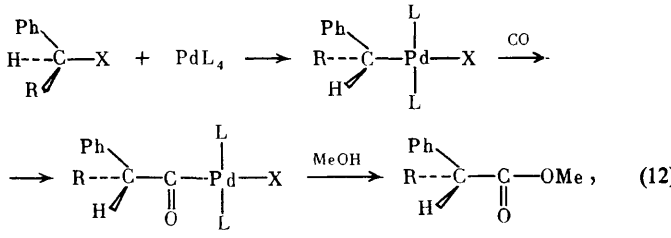
mechanism. This is confirmed by inhibition of the reaction with galvinoxyl and duroquinone, by the initiating effects of azodiisobutyronitrile and benzoyl peroxide, and by the fact that chiral substances are racemised.[26]

$$\left.\begin{array}{l} Q^{\cdot} + Ir(I) \rightarrow Ir(II)-Q \\ Ir(II)-Q + R-X \rightarrow X-Ir(III)-Q + R^{\cdot} \end{array}\right\} \text{initiation}$$



$$\left.\begin{array}{l} R^{\cdot} + Ir(I) \rightarrow R-Ir(II) \\ R-Ir(II) + R-X \rightarrow R-Ir(III)-X + R^{\cdot} \text{ etc.} \end{array}\right\} \text{chain extension} \qquad (9)$$

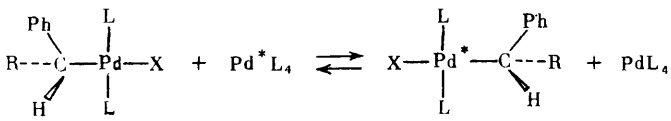
The stereochemistry of reaction (9) was studied using racemic diastereoisomers and pure enantiomers.[27]



(10)

Oxidative addition involving d^{10} platinum and palladium complexes proceeds by an even more complicated pathway than reaction with Ir(I) complexes.[28] Alkyl halides which do not possess a β-hydrogen atom react with zero-valent palladium complexes to give stable alkylpalladium complexes.[29] However, with halides which do have a β-hydrogen atom, β-elimination of metal hydride takes place and the σ-alkyl complex is not isolated.

(11)

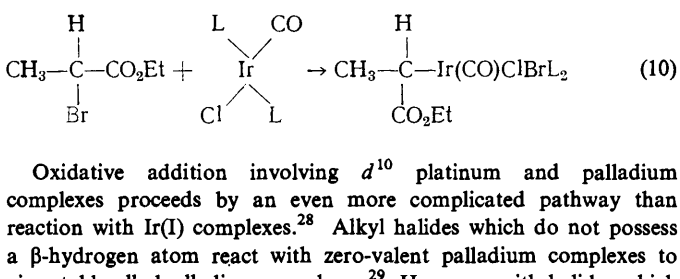


An S_N2-type mechanism prevails for reactions with palladium complexes since chiral benzyl halides react predominantly with inversion of configuration at the benzylic carbon atom.[30] Both primary and secondary benzyl halides react according to this mechanism.

(12)

R = D, CH_3; L = PPh_3.

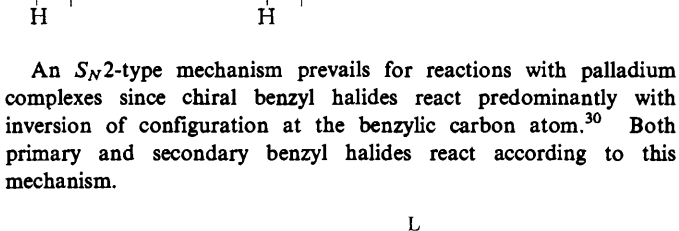
It has been suggested that the observed partial racemisation is a consequence of a metal–metal exchange involving Pd(0) and Pd(II) complexes, rather than intervention of a radical process.[30]



(13)

Alkylation of palladium complexes having the more basic phosphine ligand, L = PEt_3, also proceeds with inversion of configuration, but the optical yield is relatively low.[31]

With such halides as 9-bromofluorene, α-carbethoxybenzyl bromide, and trimethylsilylchloride, the corresponding dimers are obtained, rather than products derived via oxidative addition:[29]



$$2RX + PdL_4 \xrightarrow[-2L]{} R-R + PdX_2L_2. \qquad (14)$$

In contrast to palladium(0) complexes, platinum(0) analogues react with organic halides essentially by a radical mechanism.[28,32,35] Thus, the reaction of n-butyl bromide with $Pt(PEt_3)_3$ is inhibited by galvinoxyl. It has been reported, in fact, that galvinoxyl interacts with a Pt(0) complex.[28] Methyl iodide reacts with $Pt(PEt_3)_3$ via oxidative addition, the process being overall of the second order. The interception of free radicals by radical traps, such as tert-BuNO', is indicative of the participation of radical intermediates.[28] A radical-chain process is proposed for such reactions involving a one-electron transfer step.[28]

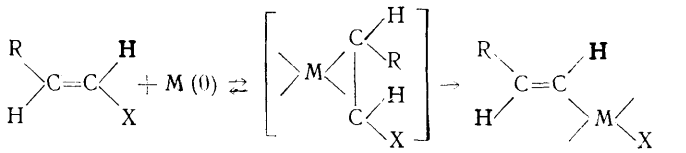
$n = 2, 3$: RX = MeI, $MeCH_2I$: L = PPh_3. (15)

A mechanism involving an initial complex formation between halide and complex, $M(0)L_n$, is involved for reactions of unsaturated organic halides.[34]

(16)

Contrasting with nucleophilic aromatic substitution,[35] the reactivity of aryl halides decreases in the following order: I > Br > Cl. Electron-accepting substituents in the aromatic ring facilitate oxidative addition.[36]

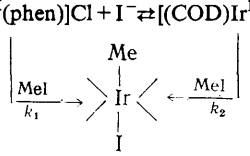
Oxidative addition of aryl halides to zero-valent nickel complexes leads to the formation of a paramagnetic Ni(I) complex in addition to a *trans*-arylnickel(II) halide.[37,38] The proportion of each depends on the nature of the halogen in ArX, the type of ring substituent, and the solvent. The reaction is overall of the second order. It is proposed that the rate-determining stage is the one-electron oxidation of the Ni(0) complex with the aryl halide; the radical-ion pair thus formed reacts by two independent pathways affording the product of oxidative addition and an Ni(I) complex. It is possible that the electron transfer step precedes π-complex formation between the reactants.



(17)

It should be pointed out that Ni(I) complexes may react with aryl halides with the formation of arylnickel(III) complexes; however, this reaction proceeds far more slowly than the reaction of ArX with an Ni(0) complex. According to one report,[38] oxidative addition to Ni(I) is the key step in the synthesis of biaryls from aryl halides in the presence of nickel complexes and metallic zinc.

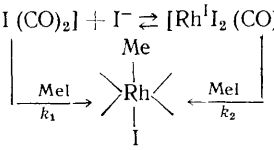
$$Ni^{I}X + ArX \rightarrow ArNi^{III}X_2,$$
$$ArNi^{III}X_2 + ArNi^{II}X \rightarrow Ar_2Ni^{III}X + NiX_2,$$
$$Ar_2Ni^{III}X \rightarrow Ar{-}Ar + Ni^{I}X. \quad (18)$$



The reaction of vinyl halides with Pt-, Pd-, and Ni-complexes takes place with retention of the (*E*) or (*Z*)-configuration of the unsaturation, leading to the corresponding σ-vinylmetal complex.[39–44] It is proposed[44] that oxidative addition precedes formation of a π-olefin complex. Such a complex has, in fact, been isolated, and characterised, from the reaction of perhalogenoethylenes with Pt(0).[45]

(19)

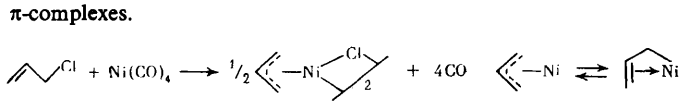
It is unlikely that oxidative addition of vinyl halides proceeds via formation of free radicals as vinyl radicals readily undergo configurational isomerisation.[46]



There are several examples of anionic catalysis in oxidative addition.[47–49] The coordination of anions, such as iodide ion, leads to the formation of anionic complexes which display significantly higher activity than the corresponding uncharged complexes in oxidative addition. Of the two examples shown below, the second provides the basis of the industrial synthesis of acetic acid (Monsanto).

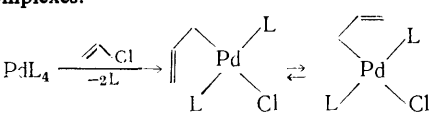
$$[(COD)Ir^{I}(phen)]Cl + I^- \rightleftarrows [(COD)Ir^{I}(phen)I]^-$$

(20)



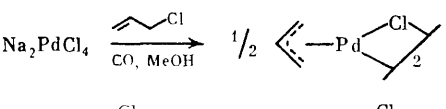
$$k_2 \simeq 7k_1$$

$$[Rh^{I}I(CO)_2] + I^- \rightleftarrows [Rh^{I}I_2(CO)_2]^-$$

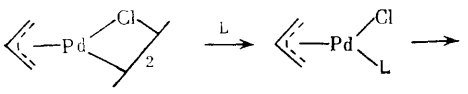


(21)

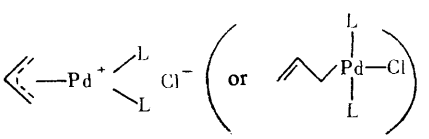
$$k_2 > k_1$$



Allyl halides are more active than alkyl, vinyl or aryl halides in oxidative addition. They readily react with nickel, palladium and platinum complexes even in the absence of strong donor ligands. Thus, nickel tetracarbonyl interacts with allyl halides to produce dimeric π-allyl complexes.[50] According to PMR data, a mobile equilibrium is established between the corresponding σ- and π-complexes.

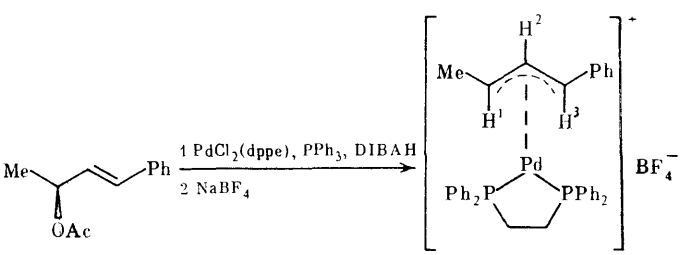


(22)



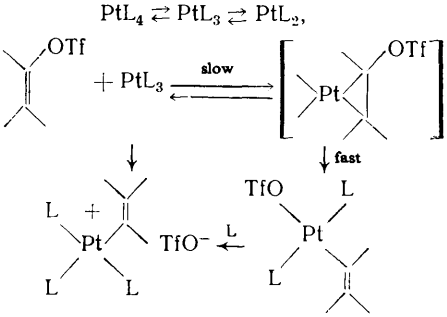
The reaction of allyl chlorides with tetrakis(triphenylphosphine)-palladium(0) leads to the formation of an equilibrium mixture of allyl complexes.[51]

(23)



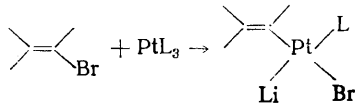
Palladium(0), generated by reduction of Pd(II) salts, interacts with allyl chlorides to give the corresponding bis(π-allylpalladium chlorides).[52] Treatment of the latter with excess of phosphine affords either a cationic π-allyl complex or a σ-complex, depending on the nature of the solvent.[51]

(24)



(25)

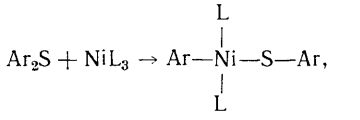
Oxidative addition of allylic substrates to zero-valent palladium complexes proceeds with inversion of configuration.[53]



(+)-(1*R*, 2*S*, 3*S*) (26)

Substrates having a leaving group other than halogen may also participate in oxidative addition; however, such reactions have been studied relatively little. There are, however, a large number of catalytic reactions of organometallic compounds with organic triflates,[54] phosphates,[55] with simple and allylic silyl enol ethers,[56,57] and sulphides,[58] tellurides,[59] and with selenides.[60] The mechanism of the reaction of vinyl triflates with zero-valent platinum complexes has been studied.[61] On the basis of a detailed product analysis, a study of the kinetics and stereochemistry of the reaction, a comparison of the reactivity of structurally diverse vinyl triflates, and an NMR study of intermediates, the mechanism of the reaction would appear to involve formation of a vinyl triflate π-complex with Pt(0).

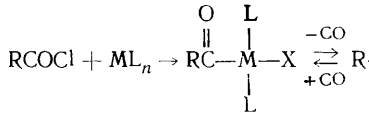
$$PtL_4 \rightleftarrows PtL_3 \rightleftarrows PtL_2,$$



(27)

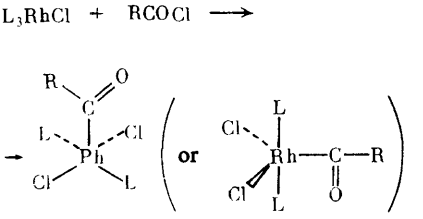
It should be pointed out that neutral complexes are obtained on reaction of vinyl bromides with PtL_3, rather than cationic complexes as are formed with vinyl triflates.

(28)



The interaction of diaryl sulphides with tris(tri-n-butylphosphine)-nickel leads to products of oxidative addition across the carbon–sulphur bond, as evident from NMR data and X-ray structural analysis.[62]

(29)

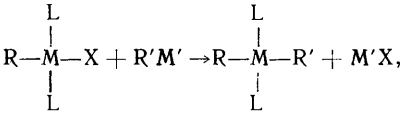


Ar = *p*-$MeOC_6H_4$, C_6F_5; L = n-Bu_3P.

Acyl chlorides also take part in oxidative addition with zero-valent nickel, palladium and platinum complexes.[63,64] Subsequent decarbonylation takes place most easily with nickel complexes.

(30)

Depending on the structure of the acyl group, reaction of acyl chlorides with Rh(I) complexes yields square-pyramidal or trigonal-bipyramidal complexes.

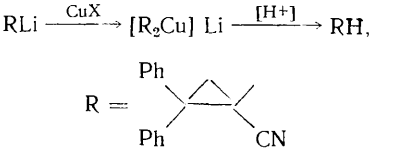


(31)

Rearrangement of acyl to carbonyl complexes proceeds reversibly ($k_1/k_{-1} = 7\times10^{-2}$) where R = $C_6H_5CH_2$, and irreversibly where R = Ar.[65,66]

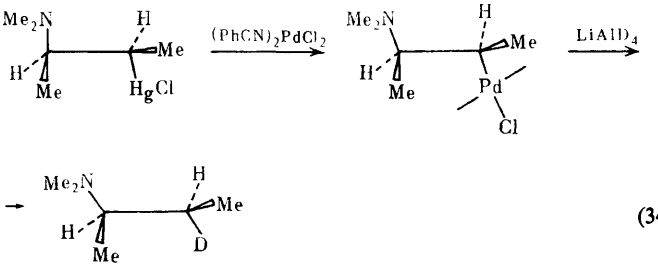
The d^8 complexes of the nickel triad formed by oxidative addition may react further with organic halides to produce the corresponding d^6 complexes. There are many examples where such complexes are formed with Pr(II),[67] and complexes of the type *fac*-L_2PtIMe_3 have been isolated and characterised. A Pd(IV) complex with three σ-bonded methyl groups, *fac*-[$PdMe_3$(2,2′-bipyridyl)I], has also been prepared for the first time and characterised structurally.[68]

III. Transmetallation



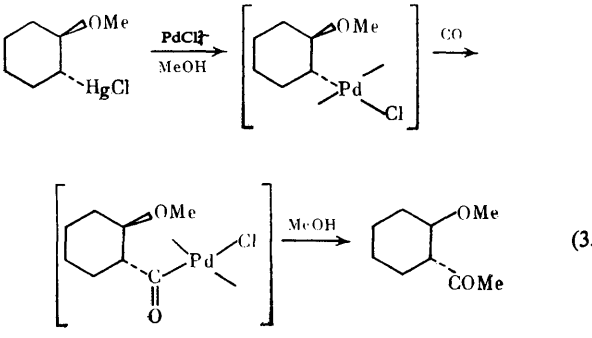
Transmetallation is the next step of the catalytic cycle in the cross-coupling of organometallic compounds with organic halides. In the process the halogen atom in the complex $RMXL_2$ is replaced by the organic residue, R′, of the organometallic compound

(32)



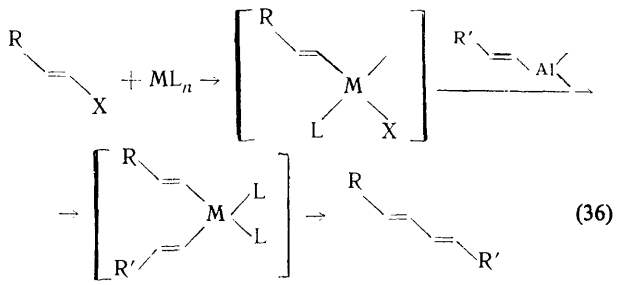
M = Ni, Pd; M′ = Li, Mg, Zn etc.

