Compounds of the *f*-elements. Chemical bonding and electronic structure

Z M Sabirov, A A Bagatur'yants
Institute of Chemistry, Bashkir Scientific Centre, Ural Branch of the USSR Academy of Sciences, Ufa
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. Recent data from experimental and theoretical studies of the nature of the chemical bonding in *f*-element compounds and their electronic structure are reviewed. Implicit and explicit methods of accounting for relativistic effects in quantum-chemical calculations are briefly examined. Results of quantum-chemical calculations of lanthanide trihalides, lanthanide and actinide cyclopentadienides, and other *f*-element compounds are analysed. Questions about the electronic and geometric structure, the nature of the π- and σ-bonding, and the role of *d*- and *f*-orbitals in forming chemical bonds are discussed.

The bibliography includes 95 references.

I. Introduction

In the lanthanide (Ce → Lu) and actinide (Th → Lr) series, electrons are placed successively in the 4*f*- and 5*f*-orbitals respectively. Therefore, lanthanides (Lns) and actinides (Ans) are frequently classified together as *f*-elements. The varied and ever expanding application of *f*-element compounds in science and technology has in the last decade stimulated interest in the study of their electronic structure and the nature of their chemical bonding.

Crystal field theory[1,2] has been widely used in the majority of earlier theoretical studies for analysing the electronic structure of Lns and Ans. The reason for this is that the *f*-electrons have features different from those for electrons in other subshells. Thus, the energy levles of the 4*f*-orbitals in Lns are rather close to those of the 5*s*-, 5*p*- and 5*d*-orbitals. However, the 4*f*-states extend little into space and the electrons in them are to a large extent localised inside the 5*s*- and 5*p*-subshells.[3] As a result, 4*f*-orbitals poorly overlap with orbitals of neighbouring atoms and the bonding in Lns is mainly due to 5*s*- and 5*p*-electrons, i.e., it is nearly purely ionic. Analogous arguments for the role of the *f*-electrons were made for actinide compounds.

However, the majority of recent studies on the electronic structure of *f*-compounds have utilised molecular-orbital (MO) methods owing to the obvious limitation of crystal field theory for describing *f*-compounds.[3] Such an approach significantly facilitates development of general concepts about the chemical bonding in compounds with *f*-electrons. Previous reports[3–8] are recommended for familiarising oneself with the current state of affairs in this area. Moreover, these references contain numerous citations to earlier reviews and reports on the respective topics.

Hence, the capabilities of quantum-chemical cluster models and methods of describing various characteristics of the electronic structure of solids based on the *f*-elements have been explored.[3,4] In these studies, special attention was paid to the orderly statement of the basic principles of the cluster approach for modelling the electronic structure of solids and the quantum-chemical approaches used in cluster calculations. The nature of interatomic interactions and the role of *f*-subshells in chemical bonding were analysed in detail.

Quantum-chemical calculations of atoms, ions and actinide molecules have been generalised and systematised in a monograph.[5] Features of the electronic structure of 5*f*-elements, the stability of the different An oxidation states, and the analogy between Lns and Ans were analysed. Isomer shifts in Mössbauer spectra were interpreted. The relative role of various mechanisms in forming chemical bonds and the influence of relativistic effects on the properties of Lns and Ans were the subjects of much attention.

The periodic (tetrad) regularity in the change of many properties of the free atoms and ions of the *f*-elements (ionisation potential, electron affinity, redox potentials, etc.) have been analysed.[6]

Relativistic effects in structural chemistry have been reviewed.[7,8] These reviews contain the most detailed information on this subject. A short but rather complete analysis of the relativistic methods of quantum chemistry that are used for calculating the electronic structure of compounds containing heavy elements is also provided.

However, it is noteworthy that few studies analyse the electronic structure of *f*-compounds within the framework of MO methods. Calculations for rather large molecular systems of interest to chemists are just beginning. Consequently, fundamental questions about the features and details of the electronic structure (participation of various groups of electrons in the chemical bonding, specific role of *f*-subshells, relation of the reactivity of *f*-compounds to their electronic structure, etc.) are far from finally resolved.

In the present review, recent results are reviewed and analysed. These have not appeared previously in monographs and reviews and are mainly theoretical studies of the fundamental chemical properties of *f*-element organometallic compounds: their electronic and geometric structure and their reactivity.

Results are also presented for calculations of the electronic and geometric structure of lanthanide trihalides (LnX_3). This material is placed in a separate section since LnX_3 have been a test case of the *f*-block for verifying the capabilities of many quantum-chemical methods.

Methodical problems related to the study of the electronic structure of the *f*-elements should also be noted. As the atomic number of an element increases (nuclear charge Z), the total and

kinetic energy of the electrons increases. For heavy elements, in particular the Lns and even more the Ans, relativistic corrections become important [these are of the order of $(v/c)^2$, where v is the velocity of the electrons and c is the speed of light]. Therefore, the role of relativistic effects and explicit and implicit methods of accounting for them in quantum-chemical calculations must be discussed, although briefly.

II. Relativistic quantum chemistry

The majority of quantum-chemical calculations of interest to chemists are based on the solution of the nonrelativistic Schrödinger equation, the Hamiltonian of which is constructed assuming that the interaction of electrons does not depend on their velocity. The relativistic dependence of the rest mass of particles on velocity is also ignored. These approximations formally correspond to an infinite speed of light. Such calculations are suitable, for example, for approximating the total energy or wave functions of light atoms or molecules consisting of them. The Schrödinger Hamiltonian is unsuitable for describing the finer details of electronic structure. The special structure of a multi-electron atom cannot be even qualitatively described using a nonrelativistic approximation.[9]

The relativistic analogue of the one-electron Schrödinger equation is the Dirac equation. The principal difference between them is that the dependence of the electron mass on its velocity is considered in the relativistic kinetic energy operator. This produces 4 × 4 matrices in the Hamiltonian instead of the usual scalar operators. The solutions of the Dirac equation are four-component wave functions.

Additional difficulties arise on going to multi-electron atoms and molecules. For instance, a complete (conclusive) relativistic theory of electron–electron interaction does not exist. One of the fundamental difficulties is that particles can be generated or absorbed owing to the equivalency of energy and mass. This can occur every time when energy equal to or greater than the rest energy of these particles is transferred during their interaction.[11] The destruction of particles can be systematically accounted for only within the framework of the quantised field concept whereas quantum field theory has its own difficulties and unsolved problems.

Therefore, relativistic effects are accounted for in the majority of cases using approximate Dirac or Dirac–Breit Hamiltonians.[7,8,12] Electron–electron interaction in the first of these is described by the usual nonrelativistic expression. In the second, a relativistic correction (of the order of α^2, where $\alpha = e^2/hc$ is a fine structure constant) to the two electron-interaction, first obtained by Breit, is considered.

Very complicated and long equations must be solved to account for relativistic effects within the framework of the MO LCAO method owing to the appearance of four-component wave functions. Fortunately, only outer valence electrons participate directly in chemical bond formation in the majority of cases. The so-called quasirelativistic approximation is entirely applicable to these. Relativistic effects in this approximation are accounted for to the accuracy given by the $(v/c)^2$ terms.[13]

It is convenient to transform the relativistic Hamiltonian of the multi-electron atom to a form where its nonrelativistic part is clearly separated in order to follow in more detail the relative role and physical meaning of relativistic effects.[14,15] After such a transformation using the Pauli approximation (accounting for terms up to α^2) and in the absence of external magnetic and electric fields, the relativistic Hamiltonian H can be written[8]

$$H = H_0 + H_D + H_{mv} + H_{so},$$

where H_0 is the nonrelativistic Hamiltonian, H_D is the correction for Darwin interaction (the Darwin term has no classical interpretation), H_{mv} is a correction to the kinetic energy accounting for the dependence of particle masses on their velocity, and H_{so} is a correction for spin–orbit coupling.

The correction H_{mv}, which accounts for the dependence of particle masses on their velocity, causes a relativistic contraction of orbitals. This is most noticeable for inner 1*s*- and 2*s*-electrons moving at large velocities.[5,7,8] The inner *p*-orbitals contact to a smaller extent. Owing to the relativistic contraciton of *s*- and *p*-orbitals, electrons in them more effectively screen the nuclear charge. Electrons in *d*- and *f*-orbitals are more weakly attracted to the nucleus. As a result, the *d*- and *f*-orbitals become more diffuse and energetically destabilised (energy levels shift upward relative to their nonrelativistic values).

The correction for spin–orbit coupling H_{so} causes levels to split into sublevels corresponding to different values of total momentum $j = l \pm 1/2$ (l is the orbital moment). Thus, the *p*-level splits into $p_{1/2}$- and $p_{3/2}$-sublevels; the *d*-level, into $d_{3/2}$- and $d_{5/2}$-sublevels, etc.

These relativistic corrections are essential and have a significant influence on the electronic properties of heavy atoms and molecules containing heavy atoms. For example, the lanthanide contraction (decrease of ionic radius on going from La to Lu), which is usually related to incomplete screening of the nuclear charge by 4*f*-electrons, is to a certain degree due to a relativistic effect. A comparison of atomic calculations by Hartree–Fock (nonrelativistic) and Dirac–Fock (relativistic) methods revealed that the lanthanide contraction is 27% due to a relativistic effect.[8,16]

Various quantum-chemical relativistic and quasirelativistic methods for calculating the electronic structure of atomic and molecular systems have been described.[3–5,7,8,16–23] Therefore, we will briefly discuss only those methods that have been used in subsequent studies.

Calculations based on the quasirelativistic or relativistic extended Hückel and *X*α-scattered wave (*X*α-SW) or *X*α-discrete variational (*X*α-DV) methods have been most widely used.

A local approximation for the exchange-correlation potential is used in the *X*α methods. This produces a one-electron Hartree–Fock–Slater equation.[24] There are two methods for solving this equation, which are reflected in their names: *X*α-DV and *X*α-SW.[25,26] Incorporating relativistic corrections does not significantly change the calculation structure of these methods. Relativistic effects have been accounted for within the framework of the *X*α-DV method.[27,28] Relativistic[29,30] and quasirelativistic[31] *X*α-SW methods have been developed. It is noteworthy that *X*α-methods have been successfully employed to interpret photoelectron spectra.

The Hamiltonian is not examined in an explicit form in the relativistically parametrised extended Hückel method,[32–36] like in the nonrelativistic method. The diagonal matrix elements of the effective one-electron Hamiltonian H_{ii} are usually set equal to the orbital energies that are either estimated from experiment or are taken from Dirac–Fock atomic calculations.[37] The off-diagonal elements H_{ij} are estimated using the standard Wolfsberg–Helmholtz formula.

In the quasirelativistic extended Hückel method,[38,39] the usual (quasirelativistic) atomic functions (*p*-, *d*- and *f*-) are used. These are obtained from relativistic ($f_{7/2}$, $f_{5/2}$, $d_{5/2}$, $d_{3/2}$, $p_{3/2}$ and $p_{1/2}$) functions by using the weighted average of each multiplet. This enables such relativistic effects as the relativistic contraction of atomic *s*- and *p*-orbitals and the increased diffuseness of the *d*- and *f*-orbitals in addition to the average shift of the energy levels to be explicitly accounted for. The spin-orbit splitting of the levels and the difference in diffuseness of the two multiplets of the *p*-, *d*- and *f*-orbitals remain unaccounted for. It is proposed that the last two factors have little effect on such properties as the geometry and reactivity.

The principal merit of the extended Hückel method is the complete accounting for overlap intergrals. This enables wave functions with the correct normalisation to be obtained and exchange repulsion effects of filled shells to be qualitatively correctly described. This is very important in describing the structure of complexes. Drawbacks of the extended Hückel method are connected with the lack of accounting for electron-electron interaction, with approximation of the total energy of all orbital energies, and with problems in constructing a satisfactory approximation for the off-diagonal matrix elements H_{ij}. Therefore, this method was very useful for describing conformational effects and other properties that can be interpreted by orbital-energy correlation diagrams. However, it is in general unsuitable for describing the formation and dissociation of chemical bonds and does not treat electrostatic effects.[40]

Naturally, each of the listed methods has its advantages and shortcomings, enables with a different degree of accuracy calculation of the electronic structure, and considers relativistic effects in calculations. Results of various calculations of gaseous LnX_3 are compared in the following section as an illustration of the capabilities of these methods.

III. Lanthanide trihalides

One of the first studies of the nature of the bonding and geometric features of LnX_3 (in the vapour phase) was carried out using the nonrelativistic extended Hückel method (4*f*-orbitals were not included in the valence basis set).[41] The effect of 4*f*-electrons was considered indirectly in the choice of the empirical parameters (the values of the diagonal elements H_{ii}). The most important result of the calculations was the conclusion that a pyramidal structure for these molecules represents the minimum in total energy. An orbital-correlation analysis demonstrated that such a structure enables the optimum interaction between the metal *d*-orbitals (especially d_{z^2}) and the halide *p*-orbitals. The calculated charge on the metal in LaX_3 is much less than +3: +1.10 for LaF_3, +0.66 for $LaCl_3$, +0.54 for $LaBr_3$, and +0.38 for LaI_3. Therefore, these data suggest that the bond in LaX_3 is not purely ionic even for the fluorides and that the covalency increases down the halogen series (F → I).

The structures of LnX_3 have been analysed by the Wolfsberg–Helmholtz method.[42] This is a variation of the extended Hückel method and includes an additional self-consistency procedure for atomic charges. Low-lying excited states of LnX_3 were studied in this work. The transition energies from *f*- to *d*-levels were estimated. A total of 56 molecules were examined. The results obtained (orbital energies, transition energies, atomic charges, etc.) provided a basis for choosing promising molecules for fabrication of new gas lasers.

The electronic structures of MI_3 (M = La, Gd, Lu)[33] have been calculated by the relativistically parametrised extended Hückel method. The experimental data reveal that MI_3 are polar and that a nonplanar structure (pyramidal) represents the minimum in total energy.

The most detailed and thorough of the electronic structures of LnX_3 has been carried out by Ruscic et al.[43] They studied photoelectron spectra (using He I and He II excitation sources) of $LaCl_3$, $LaBr_3$, $CeBr_3$, $NdBr_3$, $LuBr_3$, LaI_3, CeI_3, NdI_3, ErI_3 and LuI_3. The electronic structure of all compounds was calculated by the relativistic $X\alpha$-DV method. An analysis of the results obtained, taking into account literature data for the photoelectron spectra of Ln fluorides and chlorides in addition to mass spectra, demonstrated that the SCF-$X\alpha$ method correctly reproduces the experimental features of the spectra. Regularities found experimentally in the change of the nature of the bonding, the ionisation potentials, and the valence band widths in both the Lns (La → Lu) and the halides (F → I) are discussed.

It has been found[43] that the ionisation energies of the 4*f*-orbitals of light(early) Lns are less than those of the ligand *p*-orbitals. These energies are comparable for the middle Lns. For the heavy (late) Lns, the energies of the 4*f*-electrons decrease so much that they act like core electrons. Although the ionisation energies of the Ln 4*f*-orbitals for the majority of LnX_3 are very close to those of the halide valence orbitals, nevertheless, the 4*f*-orbitals interact very weakly with the halide orbitals. The reason for this is that the 4*f*-electons of the Lns and the valence electrons of the halides are localised in physically separated regions of the molecule. Therefore, the overlap of the respective orbitals is very poor. The corresponding radii of maximal electron density can be used as a measure of the localisation of the Ln orbitals. For the principal component of the $4f_{7/2}$-orbital, the radial electron density is maximal at $r \sim 0.4$ Å for $La^{+1.5}$ and $r \sim 0.3$ Å for $Lu^{+1.01}$ (r is the distance from the nucleus) whereas the maxima for the $5d_{5/2}$-, $6p_{3/2}$-, and 6*s*-orbitals are reached at r = 1.22, 2.27 and 1.89 Å, respectively. Moreover, the electron density in the 4*f*-states is mainly concentrated in the narrow region between 0.2 and 0.7 Å. Such localisation ensures that the 4*f*-orbitals will have a very low chemical activity.

Theoretical and experimental data indicate that the bonding in LnF_3 is primarily ionic ($Ln^{+2.2}$). A more covalent nature is acquired on going to the chlorides ($Ln^{+1.6}$), bromides ($Ln^{+1.3}$) and iodides ($Ln^{+1.01}$). As already demonstrated above, the reason for the highly ionic bonds in the fluorides is the poor overlap between the halide and metal orbitals. The covalency increases primarily as a result of the involvement of 5*d*-, 6*p*- and 6*s*-orbitals. This is confirmed by an analysis of the corresponding overlap integrals between the orbitals and the outer *p*-orbitals of the halides.

The ground state, only La, Ce, Gd and Lu atoms have the electronic configuration $4f^n5d6s^2$. This corresponds to trivalent Lns in organometallic compounds where on 5*d*- and two 6*s*-electrons participate in the bonding. The electronic configuration of other Ln atoms in the ground state does not include the *d*-level. The energy ΔE must be lost in promoting an electron from the 4*f*- to the 5*d*-level (the $4f^n6s^2 \rightarrow 4f^{n-1}5d6s^2$ transition) and convering these Lns to the trivalent state. Naturally, it is expected (under otherwise equal conditions) that as the energy ΔE that must be lost increases, the energy subsequently gained in bond formation decreases. This is confirmed by the fact that the enthalpy change for atomisation of

LnX_3 and lanthanide monoxides correlates with the energy change of the $4f^n6s^2 \rightarrow 4f^{n-1}5d6s^2$ transition in the Ln series.[43,44]

It has been found[43] that the dissociation energy of La, Ce, Gd and Lu monoxides (i.e., Lns that have a populated *d*-level in the atomic ground state) into the atoms (E_d^*, kcal mole^{-1}) decreases smoothly with increasing atomic number according to the law $E_d^* = 190.6 - 3.75N + 0.094N^2$, where $N = Z$(atomic number) $- 57$. In this instance, the change in lanthanide monoxide dissociation energies along the whole series La → Lu should be described by the equation $E_d(N) = E_d^*(N) - \Delta E(N)$, where $\Delta E(N)$ is the energy of the $4f^n6s^2 \rightarrow 4f^{n-1}5d6s^2$ transition for Ln atoms that do not have a populated 5*d*-level in the ground state. The E_d values calculated in this manner[44] correctly describe the experimentally observed double periodicity in the change of dissociation energy of lanthanide monoxides (Fig. 1).

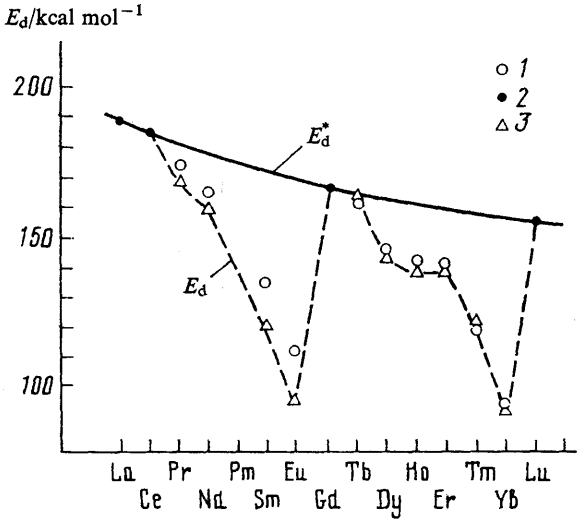

Figure 1. Change of lanthanide monoxide dissociation energy as a function of atomic number.[44] Experimental data (*1*), experimental data used to construct the dependence of E_d^* on N (*2*), calculated E_d (*3*).

The data plotted in Fig. 2 [43] demonstrate an analogous periodicity in the change of enthalpy of atomisation for LnX_3.

It is noteworthy that the average bond energy Ln–X (X is a halide) decreases on going from F to I. Hence, the average enthalpy of atomisation of LnF_3, $LnF_3(g) \rightarrow Ln(g) + 3F(g)$, is about 420 kcal mol^{-1}. Consequently, the Ln–F bond energy is 140 kcal mol^{-1}.[43] The corresponding values for $LnCl_3$ are 325 and 108 kcal mol^{-1}; for $LnBr_3$, 290 and 97 kcal mol^{-1}; and for LnI_3, 228 and 76 kcal mol^{-1}.[43] The conclusion is also reached that electrostatic forces provide the principal contributions to the bonding although the positive charges on the Ln ions is always much less than three. This occurs since the overlap integrals between the atomic orbitals of the Lns and halides (which can be viewed as a measure of the covalency) are very small.

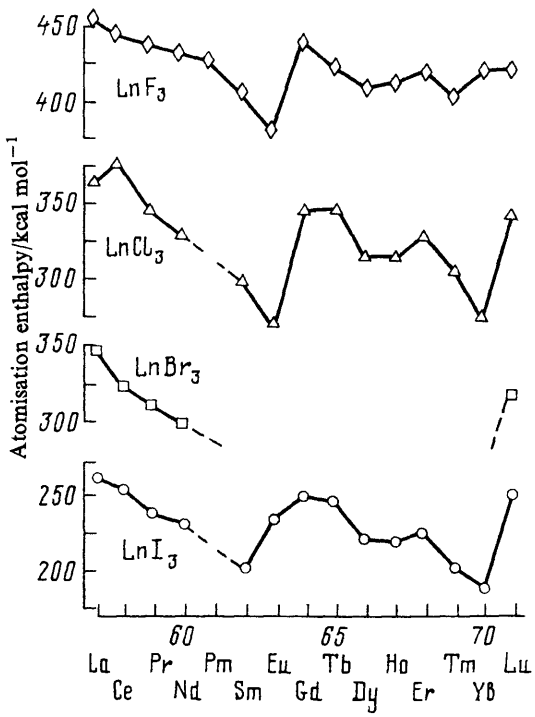

Figure 2. Dissociation enthalpy of LnX_3 into free atoms as a function of Ln atomic number.[43]

Spin-orbit splitting of filled valence and core levels in LnX_3 has been studied.[45] Calculations were made using the relativistically parametrised extended Hückel method. A total of 60 LnX_3 molecules were examined, where X = F → I and Ln = La → Lu. The geometric structure was selected to be the same as in previous studies[43] in order to facilitate comparison with results obtained by the $X\alpha$-DV method. The following basic principles were found. On going from F to I, the positions of the *p*-orbital energy levels of the halides X(*np*) are raised and the width of the valence band (the difference between the highest and lowest energy levels of these orbitals) increases from 1.2 to 2.8 eV. The latter agrees well with photoelectron spectra for La, Gd and Lu trihalides. The width of the X(*ns*)-level band changes from 0.25 to 1.0 eV. The ligand-field splitting of the Ln($5p_{3/2}$)-levels is small [from 0.25 (La) to 0.75 eV (Lu)] compared with the spin-orbit splitting $p_{3/2} - p_{1/2}$, which increases on going from La to Lu from 2.73 to 7.29 eV. On going from F to I and from La to Lu, the splitting of the $5p_{3/2}$-levels decreases. The spin-orbit splitting of the $4f_{7/2}$- and $4f_{5/2}$-levels agrees well with the experimental values obtained for GdX_3 and LuX_3. The charges on the Ln atoms (calculated according to Mulliken) in LnX_3 decrease on going from F to I. The values for LuX_3 are 2.82 (F), 2.37 (Cl), 2.31 (Br) and 2.01 (I). These changes in the charges occur in concert with the decrease of ionisation energy of the 4*f*-electrons and reflect the increasing population of the 6*s*- and 5*d*-orbitals of the Ln. Thus, the orbital charges for LuX_3, where X = F, Cl, Br, and I, are 0.029, 0.156, 0.168 and 0.245 for 6*s*; 0.070, 0.196, 0.220 and 0.326 for $5d_{3/2}$; and 0.090, 0.284, 0.307 and 0.424 for $5d_{5/2}$-orbitals, respectively.

Nonrelativistic nonempirical *ab initio* calculations on LaH_3, LaF_3 and $LaCl_3$ using the program GAUSSIAN-82[45] were also carried out in order to refine further the geometric structures of LnX_3. It was found that the pyramidal C_{3v}-structure is energetically favorable for LaH_3 and LaF_3 whereas the total energy minimum for $LaCl_3$ corresponds to the planar D_{3h}-structure (Table 1).

Table 1. Equilibrium geometric structure parameters of planar (D_{3h}) and pyramidal (C_{3v}) LaX_3.[45]

Molecule	Symmetry	La–X bond length, Å	X–La–X angle, deg	ΔE^*, cm^{-1}
LaH_3	C_{3v}	2.129	114.7	239
	D_{3h}	2.137	120.0	
LaF_3	C_{3v}	2.080	112.0	921
	D_{3h}	2.089	120.0	
$LaCl_3$	C_{3v}	2.613	112.0	−381
	D_{3h}	2.623	120.0	

*$\Delta E = E(D_{3h}) - E(C_{3v})$ is the difference of total energies.

Table 2. Geometric structure and ionisation potential of $LnCl_3$.[47]

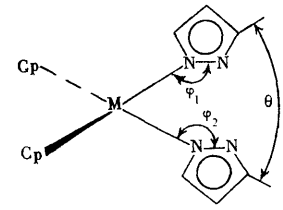
The structures of LnX_3 have also been analysed by the INDO method. The electronic structure of LnF_3 has been studied.[46] It was found that the 4*f*-orbitals of Ln atoms have almost no contribution to bond formation. The covalent bonding between Ln and F is mainly due to the Ln 5*d*-, and to a lesser extent, the 6*s*- and 6*p*-orbitals.

Other results[47] demonstrate that the INDO calculations reproduce well the geometric structure and ionisation potentials of LnX_3 (Table 2). The pyramidal structure is energetically favourable (i.e., corresponds to the total energy minimum). It was demonstrated that the *f*-orbitals contribute little to the bonding. Nevertheless, the calculated Ln–Cl bond lengths agree better with the experimental values if the *f*-orbitals are included in the calculations.

Therefore, results of quantum-chemical calculations using various methods suggests, firstly, that the bonding in LnX_3 is purely ionic even for such molecules as LnF_3. The covalency of the Ln–X bond increases in the order F → I. The principal contribution to the covalency comes from the Ln 5*d*-, and to a lesser extent, the 6*s*- and 6*p*-orbitals.

Secondly, the majority of LnX_3 in the vapour phase have a pyramidal structure. It is possible that this is a consequence of the participation of 5*d*-orbitals in the chemical bonding. However, a clear link between the pyramidal structure of LnX_3 and the degree of covalency of the Ln–X bond in them has not been established. It is noteworthy that spectral and electron-diffraction investigations are also consistent with a pyramidal structure for LnX_3.[48]



Thirdly, the change of Ln–X bond dissociation energy in LnX_3 correlates with the change of $4f^n6s^2 \rightarrow 4f^{n-1}5d6s^2$ transition energy in the Ln series. This means that the mutual position of the 4*f*- and 5*d*-levels can significantly affect the reactivity of the nascent bond although the 4*f*-orbitals themselves participate little in the bonding.

Fourthly, it is interesting that all calculational methods give results that mainly agree with each other and experiment.

IV. Cyclopentadienyl derivatives of lanthanides and actinides

The most intriguing structural feature of An biscyclopentadienides is that certain $Cp^*_2AnL_2$ [Cp* = pentamethylcyclopentadiene, L = η^2-pyrazolyl (pz), η^2-acyl, etc.] have a 20-electron configuration (considering the total number of valency electrons that is obtained by adding the number of electrons donated by the ligands to the formal number of metals *d*-electrons). However, the majority of transition metal complexes obey the 18-electron rule.[39] Examples of the 20-electron compounds are $Cp^*_2U(\eta^2\text{-pz})_2$,[49] $Cp_2U(acac)_2$,[50] $Cp_2U[O_2C_2CHPMePh_2Fe_2Cp_2(CO)_2]_2$,[51] $Cp^*_2An(\eta^2\text{-COR})_2$ and $Cp^*_2An(\eta^2\text{-CONR}_2)_2$.[52] In particular, the ligands pz^-, COR^- and $CONR_2^-$ can coordinate using one atom (η^1-coordination) or two (η^2-coordination). In the first instance, they act as 2-electron donors; in the second, as 4-electron. The reasons causing such behaviour of the ligands have been analysed in a series of studies.[38,39,53–59] using the quasirelativistic extended Hückel method. In addition, other structural featurs of Th and U biscyclopentadienides were studied.

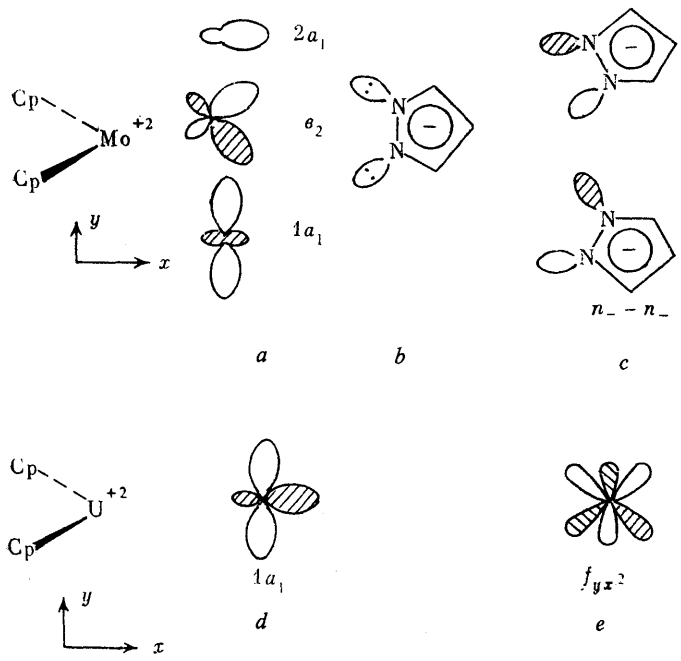
Three compounds, $Cp_2Mo(pz)_2$, $Cp_2Mo(pz)_2^{2+}$ and $Cp_2U(pz)_2$ (the metal atom in the first molecule has the d^2-electron configuration; in the second d^0), have been examined in order to study the differences in the electronic structure of complexes of *d*-transition metals and Ans.[39] The potential energy surface for these model complexes was calculated as a function of the angles M–N–N and pz–M–pz (angles φ_1, φ_2, and θ).

(I)

The total energy minimum for $Cp_2Mo(pz)_2$ corresponds to the structure with $\eta^1-\eta^1$-coordination of the pyrazoles ($\varphi_1 = \varphi_2 = 128°$, $\theta = 52.5°$). Such structure conforms to the 18-electron rule. The structures with $\eta^1-\eta^2$- and $\eta^2-\eta^2$-coordination of 20- and 22-electron configuration were found to be less stable. On going from the d^2- to the d^0-configuration [i.e., to $Cp_2Mo(pz)_2^{2+}$], the complex with $\eta^1-\eta^2$-coordination becomes more stable. The deficiency of electrons owing to the decreased number of *d*-electrons is reasonably compensated for by η^2-coordination of one of the pz ligands. Thus, the 18-electron rule is again obeyed.

The U complex (in addition to the Th) $Cp_2U(pz)_2$ is ostensibly an analogue of $Cp_2Mo(pz)_2^{2+}$ in the sense that both formally have the d^0-configuration. Nevertheless, the optimal coordination of the pz ligands for them is complete different. Calculations demonstrated that the total energy minimum corresponds to the complex with $\eta^2-\eta^2$-coordination ($\varphi_1 = \varphi_2 = 73°$, $\theta = 113°$). The surprising agreement of these results with the X-ray structure ($\varphi_1 = 75.4°$, $\varphi_2 = 75.1°$ and $\theta = 112.2°$) should be noted.

The geometric structure of these complexes can be understood by analysing the interaction of the frontier orbitals of the fragments. There are three low-energy *d*- and *sp*-hybrid orbitals in the Cp_2Mo^{2+} fragment (Fig. 3*a*). These are the $2a_1$, b_2, and $1a_1$ orbitals. Each pz^- ligand has two orbitals occupied by unshared electron pairs of the N atoms (Fig. 3*b*).



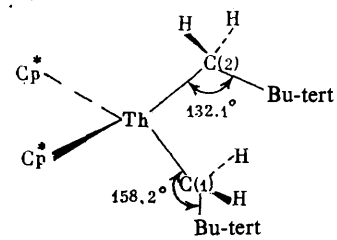


Figure 3. Structure of frontier orbitals of fragments in $cp_2M(pz)_2$ (M = Mo, U). For explanation, see the text.

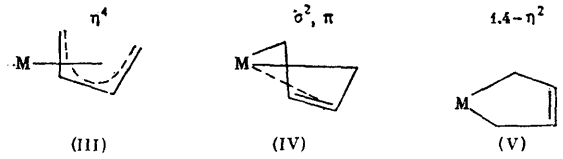
For the d^2-configuration of Mo, the vacant $2a_1$- and b_2-orbitals of the Cp_2Mo^{2+} fragment interact with one orbital of each pz^- ligand forming the $\eta^1-\eta^1$-coordination. The filled $1a_1$ orbital does not participate in the bonding. For the d^0-configuration, the $1a_1$-orbital can also participate in the bonding. As a result, the structure with $\eta^1-\eta^2$-coordination becomes energetically favorable. The structure with $\eta^2-\eta^2$-coordination always remains energetically unfavorable since the orbitals of the Cp_2Mo^{2+} fragment interact (overlap) poorly with the $(n_- - n_-)$-orbital (Fig. 3*c*), which forms if two pz^- ligands are simulaneously η^2-coordinated.

The Cp_2U^{2+} fragment also has vacant $2a_1$-, b_2- and $1a_1$-orbitals. However, they lie at much higher energy and are more diffuse than the frontier orbitals of Cp_2Mo^{2+}. The shape of the $1a_1$-orbital of Cp_2U^{2+} is different (Fig. 3*d*) from that of Cp_2Mo^{2+}. The components of this orbital for Cp_2U^{2+} along the *x* and *y* axes are about equal whereas the $1a_1$-orbital in Cp_2Mo^{2+} has a shape very close to the pure d_{z^2}-atomic orbital. Another feature is the presence of a vacant f_{yx^2}-orbital for U (Fig. 3*e*) that has the proper symmetry for good overlap with the $(n_- - n_-)$-orbital of two pz^- ligands. Taken together, these features cause the total energy minimum to correspond (i.e., to be energetically favorable) to the $Cp_2U(pz)_2$ complex with $\eta^2-\eta^2$-coordination.

It was also found that these differences in the frontier orbitals affect the structure of $Cp_2M(COR)_2$ and $Cp_2M(CONR_2)_2$, where M = Ti and U.[39,54,56–58] A search for the total energy minimum demonstrated that $\eta^2-\eta^2$-coordination is energetically favorable for M = U whereas $\eta^1-\eta^2$-coordination occurs for M = Ti. In this instance, interaction between donor orbitals of the acyl groups (RC=O) and *f*-orbitals of the An significantly stabilise $\eta^2-\eta^2$-coordination. It is noteworthy that these conditions were also fruitful in understanding the unique reactivity of η^2-coordinated acyl ligands in biscyclopentadienides that is due to the presence of low-lying (in energy) carbene-like acceptor orbitals.[39,57]

The effect of Cp_2An^{2+} (where An = Th) frontier orbitals is evident in the unusual structure of $Cp_2Th(CH_2Bu\text{-}tert)_2$ (II). According to neutron-diffraction data, the angle Th–C(1)–C(alkyl) is 158.2° whereas the other analogous angle Th–C(2)–C is 132.1°.[39,60]



(II)

The quasirelativistic extended Hückel method has been used[39,59] to calculate the potential energy curve for rotation of the ethyl group in Cp_2ThEt_2. The curve was found to be very gently sloped with a shallow minimum at $\alpha = 160°$. An analysis demonstrated that the ethyl group remains strongly bound to the Th in spite of the large deformation (large α). The calculated populations of the overlapping orbitals of the perturbed ethyl group forming the Th–C bond are even slightly greater than those of the unperturbed one. This agrees with the experimentally observed geometric structure of $Cp_2Th(CH_2\text{-}tert)_2$.

Other interesting examples demonstrating the influence of electronic structure on geometric structure are the 1,3-diene complexes $Cp_2M(C_4H_6)$ (where M = Zr and Th). The diene $Cp_2Zr(C_4H_6)$ is known to be able to adopt both the *s-cis*- and *s-trans*-configurations. For example, two geometric isomers of $Cp_2Zr(C_4H_6)$ coexist in solution at 25 °C in the ratio *s-cis*/*s-trans* = 55/45.[61] The *trans* structure becomes more preferred if the terminal

H atoms are replaced by Me- or Ph-groups. The dienes in the isolated An complexes $Cp^*_2Th(C_4H_6)$, $Cp^*_2U(C_4H_6)$, $Cp^*_2Th(CH_2.CMeCMeCH_2)$ and $Cp^*_2Th(CPhHCHCHCPhH)$ have exclusively the *s-cis*-configuration.[38,62,63] Furthermore, whereas low-temperature irradiation of $Cp_2M(s\text{-}cis\text{-}C_4H_6)$ (M = Zr and Hf) leads to formation of the *trans* complexes, such *cis*–*trans* isomerisation is not observed for the analogous Th complex.

The ligand *cis*-butadiene can in principle be bonded to the metal in various ways: by η^4- (III); σ^2,π- (IV); and 1,4-η^2-coordination (V).

(III) (IV) (V)

For example, η^4-coordination is found in $Fe(CO)_3(C_4H_6)$ whereas σ^2,π-coordination (IV) is dominant in complexes of Group IV and V metals. According to X-ray structure analysis, σ^2,π-coordination occurs in Th complexes of butadiene.

Factors determining the preference of butadiene for *s-cis*-coordination in $Cp_2An(C_4H_6)$ (An = U and Th) have been investigated.[38] The total energies of the isomeric forms of the model An complexes $Cp_2An(s\text{-}cis\text{-}C_4H_6)$ (Fig. 4*a*) and $Cp_2An(s\text{-}trans\text{-}C_4H_6)$ (Fig. 4*b*) as functions of the variables L, θ and φ were calculated by the quasirelativistic extended Hückel method.

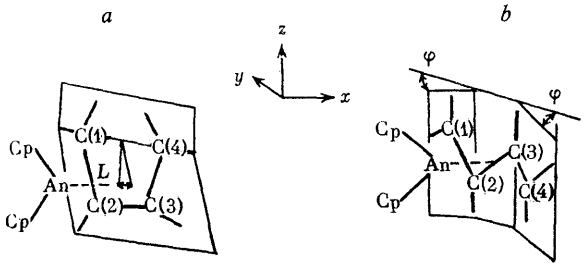


Figure 4. Structure of two isomeric $Cp_2An(C_4H_6)$: *s-cis* (*a*) and *s-trans* (*b*).[38] The variable describes the movement of butadiene as a whole along the *x* axis. The angle θ describes rotation of the molecule around the axis passing through atoms C(1) and C(4). The variable φ (only for the *trans* isomer) characterises the synchronous movement of the two terminal methyl groups toward the metal.

It was found that *s-cis*-coordination is in fact energetically more favourable in the An complex. The corresponding ΔE is 0.74 eV for $Cp_2Th(C_4H_6)$ and 0.42 V for $Cp_2U(C_4H_6)$. The values L and θ for the equilibrium structure are consistent with σ^2,π-coordination of *cis*-butadiene to the An. The experimental data are also consistent with this structure. Calculations for the Zr complexes[38,64] indicate that the total energy for $Cp_2Zr(s\text{-}cis\text{-}C_4H_6)$ is more favourable by 0.07 eV than that for $Cp_2Zr(s\text{-}trans\text{-}C_4H_6)$. As in the examples examined above, such a difference between the An and Zr complexes is due to the difference in the structure of the frontier $1a_1$-orbital of Cp_2M^{2+} (M = Zr, U and Th) in addition to the participation of U and Th 5*f*-orbitals in the bonding.

The butadiene molecule has four π-orbitals (π_1, π_2, π^*_3, π^*_4). It has been demonstrated[38] that the bonding Th–π^*_3MO in $Cp_2Th(s\text{-}cis\text{-}C_4H_6)$ contains contributions from the *d*- (16%) and *f*-orbitals (17%) of Th. These orbitals also contribute to the Th–π_2MO at 13 and 2% respectively. Uranium bonds to butadiene in an analogous manner, but there is a slight difference. In the U complex, the 5*f*-orbitals are more involved in the bonding whereas the contribution from the *d*-orbitals decreases. Thus, the bonding U–π^*_3MO is composed of 6 and 48% of U *d*- and *f*-orbitals, respectively.[38]

An important feature of the electronic structure of $Cp_2Th(s\text{-}cis\text{-}C_4H_6)$ is the greater overlap between Th and the terminal C(1) compared with that of the Th–C(2) bond (Table 3). This population difference (ΔP) can serve as an index indicating the preference for one mode of diene coordination or another. The data of Table 3 clearly show that the diene has σ^2,π-coordination in $Cp_2Th(s\text{-}cis\text{-}C_4H_6)$. The value ΔP decreases little on going from Zr to Th. However, it remains larger in both cases than in $Fe(CO)_3(C_4H_6)$. This agrees with experimental data indicating that η^4-coordination occurs in $Fe(CO)_3(C_4H_6)$.

For *s-trans*-coordination, the interaction Th–π^*_3 is weaker and the energy level of this orbital is 0.23 eV higher than for $Cp_2Th(s\text{-}cis\text{-}C_4H_6)$. This is the reason for the relative instability of $Cp_2Th(s\text{-}trans\text{-}C_4H_6)$.

In contrast with the An complexes, the interactions Zr–π^*_3 in $Cp_2Zr(s\text{-}cis\text{-}C_4H_6)$ and $Cp_2Zr(s\text{-}trans\text{-}C_4H_6)$ are approximately equal. This determines the approximate equal total energies of these complexes.

The electronic structure of U biscyclopentadienides with other ligands is also interesting. Calculations for Cp_2UMe_2 and Cp_2UCl_2 by the $X\alpha$-SW method with relatistic corrections[65] demonstrated that the U 5*f*- and 6*d*-orbitals contribute noticeably to the U–Cp bonds. It was found that the highest occupied molecular orbital in both complexes has almost pure 5*f*-character. The ionisation potentials calculated using the transition-state formalism agree well with expermental data even when spin–orbit coupling is ignored.

Photoelectron spectra of gaseous complexes Cp_2UL_2 (L = BH_4, NEt_2, OCBu-tert, S_2CNEt_2) have been investigated.[66] It was found that the first ionisation potential always correspond to removal of *f*-electrons. For L = NEt_2, the next occupied (after the 5*f*-orbitals) MO is almost purely the atomic 2*p*-orbital of N (with an unshared electron pair). For the other compounds, the next occupied MO is the π-orbital of the Cp ligands. Such a result is consistent with the high reactivity of amidocomplexes relative, for example, to molecules containing polar double bonds and with the smaller lability of the U–Cp bonds in this complex compared with other Cp_2UL_2 complexes.

Data also exist for the electronic structure of Ln biscyclopentadienides. The electronic structure and the nature of the chemical bonding in $Cp_2LuCl.OC_4H_8$ have been studied by the INDO method.[67] The bonds in this complex were found to be covalent. Thus, the bond order (according to Mulliken) Lu–Cl, Lu–O and Lu–C are 0.656, 0.314 and 0.254, respectively (Table 4). The charge on Lu is +0.542. This is far from the +3 predicted by the ionic model. The overlap between the 4*f*- and other orbitals is zero. This means that the 4*f*-orbitals in the complex remain essentially atomic. The overlap data for various orbitals (Table 4) confirm that the 5*d*-orbitals of Lu play a dominant role in the bonding.

Table 3. Electronic population of bonds (P) and atomic charges (Q) in $Cp_2M(s\text{-}cis\text{-}C_4H_6)$, $Cp_2M(s\text{-}trans\text{-}C_4H_6)$ (M = Zr, Th, U) and $Fe(CO)_3(C_4H_6)$.[38]

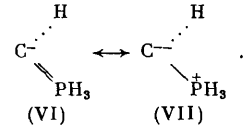
The nature of the bonding in Cp_2Ln (Ln = Sm, Eu, Yb) has been studied by comparing photoelectron spectra and quasirelativistic calculations by the $X\alpha$-SW method.[68] An analysis of the MOs revealed that the metal–ring bond is slightly covalent. The small ligand splitting of the 4f-orbitals and their strict localisation are evidence of the ionic interaction. The MOs in Cp_2Eu are ordered the same as in Cp_2Yb. This means that the 4f-levels of divalent Lns do not change their position relative to the energy levels of ligand valence orbitals. This is in contrast with results for LnX_3, where the position of the 4f-orbital energy levels (relative to those of the ligand valence orbitals) depends significantly on the nature of the ligand. The calculated ionisation potentials agree well with the experimental values.



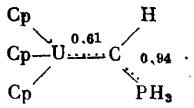
The nature of the bonding of two $LnCp_2$ fragments through H bridges has been studied by the quasirelativistic extended Hückel method.[69] The Ln d-orbitals (in the electronic configuration d^0f^n) apparently stabilise the bridging H atoms. Bonding through symmetric H bridges is energetically more favorable compared with asymmetric bridges.

Besides An biscyclopentadienides, complexes with three cyclopentadienide ligands Cp_3AnL frequently form (in contrast with d-transition metals). The majority of known complexes contain a monodentate anionic ligand (L) such as halide or alkyl and have a trigonal-pyramidal or pseudotetragonal structure. An interesting feature of the Cp_3U fragments is the fact that they can be bonded to η^2-acyl, η^2-pyrazolyl and even η^5-cyclopentadienide ligands in spite of seemingly large steric hindrances to coordination of the last.

The electronic structure of tris(η^5-cyclopentadienyl)An complexes has been studied by the quasirelativistic extended Hückel method.[70,71] Two ligand orbitals in the Cp_3U fragment (C_{3v} symmetry) have a_2 symmetry and can interact only with U $f_{y(3x^2-y^2)}$-orbitals. This means that the f-orbitals can play a significant role in stabilising the An–Cp bond in Cp_3An complexes. Nevertheless, the calculations suggest that the contribution of the $f_{y(3x^2-y^2)}$-orbital to the bonding MO a_2 is amll and reaches only 5–8%. The remaining f-orbitals are essentially nonbonding. The U 6d-, 7s- and 7p-orbitals also participate very little in the bonding. As a result, the population (according to Mulliken) of the U–C(Cp) bonds is very small and reaches only 0.05. Taking into account contributions from H atoms of the C_5H_5 groups, the total overlap U–Cp decreases to 0.01. This contrasts with the high population of M–Cp bonds in transition metal complexes. For example, this value for $CpFeMe(CO)_2$ is 0.57. The small population of the U–Cp bonds indicates that this bond is very weakly covalent and much weaker than the Fe–Cp bond.

Examination of the model complex Cp_3UMe enabled the nature of the σ-bond in An complexes to be analysed. The methyl σ-orbital overlaps mainly with the $6a_1$-orbital (consisting primarily of the U $6d_{z^2}$-orbital) of the CpU fragment. Two other orbitals of the fragment, $3a_1$ and $4a_1$, make a smaller contribution to the bonding interaction. The last two orbitals are primarily f_{z^3} in character. A strong covalent bond between U and Me forms owing to such interactions. The covalent nature of the bonding is consistent with the large overlap of 0.40 in the U–C(Me) bond. It is noteworthy that the corresponding value is 0.44 for the Fe–C(Me) bond in $CpFe(Me)(CO)_2$. The U 7s- (2%), 7p_z- (6%), 6d_{z^2}- (4%) and 5f_{z^3}-orbitals (4%) participate in forming the strong U–C(Me) σ-bond. The contribution of each orbital is small but the sum is 16%.

The nature of the bonding in $Cp_3UCHPPhMe_2$ is of great interest. The anionic ylide ligand can be assigned two resonance forms



(VI) (VII)

Structure (VII) is formally a dianionic ligand, analogous to a carbene. Hence, U–C double bond can form on coordination of the ylide to U. Quantum-chemical calculations (quasirelativistic extended Hückel method) of the simplified model Cp_3UCHPH_3 demonstrated that the ligand $CHPH_3^-$ has two occupied frontier orbitals. These are a π-orbital with energy −11.3 eV and a σ-orbital with energy −11.9 eV.

Interaction of the σ-orbital with vacant $6a_1$-, $4a_1$-, and $3a_1$-orbitals of Cp_3U^+ forms σ-bonding MO. Furthermore, interaction of the π-orbital with the 8*e*-, 5*e*- and 4*e*-orbitals of Cp_3U^+ forms a π-bonding MO. It should be noted that the 5*e*- and 4*e*-orbitals have primarily f_{yz^2} character. The double bond formed is not localised but has a π-delocalised character U ⋯ C ⋯ P:

Nevertheless, the population of the U–C bond is 0.61 (the contribution from the π-component is 0.19). This surpasses the population in other complexes. In general, the calculations demonstrated that the population of the U–C bond in various complexes decreases in the order $Cp_3UCHPH_3 \simeq Cp_3U(C{\equiv}CH) > Cp_3UCH_3 > CpU[CH_2CH_2PH_2]_3$. This correlates with the increasing U–C bond length in this order.

Additional and more accurate data on the electronic structure of tris(cyclopentadienyl)An complexes have been obtained using quasirelativistic *X*α-SW calculations.[72–76] The complexes Cp_3U and Cp_3Th were examined. It was confirmed that the U *f*-orbitals can play an important role in the bonding. It was demonstrated that the U–Cp bond forms through donation of electron density from the π_2-orbital of the Cp ligand into the U 6*d*- and $5f_{y(3x^2-y^2)}$-orbitals. It was found that the highest occupied orbital in Cp_3Th has primarily $6d_{z^2}$ character (89%) and is located 1 eV below the 5*f*-orbitals. The energy level of the 5*f*-orbitals decreases along the series Th → Pu. At the end of the series, it is below the level of the 6*d*-orbitals.

Analysis of the electronic structure of Cp_3UL (where L = H, CO, NO, OH) demonstrated that mainly the U $6d_{z^2}$-orbital participates in bonding to the σ-ligands. The 5*f*-orbitals are not additionally split (compared with Cp_3U). Thus, the bonding orbital for Cp_3UH is 56% hydride in character with the principal contribution coming from the U $6d_{z^2}$-orbital (24%) and small contributions from the $5f_{z^3}$- (1%), 7*s*- (3%) and $7p_z$-orbitals (3%). It must be noted that the relative contribution of the 5*f*-orbitals is greater than the shorter the U–H bond. However, the role of the 6*d*-orbitals in chemical bond formation remains dominant.[74] The contribution of the σ-component remains substantial for Cp_3U complexes with both π-acids (CO, NO) and π-bases (OH). Besides the σ-bonding, π-backbonding occurs in which electrons are donated from the U *f*π-levels into the CO and NO π*-orbitals. Thus, interaction of the CO 2*p*-orbitals with U 5*f*-orbitals in Cp_3UCO forms a bonding orbital consisting of 14% CO orbitals and 84% U orbitals. Such an interaction stabilises the U 5*f*-levels. As with carbonyl complexes of *d*-transition metals, backbonding into a CO antibonding orbital decreases the vibrational frequency of the CO double bond compared with ν_{CO} of the free molecule.

The electronic structure of Cp_3UX (X = F, Cl, Br) has been investigated theoretically (nonrelatistivic *X*α-DV calculations) and experimentally (photoelectron spectra using He I and He II excitation sources).[77] The calculated ionisation potentials for the high (in energy) MOs of Cp_3UCl agree with the experimental values. The conclusion was made that the nonrelativistic calculation can give a good analysis of the photoelectron spectra and an adequate description of the nature of the bonding in An complexes. Nevertheless, the nonrelativistic approach underestimates the contribution of the 6*d*-orbitals (relative to the 5*f*) in forming the metal–ligand bonds. Therefore, a relativistic calculation is required for more accurate information.

Therefore, the following conclusions can be made in finishing this section. Firstly, many of the structural features of An (Th and U) cyclopentadienides, for example, the stability of complexes with a 20-electron configuration, the highly favourable energy of $Cp_2An(s\text{-}cis\text{-}C_4H_6)$ compared with its *trans* isomer, and the unusual geometry of the $Cp_2Th(CH_2Bu\text{-}tert)_2$ structure, are due to participation of both An 6*d*- and 5*f*-orbitals in the chemical bonding.

Secondly, the Ln 4*f*-orbitals in the cyclopentadienides remain essentially atomic. The 5*d*-orbitals play the dominant role in bond formation.

Thirdly, the metal–ligand bonds in Ln and especially in An complexes are not purely ionic but have a significant covalent character.

Application of the quasirelativistic extended Hückel method enables many features of the electronic and geometric structure of cyclopentadienides to be understood qualitatively (and sometimes quantitatively). However, more complicated calculations must be used to obtain more accurate and reliable information on the details of the electronic structure.

Table 5. Electronic population of orbitals and charges on atoms in $M(BH_4)_4$ (M = Zr, U).[85]

A. $Zr(BH_4)_4$

V. Other *f*-element compounds

The electronic structure of uranocene $U(C_8H_8)_2$, which has been investigated in sufficient detail, should be discussed. Calculations have been performed for this molecule using the relatistically parametrised Hückel method,[32] $X\alpha$ (nonrelativistic and relativistic) method.[78–81] and the nonempirical SCF MO method including spin–orbit coupling and a relativistic core potential. In general, results of all these studies agree. It has been found[78–80] that both 5*f*- and 6*d*-orbitals of the metal participate in bonding to the ring. Chang and Pitzer[82] emphasise that the 6*d*-orbitals play the principal role in the covalent bonding; the 5*f*-orbitals, a secondary role. It was also demonstrated that the electronic ground state of uranocene is E_{3g} and the characteristic green colour of uranocene is due to transitions to E_{2u} and E_{3u} excited states. In agreement with the compositions of the MOs, these transitions are qualitatively described as $5f \rightarrow 6d$-transitions.

Of other metallocenes, $Th(C_8H_8)_2$ and $Ce(C_8H_8)_2$ have been investigated.[78,79] The bonding in cerocene was found to be less covalent (more ionic) than in uranocene and thorocene. A study of the photoelectron spectrum also confirms the high covalency of thorocene.[83]

Relativistic and nonrelativistic $X\alpha$-DV methods have been used to study the electronic structure of the borohydrides $M(BH_4)_4$ (M = Zr, U). The results obtained agree with calculations by the $X\alpha$-method.[85] The calculated and experimental ionisation potentials were in good agreement. The relativistic solution better describes the metal–ligand bonding in the U complex. It was demonstrated that the contribution from U 5*f*-orbitals is overestimated and that of the 6*d*-orbitals underestimated in the nonrelativistic approach (Table 5).

Structures of the two η^6-arene complexes $Sm(C_6Me_6)(AlCl_4)_3$ and $U(C_6Me_6)(AlCl_4)_3$ have been compared.[86] The differences in metal–ligand bond lengths was found to be determined by the difference in the U and Sm ionic radii. According to the authors, this means that the acceptor orbitals in the An and Ln complexes are comparable and, therefore, the *f*-orbitals are not involved in bonding to the arene.

Calculations have been performed using the $X\alpha$-SW method for $Eu(C_2H_4)_2$ assuming C_{2v} symmetry.[87] The calculations demonstrated that the complex is weakly bonding owing to donation of charge density from the doubly occupied $f_{z(x^2-y^2)}$-orbital of Eu into the π^*-orbitals of ethylene. However, little density is directly donated from filled ethylene orbitals onto the metal.

A rather large number of molecules and clusters containing 4*f*- and 5*f*-elements has been calculated by the relativistically parametrised extended Hückel method. Reviews of the results have been published.[7,32–35,88] It was demonstrated that this method qualitatively correctly estimates the spin–orbit splitting energies of the valence levels and the role of relativistic effects in the chemical bonding. In particular, it is emphasised[88] that the early 5*f*-elements can be treated as 6*p*-elements in the sense that the 6*p* atomic orbitals of these elements are mixed with ligand orbitals.[7,89] This mixing is especially large in uranyl and other actinyls. Direct experimental proof of the mixing of U 6*p*-orbitals with O 2*p*-orbitals in uranyl and other compounds has been given.[90,91] The contribution of 6*p*-orbitals to nuclear quadrupole coupling has been interpreted on the basis of these results.[35,88]

The electronic structures (quasirelativistic extended Hückel method) of $C_4H_7NdCl_2$. $C_4H_7NdCl_2.3THF$ (THF = tetrahydrofuran) and $C_4H_7Nd(AlCl_4)_2$ (Fig. 5) have been analysed.[92–94] These compounds model the active polymerisation centres of butadiene in the Nd–Al catalytic system. Data for the electronic structure of the *anti*- and *syn*-forms of $C_4H_7NdCl_2$ are presented in Table 6. It was found that the contribution of Nd 4*f*-orbitals to the covalent bonding is insignificant. The partial covalency of the Nd–C bond is due mainly to participation of Nd 5*d*-orbitals in the bonding.

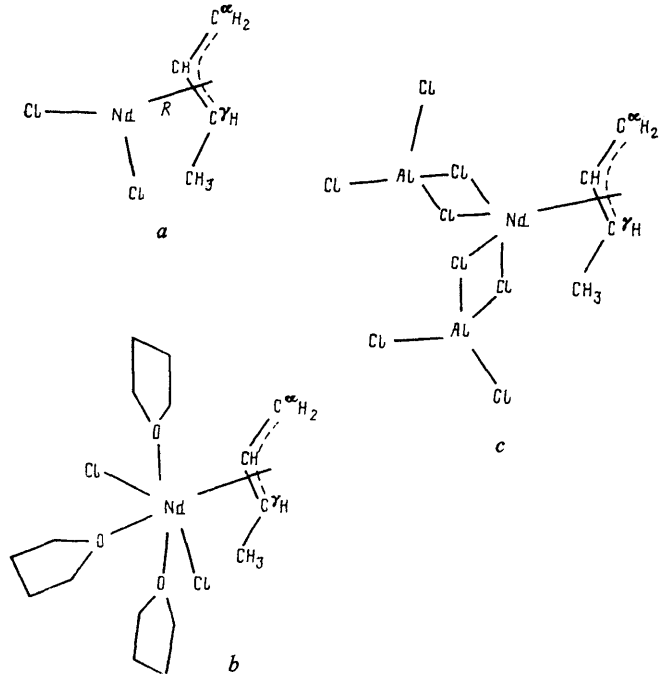

Figure 5. Diagram of active center models, *syn*-$C_4H_7NdCl_2$ (*a*) (*R* is the distance from Nd to the plane of the crotyl group), *syn*-$C_4H_7NdCl_2.3THF$ (*b*), *syn*-$C_4H_7Nd(AlCl_4)_2$ (*c*).

Table 6. Electronic structure of $C_4H_7NdCl_2$ isomers.[93]

$H_{ii}(4f)$, eV	$H_{ii}(5d)$, eV	Isomeric form	ΔE *1	q_i *2				
				$q_{C^{\alpha}}$	$q_{C^{\gamma}}$	q_{Nd}	P (Nd–C^{α}) *3	P (Nd–C^{γ}) *3
−9.82	−8.82	*anti*	10.6	−0.48	−0.33	1.95	0.07(5)	0.08(3)
		syn		−0.45	−0.34	1.93	0.06(5)	0.09(3)
−11.0	−10.8	*anti*	15.5	−0.25	−0.10	0.93	0.12(5)	0.14(4)
		syn		−0.23	−0.11	0.91	0.12(3)	0.16(3)

*$\Delta E = E_{syn} - E_{anti}$, where $E_{syn}(E_{anti})$ is the total energy (kJ mol^{-1}) of the *syn* (*anti*) form; *^2q_i is the excess of electronic charge on the *i*-th atom; *^3P(Nd–C_i) is the electronic population of the Nd–C_i bond. Contributions (%) of partial populations Nd(4*f*)–C_i(2*p*) to the corresponding total populations are given in parentheses.

It was demonstrated that the *syn*-form of the active centres is energetically more favorable than the *anti*-form with respect to the total energy. It was proposed on the basis of the results that kinetic and steric control of the microstructure of polybutadiene is possible in Ln catalytic systems. This validity of this conclusion has been confirmed experimentally.[93,95]

Therefore, existing quantum-chemical methods enable useful information about the electronic and geometric structure of large chemical containing *f*-elements to be obtained. Metal–halide and M–C bonds in these compounds are not purely ionic. The degree of covalency increases on going from Ln to An compounds. The *d*-orbitals of the Lns and Ans make the principal contribution to the chemical bonding. For the latter, the 5*f*-orbitals noticeably participate in forming chemical bonds. This is responsible for many of the strucural features of An compounds. The Ln 4*f*-orbitals interact very weakly with ligand valence orbitals. Their direct contribution to forming chemical bonds is insignificant.

The verdazyl method for the study of the kinetics and mechanisms of the unimolecular heterolysis reactions of organic compounds

G F Dvorko, E A Ponomareva
Kiev Polytechnic Institute

ABSTRACT. **Data concerning the use of triphenylverdazyl radicals as internal indicators to study of the kinetics and mechanisms of the heterolysis of organic substrates in various protic and aprotic solvents are surveyed. The application of the verdazyl method made it possible to put forward a new mechanism of the heterolysis of a covalent bond—the reaction proceeds via the consecutive formation of contact, spatially separated, and solvent-separated ion pairs.**

The bibliography includes 135 references.

I. Introduction

The unimolecular heterolysis reactions of organic compounds (S_N1, $E1$, $F1$, solvolysis) are widely used in laboratory and industrial synthesis.[1–3] Depending on the conditions in the heterolysis of, for example, 1-halo-1-phenylethane, one of three reactions can take place:[4,5]

$$\mathrm{PhCHXMe}\left\{\begin{array}{ll}\xrightarrow[S_N1]{Y^-} & \mathrm{PhCHYMe}+X^-,\\ \xrightarrow[E1]{} & \mathrm{PhCH{=}CH_2}+\mathrm{HX},\\ \xrightarrow[\text{solvolysis}]{ROH} & \mathrm{PhCH(OR)CH_3}+\mathrm{HX}.\end{array}\right. \qquad (1)$$

The decomposition of 1-adamantyl chloroformate may serve as an example of the fragmentation reaction:[6]

(2)

The study of the mechanism of unimolecular heterolysis reactions is in the vanguard of the mechanistic research in organic chemistry.[1,2,7,8] The mechanism of these reactions is interpreted on the basis of Winstein's ionisation-dissociation scheme (see, for example, Refs. 7–10):

$$\mathrm{RX} \rightleftharpoons \underset{\text{CIP}}{\mathrm{R^+X^-}} \rightleftharpoons \underset{\text{SSIP}}{\mathrm{R^+\,|\,Solv\,|\,X^-}} \rightleftharpoons \mathrm{R^+}+\mathrm{X^-}. \qquad (3)$$

It has been suggested that the reaction begins with the formation of a contact ion pair (CIP), which is then slowly converted into a solvent-separated ion pair (SSIP) and the latter rapidly decomposes, affording the free carbonium ion. The reaction products are formed from the last two intermediates. They in fact determine the type of reaction occurring. The rate of reaction is described by a first-order kinetic equation:

$$v=k[\mathrm{RX}]. \qquad (4)$$

The rate increases sharply with increase in the polarity of the medium.[10–13]

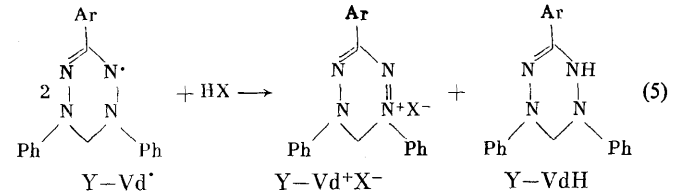
The rate of the $E1$ and solvolysis reactions can be conveniently followed from the acid evolved.[14,15] The reaction is usually performed in the presence of an amine, which binds the acid and thus suppresses the reverse reaction and eliminates the possible catalytic effects of the acid. However, in an aprotic medium, the salt formed can lead to appreciable errors in the determination of the reaction rate.[16,17] The rate of the solvolysis reaction is relatively insensitive to the action of salts.[7] In a number of instances, this is true also of the $E1$ reactions.[7,11] The above method for the study of the kinetics of such reactions therefore generally yields satisfactory results.

The rates of S_N1 reactions in an aprotic medium depend greatly on the added salts,[18] which makes it difficult to obtain reliable results. The kinetics of these reactions are usually investigated by measuring the rate of the radioactive exchange of the nucleofugal species in the substrate[19] or by carrying out the reaction in the presence of strong nucleophiles (PhONa [20]). However, these methods are complex to carry out and are insufficiently correct owing to the influence of the salts present in the solution. The latter complicates the interpretation of the experiment and sometimes leads to gross errors.[20,21]

Before the appearance of the verdazyl method for the study of the unimolecular heterolysis reactions,[18,22] there was no effective method available in the literature for the study of the kinetics of S_N1 reactions in an aprotic medium. In certain cases (in polar aprotic solvents), the problem was solved by determining the rate of reaction in the presence of small amounts of water,[23,24] i.e. in a sense the rate of solvolysis was determined. However, it is noteworthy that, in order to obtain reliable results, it is necessary in this instance to carry out special investigations of the influence of water on the rate of reaction.

The interpretation of the mechanism of the *Fl* reactions occurring via an ionisation-fragmentation pathway frequently gives rise to difficulties[25,26] owing to the presence in this instance of not only consecutive but also of parallel stages.[27]

The study of the kinetics of the heterolysis of organic substrates in aprotic solvents is significantly hindered also by the fact that such reactions are very slow. Thus the half-reaction time for t-BuCl in hexane at 25 °C is $\sim 1 \times 10^9$ years[17] and the rate of heterolysis of certain skeletal compounds is even lower, by several orders of magnitude.[7,10] The accumulation of kinetic data has therefore been slow and difficult. The detailed specification of the mechanism stopped at the level of Winstein's scheme, which was proposed as early as the middle 1950s.[9,28] Attention was concentrated on the study of the solvolysis reactions, which, however, yield inadequate information since the kinetic relations for them are indefinite, the solvation effects are uniform, and the salt effects are indistinct.



Considerable progress in the study of the kinetics and mechanism of the unimolecular heterolysis reactions was achieved by virtue of the development and wide scale application of the verdazyl method,[18,21,22,27,29–80] which uses triphenylverdazyl radicals as internal indicators. The indicator methods had been used earlier only for the study of solvolysis reactions,[81,82] but since they had no significant advantages they were not applied on a wide scale.

II. The verdazyl method for the study of the kinetics of the heterolysis of organic compounds

The application of triphenylverdazyl radicals as internal indicators in the determination of the rate of heterolysis of organic compounds is based on the fact that they react rapidly and quantitatively with the reaction products (acids[83]) or the cationoid intermediate derived from the substrate, formed after the rate-limiting stage, which makes it possible to follow the rate of reaction from the consumption of triphenylverdazyl (Y—Vd$^{\cdot}$) and/or from the formation of the verdazyl salt (Y—Vd$^+$X$^-$).

Triphenylverdazyl radicals are some of the most stable free radicals.[84] They can be readily synthesised and purified. They can be stored in air in the crystalline state for more than 10 years without appreciable changes. A solution of Y—Vd$^{\cdot}$ in non-polar solvents is stable for several days and in polar solvents for ~ 10 h.

Triphenylverdazyls react rapidly and quantitatively with hydrogen halides and the halogens:[84,85]

(5)

$$2Y\text{—}Vd^{\cdot} + X_2 \rightarrow 2Y\text{—}Vd^+X^- . \qquad (6)$$

The reaction can be readily followed spectrophotometrically from the consumption of Y—Vd$^{\cdot}$ and the formation of Y—Vd$^+$X$^-$. By virtue of the different stoichiometries of reactions (5) and (6), it is possible to determine quantitatively the content of the halogen and the hydrogen halide when they are present jointly in the solution.

The reaction of Y—Vd$^{\cdot}$ with carboxylic acids is reversible.[86–88] In an aprotic medium, the rate of reaction is described by a third-order kinetic equation:[87]

$$v = k[Y\text{—}Vd^{\cdot}]^2[RCO_2H].$$

In aprotic solvents of low polarity, I_2 reacts with Y—Vd$^{\cdot}$ also reversibly,[89] the rate of reaction being described by a fourth-order kinetic equation:[90]

$$v = k[Y\text{—}Vd^{\cdot}]^2[I_2]^2.$$

It is necessary to take this into account in the study of the heterolysis of organoiodine compounds in a non-polar medium[89] and in the study of the influence of salts of hydriodic acid on the rate of heterolysis of organic substates.[40,49] In the reaction of Y—Vd$^{\cdot}$ with Cl_2, Br_2, hydrogen halides, and other strong acids, the reaction equilibrium is almost wholly displaced towards the products.[46]

Triphenylverdazyls are powerful electron donors,[91,92] reacting readily with Lewis acids,[93–95] tetranitromethane,[98] tetracyanoethylene,[97] iminoxyls and phenoxyls,[98] the tropylium cation,[99] and the ion pair $PhN_2^+BF_4^-$.[100] These reactions proceed via electron transfer from the radical to the electrophile and the rate of reaction is described by a second-order kinetic equation, i.e.

$$v = k[\text{electrophile}][Y\text{—}Vd],$$

and increases with the enhancement of the electron-donating properties of the substituent in the radical. Clearly the Y—Vd$^{\cdot}$ radical should also react readily with the intermediate cationoids formed in the heterolysis of an organic substrate, for example with a solvent-separated ion pair.

In the heterolysis of organic substrates in the presence of Y—Vd$^{\cdot}$, identical stoichiometric ratios are usually observed regardless of the type of reaction: 2 moles of the verdazyl radical are consumed per mole of the substrate and one mole of the verdazyl salt is formed:

$$RX + 2Y\text{—}Vd^{\cdot} \begin{cases} \xrightarrow{\text{solvolysis}} Y\text{—}Vd^+X^- + Y\text{—}VdH + ROS, \\ \xrightarrow{S_N1} Y\text{—}Vd^+X^- + Y\text{—}VdR, \\ \xrightarrow{E1} Y\text{—}Vd^+X^- + Y\text{—}VdH + \text{olefin}. \end{cases} \qquad (7)$$

Verdazyls were used for the first time to study the kinetics of the dehydrohalogenation of t-butyl halides.[22,29–36,38] Apart from 1,3,5-triphenylverdazyl (Vd$^{\cdot}$), the following radicals were also used: 3-(4-methoxyphenyl)-1,5-diphenylverdazyl (MeOVd$^{\cdot}$), 3-(4-methylphenyl-1,5-diphenylverdazyl (MeVd$^{\cdot}$), 3,5-di(4-methoxyphenyl)-1-phenylverdazyl [$(MeO)_2$Vd$^{\cdot}$], 3-(4-chlorophenyl)-1,5-diphenylverdazyl (ClVd$^{\cdot}$), and 3-(4-nitrophenyl)-1,5-diphenylverdazyl (NO_2Vd$^{\cdot}$). It was postulated that Y—Vd$^{\cdot}$ reacts with the hydrogen halide split off.[22,30–32] Leucoverdazyl, which is comparatively readily oxidised by atmospheric oxygen to verdazyl, is formed in the course of E1 and solvolysis reactions. Under the conditions of the kinetic experiment, leucoverdazyl is preserved without change over a period of ~ 8 h.

In the kinetic experiment, a solution of the verdazyl at a concentration suitable for spectrophotometric determinations ($\sim 10^{-4}$ M) is mixed with a solution of the substrate at a concentration ensuring an acceptable reaction rate (from 10^{-5} to 1 M depending on the reactivity of the substrate). The solution obtained

is placed in the thermostatted cell of the spectrophotometer and the absorption strength is measured at 720 and 540 nm. Although the values of λ_{max} for Y—Vd$^{\cdot}$ and Y—Vd^{+}X^{-} and their extinction coefficients depend comparatively little on the nature of the substituent and the solvent,[53,56,64,66,76] the values of λ_{max} corresponding to the given verdazyl must be used in order to obtain valid data.

In the study of the kinetics of rapid reactions, the substrate concentration during the experiment may be comparable to the concentration of Y—Vd$^{\cdot}$ [29] or may slightly exceed it.[66] In this case, the "Y—Vd$^{\cdot}$ (Y—Vd^{+}X^{-}) concentration—time" relation is curved and the rate of reaction in each individual experiment is calculated from the kinetic equation (4). In such experiments, the degree of conversion of the substrate can reach 100%. Cases of this kind are observed rarely because the heterolysis of organic compounds is comparatively slow. The concentration of Y—Vd$^{\cdot}$ is usually appreciably lower than the substrate concentration (by a factor of $5-10^5$), which makes it possible to carry out reliable determinations of the rates of reaction for low and very low degrees of conversion of the substrate (0.001—5%) and thus in the course of several hours one can determine the rate of a reaction with a half period reaching 1000 years. In these experiments, the substrate concentration hardly changes during the kinetic experiment, so that in each individual experiment the rate of reaction is described by the pseudo-zero-order kinetic equation $v = k_0$, the Y—Vd$^{\cdot}$ and Y—Vd^{+}X^{-} concentrations varying linearly as a function of time. The first-order rate constant is calculated from the equation $k = k_0[RX]$. Thus the verdazyl method is in this case based on the determination of the initial rates of reaction.

The determination of the rate of heterolysis from the consumption of Y—Vd$^{\cdot}$ and the formation of Y—Vd^{+}X^{-} leads to satisfactorily concordant results, the rate of reaction being independent of the concentration of Y—Vd$^{\cdot}$ and of the nature of the substituent in the latter. Consequently the verdazyl enters into the reaction after the rate-limiting stage.