Transition metal complexes with σ-bonded organic residues may be generally prepared via transmetallation. It involves the interaction of a transition metal halide with an organometallic compound of a non-transition element to produce a transition metal compound with one or more σ-bonded organic groups.[21] The detailed mechanism by which the organic residue of the organometallic compound is transferred to the transition metal has not, as yet, been established; however, in a number of cases, it has been shown that this process takes place stereospecifically. Thus, the cyclopropyl group of lithiated cyclopropanes is transferred to copper with retention of configuration.[69]



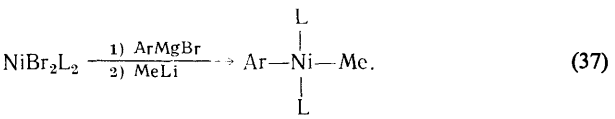
(33)

Organomercury compounds are widely used for the preparation of transition metal complexes.[70] Mechanistically, the reaction involves electrophilic cleavage of the mercury–carbon bond with the transition metal halide. The alkyl group of the organomercury compound transfers to Pd(II) with retention of configuration, as shown in the reactions of the *erytho*- and *threo*-isomers of β-amino-ethylmercury chlorides with bis(acetonitrile)dichloropalladium(II).[71]



(34)

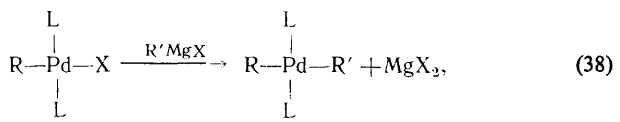
Retention of configuration on transmetallation is also observed with cyclohexylmercury compounds.[72]



(35)

The configuration at the sp^2 carbon atom is retained at all stages of the catalytic cycle, as illustrated in the reactions of vinylalanes with vinyl halides catalysed by nickel and palladium complexes.[73]

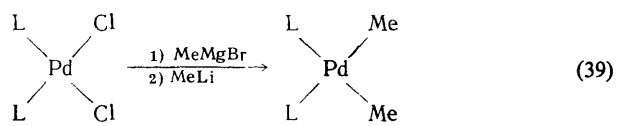
(36)



Nickel(II) complexes with two σ-bonded organic groups have also been obtained by transmetallation.[74]

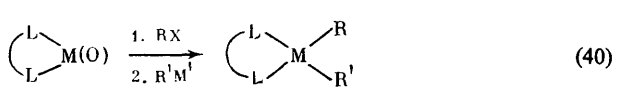
(37)

L = PEt_3



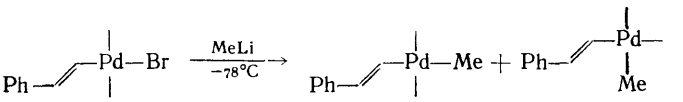
The *trans*-configuration of the nickel complexes has been confirmed by a ^{31}P NMR study.[74] Complexes of the type, *trans*-$RPdR'L_2$, have been isolated by reaction of Grignard compounds with $RPdXL_2$ complexes obtained by oxidative addition of RX to Pd(0).[19,75]

(38)



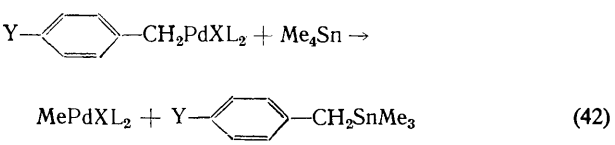
L = PEt_2Ph, PEt_3.

The corresponding *cis*-palladium complexes have been prepared from *cis*-$PdCl_2L_2$ by sequential transmetallation with organomagnesium and -lithium compounds.[76]



(39)

Nickel and palladium complexes with bidentate, configurationally locked, ligands may react sequentially with organic halides and organometallic compounds with the formation of the corresponding *cis*-diorgano-complexes.



(40)

By a ^{31}P NMR study,[77] it has been shown that transmetallation of palladium *trans*-(*E* or *Z*)-styryl complexes with methyllithium leads to a mixture of *trans*- and *cis*-methyl(styryl)palladium complexes.

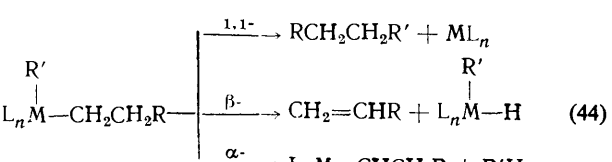
(41)

The interaction of benzylpalladium(II) complexes with tetramethyltin in HMPA at 25 °C results in exchange of the benzyl group by methyl, rather than exchange of a halogen atom on the metal.[78]

(42)

The interaction of organolithium compounds with L_2PdCl_2 complexes leads to tri- and tetra-organopalladates.[79] The resistance of the latter to reductive elimination (see below) is evidently the reason why lithium acetylides are inert towards cross-coupling.[15]

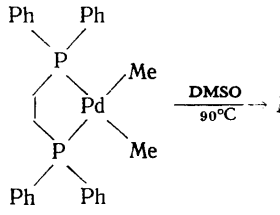
IV. Reductive elimination



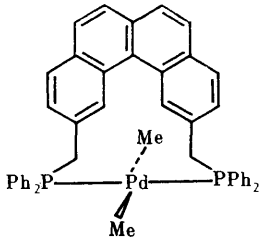
Reductive elimination, the reverse of oxidative addition, proceeds with formation of a bond between ligands X and Y and reduction of the coordinated metal. This type of conversion is particularly important because it results in the liberation of the desired organic product in the final step of the catalytic cycle of the cross-coupling. The same process is involved in the majority of other homogeneous catalytic reactions.

(43)

In an earlier review,[80] the basic features of reductive elimination, namely the associated formation of carbon–carbon, carbon–hydrogen and carbon–heteroatom bonds, have been outlined. Here we shall focus primarily on that process by which the carbon–carbon bond is formed.



β-Elimination is notably prevalent with transition metal alkyl complexes. If this elimination is not possible (where, for example, there is no β-hydrogen atom, or where a free coordination site on the metal complex is not available, etc.), the complex undergoes α-elimination or 1,1-reductive elimination.



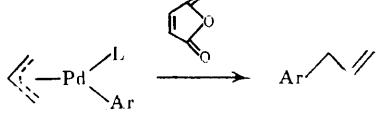
(44)

1,1-Reductive elimination of two organic residues with subsequent formation of a new carbon–carbon bond is the key step in catalytic cross-coupling. Before reductive elimination takes place, the ligands must be *cis*-oriented. As seen in the examples below, ethane is

readily eliminated from two *cis*-oriented methyl ligands, while *trans*-oriented groups fail to react.[76]

$$\xrightarrow[90^\circ C]{DMSO} Me{-}Me \qquad (45)$$

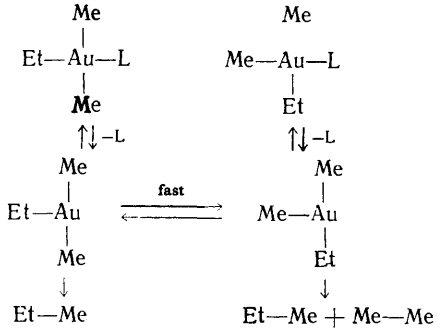
$$\xrightarrow[100^\circ C]{DMSO} \text{no reaction} \qquad (46)$$



The rate of reductive elimination is increased if there is a positive charge on the complex. Thus, the Pt(IV) complex, $PtL_2Ph_2I_2$, is stable in benzene but readily eliminates iodobenzene in methanol. Evidently, the cationic complex formed by dissociation of iodide ion eliminates iodobenzene far more readily than the corresponding neutral complex.[81]

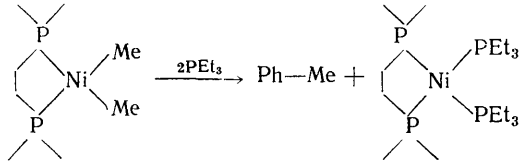
$$\begin{array}{ccc} PtL_2Ph_2I_2 & \overset{MeOH}{\rightleftharpoons} & [PtL_2Ph_2I\,(MeOH)]^+I^- \\ \downarrow PhH & & \downarrow -PhI \\ \text{no reaction} & & [PtL_2Ph\,(MeOH)]^+I^- \\ & & \downarrow \\ L = PEt_3 & & PtL_2PhI \end{array} \qquad (47)$$

An oxidant may be employed to initiate reductive elimination. It has been shown, for example, that ethylene and ethane are isolated as the initial elimination product by thermolysis of the neutral complex, $Et_2Fe(bipy)_2$;[82] however, rapid and selective formation of butane can be achieved by 2-electron oxidation of the complex by electrochemical means or on treatment with $[IrCl_6]^{2-}$.



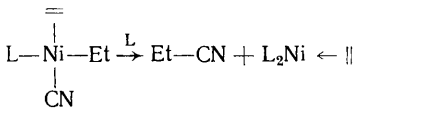
$$Et_2Fe\,(bipy)_2 \xrightarrow{-2e^-} n\text{-}C_4H_{10}. \qquad (48)$$

Even the formation of charge-transfer complexes with electron-deficient olefins may initiate elimination of alkane from dialkyl complexes of the type $Et_2Ni(bipy)$.[83] Thus, olefins such as maleic anhydride and tetracyanoethylene induce reductive elimination from palladium π-allyl complexes with formation of coupling products of the type allyl–allyl and allyl–aryl.[84,85]



(49)

The accelerating effect of the positive charge does not require any further explanation since reductive elimination is, in itself, a process involving oxidation by the metal atom—in this case oxidation of two organic ligands. In the process by which the ligands (even the neutral ones) are dissociated, there is an increase in the actual positive charge on the metallic centre, and the rate of reductive elimination increases. Planar gold complexes of the type R_3AuL undergo reductive elimination through formation of tri-coordinate *T*-shaped intermediates. Because *cis*- and *trans*-$EtMe_2AuL$ afford a mixture of ethane and propane in equal amount, it follows that *T*-shaped complexes isomerise more readily than undergo elimination of R–R.[86]



(50)

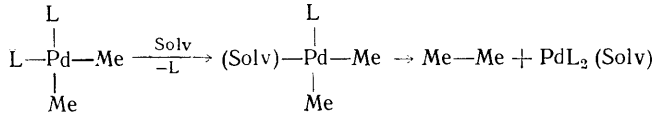
However, some reductive eliminations do not require preliminary dissociation of the ligand. Examples are known wherein elimination is enhanced if coordination of another ligand takes place.[87,88]

(51)

(52)

According to one report,[74] two concurrent processes are involved in the reductive elimination of planar nickel complexes of the type $ArNiMe(PEt_3)_2$. A dissociative mechanism is at play during thermolysis of the complex, by which a preliminary cleavage of the ligand takes place.

$$ArNiMeL_2 \rightleftarrows ArNiMeL + L,$$



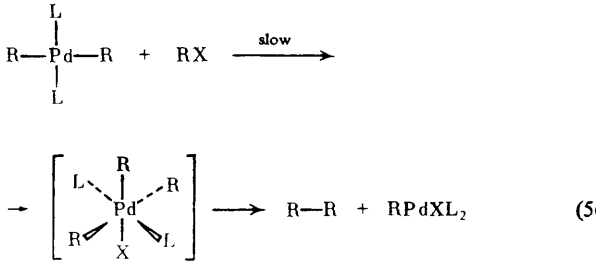
$$ArNiMeL \rightarrow Ar{-}Me + NiL. \qquad (53)$$

Aryl halides induce the second step which involves a radical-chain process with the participation of paramagnetic Ni(I) and Ni(III) species. The radical character of this step is indicated by the formation of radical products, by an induction period, and by the strong influence of promoters and inhibitors on the reaction rate.

$$\left.\begin{array}{l} ArNiMe \xrightarrow{\Delta} ArMe + Ni^0, \\ ArX + Ni^0 \rightarrow Ar^{\cdot} + Ni^{I}X, \\ Ar^{\cdot} + Ni^0 \rightarrow ArNi^{I}, \end{array}\right\} \text{initiation}$$

$$\left.\begin{array}{l} ArNi^{I} + ArX \rightarrow Ar_2Ni^{III}X, \\ Ar_2Ni^{III}X + ArNi^{II}Me \rightarrow ArNi^{II}X + Ar_2Ni^{III}Me, \\ Ar_2Ni^{III}Me \rightarrow ArMe + ArNi^{I} \text{ etc.} \end{array}\right\} \text{chain extension} \qquad (54)$$

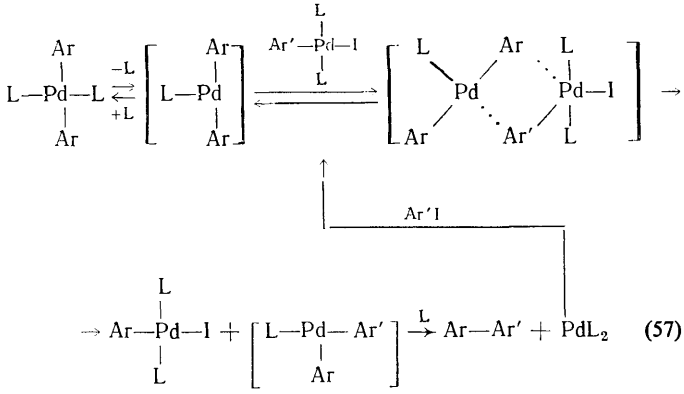
The key characteristics of reductive elimination have been studied in detail with palladium complexes, R_2PdL_2. Thus, it has been established that elimination of ethane from *cis*-Me_2PdL_2 is a first-order reaction involving a dissociative mechanism.[89]



Solv – solvent

(55)

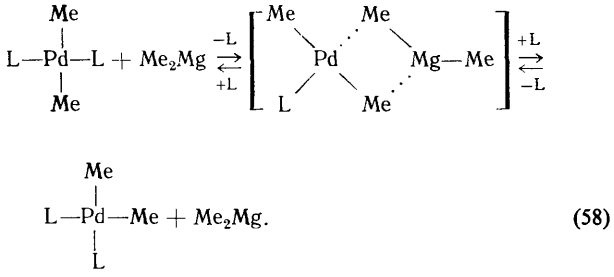
This mechanism is in accord with theoretical calculations for the reductive elimination of ethane from bis(phosphine)dimethylpalladium complexes.[90] The main conclusions drawn from these calculations are the following. Strong donor ligands *trans* to a methyl group hinder elimination. Reductive elimination of ethane from 4-coordinate complexes, *cis*-Me_2PdL_2, is allowed by symmetry, and determined by the energy of the antisymmetrical b_2 orbital of the palladium complex. The value of the energy barrier for elimination from palladium complexes is far higher than the corresponding value for nickel complexes in which the energy of the b_2-orbital is lower. The activation energy for elimination of ethane from 3-coordinate *T*- and *Y*-shaped intermediates is less than that for complexes Me_2PdL_2. The energy barrier for isomerisation from one *T*-structure to another is significantly greater than the barrier for elimination from *T*- and *Y*-shaped complexes (compare reductive elimination of R–R from R_3AuL [50]).



The foregoing explains why *trans*-R_2PdL_2 complexes, which routinely participate in catalytic cross-coupling, must initially isomerise into *cis*-R_2PdL_2. A coordinating solvent (THF, DMSO, DMF) of an additional phosphine ligand is required for isomerisation, i.e. *trans-cis* isomerisation takes place by an associative mechanism.[76] If *trans-cis* isomerisation is not possible for steric reasons, then the complexes resist reductive elimination.[46] Yet *trans*-Me_2PdL_2 complexes do react with CD_3I, even at 20 °C, to give 1,1,1-trideuterioethane exclusively.[76] Added CH_3I also increases the rate of formation of ethane from *cis*-dimethylpalladium complexes.[89] According to certain authors,[89] these data confirm that reductive elimination from R_2PdL_2 in the presence of organic halide proceeds through intermediate formation of palladium(IV) intermediates.