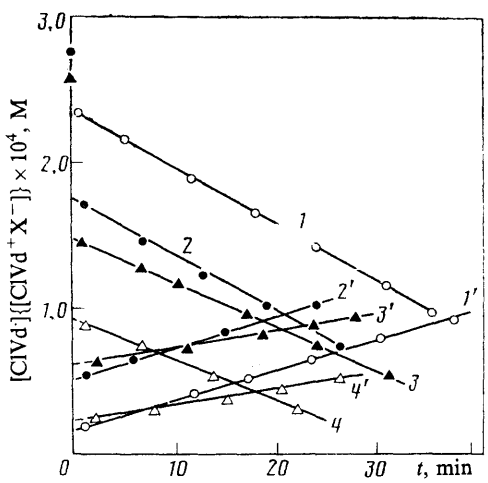


Figure 1. Kinetics of the heterolysis of t-BuBr in propylene carbonate in the presence of ClVd$^{\cdot}$: *1*, *1'*, *2*, and *2'*, [t-BuBr] = 0.0105 M, [ClVd$^{\cdot}$] = 2.75 × 10^{-4} M, 25 °C, k = 3.20 (3.16) × 10^{-6} s^{-1}; *3* and *3'*, [t-BuBr] = 0.025 M, [ClVd$^{\cdot}$] = 2.60 × 10^{-4} M, 32.5 °C, k = 8.48 × 10^{-6} s^{-1}; *4* and *4'*, [t-BuBr] = 0.025 M, [ClVd$^{\cdot}$] = 1.3 × 10^{-4} M, 32.5 °C, k = 8.67 × 10^{-6} s^{-1}.

Fig. 1 presents a series of characteristic curves for the heterolysis of t-BuBr in propylene carbonate in the presence of ClVd$^{\cdot}$ under conditions such that [t-BuBr] ≫ [ClVd$^{\cdot}$].[29] The ClVd$^{\cdot}$ (straight lines *1—4*) and ClVd^{+}Br^{-} (straight lines *1'—4'*) concentrations vary linearly with time beause the t-BuBr concentration is constant during the experiment. According to the stoichiometric Eqn. (7), the rate of reaction in each individual experiment is described by a pseudo-zero-order kinetic equation:

$$-d[Y-Vd^{\cdot}]/2dt = d[Y-Vd^{+}X^{-}]/dt = k_0. \quad (8)$$

The abrupt change in the concentrations of the radical and the salt over the initial section of the kinetic curve is caused by the rapid reaction of the radical with the hydrogen halide formed as a result of the decomposition of t-BuBr before the start of the measurements. The size of the jump increases with increase in the time interval between the preparation of the substrate solution and its mixing with the verdazyl solution. In conformity with the stoichiometry of reaction (7), on decomposition of t-BuCl the abrupt changes in the concentrations of the radical and the salt are in the ratio 2 : 1. In the case of t-BuBr and especially t-BuI, the changes in the concentrations of Y—Vd$^{\cdot}$ and Y—Vd^{+}X^{-} in the initial period usually differ by a factor less than 2 and in certain cases (t-BuI) the ratio is 1 : 1. This is associated with the fact that the HBr(HI) formed before the start of the measurements is fully or partly oxidised by atmospheric oxygen to the halogen.

Apart from t-butyl halides,[27,29—36,38,50,51,68,71,73] the verdazyl method has been applied to the study of *E*1 reactions involving 7α-bromocholesteryl benzoate,[59,63,64,70,74,75] 1-chloro-1-phenylethane,[60,65,69] 2-bromo-2-methyladamantane,[50,55,57,68] 2-chloro-2-methyladamantane,[71] and cumenyl chloride.[79] Similar kinetic relations were observed in all cases.

It has been shown in relation to 7α-bromocholesteryl benzoate,[70] t-BuBr,[50,68,73] t-BuCl,[68,71] cumenyl chloride,[79] 2-bromo-methyl-adamantane,[68] and 2-chloro-2-methyladamantane[68,71] that, in the course of the *E*1 reaction, the Y—Vd$^{\cdot}$ radical reacts not with the hydrogen halide, as postulated initially, but with the solvent-separated ion pair comprising the substrate:

$$R^{+}|Solv|X^{-} + 2Y-Vd^{\cdot} \longrightarrow Y-Vd^{+}X^{-} + [Y-Vd-R] \xrightarrow{(I)} Y-VdH + \text{olefin}. \quad (9)$$

This reaction apparently results in the initial formation of the product of the alkylation of the verdazyl (I), which then decomposes comparatively rapidly into an olefin and leucoverdazyl, which agrees with the stoichiometric Eqn. (7). This conclusion was reached in the study of salt effects, which demonstrated that Y—Vd$^{\cdot}$ and the salt act on the same cationoid intermediate.

The quantitative formation of leucoverdazyl in solution can be readily followed with the aid of the disproportionation reaction[101]

$$Y-VdH + Y-Vd^{+}X^{-} + NaOH \rightarrow 2Y-Vd^{\cdot} + NaX + H_2O. \quad (10)$$

After the addition of one drop of a 1 M aqueous NaOH solution to the reaction mixture at the end of the kinetic experiment, the initial verdazyl concentration is restored in the solution.

In contrast to t-butyl halides, 2-bromo-2-methyladamantane, and cumenyl chloride, the rate of heterolysis of 1-chloro-1-phenylethane[65,69] and especially 7α-bromocholesteryl benzoate[70,75] depends comparatively strongly on the verdazylium salt formed during the reaction, which leads to an appreciable distortion of the "$Y-Vd^{\cdot}$ ($Y-Vd^{+}X^{-}$) concentration–time" relation. The rate of reaction was calculated in this case from the initial linear section of the kinetic curve.

It has been shown in relation to the heterolysis of t-BuBr and t-BuCl in acetonitrile[22] and acetone,[30] of t-BuCl in isopropyl alcohol and t-butyl alcohol,[38] of PhCHClMe in ethanol,[65] and of $PhCMe_2Cl$ in acetonitrile[79] that the data obtained by the verdazyl method agree satisfactorily with the results obtained by other methods.[102–108] The gross errors made in the determination of the rate constants for the solvolysis of t-BuCl in isopropyl alcohol and t-butyl alcohol and of t-BuBr in t-butyl alcohol were detected by means of the verdazyl method. The rate constants quoted by Viana and coworkers[109,110] differ by 1–3 orders of magnitude from the values found by the verdazyl method[38] and also those quoted by Rudakov.[107]

The application of the verdazyl method proved to be particularly effective in the study of S_N1 reactions. There exist data at present on the heterolysis of Ph_2CHBr,[34,35,38–45,72] Ph_2CHCl,[21,38] 1-adamantyl iodide (1-AdI),[47,49,51] 1-AdBr,[36,48] 1-adamantyltoluene-*p*-sulphonate (1-AdOTs),[46,48,54,80] 1-adamantyl picrate (1-AdOPic),[52,53,56,80] 3-bromohomoadamantane,[58] $PhCCl_3$,[61,67,76] *p*-methoxy(trichloromethyl)benzene,[62,66] Ph_2CCl_2,[69,77] *p*-methoxybenzylidene chloride,[77,78] and di(*p*-chlorophenyl)dichloromethane.[69]

In these cases, the rate of reaction is also described by the kinetic Eqn. (4) and is as a rule independent of the concentration and nature of $Y-Vd^{\cdot}$. Consequently verdazyl enters into the reaction after the rate-limiting stage, which in fact makes it possible to use it as an internal indicator.

The rates of S_N1 reactions in an aprotic medium are very sensitive to the influence of salts, including those which are formed during the reaction. In certain cases,[40,62,68,69] the salt effect is so great that, when $[Y-Vd^{+}X^{-}] \simeq 10^{-4}-10^{-5}$ M, the "$Y-Vd^{\cdot}$ concentration–time" relation is greatly distorted. The rate constant for the pseudo-zero-order reaction was calculated in this case either from the initial linear section of the kinetic curve, if it can be identified, or was found by extrapolating the values of k_0 or k to the $[Y-Vd^{+}X^{-}] = 0$ zero straight line.[62]

It has been shown in relation to the heterolysis reactions of Ph_2CHCl in methanol,[21] 1-AdOTs in isopropyl alcohol,[46] 1-AdOPic in sulpholan, methanol, and ethanol,[52,56] $PhCCl_2$ in aqueous ethanol,[76] Ph_2CCl_2 in ethanol and aqueous dioxane,[69,77] and *p*-$MeOC_6H_4CHCl_2$ in aqueous dioxane[77,78] that the rate constants found by the verdazyl method agree satisfactorily with those determined by other procedures.[24,111–117] The rate constant for the heterolysis of Ph_2CHCl in acetonitrile, found by the verdazyl method,[21] proved to be ~3 orders of magnitude lower than the value obtained in the presence of PhONa.[118] The presence of a gross error in the study of Okamoto et al.[118] has been demonstrated.[21] An even greater error was made in an investigation[119] where the rate constant for the hydrolysis of $(p\text{-}ClC_6H_4)_2CCl_2$ at 25 °C, calculated from the results of this study, proved to be ~5 orders of magnitude lower than the value found by the verdazyl method.[69]

Fig. 2 presents the temperature dependences of the logarithms of the rate constants for the heterolysis of t-BuBr in acetone[30,104] ($E1$ reaction) and of 1-AdOPic in sulpholan[52,112] (S_N1 reaction), obtained by the verdazyl method and other independent methods. In both cases, all the points lie on a single straight line, which illustrates the validity of the verdazyl method. The most convincing evidence for the validity of the method is that the enormous amount of experimental data obtained by this procedure for 21 substrates (each in 10–40 solvents) is fully consistent with the available literature data for the unimolecular heterolysis of organic compounds.

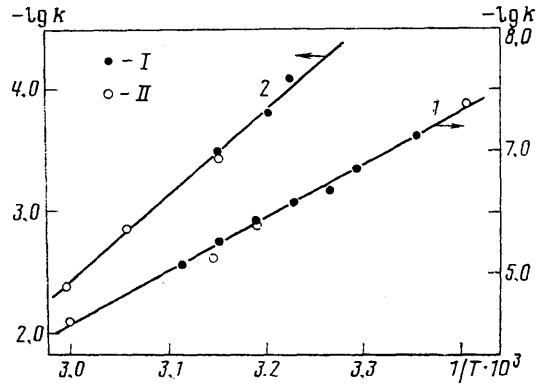

Figure 2. Temperature variation of the rate of heterolysis of t-BuBr in acetone (line *1*) and of 1-AdOPic in sulpholan (line *2*); *I*, verdazyl method; *II*, other methods.[24,104,112]

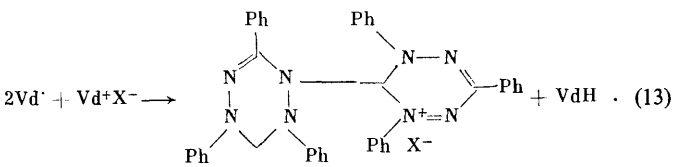
Valuable information about the mechanism of S_N1 reactions is provided by the reaction products formed with participation of verdazyl. Depending on the nature of the substrate and the reaction conditions, they can be various, different stoichiometric $[RX]:[Y-Vd^{\cdot}]:[Y-Vd^{+}X^{-}]$ ratios and different forms of the kinetic pseudo-zero-order equations being observed. The verdazyl alkylation products are usually formed in the course of the reaction:[39,49,51,54]

$$RX+2Vd^{\cdot} \rightarrow Vd-R+Vd^{+}X^{-}, \quad R=Ph_2CH,\ 1\text{-Ad}. \tag{11}$$



The rate of reaction is in this case described by the kinetic Eqn. (8) subject to the condition $[RX] \gg [Y-Vd^{\cdot}]$.

The solvent molecule, for example that of acetonitrile, can participate in the formation of the reaction product:[46,47,52]

$$1\text{-AdX} + 2Vd^{\cdot} \xrightarrow{MeCN} 1\text{-Ad}-N=\overset{\displaystyle Me}{\overset{|}{C}}-Vd + Vd^{+}X^{-}. \tag{12}$$

Reaction (12) indicates the intermediate formation of the ion pair $1\text{-Ad}-N=C(Me)^{+}X^{-}$, apparently via the addition of 1-AdX to the triple bond of acetonitrile located in the interionic space of the solvent-separated ion pair $1\text{-Ad}^{+}|MeCn|X^{-}$. The new ion pair formed subsequent reacts rapidly with the indicator. In this case, the kinetic relatins remain the same as in reaction (11).

The isolation of the reaction products is hindered by the occurrence of the side reaction of $Y-Vd^{\cdot}$ with $Y-Vd^{+}X^{-}$, which leads to the formation of the sparingly soluble verdazylium salt (II) and of leucoverdazyl:[26,46,47,49,52,62,120]

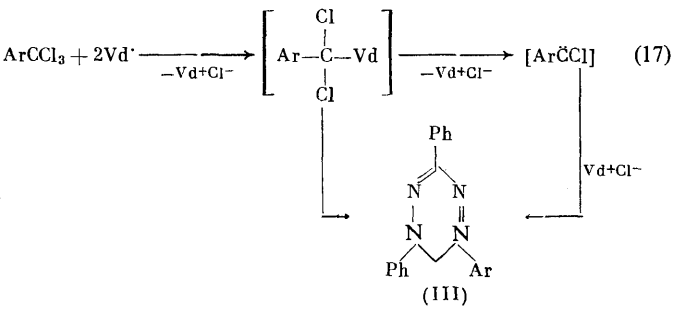
(II)

This rection proceeds only at comparatively high concentrations of the reactants (~0.1 M). Under the conditions of the kinetic experiment at low $Y-Vd^{\cdot}$ and $Y-Vd^{+}X^{-}$ concentrations ($\sim 1 \times 10^{4}$ M), it does not take place.[120]

In the heterolysis of polychlorinated organic compounds ($ArCCl_3$, Ph_2CCl_2, $ArCHCl_2$),[62,66,69,77,78] the verdazyl alkylation products are also apparently formed initially ($ArCl_2C-Vd$, $Ph_2ClC-Vd$, $HArClC-Vd$) and readily undergo further reactions. As a result of this, the stoichiometry of these reactions and their kinetic equations depend greatly on the nature of the substrate and the experimental conditions.

The heterolysis reaction of $PhCCl_3$ is isopropyl alcohol is described by the stoichiometric equation:

$$PhCCl_3 + 6Vd^{\cdot} \xrightarrow{iso-PrOH,\ H_2O} PhCO_2Pr-iso + 3Vd^{+}Cl^{-1} + 3VdH. \quad (14)$$

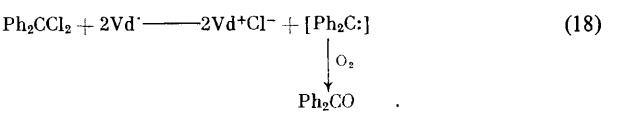


Two explanations are possible for these results. The first is that the substrate is initially solvolysed with formation of 3 moles of HCl, which then rapidly reacts with 6 moles of the indicator, while the second is that the verdazyl alkylation product formed in the first stage of the reaction is rapidly converted into $Vd^{+}Cl^{-}$ and PhCOCl and the latter is known[121] to be solvolysed ~3 orders of magnitude faster than $PhCCl_3$.[122] Regardless of the way in which this reaction takes place, it is described by the pseudo-zero-order kinetic equation

$$-d[Vd^{\cdot}]/6dt = d[Vd^{+}Cl^{-}]/3dt = k_0. \quad (15)$$

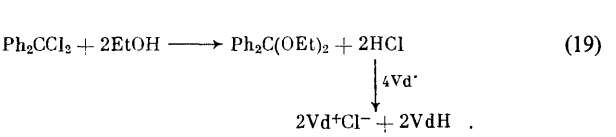
In the heterolysis of p-$MeOC_6H_4CCl_3$ in propylene carbonate, sulpholan, chloroform, and butyl acetate, the verdazyl alkylation product formed ($ArCl_2C-Vd$) is stable during the kinetic experiment and the rate of reaction in these solvents is therefore described by the pseudo-zero-order kinetic Eqn. (8).[66] In acetonitrile, γ-butyrolactone, ethyl methyl ketone, 1,1,2,2-tetrachloroethane, acetophenone, nitrobenzene, benzonitrile, and methylene chloride, the above product decomposes rapidly during the kinetic experiment with formation of $Vd^{+}Cl^{-}$. The rate of reaction in these solvents is therefore described by the pseudo-zero-order kinetic equation[62,66,76]

$$-d[Vd^{\cdot}]/2dt = d[Vd^{+}Cl^{-}]/2dt = k_0. \quad (16)$$



In preparative experiments carried out with $PhCCl_3$, p-$MeOC_6H_4CCl_3$, and p-$MeC_6H_4CCl_3$ in acetonitrile, the triazine (III) was isolated:[62,67,123]

(III)



Compound (III) is apparently formed via an intermediate arylchlorocarbene or via the recyclisation of the verdazyl alkylation product.

Reaction (18) takes place[68] in the heterolysis of Ph_2CCl_2 in aprotic solvents in the presence of verdazyl and its rate is described by Eqn. (16):

The verdazyl alkylation product is apparently formed initially and then decomposes rapidly into $Vd^{+}Cl^{-}$ and diphenylcarbene. The latter is oxidised by oxygen to benzophenone.

The heterolysis of Ph_2CCl_2 takes place in ethanol in accordance with the equation:[69]

In conformity with the stoichiometry of this reaction, its rate in each individual experiment is described by a pseudo-zero-order kinetic equation:

$$-d[Vd^{\cdot}]/4dt = d[Vd^{+}Cl^{-}]/2dt = k_0. \quad (20)$$

In 85% aqueous dioxane, the verdazyl alkylation product Ph_2CCl_2 is stable during the kinetic experiment and the rate of reaction is described in this case by the kinetic equation (8).[69,77] Thus the stoichiometric ratios $[Ph_2CCl_2]:[Vd^{\cdot}]:[Ph^{+}Cl^{-}]$ depend greatly on the nature of the solvent in the heterolysis of the Ph_2CCl_2 in the presence of verdazyl. In an aprotic medium, they are 1:2:2, in ethanol they are 1:4:2, and in 85% aqueous dioxane they are 1:2:1.

A similar wide variety of stoichiometric ratios has been observed also in the heterolysis of trichloromethylbenzenes.[61,62,66,76] This is a characteristic feature of organic polychloro-compounds which afford unstable alkylation products on interaction with verdazyl.

A characteristic feature of the verdazyl method is that the indicator always reacts with the solvent-separated ion pair of the substrate. This occurs also in an aprotic medium where there is no

nucleophile other than Y—Vd· and in a protic medium where verdazyl must compete with a solvent molecule for the cationoid. For example, in 85% aqueous dioxane in the presence of 1×10^{-4} M Vd·, the heterolysis of Ph_2CCl_2 and *p*-$MeOC_6H_4CHCl_2$ takes place fully via the pathway leading the formation of verdazyl alkylation products and not hydrolysis products. This shows that the solvent-separated ion pair reacts very rapidly with verdazyl.

The verdazyl method made it possible to investigate in detail the influence of small amounts of water (0.05—0.3 M) on the rates of S_N1 and $E1$ reactions in aprotic solvents and to determine the relative yields of products formed with participation of Y—Vd· and water in S_N1 reactions.[18,21,39,41—44,46,47,49,50,52,54,59,62,69,70] Water cooperates with the heterolysis reactions in all cases by virtue of the formation of hydrogen-bonded complexes ($RX\ldots H_2O$) and increases the rate of reaction. The kinetic effect of water is determined by the parameter b in Winstein's equation (21) and greatly depends on the nature of the substrate and the solvent:

$$k_{H_2O}=k(1+b[H_2O]). \qquad (21)$$

Here k_{H_2O} and k are the rate constants for heterolysis in the presence of water and in its absence.

The kinetic effect of water yields information about possible errors in the determinatin of the rate of heterolysis due to undetermined admixtures of water in the aprotic solvent. The lowest value of b (1—3 litre mol^{-1}) were found for the heterolysis of t-butyl and adamantyl substrates. Usually b = 5—10 litre mol^{-1}, reaching 30—50 litre mol^{-1} in some cases (7α-bromocholesteryl benzoate in PhCN and $PhNO_2$).[59,70] Analysis of the data presented shows that the undetermined admixtures of water (<0.05 M) have hardly any effect on the rate of heterolysis of t-BuX and 1-AdX in aprotic solvents; for b = 10 litre mol^{-1}, the error in the determination of the rate can be 10—15%, while for b = 50 litre mol^{-1} the error is 30%. The values quoted refer to polar aprotic solvents (MeCN, propylene carbonate, $PhNO_2$, PhCN). On reducing the polarity of the solvent, the kinetic effect of water increases, but the water content then falls so much that the real effect becomes insignificant.

On heterolysis of Ph_2CHX (X = Cl, Br) in the presence of Vd· in moist acetonitrile with $[H_2O] \simeq 0.045$ M, two reaction products are formed from the substrate—the verdazyl alkaylation product and diphenylmethanol:[21,39]

$$Ph_2CHX \begin{cases} \xrightarrow{2Vd^{\cdot}} Ph_2CH{-}Vd + Vd^+X^-, \\ \xrightarrow{H_2O} Ph_2CHOH + HX \end{cases} \qquad (22)$$

$$Ph_2CHOH + HX \xrightarrow{2Vd^{\cdot}} Vd^+X^- + VdH\ .$$

Regardless of the relative yields of these products, the rate of reaction is described by the kinetic equation (8).

The method makes it possible to determine the amount of Ph_2Cd—Vd and VdH formed in the kinetic experiment. As already mentioned, an equimolecular mixture of Vd^+X^- and VdH is quantitatively converted into Vd· when acted upon by alkali. If formaldehyde is added, then the excess Vd^+X^- is also converted quantitatively into verdazyl.[124,125] In practice, this is achieved by adding a drop of an alkaline solution of formaldehyde to the reaction mixture. Since the relative yields of Ph_2Cl—Vd and VdH are determined by the competition between Vd· and H_2O for the formation of the solvent-separated ion pair $Ph_2CH^+|Solv|X^-$, then, knowing the concentrations of both nucleophiles in the solution, it is possible to calculate their relative reactivities in the reaction with the solvent-separated ion pair. In the heterolysis of Ph_2CHX (X = Cl, Br) in MeCN at 25 °C, the ratio $k_{Vd^{\cdot}}/k_{H_2O} \simeq 10^4$. Consequently Vd· is a very powerful nucleophile compared with H_2O. Indeed in the case of a strong nucleophile such as N_3^-, the ratio k_{N_3}/k_{H_2O} for Ph_2CHCl is only 170.[126]

In the heterolysis of 1-AdI in moist acetonitrile, $k_{Vd^{\cdot}}/k_{H_2O} \simeq 10^4$, while in the heterolysis of 1-AdOTs the ratio is $\sim 10^3$.[46,49]

The high reactivity of verdazyl compared with water in the reaction with the solvent-separated ion pair is apparently due to the different mechanisms of these reactions—the reaction with H_2O involves an S_N2 process during which the cationoid should be desolvated, while the reaction with Vd^+ apparently involves an outer-sphere electron transfer (an *SET*2 reaction) without the decomposition of the solvation shells of the reactants. This explains why triphenylverdazyls proved to be such effective internal indicators for unimolecular heterolysis reactions.

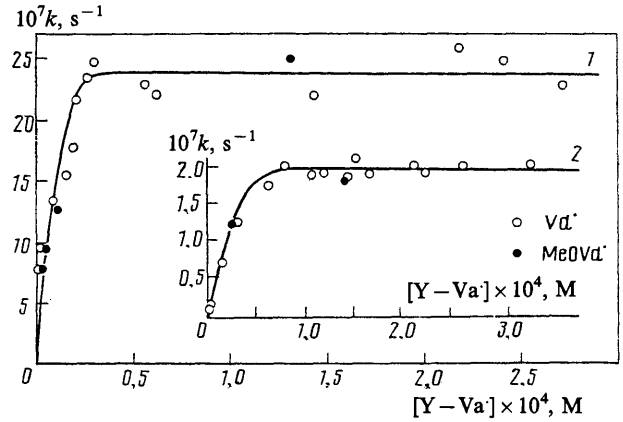


Figure 3. The influence of the concentration and nature of Y—Vd· on the rate of heterolysis of Ph_2CCl_2 in acetonitrile (line *1*) and acetone (line *2*) at 25 °C.

The data currently available for the heterolysis of organic substrates in the presence of verdazyls (Ph_2CHBr,[40—45,72] Ph_2CHCl,[21] 1-AdOTs,[46,54,56,80] 1-AdI,[47,49] 1-AdOCOCl,[27] 1-AdOPic,[52,56,80] 7α-bromocholesteryl benzoate,[59,70,75] PhCHClMe,[60,65,69] *p*-MeO.$C_6H_4CCl_3$,[62] Ph_2CCl_2,[69,77] t-BuBr,[68,73] t-BuCl,[71] *p*-$MeOC_6H_4$.$CHCl_2$,[77,78] cumenyl chloride,[79] 2-bromo-2-methyladamantane,[68] and 2-chloro-2-methyladamantane[71]) show that these radicals always react with the solvent-separated ion pairs of the substrate—both in S_N1, $E1$, and $F1$ reactions and in solvolytic reactions. This is a characteristic feature of the verdazyl method. The solvent-separated ion pair is formed after the rate-limiting stage of the heterolysis. Clearly verdazyls can be used as indicators subject only to the condition that the rate of the reaction of the solvent-separated ion pair with Y—Vd· is higher than the rate of formation of this intermediate. It is easy to assume that, on reducing the

concentration of the indicator, it is possible to achieve a situation where the reaction of Y—Vd˙ with the solvent-separated ion pair limits the overall rate of the process. This has been demonstrated in the heterolysis of Ph_2CCl_2,[69,77] p-$MeOC_6H_4CHCl_2$,[77,78] and $(p\text{-}ClC_6H_4)_2CCl_2$.[69]

The influence of the concentration and nature of the verdazyl on the rate of heterolysis Ph_2CCl_2 in acetonitrile and acetone is illustrated in Fig. 3, while Fig. 4 demonstrates their influence on the rate of solvolysis of Ph_2CCl_2 and p-$MeOC_6H_4CHCl_2$ in 85% aqueous dioxane.

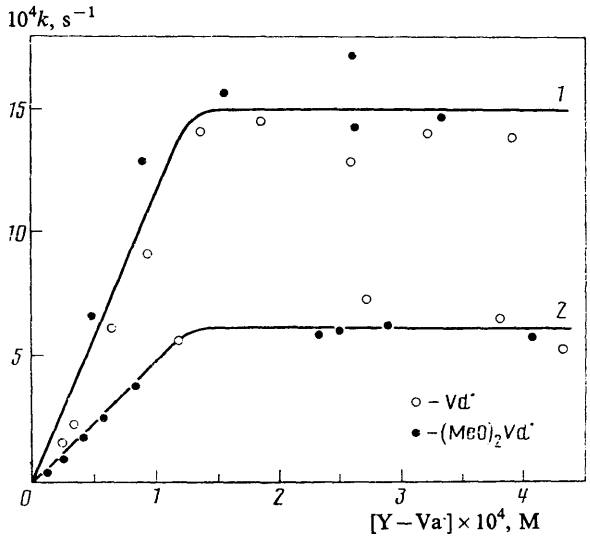

Figure 4. The influence of the Vd˙ concentration on the rate of heterolysis of p-$MeOC_6H_4CHCl_2$ (line *1*) and Ph_2CCl_2 (line *2*) in 85% aqueous dioxane.

Evidently the k—[Y—Vd˙] relation consists of two sections; at relatively high indicator concentrations, the rate of reaction is independent of the concentration of Y—Vd˙ and of the nature of its substituent, while at low indicator concentrations a direct proportionality is observed between the quantity k and the Y—Vd˙ concentration. In the former case, the rate of reaction is described by Eqn. (4), while in the latter it is described by a second-order kinetic equation:

$$v = k_2[RX][Y—Vd˙]. \quad (23)$$

Thus, on reducing the indicator concentration, the rate-limiting state of the reaction changes: at comparatively high verdazyl concentrations, the rate-limiting stage involves the formation of a cationoid intermediate (S_N1 reaction), while at a low verdazyl concentration Y—Vd˙ reacts with the solvent-separated ion pair of the substrate (*SET*2 reaction) in the rate-limiting stage.

The change in the kinetic relations and hence the change in the reaction mechanism in the heterolysis of Ph_2CCl_2 in acetonitrile, acetone (Fig. 3), ethanol (not shown in the Figure), and 85% aqueous dioxane (Fig. 4) occurs at Vd^+ concentrations of 2.0×10^{-5}, 6.2×10^{-5}, 11×10^{-5}, and 13×10^{-5} M respectively. In γ-butyrolactone and propylene carbonate, the rate of reaction is independent of the indicator concentration up to [Vd˙] ≃ 2×10^{-6} M. In the solvolysis of p-$MeOC_6H_4CHCl_2$ in 85% aqueous dioxane, the kinetic relations change at a verdazyl concentration of 11×10^{-5} M (Fig. 4). In the solvolysis of $(p\text{-}ClC_6H_4)_2CCl_2$ in alcohols, the change occurs at [Vd˙] > 1×10^{-4} M.[69] These data demonstrate that, when verdazyls are used in a proton-donating medium, the indicator concentration must be higher than 1×10^{-4} M, whereas in an aprotic medium it can be appreciably lower. In the study of the kinetics of the heterolysis of organic compounds by the verdazyl method, it is necessary to obtain proof that the rate of reaction is independent of the indicator concentration for each reaction system.

It is seen from Figs. 3 and 4 that the rates of heterolysis of Ph_2CCl_2 and p-$MeOC_6H_4CHCl_2$ are independent of the nature of the substituent in the verdazyl even when the rate of reaction depends on its concentration. This demonstrates that the reaction of Y—Vd˙ with the solvent-separated ion pair consists of many stages: in one stage, verdazyl plays the role of an electron donor (formation of a charge-transfer complex), whilst in another it behaves as an electron acceptor (decomposition of the charge-transfer complex), which leads to the compensation effect of the substituent in the indicator. Thus, by changing the concentration of the indicator, it is possible to change the rate-limiting stage of the reaction and to obtain information about the mechanism of the product-forming stage.

In the course of the development of the verdazyl method, important conclusions were reached concerning the essential features of the unimolecular heterolysis of organic compounds investigated. The application of the method demonstrated that the stage involving the external return of the ion pair ($R^+|Solv|X^- \rightarrow R^+X^- \rightarrow RX$) is not very important, although this idea is still always used in the interpretation of the reaction mechanism.[7—9,40,45,109,110] If this stage could influence appreciably the overall rate of reaction, the rate constant determined in the presence of verdazyl would have depended on the concentration and nature of Y—Vd˙ owing to the competitive decompositon of the solvent-separated ion pair in the ion pair recovery reaction and the reaction with the indicator:

$$RX \leftarrow R^+X^- \leftarrow R^+|Solv|X^- \xrightarrow{Vd˙} \text{products}.$$

Hitherto this has never been observed in the study of the kinetics of the heterolysis of all the substrates listed above in various protic and aprotic solvents.

Since the data obtained by the verdazyl method agree well with the results of other procedures, one may claim that the stage involving the external return of the ion pair is not very important both in the presence of verdazyls and without them, although the opposite view is frequently adhered to in the literature.[7,109,110,113,116,117] For example, it is believed[116,117] that the rates of solvolysis of Ph_2CCl_2 and p-$MeOC_6H_4CHCl_2$ in 85% aqueous dioxane, determined spectrophotometrically from the formation of Ph_2CO and p-$MeOC_6H_4CHO$, depend greatly on the stage involving the external return of the ion pair and it is postulated that the rate-limiting stage involves the interaction of the solvent-separated ion pair of the substrate with water. It has been demonstrated by the verdazyl method[69,77,78] that, under conditions where the rate of reaction is independent of the concentration and nature of Y—Vd˙, the results of both studies agree satisfactorily. Consequently in both cases the mechanism of the external return of

the solvent-separated ion pair is unimportant. Under the conditions of the studies of Vitullo and Vilgis,[116,117] the solvent-separated ion pair reacts with water, while under the conditions of the studies of Dvorko and co-workers[69,77,78] it reacts with Y—Vd˙. The agreement between the rate constants shows that the rate-limiting stage in these reactions is the formation of the cationoid intermediate and not the reaction of the solvent-separated ion pair with the nucleophile.

The application of the verdazyl method makes it possible to shorten greatly the time required to study the kinetics of the heterolysis reactions and to obtain reliable data in those cases where the rate of reaction depends comparatively greatly on the salt concentration. This made it possible to determine the rates of heterolysis of the majority of the substrates listed above in a large set of protic and aprotic solvents (20—40 solvents) and to carry out a quantitative analysis of the solvation effects.[11,34,48,51,53,55—57,64—66,68—70,76] It was shown that the rate of reaction is determined mainly by the polarity and electrophilicity of the solvent and that the nucleophilic cooperation of the solvent with the heterolysis does not take place. The rates of heterolysis of PhCHClMe, Ph_2CHBr, 1-AdOTs, and $PhCMe_2Cl$ are altogether independent of the nucleophilic properties of the medium, while in the heterolysis of 7α-bromocholesteryl benzoate, t-butyl halides, 1-AdI, 1-AdBr, 1-AdOPic, 2-bromo-2-methyladamantane, and p-$MeOC_6H_4CCl_3$, the negative effect of nucleophilic solvation is observed.

If the rate of heterolysis has been limited by the conversion of the contact ion pair into the solvent-separated ion pair (Scheme 3), as is generally assumed,[7,8,10] the nucleophilicity of the solvent would have promoted the reaction. In order to overcome this contradiction, a new intermediate was introduced into Winstein's scheme—a space-separated ion pair (SPSIP), formed on conversion of the contact ion pair into the solvent-separated ion pair:[49,60,62,68—70]

$$RX \rightleftharpoons R^+X^- \rightleftharpoons \underset{\text{SPSIP}}{R^+ \ldots X^-} \rightleftharpoons R^+|Solv|X^-. \qquad (24)$$

It is postulated that the rate-limiting stage of the heterolysis is the separation of ions in the contact ion pair with formation of a vacancy between them. Consequently a solvent molecule is rapidly incorporated in the interionic space within the space-separated ion pair.

On solvolysis of organic substrates via the S_N2—ion pair mechanism ($PhCH_2Cl$, PhCOCl, allyl tosylate), the rate of reaction increases with increasing nucleophilicity of the solvent.[37,61]

The application of the verdazyl method to the study of an *F*1 reaction for 1-AdOCOCl as an example yielded an unexpected resut:[27,56] the rate constants [Eqn. (4)] found in protic and aprotic solvents differed as a rule from the values obtained from the consumption of the substrate.[26,127] This is associated with the fact that the decomposiiton reaction of 1-AdOCOCl is a consecutive-parallel process and different methods for the determination of the reaction rate reflect different aspects of this process. The data obtained supplement one another. This leads to new possibilities for the study of *F*1 reactions. The use of verdazyls made it possible to demonstrate the fragmentation process proceeds via the formation of both a contact ion pair and a solvent-separated ion pair.

The rate of heterolysis of organic substrates is determined under the conditions of a stationary process where the concentration of cationoid intermediates [Int] remains constant during the kinetic experiment, i.e. for $d[Int]/dt = 0$.[128] However, time is required for the reaction system to attain a stationary state. The verdazyl method makes it possible in some cases to follow the process by determining the rate at very low conversions of the substrate ($\sim 10^{-4}$—10^{-5}%). This was observed in the heterolysis of Ph_2CCl_2 in propylene carbonate[69] and of cumenyl chloride in acetonitrile, propylene carbonate, and γ-butyrolactone.[79] In these cases, and induction period, reflecting the attainment of the stationary state by the system, appears (Fig. 5) on the kinetic curve. A delay in the attainment of a stationary state by the system may be caused by undetermined impurities in the solvent and by added salts (LiBr, $Bu_4N^+Br^-$, $Et_3PhCH_2N^+Cl^-$) or a crown-ether. These compounds apparently trap the intermediate formed before the rate-limiting stage (for example, a contact ion pair) and for a time direct the process towards the formation of an inactive complex. The addition of $LiClO_4$, which catalyses the conversion of the contact ion pair into an intermediate with a greater degree of charge separation, eliminated the induction period.

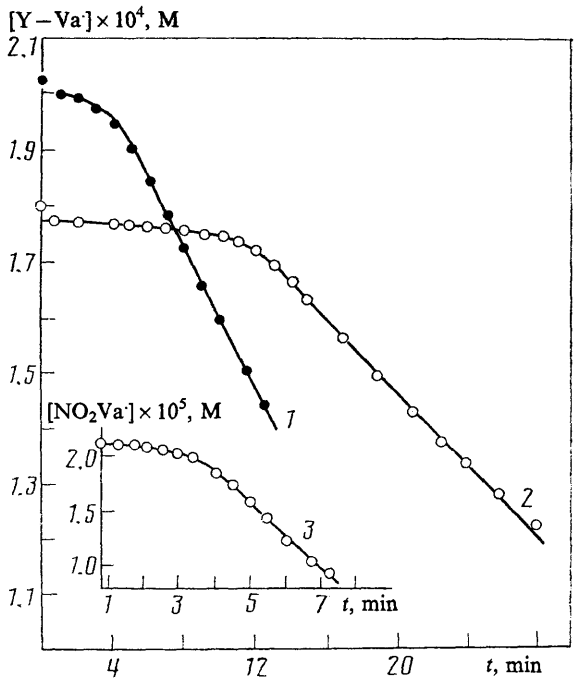

Figure 5. Kinetics of the heterolysis of $PhCMe_2Cl$ in propylene carbonate in the presence of salts at 25 °C: *1*, $[PhCMe_2Cl] = 0.00645$ M, $[Vd˙] = 2.03 \times 10^{-4}$ M, $[Bu_4N^+Br^-] = 0.1$ M, $k = 8.03 \times 10^{-6}$ s^{-1}; *2*, $[PhCMe_2Cl] = 0.00688$ M, $[(MeO)_2Vd˙] = 1.80 \times 10^{-4}$ M, $[Et_3(PhCH_2)N^+Cl^-] = 0.05$ M, $k = 4.30 \times 10^{-6}$ s^{-1}; *3*, $[PhCMe_2Cl] = 0.00636$ M, $[NO_2Vd˙] = 2.2 \times 10^{-5}$ M, [LiBr] = 0.0599 M, $k = 4.02 \times 10^{-6}$ s^{-1}.

III. Application of the verdazyl method to the study of salt effects

Salt effects constitute a fine instrument for the investigation of the details of the mechanisms of organic reactions and for the establishment of the nature of the catalytic effects.[1,7,8] This is one of

the most difficult problems in physical organic chemistry. The application of verdazyls makes it possible to study in detail the salt effects in heterolysis reactions, to elucidate their nature, and to specify in a concrete form the mechanism of the heterolysis itself. Particularly valuable data have been obtained in the study of S_N1 and $E1$ reactions in an aprotic medium.[40,43,45–47,49,50,52,54,56,61,62,65,68–73,75,76–80]

The interpretation of the unusual salt effect of perchlorate put forward by Winstein has given rise to much controversy.[1,7–9,40,45,129] It reduces to the postulate that the sharp increase in the rate of reaction in the presence of small amounts of the salt is caused by the exchange of the nucleofugal species in the solvent-separated ion pair with formation of the ion pair (IV), which is incapable of being converted into a contact ion pair:

$$\underset{}{ClO_4^-}+R^+|Solv|X^- \rightleftharpoons \underset{(IV)}{R^+|Solv|ClO_4^-}+X^- \quad . \qquad (25)$$

In other words, the presence of the unusual salt effect is explained by the suppression of the stage involving the external return of the ion pair. As already mentioned, it has been demonstrated with the aid of the verdazyl method that this stage is unimportant. Winstein's intepretation is incorrect.[40,43,45] Detailed study of the unusual salt effect by the verdazyl method led to the conclusion that the catalytic effect of perchlorate is caused by the effect of ClO_4^-,[40] Li^+,[70,75] or of the salt ion pair[68–70] on the contact ion pair of the substrate, which leads to the formation of the ion triplets (V) and (VI) or the quadrupole (VII), which are converted more readily than the contact ion pair itself into the cationoid intermediate with a greater charge separation:

$$\underset{(V)}{ClO_4^-|Solv|R^+X^-}, \quad \underset{(VI)}{R^+X^-Li^+}, \quad \underset{(VII)}{R^+X^-, M^+Y^-} \quad .$$

Comparison of data for the kinetics of the hydrolysis of Ph_2CCl_2 in acetone, obtained by the verdazyl method,[69] with the results of a study[130] where the reaction of Ph_2CCl_2 with NaI was investigated in the same solvent in the presence of $LiClO_4$ provided evidence in support of the fact that the catalytic effect of $LiClO_4$ under the conditions of the unusual salt effect is caused by the action of the salt on the contact ion pair and not on the covalent substrate. In the latter case, the catalytic effect of the salt is lower by approximately two orders of magnitude.

Analysis of data for other positive salt effects, obtained by the verdazyl method, showed that they are associated with the formation of the quadrupole (VII) and not with the increase in the ionic strength of the solution.[21,40,43,46,47,49,52,54,62,68–71] The unusual salt effect is a variety of the normal salt effect.

The concentration and nature of Y—Vd$^{\cdot}$, both in the presence of salts increasing the rate of reaction and in their absence, do not affect the rate of reaction.

The verdazyl method has also made it possible to discover a new salt effect, which was called the negative salt effect.[40,43,46,47,49,52,54,56,62,68–71,76,80] Its characteristic feature is that of the addition of a salt having an ion in common with the ion pair lowers the rate of reaction under conditions where a free carbonium ion is not formed. Such reduction in the rate of reaction is usually attributed to the salt effect caused by the Law of Mass Action, i.e. by the reaction involving reformation from the free carbonium ion:[1–3,7–9,129]

$$R^+ + X^- \rightarrow R^+|Solv|X^- \rightarrow R^+X^- \rightarrow RX.$$

However, the negative salt effect is usually manifested in an aprotic medium where heterolysis does not go so far as the formation of a free carbonium ion.

This salt effect is associated with the reaction involving the external return of the ion pair: the salt or its anion form with the solvent-separated ion pair or the space-separated ion pair a quadrupole or an anionic triplet, which are more readily converted into the contact ion pair and subsequently into the covalent substrate than the solvent-separated and space-separated ion pairs themselves:

$$RX \rightleftharpoons R^+X^- \overset{X^-}{\rightleftharpoons} R^+ \ldots X^- \rightleftharpoons R^+|Solv|X^- \xrightarrow{Y-Vd^{\cdot}} \text{products}. \qquad (26)$$

The decrease in the rate of reaction in the presence of a salt with a common ion is caused by the catalysis of the reaction involving the external return of the ion pair.

For low degrees of conversion of the substrate, where the nucleofugal species exchange reaction is unimportant, a negative salt effect of a similar kind is manifested also in the presence of a salt with a non-common ion. In all cases its nature is the same: a decrease in the concentration of the product-forming intermediate (a solvent-separated ion pair).

It is seen from Scheme (26) that the verdazyl always acts on the solvent-separated ion pair, while the salt can act both on the solvent-separated ion pair and on the space-separated ion pair. In the former case, there is competition between the salt and the verdazyl for the cationoid and the rate of reaction should depend on the nature and concentration of Y—Vd$^{\cdot}$. In the latter case, this should not be observed.

Detailed study of the influence of the concentration of the verdazyl and of the nature of the substituent in it on the rate of reaction in the presence of salts reducing the rate of reaction demonstrated that the nature of the negative salt effect depends greatly on the structure of the substrate and on the nature of the salt and the solvent. Thus the decrease in the rate of heterolysis of *p*-$MeOC_6H_4CCl_3$ in acetonitrile in the presence of LiCl is caused by the interaction of the salt with the space-separated ion pair.[62] A similar picture is observed in the heterolysis of 1-AdI in propylene carbonate in the presence of $Et_4N^+OPiC^-$.[49] In the heterolysis of Ph_2CCl_2 in acetonitrile, γ-butyrolactone, and propylene carbonate, the negative salt effect of chlorides and bromides is associated with their interaction with the solvent-separated ion pair,[69] whereas in the heterolysis of 7α-bromocholesteryl benzoate in γ-butyrolactone, the negative salt effect of the chloride is caused by the reaction of the salt with the space-separated ion pair while in nitrobenzene and *o*-xylene it is due to interaction with the solvent-separated ion pair.[70] The negative salt effect of $Et_3(PhCH_2)N^+Cl^-$ in the heterolysis of cumenyl chloride in acetonitrile and γ-butyrolacetone is also associated with the effect of the salt on the solvent-separated ion pair, while propylene carbonate it is due to its effect on the space-separated ion pair, while in propylene carbonate it is due to its effect on the space-separated ion pair.[79] In the heterolysis of t-BuBr, t-BuCl, 2-bromo-2-methyladamantane, and 2-chloro-2-methyladamantane, and 2-chloro-methyladamantane in γ-butyrolactone, the negative salt effect of the chloride and thiocyanate is associated with their interaction with the solvent-separated ion pair.[68,73] On the other hand, in the heterolysis of Ph_2CHBr in acetonitrile the salts $Et_4N^+I^-$ and $Et_4N^+Br^-$ act on the space-separated ion pair, while

$Et_4N^+Cl^-$ and $Et_3(PhCH_2)N^+Cl^-$ act on the solvent-separated ion pair.[40,72]

When the rate of heterolysis in the presence of a salt reducing the rate of reaction depends on the Y—Vd˙ concentration, then it usually depends also on the nature of the substituent in the indicator, the rate increasing with enhancement of the electron-donating properties of the radical. This is associated with the idea that the reaction of the solvent-separated ion pair with Y—Vd˙ proceeds via electron transfer from the radical to the cationoid.[91—96] In the heterolysis of Ph_2CCl_2 in acetonitrile in the presence of chlorides, the rate of reaction increases with increasing Y—Vd˙ concentration but is independent of the nature of the substituent in the radical,[69] while in the heterolysis of Ph_2CHBr in acetonitrile in the presence of $Et_3(PhCH_2)N^+Cl^-$ the rate of reaction falls on enhancement of electron-donating properties of Y—Vd˙.[72] These data confirm the conclusion that the reaction between the solvent-separated ion pair and Y—Vd˙ proceeds in several stages.

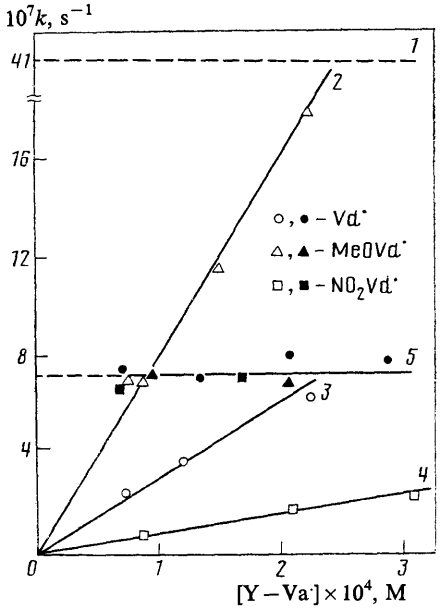

Figure 6. The influence of the concentration and nature of Y—Vd˙ on the rate of heterolysis of 1=AdOTs in γ-butyrolactone in the presence of 0.03 M $Et_4N^+Cl^-$ (lines *2—4*) and 0.03 M $Et_4N^+Br^-$ (line *5*) at 35 °C and in the absence of salts (line *1*).

The study of the k—[Y—Vd˙] relations in the presence of salts reducing the rate of reaction makes it possible to observe also fine differences between salt and solvation effects. Thus the rate of heterolysis of 1-AdOTs and 1-AdOPic in acetonitrile, γ-butyrolactone, and propylene carbonate in the presence of $Et_3(PhCH_2)N^+Cl^-$ or $Et_4N^+Cl^-$ increases with increase in the concentration of Y—Vd˙ and with increase in its electron-donating properties[52,54,56] (Figs. 6—9). Consequently the negative salt effect of the chloride is caused by the reaction of the salt with the solvent-separated ion pair. The addition of $Et_3N^+Br^-$ in the heterolysis of the substrates indicated in γ-butyrolactone and propylene carbonate also reduces the rate of reaction but only in the case of 1-AdOPic in γ-butyrolactone (Fig. 7) does the rate of reaction in the presence of this salt depend on the concentration and nature of Y—Vd˙. Consequently the verdazyl and the chloride act in all these cases on the solvent-separated ion pair, whereas the bromide ion acts on the solvent-separated ion pair in some instances and on the space-separated ion pair in others. On the other hand, in acetonitrile, where the positive salt effect o $Et_4N^+Br^-$ is manifested, the latter salt acts on the contact ion pair.

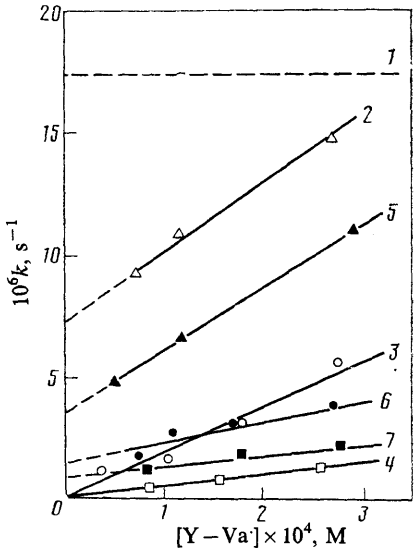

Figure 7. The influence of the concentration and nature of Y—Vd˙ on the rate of heterolysis of 1-AdOPic in γ-butyrolactone in the presence of 0.03 M $Et_3(PhCH_2)N^+Cl^-$ (lines *2—4*) and 0.03 M $Et_4N^+Br^-$ (lines *5—7*) at 25 °C [*1*, the heterolysis rate constant in the absence of salts]; verdazyl: *2* and *5*, $(MeO)_2$Vd˙; *3* and *6*, Vd˙; *4* and *7*, NO_2Vd˙.

Analysis of the nature of the salt effects in an aprotic medium[80] has shown that ClO_4^- acts on the contact ion pair, Br^- acts as a rule on the space-separated ion pair, while Cl^- acts on the solvent-separated ion pair, i.e. with increase in the hardness of the anion there is an increase in the tendency of the salt to react with the later intermediate—with the cationoid having a greater charge separation. Consequently the site where the salt acts during the ionisation of the covalent bond is determined by the principle of hard and soft acids and bases (HSAB), because an increase in the hardness of the carbonium ion is to be expected in the CIP—SPSIP—SSIP series.

The differences between the space-separated and solvent-separated ion pairs are apparently small and their negative activity in the reaction with the salt therefore depends greatly both on the structure of the substrate and on the nature of the solvent.[52,56,70—72,77—79] In the solvolysis of *p*-$MeOC_6H_4CHCl_2$ in aqueous dioxane, Cl^- acts on the space-separated ion pair, while Br^- acts on the solvent-separated ion pair,[78] which is caused by the inversion of the

nucleophilicity of the halide anion in water compared with the aprotic medium.

The application of the HSAB principle to the interpretation of the salt effects in unimolecular heterolysis reactions and other carbonium ion processes[131,132] makes it possible to explain why the catalytic effect in the carbonium generation process is manifested by the weakest nucleophile. This is associated with the fact that it begins to act in the earliest stages.

The application of the verdazyl method showed that, in the heterolysis of organic substrates, a superposition of the positive and negative salt effects is frequently observed.[52,54,56,65,68–71,73]

Figs. 8 and 9, where the $k-[Y-Vd^{\cdot}]$ relations are presented for the heterolysis of adamantyl substrates in acetonitrile in the presence of chlorides, show that the form of the $k-[Y-Vd^{\cdot}]$ curves for 1-AdOTs differs significantly from that for 1-AdOPic. In the case of 1-AdOTs (Fig. 8), an increase in the $Y-Vd^{\cdot}$ concentration results in the attainment of by k of the value of the rate constant for heterolysis in the absence of salts (indicated by a dashed line), after which k no longer changes on increase in the indicator concentration. In the heterolysis of 1-AdOPic, the value of the rate constant for heterolysis in the absence of salts is also rapidly attained as the indicator concentration rises, but in this case k continues to increase on further increase in the indicator concentration. This shows that in the latter case the negative salt effect is accompanied also by a positive salt effect, which is due to the action of the salt on the contact ion pair.

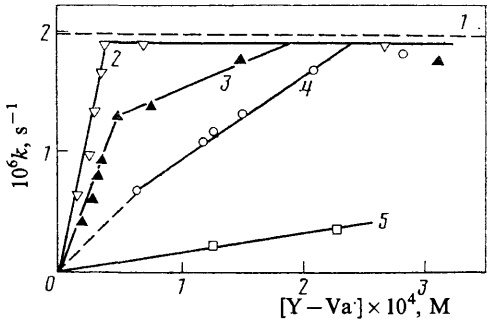

Figure 8. The influence of the concentration and nature of $Y-Vd^{\cdot}$ on the rate of heterolysis of 1-AdOTs in acetonitrile in the presence of 0.03 M $Et_4N^+Cl^-$ at 25 °C [*1*, the heterolysis rate constant in the absence of salts]; verdazyl: *2*, $(MeO)_2Vd^{\cdot}$; *3*, $MeOVd^{\cdot}$; *4*, $Vd^{\cdot}$; *5*, $NO_2Vd^{\cdot}$.

The superposition of the salt effects is manifested particularly well when one follows the influence of the salt concentration on the rate of reaction in the presence of the same concentration of verdazyls. Fig. 10 shows how markedly the manifestation of the salt effect changes as a function of the nature of the indicator in the heterolysis of t-BuBr in γ-butyrolactone in the presence of $Et_3(PhCH_2)N^+Cl^-$:[68,73] in the presence of $MeOVd^{\cdot}$, the salt hardly affects the rate of reaction, in the presence of $Vd^{\cdot}$ and $NO_2Vd^{\cdot}$ the rate of reaction falls with increase in the salt concentration, while in the presence of $(MeO)_2Vd^{\cdot}$ it increases. These relations can be explained by the superposition of the negative and positive effects of $Et_3(PhCH_2)N^+Cl^-$, the negative salt effect being due to the reaction in the salt (as well as the verdazyl) with the solvent-separated ion pair, while the positive effect is due to the reaction with the contact ion pair. In the presence of $MeOVd^{\cdot}$, both effects are approximately the same, in the presence of $Vd^{\cdot}$ and especially $NO_2Vd^{\cdot}$ the negative salt effect predominates, while in the presence of $(MeO)_2Vd^{\cdot}$, which traps the solvent-separated ion pair almost completely and hence suppresses the negative salt effect, the positive salt effect predominates.

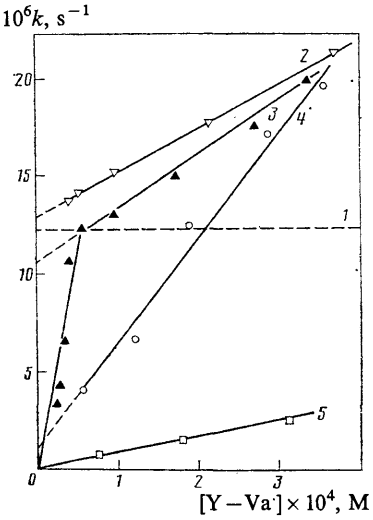

Figure 9. The influence of the concentration and nature of $Y-Vd^{\cdot}$ on the rate of heterolysis of 1-AdOTPic in acetonitrile in the presence of 0.03 M $Et_3(PhCH_2)N^+Cl^-$ at 25 °C [*1*, the heterolysis rate constant in the absence of salts]; verdazyl: *2*, $(MeO)_2Vd^{\cdot}$; *3*, $MeOVd^{\cdot}$; *4*, $Vd^{\cdot}$; *5*, $NO_2Vd^{\cdot}$.

It is seen from Figs. 8–10 that at certain $Y-Vd^{\cdot}$ concentrations the negative salt effect is completely eliminated. The relative reactivities of the verdazyl and the salt in the reaction with the solvent-separated ion pair were calculated from these data.[52,54,56,69,70–79] In the heterolysis of 1-AdOTs, 1-AdOPic, $PhCMe_2Cl$, and t-BuBr, the solvent-separated ion pair reacts ~2 orders of magnitude faster with the verdazyl than with the salt. This agrees with the hypothesis that $Y-Vd^{\cdot}$ reacts with the solvent-separated ion pair and not with the free carbonium ion. In the heterolysis of Ph_2CCl_2, the verdazyl and the chloride react with the sovent-separated ion pair at approximately the same rates.[69]

The decrease in the rate of heterolysis in the presence of a salt having a common ion is almost always explained by the salt effect caused by the Law of Mass Action, i.e. by the formation of a free carbonium ion [see Scheme (3)].[1,3,8,129] It was demonstrated above that such a decrease in the rate can be associated with the action of the salt on the solvent-separated or space-separated ion pair. The verdazyl method makes it possible to specify in a more concrete form the cause of the decrease in the rate of reaction in the presence of a salt having a common ion.

As an example, we shall consider the heterolysis of p-$MeOC_6H_4CHCl_2$. The rate of solvolysis of this substrate has been determined[117] in 75% aqueous dioxane from the formation of p-$MeOC_6H_4CHO$. It was shown that the addition of chlorides (LiCl, $Bu_4N^+Cl^-$) diminishes the rate of reaction; it was concluded that the reaction proceeds via the formation of a fre carbonium ion. The study of the kinetics of the solvolysis of p-$MeOC_6H_4CHCl_2$ by the verdazyl method under similar conditions showed that Cl^- and the verdazyl act on different intermediates.[78] If it is supposed that Vd$^\cdot$ reacts with the free carbonium ion, then Cl^- should react with the solvent-separated ion pair. On the other hand if Vd$^\cdot$ reacts with the solvent-separated ion pair, then Cl^- should react with the space-separated ion pair. Consequently, in the heterolysis of p-$MeOC_6H_4CHCl_2$ in 75% aqueous dioxane, Cl^- never reacts with the free carbonium ions; the observed decrease in the rate of reaction is caused by the negative salt effect associated with the reaction of the salt with the substrate ion pair. In the solvolysis of p-$MeOC_6H_4CHCl_2$, a free carbonium ion is not formed.[78]

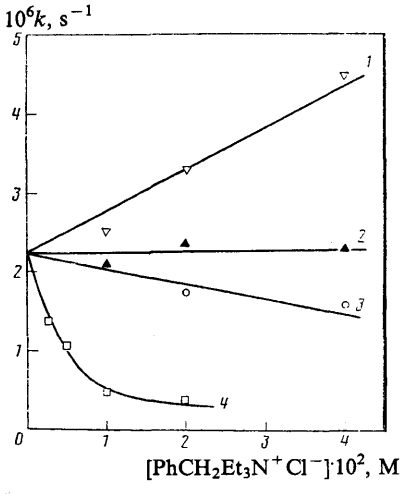

Figure 10. The influence of the concentration of $Et_3(PhCH_2)N^+Cl^-$ and of the nature of Y—Vd$^\cdot$ (3.2×10^{-4} M) on the rate of heterolysis of t-BuBr in γ-butyrolactone at 25 °C; verdazyl: *1*, $(MeO)_2Vd^\cdot$; *2*, $MeOVd^\cdot$; *3*, $Vd^\cdot$; *4*, $NO_2Vd^\cdot$.

The study by the verdazyl method of the salt effects in unimolecular heterolysis reactions confirmed the reaction mechanism represented by Scheme (24).

IV. Conclusion

The application of the verdazyl method to the study of the kinetics and mechanisms of S_N1, $E1$, and $N1$, and solvolysis reactions made it possible to reduce greatly the duration of the experiment and to obtain an extensive set of kinetic data which in many cases are inaccessible by other methods. These data have been used for the quantitative analysis of the solvation effects over a wide range of substrates. The application of the method to the study of S_N1 reactions has been shown to be especially effective. Other available methods for the study of the kinetics of these reactions generally yielded invalid results owing to the impossibility of taking into account the salt effects.

The application of the verdazyl method made it possible to investigate in detail the salt effects, to elucidate their nature, and to specify in detail the mechanism of the heterolysis of the covalent bond. For example, it has been shown that the conclusion that a free carbonium ion is formed, reached on the basis of the decrease in the rate of reaction in the presence of a salt with a common ion, is unjustified. In the study of $F1$ reactions, the verdazyl method proved to be an important complement to other procedures.

The verdazyl method has been widely tested.[18,21,22,27,29–80] The kinetics and mechanisms of the heterolysis of 21 substrates have been investigated with its aid. The results obtained for the solvation and salt effects have led to a new mechanism of the heterolysis of the covalent bond [see Scheme (24)] which includes the formation of a space-separated ion pair. It has been shown that the nature of the cationoid, which is subjected to nucleophilic attach by the salt anion, is determined by the principle of hard and soft acids and bases.

The verdazyl method is being vigorously developed at the present time. Further expansion and deepening of its possiblities should lead to significant mechanistic results.

The verdazyl method makes it possible to study the kinetics of the solvolysis of substrates, for example PhCOCl, which react via an S_N2 mechanism.[61] Verdazyls can also be used to study the kinetics of the photolysis of chlorohydrocarbons,[133,134] and for the selection of stabilisers for the latter.[135]

The electroreduction of organic compounds in the presence of catalysts causing catalytic evolution of hydrogen and the electrosynthesis of chiral compounds

S G Mairanovskii
N D Zelinskii Institute of Organic Chemistry, Academy of Sciences of the USSR, Moscow

ABSTRACT. **A critical examination has been made of the mechanism of catalysts (particularly alkaloids) of the electrochemical catalytic evolution of hydrogen in their effect on the electroreduction of various organic compounds and on the induction of optical activity when prochiral compounds participate. Particular attention has been paid to processes occurring at electrodes modified by chiral compounds and to the preparation of optically active products in media containing asymmetric cosolvents.**

I. Introduction

At the end of the sixties it was established by three groups of investigators, independently of one another in different countries, that catalysts causing the appearance on polarograms of currents of the catalytic evolution of hydrogen may also facilitate the electroreduction of certain classes of organic compounds. In addition, if the catalyst is optically active then when prochiral compounds participate in the electrode reaction the formation of enantiomers is possible, i.e. it is possible to effect asymmetric electrosynthesis during electroreduction or electrooxidation in the presence of such catalysts.

In spite of the significant number of studies devoted to such electrode processes their mechanism is still unclear. An attempt is made in the present review to bring together the results of the many investigations in this area and to discuss critically, in chronological order if possible, the development of the ideas of the various schools of investigators on the effect of catalysts on the catalytic evolution of hydrogen when facilitating the electroreduction of several classes of organic compounds and, in the case of prochiral substrates and optically active catalysts, on the mechanism of formation of enantiomeric products.

II. The nature of the electrochemical catalytic evolution of hydrogen

The phenomenon of the catalytic evolution of hydrogen in the polarograph was first revealed in the thirties by the well-known Czechoslovakian scientist Brdicka (for the history and nature of the phenomenon see the review[1]).

Brdicka discovered that the onset of cathodic polarographic waves in solutions of certain compounds is explained not by the reduction of these compounds but by the electrochemical evolution of hydrogen, which is facilitated (catalysed) in their presence. Such substances are organic bases (B), containing heteroatoms with an unshared pair of electrons (nitrogen, phosphorus, oxygen, sulphur, arsenic, etc.) which may add a hydrogen ion (from any proton donor DH^+) and form onium cations.

$$B+DH^+ \rightleftarrows D+BH^+ . \quad (I)$$

The onion cations BH^+ may decompose on the electrode (transfer of the electron usually occurs reversibly) with the formation of particles having the character of free radicals.

$$BH^+ + e^- \rightleftarrows BH^\cdot . \quad (II)$$

The bimolecular reaction of these radicals[1] leads to the formation of a hydrogen molecule and regeneration of the catalyst in the base form.

$$2BH^\cdot \rightarrow 2B+H_2 . \quad (III)$$

Base B is once again protonated and the whole cycle is repeated so that the result of the process is discharge of the proton donor by the catalyst with the formation of hydrogen. Cations such as H_3O^+, NH_4^+, uncharged molecules such as H_2O, CH_3COOH, etc. and anions able to give up a proton, such as $H_2PO_3^-$, may act as donors.[1]

III. First observations of the phenomenon

As already mentioned, the catalysts indicated also facilitate the electroreduction of certain classes of organic compounds. Grimshaw and collaborators[2] showed that the waves of the electroreduction of coumarin and 4-methylcoumarin in citrate buffer solution in the presence of alkaloids (narcotine, nicotine, codeine, brucine, sparteine

and yohimbine) became less negative, while under preparative electrolysis conditions the yield of the dimeric pinacol falls in the majority of cases but the yield of the secondary alcohol, dihydrocoumarin, is increased compared with experiments in the absence of alkaloid.[2] On the basis of the scheme outlined above for the catalytic evolution of hydrogen it was proposed[2] that the radical BH· formed by reaction (II) transfers a hydrogen atom to the intermediate reduction product of the ketone, a free radical, which enables the yield of secondary alcohol to be increased as a result of the fall in yield of pinacol. It was shown in the same study[2] that in several cases the alcohol obtained was optically active. The difference in the action of the alkaloids studied was explained by their different adsorbability to the electrode surface.

It was shown by us[3] that the products of electroreduction of aromatic nitroalcohols, viz. the corresponding hydroxylamines and amines, accelerate the electroreduction of the starting material so that the process is autocatalytic. The acceleration of the electroreduction of nitroalcohols by certain amines (pyridine, 2-picoline, 2,6-lutidine), amino acids (cysteine) and alkaloids (ephedrine, quinine) is explained[3] by the fact that the protonated form of the amine facilitates protonation of the depolariser. It was shown[3] in separate experiments by adding tetraalkylammonium salts that the shift in the reduction wave of nitro compounds, observed in the presence of amines, in the direction of less negative potentials in this case, was not linked with a change in the structure of the electric double layer on the electrode surface.

In subsequent work it was shown[4] that pyridine and diethylaniline accelerate the electroreduction of nitroethanol and also increase the first kinetic wave of the reduction of acetophenone which is observed on polarograms in a medium with a sufficiently high proton-donating activity, such as in acetate buffer solutions of pH greater than 5.0.[5] These phenomena were explained[4] by acceleration of the protonation reaction during electroreduction of the compounds indicated by catalysts causing the catalytic evolution of hydrogen. It was established in separate experiments[4] that these catalysts may facilitate the electroreduction of organic compounds by accelerating the protonation reaction occurring both on the electrode surface and in the bulk of the reaction layer.

Horner and collaborators showed[6] that in the electroreduction of acetophenone in methanol solution containing optically active ephedrine hydrochloride (at a concentration of 0.5 M) as electrolyte the corresponding alcohol was obtained with an optical activity of 5%. The pinacol formed (yield 40%) possessed no optical activity.[6] It was proposed that ephedrine adsorbed on the electrode influenced the reduction. On reducing the ephedrine concentration to 0.3 M the optical activity of the alcohol was reduced to 3.1%, but was unchanged on increasing it to 1 M. The effect of changing the temperature from −20 °C to boiling the solution on the optical purity of the resulting alcohol was also studied.[6] This effect proved to be maximal at 25−35 °C.

IV. Effect of various factors on the facilitation of electroreduction and the induction of chirality

After the short communications,[2,6] more detailed papers followed from the same authors[7–9] in which details of the investigations carried out were given, and some new data were presented. In one study[7] the electroreduction of 5-methoxy-4-methylcoumarin in the presence of the same set of alkaloids was also reported.

The reduction of acetophenone N-benzylimine in the presence of tetrasubstituted chiral ammonium salts, of the type of trimethylbenzylammonium iodide or dimethylated (at nitrogen) ephedrine, leads to the amine or to the dihydro dimer depending on the conditions.[8] Amines with an optical purity of 5−7% were obtained on electrolysis. Most investigations have been conducted with aliphatic-aromatic ketones, and the effect of the alkyl chain length of the alkyl aryl ketone on the ratio of the resulting pinacol and alcohol has been studied.[9] In methanol solutions containing tetramethylammonium salt as base electrolyte, the yield of alcohol grew with an increase in alkyl chain length at the expense of a reduction in the yield of pinacol.

The effect has also been studied of the length of the alkyl chain of the alkylammonium salt on the yield of hydrodimer in the electroreduction of cinnamic acid ester.[10] The results of these studies are summarised in a review.[11]

Subsequently Horner and collaborators showed[12] that inversion of the absolute configuration of the catalyst−inducer led to inversion of the configuration of the alcohol obtained. The optical purity and configuration of the alcohol may change depending on the extent of methylation of the ephedrine nitrogen atom (a maximum optical activity of 13.9% was achieved with completely methylated ephedrine). On replacing the hydroxyl group of ephedrine by hydrogen the optical purity of the resulting alcohol was reduced but the configuration was retained. These data are correlated in a review,[13] but a detailed description of these and other experiments is contained in the thorough paper of Horner and Degner.[14] In particular it was recorded that methylation of the ephedrine nitrogen atom permits not only an increase in optical purity but also inversion of the configuration of the resulting carbinol. It is interesting that introduction of a hydroxyl group into the position β to the quaternary nitrogen atom of desoxyephedrine leads to a change in the configuration of the alcohol obtained.[14] It was also shown that the pinacol formed on reduction of acetophenone in the presence of chiral inducers did not possess optical activity. In the presence of tetrasubstituted ammonium salts and ephedrine the *meso*-form of the pinacol is mainly formed while in the presence of ephedrine hydrochloride the DL-form results almost exclusively. The absence of optical activity for the pinacol prompted the authors to consider that the chirality is induced at the transfer of the second electron (and proton) to the ketone molecule.[14]

These studies served as a stimulus for similar investigations in several other laboratories. Particularly major contributions in this direction have been made by the French scientists Jubault, Raoult, Hazard and Tallec and also by Kariv, Miller and Gileadi (Israel) and recently by Wendt (FRG) and Nonaka (Japan).

In the preparative electroreduction of acetophenone in acetate buffer in methanol as base electrolyte in the presence of alkaloids, the yield of alcohol was increased with a concomitant reduction in the yield of pinacol, which may be explained by the inhibition of radical dimerisation by the adsorbed alkaloid.[15] The phenylethyl alcohol formed in the presence of alkaloids possessed optical activity, the maximum optical yield (14.9%) being achieved in the presence of quinine. Comparison of the optical yields achieved in the presence of quinine and quinidine on the one hand and cinchonine and cinchonidine (this pair differs from the first by the absence of a methoxyl group in the quinoline ring) on the other, showed that in the presence of alkaloids having no methoxyl group the yield was significantly less. This was linked[15] with the weaker adsorbability of the latter (although the adsorbability of the alkaloids was not assessed in this study). It was considered[15] that a specific interaction

took place between the adsorbed alkaloid and the reactant on the electrode which caused the appearance of optical activity in the product. The fact that in the presence of alkaloids of the opposite configuration, as in the pairs indicated above, the sign of the rotation of the products is reversed was considered as confirmation of this conclusion. Under the conditions of the experiments,[15] electro-reduction occurred up to potentials of the onset of catalytic evolution of hydrogen consequently the authors[15] doubted the hypothesis of Grimshaw and collaborators[2,7] on the transfer of hydrogen from the catalyst to the free radical of the ketone.

Subsequently the same authors[16] studied the electroreduction of acetophenone in the presence of several alkaloids and particularly in the presence of quinidine in aqueous methanolic acetate buffer solutions (pH 4.8). In these experiments quinidine was first reduced electrochemically to a mixture of products of hydrogenation of the nitrogen-containing quinoline ring, the methoxyl group remaining unaffected. In the presence of hydrogenated cinchonine the polarographic wave of acetophenone was shifted somewhat towards negative potentials while the catalytic wave of hydrogen in the presence of acetophenone became less negative. While criticising the mechanism of action proposed by Grimshaw and collaborators for the catalyst it was indicated[16] that the catalytic evolution of hydrogen sets in at more negative potentials than the electro-reduction of acetophenone itself. However, it follows from Fig. 1[16] that even in the absence of acetophenone at a potential of −1.8 V (at which the greatest optical yield of alcohol is observed) the catalytic current for hydrogen is about 10% of the limiting current of the acetophenone wave, and as already mentioned acetophenone markedly facilitates the catalytic evolution of hydrogen. It was shown[16] that methylation of the quinidine nitrogen atom sharply reduces the optical yield and changes the sign of the rotation of the resulting alcohol. Retention of the inducing ability of methylated quinidine is also considered as an argument against the criticised scheme for the process proposed by Grimshaw and collaborators.[2,7] However it is known[17,18] that on discharge of tetraalkylammonium cations containing different substituents on the nitrogen atom, one of the substituents is removed from the free radical (or is transferred to the substrate) and in this way a trisubstituted amine is formed, which is capable of being protonated and catalysing hydrogen evolution. In our opinion the change in sign of the rotation of the product is probably explained by the formation of such an amine, which may differ in conformation from the initial alkaloid, or by the alkylation of the substrate. In addition the free radical formed on discharge of tetrasubstituted ammonium may serve as the transferer of the electron.[18,19]

The fission of alkyl on discharge of a completely alkylated amine apparently does not always occur. As long as fission of alkyl and protonation of the dealkylated catalyst does not occur then the action shown by the completely alkylated catalyst is caused by the creation of an asymmetric field near the substrate on formation of a hydrophobic adduct between them. The significantly lower optical yield observed in this situation is seemingly achieved on transfer of a hydrogen atom from the discharged protonated amine, within the restrictions of its adduct with the substrate.[16] The completely alkylated inducer may serve only as the transferer of an electron from the electrode to the substrate. The change in sign of the rotation of the product, on reduction of the substrate in the presence of completely alkylated amine,[16] may be explained by the fact that protonation of the substrate anion-radical in its adduct only occurs at the expense of proton donors of the solution, which evidently approach the substrate from the side opposite the inducer. The strength of the asymmetric field generated by the alkylated alkaloid on that part of the adduct opposite to it where proton is being added from the solution is markedly less than when proton is added from the alkaloid itself. Consequently the optical yield on induction by an alkylated alkaloid is significantly less than in the case of a protonated alkaloid.