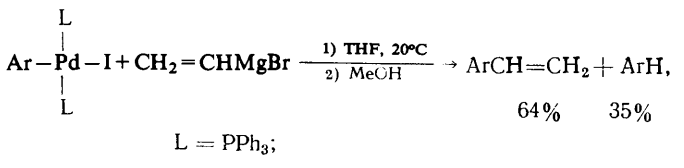
(56)

There is, in fact, one report on the isolation and full characterisation of a Pd(IV) complex, *fac*-$Me_3PdI(bipy)$.[68] The possible participation of Pd(IV) intermediates has been critically evaluated.[91]



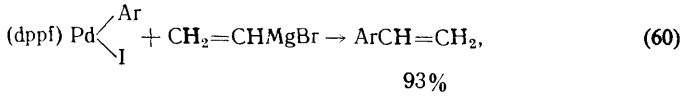
According to another report,[92] the rate of reductive elimination of biaryls from *trans*-Ar_2PdL_2 in the presence of aryl iodide is not dependent on the intermediate formation of a Pd(IV) complex, but rather on the facile isomerisation of *trans*-Ar_2PdL_2 into the *cis*-complex under the influence of *trans*-$Ar'PdIL_2$, obtained by oxidative addition of Ar'I to the Pd(0) complex.

(57)



The catalysed isomerisation of Ar_2PdL_2 by $Ar'PdIL_2$ is accompanied by a profound reorganisation of organic residues, leading to the formation of three types of biaryl: ArAr', Ar_2 and Ar'_2.[92]

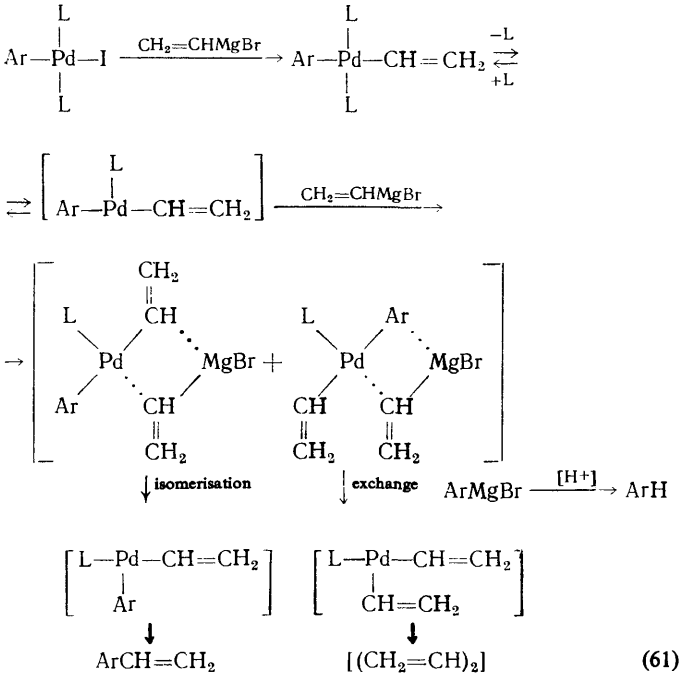
However, under the conditions for catalytic cross-coupling with organomagnesium compounds ($RX:R'MgX:PdL_n$ = 1:1.5:0.01), the process shown in Eqn. (57) is unlikely because $RPdXL_2$ complexes readily react with R'MgX to give $RPdR'L_2$. At the same time, it has been shown that *trans-cis* isomerisation proceeds readily on treatment with organomagnesium compounds.[79]



(58)

In this context, it is unlikely that *cis-trans* isomerisation would take place in the presence of organomagnesium compounds under the conditions of the actual catalytic cycle of the cross-coupling between RX and R'MgX. The following data (schemes 59 and 60), taken from a product analysis[93] of the reaction of *trans*-$ArPdIL_2$ and *cis*-ArPdI(dppf) [where dppf is 1,1'-bis(diphenylphosphino)-ferrocene] with vinylmagnesium bromide ($ArPdIL_2:CH_2=CHMgBr$ = 1:100), support this contention.

L = PPh_3;



(59)

Ar = *p*-PhC_6H_4.

(60)

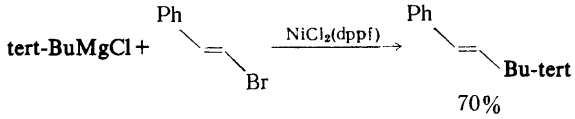
It should be pointed out that the corresponding catalysed reaction of *p*-iodobiphenyl with $CH_2=CHMgBr$ leads to the same type of products. The results are summarised in scheme (61). Here, the interaction of a *trans-T*-type intermediate, $ArPd(CH=CH_2)L$, with vinylmagnesium bromide is critical. This takes place by two independent routes: via *trans-cis* isomerisation and via exchange of organic residues beteween the organopalladium and organomagnesium compounds.

(61)

If the *trans-cis* isomerisation had taken place with the participation of the complex $ArPdIL_2$, then the tetraphenyl *p*-quaterphenyl would have been present in the reaction product.[59]

The absence of side-products from reactions involving palladium complexes with bidentate ligands, by which mono- and diorganocomplexes are formed with the *cis*-configuration, would suggest that transmetallation and subsequent reductive elimination take place in such cases far more readily than the exchange process.

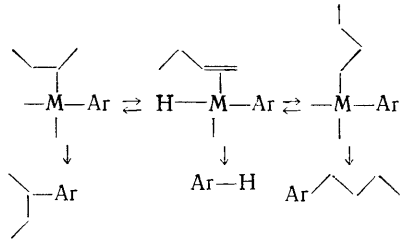
V. The influence of the ligand environment in the transition metal complex on the efficiency of cross-coupling



The correct choice of ligand for the nickel of palladium complexes is critical for the cross-coupling to succeed. A comparison has been made of various nickel complexes as catalysts for the reaction of chlorobenzene with n-butylmagnesium bromide.[94]

$$PhCl + n\text{-}BuMgBr \xrightarrow{NiCl_2L_2} n\text{-}Bu-Ph \quad 81—100\% \qquad (62)$$

L_2 = dppp[1,3-bis(diphenylphosphino)propane], dmpf[1,1′-bis(dimethylphosphino)ferrocene].



Nickel complexes with other phosphine ligands have little catalytic activity.[62] Generally speaking the choice of ligand is governed by the structure of the organic residue in RX and R′MgX.[94]

For cross-coupling of n-, *sec*- and tert-alkylmagnesium halides with aryl and vinyl halides, it has been shown that nickel and palladium catalysts with the bidentate ligand, 1,1′-bis(diphenylphosphino)ferrocene (dppf), are selective and afford the desired products in high yield.[95,96]

(63)

The correct choice of ligand is especially important in the alkylation of aryl halides where isomerisation of *sec*-alkyl groups and reduction of ArX to ArH could complicate the desired cross-coupling. The mechanism of these side reactions, i.e. isomerisation and reduction, has been examined [97] (see scheme 64).

(64)

The absence of side-products when dppf is used as ligand confirms that, in this case, reductive elimination with the formation of *sec*-BuAr proceeds significantly more rapidly than β-elimination.

Thus selectivity and catalytic activity of palladium complexes with bidentate bis(diphenylphosphino) ligands depends on the distance between the two diphenylphosphino groups.[98] For alkylation in the presence of bis(diphenylphosphino)palladium complexes, selectivity increases as the P—Pd—P bond angle increases in the sequence dppe < dppp < dppf, and as the Cl—Pd—Cl bond angle decreases in the sequence dppe > dppp > dppf. As is the case with *cis*-(*sec*-Bu)$PdArL_2$ complexes, the increase in selectivity (in the order dppe < dppp < dppf) is, in all likelihood, associated with the increased rate of reductive elimination, determined by the more facile approach of the organic residues.

It has been shown that nickel complexes with bi- and tetra-dentate ligands (β-diketones, β-ketothiones, β-ketoimines, amino-acids, diamines, etc.) exert a high catalytic activity in the reactions of aryl-Grignard compounds with aryl halides.[99]

$$PhMgBr + o\text{-}PhC_6H_4I \xrightarrow{«Ni»} o\text{-}PhC_6H_4Ph \quad \text{up to } 90\% \qquad (65)$$

Recently, $PdCl_2$(dppf) was shown to have high catalytic activity in the reactions of alkylboron compounds with aryl and alkenyl halides.[100]

In conclusion, it should be pointed out that, of all the catalysts used at the present time in cross-coupling, $PdCl_2$(dppf) is the most versatile by virtue of its high activity and selectivity.

Metal complex catalysis in the chemistry of solid organic raw material

B N Kuznetsov
Institute of the Chemistry of Natural Raw Materials, Siberian Division of the USSR Academy of Sciences

ABSTRACT. The applications of metal complexes in processes involving the conversion of solid organic raw material is examined. Data are presented on the use of metal complex catalysts for the preparation of organic compounds, synthetic fuels, and cellulose and its derivatives from coal and plant biomass.

The bibliography includes 81 references.

I. Introduction

The principal sources of natural raw materials are petroleum, natural gas, coal, oil shale, and plant biomass. At the present time the world production of petroleum and natural gas approaches the maximum possible amount and in the near future will begin to fall. In order to overcome the deficiency of petroleum raw material, it is planned in the industrially developed countries to manufacture synthetic hydrocarbon fuels from coal, the available amount of which greatly exceeds that of petroleum and gas. Almost all the most important petrochemical products can be obtained by the chemical processing of coal. Two aspects of the preparation of synthetic fuels and chemical products from coal are most promising: liquefaction and gasification. The liquid and gaseous products formed thereby are subjected to further conversion into motor fuels and valuable organic substances.

Plant biomass is a continuously renewed source of organic raw material. Photosynthesis generates annually about 200 billion tons of biomass on our planet, which greatly exceeds the world production of mineral organic fuels. Chemical wood conversion processes have as a rule two principal aims: the isolation of individual components of wood (for example, cellulose) or the depolymerisation of wood with formation of lower-molecular weight products (for example, sugars and furfural). Not only the entire set of compounds which are nowadays synthesised from petroleum but also a whole series of unique products, for example biologically active substances, can be obtained from primary products of plant origin. The preparation of synthetic liquid and gaseous fuels from the plant biomass is promising.

The majority of the methods for the chemical conversion of coal and biomass used at present are less efficient than petrochemical processes. The solid organic raw material is less susceptible to conversion into low-molecular-weight products than petroleum and requires more severe reaction conditions. In order to intensify the coal and biomass conversion processes, catalysts developed initially for the conversion of liquid and gaseous organic raw material are being used on an increasing scale.[1,2] However, the possibilities of traditional catalysis in this field are limited by the difficulty of ensuring a sufficiently close contact between the solid raw material and the catalysts. It is therefore useful to use liquid catalytic systems capable of penetrating into the pores of the solid organic reactant. Many reactions occurring in the chemical conversion of coal and plant biomass include, together with heterolytic stages, also homolytic stages. In order to accelerate the latter, one can use a wide range of metal complex catalysts or bifunctional catalytic systems in solution. There exist fairly numerous examples of the effective employment of metal complex catalysts for the acceleration and increase in the selectivity of the synthesis of organic compounds from coal and wood and also for the improvement of processes leading to the formation of synthetic fuels. The introduction of metal complexes into the pores of the organic raw material or their fixation on the surface is also used on an increasingly wide scale to effect energochemical solid fuel conversion processes (gasification, pyrolysis, liquefaction). Metal complexes are frequently used in this connection as precursors of highly dispersed particles formed at elevated temperatures.

This review deals with certain aspects of the application of metal complex catalysts in the chemistry of solid organic raw material and an attempt is made to give a systematic account of the experimental data obtained during the last 5–8 years in this non-traditional field of catalysis.

II. Characteristics of the catalytic reactions of solid organic raw material

The use of catalysts to convert solid organic raw material has a number of features distinguishing it from the traditional conversion reactions of liquid and gaseous products.[3] In the technological application of catalytic solid fuel conversion processes, it is essential to take into account the characteristic features of the composition and structure of the fuel.

1. Composition and reactivity of different types of coal and wood

According to generally accepted ideas, the organic mass of coal consists of condensed aromatic nuclei linked via aliphatic side groups, which include carbon, hydrogen, oxygen, sulphur, and nitrogen atoms.[4,5] Oxygen-containing groups promote the formation

of bonds between organic and inorganic components of coal. Such groups are present in phenols, alcohols, ethers, carboxylic acids, and carbonyl compounds. The structure of the vitrinite component of coal, whose amorphous macromolecular lattice consists of a series of stable cluster units or aggregates linked by relatively weak bridges made up of aliphatic carbon atoms or by ether bridges as well as weak hydrogen or donor–acceptor bonds, has been studied in greatest detail.

Overall, natural types of coal have a much more complex chemical composition than petroleums. The molecular groups forming part of coal are to a large extent linked to one another by chemical bonds. The aim of the chemical processing of coals is their depolymerisation with formation of low-molecular-weight products which would have a homogeneous composition. The conversion of coal into individual organic compounds to which the chemist is more accustomed is achieved by heat treatment and treatment with various reagents. This entails in the first place the rupture of weakest aliphatic chains linking the condensed aromatic structures and donor–acceptor bonds.

Wood biomass consists mainly of cellulose (40–50%), lignin (16–33%), and hemicelluloses (15–30%). The remaining small fraction consists of extractable substances and inorganic components.[6] The most valuable substance in wood, namely cellulose, is a linear polysaccharide made up of $C_6H_{10}O_5$ units linked by 1–4 glycosidic bridges. Hemicelluloses are polysaccharides with shorter chains made up of $C_5H_8O_4$ units. Lignin is less reactive than cellulose and hemicelluloses. Among all the components of wood, it is closest in its composition and properties to brown coal. The aromatic structures of lignin are believed to include combination of phenylpropane structural units linked by ether or carbon–carbon bonds.

The characteristics of the structure and reactivity of the components of coal and biomass must be taken into account in selecting the optimum procedures for the introduction of catalysts into the solid organic raw material.

2. Applications of metal complex catalysis

It is useful to distinguish the following aspects of the use of metal complexes to effect the catalytic conversions of solid organic raw material: catalysis by soluble metal complexes introduced into the pores of the organic substance; catalysis by metal complexes fixed on the surface of the solid reactant; catalysis by highly dispersed particles or clusters formed on decomposition of the metal complexes introduced into the raw material or fixed on its surface.

The possible applications of metal complexes in solution are limited by the threshold of their thermal stability (in most cases 150–200 °C). The mechanism of the catalytic conversion can include a stage in which the metal complex is adsorbed on the reactive sections of the surface of a solid organic raw material. Catalytic reactions can also take place in solutions where metal complexes accelerate the reactions of the products of the thermal fragmentation of coal or of the components of the biomass.

If the catalyst accelerates the conversion of liquid or gaseous substituents of the reaction mixture without interacting at the same time with the solid raw material, an atypical pathway can be achieved in the catalytic process. Catalytic reactions of this type are an example of mediated catalysis, which is being used on an increasingly wide scale in the conversion reactions of coal and plant raw material.

The closest contact between the raw material and the catalyst can be achieved by binding catalytically active metal complexes to the surface reactive groups of coal and wood such as phenolic, acid, aldehyde, and lactone groups. They all enter into the composition of cellulose, lignin, and other components of wood, which leads to extensive possibilities for a uniform distribution of catalytically active compounds in the solid raw material.

The methods for the chemical fixation of metal complexes on the surfaces of oxide and polymeric carriers have been thoroughly developed.[7–9] There are also data concerning the fixation of various transition metal compounds on cellulose materials. Thus cations can be arranged in the following sequence in terms of their ability to be sorbed by cellulose: $Cd^{2+} > Zn^{2+} > Cu^{2+}$.[10] The maximum sorption capacity of the Cd^{2+} cations is due to their high polarisability. In an acid medium, the exchange adsorption of cations increases as a consequence of their being bound to the COOH and SO_3H groups. A reactive oxygen-containing group (e.g. an acid or phenolic group) can be obtained at high concentrations also on the surfaces of different types of coal as a result of special activating treatment.

The metal complexes introduced into the raw material are not only themselves catalysts of the various reactions of coal and the biomass but can also be converted into other catalytically active compounds as a result of thermal and chemical influences. Thus thermally unstable compounds can afford oxide or metallic particles on heating in air or in an inert atmosphere. Hydroxide or oxide compounds can be obtained by treatment with alkali. As an example of the formation of metallic clusters in the cellulose structure, one may refer to a study[11] in which zerovalent metal atoms were introduced into cellulose by dissolving the latter in a copper-ammonia solution which was then extracted by an aqueous solution of alkali. Next, the cellulose, containing up to 16% of Cu^{2+} atoms, was reduced with sodium dithionate or hydrazine; this resulted in the formation of zerovalent copper atoms linked to the cellulose matrix by coordinate bonds. The subsequent treatment of the copper-containing cellulose with solutions containing metal cations with lower electrochemical potentials ($PtCl_2$, $PdCl_2$, H_2PtCl_6) makes it possible to achieve a partial replacement of copper by the atoms of another metal.