The absence of a correlation between the ability of various alkaloids to catalyse the evolution of hydrogen and the size of the optical yield was also considered[16] to be an argument against the mechanism proposed.[2,7] However it is relevant to emphasise that only in the case of simple catalysts causing volume catalytic waves of hydrogen was a link successfully established between the structure of the catalyst (more precisely its pK_a) and its ability to catalyse the evolution of hydrogen (see Ref. 1, p. 244). In the case of catalysts of complex structure, such as alkaloids, that link has not yet been successfully established.

The effect of the potential of the mercury cathode during electrolysis on the optical yield of alcohol and the alcohol : pinacol ratio has been studied.[16] The maximum optical yield (up to ~17%) was observed at −1.8 V (relative to a mercury sulphate reference electrode). Maximum adsorption of the acetophenone–catalyst complex was achieved at these same potentials,[16] while maximum yield of alcohol was obtained at the very negative potential of −2.10 V. The optical yield was increased on reducing the temperature which is linked with the increase in adsorbability of the complex indicated.

Study of the electroreduction of acetophenone in the presence of ephedrine showed that in strongly acidic and strongly basic media the optical yield falls and an inversion of its configuration occurs compared with the product obtained at medium pH values. This is explained by the fact that at extreme pH values protonation occurs at the expense of proton donors in solution and in the region of medium pH at the expense of protons from ephedrine (in strongly acidic medium acetophenone itself is protonated and in alkaline ephedrine is in the base form). Other conditions being equal, an increase in optical yield of the carbinol occurs on reducing the dielectric constant of the medium (water–methanol, methanol, methanol–isopropanol), which is linked with the increase in stability of the ephedrine–acetophenone complex in which proton transfer occurs. It was noted that replacement of the mercury cathode by lead did not change the optical yield of alcohol.

Phenylglyoxylic acid was used as a subject for reduction for the first time by Jubault, Raoult and Peltier to study the influence of alkaloids on the induction of optical activity.[21] Unlike acetophenone this acid is reduced over a wide pH range directly to phenylglyoxylic alcohol (with $n = 2$) and the process takes place at less negative potentials. This circumstance and also the absence of dimer significantly facilitate the study of the mechanism of the process. The effect of the nature of the alkaloid (15 different inducers were taken) on the optical yield of the product has been studied in detail.[22] In general the greater the adsorbability of the alkaloid-inducer the greater was the optical yield, other conditions being equal. However a specific effect of the alkaloid also became apparent. Thus the strongly adsorbed narcotine induced practically no optical activity but strychnine acts almost twice as strongly as brucine while showing approximately the same ability to be adsorbed.[22] A detailed study of the effect of various factors on the optical yield led the authors to the conclusion[22] that the process of inducing optical activity occurs with the participation of the inducer adsorbed on the electrode and all the factors aiding its adsorption lead to an increase in the optical yield of product. For example,

with an increase in the temperature of the experiment and on adding an organic solvent to the solution (both reduce adsorption of the alkaloid) the optical yield was reduced. The addition of quinine, which is strongly adsorbed under these conditions but is not an inducer, to the inducer (strychnine) also reduces the optical yield by displacing strychnine from the electrode surface. The dependence of the optical yield of product on the alkaloid concentration is close in shape to the adsorption isotherm of the alkaloid. This also confirms the important role of catalyst adsorption in the induction of optical activity. As already mentioned[22] it is apparently true[15] that the induction of optical activity occurs on forming a complex between the inducer and the substrate itself or an intermediate in its reduction, such as the anion-radical or free radical. The preparation of an optically active product, L-menthyl (*S*)-mandelate, on electroreduction of phenylglyoxylic acid ester with L-menthol in the absence of other inducers points in favour of that hypothesis.[21] In the latter case the induction of optical activity is provided by the asymmetric field of L-menthol.

It must however be noted that the maximum optical yield when reducing phenylglyoxylic acid in the presence of strychnine is observed at a strychnine concentration of 10^{-3} M, at higher concentrations the optical yield falls.[12] A similar phenomenon has been explained[15] by 'association of the alkaloid'. Seemingly this effect is caused either by inhibition of the process due to the formation of a dense film of alkaloid adsorbed on the electrode,[23] or by double-layer adsorption of the alkaloid,[24] which hinders the formation of a complex between the substrate and the alkaloid.

The optical yield depends markedly on the pH of the medium.[22] When reducing phenylglyoxylic acid in the presence of strychnine it is maximal in pH 4.8 acetate buffer solution and gradually falls to zero in strongly acidic and strongly alkaline media. It is claimed that this is linked with hindrance of the formation of a complex between the inducer and one of the forms of the substrate in these media. It must be noted that in the case of the reduction of acetophenone in the presence of ephedrine, passing from a strongly acidic to a strongly alkaline medium leads only to a change in the sign of rotation of the product.[20]

Several valuable recommendations have been made[22] for preparative asymmetric reduction. The benefit of agitating the surface of the mercury cathode (i.e. cleaning it) and of introducing the substrate into the electrolyser in appreciable portions was particularly noted.

Jubault and collaborators[25] have analysed the effect of various alkaloids on the shape of the reduction curve of phenylglyoxylic acid and showed that strongly adsorbed alkaloids such as strychnine at small concentrations (2×10^{-5} M) in weakly acidic media shift the reduction wave to a lower cathode potential, i.e. the electrode process is accelerated, while at large concentrations it is inhibited. On 'instant current–time' curves, taken during the life of the mercury drop, in the presence of low strychnine concentrations the current reaches a maximum value (corresponding seemingly to the achievement of adsorption equilibrium with the inducer), then is reduced somewhat and once again increases but more slowly (evidently due to the increase in the surface of the dropping electrode). The current is markedly greater in the presence of strychnine than in its absence. The authors explain this by the development of the ψ_1 effect, i.e. by a reduction in the potential fall beyond the Helmholtz plane and by the consequent increase in the actual potential difference between the electrode and reacting particles (see for example[26]), as a consequence of the adsorption of protonated forms of strychnine on the electrode. However, as follows from Fig. 1, the rise of the reduction wave current for phenylglyoxylic acid is observed at a potential of −0.63 V relative to a saturated calomel electrode (vs. SCE). On introducing 1.81×10^{-5} M strychnine into the solution the lower part of the wave is shifted to a less negative potential by approximately 30 mV. This wave is located close to the point of zero charge and all the values of the ψ_1 potential are in this case about 20 mV[26] (allowing for the fact that the potentials were given[26] relative to the normal calomel electrode). Seemingly the effects of the double layer, if they develop, play a secondary role in this case. In our opinion the reduction is facilitated by the interaction of the intermediate product with the protonated inducer or even with its uncharged form which transfer a hydrogen atom to the particle being reduced. In the first case the shift of the wave to a lower cathode potential is explained (see Ref. 1, p. 198 or Ref. 27) by linking the reduced form with a reversible redox system (in this case phenylglyoxylic acid, which is reduced reversibly judging by the shape of the polarogram in Fig. 1). An even more weighty argument in favour of the effects of the double layer not playing a decisive role in the acceleration of the electrode process in the present case are the data[25] that the $i-t$ curves of the reduction of phenylglyoxylic acid methyl ester in acetate buffer are increased sharply in the presence of strychnine at a potential even more positive than the point of zero charge, when the ψ_1 potential, although small, is positive. In addition, it is known (for example, Chapter VII, Ref. 28) that transfer of the first electron to the carbonyl-containing compound is reversible in many cases and the structure of the double layer does not affect reversible electrode processes. As already mentioned above, the shape of the reduction wave of phenylglyoxylic acid (Fig. 1) corresponds to a reversible transfer of an electron in the potential-determining step of the process.

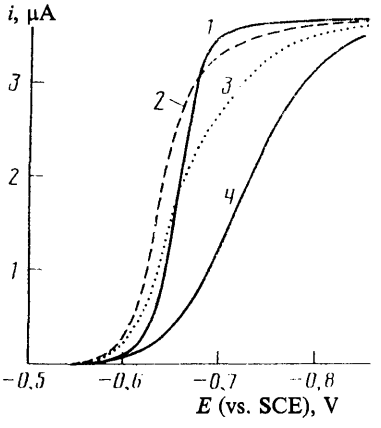

Figure 1. Polarogram of the reduction of phenylglyoxylic acid (5×10^{-4} M) in 0.5 M acetate buffer (pH 4.8) in the presence of strychnine at concentrations (10^{-5} M): *1*, 0; *2*, 1.81; *3*, 2.94; *4*, 16.7.[25]

It is interesting that the addition of alkaloids proved to have no marked effect on the reduction of *p*-nitrobenzoic and picric acids which seemingly indicates some specificity in the reaction of

substrate and inducer. On the other hand strychnine accelerates the reduction of pyruvic acid.[25]

Proceeding from the hypothesis that the formation of an adduct between the substrate and an asymmetric inducer is necessary for the induction of optical activity in an electroreduction product, Jubault and collaborators[29] selected as a model for thorough investigation the phenylglyoxylic acid ester of (−)-menthol in which the asymmetric inducer is one part of the molecule and the prochiral substrate being reduced is the other. In the majority of cases the (*R*)-conformer of mandelic acid menthyl ester predominates in the products of electroreduction of this ester. Its optical yield depends markedly on the pH of the medium,[29] it is maximal (20.6%) in 1 N H_2SO_4 and falls with increasing pH, it passes through a minimum at pH 3−4 and increases once again in neutral and alkaline solution. It is important to note that addition of di-n-butylamine in ammonia buffer solution increases the optical yield from 19.8 to 30%, while a tetrasubstituted ammonium salt reduces the yield under these conditions to 5%. The effect of pH is explained by competition between the reactions of protonation of the intermediate anion-radical and its transformation with inversion of configuration. Naturally the rate of protonation is highest in acid solutions. Protonation also explains the effect of dibutylamine added to the alkaline solution which forms an adduct with the anion-radical in which proton transfer is effected. A similar mechanism, in the opinion of the authors,[29] also takes place in electroreduction in the presence of inducer-alkaloids. The inhibitory action of tetra-alkylammonium cations is explained[29] by displacement of the particle being protonated from the electrode surface. It was established[29] that the maximum optical yield is observed on electrolysis in the vicinity of the zero charge potential. At higher negative potentials the optical yield is reduced which is explained by acceleration of the (*R*)→(*S*) transformation of the anion-radical by the electrode field.[29] The increase in optical yield in acidic medium on increasing the intensity of stirring the solution in the electrolyser is linked with the additional supply of proton donors to the electrode surface where their concentration is reduced as a result of their reaction with the substrate.[29]

Most interesting results were obtained subsequently by Raoult, Jubault and Peltier[30] in a detailed study of the effect of strychnine and *N*-methylstrychnine (which is devoid of proton-donating ability) in the electroreduction of phenylglyoxylic acid, its methyl ester, the two oximes of the acid (*anti* and *syn*), the two isomeric oximes of the methyl ester and the phenylhydrazone of the acid. The introduction of alkaloid into the polarograph solution of the compounds indicated changes the shape of the polarograms, which is a reflection of the change of the kinetics of the individual stages of the process. Reduction of the keto group requires altogether the participation of two electrons and two protons and is accompanied by the formation of a secondary alcohol. The oximes are reduced with the participation of four electrons and protons to primary amines. The preferred configuration of the product, in the authors' opinion,[30] is determined either by stereoselective protonation of the intermediate reduction product, the anion-radical, with an optically active proton donor, the inducer (as also proposed[5,31]), or by the substrate-inducer interaction[14,22,25,29] which, in the authors' opinion,[30] is preserved during many stages of the process. The formation of an adduct with the optically active inducer determines the preferred configuration of the product and the nature of the proton donor plays no role in this case.

In acidic medium (1 N H_2SO_4) addition of increasing quantities of both strychnine and methylstrychnine to the solution leads to a shift of the $E_{1/2}$ of waves of all the compounds studied to a more negative potential. The greatest shift is observed at small concentrations of additive but with its growth the size of $E_{1/2}$ tends to a limit. The displacement of the $E_{1/2}$ of waves for the reduction of the keto group is far greater than for the oxime. It is evident that under these conditions (i.e. at an excess of a strong proton donor) both additives inhibit the electrode process by blocking the electrode surface on which their adsorption depends.

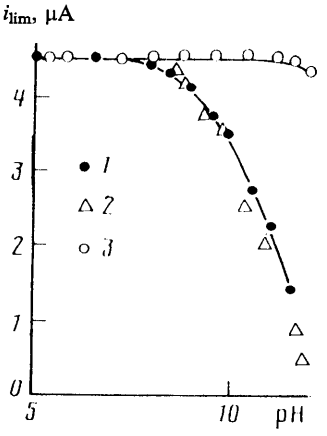

Figure 2. Effect of pH on wave height in the reduction of the oxime of phenylglyoxylic acid ester (5×10^{-4} M) in Britton-Robinson buffer solutions (with 10% ethanol). *1*, Without additions; *2*, in the presence of 9×10^{-5} M methylstrychnine; *3*, in the presence of 9×10^{-5} M strychnine.[30]

In the case of the oxime of phenylglyoxylic acid ester at a solution pH above 7, strychnine and also ammonium ions facilitate reduction while methylstrychnine has almost no effect on the polarograms. It is important to note that in the absence of additives at pH values above 7, a reduction is observed in the wave height for this oxime and it acquires a kinetic character. Methylstrychnine has no effect on the height of the kinetic wave while strychnine increases it to the level of the diffusion current (Fig. 2). The latter effect is caused by the proton-donating properties of protonated strychnine, the strychninium ion. The same properties explain the appreciable displacement of $E_{1/2}$ of the reduction wave of the oxime ester to a lower cathode potential in neutral media on introducing strychnine into the solution. At pH > 10 the $E_{1/2}$ of this wave in the presence of strychnine was almost the same as in the absence of additives or in the presence of methylstrychnine.[30] In weakly acidic medium both strychnine and methylstrychnine inhibit the process, the action of the latter being much stronger. It is interesting that the pK_a of the strychnine cation is 7.4 since with an increase in pH above 7.4 the displacement of $E_{1/2}$ by strychnine is reduced.

In the reduction of the *anti*-oxime of phenylglyoxylic acid in pH 5.4 acetate buffer solution, the addition of strychnine (see Fig. 3) leads to a shift in the lower part of the wave in the direction of greater cathode potentials and simultaneously to the appearance of a more negative wave, which becomes less negative on increasing the

strychnine concentration and blends in with the main reduction wave. The unique wave emerging in the presence of strychnine proved to be far steeper and almost 1.5 times greater than in its absence (see Fig. 3). The authors[30] explain this phenomenon by the suppression of the surface protonation of the oxime on adsorption of strychnine and by the increase of the wave by limited volume overprotonation of the oxime. In our opinion a change occurs in the mechanism of the process in this case. The strychninium cation is discharged and the radical formed transfers its hydrogen atom to the substrate,[2,4] reducing it. The change in the shape of the wave occurring in this way reflects the transition from an irreversible reduction of the oxime to a reversible discharge of the strychninium ion[1] (in this case $E_{1/2}$ of the catalytic hydrogen wave is about −1.1 V). The discharge of the strychninium ion is therefore the rate-determining step of the whole process.

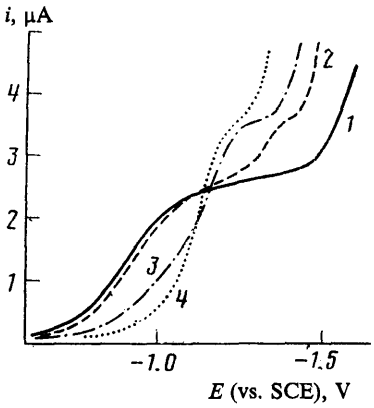

Figure 3. Polarograms of the reduction of the oxime of phenylglyoxylic acid in acetate buffer solution (without ethanol) at pH 5.4. *1*, Without additives; *2*–*4*, in the presence of strychnine (10^{-5} M); *2*, 1.5; *3*, 4.5; *4*, 10.[30]

In several cases facilitation of electroreduction was observed[30] on introducing methylstrychnine into a solution of certain compounds in pH 9.8 buffer containing Li cation (i.e. under conditions when there is no prior protonation) (Fig. 4). This was explained[30] by the formation of hydrophobic ('physical') positively charged complexes (more precisely adducts) between tetrasubstituted ammonium cation and the organic molecule,[32] which increases the substrate concentration close to the electrode.[33] It is however impossible to exclude the possibility that the observed shift is also linked with effects of the double layer since they are displayed in the case of the more cathodic waves on polarograms which may correspond to the reduction of both negatively charged ions, formed on dissociation of the substrate, and of the intermediate anion-radicals. For example, it follows from Fig. 4 that addition of methylstrychnine to a solution of the *anti*-oxime of phenylglyoxylic acid ester in Britton-Robinson buffer (pH 9.8) has practically no effect on the first wave but displaces the second wave appreciably, by almost 200 mV, to a less negative potential and simultaneously removes the fall in current after the first wave (evidently caused by the depolariser). Removal of the fall may be linked with an increase in adsorption of depolariser as a result of the formation by it of an adduct with methylstrychnine and the significant shift of $E_{1/2}$ of the second wave may be linked with the additional effect of a reduction in ψ_1-potential as a result of the adsorption of methylstrychnine cation.

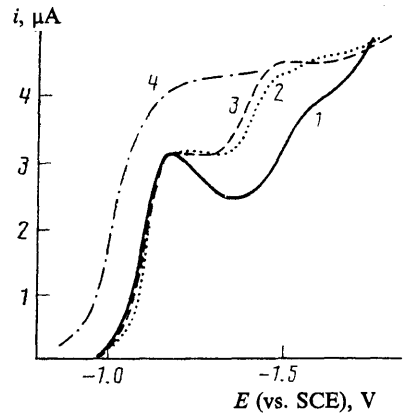

Figure 4. Polarograms of the reduction of the oxime of phenylglyoxylic acid methyl ester (5×10^{-4} M) in pH 9.8 Britton-Robinson buffer solution (with 10% ethanol and 0.01 M Li^+) of pH 9.8. *1*, in the absence and *2*, *3*, in the presence of methylstrychnine (10^{-5} M); *2*, 4.5; *3*, 5.0. *4*, Polarogram of phenylglyoxylic acid ester in 0.5 M ammonia buffer pH 9.8 with 10% ethanol.[30]

In our opinion, the increase in the region of the adsorption potentials of *p*-bromoacetophenone and tetraethylammonium salts when both are present in aqueous medium, described by van Tilborg and collaborators,[34] also indicates the formation of a strongly adsorbing adduct between them, although the authors considered[34] that adducts are not formed and the role of the R_4N^+ cation in facilitating reduction of the ketone is 'polarisation of the C=O bond on collision of R_4N^+ with the carbonyl group'. At very high concentrations of the tetraethylammonium salt, its cations, in the opinion of the authors,[34] displace the ketone from the electrode surface so that the ketone is situated on a layer of ammonium cations adsorbed on the electrode. This also shows the salts own action on the induction of asymmetric reduction on desorption of chiral cations on the electrode.

Subsequently van Tilborg and collaborators[35] studied the effect of tetraalkylammonium salts on the reduction of acetophenone in dry acetonitrile. A very interesting phenomenon was discovered. With LiF as base electrolyte acetophenone was not reduced down to a potential of −3.0 V. On adding a tetraalkylammonium salt to the solution a two-step reduction wave was observed. At a low concentration of R_4NClO_4 the height of the first wave of acetophenone changed with the growth in its concentration according to a curve reminiscent of the shape of the Langmuir isotherm. In the opinion of the authors[35] it therefore follows that reduction occurs only of adsorbed acetophenone. The dependence of the limiting current on the square root of the height of the mercury column implies kinetic limitation of the current. On increasing the

tetraalkylammonium salt concentration the limiting current becomes diffusion in character and changes in proportion to the acetophenone concentration. Judging by one study[35] the dependence of i_{lim} of the acetophenone wave on its concentration becomes nonlinear at values comparable with the concentration of tetraalkylammonium ions. In our opinion only the adduct of acetophenone with the R_4N^+ cation is reduced on the electrode under these conditions.[35] The kinetic character of the current at an excess of acetophenone is caused by R_4N^+ cations on the electrode surface, freed after reduction of acetophenone, combining with other acetophenone molecules diffusing from the solution. The comparatively low rate of formation of such adducts is evidently the reason for the kinetic limitation of the current.

It is also necessary to note the extremely interesting shape of the current intensity–time curves observed in several cases in the process of growth of the mercury drop.[30] When strychnine or methylstrychnine are present in the solution the reduction current of the oxime of phenylglyoxylic acid ester grows from the moment of formation of the mercury drop, reaches a certain limit, falls and then begins to grow once again (Fig. 5). The presence of the first maximum is evidently caused by the inhibition of the electrode process at complete coverage of the surface of the dropping electrode by the adsorbed additive. The subsequent rise in current when methylstrychnine is present is seemingly linked with the formation of hydrophobic adducts and their adsorption on the electrode which may compete successfully with the adsorption of the additive itself. When strychnine has been added to the solution, this rise in current may be explained by the development of a catalytic effect. Numerous examples of such a current increase are given in the studies considered above.

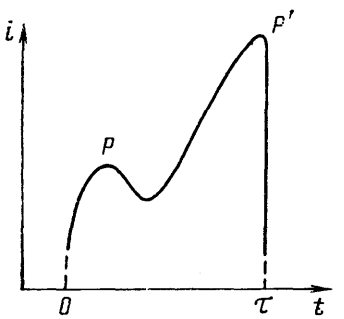

Figure 5. Diagram outlining the shape of $i-t$ curves at the time of the growth of the mercury drop in buffered solutions of phenylglyoxylic acid (and its esters and oximes) in the presence of strychnine and methylstrychnine.[30]

As already mentioned, the optical yield of product on reduction of phenylglyoxylic acid and its oximes in the presence of strychnine depends on the pH of the medium and on the electrode potential.[22,36] For example, on reducing both the *syn* and *anti* isomers of the oxime of phenylglyoxylic acid in acetate buffer in the presence of strychnine at a mercury cathode in the potentiometric mode at a cathode potential of −0.95 V (vs. SCE), the (*R*)-enantiomer of phenylglycine is formed in 17.1% optical yield.[36] On increasing the cathode potential the optical yield of (*R*)-enantiomer falls, reaching zero at −1.14 V, and on increasing the cathode potential further the (*S*)-enantiomer is formed predominantly. The optical yield of the (*S*)-enantiomer increases with the potential and reaches 11.1% at a potential of −1.35 V.[36] As had been shown by Jubault,[37] the optical yield also depends strongly on the strychnine concentration (c_{str}). Using the example of the electroreduction at the mercury cathode of phenylglyoxylic acid and its *anti*-oxime in pH 4.7 acetate buffer solution, it was shown that the optical yield initially rose rapidly with an increase in c_{str} reaching a maximum at $c_{str} = 1 \times 10^{-4}$ M, and then fell slowly, moving towards a fairly constant value. It is interesting that the optical yield reaches its greatest values at an electrode potential of −0.85 V (vs. SCE) for the acid and −0.95 V for the oxime and was reduced to zero on further increasing the cathode potential. Under conditions of high strychnine concentrations ($c_{str} > 2 \times 10^{-3}$ M for the acid and $c_{str} > 2 \times 10^{-4}$ M for the oxime) even the sign of rotation of the resulting mixture of enantiomeric products was changed. At low c_{str} and low cathode potentials (*R*)-(−)-mandelic acid and (*R*)-(−)-phenylglycine respectively predominated and at larger cathode potentials and high c_{str} mainly the (*S*)-(+) enantiomers predominated (Fig. 6). This phenomenon is as yet unexplained. In our opinion, at high concentrations strychnine not only completely covers the electrode surface with a monolayer but is also adsorbed in a second layer, like quinine.[24] The complex of strychnine ion and substrate adsorbed on the electrode surface gives the (*R*)-(−)-enantiomer on reduction but in the second layer a different orientation of strychnine, in comparison with that on the electrode surface, is possible and it may interact differently with the substrate leading to an effect opposite to that on the electrode surface, i.e. to the formation of the (*S*)-(+)-enantiomer. As c_{str} is increased the quantity of strychnine in the second layer grows and its quantity in the first layer (directly on the electrode surface) remains unchanged. Consequently the quantity of (*R*)-form resulting remains unchanged and the proportion of (*S*)-form increases with the growth in c_{str}. This is reflected in the curves given by Jubault.[37] The optical yield approaches zero at not very negative potentials as c_{str} increases.[37] It may be proposed that in this case the formation of (*R*)-form in the first layer is compensated by the formation of approximately the same quantity of (*S*)-form in the second layer. As the cathode potential is increased at high c_{str}, polylayer adsorption occurs due to the electrostatic attraction for strychnine cations and the positively charged adducts of these cations with substrate molecules. This results in the quantity of adducts in the second and subsequent layers becoming greater than in the first layer and the proportion of (*S*)-enantiomer formed exceeds the proportion of (*R*)-form. A change of electrode potential when complex organic molecules, which are inducers, are adsorbed on it frequently causes reorientation of the adsorbed molecules, which may be displayed in the direction of the rotation of the plane of polarisation of the product formed on reduction. This may be an explanation of the extremely interesting observations described.[36,37]

Halogen atoms in organic molecules are apparently particularly prone to interact with tetrasubstituted ammonium cations with the formation of hydrophobic adducts.[38] Consequently on adding 1,1-dibromo-2,2-diphenylcyclopropane to an acid polarograph solution of the alkaloids strychnine, emetine, yohimbine and also methylstrychnine salts an appreciable shift is observed in the reduction wave of this compound to a lower cathode potential.[39] The electroreduction of the compound indicated occurs with the

overall consumption of $2e^-$, by the fission of bromine ion and by protonation of the intermediate anion. The $E_{1/2}$ potential of the reduction wave did not depend on pH and was −1.46 V (vs. SCE), however in the presence of alkaloids it became more positive when reducing the pH. On changing pH from 10 to 4 in the presence of strychnine, $E_{1/2}$ was displaced from −1.45 V (vs. SCE) to −1.25 V. An even larger shift was observed in the presence of emetine, viz. from −1.41 to −1.05 V, for the same change of pH. Methylstrychnine also facilitates the reduction, in its presence $E_{1/2}$ = −1.27 V and did not depend on pH. These phenomena were explained[39] by the interaction of the cationic form of the alkaloid with the depolariser. The fact that strychnine facilitates the reduction to a markedly greater extent than methylstrychninium and in its presence $E_{1/2}$ depends on pH, indicates an effect on the size of $E_{1/2}$ and on the kinetics of protonation of the intermediate. The formation of optically active electroreduction products indicates the important role of protonation when carrying out electrode processes. The (*R*)-enantiomer was formed in the presence of strychnine and emetine and the (*S*)-form in the presence of yohimbine. The optical yield was zero on introducing into the solution methylstrychnine, having no labile hydrogen.[39] In the presence of alkaloid the reduction of dibromide was facilitated both by the electrocatalytic action of the adducts formed with the participation of the alkaloid cation (by transfer of a proton of the inducer or a hydrogen atom from the uncharged alkaloid) and by the change in structure of the double layer, i.e. by a reduction in the absolute value of the ψ_1 potential in the presence of the strongly adsorbed cations (protonated alkaloids or methylstrychninium) which facilitate the irreversible electrochemical fission of the C−Br bond.

Kopilov and co-workers[31,40,41] have studied the electroreduction of the three acetylpyridines in aqueous alcoholic acetate buffer solutions in the presence of alkaloids. Both secondary alcohols and pinacols are formed when reducing acetylpyridines. In the presence of strychnine and brucine, 2- and 4-acetylpyridine give an optically active alcohol.[41] Only the racemate is formed from the 3 isomer. In all cases the pinacols were optically inactive. When reducing 2-acetylpyridine the maximum optical yield (31.2%) was achieved in the presence of brucine. In the presence of quinidine none of the acetylpyridines gave an optically active reduction product. It is interesting that addition of alkaloid to the 2 and 4 isomer markedly increased the yield of alcohol by reducing the quantity of pinacol formed,[31,41] while the yield of alcohol from 3-acetylpyridine was reduced in the presence of alkaloid. In the opinion of the authors[41] the stage determining the optical yield is the protonation of the intermediate by the chiral alkaloid present on the electrode surface in the cationic protonated state. In contrast to the 2 and 4 isomers the 3 isomer gives a stable zwitterion, the intermediate product of which is protonated not by the alkaloid but by the acid of the buffer solution.[41] The increase in the yield of alcohol from the 2 and 4 isomers in the presence of alkaloid also indicates the important role of protonation of the alkaloid in this process. In the case of the 3 isomer, when the alkaloid does not participate in the protonation, the yield of alcohol is markedly reduced in its presence.[41]

The effect of eleven different alkaloids on the electroreduction of the isomeric acetylpyridines has been studied.[31] The highest optical yield of alcohol was achieved in the presence of strychnine, viz. 47.5% for the 2 isomer and 41% for the 4 isomer. In all cases when asymmetric reduction occurred the (+)-enantiomer was formed. Only in the presence of yohimbine was the (−)-isomer obtained with yields for the 2 and 4 isomers for 5 and 4% respectively. The reduction products of the acetyl pyridines possessed no optical activity in the presence of quinine, quinidine, reserpine, eserine and ephedrine,[31] although, as already mentioned, some of these alkaloids are inducers of asymmetry when reducing other compounds. In our opinion, an important factor assisting asymmetric induction is the possibility of forming an associate between the substrate and the inducer which is evidently determined by the specificity of the interaction between them. This specificity is displayed in the varying shift of the $E_{1/2}$ potential of the polarographic wave of the reduction of alkyl bromides in the presence of tetrasubstituted ammonium salts, depending on the nature of the alkyl group.[42] It was also noted[31] that in those cases when asymmetric induction was observed, a marked increase occurs in the yield of alcohol at the expense of a reduction in the yield of pinacol, i.e. the formation of an adduct aids protonation of the intermediate reduction product by hydrogen from the inducer and also facilitates transfer of a second electron.

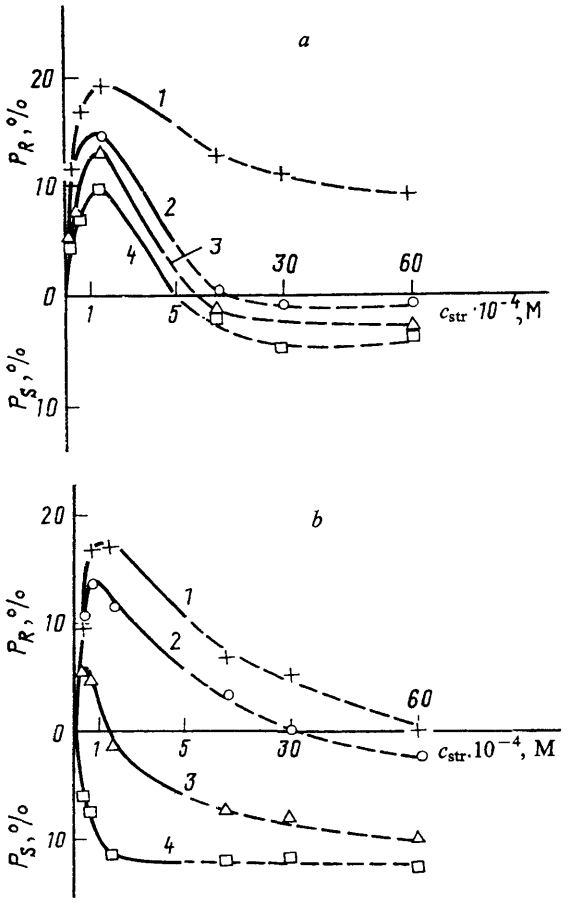

Figure 6. Dependence of enantiomer composition [%(*R*) and (*S*) forms] of the reduction products of (*a*) phenylglyoxylic acid and (*b*) its oxime in pH 4.7 acetate buffer solution on the concentration of strychnine (above c_{str} 0.5 mM the concentration scale is reduced 5-fold) at electrolysis potentials (vs. SCE, V) in (*a*) of *1*, −0.85, *2*, −1.10, *3*, −1.20, *4*, −1.30 and in (*b*) of *1*, −0.958, *2*, −1.05, *3*, −1.15, *4*, −1.30.[37]

A similar phenomenon was repeatedly observed in the reduction of acetophenone in the presence of ephedrine derivatives.[43,44]

A fairly detailed study of the effect of various factors on the optical yield and pinacol: secondary alcohol ratio in the electroreduction of acetophenone, particularly in the presence of methylephedrine[44] showed that the maximum optical yield of alcohol (18%), when carrying out electrolysis under previously selected standard conditions,[43] was achieved at a cathode potential of –1.37 V and falls to 12–13% on increasing the potential to –1.80 V, while the yield of product (alcohol) was increased by this from 14 to 70%. The reduction in optical yield with the growth in cathode potential is explained by the increase in the rate of direct transfer of the second electron to the radical and not to its adduct with the inducer. As proposed previously[14] optical activity is induced on transfer of the second electron. Maximum optical yield is achieved at solution pH 3.0.[44] The nature of the solvent also affects the optical yield of alcohol, the maximum value is observed on carrying out the electrolysis in ethanol. Addition of water to the alcohol or dioxan leads to a reduction in optical yield, the minimum yield occurring in pure aqueous solution. On reducing the temperature the optical yield grew again, the maximum (20%) was reached at –10 to –30 °C, but then was reduced once more.[44]

If the proton-donating ability of the inducer is eliminated, such as by complete methylation of ephedrine, and the electroreduction of acetophenone is carried out in anhydrous acetonitrile in the presence of this inducer, then the pinacol becomes practically the sole reduction product with an enantiomeric excess of 26.3%.[45] This, by the way, is the first case of the asymmetric synthesis of a pinacol. It is curious that in the presence of proton donors, i.e. under conditions when two radicals and not two anion-radicals react, the optical yield of pinacol is reduced to zero.[45] Asymmetric induction arises only on dimerisation of anion-radicals when at least one of them forms a tight ion pair with the inducer cation.[45]

As on reduction of phenylglyoxylic acid and its derivatives,[22,36] the maximum optical yield of pyridylethanol is observed at an electrode potential of –0.7 to –0.8 V and it is reduced at more negative potentials.[31] The optical yield of carbinol when reducing acetophenone in the presence of an inducer, such as substituted ephedrine, reaches a maximum (18%) at a potential of –1.37 V and is reduced somewhat with an increase in the cathode potential, although the overall yield of carbinol grows at the expense of a reduction in yield of the corresponding pinacol.[44] The optical yield also varies with the inducer concentration. In the case of strychnine it reaches a maximum value at $c_{str} = 5 \times 10^{-4}$ M. A reduction in temperature causes an increase in the optical yield,[31] which is seemingly explained both by an increase in adsorption of the components and by facilitation of the formation of an adduct between the intermediate reduction product and strychnine. A change in the alcohol content and replacement of ethanol by methanol and isopropanol in the mixture with aqueous acetate buffer has little effect on the optical yield of pyridylethanol, but addition of acetone sharply reduces the optical yield of the 4 isomer.[31] The relationships of the yield of both the 2 and 4 isomers of pyridylethanol to the solution pH pass through a maximum at pH 4.5, falling in more acidic and more alkaline solutions.[31] On gradually adding quinidine with strychnine to the solution the optical yield of alcohol was reduced continuously.[31] Quinidine itself is not an inducer of optical activity but its strong adsorption on the electrode aids displacment of strychnine and its adducts with the intermediates of acetylpyridine reduction. It was considered[31] that the alcohol becomes optically active at the stage of protonation of the product of the $2e^-$ reduction of the carbonyl group, viz. the enol (if the compound is protonated at the nitrogen atom) or the anion. Protonation proceeds through a hydrogen ion belonging to the strychnine cation which is on the electrode in the adsorbed state. Consequently strychnine methylated at nitrogen does not induce optical activity.[31]

It is important to note that the surface character of the chemical stage of the electrode process responsible for the induction of the optical activity requires specially pure reagents and mercury for the electrode.[40] Careful purification of all the components of the solution and the mercury, reducing the current density by increasing the surface of the mercury cathode, gradual dropwise addition to the electrolyser of the initial acetylpyridine solution[16] and reduction of the duration of electrolysis, i.e. use of all the factors reducing the effect of contaminants adsorbed on the electrode, led to an increase to 50% in the optical yields on electroreduction of 2- and 4-acetylpyridines in the presence of strychnine and to 80% in the total yield of alcohols.[40]

When studying the reduction of acetylpyridines in the presence of alkaloids, Wendt and collaborators[46] found that the reduction wave of 2-acetylpyridine in pH 4.5 acetate buffer solution after addition of 5×10^{-4} M strychnine became appreciably more positive and significantly more steep (Fig. 7). As correctly recorded,[46] this is linked with the proton-donating properties of the strychnine ion, which is adsorbed on the electrode and reacts with the intermediate product, the free radical.

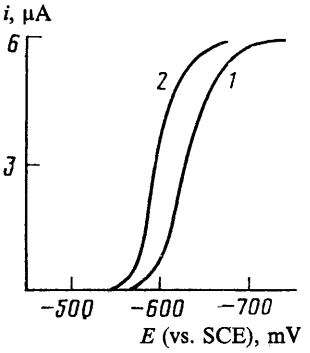

Figure 7. Polarogram of *1*, 2-acetylpyridine (1 mM) in pH 4.5 aqueous acetate buffer solution and *2*, the same in the presence of 0.5 mM strychnine.[46]

In our opinion it is not excluded that, simultaneously with the transfer of an electron (and possibly a proton as well) to acetylpyridine, discharge of the strychninium ion also occurs thereby increasing the steepness of the overall wave due to the reversible discharge of the strychninium ion[47] (see following Chapter).

V. The reversible character of the discharge of the catalyst and the features of the adsorption of organic compounds on the electrode surface

First some additional information is given on the mechanism of the catalytic evolution of hydrogen by organic catalysts and on the rules for the adsorption of organic compounds on electrodes.

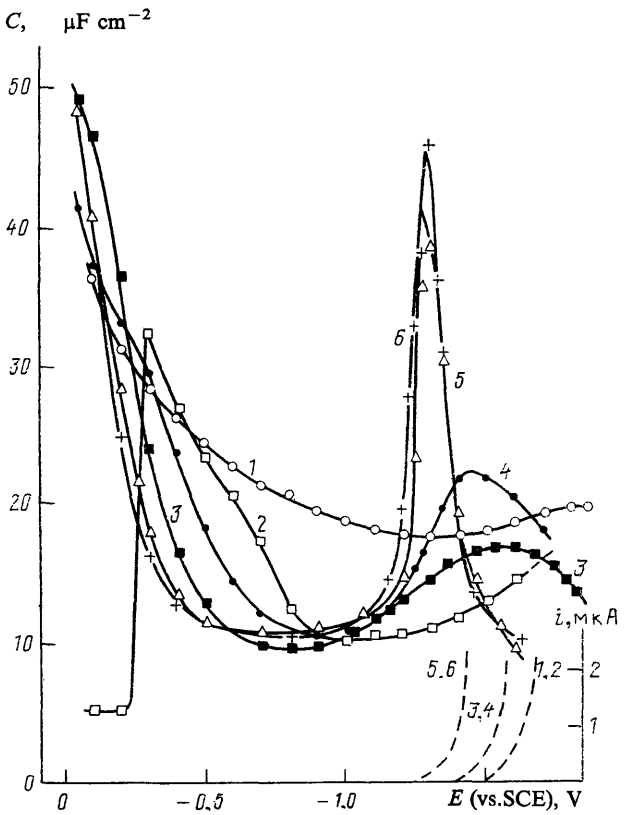

Figure 8. Differential capacity (C) curves (frequency of alternating current 179 Hz) for 0.1 mM alkaloid solutions in 0.5 M acetate buffer: *1*, buffer solution; *2*, *N*-methylstrychnine iodide; *3*, emetine; *4*, codeine; *5*, brucine; *6*, strychnine. Below are the initial portions of classical curves of the catalytic waves of hydrogen and buffer.[47]

As already mentioned at the beginning of this review, the transfer of an electron to the catalyst in the protonated form [i.e. reaction (II)] usually proceeds reversibly. The reversible character of the discharge process for pyridinium ions has been demonstrated.[48] The reversibility of electron transfer to a protonated molecule of the alkaloid pachycarpine on catalytic evolution of hydrogen into its solutions in buffer has also been proved.[49] The reversibility of the electron transfer step on catalytic evolution of hydrogen from buffer solutions of strychnine and brucine is indicated by the pseudocapacity peaks on the differential capacity curves (Fig. 8), which are caused by the discharge–ionisation process of the protonated form of the catalyst when applying an alternating current to the electrode. That the peaks mentioned are peaks of reaction pseudocapacity and not of adsorption–desorption is indicated by the correspondence of their potentials with the potentials at which the rise in current occurs in the catalytic hydrogen waves on classical polarograms obtained in solutions of these catalysts (curves in the lower portion of Fig. 8) and also by the drop in capacity after these peaks.

It is noteworthy that the catalytic hydrogen waves in buffer solutions of strychnine undergo a significant shift, with growth of the catalyst concentration, towards less negative potentials, of approximately 140 mV over a ten-fold increase in strychnine concentration (Fig. 9). There are several reasons for this. An increase in depolariser concentration always causes an earlier discharge of it, i.e. discharge at less negative potentials in the present case. In addition the subsequent bimolecular reaction in the catalytic cycle [reaction (III)] is sharply accelerated on increasing the catalyst concentration, which in its turn also leads to an appreciable shift of the reversible wave in the direction of less negative potentials.[50]

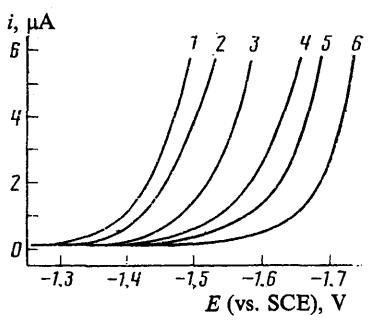

Figure 9. Classical polarographic curves for the catalytic evolution of hydrogen from buffer solutions with different strychnine concentrations (10^{-5} M): *1*, 50; *2*, 14.3; *3*, 6.52; *4*, 4.55; *5*, 2.38; *6*, 0.[47]

According to the theory of A N Frumkin[51] the adsorption of organic molecules on the electrode is maximal at the so-called potential of maximum adsorption (E_M) which is close to the zero charge potential of the electrode or the maximum of the electrocapillary curve. On moving the potential of the electrode both to the positive and to the negative side the adsorbability of compounds β falls according to the equation

$$\beta=\beta_0 \exp(-a\varphi^2), \quad (1)$$

where β_0 is the maximum adsorbability at potential E_M, φ is the potential measured from E_M, i.e. $\varphi = E-E_M$, a is a constant characteristic of each substance. The significant decrease in adsorbability of the catalyst, which depends on the extent of the difference between the electrode potential and E_M, is the reason for the characteristic hump-like shape of the surface catalytic hydrogen waves (see Chapter VI, Ref. 1 and Ref. 52).

The catalytic hydrogen waves become less negative at increased concentrations of strychnine. Under these conditions the adsorbability of strychnine is increased significantly which once again leads to an increase in the catalytic current and a shift in the wave to a less negative potential. The three factors indicated also

determine, in our opinion, the sudden shift mentioned above in the catalytic hydrogen wave in a buffer solution of strychnine on increasing the concentration of the latter, as follows from Fig. 9.

The gradual reduction in the quantity of catalyst adsorbed, which is observed on increasing the cathode potential, is the reason (see chapter VI, Ref. 1) for the fact that the slope of the semilogarithmic plots of the catalytic hydrogen waves is far greater than in the case of the usual reversible waves. The catalytic waves in buffer solutions of strychnine (Fig. 9) are an example. However under conditions of complete occupation of the electrode surface by the adsorbed catalyst, when there is no appreciable desorption, the slope of the semilogarithmic plot (in the absence of subsequent bimolecular reaction as takes place in the case of the catalytic hydrogen waves caused by pachycarpine) is 59 mV at 25 °C,[49] i.e. it corresponds to the value predicted theoretically.

VI. The mechanism of action of asymmetric inducers

Returning to the data on the effect of strychnine on the steepness of the reduction wave of acetylpyridine (Fig. 7) it is noted that discharge of the strychnine ion occurs at appreciably more negative potentials than acetylpyridine reduction. If the product of the reversible discharge of strychnine adsorbed on the electrode reacts rapidly with the product of electron transfer to acetylpyridine (i.e. with its anion–radical or, on protonation, with the radical)

$$StrH^+ + e^- \rightleftharpoons StrH^{\cdot}, \qquad (IV)$$

$$StrH^{\cdot} + AcPy^{-} \ (\text{or } AcHPy^{\cdot}) \rightarrow Str + AcHPy^{-} \ (\text{or } AcH_2Py)_2 \qquad (V)$$

then these interactions shift the discharge of strychnine to a lower cathode potential. Finally, the electroreduction of strychninium ions may also be facilitated by the formation by them of adducts with acetylpyridine. This was shown in the example of the catalytic hydrogen wave caused by cinchonine which becomes less negative in the presence of acetophenone.[16]

All the above-cited on the possibility of the start of discharge of protonated catalyst ions in the presence of substrate at far less negative potentials than in the case of the catalytic hydrogen wave in a pure catalyst solution, also explains the observation described above (Kariv and collaborators[15]) according to which the effect of the alkaloid on the reduction of the substrate is displayed up to the potential corresponding to the appearance of catalytic hydrogen wave.

It is necessary to note that the corresponding alcohol is formed in 47.5% optical yield in the preparative electrolysis of acetylpyridine in the presence of strychnine at the mercury cathode.[46] On a lead cathode, which is close in properties to mercury, a high optical yield is also achieved, while on a cadmium electrode, to which strychnine is almost not adsorbed, only racemic products were formed.[46] The factors aiding displacement from the electrode of starting materials and intermediates adsorbed onto it, such as the addition of a strongly adsorbing alkaloid or tetrabutylammonium salt, clearly reduce the yield of dimeric pinacol and as a result increase the yield of alcohol.[46] It is possible however to add that the electrolytes introduced into the solution not only displace starting materials and intermediates of their reduction from the electrode surface but often increase their solubility due to the so-called 'salting in' effect (see for example review[53]). The problem of the effect of the adsorption of organic substances on the kinetics and selectivity of their conversions both on a platinum anode and on a mercury cathode was considered even earlier.[54] The action of the inducer clearly grows due to a significant growth in its concentration in the reaction zone as a result of adsorption. The extremely thorough investigation of Koster, Wendt and Lebouc[55] is devoted to the role of the adsorption of components of the chemical reaction of protonation on the electrode in the kinetics of the electroreduction of prochiral compounds in the presence of inducers. The mechanism and kinetics of the electro-reduction of the three isomeric acetylpyridines on electrodes of various metals were studied. The reduction of the acetylpyridines on the dropping mercury electrode and, preparatively, on a large mercury cathode in the presence and absence of strychnine, tetrabutylammonium salts and camphoric acid were examined particularly carefully. The adsorbability of the acetylpyridines, of their reduction products and of strychnine on solid electrodes of various metals was also studied. At pH $\leqslant$ 10 the strychnine cation, which is as well adsorbed on a lead electrode as on mercury (or amalgamated copper), causes an intense catalytic evolution of hydrogen. Strychninium is adsorbed far more strongly than the acetylpyridines and their reduction products. A somewhat weaker adsorption of strychnine and a weaker action on the catalytic evolution of hydrogen was displayed when using bismuth and antimony cathodes. No adsorption of strychnine or catalytic hydrogen evolution was observed on cadmium and zinc electrodes.[55]

The effect of the nature of the cathode metal on optical yield when reducing in the presence of ephedrine methochloride was also studied by Horner and Schneider.[43] The optical yield of alcohol fell in the series Cd > Hg > Pb > Al > Sn, while the overall yield of the secondary alcohol fell along the sequence Pb > Cd > Al > Hg > Sn. The addition of strychnine to the electrolyser when reducing 2-acetylpyridine in acidic medium causes an appreciable shift in the current–potential curve, which has a quasi-reversible character, to a less negative potential on amalgamated copper and lead cathodes. A small shift in the same direction takes place on bismuth and antimony cathodes while strychnine showed no action on the completely irreversible wave for the reduction of 2-acetylpyridine on cadmium and zinc electrodes.[56] On polarography of 2- and 4-acetylpyridines in strongly acidic medium[55] the shape of the first one-electron reduction wave corresponds to a reversible process with subsequent surface dimerisation of the radicals formed, as observed in the reduction of 2-acetylpyridine in acidic medium at not very low concentrations (see final section of Chapter VIII, Ref. 1 and Ref. 56). All the facts given above indicate persuasively that the critical step of the process of inducing optical activity in the presence of an inducer is the interaction in the adsorbed state of the protonated inducer and the intermediate reduction product of the substrate, a ketyl radical in the present case.

It was recorded even in studies[31,40] that 3-acetylpyridine differs electrochemically from the 2 and 4 isomers. In particular the presence of strychnine does not affect the reduction of the 3 isomer and the product of its reduction is the optically inactive pinacol. With a view to clarifying the reason for the special position of the 3 isomer Koster, Wendt and Lebouc[55] studied the polarographic behaviour of all three isomers of acetylpyridine in DMF in the presence and absence of proton donors. The relative basicities of the ketyl radicals of all three isomers were assessed from the values of the half-wave potentials. It turned out that the basicity of the radical of the 2 isomer exceeded by seven orders of magnitude, and that of the 4 isomer by five orders, the basicity of the ketyl radical of the 3 isomer. The relatively low protonation rate of the 3 isomer ketyl radical is also the reason for the particular electrochemical behaviour of the 3 isomer compared with the 2 and 4 isomers. In

view of the low basicity of the 3-acetylpyridine ketyl radical the comparatively strong camphoric acid was very wisely used as inducer and proton donor.[55] In its presence a small shift was observed in the reduction wave of 3-acetylpyridine to a less negative potential which seemingly must lead to the formation of an optically active product in preparative electrolysis. In fact in a subsequent study an optically active product, though in low optical yield (7%), was successfully obtained by the same authors[57] in the preparative electrolysis of 3-acetylpyridine in the presence of camphoric acid. Data are given in the same study on the preparative electrolysis of 2- and 4-acetylpyridines on the mercury and some solid electrodes in the presence of strychnine. Confirmation was obtained of the high optical yields of alcohol, particularly on a lead cathode, which had previously been observed by Kariv and collaborators.[16]

In a detailed review[58] Wendt showed, with numerous examples, the nature of the three main types of electrocatalysis in organic electrochemistry and considered in particular the catalysis with asymmetric inducers – proton donors.

Highly interesting experimental data and extremely valuable correlations and conclusions related to the mechanism of inducing optical activity when reducing organic compounds in the presence of chiral inducers are contained in the study by Hazard and collaborators.[59] The action of several alkaloids, viz. strychnine, strychnine methiodide, brucine, emetine, yohimbine, narcotine and sparteine, on the reduction of 1-mono and 1,1-dibromo derivatives of 2,2-diphenylcyclopropane was studied under various conditions. The highest optical yields of products (up to 44.3% in the reduction of dibromodiphenylcyclopropane) were obtained in the presence of emetine and the lowest in the presence of narcotine and sparteine. It is interesting that in the presence of emetine the optical yield did not depend on the electrode potential nor on the pH of the medium. While noting the importance of the adsorption of the inducer, the authors[59] nevertheless stressed the absence, discovered previously,[22] of a correlation between the optical yield and the adsorbability of the inducer. The main factor determining the development of asymmetry in the reduction product was considered to be the formation of an adduct between the substrate and the inducer,[32,42] which is protonated after receiving an electron. This protonation of the anion-radical in the adduct by the asymmetric inducer (and most frequently with transfer of a proton from it[31]) determines the formation of the enantiomer. As was indicated, the shift of $E_{1/2}$ for the reduction wave of the bromocyclopropanes to a less negative potential, on adding an inducer to the solution being polarographed, points to the formation of an adduct. It must, however, be mentioned that in this case the shift of $E_{1/2}$ for the wave of the irreversible fission of the C–Br bond is determined to a known extent by the change in structure of the double layer on introducing into the solution cationic inducers adsorbing strongly to the electrode. Nevertheless, as follows from the Tables presented in that study,[59] in the presence of strychnine in fairly acid solution (so that strychnine is in the protonated form) the shift of $E_{1/2}$ for the reduction wave of the bromocyclopropanes to a less negative potential was appreciably greater than in the presence of methylstrychnine. This confirms the correctness of the conclusion[59] that an adduct is formed and a proton is transferred to it from the protonated inducer.

The appreciable increase in optical yield on going from a mono to a dibromo derivative of diphenylcyclopropane is extremely interesting.[50] This is seemingly due to the presence of two stereotopic positions in the molecule being reduced.[50] It has also been considered[59] that ion-pairs are generated in addition to the adduct formed by the inducer and the anion-radical (the intermediate reduction product). The preparation in certain cases of an optically active product (though in low optical yield) in the presence of methylstrychnine is explained by this.[59] It is noteworthy that the sign of the rotation of the product is in this case opposite to that of the reduction product in the presence of strychnine, other conditions being equal. This is due to protonation of the anion-radical in the presence of strychnine occurring with a proton from strychnine while in the presence of methylstrychnine the proton donor is in the solution and the proton approaches the anion-radical from the opposite side.[59]

1-Bromo-2,2-diphenylcyclopropane-1-carboxylic acid was one of the subjects of investigation.[59] This compound gives two waves on the polarogram and the second wave, having a kinetic nature in weakly acidic media, increases in the presence of inducers due to acceleration of protonation. It is interesting that in ammonium acetate solution the shift of $E_{1/2}$ for the waves of the bromides studied[59] is reduced on addition of inducers. Evidently this is caused by competition between ammonium and inducer ions both when forming adducts with the substrate and when building up the outer covering of the electrical double layer on the electrode.

The considerable experimental data contained in study[59] confirm the series of observations and conclusions made previously. The relationships of optical yield to the electrode potential and to the solution pH are, as a rule, described by bell-shaped curves (although in the presence of strychnine and brucine the yield grows with an increase in cathode potential). The highest yields were reached at comparatively low inducer concentrations and by reducing the temperature of electrolysis. The inversion occasionally observed of the sign of the rotation of the enantiomer on increasing the cathode potential is linked with the effect of the electric field on the anion-radical.[36]

It is interesting that the electroreduction of 2,2-disubstituted 1,1-dibromocyclopropanes in the absence of inducers in aqueous alcoholic medium on a mercury cathode with a two-electron fission of one C–Br bond occurs stereoselectively with the formation of the *cis* isomer, particularly if one of the substituents at the 2 position is hydrogen and the second $-CO_2H$ (or CO_2Me, CO_2Et). The yield of *cis* isomer exceeds 90% in the presence of tetraalkylammonium salts.[60]

Somewhat earlier Nonaka and collaborators[61] considered in detail the problem of the preferential formation of one diastereoisomer on electroreduction of ketones, having a chiral carbon atom and substituents of various size in the position α to the carbonyl group, in relation to the orientation of the initial ketone on its adsorption on the electrode.

Horner has analysed the mutual disposition of methylephedrine and acetophenone on the electrode in order to explain the induced asymmetric electroreduction. In the opinion of the authors a particular orientation of acetophenone on the electrode causes the formation of a chiral anion-radical on transfer of an electron from the electrode to the acetophenone molecule.[62]

On electroreduction of 4-carbethoxycoumarin in the presence of small quantities of alkaloids the 3,4-dihydro derivative is formed in almost quantitative yield and up to 20% optical yield. However dextrorotatory *o*-hydroxyphenyl monoethyl succinate is formed as a result of the reversible hydrolysis of the obtained laevorotatory lactone,[63] i.e. in time a change occurs in the direction of rotation of the plane of polarised light in the solution after electrolysis.

According to Klabunovskii (see Ref. 64, p. 4), the presence of a disymmetric component, which controls the process stereochemically,

in the transition state is necessary in order to obtain an asymmetric product. Such a component may be an optically active solvent or one of the components of a mixed solvent. Processes have been described for obtaining enantiomeric products when carrying out electrolysis in an optically active solvent. In the studies of Seebach and collaborators (for example Ref. 65) (*S, S*)-1,4-bisdimethylamido-2,3-dimethoxybutane (i.e. the tetramethylamide of dimethoxysuccinic acid) was used mixed with methanol as the optically active component of the solvent. The pinacol, enriched with the (*R,R*)-conformer, was obtained on electroreduction of acetophenone in this medium with lithium bromide as based electrolyte. It was shown[65] by special experiments by photolysis of the solution being electrolysed that the formation of the pinacol occurs at a certain distance from the electrode surface. The shape of the polarographic wave of acetophenone is described, as a rule, by an equation for the reversible transfer of an electron with subsequent dimerisation of the intermediates in the solution.[66] This indicates that the dimerisation of the intermediates of the reduction of acetophenone occurs within a certain volume of the reaction layer. In the opinion of Seebach and collaborators[65] complexes of anion-radicals (or radicals) with dimethoxysuccinic acid tetramethylamide (or its cationic form in acidic media) may emerge as such intermediates. The adsorption of the starting materials or intermediates accelerates the process significantly and aids the increase in optical yield of enantiomers but is not strictly obligatory. This is also indicated by the accelerating effect of pyridine, creating the volume catalytic hydrogen wave, in the electroreduction of aromatic carbonyl-containing compounds.[4]

The enantiomeric alcohol, albeit in very small optical yield (about 2%), was obtained on electroreduction of acetophenone in the presence of the potassium complexes of chiral crown ethers.[67] It is known that a crown ether may give complexes of the 'guest–host' type with organic molecules having an acidic hydrogen atom[68] as a result of the formation of hydrogen bonds between this atom and the oxygen positions of the cavity of the crown ether. However there are no sufficiently acidic hydrogen atoms in acetophenone for it to form a similar complex. The effect of the crown ether in this case may be explained by the fact that it is adsorbed on the electrode surface,[69] creating by its chirality a local asymmetric field near to which the asymmetric reduction of acetophenone occurs. It may also be proposed that the proton donors existing in the solution form a complex with the crown ether and thereby show an asymmetric action on the protonation of the anion-radical or radical. A water molecule, which often enters the cavity of a crown ether, may serve as such a proton donor.[70]

When reducing methyl acetoacetate in the presence of L-cysteine or cystine at a mercury cathode Nonaka and collaborators[71] obtained an enantiomer of 3-hydroxybutyric acid ester with an optical yield of about 1%. From citraconic acid under the same conditions (*R*)-(+)-methylsuccinic acid was successfully obtained with an optical yield of 2.4%. The use of (*R*)-(−)-benzylmethylphenylpropylphosphonium bromide as inducer in the reduction of phenylglyoxylic acid oxime in anhydrous and in aqueous methanol gave (*S*)-(+)- and (*R*)-(−)-phenylglycine respectively in optical yields in each case of about 1.9%.[71]

VII. The use of electrodes with a modified surface

The electroreduction of hexan-2-one on a powdery electrode, Raney nickel, occurs at −1.0 V (vs. SCE) with a yield on current of over 67% (on the mercury cathode reduction begins at a potential greater than −2.0 V).[72] On modifying such an electrode with optically active tartaric acid an enantiomer of hexan-2-ol was obtained in 2–6% optical yield. Heptan-2-one and octan-2-one were also reduced in a similar manner.[72]

The action of the chiral inducer must evidently be significantly enhanced if it is not adsorbed on the electrode surface but is chemically bound to it.[73] This fruitful concept was investigated for the first time by Watkins, Behling, Kariv and Miller.[73] They oxidised graphite rods (by heating in air to 160 °C), so that carboxyl groups were formed on their surface which could be titrated with alkali. By treatment with thionyl chloride in dry benzene these surface carboxyl groups were converted into acid chlorides, which were then converted into substituted amides of carboxylic acids by reaction with chiral phenylalanine ester in dichloromethane. Such electrodes, both in outward appearance and according to current–potential curves taken on them (on polarisation from −0.5 to −1.5 V), did not differ in any respect from unmodified graphite electrodes. Reduction of 4-acetylpyridine in aqueous-alcoholic acetate buffer solution on a modified electrode afforded the corresponding enantiomeric alcohol, albeit in small optical yield. On electrolysis of a solution of phenylalanine in acetate buffer on an unmodified graphite cathode, catalytic evolution of hydrogen was observed which was suppressed on introducing 4-acetylpyridine into the solution. On reducing the latter in this system the preparation of optically active alcohol was unsuccessful. On reducing phenylglyoxylic acid ester on a graphite electrode modified with phenylalanine, a diastereomer of mandelic acid ester was formed in 94% yield and an optical purity of 9.7%.[73] Although reproduction of these results was unsuccessful,[74] after publication of the paper[73] several studies appeared in which electrodes modified with chiral compounds were used for carrying out asymmetric electrosyntheses.

It has been established[75] which of the faces of crystalline graphite (two types of face exist) acquires on treatment the property to induce asymmetry in a product of an electrode reaction. Separate faces were clearly distinguishable in a sample of highly ordered pyrolytic graphite (Union Carbide Corporation, Parma, Ohio). On sealing first one and then the other face with silicone rubber and modifying them with amino acids both on the face of 'edge' atoms and on the face corresponding to the basal layer, the total yield of alcohol was 90% on reduction of 4-acetylpyridine. An enantiomeric excess (2%) was observed only on the 'edge' carbon atoms which, as is known, are readily oxidised with the formation of carboxyl groups.

It was also established[75] that a graphite electrode modified with amino acids may operate at high anode potentials. A graphite electrode modified with phenylalanine methyl ester was used for the oxidation of methyl *p*-tolyl sulphide to the sulphoxide. The yield of sulphoxide reached 90% and the enantiomeric excess of (−)-sulphoxide was 2.5%.

Instead of modifying electrodes with chiral substances, which provide only a comparatively small surface coverage, Abe, Nonaka and Fuchigami[76] proposed the use of electrodes coated with polymeric films obtained from chiral monomers.

An example has already been described of the electrochemical polymerisation of a pyrrole on a platinum electrode and the properties of the electrode modified in this way have been reported.[77] It turned out[78] that on changing the structure of the monomer (*N*-phenyl substituted pyrrolium cations having various substituents in the *para* position of the phenyl ring) used to obtain the polymeric films, the rate constants for electron transfer from a ferrocene molecule in acetonitrile solution to a platinum electrode coated with polymer varied appreciably.

An electrode, coated with a polymeric film obtained from chiral monomers, was used for the first time[76] for the electrochemical preparation of optically active compounds. On reduction of citraconic acid, on a graphite electrode coated with a film of poly-L-valine, in pH 6.0 phosphate buffer solution, an enantiomeric methylsuccinic acid was obtained with an optical yield of 25%, which is approximately 10 times greater than on the usual electrode in the presence of inducers adsorbed on it.[71]

The use has been described of a graphite electrode coated with poly-L-valine for the electroreduction of prochiral ketones, oxides and *gem*-dihalides.[79] The greatest optical yield (16.6%) was obtained on reducing 1,1,-dibromo-2,2-diphenylcyclopropane to the corresponding monobromo derivative.

There are procedures involving the formation of covalent binding of amino acids to graphite which enable the preparation of more stable polymeric films and multiple use of electrodes.[80]

Nonaka, Abe and Fuchigami[81] have used graphite electrodes modified with chiral polyamino acid films for the asymmetric reduction of citraconic acid, its dimethyl ester and of mesaconic acid.[81] The reduction of citraconic acid was carried out on electrodes coated with six different polyamides. The best yield, 26% methylsuccinic acid, was obtained with a poly-L-valine coating. Coating of lead and especially zinc electrodes with the same film did not enable such high optical yields to be reached as on a graphite electrode. This is apparently linked with the lower adhesion of the polymeric film to a metal electrode.[81] The optical yield when reducing dimethyl citraconate under optimum conditions (pH 6.0, 0 °C, $E = -1.0$ V) was far less than when reducing the acid itself (2.3%). This evidently indicates the important role of hydrogen bonds on inducing chirality.[81] The reduction of mesaconic acid occurred with an appreciably lower optical yield (10%) than did the reduction of citraconic acid, but they both gave predominantly enantiomers with the (*S*) configuration. Since the polymeric film is not conducting but is permeable to protons and substrate molecules (the film does not increase the voltage), the process, in the opinion of the authors,[81] proceeds at the graphite/film boundary and induction is effected on transfer of an electron and not a proton.

Komori and Nonaka[82] have described a method of modifying electrode surfaces, by coating the surface of a platinum electrode a polyamide film. It was established that such an electrode is stable to high anode potentials which enables its use for chiral electrooxidation.[82] On a platinum electrode coated with a poly-L-valine film, cyclohexyl phenyl sulphide is oxidised to the sulphoxide in up to 54% yield.[82]

In a subsequent study,[83] the same authors described the oxidation on platinum anodes, coated with films of polymeric chiral compounds, of seven different unsymmetrical alkyl phenyl and cyclohexyl phenyl sulphides to the corresponding sulphoxides. The highest optical yield (93%) was obtained on oxidising t-butyl phenyl sulphide on a platinum electrode coated with a double layer of polypyrrole and poly-L-valine.

It is interesting that such a modified electrode was used by Komori and Nonaka[84] for the enantiomerically differentiating oxidation of racemic 2,2-dimethyl-1-phenylpropan-1-ol to the ketone.[84] After oxidising half of this alcohol on a lead-lead oxide anode, twice coated with polypyrrole and poly-L-valine, 43% of optically pure (*S*)-(−)-enantiomer of the alcohol was in the unreacted state. This is the first example of the kinetic enantiomeric electrochemical resolution of a racemic alcohol.

The high optical yields of products on electrooxidation of sulphides on modified anodes have attracted attention.

There is considerable interest in an electrode coated with a thin film of clay. Certain racemic tris-complexes of metal ions with organic ligands, such as the trisphenanthroline complexes of iron(II), adsorb on the clay surface in such a manner that their enantiomers alternate in a staggered order.[85] An enantiomeric tris-complex occupies only half the area of the electrode, i.e. only its own space. This enabled a tin-tin oxide electrode coated with clay and an enantiomeric tris-complex $Ru(phen)_3^{+}$ to be used for the selective electrooxidation of racemic $Co(phen)_3^{2+}$.[86]

A review[87] has been devoted to the preparation and use of electrodes, the surface of which is modified by films of organic substances and polymers, and to the effect of such electrodes on electrochemical processes.

VIII. Intramolecular induction

The presence in a molecule of an asymmetric atom and a prochiral centre near to it, as already indicated,[61] enable diastereomers to be prepared by electrode processes. Intramolecular induction is observed in the case of prochiral ketones having an asymmetric centre in the positions α or β to the keto group.[88] On reduction of 2,2,3-trimethylindan-1-one on a mercury cathode in aqueous methanolic alkaline solution a diastereomer is formed with an optical yield up to 82%.

An asymmetric centre may be introduced into the molecule of an acid to be reduced by esterification with L-menthol or D-neomenthol.[89] A chiral product was successfully obtained in optical yield up to 5% by the esterification of itaconic, mesaconic, citraconic and phenylmaleic acids and subsequent reduction.

The electroreductive alkylation of phenylacetates of L-menthol and L-borneol in the presence of dimethyl sulphate (and also methylethyl and methylisopropyl sulphate) at −20 to −40 °C on a platinum cathode leads to replacement of the α-hydrogen atom (relative to the carboxyl group) by alkyl in an overall yield of 78% and an optical yield of up to 22%.[90]

On treating the products of deprotonation of the cyclopentadienyl-tetralin-iron cation with menthyl nitrite, a chiral oxime is formed giving a chiral ketone on hydrolysis. On electroreduction in acidic medium the oxime gives an optically active *endo*-amine and the ketone gives an *endo*-alcohol.[91] The small optical yields of products are caused by the very low optical yield on nitrosation (4−7%). On two-electron electroreduction of (*S*)-(+)-1-bromo-1-carboxy-2,2-diphenylcyclopropane and its ester on a mercury electrode in aqueous acetate buffer solution containing ammonium ions, the debromination product retains the initial configuration (up to 70%) for the ester. The configuration is inverted in the presence of tetraalkylammonium, the extent of inversion did not depend on the electrode potential but was increased on increasing the length of the group in the tetraalkylammonium cation.[92] When reducing the ester in the presence of tetrabutylammonium the inversion reached 60%. Similar results were obtained in ammonia buffer but inversion in the presence of tetraalkylammonium salts depended on the potential in this case.[92]

Mandelic acid amide is formed almost quantitatively on electroreduction of aqueous alcoholic buffer solutions of (*S*)-(−)-*N*-(α-methylbenzyl)benzoylformamide on a mercury cathode. In strongly acidic medium the (*R*,*S*) isomer is mainly formed (maximum optical yield 12.5%) and in ammonia buffer the (*S*,*S*)

isomer (optical yield 8.5%).[93] However at a more negative potential the (*R,S*) isomer is formed in the presence of tetrabutylammonium salt.

Some years earlier A Tallec published a fairly detailed review[94] on electrochemical synthesis of chiral compounds, describing the conditions of electrolysis capable of increasing optical yields. The mechanism of inducing optical activity was almost not touched upon, however the author rejected the hypothesis of Grimshaw[2,7] on hydrogen atom transfer from the uncharged form of the protonated inducer to the substrate molecule, within the confines of an adduct between them, as the step at which asymmetry of the product is provided, citing the paper of Kariv and collaborators.[16] The review indicated[94] may serve as a good information manual on work in the area of asymmetric electrosynthesis. There is much factual material in it on the conditions of electrolysis and yields of products.

IX. The use of electrode–catalysts

E I Klabunovskii and collaborators[95] discovered high enantioselectivity when hydrogenating esters on nickel black modified with (*R,R*)-tartaric acid. In subsequent work[96] this catalyst was used for the electrohydrogenation of ethyl acetoacetate. Finely dispersed catalyst was applied in a uniform layer on a horizontal platinum plate (7 cm^2) serving as a cathode. When hydrogenating ethyl acetoacetate in 0.1 M aqueous NaOH solution or 50% aqueous ethanolic 0.3 M KCl both at the potential of the hydrogen region of the electrode (i.e. in the layer of hydrogen adsorbed on the electrode) and in the region of hydrogen overvoltage potentials, ethyl β-hydroxybutyrate was obtained in practically quantitative yield and the optical yield of the (*R*) isomer was in all cases close to 10%.

Slemcu[97] has described the use of the dielectric Electret applied as a 1 mm layer to a metallic foundation as an electrode for the reduction of fumaric acid from aqueous alkaline solution. At 500 V and a current strength of about 1 mA for 150 h at 100 °C, an 18% excess of laevorotatory enantiomer of malic acid was achieved. Electret consists of mica plates and barium titanate, fused in carnauba wax. The latter, evidently, provides chirality to the electrode surface. It remains unclear why malic and not succinic acid was formed. It is possible that the electric current stimulated the hydration of fumaric acid without electroreduction.

Finally it has been shown[98] very recently by a conductiometric method that phenylglyoxylic acid forms an adduct in water with strychnine of composition 1:1 within which optical activity is induced in the mandelic acid formed on electroreduction.

Mass spectrometry of halogen-containing organic compounds

V V Takhistov, A A Rodin, B N Maksimova
Leningrad State University
State Institute of Applied Chemistry, Leningrad

ABSTRACT. The mechanisms involved in the formation of the mass spectra of halogen-containing compounds are correlated. All types of processes involving halogens are examined, the material being presented according to the type of fragmentation.

The bibliography includes 192 references.

V. Analytical aspects of the mass spectrometry of halogen-containing compounds 1109

I. Introduction

Halogen-containing compounds (with the exception of purely synthetic laboratory chemicals) frequently form part of complex mixtures, so their identification and structural determination are mainly carried out by mass spectrometric methods, which are the most informative and particularly effective when combined with chromatographic separation methods. Hence there is an obvious need to elucidate the general mechanisms involved in the formation of the mass spectra of halogen-containing compounds. As a rule, this information is dispersed amongst a large number of articles in which, with the exception of a number of publications,[1–7] only a small proportion of the problems relating to the interpretation of the mass spectra of halogen-containing organic compounds are reviewed.

In this review, in contrast to the traditional approaches, all types of processes involving halogens rather than classes of halogen-containing compounds are reviewed.

By presenting the material according to the type of fragmentation the authors have been able to adopt a thermochemical approach to the interpretation of the mass spectra. This approach is used throughout the whole article both in examining simple bond cleavage and in analysing the peak intensities of the molecular ions, including ways of stabilising a molecular ion. The source of organic compounds in environmental materials, as has now been established, is mainly provided by human activity and to a much lesser extent by natural chlorine-, bromine-, and iodine-containing compounds of vegetable (including petroleum) and animal origin. Therefore we consider it necessary to consider the analytical aspects of the mass spectrometry of halogen-containing compounds in a separate section.