III. Synthesis of organic compounds from coal and biomass

The total number of wood conversion products known at the present time exceeds 2500. These are sugars, ethyl alcohol, furfural, laevoglucosan, xylitol, polyhydric alcohols, phenolic derivatives, organic acids, paraffinic hydrocarbons, biologically active compounds, and other products. Many of them are formed in processes involving the hydrolysis, oxidation, and pyrolysis of the solid organic raw material.

The chemicals obtained from coal and plant biomass may in time replace many of the products of petrochemical synthesis.

1. Hydrolysis of cellulose-containing products

The hydrolysis of cellulose-containing products, used to obtain sugars and furfural, includes a multiplicity of a wide variety of reactions, most of which have a heterolytic mechanism. The traditional catalysts of hydrolytic reactions are acids and bases. In order to obtain furfural, it is essential to ensure that pentosans are hydrolysed and the resulting pentoses are dehydrated.

Transition metal compounds can be used as catalysts of the dehydration of pentoses to furfural.[12] Some of them, for example, chromium salts, are 10–15 times more active than sulphuric acid. The combined use of inorganic acids together with metal compounds in many cases both accelerates the formation of furfural and increases its yield.

The catalytic activity of metal complex catalysts can be explained by the formation of metal–sugar complexes, which weakens the intermolecular bonds in pentosans as a consequence of the polarising action of the cation.[12] The catalytic activity of metal complexes increases with increase in the charge on the metal cation, i.e. with increase in its polarising activity. The nature of the ligands is also quite important because metal complexes can undergo partial hydrolysis under the reaction conditions. Anions can then give rise to the corresponding acids, which are capable in turn of influencing the rate of cleavage of polysaccharides and of the dehydration of monosaccharides.

By means of catalysis, it is possible to direct the conversion of the plant raw material via new pathways. Thus in the treatment of aspen wood in a stream of steam at 200–400 °C in the presence of certain transition metal compounds (for example, iron compounds), it has been possible to obtain laevoglucosenone in up to 5 wt.% yield relative to the initial raw material.[13] This compound is promising for the synthesis of valuable substances used in perfumery, medicine, and the food industry.

2. Oxidation and pyrolysis of solid organic raw material

When metal complexes are introduced into a solid organic raw material, the metal cations are frequently bound to the functional groups forming part of the composition of the solid fuel. The same metal ion forming part of the composition of humates can increase the resistance of the substrate to degradation, while in combination with phenoxide ions it can promote the decomposition processes. This leads to the appearance of the possibility of regulating thermochemical conversion reactions of coal and biomass by the selective introduction of metal-catalyst cations into the functional groups of the solid raw material.

There exist examples of the effect of transition metal compounds introduced into coal on the catalytic conversion of the latter into aliphatic polycarboxylic acids.[14] The introduction of iron, manganese, and copper ions as well as metal tungstates and molybdates accelerates the oxidation of wood lignin by hydrogen peroxide which proceeds in an acid medium with decomposition of aromatic rings and the formation of oxalic, malonic, acetic, and formic acids.[15] The oxidation of lignin is accelerated by the potassium hexacyanoferrate(III)/hexacyanoferrate(II) catalytic system; the catalytic effect depends on the potential of the oxidation-reduction system.[17,18]

The catalytic effect of copper chloride was manifested by an increase in the rate of the oxidative ammonolysis of lignin in an aqueous medium or methanol at 127 °C.[16]

Certain metal complex catalysts make it possible to increase the yield of the volatile organic compounds formed in the pyrolysis of wood. Thus the introduction of manganese chloride into wood from deciduous trees increases the yield of laevoglucosan in steam pyrolysis to 10–13.4 wt.% relative to the weight of the absolutely dry wood.[19]

3. Reactions of compounds originating from coal and wood

Organic substances of plant and coal origin have found extensive applications in the national economy. Catalytic processes have been used recently on an increasing scale for their conversion. Some of the most important monosaccharide conversion products are furfural and its derivatives.

Zirconium complexes fixed on a polymeric carrier are effective catalysts of the preparation of furfural by the dehydration of a 2–5% solution of pentoses.[20] The use of the vanadyl-porphyrin complex as the catalyst makes it possible to raise the yield of 5-hydroxymethylfurfural in the conversion of an aqueous solution of sucrose at 90–100 °C.[21] The zirconyl chloride catalyst has also been used to obtain hydroxymethylfurfural from sugars and glucose.[21] In the presence of the titanium sulphate catalyst on a polymeric carrier, the degree of conversion of xylose into furfural reaches 87%.[22] There are data concerning the use of titanium-porphyrin complexes immobilised in a polymer gel in the dehydration of xylose.[23]

It has been suggested that metal chlorides be used as catalysts in the processing of cellulose-containing waste.[24] This makes it possible to hydrolyse part of the cellulose to glucose under mild conditions and the remainder can be converted into wood charcoal.

The reactions of reactive compounds obtained from plant raw material, such as xylitol (a pentahydric alcohol), laevoglucosan (containing a strained anhydride ring and three reactive OH groups), and dioxanorbornene (containing an anhydride ring and a carbon–carbon multiple bond) are also catalysed by dissolved and heterogenised metal complexes.

Valuable products of small-scale chemistry are also obtained in the catalytic processing of extractable substances. The use of catalysts leads to new possibilities for the synthesis of pyrethroids, pheromones, fungicides, and other biologically active substances from the volatile monoterpenoids present in turpentine and also in the essential oils obtained from the bark and green matter of conifers.

An important aspect of the synthesis of organic products from solid organic raw material is the catalytic processing of the mixture of carbon monoxide and hydrogen formed on gasification of coal or biomass. In the presence of heterogeneous Fischer–Tropsch catalysts, mainly complex hydrocarbon mixtures are formed.[25]

The use of metal complex catalysts makes it possible to carry out many reactions leading to the synthesis of individual organic compounds, based on the reaction of CO with molecular hydrogen and other substrates—methanol, formaldehyde, alkenes, dienes, acetylenes, and allyl and chloro-substituted compounds.

The problems of metal complex catalysis in the processing of synthesis gas have been examined in detail in a monograph.[26] Catalysts of a new type used in this field, namely transition metal carbonyl clusters deposited on oxide supports, ensure the formation of individual hydrocarbons (in particular C_2–C_4 alkenes) with a high selectivity at moderate temperatures. When iron and iron-cobalt clusters deposited on silica gel are used, the selectivity in the formation of ethylene or propene reaches 90%.[27]

IV. Preparation of cellulose from wood

1. Delignification of wood in order to obtain cellulose

The delignification of wood is a process involving the removal of lignin from the lignocellulose material by treatment with chemical reagents.[28] The delignification of wood is used to obtain celluloses, which are widely used in industry, especially in the manufacture of paper and chemical fibres.

The results obtained indicate the occurrence of heterolytic and radical reactions in the delignification process. This made it possible to achieve a more specific approach to the selection of catalysts from this process. Catalysts of the oxidation-reduction type based on anthraquinone and its derivatives have been investigated in greatest detail in this process.[29]

There has been a growth of interest recently in the application of metal complex catalysts for the intensification of the preparation of cellulose. Cobalt, manganese, copper, iron, and chromium complexes with organic ligands are used as catalysts in order to replace scarce anthraquinone.[30] The study of the reactions of compounds modelling lignin showed that cobalt and iron complexes with *meso*-tetra-*p*-sulphophenylporphyrin groups promote to a greater extent the acceleration of the dissociation of the β-ether linkages and increase the yield of guaiacol to a greater extent than does anthraquinone.[30] The degree of delignification of wood in the sulphate and sulphite methods of preparation of cellulose increases after the introduction into the solution of 0.005–0.025% of molybdenum in the form of molybdenum-containing compounds.[31]

New methods for the oxidative delignification of plant raw material in a medium containing sodium hydroxide or sodium carbonate are being developed: the oxygen-alkaline or oxygen-soda delignification.[29] They are based on the ability of wood lignin to be converted by oxidants into soluble compounds with rupture of lignocarbohydrate linkages. The cheapest and ecologically cleanest reagent for the oxidation of lignin is molecular oxygen. The oxidation of organic compounds by molecular oxygen constitutes a thoroughly investigated field of catalysis. The selection of catalysts for the process presents no difficulties.[32] Here it is important to protect cellulose from degradation. This requires the development of rational methods for the introduction of catalysts into the wood raw material, the use of inhibitors preventing the oxidation of cellulose, and the selection of optimum process conditions.

An example of the use of metal complex catalysts in the oxygen-alkaline delignification may be provided by the increase by a factor of 2–3 of the rate of delignification of wood in the presence of catalytic amounts of transition metal complexes of *o*-phenanthroline (0.1–0.3% of the mass of the absolutely dry wood). Such complexes are formed as a result of the interaction of *o*-phenanthroline with the variable-valence metals present in the reaction mixture.[33]

The catalytic activity of transition metal ions can change during the oxygen-alkaline delignification process as a consequence of the change in the composition of the reaction mixture. For this reason, the introduction of $MnCl_2$ in the initial stage accelerates the degradation of wood polysaccharides. On the other hand if manganese chloride is introduced in a subsequent stage, the yield of cellulose rises (by 0.8–4.1%) and the quality of its fibres improves.[34]

In the presence of hexacyanoferrate(II) ions and additives preventing the degradation of cellulose (alcohol, amines, ethers), the yield of cellulose as the product of the oxygen delignification of lignocellulose raw material in an aqueous medium at 65 °C and pH 10–14 increases.[35] Certain catalysts, for example, tungsten and molybdenum oxyanions, promote the delignification of wood by hydrogen peroxide. This process can be achieved under comparatively mild conditions. Thus the delignification of firwood chips in the presence of tungstic acid (2% of the weight of the absolutely dry wood) takes place at 95 °C.[36]

There are instances of the effective application of metal complex catalysts in the bleaching of cellulose, although their role is not always ultimately clear. The selectivity of the delignification of cellulose in acid–alkaline bleaching increases in the presence of molybdenum and tungsten complexes introduced in an amount of 0.001% of the weight of the fibre.[37] The maximum effect is obtained when these catalysts are used together with stabilisers such as urotropine, triethanolamine, and trisodium phosphate.

The Co^{2+} complex of a Schiff base (*N,N'*-bis-salicylidene-ethylenediamine) accelerates the delignification and bleaching of beechwood,[38] the efficiency of its action increasing with decrease in the basicity of the medium. In oxygen-alkaline bleaching, the high-molecular-weight component of lignin undergoes oxidative degradation to fragments which are soluble in the bleaching solution. An amount of the catalyst such that the cobalt content is 0.1% of the weight of the lignin is optimal. Bis(3-salicylideneaminopropyl)-amine cobalt is the most stable under the conditions of the oxygen-alkaline delignification of wood.[39]

The compounds of certain transition metals (for example, titanium and vanadium) accelerate the peroxide delignification and bleaching of lignocellulose materials, preventing at the same time the oxidative degradation of the cellulose component of the plant raw material.[40] In the presence of tungsten, molybdenum, and chromium ions, the quality of the cellulose obtained improves.[41]

Catalysts can exert a positive effect also on non-oxygen cellulose bleaching processes. Thus, in the catalysis by Cu^{2+} ions (0.1–0.3%) of the hypochlorite bleaching of natron cellulose, the activation energy for the reactions occurring diminishes.[42]

2. Preparation of cellulose derivatives

Catalytic processes are being applied on an increasing scale in the chemical modification of cellulose in order to synthesise a wide variety of its derivatives. The conversion into ethyl groups and other reactions of the OH groups of cellulose are achieved and graft copolymers are obtained with participation of catalysts of the acid–base type and metal complex systems.

The $Fe^{2+}-H_2O_2$ oxidation-reduction system in which Fe^{2+} ions are bound to the COOH groups of cellulose initiates the grafting to cellulose of various monomers—vinyl acetate, methyl-5-vinyl-tetrazole, and dimethyl(carboxymethyl) ammoniaethyl methacrylate bromide.[43,44] The mechanism of the formation of graft polymers using the $Fe^{2+}-H_2O_2$ system postulates the oxidation in the first stage of Fe^{2+} ions to Fe^{3+} by hydrogen peroxide.[45] The Fe^{3+} ions promote the development of oxidation processes in cellulose, a decrease in the degree of its polymerisation, a decrease in the number of COOH groups, and an appreciable accumulation of carbonyl groups. The bulk of the graft polymer is formed in the subsequent stage initiated by the $Fe^{2+}-H_2O_2-$reductant system. The carbonyl groups of cellulose, formed in the initial stage of the process, can play the role of the reductant. The additional introduction of reductants (for example, hydroxylamine or hydrazine) makes it possible to eliminate the development of degradative processes in the first stage of the copolymerisation.

When cellulose is treated with an alcohol–benzene solution of $KMnO_4$, Mn^{3+} complexes, bound strongly to cellulose, are produced.[46] The formation of C–O–Mn linkages weakens the carbon–oxygen bond, which leads to the appearance of unpaired electrons on the carbon atoms in the 1-, 2-, and 3-positions in the anhydroglucose unit of cellulose. The free radicals arising as a result of the presence of an unpaired electron on the C(2) and C(3) atoms are capable of initiating the grafting of various compounds at the C(1) atom—they initiate the block copolymerisation of these compounds.

Ce^{4+} ions catalyse the grafting to cellulose of acrylonitrile, styrene, vinyl fluoride, vinylidene fluoride, methyl methacrylate, ethyl

acrylate, acrylamide, and the styrene–methyl methacrylate mixture.[47–49] Methyl methacrylate is grafted to cellulose in the presence of vanadium(V) acetyl-acetonate.[50] The use of the V^{5+}–cellulose xanthate oxidation-reduction system makes it possible to achieve a continuous method for the preparation of modified viscose fibre containing simultaneously quaternary ammonium and carboxy-groups.[51]

There are data[52] concerning the preparation of graft copolymers of cellulose with acrylic acid and the grafting of 4-vinylpyridine to cellulose in the presence of Co^{3+} ions. In order to obtain cellulose derivatives with a grafted lactone, polymerisation catalysts, especially tetramethyltitanium, are used.[53] Oxycellulose with a high content of carboxy- and carbonyl groups has been obtained by the catalytic oxidation of cellulose in the presence of $RuCl_3$.[54] In an acid medium, the reaction takes place at a higher rate even at 20 °C without appreciable degradation of cellulose.

V. Preparation of synthetic fuels

1. Liquefaction of coal

The heterogeneous catalysts for the liquefaction of coal have now been investigated in greatest detail.[55] However, there are also fairly numerous examples of the effective employment of homogeneous metal complex catalytic systems for this purpose.

Two main aspects of the use of dissolved catalytic systems in carrying out such processes have been established. One of them is associated with the search for low-temperature dissolved catalysts. The other is based on the application of solutions of catalytically active compounds as precursors of catalysts formed as a consequence of the decomposition of the initial substances at temperatures above the threshold of their thermal stability. It is noteworthy that it is not always possible to draw a clear-cut boundary between these versions owing to the insufficient information about the state of the catalyst employed.

It has been suggested that dissolved rhodium complexes with phosphine or amine ligands [for example, $RhCl(PPh_3)_3$ and $Rh_2(HCOO)_2(bipy)Cl_2$] as well as catalytic systems consisting of rhodium salts and added triphenylphosphine be used for the hydrogenation of coal under mild conditions.[56] Dissolved catalytic systems, obtained by the reaction of $FeCl_3$ and $Ni(COOH)_2$ with organoaluminium compounds and treated with H_2, exhibit a high activity in coal hydrogenation processes.[57]

At 400 °C and a hydrogen pressure of 13.5 MPa, the degree of conversion of brown coal in the presence of the above catalysts is 90%. At an elevated temperature and pressure, a high degree of liquefaction of coal is attained in the presence of organocobalt complexes soluble in the reaction mixture.[58]

Cheap iron catalysts for the hydrogenation of coal are of greatest interest from the practical standpoint. The influence of the composition of iron compounds and of the methods for their introduction into coal on the liquid product formation processes has been investigated. The iron cations introduced into coal by ion exchange are not inferior in their catalytic activity to industrial aluminocobalt–molybdenum catalysts of the hydrogenation of brown coal.[59]

The reaction of coal with iron salts under the conditions of the synthesis of ferrocene affords iron compounds resistant to the action of acids and alkalis.[60] NMR and IR spectroscopic data, comparison of model substances, and analysis of literature data have made it possible to conclude that, on interaction with coal, iron forms π-complexes of the type of ferrocene.