II. Electron-impact mass spectrometry

1. Positive ions

One of the pathways of the fragmentation of organic monohalogen-containing compounds RCH_2X from electron impact (EI) leads to ions of the type $\overset{+}{C}H_2-\ddot{X}\longleftrightarrow CH_2-\overset{+}{X}$, in the same way as other electron-donating groups (alkyl, OR, SR, NH_2, $CH=CH_2$, Ph, etc.). A comparison of the exothermicities Q of the isodesmic[4,8] reaction

$$CH_3^+ + CH_3X \rightarrow \overset{+}{C}H_2X + CH_4$$

gives the following series of stability of these ions compared to the CH_3^+ cation (kcal mol^{-1}): CH_3^+ (0), $\overset{+}{C}H_2F$ (25), $\overset{+}{C}H_2Cl$ (31), $\overset{+}{C}H_2Br$ (35), $\overset{+}{C}H_2I$ (35), $\overset{+}{C}H_2CH=CH_2$ (59), $\overset{+}{C}H_2OH$ (65), $\overset{+}{C}H_2SH$ (69), $\overset{+}{C}H_2NH_2$ (96).

This means that in terms of their donor properties halogens are inferior to other groups, and the stabilising ability of halogens increases in the series F < Cl < Br < I. Halogens can be eliminated as free radicals X$^\cdot$, and the exothermicity Q (kcal mol^{-1}) of the isodesmic reaction

$$\dot{C}H_3 + HX \rightarrow CH_4 + X^\cdot,$$

that reflects the relative thermodynamic stability of X$^\cdot$ decreases in the series I$^\cdot$ (33.5) > Br$^\cdot$ (17) > Cl$^\cdot$ (1.6) > F$^\cdot$ (−31.5).[4] Therefore abundant loss of X$^\cdot$ is to be expected only for I$^\cdot$ and Br$^\cdot$. Together with dehalogenation, dehydrohalogenation with elimination of HX is also typical of halogen-containing compounds.

Calculated[4] thermochemical properties of the simple bond cleavage processes and loss of HX for a C_2H_5X molecule are given in Table 1, and the peak intensities of the corresponding ions are given in Table 2.[9] The enthalpies of formation of molecules, ions, and radicals are taken from a monograph[4] while the ionisation potentials (IP) are taken from a reference book[10] (E_{cr} = AP − IP, the critical energy or energy of activation for dissociation of $[C_2H_5X]^+$ molecular ions (AP is the appearance potential of a fragment ion).

Contrary to expectation the critical energies for separation of X were similar for all halogens (0.78 − 1.22 eV). This occurs because, whereas during homolytic cleavage of a bond by the direct process

$$C_2H_5\text{—}X \longrightarrow C_2H_5^\cdot + X^\cdot$$

the strength of the bond with X decreases in the series F, Cl, Br, I because the stability of X$^\cdot$ increases in the same series, on electron impact it is the molecular ion that dissociates rather than the initial molecule. In the latter, (because of the increase in IP in the series RI→RBr→RCl→RF) the value of E_{cr} decreases in this series, although the absolute values of IP increase from I to F in complete

agreement with processes involving homolytic bond cleavage. The competing fragmentation processes for formation of $CH_3\overset{+}{C}HX$ and $\overset{+}{C}H_2X$ can only occur in organofluorine compounds (both processes have a similar (AP), whereas when X = Cl, Br, I its AP and E_{cr} are substantially higher than for processes involving separation of X. Therefore, in the mass spectra of aliphatic monohalogen derivatives intense peaks due to $\overset{+}{C}H_2F$ and $R\overset{+}{C}HF$ ions occur but there are only weak peaks due to the other $\overset{+}{C}H_2X$ and $R\overset{+}{C}HX$ ions. Simple bond cleavage processes involving a single halogen atom are restricted to those considered above, to which can only be added the loss of neutral [XC≡CH from halobenzenes; XCH=CHR; H(X)C=O; XC≡N] or charged ($\overset{+}{X}C=\ddot{O}$ in a number of disubstituted furans) ring fragments from carbocyclic and heterocyclic compounds. They may be extended to all classes of compounds.[1,4]

In compounds containing other substituents in addition to halogens, the primary fragmentation processes (they constitute a determining factor in establishing the structure of the initial compound if it is not known) are controlled by these substituents (this relates in particular to fluorine- and chlorine-containing compounds). However, here also—at advanced stages of the fragmentation—the participation of halogens definitely manifests itself, primarily in the elimination of HX and by the presence of peaks of metastable ions corresponding to these processes.

Let us examine the behaviour on electron impact of polyhalogen-containing compounds in simple bond cleavage processes. In systems that have the perhalogen-containing groups CCl_3-, CBr_3-CBr_2-, $-CCl_2-$ (for perfluoroalkyl groups, see below), abundant loss of Cl or Br occurs because of the increase in IP of the molecule and the decrease in bond strength (polyiodine-containing compounds have hardly been studied at all).[4,11] Of perfluoroalkyl ions it is only CF_3^+ ions that are intense, as a rule. While the stability of alkyl cations increases in the series: $CH_3^+ < C_2H_5^+ < CH_3CH_2CH_2^+ < (CH_3)_2CH^+ < (CH_3)_3C^+$, for perfluoroalkyl cations the stability decreases in a similar series: $CF_3^+ > CF_3CF_2^+ > CF_3CF_2CF_2^+ > (CF_3)_2CF^+ > (CF_3)_3C^+$, which is due to the presence of powerful electron-withdrawing CF_3 groups on the cation site. This also follows from a comparison of the IP of the corresponding free radicals R_F (eV): $\dot{C}F_3$ (8.9); $C_2\dot{F}_5$ (9.1); $CF_3CF_2\dot{C}F_2$ (9.2); $(CF_3)_2\dot{C}F$ (9.5) and $(CF_3)_3\dot{C}$ (10.2).[12] Such high values of the IP have the result that in functional compounds such as $RCOCH_2COR_F$ when the $C-R_F$ bond is cleaved, the charge always remains on the residue not containing R_F, and the latter is released as a free radical. In perfluoroalkyl-containing compounds, in particular perfluoroalkanes, perfluoroalkylperfluorocycloalkanes, fluorinated esters, perfluoroalkyl-1,3-diketones, and others, a peak due to the CF_3^+ ion with mass 69 is observed. The other ion homologues as a rule do not give intense peaks. Nevertheless, peaks from 119^+ or 169^+ ions ($C_2F_5^+$ and $C_3F_7^+$ respectively) appear in the mass spectra of certain compounds. We can attribute this formation of R_F^+ at the advanced stages of fragmentation of $M^{\overset{+}{\cdot}}$ to a pair with very stable neutral molecules that compensate the instability of R_F^+:[12]

$$C_2F_5^+ \longleftarrow\!/\!- \underset{M^{\overset{+}{\cdot}}}{CF_3CF_2CF_2COOCH_3^{\overset{+}{\cdot}}} \longrightarrow \underset{[M-OCH_3]^+}{CF_3CF_2-CF_2-C\equiv\overset{+}{O}} \longrightarrow$$

$$\longrightarrow CF_3\overset{+}{C}F_2 + CF_2=C=O,$$

2.5% base. (70 eV)

$$C_3F_7-CF_2-CF_2-CF_2-CO-CH_2-\overset{+}{C}-\ddot{O} \longrightarrow$$

$$\uparrow\ [M-CF_2]^+$$

$$M^{\overset{+}{\cdot}} -\!/\!\longrightarrow C_3F_7^+$$

$$\longrightarrow C_3F_7^+ + C_2F_4 + CF_2=C=O + CH_2=C=O.$$

%Σ: 2.4 (70 eV): 3.5 (20 eV): 3.2 (12 eV).

The stability of the neutral residues in the absence of more favourable fragmentation pathways explains the appearance of intense peaks from ions with acceptor groups—$(CF_3)_2\overset{+}{C}Cl$ (100%) from $(CF_3)_2CClSO_2Cl$ and $(CF_3)_2CH$ (100%) from $(CF_3)_2CHSO_2OH/H_2O$.[13]

Simple bond cleavage processes have the most direct bearing on such an important characteristic of a compound and its mass spectrum as the intensity of the molecular ion peak. It is the value of the critical energy E_{cr} for the most favourable simple bond cleavage that governs the intensity of the $M^{\overset{+}{\cdot}}$ peak (see Table 2). The value of E_{cr} is determined by two quantities—the AP and IP. The absence of peaks due to $M^{\overset{+}{\cdot}}$ ions in the mass spectra of many polyfluorine-, polychlorine-, and polybromine-containing compounds is due primarily to high values of the IP, since halogen-containing groups that include powerful withdrawing halogen atoms (especially F and Cl) increase the IP and, as a result, reduce E_{cr}. If E_{cr} is equal to zero, i.e., the thermochemical threshold for formation of the fragment ion obtained by simple bond cleavage is the same or less than the IP of the molecule, any $M^{\overset{+}{\cdot}}$ immediately decomposes and is therefore not recorded. Examples of compounds, mainly fluorine-containing ones, which do not produce an $M^{\overset{+}{\cdot}}$ peak are

given in Table 3. It follows from Table 3 that identification of the molecule ion is possible from the primary fragment ion (by mass), usually $[M - F]^+$, but this method is not always reliable. It is advisable to change the method of ionisation, and to use chemical ionisation in particular (see below).

*In the EI mass spectrum.

Another way of obtaining an M^+ peak is chemical modification. The introduction of a group that has a substantially lower IP than an unmodified molecule gives rise to a new fragmentation pathway with E_{cr} not equal to zero, which makes it possible to generate an M^+ peak. This method can only comparatively rarely be applied to halogen derivatives, but nevertheless such examples do exist. In the electrochemical fluorination of acid chlorides, acid fluorides are obtained with a fluorinated chain (more frequently an acid mixture is obtained). Since neither they, nor the methyl esters or trimethylsilyl esters to which it is usual to convert the reaction mixture of acid fluorides give M^+ peaks, it is advisable to react this mixture with phenols or naphthols:[4,11] aryl esters of fluorinated acids give M^+ peaks. For example, the M^+ peak in $C_2F_5COOCH_3$ can only just be detected (0.07% base at 12 eV), the M^+ peak in $C_2F_5COOSi(CH_3)_3$ does not appear, whereas the M^+ peak in $C_2F_5COOC_6H_5$ amounts to 25 and 100% at 70 and 20 eV respectively.[11]

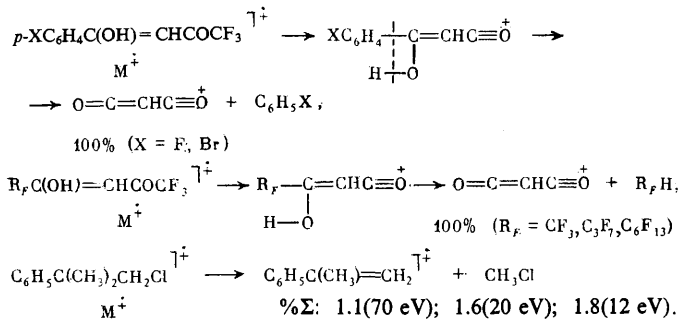
An iodine atom can serve as a group that reduces the IP of a molecule and stabilises M^+, while in compounds with acceptor groups even a bromine atom can be used. Thus, the M^+ peak is absent from the mass spectrum of $RCF_2OCF_2CF_2SO_2F$ (R = C_2H_5) and appears (0.4%) when R = $(CH_2)_4I$.[23] In $CH_2=CHCF_2R$ compounds, where R = $-CF_2CH=CH_2$, $-CF_2CH_2CH_2C_2F_5$, and $-CF_2CHICH_2C_2F_5$, the intensity of the M^+ peak is 0, 2.9, and 33% respectively.[29]

Hydrogen rearrangements for halogen-containing groups are quite similar and they actually comprise a single type of process — loss of

HX. The data in Table 1 (see above) clearly show that loss of HF is extremely favourable; E_{cr} for this process in C_2H_5F is equal to zero, but the actual thermochemical threshold for formation of $[M-HF]^{+\cdot}$ is even lower (by 1.1 eV) than the IP of the molecule. This process is always accompanied by the appearance of a peak of the corresponding metastable ion, which makes it possible (when the $M^{+\cdot}$ peak is absent) to reach the mass number of the molecular ion. In fluorine- and chlorine-containing (to a lesser extent bromine-containing) compounds loss of HX definitely occurs also at the advanced stages of fragmentation, even if the halogen atom is situated in a "strong" position (on the aromatic ring or on a multiple bond). For example:[30,31]

In recent years radical cations with separate cation and radical sites, so-called "distonic" ions[4] such as $CH_3\overset{+}{X}\dot{C}H_2$, $CH_3\overset{+}{X}\dot{C}HX$ (X = Cl, Br),[32] $CH_3\dot{C}H\overset{+}{X}H$ (X = Cl, Br),[33] $\dot{C}H_2\overset{+}{X}H$ (X = F, Cl),[34] have been detected and carefully studied (including a determination of the mechanisms of their formation and thermochemical properties). The appearance of I^+ (together with CH_3^+) in the mass spectrum of CH_3I may also, in our opinion, be due to the involvement of the $\dot{C}H_2\overset{+}{I}H$ ion in the process, without having to resort to assumptions about separate states of $M^{+\cdot}$, as Weber et al. have done.[35] A fluorine shift with formation of the unusual ion $HF\overset{+}{C}\dot{C}HFCl$ was observed by Seibl.[36]

By neutralisation and reionisation (repeated ionisation) of such ions it was possible to prove the existence of the uncharged species

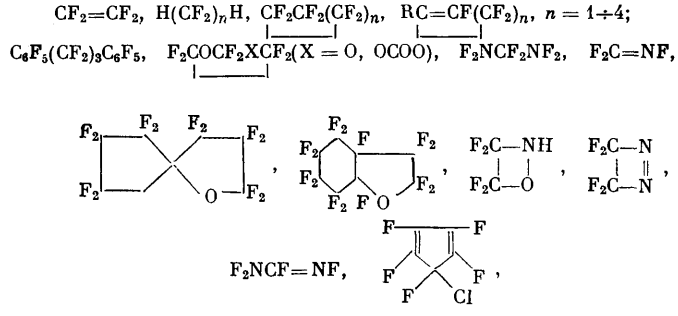


$$CH_3\dot{C}H-Cl-H,\ \dot{C}H_2CH_2ClH,\ \dot{C}H_2-CH_2-Br-H$$

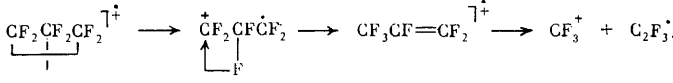
and

$$CH_3CH-Br-H$$

in the mass spectrometer.[37] An attempt to identify neutral CH_2XH (X = F, Cl) was not successful.[34]

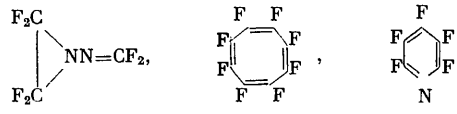


Apart from loss of HX, elimination of RH, where R are halogen-containing groups, occurs in certain cases:[12,3]

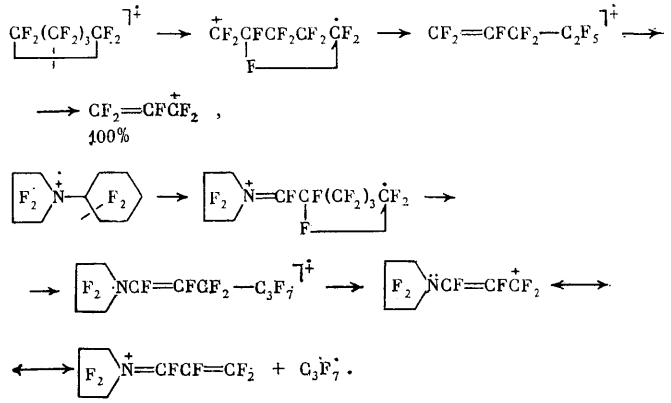


On the whole the role of hydrogen rearrangements in the fragmentation of halogen-containing compounds, with the exception of HX loss, is minor.

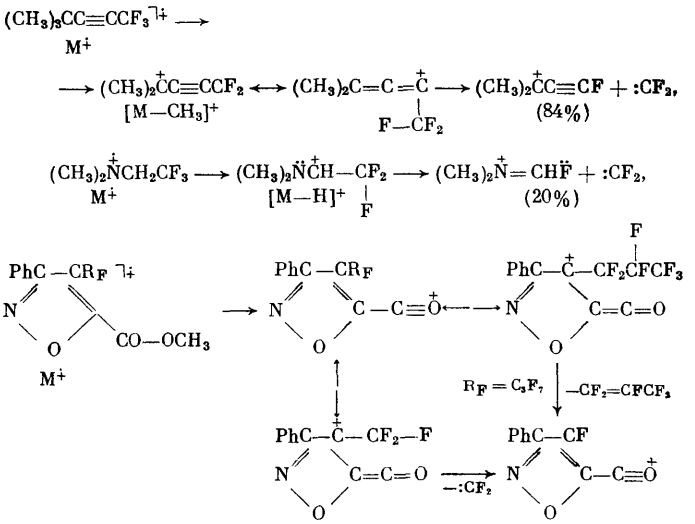
2. Skeletal rearrangements



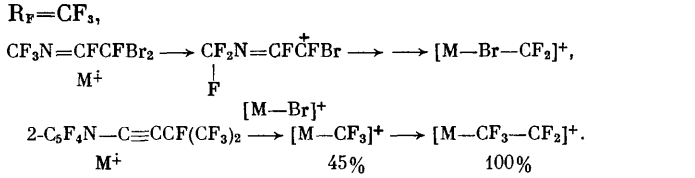
Skeletal rearrangements occur widely in a number of halogen-containing compounds when subjected to electron impact. We shall only examine those rearrangements in which halogens and halogen-containing groups are directly involved. A knowledge of them is necessary for an accurate determination of the structure of a compound if it is unknown. Thus, in the mass spectra of many compounds an intense peak from the CF_3^+ ion occurs when this fragment is not present in the initial molecule.[1,4,9,13–15,18,39,40]



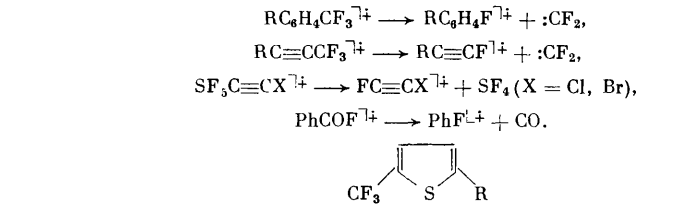
The CF_3^+ ion is formed in cyclic compounds after ring opening (while in aliphatic compounds it is formed in a fragment ion) by migration of an F atom (or atoms) to a cation or radical site. For example:



The $M-CF^{+\cdot}$ ion is obtained in a similar manner in the following compounds:[9,14]

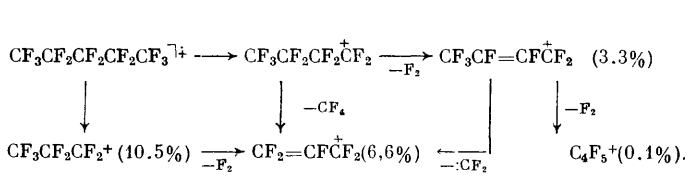


The perfluoroallyl cation is formed by the same route in cyclic compounds:[9,41]



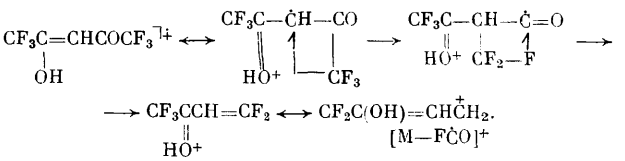
A fluorine atom can migrate to a C atom on which there are no other fluorine atoms:[12,14,18,42,43]

$R_F = CF_3$,



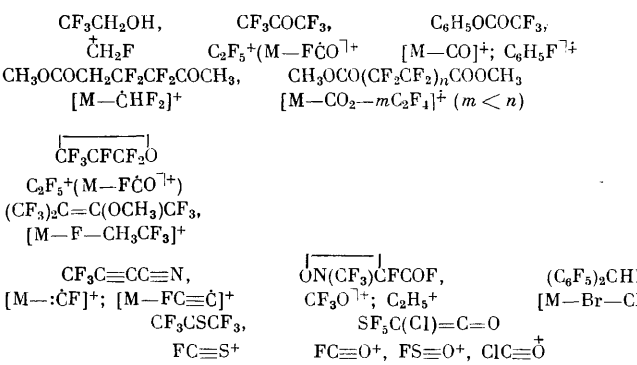
A fluorine atom can migrate to a π-system in a radical cation, particularly in the molecular ion:[9,44,45]

$[M-CF_2]^+$: 50% (R = H); 43% (CF_3); 32% (C≡CH).



However, this process does not occur with all R groups. For example, in $RC_6H_4CF_3$ (R = $COOCH_3$), OCH_3 rather than CF_2 is eliminated.[46] In $RC{\equiv}CCF_3$ migration of F occurs when R = $C(CH_3)_3$, but not when R = $Si(CH_3)_3$ or $Ge(CH_3)_3$.[42] It is true that elimination of CF_2 takes place in the fragment ions $M-OCH_3^+$ and $M-CH_3^+$ respectively.[42,46]

In perfluorcarbons, since R_F^+ ions are unstable (apart from CF_3^+), stable allylic types of ions are formed. For the latter to be obtained, a skeletal rearrangement occurs in the system with formation of F_2, CF_4, etc.:[9]



The elimination of other F-containing neutral molecules should be noted:[12,14,18,20,46]

The driving force of all these processes is not only the formation of stable F-containing neutral molecules or difluorocarbene (with low enthalpies of formation) but also the conversion through rearrangment of powerful acceptor substituents (CF_3, R_F, CF_3CO, $-CF_2-$) (destabilising a positively charged system) to donor groups, when the F atom (or atoms) either on a cation site or on a π-system is conjugated with that site. This is shown particularly clearly in aromatic systems with several substituents, when as a result of a very complex rearrangement of the fragment ion (involving ring expansion), F-substituted analogues of the tropylium ion $C_7H_7^+$ are formed at the last stage[12,46] (Table 4). The abundant loss of F from the CF_3 group in a heterocyclic aromatic system most likely also occurs with ring expansion as in its CH_3 analogue.[47] Thus, it is difficult to explain the high intensity of the peak from the $M-CF_3^+$ ion or possibly $M-F-CF_2^+$ ion (87%) in the fragmentation of 2,5-di(trifluoromethyl)thiophene.[45] We can give an example of a complex skeletal rearrangement with a rare case of the migration of CF_3 to a radical site:[39,48]

We can give examples of complex skeletal rearrangements involving F atoms or fluorinated groups with a mechanism that is unclear. A knowledge of these together with the rearrangements examined above is useful for an interpretation of the mass spectrum of both a known and an unknown structure in order to rule out possible suspicions of impurities being present. This doubt always arises if it is not possible to explain the appearance of a given unusual ion:[1,9,11,14,49]

The formation of peaks from $M-COX^+$ ions as well as $M-2COX^+$ (dioxins) and $M-COX-X_2^+$ (furans), where X = Cl, Br, in the mass spectra of polychloropolybromodibenzo-dioxins and

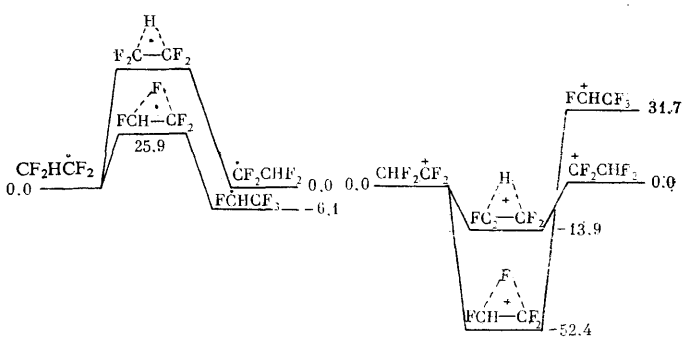
-furans[50] must be accompanied by complex skeletal rearrangements. The unusual ions $M-C_2H_5^+$ occur during fragmentation of $I(CH_2)_4CF_2CF_2OCF_2CF_2SO_2F$[23] and $TeBr_2^+$ is formed from F_5TeN = CBr_2.[21] We can attribute the high intensities of the $M-CF_3^+$ and $M-I^+$ peaks (100% at 12 eV) in the mass spectra of $(CH_3)_3CC{\equiv}CCF_3$ and $(CH_3)_3CC{\equiv}CI$ [42] respectively to isomerisation of their molecular ions to the isomeric cyclopropenyl radical cations,[51] since simple bond cleavage to form ethynyl cations is evidently unfavourable. The loss of CH_3Cl in the fragmentation of the molecular ions of *o*-$CH_3OC_6Cl_4OC_6Cl_5$ [52] and the elimination of Cl_2 in the fragmentation of $(C_6Cl_5)_2$ [53] and $C_{10}Cl_8$ [54] have been recorded.

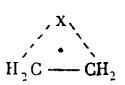
The migration of F in organoelemental and organometallic compounds is particularly marked. The driving force of these processes is the formation of an element–fluorine or metal–fluorine bond, since radical cations, fragment cations, radicals, and neutral molecules that are isomeric with the initial molecular ions and which contain F on the element or metal have extremely low enthalpies of formation. Thus, while replacement of CH_3 by F in neopentane, i.e., $(CH_3)_4C{\rightarrow}(CH_3)_3CF$, reduces the enthalpy of formation of the molecule by only 8 kcal mol^{-1}, a similar replacement in the Si analogue, i.e., $(CH_3)_4Si{\rightarrow}(CH_3)_3SiF$, leads to a reduction of 56 (!) kcal mol^{-1}. A similar replacement of CH_3 by other halogens, i.e., $(CH_3)_4Si{\rightarrow}(CH_3)_3SiX$ reduces the enthalpy of formation by 42 (Cl), 40 (Br) and 35 (I) kcal mol^{-1} respectively.[4,12] Several conclusions can be drawn from these observations: 1) the driving force of rearrangement is formation of a much more stable shell of the ion (radical, neutral molecule) rather than a better charge stabilisation on the element atom compared to a C atom; 2) migration of a halogen to an element (metal) will occur in both a radical cation (primarily in the molecular ion) and a cation; 3) the migrating ability of the F atom is higher than that of the other halogens.

It is interesting to note that the size of the transition state for migration of halogens in both a cation and the radical part of a radical cation has no fundamental significance. Thus, on the one hand, a halogen atom "finds" an element atom at any distance between them. For example, the $(CH_3)_2SiX^+$ ion (X = F, Cl, Br, I) in $X-(CH_2)_nOSi(CH_3)_3$ is formed when n = 2–11, although with different intensities for different X at different values of n.[55] The $(CH_3)_2SiX^+$ ion (*m*/*z* 77) is formed in the fragmentation of compounds of virtually any structure:[1,11,14,42,44,56]

$(CH_3)_3SiCF_2CF_2CHF_2$; $(CH_3)_3SiC{\equiv}CCF_3$; $R_FCOOSi(CH_3)_3$, (R_F=CF_3, C_2F_5); $F(CH_2)_nSi(CH_3)_3$; $(CH_3)_3SiC{\equiv}CSF_5$;



m-$(CH_3)_2Si(H)C_6H_4(CF_2)_nC_6H_4Si(H)(CH_3)_2$; $C_6F_5Si(CH_3)_2X$, (X = CH_3, OR, OCOR, NH_2, NHR); $(CH_3)_3SiN{=}C{=}NCOCF_3$;



Peaks from $FSi^+(CH_3)OCH_3$ ions occur in the mass spectrum of $C_6F_5Si(OCH_3)(CH_3)_2$ [57] while peaks from $[M-SiF_3]^+$ and SiF_3^+ ions are present in the mass spectrum of $(C_6F_5)_3SiH$.[58]

On the other hand, migration of F via a three-membered transition state (1,2-shift) is more favourable than the analogous H

shift, as follows from quantum-chemical calculations[59] for carbon analogues (enthalpy of formation in kcal mol^{-1}):

The evidently favourable nature of a three-membered transition state for an F shift in a cation should be noted, although in our view the values quoted are too optimistic (especially -52.4 kcal mol^{-1}). According to other data[60] the cyclic isomer

is more stable for X = Cl, Br, I and slightly less stable for X = F than its open isomer $XCH_2\dot{C}H_2$.

In the mass spectra of compounds containing both Si and F atoms, peaks from other types of rearranged ions also occur:[1,11,14,42,61]

$CH_3C{=}CH$, $(CF_3C{\equiv}C)_4Si$, $C_6F_5Si(OCH_3)(CH_3)_2$, $(CH_3)_3EC{\equiv}CCF_3$,
$F_2Si{-}SiF_2$ $E = Si, Ge$
$\overset{+}{S}iF_3$ $[M{-}SiF_3]^+$ $F\overset{+}{S}i(O)$ $(CH_3)_2\overset{+}{E}F$; $CH_3\overset{+}{E}F_2$
$(CH_3)_3SiN{=}C{=}NCOCF_3$, $(CF_3)_2NSi(CH_3)_3$, $ArSiF_2Ar'$,
$F\overset{+}{S}i{=}O$ $F_2\overset{+}{S}i$ $[M{-}SiF_2]^+$
$RCH(NHCOCF_3)COOSi(CH_3)_3$, $F_2CHCOOSi(CH_3)_3$
$[M{-}CO_2{-}(CH_3)_3SiF]^+$ $[M{-}CH_3{-}CO]^+$, $(CH_3)_2\overset{+}{S}iF$

Numerous examples of the migration of F (including repeated migration) to atoms of elements and metals containing fluorine groups or ligands are given in two monographs.[1,62] As there has been no slackening of interest in research into these compounds, new studies on their mass spectra continue to appear, as for example those of the chelates of fluorinated diketones ZrR_4 (R = R′COCH$_2$COR″, where R′ = Ar, CH$_3$; R″ = CHF$_2$, CF$_3$, C$_2$F$_5$, C$_3$F$_7$),[63] in which are observed peaks from ions obtained by an F shift to the metal. The migration of other halogen atoms to elements and metals also occurs on electron impact[1,62] (see also above for the Si atom). In addition to the processes common to F-containing compounds, the migration of CH_2Br can occur for Br-containing compounds (because of the lower electronegativity of Br).[12] We should mention those studies in which migration of chlorine to a Si atom was recorded: trimethylsilyl esters of chlorine-containing acids;[1,10] trimethyl- and t-butyldimethyl-silyl ethers of chlorine-containing alcohols;[61] and the loss of $SiCl_2$ in $ArSiCl_2Ar'$ compounds.[61]

III. Negative-ion mass spectrometry

The fragmentation mechanisms of organic compounds in dissociative electron capture (DEC) with the formation of negative ions has been studied in detail in three monographs,[4,66,67] in which considerable attention is given to halogen-containing compounds. An atlas of mass spectra has been published, but unfortunately it is in a deposited version.[68] We shall therefore only examine the general fragmentation mechanisms of anions and radical anions. The large values of the electron affinity (EA) of halogen atoms—3.448 (F), 3.614 (Cl), 3.37 (Br), and 3.059 (I)—give rise to the appearance of intense peaks from X^{-1} ions, and the formation of other stable anions is suppressed:[11]

$$CH_3O^- \leftarrow XCH_2COOCH_3{}^{\dagger\ddagger} \rightarrow X^-$$

X=Cl	0.38% Σ (6.6 eV)†	M—none	Cl^- 99.2% Σ (0.3 eV)
X=Br	3.50% Σ (5.5 eV)	XCH_2COO^-	Br^- 92.4% Σ (0 eV)
X=I	0.0004% (4.0 eV)	Cl 0.18% Σ (1.6 eV)	I^- 84.7% Σ (0.2 eV)
		Br 0.04% Σ (1.5 eV)	
		I 0%	

Of the other halogen-containing ions that give intense peaks, we should mention $(CF_3)_3C^-$, $(CF_3)_2\bar{C}R$, $C_6F_5^-$, CF_3O^-, CF_3S^- [46,67,69] (EA = 4.1, 3.3, and 2.9 eV for $(CF_3)_3\dot{C}$, $(CF_3)_2\dot{C}H$, and $(CF_3)_2\dot{C}F$ respectively):[4,67]

$(CF_3)_2\bar{C}CH_2C_6H_4COOCH_3 \leftarrow$ *m*-$(CF_3)_3CCH_2C_6H_4COCCH_3 \rightarrow (CF_3)_3C^-$
5.7% Σ (3.2 эВ) M$^-$ 90% Σ (0.5 eV)
3.1% Σ (3.1 eV)

$F^-(0.3\%) \leftarrow CF_3SCF_3{}^{\dagger\ddagger} \rightarrow CF_3S^-$ (100%).

However, the high electronegativity values of the radicals and hence the high thermodynamic stability of their corresponding anions do not always determine the fragmentation pathway. Thus, even though the EA for F is similar to the EA of other halogens, the intensities of the peaks due to F^- ions are small in comparison with those of other halogens. For example, the contribution of the F^- ion to the spectrum of XCH_2COOCH_3 is 15% Σ compared to 99.92, and 85% Σ for Cl^-, Br^-, and I^- respectively. Similarly, despite the presence of many F atoms and the many ways of forming F^- in C_2F_5CN and n-C_3F_7CN, the intensity of its peaks at several resonance states is less than 0.5%, whereas the main ion is $^-C{\equiv}N$,[70] although the EA values for F$^\cdot$ and $^\cdot C{\equiv}N$ are similar (3.45 and 3.82 eV respectively).[4] Another phenomenon that is currently still hard to explain is that the intensities of the peaks due to $XC_6H_4COO^-$ ions are unusually small or these ions are not formed at all,[46] despite the high EA (3.4 eV) [4] for $C_6H_5COO^\cdot$ and the evidently even higher EA for $XC_6H_4COO^\cdot$ with electron-withdrawing groups X:

n-$XC_6H_4COOCH_3{}^{\dagger\ddagger}$ (M$^{\pm}$) $\rightarrow$ $XC_6H_4COO^-$ (X = CCl_3, FCH_2, $(CF_3)_3CCH_2$, C_2F_5, $(CF_3)_2CF$)
$\rightarrow$ $XC_6H_4COO^-$
0.22% (CF_3); 0.007% $(CF_3)_3C$.

It is true that in the aliphatic series the intensities of the peaks due to haloalkanecarboxylate ions are high[6] (EA = 4.5 eV for $CF_3COO^\cdot$):[4]

$CF_3COOR^{\dagger\ddagger}$ (M$^{\pm}$) $\rightarrow$ CF_3COO^-, 100%
R = CH_3, $C(CH_3)_3$, iso-C_4H_9, $CH_2CH{=}CH_2$,
$C_2F_5COOR^{\dagger\ddagger}$ (M$^{\pm}$) $\rightarrow$ $C_2F_5COO^-$, 100% ($C(CH_3)_3$); 30% (CH_3)
n-$C_3F_7COOCO_3{}^{\dagger\ddagger}$ (M$^{\pm}$) $\rightarrow$ $C_3F_7COO^-$, 28%

† Here and subsequently the position of the resonance maximum (i.e., the maximum on the ionisation efficiency curve) is given in brackets in eV; the intensity is recorded at this maximum.

We should note that halogen atoms directly situated on an anion site stabilise the latter by the inductive effect and destabilise it by a conjugation mechanism with the result that the intensities of the $C_2F_5^-$, CF_3^-, F_2CH^-, FCH_2^- are low—the EA of their corresponding radicals are 1.92, 1.74, 0.7, and 0.11 eV.[4] Because the polarisability of other halogens is greater than for F, the EA in $\dot{C}H_2X$, $\dot{C}HX_2$, and $\dot{C}X_3$ (X = Cl, Br, I) increases and the peak intensities of their corresponding ions are greater.[1,10] Amongst simple bond cleavage processes we should mention the loss of the ring fragment $CF_2=O$ in the fragmentation of perfluoro-2-propyltetrahydropyran and perfluoro-2-butyltetrahydrofuran.[71]

In contrast to the previously expressed view[66] that rearrangement processes are not very typical of DEC mass spectra, in recent years in studies on negative ions formed from esters of haloalkanecarboxylic and haloalkylbenzoic acids[4,11,12,46] it has been shown that various rearrangement processes frequently predominate in the fragmentation of anions. In these studies there are numerous examples of rearrangements that are both similar to those of positive ions and characteristic only of anions and radical anions. For example, in the mass spectra of $RCOOCH_3$ compounds, instead a peak due to the $RCOO^-$ ion (which is of low or medium intensity) an intense peak due to the $M-HF^{\dagger\cdot-}$ ion appears: 100% [R = FCH_2, C_2F_5, n-C_4F_9, p-$FCH_2C_6H_4$, p-$(CF_3)_2CFC_6H_4$]. The analogous ion $M-RF^{\dagger\cdot-}$ occurs in the fragmentation of CF_3COOR': 3.3% (R' = CH_3), 3.2% [R' = $CH_2CH(CH_3)_2$], 12% [R' = $C(CH_3)_3$], 16% (R' = $CH_2C\equiv CH$), 44% (R' = C_6H_5), 100% [R' = $Si(CH_3)_3$]. In these studies it was established for the first time that there are many hidden rearrangements. For example, in $R_FC(R_F')FCOOCH_3$ compounds there is a peak from the $M-OCH_3^{\dagger-}$ ion, which is attributed to the structure of the stable rearranged ion $R_F\bar{C}(R_F')-CFO$ rather than its unstable isomer $R_FC(R_F')(F)-\bar{C}=\ddot{O}$.[4,11,12]

We should mention the formation of the rearranged ions CF_3^- and $F_2^{\dagger\cdot-}$ in the fragmentation of perfluorocyclobutane,[72] CF_3O^- from perfluoro-2-propyltetrahydropyran and perfluoro-2-butyltetrahydrofuran,[71] and $Cl_2^{\dagger\cdot-}$ from cyclic perchlorocarbons.[73]

Thus, in studying new halogen-containing compounds, the appearance of peaks from rearranged ions involving halogens in their DEC mass spectra is to be expected.