There are data showing that the degree of conversion of brown coal at 450 °C increases in the presence of the ferrocene complex of iron and iron pentacarbonyl, acetate, acetylacetonate, and chloride.[61] The iron pentacarbonyl complex $Fe(CO)_5$ exhibits the highest activity.[62] Being liquid at the usual temperature, it mixes readily with organic solvents, penetrates deeply into the coal pores, and decomposes at 300 °C with formation of highly dispersed metallic iron. The catalytic effect of iron pentacarbonyl and also of molybdenum and tungsten carbonyls intensifies when they are used together with elemental sulphur. Under these conditions, highly dispersed particles of the metal sulphides are formed in the course of the reaction. They are more active in the liquefaction of coal than the metals themselves.

From the economic standpoint, it is preferable to use the $CO + H_2O$ mixture for the liquefaction of coal instead of the expensive H_2. This process can be accelerated by the oxyanions of certain transition metals.[63] In the course of the liquefaction of coal at 400 °C, the complexes of tungsten, molybdenum, chromium, and manganese in the highest oxidation states are reduced, forming compounds insoluble in water, which makes it possible to remove the catalytically active metal from the solution. It has been suggested that metal-carboxylic acids are formed in the presence of CO and then decompose to the metal hydride and CO_2. Metal hydrides reduce coal or react with H_2O, liberating H_2.

2. Liquefaction of the plant biomass

The high content of oxygen in the plant biomass makes it irrational to use H_2 in the liquefaction processes, since a large amount of it is consumed on the removal of oxygen in the form of H_2O. Nevertheless, there are examples of the use of heterogeneous and homogeneous catalysts in processes involving the hydrogenation of wood and its principal components by molecular hydrogen. Thus, in the presence of dissolved catalytic systems based on iron, molybdenum, cobalt, and copper compounds, the degree of conversion of cellulose reaches 93% at temperatures in the range 250–350 °C and an initial H_2 pressure of 5 MPa.[64] Mainly water-soluble organic compounds and gaseous products, among which CO and CO_2 predominate, are formed. Competing reactions involving the hydrolysis, pyrolysis, and hydrogenation of cellulose take place simultaneously. Pyrolysis predominates at 250 °C, hydrogenation begins to prevail on raising the temperature to 300 °C, and dehydrogenation and charring of the cellulose predominate at 350 °C. The best hydrogenation catalysts at all temperatures are molybdates. The minimum consumption of H_2 is achieved when chloride catalysts—$CuCl_2$ and $FeCl_3$—are used.

In the presence of solvents with H-donor properties, the wood raw material is liquefied without the participation of H_2. The use of compounds such as $CoCl_3$ and $CuCl_3$ as dissolved catalysts makes it possible to convert cellulose into products soluble in aqueous or aqueous-organic media.[65]

Catalytic biomass liquefaction processes in an aqueous medium on treatment with carbon monoxide and synthesis gas have been vigorously investigated in recent years. The use of CO, which is cheaper than hydrogen, makes it possible to trap the oxygen of the biomass in the form of CO_2. The catalytic effect when carbon monoxide is used as the reductant is achieved as a result of the formation of metal formates, which act as reductants. The virtually complete conversion of wood in water (up to 99% relative to the dry ash-free mass) can be attained by impregnating it with

$Fe(NO_3)_3.3H_2O$ or $Co(NO_3)_3.6H_2O$ solutions and by subsequent treatment at 350–420 °C under a pressure of synthesis gas of 10.5–36.4 MPa.[66] The yield of the liquid products is 75%. Nickel compounds can also serve as catalysts. Thus, when $NiCO_3$ is added to a suspension of wood filings in water, the degree of conversion of wood increases by a factor of 3.[67]

3. Thermochemical reactions of solid fuels

In the high-temperature catalytic pyrolysis and gasification of coal and biomass, metal complexes were used in the stage involving the formation of catalytically active surface compounds or highly dispersed particles of the active component.

The influence of catalysts on the yield and porous structure of wood charcoal in the pyrolysis of wood and its components has been investigated. The use of metal chlorides with acid properties, for example, $TiCl_4$, $CrCl_3$, and $FeCl_3$, increases the rate of pyrolysis of hemicelluloses and cellulose by a factor of 10, reduces the wood degradation temperature by 100–150 °C, and increases the yield of the charcoal by a factor of 1.5.[68,69] It has been suggested that catalysts of this type accelerate the dehydration reaction. The compounds formed, containing aldehyde groups, condense to high-molecular-weight substances, which lead ultimately to an increased yield of wood charcoal.

Definite information about the processes occurring in the catalytic pyrolysis of wood is provided by the study of the thermal reactions of metal-containing celluloses.[70] The active role of molybdenum ions in the condensation reactions of partly degraded cellulose fragments is indicated by the results obtained when molybdenum-containing cellulose hydrate is exposed to high temperatures. During the pyrolysis of the iron-containing cellulose, the carboxylate ions are initially decarboxylated with the simultaneous reduction of Fe^{2+} cations to the metal. In the next stage, highly dispersed iron inclusions are oxidised to Fe_2O_3, which is accompanied by a significant loss of organic mass.

Catalytic pyrolysis can be used to obtain metal-containing carbon sorbents. During the pyrolysis of wood impregnated with iron, cobalt, nickel, and copper compounds, sorbents are formed with a porous carbon structure in which metallic particles are inserted.[71] On thermal decomposition of monocarboxycellulose substituted by Fe^{3+} cations, highly dispersed oxides seemingly retaining the lattice of the initial fibre, are formed.[72]

The conversion of the solid carbonaceous raw material into gaseous products of different composition takes place when it is subjected to a heat treatment in oxygen, water vapour, carbon dioxide, or hydrogen. The effect of certain catalysts makes it possible to accelerate the gasification process or to reduce its temperature while retaining a higher rate and, what is no less important, to regulate the composition of the gas formed.

In order to introduce catalysts into wood charcoal, the reactive groups of wood were subjected to ion exchange for metal compounds, after which the modified wood was subjected to pyrolysis.[73] The catalysts for the gasification of wood charcoal by carbon dioxide at 800 °C can be arranged in the following sequence in terms of their activities:

$$Co > Ca > Ni > Mg \sim K \sim Na > Cu.$$

The ion-exchange cobalt catalyst exhibits a very high activity. For example, wood charcoal is fully gasified by CO_2 at 600 °C after only 5 min.

Surface transition metal complexes play an important role in the catalytic gasification of solid fuel. Technical carbon, carbon fibre, and graphite containing titanium, vanadium, and chromium surface compounds of the C–O–M type were used as model objects in one of the studies.[74] The grafting of the transition metal complexes to the surface of the solid material makes it possible to increase by two orders of magnitude the rate of gasification and to lower the temperature and activation energy for the reaction.

In order to investigate the activities of iron catalysts in processes involving the gasification of carbonaceous materials by steam and hydrogen, iron compounds were introduced into a carbon support by impregnating the latter with the corresponding aqueous solutions or by means of ion exchange. It is suggested that in the course of the reaction the surface metal complexes are reduced, forming highly dispersed species which effectively catalyse the gasification process at temperatures above 700 °C.[75]

When two-component catalytic systems, including a transition and an alkali metal, are used for the gasification of carbonaceous materials, synergistic effects are observed. In processes involving the gasification of coal by steam at 700–800 °C, the maximum activity is shown by the $Na[HFe(CO)_4]$ and mixed $Fe(NO_3)_3 + Na_2CO_3$ systems.[76] Sodium hydrotetracarbonylferrate accelerates the gasification of coal by steam at 700 °C by a factor of 4.5.[77] For comparison, we may note that an increase in the rate of the non-catalytic gasification by a factor of 6 requires an increase in temperature from 700 to 1000 °C.

The observed non-additive increase in the activity of the mixed system has been explained by the fact that alkali metals facilitate the stage in which iron oxides are reduced by carbon, which limits the rate of the process as a whole. There are data showing that iron and nickel acetylacetonate complexes behave as process catalysts, while K_2CO_3 increases the surface area of the carbonaceous material in the gasification process.[78]

A specific feature of the gasification of solid fuels is that under the reaction conditions carbon is not only one of the reactants but also serves as the carrier for the catalyst. There are data indicating the formation of intercalation compounds of the metal during heat treatment at elevated temperatures.[79] It has been suggested[80] that metal–carbon inclusion complexes can play the role of catalytic centres in the gasification reactions. At the beginning they are not accessible to the gasifying agent but are involved in the process to the maximum extent for a degree of conversion of carbon up to 80%. The formation of metal–carbon complexes also prevents the vaporisation of the deposited metal compounds during heat treatment; they become active after the burning away of an appreciable proportion of the carbonaceous material. It is entirely possible that the mechanism of the catalytic gasification of the biomass includes as the main stages the interaction of the metal-catalyst cation with the surface phenolic, alcoholic, and acid groups of the organic matrix and the subsequent thermal decomposition of the resulting surface metal complexes.[81]

Metal-complex catalysis of the polymerisation of α-olefins

B A Krentsel', L A Nekhaeva
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The progress in the development and application of metal-complex catalysis in the polymerisation of α-olefins during the last ten years is reviewed and evaluated. The methods of modifying previously known catalytic systems are characterised and the experimental results of studies on novel types of catalysts, including Ti–Mg, metallocene, lanthanide, and ylide systems are reported. Some views about further improvement of the activity and stereospecificity of metal-complex catalysts in relation to the chemistry of polyolefins are stated.

The bibliography includes 242 references.

I. Introduction

An event which caused a revolution in chemistry in this century was the discovery by K Ziegler and G Natta of the metal-complex catalysis of the polymerisation of olefins. This discovery was not only of outstanding scientific importance but also gave rise to a fundamentally new and simple method of obtaining one of the most important industrial polymers — polyethylene — and to the synthesis of previously unknown crystalline stereoregular polyolefins such as polypropylene and several others. It is perhaps difficult these days to find an area of chemistry that has not experienced in its theoretical and practical aspects the influence of metal-complex catalysis to a greater or lesser extent. Metal-complex catalysis has had a considerable effect on the devlopment and refinement of the priority areas of theoretical and applied chemistry such as the polymerisation of dienes and the production of stereoregular rubbers, the activation of alkanes, highly effective and selective processes for the hydrogenation of unsaturated compounds, hydroformylation, and many others.

It has gained firmly established positions in the present-day chemical industry both in the production of large-tonnage products which govern the industrial potential of a country and in the preparation of products of so-called fine chemistry. Note the final role is also played by metal-complex catalysis in the development of certain biotechnological processes, the significance of which has grown in recent years.

However, the most important area of application of metal-complex catalysis (MCC) in industry still remains the polymerisation of unsaturated hydrocarbons — α-olefins, dienes, acetylenes, and, for the time being to a lesser extent, allenes.

A metal-complex catalytic system used for the polymerisation of α-olefins consists of three main components: 1) a transition metal; 2) a ligand (or several different ligands) bound to the transition metal); and 3) an electron-donor and/or electron-acceptor compound which has a direct effect on the activity and selectivity of the whole system, including the stereoselectivity (in the polymerisation of C_3 olefins or higher). Moreover, if a heterogeneous metal-complex catalyst is used, it contains a polymeric or other type of support as a matrix, the nature of which also affects the stability, selectivity, and activity of the whole catalytic system.

A virtually unlimited number of catalytic systems can be produced by varying the types of components as mentioned above. And in fact, since the discovery and application of Ziegler–Natta metal-complex catalysts, many hundreds if not thousands of catalytic systems for the polymerisation of ethylene, the stereospecific polymerisation of α-olefins (C_3–C_6), dienes, and acetylenic and allenic hydrocarbons have been proposed and in the majority of cases patented. However, until recently only certain compounds of transition metals such as Ti, V, and Cr have found practical application. Many fundamental studies and practical developments have been devoted to metal-complex systems based on them.

There is now no doubt that a necessary condition for catalysis to take place is the coordination of substrate (this is the monomer in polymerisation reactions) with a transition metal compound. The resulting organometallic intermediates participate in the polymerisation process, govern its mechanism, and have a considerable effect on the reaction kinetics and structure of the polymer formed.

However, up to the present time the nature of the active sites and the means of regulating their action have remained in many respects uncertain.

The composition of the intermediates depends on the nature of the transition metal in the catalytic complex, the type of ligand environment, and the donor-acceptor interactions that occur in the reaction sphere. All of these factors cause complications in making a reliable determination of the structure and mechanism of the active sites, which at the present time is made even more difficult because of the widespread use of metal-complex systems immobilised on a polymeric (or other) matrix, since in this case the actual structure of the active site may be considerably modified.

In the development of a metal-complex catalyst it is necessary to aim for a suitable combination of effectiveness, stability, and stereoselectivity. Many groups of researchers are working on a solution to these problems.

This is usually achieved through modification of classical Ziegler–Natta catalytic systems or through the development of new types of catalytic systems.

There is a whole series of theoretical and experimental publications and reviews in the Soviet and foreign literature on this topic.[1–22] Despite this, the problems of MCC in the polymerisation are still a long way from a complete solution and they leave open a sufficiently wide field for scientific research and advances. This has been the reason for writing the present review.

II. Modification of classical Ziegler–Natta catalytic systems

Bearing in mind the undoubtedly provisional nature of the classification that we have adopted, we shall classify catalytic systems made up by compounds of Ti, V, Cr, and certain other transition metals in combination with Al alkyl derivatives as classical Ziegler–Natta systems. The greatest number of studies are devoted to Ti-containing catalytic systems, which were discovered and first studied by Ziegler and Natta et al.[2]

In the polymerisation of ethylene and other α-olefins with catalysts containing Ti compounds, the high activity of the Ti–C bond is of considerable importance. This activity is related to its low energy and the possibility of selective excitation by insertion of a polymerising monomer.[23,24]

In a number of fundamental studies by Soviet research workers who had studied the properties of the Ti–C bond in quite considerable detail, a theory concerning the "lability" of this bond was advanced. The concept of "lability" denotes that the energy profile of the titanium-carbon bond (and in the final analysis its energy) is highly sensitive towards the ligand environment of the metal and towards association and dissociation, protonation and complexation.[8]

Some experimental results indicate the possibility of activation of the Ti–C bond, and hence an increase in activity of the whole catalytic system in the polymerisation of olefins. Thus, it was shown[24–32] that the activation of the metal-carbon bond (through to its homolytic decomposition) occurs on treatment of organic bases, Lewis acids, proton-donating compounds, and also microquantities of water.

The form of the titanium-containing components used in metal-complex systems has a considerable effect on the activity and stereoregularity of polymerisation (in the case of propylene polymerisation).[33–43] Thus, by using microspherical $TiCl_3$ it is possible to achieve a 98% (or higher) degree of isotacticity of the resulting polypropylene.[44–47] It is also significant that microspherical $TiCl_3$ makes it possible directly to obtain granulated polypropylene, which cannot be produced using traditional Ziegler–Natta catalytic systems, and hence an energy-consuming stage—granulation of the polymer—can be eliminated in the production of polypropylene. The structure (sphere) of the catalyst is replicated, as it were, in the polymer.[37]

Improvement of the classical catalytic system $TiCl_3 + AlR_3$ has mainly proceeded in the direction of the introducing certain activating additives, amongst which organomagnesium compounds are of the greatest interest.[48–51] Catalysts modified with these additives constituted the prototype of novel Ti–Mg metal-complex systems that will be examined below.

Table 1[52] contains the experimental results that characterise the activity of modified catalysts for the polymerisation of ethylene. For comparison we can indicate that on typical Ziegler–Natta systems the yield of polyethylene per unit of catalyst is lower by a factor of about 1.5–2.

Table 1. Activity of Ti–Al ethylene polymerisation catalysts modified with organomagnesium compounds.

Components of the catalytic system			Output g PE (g Ti)$^{-1}$	[η], dl g^{-1}
Ti	Al	Mg		
$TiCl_4$	$(C_2H_5)_3Al_2Cl_3$	$(C_6H_5)_2Mg$	18 420	13.8
	$(C_2H_5)_2Al_2Cl_4$	$(C_6H_5)_2Mg$	19 300	13.0
	$(C_2H_5)_3Al$	$(C_6H_5)_2Mg$	31 600	11.2
	$(C_4H_9)_3Al$	$(C_6H_5)_2Mg$	21 140	12.3
	$(C_2H_5)_x(C_4H_9)_yAl$	$(C_6H_5)_2Mg$	18 380	14.2
	$(C_2H_5)_2AlCl$	**$(t\text{-}C_4H_9)Mg$**	18 375	18.6
	$(C_2H_5)_2AlCl$	**$(n\text{-}C_3H_7)_2Mg$**	32 700	16.2
	$(C_2H_5)_2AlCl$	**$(n\text{-}C_4H_9)(OC_3H_7)Mg$**	24 500	17.2
	$(C_2H_5)_2AlCl$	$C_{12}H_{25}MgBr$	34 160	19.9
$Ti(OC_4H_9)_4$	$(C_2H_5)_2AlCl$	$(C_6H_5)_2Mg$	20 120	22.6
$Ti(OC_4H_9)_3Cl$	$(C_2H_5)_2AlCl$	$(C_6H_5)_2Mg$	21 000	20.8
$Ti(OC_4H_9)_2Cl_2$	$(C_2H_5)_2AlCl$	$(C_6H_5)_2Mg$	22 400	24.1
$Ti(OC_4H_9)Cl_3$	$(C_2H_5)_2AlCl$	$(C_6H_5)_2Mg$	20 800	23.8

It had already been established in the earliest studies on the polymerisation of ethylene on Ziegler–Natta catalysts that the molecular weight of polyethylene can be controlled by adding hydrogen, which terminates the chain.[53–56] However, it was shown recently that in certain cases hydrogen can at the same time increase the activity of the catalyst.[55] At the present time the mechanism of this phenomenon is the subject of study and so far there is no unequivocal view about the activating role of hydrogen.

The activating effect of hydrogen on metal-complex catalysis was observed not only in the polymerisation of ethylene but also that of propylene and other α-olefins.[57–59]

Microspherical $TiCl_3$ has also been successfully used for the copolymerisation of propylene and styrene.[60] The best results were achieved when the catalytic system $(RC_5H_4)_2TiMe_2$ (R = H, Me_3) + $TiCl_3$ was used. It is possible to obtain statistical copolymers of styrene and propylene by using this catalyst. When it is used, highly isotactic polymers based on propylene (isotacticity >99%), n-butene (isotacticity >98%), and polystyrene (isotacticity >99%) are obtained. For the polymerisation of ethylene highly crystalline polyethylene was formed, containing virtually no ethyl branches in the macromolecule.[44,45]

Block copolymers of propylene and ethylene were synthesised using microspherical $TiCl_3$.[61,62] In order to improve the morphology of the copolymer of ethylene and propylene obtained using δ-$TiCl_3/Al(C_2H_5)_3$, it is recommended to carry out a preliminary activation of this catalyst with small quantities of α-olefins (C_4–C_{12}) or ethylene.[63] Certain attempts were made to define the role of this process.[56,64–66] However, this phenomenon requires a more detailed investigation.

As has been mentioned above, donor-acceptor interactions which occur when electron-donating or electron-withdrawing compounds are added to the reaction sphere have a significant effect on the

activity of Ziegler–Natta catalysts. A large number of examples attesting to this effect have been reported in the literature.[67–73]

The recently published results of Seppälä and Härkönen,[74] who studied the polymerisation of propylene on Ziegler–Natta catalysts incorporating organosilicon donor components, have attracted attention. The following silicon compounds were used as donor additives: $RSi(OCH_3)_3$, $R^1R^2Si(OCH_3)_2$, $RSi(OC_2H_5)_3$, $R^1R^2Si.(OC_2H_5)_2$, $RSi(CH_3)_3$, $R_2^1R^2SiH$, $(n\text{-}C_3H_7O)_3SiCH_3$, $(CH_3)_2Si.[OC(CH_3)=CH_2]_2$.

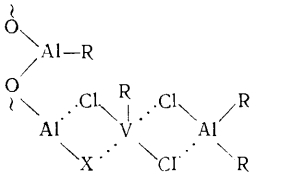
It was established that the donor components in essence selectively deactivate the atactic active sites, thus increasing the yield of high-molecular weight isotactic polypropylene. The study contains data that characterise the relationship beween the effect of the above donors and their structure.

Interesting results were recently published by Soga et al.,[75] who proposed the use of spherical $TiCl_3$ in combination with Cp_2TiMe_2 without involving organoaluminium compounds in the catalytic complex for the preparation of isotactic polyolefins from propylene, 1-butene, and 4-methyl-1-pentene.

One of the most important methods of modifying Ziegler–Natta catalytic systems is their heterogenisation or, in other words, the immobilisation of the active sites on a support. Inorganic compounds as well as polymers themselves—polyethylene, polypropylene, etc.—can be used as the supports. Immobilised metal-complex systems have considerably greater stability compared to conventional systems and also prove to be more efficient in carrying out polymerisation under industrial conditions.[1,19,76–90]

Amongst the first to start work in this area were Kabanov et al.,[91–92] who developed the so-called gel-immobilised catalytic systems (GCS). In order to obtain such catalysts, functional monomers are initially grafted on to the polymers, for example, a functional monomer such as vinylpyridine or some other is introduced on to butadiene-styrene rubber by copolymerisation (normal or block), and then transition metal compounds [$TiCl_4$, VCl_4, Cp_2TiCl_2, $Ti(OPr)_4$, etc.] are added to the solvent-swollen rubber (gel), fixing on to the functional groups. After removal of the solvent the gel-immobilised catalyst (GC) can be kept in air, not losing its potential activity over a long period. When a GC is introduced into a solvent in which the polymerisation of ethylene or another α-olefin is being carried out it swells and the active sites become accessible for interaction with the monomer and the usual co-catalysts—AlR_2Cl, AlR_3, etc. It should be noted that in those cases where the rate of polymerisation exceeds the rate of diffusion processes related to removal of polymer from the gel, it is possible to destroy the whole system. Therefore, the use of GCS proves to be most effective in processes involving oligomerisation of olefins.

The functionalisation of polyolefins for the successive fixing of transition metal compounds on to them via suitable functional groups has been carried out.[26] Thus, Ti-containing catalysts for the polymerisation of propylene that were immobilised on polypropylene via acrylate groups were obtained, having high stability and making it possible to prepare isotactic polypropylene (96–97%).



Recently the heterogenisation of homogeneous metal-complex catalytic systems was carried out by means of chelation with macroligands.[93] In order to do this, the functionalisation of the surface of PE was initially carried out. The functionalised support was then transformed through polymer-like reactions into chelating macroligands which formed a heterogenised catalyst with transition metal compounds. The transition metal compounds used were $TiCl_4$, $Ti(OC_4H_9)_4$, VCl_4, $Ni(OCOCH_3)_2$, $CoCl_2$, and $Co(OCOCH_3)_2$.

The bifunctional immobilised catalyst containing Ni and Ti (or V) compounds that is used for the single-stage preparation of linear low-density polyethylene (LLDPE) deserves particular attention. Its action is based on the effective dimerising ability of the Ni-active sites. Ti or V compounds traditionally used in Ziegler–Natta catalysts constitute the second active site in this catalyst.[93]

There is no doubt that the idea of obtaining LLDPE from ethylene in a single stage is attractive, but it is necessary to bear in mind the complexity of controlling simultaneously the different active sites that are functioning.

Attention has been drawn in the literature to the nature of the active sites of supported vanadium catalysts for the polymerisation of ethylene. For immobilisation of the components of the catalyst, supports that contained hydroxyl functional groups (and adsorbed water)—$SiO_2.Al_2O_3.H_2O$, kaolin, chalk, pyrite—and also supports with reactive alkyl groups—polyalkylalumoxanes $R_2Al(OAlR)_m-(OAlX)_m-OAlR_2.kEt_2O$, where X = Cl, OMg, iso-Bu, $OR(OC_6H_5)_2$; $n + m \geqslant 20$; $k = 0.1$—were chosen.[94–96] The higher valency vanadium compounds used were $VOCl_3$, VCl_4, $VO(OEt)_3$, and ethyl and isobutyl derivatives of aluminium were used as the organoaluminium component.

Si–O–V and V–O–Al bonds were fixed on the surface of the support. $Al(iso\text{-}Bu)_3$ served as the co-catalyst. It was shown experimentally that in catalytic complexes of supported systems chemical bonding of vanadium to the surface of the support occurs, lowering the mobility of the vanadium atom and reducing the probability of octahedrally coordinated vanadium being formed. The highest catalytic activity in the polymerisation of ethylene occurs in vanadium-alumoxane systems in which the active site is not bound chemically to the support. The structure of the active sites of vanadium alumoxane catalysts can be represented schematically as follows:

,

X = R, OR, Cl, OMgR, OP $(OC_6H_5)_2$.

The vanadium catalysts immobilised on alumoxanes are more stable than those immobilised on oxide supports. Their output is also higher by a factor of 4–6.

In one study[97] several new approaches to stereoregulation processes in the polymerisation of propylene on solid complex catalysts based on α- and δ-$TiCl_3$ (or VCl_3) + AlR_3 (or AlR_2Cl) were examined. The mechanism of polymerisation was shown to be multicentred. The active sites of the catalyst differed according to both reactivity and stereoregulating ability.[98]

It is significant that an isotactic fraction of PP that has virtually uniform stereoregularity is not of uniform molecular weight. This fact suggests that the two types of active site in the catalyst are not interrelated in terms of activity and stereospecificity. It is necessary to take into account this factor when interpreting the experimental data on the stereospecific polymerisation of propylene and other α-olefins.

Soviet research workers[99] studied the mechanism of the formation and structure of the active sites formed when organometallic catalysts are fixed to the surface of a support. This is of considerable importance for achieving controlled polymerisation of ethylene and other α-olefins on heterogenised catalysts, since the

process of fixation of the active sites on the surface of the support and the subsequent polymerisation are accompanied by a number of quite complex side reactions that have an effect on the activity of the whole catalytic system and the kinetic mechanisms of polymerisation. The fixation of metal complexes of $TiCl_4$ and $AlEt_2Cl$ or $AlEt_3$ to the surface of Aerosil was selected as a model.

It was established that in the polymerisation of ethylene and propylene on this catalytic system, different types of active site can occur depending on the conditions under which it is formed. Thus, when a titanium compound that is already fixed is treated with organoaluminium compounds (the "direct" method), titanium occurs on the surface of the support as a separate $TiCl_4$ complex, and a $TiCl_3$ phase is not formed, as was previously supposed.[82]

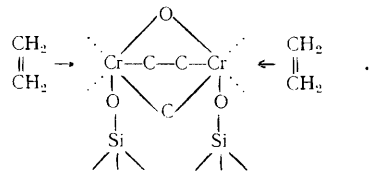
The use of the "reverse" method for fixing the catalyst, in which $AlEt_3$ is fixed first, results in the formation of a $TiCl_3$ phase on the surface of the support. When $AlEt_3$ interacts with the OH groups of Aerosil, alkyls of the type $Si-O-AlEt_2$ are formed on the surface, having good reducing ability. According to polarographic data, after interaction of such groups with $TiCl_4$ a system containing a maximum quantity of Ti^{3+} (95%) and containing virtually no Ti^{4+} or Ti^{2+} is formed.

If $AlEt_2Cl$ is used instead of $AlEt_3$, the active sites formed on the surface in the "reverse" method of producing fixed metal complexes are quite different in nature. In this case reaction with OH groups results in the formation of $Si-O-Al$ compounds of lower reactivity, and after adsorption of $TiCl_4$ a surface complex is formed in which titanium remains almost completely in the tetravalent state. Such sites are highly active in the polymerisation of propylene, as a result of which irregular low-molecular weight polypropylene is formed.

According to IR spectroscopy data the polypropylene formed on sites of this type contains a large number of irregular additions and is similar to the polypropylene obtained on classical cation catalysts (BF_3, $AlBr_3$). The atactic fraction of polypropylene is virtually no different from the traditional form.

Thus from the experimental data examined above it can be concluded that there is a possibility of the directed formation of different active sites in the polymerisation of α-olefins on heterogenised Ziegler–Natta catalytic systems.

In two studies by D'yachovskii et al.[100,101] it was found that when catalytic systems based on $Ti(OR)_4$, $TiCl_3$, and $VO(OR)_4$ fixed on graphite were used, it was possible to obtain highly isotactic PP. The theory was advanced that the graphic acts as a unique macroligand that permits the formation of active sites with a high stereoregulating capacity.[101,102] The graphite support was also successfully used in the polymerisation of 1-butene on Ziegler–Natta catalytic systems.[103]



There is no doubt that the role of a graphite support, which has unusual properties that other layered supports may also possibly have, deserves detailed study. This opens up new possibilities for the development of unconventional heterogenised metal-complex polymerisation systems.

X-Ray diffraction studies were carried out[103] on the polymerisation of 1-butene on Ziegler–Natta systems fixed on graphite and they helped to identify the properties of the graphite support with a number of transition metal compounds ($TiCl_4$, $SnCl_4$, $FeCl_3$, etc.) fixed on it. The X-ray diffraction studies demonstrated that these complexes penetrate inside the quasi-monocrystalline graphite. However, the distance between the carbon layers in the graphite when it is treated with heptane, $AlEt_2Cl$, $TiCl_4$ + $AlEt_2Cl$ does not alter, namely, the formation of layered graphite compounds does not occur with these products.

As a result of the polymerisation of ethylene and 1-butene in the presence of the catalytic system $TiCl_4$ + $AlEt_2Cl$ fixed on a quasi-monocrystal of graphite, the crystal expands and increases its width by a factor of 3–5 depending on the polymerisation conditions. This suggests that the polymerisation of olefins occurs both on the outer surface and inside the crystal. Thus, the hypothetical concept which regards graphite as a macroligand requires experimental confirmation.

At the same time as Ziegler–Natta catalytic systems, chromium oxide catalysts comprising Cr compounds deposited on Al_2O_3 (Phillips catalysts) were proposed and even found industrial application for the polymerisation of ethylene.[2,104,105] In due course the characteristics of the polymerisation of ethylene and other olefins on these catalysts were studied in detail by Topchiev et al.[106] and the chemical interaction between transition metal and support was demonstrated experimentally. The interest in chromium oxide catalysts has now diminished somewhat because of the development of new highly effective and stereoselective catalytic systems. Nevertheless, several studies have appeared in the literature in recent years[107–111] devoted to chromium catalysts for the polymerisation of ethylene.

Thus, in a recently published study by Rebentorf[112] the number of active sites in samples of a Phillips catalyst—0.5% Cr^{6+} and 0.074% Cr^{6+} (on silica gel)—was determined. It was shown that the number of active sites increases with a decrease in Cr content in the catalytic system. Rebentorf, in the same way as the Soviet scientists, assumes that in this case there is chemical reaction between Cr and the support:[112]

Gan et al.[108–110] examine a new type of chromium catalyst for the polymerisation of olefins, consisting of specially prepared chromium acetate combined with $AlEt_2Cl$. This catalyst exhibits a very high activity in the polymerisation of ethylene, amounting to 1180 g PE (g Cr)$^{-1}$ h^{-1}.

III. Novel types of catalytic systems

1. Titano-magnesium catalytic systems

In considering the different methods for modifying "classical" Ziegler–Natta catalytic systems we have already drawn attention to the activating effect of organomagnesium compounds. These studies have served as the basis for the development of a new generation of highly active Ti–Mg catalysts. At the present time heterogeneous titano-magnesium catalysts represent the most widely used metal-complex systems for the production of polyethylene and other polyolefins, in particular, isotactic polypropylene. Essentially these catalytic systems are supported, since $MgCl_2$ should legitimately be regarded as a support. Experimental data characterising the activity and stereospecificity of certain titanomagnesium catalysts used in the polymerisation of propylene are presented in Table 2.[113] It should be noted that in all cases the fairly high stereospecificity of such catalysts is due to the addition of electron-donating compounds (ethers and esters, phosphorus- and silicon-containing compounds, etc.).

Ti–Mg catalysts (in their various forms) have served as a subject of research for scientists of different countries.[1,114–123] A considerable contribution has also been made to the development and practical application of Ti–Mg catalysts by Soviet scientists (the school of Yu E Ermarkov and V A Zakharov in the Institute of Catalysis, Siberian Branch of the USSR Academy of Sciences).[82,120,124–128]

Table 2. Some results on the polymerisation of propylene on titanium–magnesium catalysts.[113]

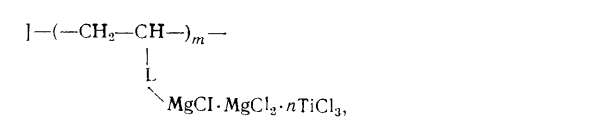
Solid catalyst	Co-catalyst	Activity, g PP (g Ti)$^{-1}$	Index of isotacticity
$TiCl_3$	$(MeC_5H_4)_2TiMe_2$	27	98
	$(MeC_5H_4)_2TiCH_2(Me)AlMe_2$	37	93
$TiCl_4/MgCl_2$	$(MeC_5H_4)_2TiMe_2$	160	90
	$Cp_2TiCH_2(Me)AlMe_2$	940	87
$TiCl_4$/EB*/$MgCl_2$	Cp_2TiMe_2	970	95
	$Cp_2TiCH_2(Me)AlMe_2$	3250	93
$TiCl_4$/n-BP**/$Mg(OEt)_2$	Cp_2TiMe_2	60	97
	$Cp_2TiCH_2(Me)AlMe_2$	2400	97
$TiCl_4$/n-BP/$MgCl_2$	Cp_2TiMe_2	90	96
	$Cp_2TiCH_2(Me)AlMe_2$	3700	95
	$AlEt_3$	4000	76

Polymerisation conditions: $P_{C_3H_6}$ = 1 atm, T = 40 °C, τ = 2 h, heptane solvent (100 ml).

* EB = ethyl benzoate. **n-BP = n-butyl phthalate.

Attention is drawn in the literature to the fact that the properties of Ti–Mg catalysts depend to a significant extent on the structure of the support and the method of fixing transition metal compounds to it. Magnesium chloride is the most suitable support for obtaining a highly active propylene polymerisation catalyst because of the similarity between the structures of $TiCl_3$ and $MgCl_2$.[129–134] Thus, an active catalyst was obtained by grinding together a mixture of anhydrous $MgCl_2$ and the complex $TiCl_4.C_6H_5-COO-C_2H_5$. The ester is an electron donor and it is needed to achieve a high degree of stereoregularity. On a catalyst prepared in this manner the yield of PP reached 9 to 17 kg (g M)$^{-1}$ h^{-1} with a degree of isotacticity of 94–95%.[135]

Polish research workers[135] showed that the presence of a given quantity of ethanol in the reaction medium during preparation of the catalyst increases the efficiency of a Ti–Mg catalyst (modified none the less with ester). During the experiment the presence of ethanol assisted the formation of the spherical type of catalyst grain. However, the specific output of the catalyst was not sufficiently high ~6 kg PP (g Ti)$^{-1}$ h^{-1}.[135]



A detailed study was made on the copolymerisation of ethylene with α-olefins on Ti–Mg and similar supported catalytic systems. The subject of the study was the suspension copolymerisation of ethylene with propylene, 1-butene, and 1-hexene on supported Ti–Mg (TMC) and V–Mg (VMC) catalysts.[111] In the copolymerisation on TMC and VMC the catalysts can be arranged in the following order of copolymerising ability: V–Mg > $TiCl_3$ > Ti–Mg. It was established in a separate series of experiments that there is a virtually constant value of the copolymerisation constant over the temperature range 40 to 80 °C.

As has already been mentioned above, the structure of the electron-donating component has a significant effect on the activity and stereospecificity of Ti–Mg catalysts.[136–145] In this respect consideration should be given to a recently published study,[146] in which a new highly active supported catalyst for the polymerisation of propylene based on $TiCl_4$ and $MgAlk_2$ compounds and sterically hindered aromatic esters is described, the esters used being ethyl 2,6-dimethylbenzoate, ethyl 2,4,6-trimethylbenzoate, or isopropyl benzoate. The support is deposited from a solution of $MgAlk_2$ with SiR_4 and then activated by treatment with $TiCl_4$ and dibutyl phthalate in chlorobenzene. A Ti–Mg catalyst prepared in this manner gives high yields of isotactic PP [16–17 kg PP (g Ti)$^{-1}$ h^{-1}] (70 °C, 10 atm).

There are reports in the patent literature[147–152] on many methods for preparing Ti–Mg catalysts which we naturally do not have the opportunity of examining within the scope of this review. A number of studies[31,122,140,142,153–175] are devoted to establishing the nature of the active sites of Ti–Mg catalysts.

The desire to increase the number of isospecific sites in a Ti–Mg catalyst has compelled research workers to seek the most effective electron-donating components which cause an increase in the number of these same active sites. Amongst the electron-donating components studied, special consideration should be given phthalate esters.[142–144] In a study of the copolymerisation of ethylene and 1-hexene, 1-decene, and 4-methyl-1-pentene on a Ti–Mg catalyst, Ivanchev et al.[176,177] and also other research workers[56,63–65,178] showed that the α-olefin molecules act as modifiers of the growth sites, increasing the rate of growth of the polymer chain by a factor of 6–9. This interaction during the suspension polymerisation process is satisfactorily represented by a scheme involving equimolar equilibrium complexation with a constant that is close to unity.

Interesting results were obtained by Krentsel' et al.[8] in a study of the polymerisation of ethylene on Ti–Mg catalysts that were immobilised on polymeric supports. The structure of the catalyst used in this study can be represented by the following general scheme:

where L is a functional group such as allyl alcohol, acrylic acid, and others. The steady-state rate of ethylene polymerisation at 70 °C and 2 atm reached 85 mol C_2H_4 (mol Ti)$^{-1}$ s^{-1}.

This type of Ti–Mg catalyst for the polymerisation of ethylene is characterised by a low Mg content which is comparable to the concentration of Ti, which, in the opinion of Krentsel' et al.,[8] makes it possible to control the molecular weight properties of polyethylene.

In general, control of the molecular weight and molecular weight distribution of polyethylene formed by the polymerisation of ethylene on Ti–Mg catalysts is a complex task. In this respect the studies which demonstrated the possibility of controlling the molecular weight distribution in the polymerisation of ethylene on Ti–Mg catalysts by the introduction of various halogenated compounds such as butyl chloride, chlorobenzene, and others are of undoubted interest.[179,180] From the experimental data obtained it

could be assumed that termination of the chain occurred as a result of the addition of a strongly polarised RX molecule or contact ion pair R^+X^-. In all of the experiments there was a narrowing of the molecular weight distribution. However, for the time being it is not possible to provide a reliable explanation for this phenomenon. The mechanism of interaction between RX and an active site is so far unclear and requires further study.

It may be assumed that there is a certain critical size of the catalyst macroparticles, depending on which the process occurs in the kinetic or diffusion region. In turn this critical size depends on the activity of the catalyst sample used, being determined by the concentration of active sites and the rate constant of growth.

From an analysis of the experimental data on the polymerisation of ethylene and other α-olefins on supported Ti–Mg catalytic systems, these catalysts can be considered to be amongst those with the greatest future potential.

2. New homogeneous metallocene catalytic systems

The most prominent event in metal-complex catalysis of the polymerisation of α-olefins since the discovery of this reaction by Ziegler and Natta was the creation by Kaminsky et al. (FRG)[181,182] of new homogeneous catalytic systems based on metallocene-alumoxane complexes. Such catalysts, having very high activity in the polymerisation of ethylene (tens of tons of polymer per gram of metal) can be used to effect stereocontrol of polymers in a homogeneous reaction medium.[183] The considerable scientific and practical interest shown at the present time in all countries in such metal-complex systems is due to this factor.

Catalysts of this type are formed by reaction of a metallocene of a transition metal such as Zr, Hf, and others, for example, bis-(cyclopentadienyl)dimethyl(or dichloro)zirconium with alumoxanes

$$-\left(-\underset{\displaystyle R}{\underset{|}{Al}}-O-\right)_n-,$$

where R = CH_3, C_2H_5, etc., n = 10–20.

During the last few years a large number of studies devoted to the polymerisation of olefins on such homogeneous complexes, in particular on zirconocene complexes with alumoxanes have been published.[178,184–202] Experimental data characterising the relative activity of such homogeneous catalysts in the polymerisation of ethylene[189] are given in Table 3.

It was calculated for the zirconium catalyst that at a polymerisation temperature of −20 °C about 70% of all zirconium atoms participate in polymerisation.

Experimental data on the polymerisation of ethylene on different Zr-containing catalytic systems[189] are given in Table 4.

Homogeneous zirconocene catalysts proved to be active not only in the polymerisation of ethylene but also in the copolymerisation of ethylene with hexene. The latter process is of considerable practical importance and is used to obtain linear low-density polyethylene (LLDPE). This polyethylene differs from low density polyethylene obtained by high-pressure radical polymerisation in its lower degree of chain branching and improved mechanical properties.

Interesting results were obtained when organozirconium compounds complexed with oligomeric alumoxanes were used as ethylene polymerisation catalysts. These catalysts are distinguished by their stability and can be used to obtain PE with a narrow molecular weight distribution. Isotactic polypropylene with a novel steroblock microstructure was obtained by using soluble bis(cyclopentadienyl)bis(phenyl)titanium/methylalumoxane catalysts.[6]

Three reports[183,192,196] indicate the unusual effects observed in the polymerisation of propylene carried out on homogeneous catalysts containing bulky or chiral ligands. Thus, Ewen[6] showed that when sterically hindered ethylenebis(1-indenyl)titanium dichloride (a mixture of the meso form and racemate) was used as a catalyst for the polymerisation of propylene, there is the formation of 63% isotactic and 37% atactic polypropylene. If chiral ethylenebis-(4,5,6,7-tetrahydro-1-indenyl)zirconium dichloride is used together with methylalumoxane $[AlMe-O-]_n$ as the co-catalyst, highly isotactic polypropylene is obtained.[183]

Table 3. Comparative activity of homogeneous ethylene polymerisation catalysts.[189]

System	Effective rate of polymerisation, litre mol^{-1} s^{-1}	Mole fraction of transition metal participating in the reaction
Cp_2ZrMe_2–MAO *	109 000	1
Cp_2TiCl_2–MAO	800	0.7
$TiCl_3 \cdot AlEt_2Cl$	2.7	0.005

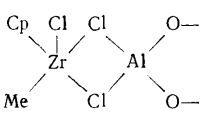
*MAO = methylalumoxane.

Table 4. Polymerisation of C_2H_4 on different Zr systems.

Compound	Type of alumoxane	Activity, kg PE mol^{-1} h^{-1} bar^{-1}	T, °C
Cp_2ZrCl_2	Methylalumoxane	820	20
	"	242 000	80
$(Cp_2ZrCl)_2O$	"	203 000	80
Cp_2ZrMe_2	"	152 000	80
$Cp_2ZrCl(OBu)$	"	73 000	80
Cp_2ZrCl_2	Ethylalumoxane	2 100	60
Cp_2ZrMe_2	Tetraisobutylalumoxane	15 900	70

It is worth noting two studies[197,198] which are concerned with the preparation of high-molecular weight atactic polypropylene on homogeneous cene catalysts. Thus, by using bis(cyclopentadienyl)zirconium dichloride it is possible to obtain almost exclusively atactic polypropylene with molecular weights of up to 600 000. This type of polypropylene is characterised by a set of mechanical properties which is unusual for this polymer and may prove important for its use in producing seals, road and roof covers, and in a number of composite materials.

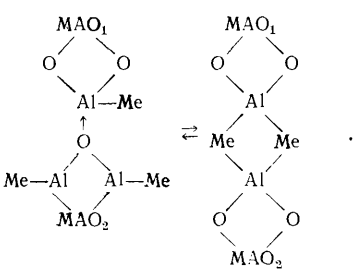
Chiral ethylenebis(4,5,6,7-tetrahydro-1-indenyl)zirconium dichloride cannot only be used to obtain isotactic polypropylene but also has polymerising activity which is 2–3 times higher than a catalyst on which only atactic polypropylene is formed. While the rates of polymerisation of ethylene and propylene on bis(cyclopentadienyl)zirconium compounds are 25 : 1, when this chiral catalyst is



used this ratio is equal to 10:1.[187,188] These experimental results once again confirm the significant role played by steric factors during the polymerisation of α-olefins on homogeneous metal-complex systems.

With the same concentrations of monomers (pressure and polymerisation temperature) the factors which affect the activity of these catalysts are the degree of oligomerisation of the alumoxane and the concentrations of the catalytic components. The activity of the catalysts increases significantly as the concentration of zirconium decreases and the concentration of aluminium increases.[107]

The presence of methylalumoxane oligomer residues in very active homogeneous coordination catalysts for the polymerisation of α-olefins is unusual. The answer to this question will serve as a key for the preparation in future of new highly active catalytic systems.[184]

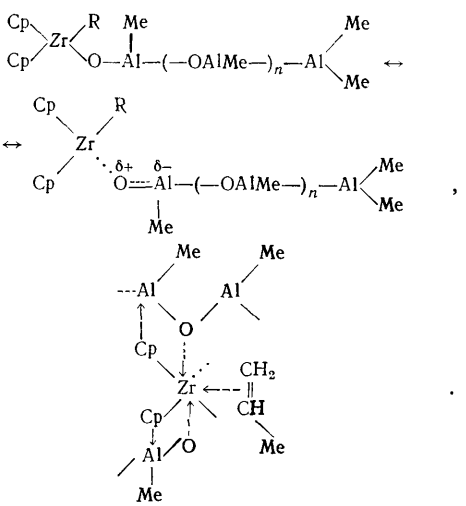


In a number of studies[199,200] particular attention is given to the role of alumoxanes in homogeneous metallocene catalytic systems. At one of the symposia on the relationship between the mechanism of heterogeneous and homogeneous catalysis, it was suggested for the polymerisation of α-olefins that alumoxanes can legitimately be regarded as a kind of support on which the active sites responsible for growth of the polymer chain are immobilised in a particular way.[81]

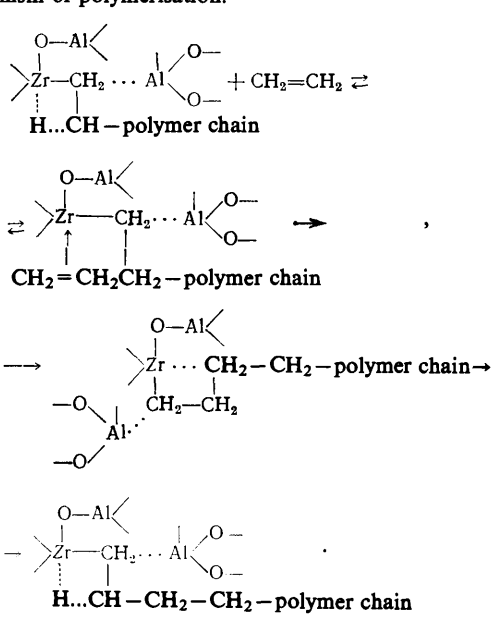
In an EPR study of the reactions that occur between a metallocene and methylalumoxane (MAO) it was found[84] that as a result of complexation and alkylation there was the formation of a compound with bridging bonds

Thus the proposal made previously about the similarity between alumoxane and a support is to a certain extent borne out. It is thought that when the metallocene reacts with MAO electron-deficient bridging complexes are formed and the bridging ligands are replaced by alkyls (from MAO) followed by elimination of the non-bridging groups as alkanes.

Consideration has been given to the probable establishment of an associative-dissociative equilibrium of MAO in which acid-base electron-deficient bridged complexes participate.



The catalytic sites deactivate each other in proportion to the concentration of Zr.[195]



The theory advanced in this study[195] is confirmed experimentally in the observed relationship between the activity of the catalytic system and the content of Zr in it.

Despite the considerable number of theoretical and experimental studies, the most important of which were considered above, up to now there has been an absence of sufficiently reliable data on the structure and reaction mechanism of the active sites in homogeneous zirconocene catalytic systems containing alumoxanes. Recently fresh attempts were made to establish the details of the mechanism of polymerisation using carbonyl groups labelled on the carbon atom which are formed by treatment of the catalytic system with ^{14}CO.[185] However, because of a number of experiment difficulties which occurred, it was not possible to obtain sufficiently accurate results. Also, the use of CH_3OT as a label proved unacceptable.[185]

Nevertheless, proposals which do not contradict the experimental data have been made about the mechanism of complexation of a zirconocene compound with MAO, based on the electronic structure of the reacting components of catalytic system and monomer.[184,186] The essence of the proposed mechanism is as follows. On treatment with MAO polarisation of the π-electrons of the double bond in propylene occurs. As a result, a partial negative charge δ-arises on the carbon atom furthest from the methyl group. Because of this propylene is inserted into the polarised $Zr^{\delta+}-C^{\delta-}$ bond strictly stereospecifically.

The following scheme has been put forward to depict the possible mechanism of polymerisation:[190,200]

"Bridging" hydrogen is replaced by ethylene, which is initially π-bonded and then inserted into the Zr–C bond. This model

conforms with the hypothesis according to which chain growth is due to the existence of electron-deficient compounds in pentacoordinate bimetallic complexes.

An experimental study of the polymerisation of ethylene on these catalytic systems showed that the ligand environment of Zr has a significant effect on the yield and molecular weight of the resulting PE [201] (Table 5). It transpired that when MAO obtained by hydrolysis of $AlMe_3$ was used, a polymer with a lower value of $\overline{M}_n$ and wider molecular weight distribution is obtained.

Table 5. Effect of Cp substituent on the molecular weights and molecular weight distribution of polyethylene.[201]

Metallocenes	Yield, g PE $(g\ M)^{-1}\ h^{-1}\ atm^{-1}$	$MW \times 10^{-3}$	MW distribution
$(MeC_5H_4)_2ZrCl_2$	467	212	3.8
$(EtC_5H_4)_2ZrCl_2$	306	171	3.8
Cp_2ZrCl_2	252	140	3.5
$C_5Me_5ZrCl_2$	71	63	4.7

Table 6. Results of polymerisation on a TBP complex—MAO.[196]

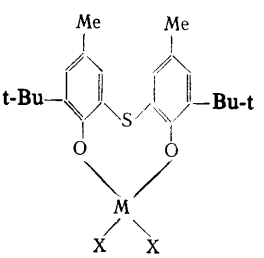
Catalyst	Activity, g polymer $(g\ M)^{-1}\ h^{-1}$	$\overline{M}_w \times 10^{-4}$	$\overline{M}_w/\overline{M}_n$
Polymerisation of ethylene*			
(TBP)$TiCl_2$	228	360	2.0
(TBP)Ti(OPr-iso)$_2$	188	420	2.5
(TBP)Zr(OPr-iso)$_2$	6	—	—
Cp_2ZrCl_2	266	62	2.0
Polymerisation of propylene**			
(TBP)$TiCl_2$	186.0	800	2.2
(TBP)Ti(OPr-iso)$_2$	87.0	800	2.0
(TBP)Zr(OPr-iso)$_2$	0.2	380	2.4
Cp_2ZrCl_2	17.6	7.6	2.0
Ti(OPr-iso)$_4$	4.8	41.15	6.9

* Ethylene polymerisation conditions: amount of catalyst = 1.1×10^{-6} mol, MAO = 5.17 mmol, toluene = 10 ml, $P_{ethylene}$ = 1 atm, T = 20 °C, τ = 10 s.

** Propylene polymerisation conditions: amount of catalyst = 1.1×10^{-6} mol, MAO = 5.17 mmol, weight of propylene = 30 g, T = 20 °C, τ = 1 h.

Mention has already been made above of the polymerisation of propylene on homogeneous zirconocene-containing catalytic systems containing chiral ligands. Experimental data have recently been published on the preparation of stereoregular polypropylene using catalytic systems with the following structure:[202]

μ-X $(C_5H_2R^1R^2)_2ZrCl_2$, where



R^1 = t-Bu; R^2 = H; μ-X = $Me_2\overset{|}{C}-\overset{|}{C}Me_2$;

R^1 = t-Bu; R^2 = H; μ-X = Me_2Si  ;

R^1 = t-Bu; R^2 = Me; μ-X = Me_2Si  ;

R^1 = iso-Pr; R^2 = Me; μ-X = Me_2Si  .

There is considerable interest in titanium and zirconium compounds with a bidentate 2,2′-thiobis(6-t-butyl-4-methylphenoxy) ligand (TBP), which in combination with MAO exhibit extremely high activities in the polymerisation of olefins or styrene.[203,204] The catalytic systems

M = Ti, Zr;
X = Cl, OPr-iso;

in combination with MAO not only are highly active but also can be used to obtain polyethylene and stereoregular polypropylene with high molecular weights (Table 6).[196]

Interesting data on the microstructure of polypropylene were obtained when the homogeneous catalytic systems—$C_2H_4Ind_2.ZrCl_2$—MAO [205] and $C_2H_4(4,5,6,7\text{-}H_4Ind)_2ZrCl_2$ [206]—were used as the polymerisation catalyst. The resulting polypropylene contains units from both 1,2- and 1,3-addition.[207–209] It was established that the stereospecific action of the catalytic system decreases with an increase in temperature of polymerisation. The polymer obtained is completely soluble in the reaction medium, in contrast to the ordinary isotactic material. These types of polymers were called "anisotactic" by Rieger and Chien as distinguished from polypropylene obtained at a lower temperature.[209] The polypropylene which was soluble in acetone and ether is waxy, while the polymer isolated from hydrocarbon solutions will be more crystalline. Ishihara et al.[206,210] showed in the case of the polymerisation of styrene that by using zirconium and other similar catalytic systems it is possible to obtain hydrocarbon polymers with a syndiotactic structure. They used heterogeneous systems in combination with MAO, such as $Ti(OBu)_4/MAO/SiO_2$, as catalysts. It was established by Pellechia et al.[211–213] that an effective catalyst for the preparation of syndiotactic polystyrene has a low ratio of MAO to Ti. In other studies[211,212,214] an organozirconium system combined with MAO was used to obtain syndiotactic polystyrene. It should be mentioned that a similar catalytic system was tested in the polymerisation of 1,3-butadiene, isoprene, and 4-methyl-1,3-pentadiene.[215] The first two monomers gave the corresponding 1,4-*cis*-polymers, while the latter gave a 1,2-syndiotactic polymer. Catalytic hydrogenation of syndiotactic poly(1,2-[4-methyl-1,3-pentadiene]) resulted in the formation of crystalline poly(4-methyl-1-pentene) mainly with a syndiotactic microstructure and a softening point of 186 °C.[215]

Brinzinger[216] in an extension of studies on the stereospecific polymerisation of α-olefins with homogeneous metallocene catalysts synthesised and studied a number of chiral metallocenes with different structures and obtained from them active catalysts for the synthesis of isotactic polypropylene. Kaminsky et al.[217] successfully used chiral zirconocene compounds complexed with MAO for the copolymerisation of ethylene and propylene with other α-olefins.

As was mentioned above, MAO plays an important part in the polymerisation of olefins in which it participates. It is appropriate to mention that the addition of MAO to the catalytic system $Ti(OBu)_4/SiO_2$ markedly increases the activity of this system in the preparation of highly syndiotactic polystyrene.[218] However, the mechanism of this effect remains unclear. It is still not understood why the catalytic system consisting of Cp_2MCl_2 (M = Ti, Zr) and MAO, which is well known as an olefin polymerisation catalyst, is ineffective in the preparation of syndiotactic polystyrene, whereas the system $Ti(OPr)_4$–MAO, which is used to obtain syndiotactic polystyrene, also catalyses the polymerisation of olefins[219] but does not assist the copolymerisation of styrene and olefins.[220]

The effect of the nature of organozirconium and organoaluminium compounds on the properties of homogeneous catalytic systems for the polymerisation of α-olefins was also studied in the case of the homo- and co-polymerisation of ethylene with higher α-olefins on different organozirconium compounds.[220–222] The results of the investigation showed that the catalytic systems based on zirconocene combined MAO can be arranged in the following order of activity:

$$(C_5H_4SiMe_3)_2ZrCl_2 > Cp_2ZrCl_2 > (C_5H_4CH_2)_2ZrCl_2 >$$
$$> (C_5H_4Bu\text{-}t)_2ZrCl_2 > Ind_2ZrCl_2.$$

It has been suggested that the increase in catalytic activity of zirconocenes is in agreement with the increase in the electron-deficiency of the Zr atom in this series. This factor facilitates the reaction of the respective zirconocene with electron-donating MAO molecules.[142] However, a study of the reaction between the zirconocene dichloride derivatives $(C_5H_4SiMe_3)_3ZrCl_2$ or $(t\text{-}BuC_5H_4)_2ZrCl_2$ and MAO in an atmosphere of argon and ethylene using IR spectroscopy, and ^1H, ^{13}C, ^{27}Al, and ^{29}Si NMR [222] showed that the difference in the relative electronic effect from the alkyl groups is comparatively small. Taking into account the complexity of the catalytic system as a whole, it is difficult to accept that it is solely the electronic effect of the substituents in the Cp rings of zirconocenes that has a decisive role in the polymerisation process.

By studying the polymerisation of ethylene on the system $(RC_5H_4)_2ZrCl_2$–MAO, Nekhaeva et al.[221] found that a zirconium compound with an isopropyl substituent had a high activity (A_m), which cannot be due solely to the steric or electronic effect of this substituent

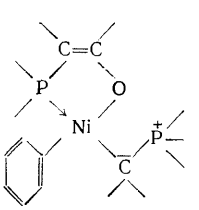
Substituents in Cp ring	H	Et	n-Pr	iso-Pr	$(iso\text{-}Pr)_2$
$A_m \times 10^{-6}$, g PE (mol M)$^{-1}$ h^{-1}	20.6	24.7	11.3	34.1	22.4

One of the factors that governs the high activity of the system with the isopropyl substituent would appear to be the development of hydride sites on the zirconium atom, in whose formation the hydrogen atoms of the α-carbon atom of the substituent participate.

Copolymers of ethylene containing from 1 to 10% of vinylcyclohexane, 4-methyl-1-pentene, and 3-methyl-1-butene were obtained on the same catalysts.[178,194]

Quite recently a very interesting report[223] was published on the use of a homogeneous catalytic system to synthesise polypropylenes with different structures depending on the experimental conditions—from stereoregular crystalline structures to amorphous products which were thermoplastic elastomers. This suggests the possibility of producing from the same hydrocarbon monomer various structural modifications which have a different set of mechanical and industrial properties.

The experimental data examined above show that the use of homogeneous metal-complex catalytic systems for the polymerisation of olefins can be used to obtain polyolefins with different structures. There is no doubt that this area will be developed further and will be extended not only to linear but also to branched higher α-olefins. There is a future for them in resolving the main scientific and practical problem—the directed synthesis of polymer structures with a given set of properties.

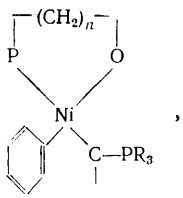


3. Catalysis based on organometallic lanthanide compounds

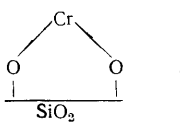
Fairly recently the first studies were published[223–228] on metal-complex catalytic systems containing organic compounds of metals of the lanthanide group, in particular neodymium. Particular attention was given to this question by Chinese research workers[229] who studied the stereospecific polymerisation of the dienes—butadiene and isoprene. Lanthanide catalytic systems have attracted the attention of research workers because of their high stereospecificity and also by the fact that in using them the possibility of oligomers being formed, which usually occurs when polydienes are being prepared in the presence of other metal-complex systems, is excluded. Thus, the absence of oligomers is of considerable importance in the development of an ecologically clean technology for obtaining stereoregular polyisoprene.[230]

Attention has also been drawn[230–233] to the future potential in using such catalytic systems in the polymerisation of α-olefins.[234] Thus the copolymerisation of α-olefins with methyl acrylate on organometallic ytterbium compounds has been reported by Japanese authors.[235,236] This opens up the possibility of carrying out the copolymerisation of olefins with polar monomers, which had previously been virtually impossible because of the "poisoning" of the active sites of the catalyst by the polar monomers.

4. Ylide polymerisation catalysts



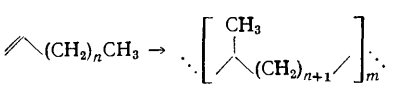
Interesting possibilities for obtaining linear and branched polyethylene are opened up by using recently proposed ylide nickel complexes as catalysts.[156,157,237] It is assumed[238] that in this type of catalyst the following coordinate structural residues occur:



Linear polyethylene has been obtained with the use of this catalyst.

In an alternative method, two successive processes—the oligomerisation of ethylene to oligomeric α-olefins and the subsequent copolymerisation of them with the initial ethylene—can be carried out on the ylide catalyst. In this case LLDPE-type polyethylene is formed.[239] In order to carry out this process, bis(ylido)nickel catalytic systems are used in combination with a heterogeneous chromium catalyst, which function successfully in the absence of aluminium alkyls as co-catalysts.[240] In this residue the nickel complex is immobilised on the chromium catalyst, and a new

active bifunctional catalyst for the polymerisation of ethylene is formed, consisting of two components, one of which causes the oligomerisation reaction and the other causes copolymerisation of the α-olefins (C_6-C_3) formed at the first stage with ethylene:
oligomerisation:



polymerisation:

By controlling the ratio of Ni to Cr and the polymerisation temperature it is possible within certain limits to change the degree of branching of PE and the length of these branches in the desired direction.

Mention should also be made of one nickel catalyst with which a novel type of polymerisation of α-olefins can be carried out. This refers to a homogeneous complex of nickel with a phosphorane ligand — bis(trimethylsilyl)aminobis(trimethylsilylimino) phosphorane.[241] Polymerisation of both linear and branched α-olefins occurs on this catalyst. The structure of the resulting poly(α-olefins) is unusual. It a linear α-olefin participates in polymerisation the polyolefin contains only one methyl branch separated by given segments of the polymer chain:

IV. Emergence of new possibilities for the development of highly effective metal-complex catalytic systems

Above we examined the main areas of metal-complex catalysis of the polymerisation of olefins that have undergone rapid development in recent years. Naturally this review has not covered all of the publications in this area, but from the results that it contains the reader can, in our opinion, form a sufficient idea of the state of this problem.

Nevertheless we thought it necessary in conclusion to draw attention to the future, and from our viewpoint, most fruitful methods of developing metal-complex catalysis in relation to the polymerisation of α-olefins.

Cossee,[242] who attempted to reveal the nature of the active sites of transition metal complexes in the polymerisation of α-olefins, showed how the metal–carbon bond (the alkyl group of α-olefins) is preserved throughout the whole reaction cycle, with the energy losses in the strength of this bond not exceeding 20% and being fully compensated by the formation of a new bond during polymerisation.

The reactions which occur in this manner can legitimately be classed as concerted reactions, which are characterised by a synchronous redistribution of electron density in the bonds, giving rise to low values of the energy of activation.[23,24]

In this respect metal-complex catalysis is similar to enzyme reactions, which also take place via the formation of intermediates and are classed as reactions that occur with a concerted mechanism. A new bond is formed in these reactions at the same time as the destruction of the old one, which helps to stabilise the transition state and accelerates the reaction.

In terms of stereoselectivity and mechanistic action there is also a certain similarity between metal-complex catalysis (in particular the polymerisation of α-olefins) and enzyme catalysis. In both cases the concerted reactions occur under mild conditions, in non-polar solvents, and at high rates. It should be noted here that the high rates that are typical for enzyme reactions have so far not been reached in metal-complex catalysis. It may be assumed that this is due to the fact that the degree of concertedness which occurs in enzyme catalysis has so far been achieved in metal-complex catalysis. It is not excluded that the required degree of concertedness can be achieved through new catalytic systems as well as through the use of reaction equipment which ensures that the reaction occurs only in the kinetic region.

Research and development on catalytic systems containing several transition metals with a different ligand environment should also prove to have future potential.

It is to be expected that new lanthanide metal-complex catalysts will be synthesised for the preparation of copolymers of α-olefins with polar monomers. At the present time only the high-pressure radical copolymerisation of ethylene with vinyl acetate and acrylic monomers is known.

The development of microheterogeneous catalytic systems has future potential. The idea for developing such catalysts is derived from the fact that high-molecular weight compounds in solution that are not cross-linked form threads which comprise macromolecules with a high content of solvent in them. On particles like this that are not cross-linked it is possible to fix in a specific way virtually any transition metal complexes whose active sites are responsible for growth of the polymer chain. Microheterogeneous catalysts are most readily designed in a form that has the greatest resemblance to enzymes. Such microheterogeneous catalysts have already been used with considerable effectiveness in hydrogenation and hydroformylation, for example. However up to the present time there has been no information on the use of such catalysts in polymerisation processes.

Interesting effects can be expected from the use of surfactants in metal-complex catalysis of polymerisation. When present in concentrations above the critical micelle concentration, surfactants are known to have colloidal properties. In a number of cases the rate constants of the reactions that occur with the participation of such micellar solutions of surfactants increase by several orders, which is due to concentration and orientation effects. There is reason to believe that these effects can also be achieved when surfactants are used in the metal-complex catalysis of polymerisation processes. In this case there is the possibility of bringing together the existing methods of ionic coordination polymerisation of olefins and emulsion polymerisation methods. There is the so-called micellar polymerisation catalysis, which in certain cases can be of definite practical interest.

Finally, the use of heterogenised cluster transition metal complexes in the polymerisation of α-olefins is attractive. There is every reason to expect a combination of high effectiveness and the necessary stereospecific action for such catalysts. It is therefore

necessary to bear in mind the possibility of achieving the introduction of microcluster transition metals into zeolites (serving as supports). On the surface the atoms of this type of microcluster have free valence bonds which make these atoms unusually reactive. A systematic investigation of cluster catalysts, including fairly complex physical methods for studying three-dimensional cluster lattices, is required for progress in the use of these catalysts.

It is probable that the trends in extensive scientific research into the improvement of existing methods and the development of fundamentally new methods in the interesting area of metal-complex polymerisation catalysis are not restricted to the examples considered here.