A further important conclusion follows from the studies considered here.[4,11,46] While for the majority of organic compounds containing functional groups or multiple C—C bonds (including aromatic systems) but not containing halogens the presence of a fairly intense peak from the $M-H^{\dagger-}$ ion is typical, which makes it possible to determine the molecular ion of the compound and its empirical formula (from the isotope peaks), there is quite a different pattern for halogen-containing compounds. It is a common occurrence for the $M^{\dagger\cdot-}$ peak to be absent in $RCOOCH_3$ compounds (where R = haloalkyl). However, an unusual feature is the absence of the $M-H^{\dagger-}$ peak (particularly strange if a mobile H is present) when R = FCH_2, ICH_2, $CHCl_2$, CCl_3, C_2F_5, cyclo-C_6F_{11}, CF_3CH_2, CF_3CHF, $(CF_3)_3CCH_2$, $(CF_3)_2CF$, n-C_3F_7, n-C_4F_9, $(CF_3)_3C$, while at the same time it occurs in compounds that are not very different from the above—when R = $ClCH_2$, $BrCH_2$, $(CF_3)_2CH$. In aromatic compounds with acceptor groups, molecular ion peaks usually occur,[4,66] but halogen-containing substituents introduce a modification here also. Thus, the intensity of the $M^{\dagger\cdot-}$ peak in p-$CF_3CF_2CF_2C_6H_4COOCH_3$ is 100% while that in its isomer p-$(CF_3)_2CFC_6H_4COOCH_3$ is 0.03% (i.e., the latter simply cannot be detected, being indistinguishable from a background peak).[46] This example indicates the highly specific nature of DEC mass spectra, which is certainly difficult to predict. There are no $M^{\dagger\cdot-}$ and $M-H^{\dagger-}$ peaks in the mass spectra of $RC_6H_4COOCH_3$ (R = p- and m-$(CF_3)_3CCH_2$), the $M^{\dagger\cdot-}$ peak is weak (0.7%) in the mass spectrum of p-$(CF_3)_3CC_6H_4COOCH_3$ and the $M-H^{\dagger-}$ peak is absent.[46] These facts should be borne in mind when the DEC mass spectra of unknown compounds are analysed.

IV. Chemical ionisation and other ionisation mass spectrometry

In continuing the previous section, let us start our examination of chemical ionisation (CI) spectra with negative ions. Under CI conditions aromatic compounds give intense peaks from $M^{\dagger\cdot-}$ molecular ions when there is a low degree of fragmentation, while peaks due to $M-H^{\dagger-}$ ions occur for compounds that do not have a system of conjugated bonds. Methane is often used as a working gas for CI, but in certain cases mixtures with halogen-containing compounds such as $CH_3OH + CHCl_3$,[74] $CH_4 + CH_2Cl_2$,[75] NF_3, CF_2Cl_2, CF_3Br [76] are used. Under these ionisation conditions studies have been made of the mass spectra and optimum detection conditions for a series of pentafluorophenyl compounds C_6F_5R (R = CH_3, F, OH, OCH_3, NH_2, SH, $OCOCH_3$, CHO, NO_2, CN),[77] pentafluorobenzoyl derivatives of amino acids,[78] chloro- and fluoro-ethylenes,[79,80] pentafluoropropionates of hydroxylamine derivatives,[81] trifluoroacetyl derivatives of polyhydric alcohols,[82] chloroglucuronides,[83] halogen-containing derivatives of dipeptides and their metabolites,[84] and α,β-difluorocinnamic acid derivatives.[85] Chemical ionisation with negative ions achieves high selectivity (for isomers) and very high sensitivity for polyhalogen-containing compounds. This is used, for example, for quantitative determinations (after GLC separation) of polychloropolybromo-dibenzo-dioxins and -furans from their $M^{\dagger\cdot-}$ and Br^- ions.[48]

Positive-ion chemical ionisation mass spectra are used to establish the molecular formula of a compound being analysed that does not give an $M^{\dagger+}$ peak in its EI mass spectrum. The $M + H^{\dagger+}$ ion, which is formed in compounds containing groups to which the proton of a π-system can be added (aromatic compounds, alkenes, alkynes), carbonyl-containing groups (ketones, aldehydes, acids and their derivatives), groups with coordinate bonds

$(NO_2, -C\equiv\overset{+}{N}\rightarrow\bar{O}, -S(O)-, -SO_2-, SO_2OR, N_3, -P(O)_2OR)$.

is used for this purpose. Thus, while the $M^{\dagger\cdot-}$ peak is absent during EI, an $M + H^{\dagger+}$ peak occurs in CI of the compounds $CF_3(CF_2)_2CF(CF_3)COOC_2H_5$,[86] $SF_5N(Cl)C_2F_5$ and $SF_5N=CFC_2F_5$,[27] $FO_2S(CF_2)_2O(CF_2)_2R$,[87] $F_5EN=CBr_2$ (E = S, Te),[21] and $CF_3O(CF_2)_2O(CF_2)_2SO_2F$.[88] The mass spectra of RSF_5 (R are fluorinated groups with an $-SO_2$ residue) obtained under CI conditions have been studied by Terjeson et al.[19] In the CI of the compound $C_2H_5(CF_2)_2O(CF_2)_2SO_2F$ the $[M + H]^+$ ion does not appear but the $M-F^{\dagger+}$ ion is recorded instead.[23] In the fragmentation of $(CF_3)_3COH$ and $C_4F_9\overset{\frown}{CF(CF_2)_3O}$, $M + F^{\dagger+}$ ions are recorded together with the formation of $M + H^{\dagger+}$.[28]

The fact that a determination of structural elements under CI conditions (if the compound is unknown) is either not feasible or only insignificant information about the structure is contained in the CI spectra is a disadvantage. The reason for this is that the general fragmentation mechanisms of the so-called pseudomolecular ions, such as $M + H^{\dagger+}$ and even more so for $M + X^{\dagger+}$ (or $M + X^{\dagger-}$), have not yet been established and only empirical rules for the formation of positive ions of the individual yet numerous classes of

organic chemicals generated during CI have been put forward.[89] Moreover, in the protonation of compounds with several "sites" for the possible addition of a proton (or other ion), it is as though a mixture of products is obtained (with an unknown relative content of each of them), each of which fragments by its own pathways. Therefore a structural analysis of halogen-containing compounds can be conducted as before (despite the development of new ionisation methods and techniques) by means of the traditional electron impact. In this respect we should mention other methods and techniques. Thus, detection of negative ions is possible during thermal spray ionisation in liquid chromatograph–mass spectrometers used for the analysis of nonvolatile or thermally unstable compounds such as certain pesticides.[90–92] The formation of anions is controlled by the addition of halogen-containing compounds to the eluent. For example, introduction of only 0.1–1% chloroacetonitrile substantially increases the sensitivity of detection of phenols through the formation of $M + Cl^{-}$ ions.

For an analysis of compounds that are nonvolatile under normal EI conditions, such as organic hydrohalide salts[92] or certain pesticides,[94] desorption from the surface in a strong electric field can be used, including that combined with separation of mixtures on a liquid chromatograph.[95] A widely used method for the analysis of unstable compounds with low volatility is fast atom bombardment, which has been used, in particular, to study fluoroalkylsulphonates,[96] metabolites of 2-chloro-*N*-isopropylacetanilide,[97] iodoxamic acid and its dimethyl ester,[98] halides of certain Group IV elements,[99] and complexes with tetrabutylammonium fluoride.[100] The mass spectra of dihalomethanes[101] have been obtained under conditions of collision-activated positive ions, and the mass spectra of chlorodibenzodioxins[102] have been obtained with negative ions. In the latter study[102] both low-energy and high-energy processes during collision with oxygen have been investigated.

The mass spectra of halomethanes,[103] 1,1-difluoroethane,[104] 1,1-dichlorodifluoroethylene,[105] fluoroethylenes,[106] and 5-fluorouracil derivatives[107] have been obtained under photoionisation conditions and interpreted. Photoionisation mass spectrometry is mainly used to obtain thermochemical characteristics of the molecules (including halogen derivatives), ionisation potentials (IP), and, what is particularly valuable, the appearance potentials (AP) of the fragment ions. The enthalpies of formation of halogen-containing ions, radicals (carbenes), and neutral molecules are calculated from the AP. In recent years various reactions involving the transfer of particles, principally H^{+} as well as CH_3^{+}, Cl, and others, have been studied in the gas phase by high-pressure mass spectrometry[108] and ion cyclotron resonance.[109] Together with photoionisation mass spectrometry, these are valuable methods for a determination of the enthalpies of formation of ions, radicals, carbenes, and neutral molecules. Without a knowledge of the latter it is impossible to represent thermochemically the ionisation, isomerisation, and fragmentation processes of halogen-containing compounds on electron impact, under chemical ionisation conditions, etc. Without them a rational interpretation of the mass spectrum and representation of the decomposition pathways and mechanisms are made difficult. By having a knowledge of the thermochemical values, it is possible to predict the direction of isomerisation and fragmentation of molecular and fragment ions. We shall give a brief summary of the sources of information on the thermochemical properties of halogen-containing compounds and their fragments. Enthalpy of formation values of halogen-containing molecules appear in two reference books,[110,111] a review,[112] and two monographs.[4,113] IP values of molecules containing halogens are included in three reference books,[10,114,115] two reviews,[116,117] and individual publications.[12,118,119] Calculated values of the IP, EA, and enthalpies of formation of all the isomeric compounds ranging from tetra- to octa-chlorodibenzo-dioxins and -furans are given by Koester and Hites.[120] Experimental values of the energies of formation (IP_2) of the doubly charged ions of 9 halomethanes and 6 haloethanes that can be obtained not only in a mass spectrometer but also above the earth's ozone layer were derived in two studies.[121,122] In the monograph by Takhistov[4] information is given on the enthalpies of formation of halogen-containing ions and the electron affinity values for 24 halogen-containing radicals. In several studies data are given on the enthalpies of formation of halogen-containing ions—haloacyl ions,[123] 20 novel fluorine-containing ions,[124] trifluoroallyl ions,[125] trifluorobenzenium ions.[126] The proton affinity (PA) values for many halogen-containing molecules and the heats of formation of $M + H^{+}$ ions calculated from the PA values are given by Lias et al.[127] Correlations between the PA of molecules and their adiabatic IP have been derived,[119] which makes it possible to obtain values for the enthalpies of formation of $M + H^{+}$ ions from the IP of halogen-containing molecules. The acidity values of halogen-containing molecules, from which in combination with the heats of formation of the corresponding radicals (see below) it is possible to calculate the heats of formation of anions, are given in several studies.[128–134] The electron affinity values of halogen-containing molecules which are needed to calculate the enthalpies of formation of radical anions are given in two studies.[131,135] We should mention the study of Lias et al.,[136] in which the reaction

$$HCXY + B: \rightarrow :CXY + BH,$$

where B is a base, X and Y = F and Cl, has been investigated; and the study of Mishima et al.,[137] in which Cl^{-} transfer was used to determine the enthalpy of formation of $XC_6H_4\dot{C}H_2$. In two further studies by Mishima et al.[138,139] the proton affinity values of 10 halogen-containing (F, Cl, CF_3) styrenes and α-methylstyrenes respectively have been obtained. In a study by McMahon et al.[140] the values of affinity towards CH_3^{+} have been obtained for a number of halogen-containing molecules.

The enthalpy of formation values of halogen-containing free radicals (formed as pairs with cations and anions in the mass spectrometer) are given in five studies.[4,141–144] In three publications[4,141,142] the energy values for homolytic bond cleavage are given, from which additional information about the enthalpies of formation of free radicals may be obtained. Takhistov[4] provides information about the enthalpies of formation of all the halogen-containing carbenes (:CXY and :CHX) as well as small molecules and radicals that are expressly of interest for mass spectrometry.

V. Analytical aspects of the mass spectrometry of halogen-containing compounds

The prevalence of halogen-containing compounds is steadily increasing. Halogen-containing compounds (freons, pesticides, polyhalobiphenyls, polyhalodibenzodioxins, polyhalodibenzofurans) head the list of those compounds whose contaminating effect has already assumed a global (worldwide) character. Of the 230 volatile organic compounds detected in the atmosphere above a large forest, 18 were halogen-containing compounds.[145] They are found in virtually any living organism in any corner of the earth. Hence there is an urgent need to identify or establish the structure of novel compounds containing halogens. It is therefore useful to summarise

the literature of recent years in which mass spectra are examined (we shall not deal with questions concerning the determination of aromatic chlorine-containing compounds by mass spectrometric methods which were considered in detail in two reviews).[148,149]

For benzene compounds, mass spectra have been obtained for benzenes polysubstituted by Br, CF_3, $CF=CCl_2$,[150] halogen-substituted stilbenes,[151] aromatic sulphones with $-CHF$ and $-CF_2-$ chain residues,[152] benzenes with CF_3CH_2X, O, or NR groups,[153] 10 phenyl-containing β−F-amines,[154] tris(*p*-chlorophenyl)methanol found in biological products,[155] novel natural hexasubstituted dichlorobenzenes,[156] S- and Cl-containing products from the bioconversion of hexachlorobenzene,[157] metabolites of chloropropham (3-chloroaniline and 3,3′-dichloroazobenzene),[158] 86 methyl polychlorobiphenyl sulphones,[159] *p*-methylthioperchlorostyrene (a product of the mussel metabolism of perchlorostyrene),[160] novel chlorine-containing aromatic compounds (anilines, benzonitriles, benzophenones, fluoroenones, xanthen-9-ones) detected during the combustion of domestic waste products,[161] methyl polychlorophenyl sulphones (products of the metabolism of polychloro- and polychloronitro-benzenes by garden plants),[162] polychlorocumenes,[163,164] α-methylstyrenes,[163] the ethylesters of isomeric chlorophenylpropionates and chlorophenylbutyrates,[165] and fluorobromobenzocyclanones.[166]

For heterocyclic compounds mention should be made of mass spectrometric studies on 2-R-substituted furans, thiophenes, pyrroles, and also benzenes [R = $-(CF_2)_nCl$, *n* = 4,6,8],[167] and furans and thiophenes containing CF_3 and $CF=CCl_2$ groups,[45] 2,5-difluoro-2,5-bis(trifluoromethyl)-2,5-dihydro-furan and -thiophene,[45] 3-chloro-4-dichloromethyl-6-hydroxy-2(5*H*)-furan and 2-chloro-3-dichloro-methyl-4-keto-butene-2-oic acid obtained in the chlorination of natural and waste water,[168] 18 mixed chloro- and bromo-dibenzodioxins and 18 mixed chloro- and bromo-dibenzofurans,[50] 3-methoxy-2,6-dichlorodibenzodioxin (a methylated product of the metabolism of 2,5-dichlorodibenzodioxin by goldfish),[169] bromosubstituted nitropyridines and their oxides,[170] imidazoles with RC_6F_4 groups,[171] quinoxalines with $(CH_3)_2CF$ and $C_2H_5(CH_3)C(F)$ groups,[172] F- and CF_3-containing *spiro*-3-indolines,[173] perfluoroalkyl-sorbitan, -isosorbide, and -isomannide (EI and CI mass spectra),[174] products of the electrochemical fluorination of *N*-cycloalkylpyrrolidines and *N*-cycloalkylpiperidines,[175] perfluorobicyclic amines and amino acids,[176] and 1,2-diazacyclopentadienes with isomeric fluorobutyl groups.[177] In a review[178] on the synthesis of heterocyclic compounds with F and CF_3 groups on the ring, references to their MS studies may also be found.

The mass spectra of aliphatic compounds have been studied in the case of β-ketoesters with perfluoroalkyl groups and F atoms at the 3-position,[179,180] 3-substituted ethyl trifluoromethylacetoacetates,[181] their derivatives and also ketones $CF_3COCH(R)(R')$,[181,182] amines with a CF_3CH_2 group and their Cl and Br derivatives,[183] ω-chloroperfluoroacyl(amino)ethylenes,[184] polynitrogen-containing compounds with an F_2NCF_2 group,[20] telomers of chlorofluoropropionitrile fluorides with hexafluoropropylene oxide,[185] the perfluoroacrylate of 1-adamantol,[186] pentamethyl-5-X-cyclopentadienes (X = Cl, Br, I),[187] and halogen-substituted thioesters.[188]

Two reference books[9,14] remain important as sources of information on the mass spectra of halogen-containing compounds.

In conclusion we shall examine certain aspects of the application of the mass spectrometry of halogen-containing compounds. The majority of high-resolution instruments are equipped with computers that are used to calculate the empirical formulae of the ions. In our view, some of the data obtained in this manner must be treated with caution, since errors are possible. Thus, in analysing the results of Hudlicky and Glass[189] we noticed that the computer set to record F-containing ions in the analysis of the compound cyclo-$C_6F_{11}CF_2COOCH_3$ yielded the formula $C_8F_{13}^+$ for the $M-47]^+$ ion with loss of an impossible CH_3OO fragment instead of $M-F-CO]^+$ (the latter is typical of F- and CO-containing compounds) or $C_8H_3F_{12}O^+$ (the authors did not detect this error). In the mass spectra of diketones with a CF_3 group, such as $XC_6H_4COCH_2COCF_3$, $CH_3COCH_2COCF_3$, and $R_FCOCH_2COCF_3$, an intense peak from an ion with *m*/*z* 69 appears, to which both a computer and operator (after manual determination of the exact value of the mass ion) with a good resolution of 10−12 000 would undoubtedly assign the formula CF_3^+. In fact, however, this is an ion with empirical formula $C_3HO_2^+$, and a better resolution (about 15−18 000) is required to distinguish it from CF_3^+, while the CF_3 fragment is eliminated in the primary process:[12]

$$\underset{M^+}{XC_6H_4C(OH)=CHCOCF_3]^+} \longrightarrow \underset{[M-CF_3]^+}{XC_6H_4C(OH)=CHC\equiv\overset{+}{O}} \longrightarrow O=C=CHC\equiv\overset{+}{O}$$

$$69^+ : [M-CF_3-XC_6H_5]\,.$$

Hence there is an obvious need for more careful treatment of the data supplied by a computer.

Some aspects of the analysis of halogen-containing compounds have been considered above. It may be noted in addition that halogens have proved to be elements that can be successfully determined using the empirical formula of compounds and it is possible to establish exactly which halogen occurs in the molecule. The presence of Cl and Br atoms in any quantity and combination is readily established from their characteristic isotope patterns.[4] Since there are several or many F atoms in the majority of F-containing compounds (fluorinated chain, R_F, SF_5, and C_6F_5 groups, several CF_3, NF_2, OCF_3, SCF_3 groups, etc.), the presence of fluorine, which is monoisotopic, can be assessed from the weak intensity of the isotopic (from ^{13}C) peak of the ion next to any peak at large masses. Taking into account its high atomic weight (127), iodine also gives a similar reduced peak. In the literature there are examples of the difficulties and occasionally the impossibility of distinguishing the isomers of fluorinated compounds obtained in a single process (in electrochemical fluorination, for example). Thus, the isomers cyclo-$C_6F_{11}CF_2COOCH_3$ and cyclo-$C_5F_9CF_2CF_2COOCH_3$ or cyclo-$C_5F_9-C_4F_9$ and cyclo-$C_6F_{11}-C_3F_7$ cannot be distinguished in the EI mass spectrum.[189] At the same time it is possible to distinguish positional isomers and the geometric isomers $ClCH=C(Br)COOCH_3$ and $BrCH=C(Cl)COOCH_3$.[24] The isomers *p*-$CF_3CF_2CF_2C_6H_4COOCH_3$ and *p*-$(CF_3)_2CFC_6H_4COOCH_3$ were readily distinguished in DEC mass spectra (in contrast to the EI mass spectra).[46]

Halogens can be used to analyse other compounds. Thus, a fluorine or chlorine "label" in the form of an XC_6H_4 or $X_2C_6H_3$ (3,5-$Cl_2-C_6H_3-$) group is used for a number of aryl (usually phenyl) groups at different positions, since the direction of fragmentation when C_6H_5 is replaced by these groups does not alter and these halogens do not introduce any new pathways for the decomposition of molecular and primary (secondary) ions (their effect only becomes evident at the advanced stages of fragmentation). The $Si(CH_3)_2CH_2Cl$ group is used in mass spectrometry to "protect" hydroxyl-containing groups; it is more successful than the traditional group—$Si(CH_3)_3$. Although the M^+ peak does not appear in the modified compound, as in the initial

HO-containing compound, the $M-CH_2Cl^+$ ion has the highest mass (and is considerably more intense than the $M-CH_3^+$ ion in $(CH_3)_3Si$ derivatives).[4] This group can also be of help in distinguishing stereoisomers.

The groups CF_3CO, C_2F_5CO, and C_3F_7CO serve as valuable protecting groups in complex molecules of biological origin. By replacing hydroxyl groups with them, it is possible to increase substantially the molecular weight of the compound being analysed and to shift the peaks of the characteristic mass ions to higher mass, having thus eliminated the effect of impurities, the solvent, metabolites, if the analysis is conducted from a biological fluid (blood, urine, plasma). Although M^+ naturally does not appear in such systems, the characteristic series $M-R_FCOOH^{+\cdot}$, such as $M-CF_3COOH^{+\cdot}$ (or $M-114^{+\cdot}$), $M-2CF_3COOH^{+\cdot}$ (or $M-228^{+\cdot}$), etc., can be detected.

A review of the methods for introducing the CF_3CO group, including those using the convenient novel reagent 2-trifluoroacetoxypyridine, is presented by Koemi et al.[190] The mass spectra of C_3F_7CO-substituted amines have been reported by Mikaya et al.[191]

Mass spectrometry is a versatile method for detecting an element in a sample even when any other element is present in the latter, owing to the unique nature of the isotopic composition of each of them. The problem is merely that of obtaining volatile forms of the elements. A versatile, synthetically accessible class of organometallic compounds that is suitable for analysis using mass spectrometric methods is made up by complexes of metals with fluorinated ketones, in particular $CF_3COCH_2COCH_3$ and $CF_3COCH_2COC.(CH_3)_3$.[4] Volatile chelates of about 60 elements of the Periodic Table are known, even including those of the "awkward" Group I elements (as double salts with rare earth elements). A series of different halogen-containing diketones and their sulphur-containing analogues are reviewed by Takhistov.[4] Methods of modifying compounds to forms that are convenient for mass spectrometric analysis are described in a monograph by Zaikin and Mikaya,[192] as well as in the above review.[4]

Enolisation of the phosphoryl group

T A Mastryukova, M I Kabachnik
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. **The potential ability of the phosphoryl group to undergo enolisation is demonstrated. The conditions for enolisation of phosphoryl and thiophosphoryl groups are examined. In order to determine the acidifying capacity of groups attached to the α-carbon atom, constants that depend on the number of substituents on this atom have been used. The limiting values of the totals of the constants that are responsible for enolisation of the phosphoryl group have been calculated. It is shown that enolisation of the phosphoryl group obeys the laws comprising the theory of prototropic tautomeric acid–base equilibrium.**

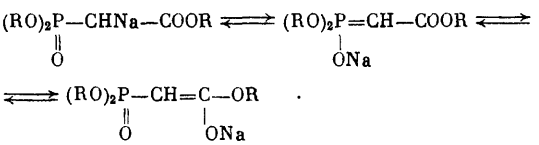
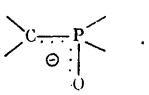
I. Introduction



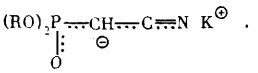
The ability of the carbonyl group to undergo enolisation is well known. It manifests itself most clearly in β-dicarbonyl compounds and in other cases where another electronegative group is situated at the β-position relative to the carbonyl group

(I)



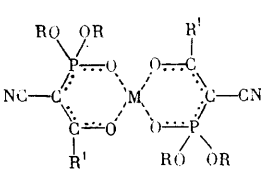
where Y and Z = COR, COOR, CN, SO_2R, etc., while Y can be H, Alk, or Ar. It is also known that simple ketones are only slightly enolised. It was established some time ago that a strong acidifying effect is needed from substituents Y and Z for enolisation to occur. This question was examined at one time by Arndt[1–4] and also Schwarzenbach et al.[5–7] in a series of studies on enolisation and acidity.

In the chemistry of organophosphorus compounds the phosphoryl group P=O is the analogue of the carbonyl group C=O. However, until the end of the 1970s not a single case of enolisation of the phosphoryl group was recorded in the literature. It may merely be mentioned that A E Arbuzov and A I Razumov in 1929 and 1934 proposed that the sodium derivative of phosphonoacetic ester undergoes tautomerism:[8,9]



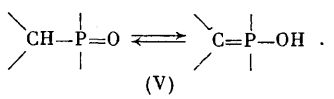
If it is borne in mind that at that time the concept of mesomeric ambident anions had not been widely developed, this report may be regarded as the first suggestion that the phosphoryl group can enolise. It was, of course, purely speculative in nature.

Subsequently lithium derivatives of di- and tri-phosphoryl-methanes were used more than once in organic synthesis.[10–13] In these Li derivatives the negative charge of the anion of the phosphorylated CH acid is undoubtedly delocalised on to the oxygen atoms of the phosphoryl groups in (II):



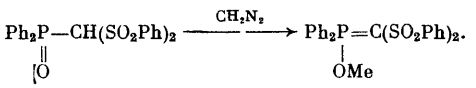
(II)

The same can be said of the metal-containing intermediates of the widely used Horner olefination that is activated by P=O.[14–16] Many examples of the alkylation and acylation of metal derivatives of β-ketophosphonates and other compounds have been reported.[7–29] However, in these cases the authors were dealing with conventional metal enolates on the carbonyl group. Nevertheless, the structure of these metal derivatives has not been studied in detail. In the studies of Kirilov and Petrov[20,22] the potassium derivative of phosphorylacetonitrile was thought to contain the ambident anion (III), whose charge is concentrated to a considerable degree on the phosphoryl oxygen atom:



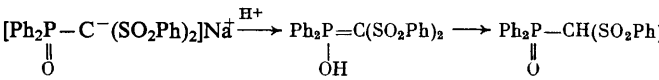
(III)

Finally, mention should be made of the crystalline magnesium and copper complexes of acylated phosphorylacetonitriles whose structure is described by Petrov and Kirilov.[30] These are *cis*-chelates with a P–O–M (IV) bond



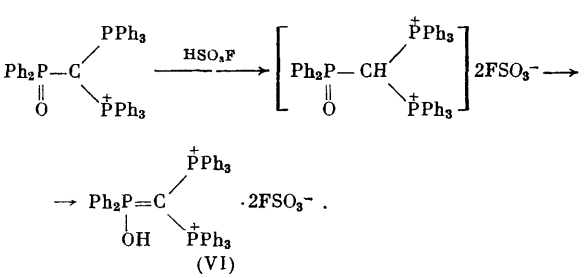
(IV)

Thus, in anions of phosphorylated CH acids the oxygen atoms of the phosphoryl group can carry, if only partially, the anion charge with a corresponding reduction in multiplicity of the P=O bond and in certain cases can form a bond with a metal cation. However, there has been no single recorded case of the tautomerism of phosphoryl and phosphaenol structures (V):



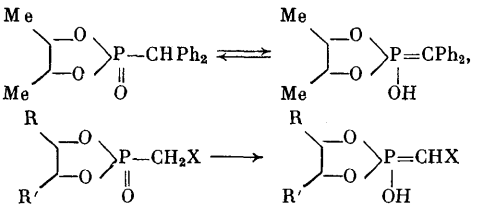
(V)

The enolisation of β-phosphorylated carbonyl compounds has been studied in great detail, but in all cases only the normal enol forms ($=\overset{|}{C}-OH$) rather than phosphaenol forms ($=\overset{|}{P}-OH$) have been observed.[20,22,26–28,31–38] The same occurs for thiophosphoryl compounds.[39] The above does not apply, of course, to the ambident reactivity of phosphoryl compounds, or more accurately their carbanions, towards electrophilic reagents. An example is the reactivity towards methylation of phosphoryl oxygen atom on treatment of diphenylphosphinylbis(phenylsulphonyl)methane with diazomethane:[40]



But this is a methylation reaction, rather than the addition of a proton which is needed to produce the phosphaenol form.

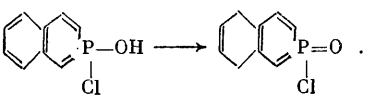
The first reports on enolisation of the phosphoryl group appeared in the latter half of the 1970s. Kolodyazhnyi[41] reported the formation of the unstable phosphaenol form of diphenylphosphinylbis(phenylsulphonyl)methane on acidification of a solution of its sodium derivative:



This phosphaenol form is rapidly and irreversibly converted to the CH form.

Mastryukova et al.[42] observed the formation of the stable phosphaenol form of diphenylphosphinylbis(triphenylphosphonio)-methane (VI) on protonation of the corresponding phosphorane-phosphonium salt with fluorosulphonic acid:

(VI)



There are two reports by Ovchinnikov et al.[43,44] on the phosphaenolisation of cyclic phosphates:

R=Me, R′=H, Me; X=COOMe, CN.

However, the phosphaenol structure of these compounds was later disputed.[45]

Finally, in 1979 Bickelbaupt et al.[46] synthesised the cyclic phosphaenol (VII), which readily and irreversibly "ketonised":

(VII)

With regard to enolisation of the thiophosphoryl group, the only example of this type (VIII) was found by Mastryukova et al.[47] It fully resembles the enolisation of the corresponding phosphoryl compound:

(VIII)

Thus, up to the beginning of the 1980s there were only isolated reports concerning phosphaenol forms in the literature and information about phosphoryl–phosphaenol (phosphoryl–hydroxy-ylide) tautomerism was absent altogether.

II. Possible enolisation of the phosphoryl group

It has been established that the position of a prototropic tautomeric equilibrium is determined by the ratio of the acidity constants of the forms in the given medium:

$$K_T = K_1/K_2. \qquad (1)$$

Here K_T is the tautomeric equilibrium constant, and K_1 and K_2 are the acidity constants of the tautomeric forms.[48] On enolisation of carbonyl groups, enol OH acids are formed, which, depending on their structure and stereochemical configuration, have an acidity that varies over a wide range—from pK_a = 10–12 for simple ketones and the least acidic β-dicarbonyl compounds to pK_a = 5–9 for normal β-dicarbonyl compounds† (data for aqueous solution).[49] Therefore, in order for enolisation to occur, it is necessary that the CH acidity of the ketone forms are similar to that of enols, i.e., pK_a = 5–10 (in water). In the case of enolisation of phosphoryl groups, the OH acidity of phosphaenols is substantially higher than

† Only when there are certain structural features of a β-dicarbonyl compound (fluorinated β-diketones, *trans*-configured cyclic enols with small rings, etc.) is an OH acidity with pK_a = 2–4 attained.[50]

that for their carbon analogues. Unfortunately, there are no comparative data for aqueous solutions. However, the acidity in water of other OH acids of phosphorus, and carbon (phosphoric and carbonic acid, methylphosphonic and acetic acids, etc.) can be compared. In this case there is very convincing evidence that phosphorus OH acids are stronger by a factor of 10^2-10^4. Therefore, for enolisation of the phosphoryl group to occur, phosphoryl CH acids must have $pK_a = 3-5$. This can only be achieved when there are strongly acidifying electron-withdrawing groups, stronger than in the chemistry of β-dicarbonyl compounds, at the β-position relative to the phosphoryl group.

Because of the need to make an objective determination of the acidifying effect of groups on CH acidity, we have developed a method of σρ correlation analysis of CH acidity based on the familiar Hammett equation:[51] $pK = pK^0 - \rho\sigma$. It was natural to use σ^- constants, which take into account directly polar conjugation of the substituent with the nucleophilic reaction site. However, difficulties related to the existence of the so-called "saturation effect" arose.[52] This means that the effect of an acidifying group attached to the central carbon atom is variable. It depends on the number of those groups that are already attached and decreases as these groups accumulate. This circumstance required the calculation of three σ^- values for each substituent — $\sigma_{CH_3}^-$, $\sigma_{CH_2}^-$, and σ_{CH}^- — depending on whether the substituent is located on a primary, secondary, or tertiary carbon atom. In developing this method of σρ correlation, the values of the $\sigma_{CH_n}^-$ constants were refined from the large quantity of experimental data in the literature on the CH acidity of different compounds and also from our own data on the CH acidity of organophosphorus compounds. Some of the derived values of the $\sigma_{CH_2}^-$ and σ_{CH}^- constants are given in Tables 1 and 2.[53-55] When these constants were used, good and excellent correlations between the pK of a large number of CH acids and the $\sigma_{CH_n}^-$ constants were obtained in different media and under different experimental conditions.

Table 1. $\sigma_{CH_2}^-$ and σ_{CH}^- constants for certain groups X.[53,54]

X	$\sigma_{CH_2}^-$	σ_{CH}^-	X	$\sigma_{CH_2}^-$	σ_{CH}^-
Me	0.12	0.13	$PhSO_2$	0.77	0.71

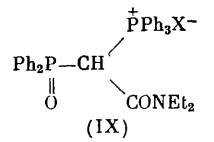
CN	0.80	0.75	$CONEt_2$	0.58 *	0.42

* See study of Matveeva et al.[54]



By using the new $\sigma_{CH_n}^-$ constants it proved possible to correlate the CH acidity of β-dicarbonyl compounds with their enolising capacity. Thus, for the completely enolised triacetylmethane, $\Sigma\sigma_{CH}^- = 1.98$; for the strongly enolised benzoylacetone, $\Sigma\sigma_{CH_2}^- = 1.86$; for the slightly less enolising acetylacetone, $\Sigma\sigma_{CH_2}^- = 1.76$; for the weakly enolising acetoacetic ester, $\Sigma\sigma_{CH_2}^- = 1.60$; and for malonic ester, which has a very low tendency to undergo enolisation, $\Sigma\sigma_{CH_2}^- = 1.44$. Thus, a range of values of $\Sigma\sigma_{CH_n}^-$ approximately from 1.6 to 2.0 in β-dicarbonyl compounds governs the strength of CH acidity that assists enolisation. It is of course necessary to take into account the OH acidity of the enol forms [cf. Eqn. (1)]. The acidifying effect of the substituents influences the OH acidity of enols, although to a lesser extent, but to a first approximation we can confine ourselves to the treatment of $\Sigma\sigma_{CH_n}^-$.

Table 2. $\sigma_{CH_2}^-$ and σ_{CH}^- constants for certain phosphorus groups X.[55]

X	$\sigma_{CH_2}^-$	σ_{CH}^-	X	$\sigma_{CH_2}^-$	σ_{CH}^-
$Ph_3\overset{+}{P}$	1.22	1.08	$Ph_2P(O)$	0.57	0.44

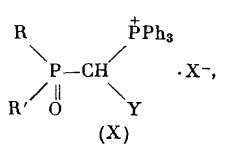
* Figures in brackets are values obtained by interpolation.

The OH acidity of phosphaenol forms is higher than in β-dicarbonyl compounds. Therefore, their CH acidity must also be substantially higher. We recently discovered that compound (IX) with $\Sigma\sigma_{CH}^- = 1.94$ does not enolise under any conditions,[56] whereas it was found previously that the corresponding diphosphonium derivative (VI) with $\Sigma\sigma_{CH}^- = 2.60$ is completely enolised.[42] Consequently, a value of $\Sigma\sigma_{CH}^-$ ranging from 2.0 to 2.6 is most favourable for enolisation of the phosphoryl group and phosphoryl–hydroxyl-ylide tautomerism:



(IX)

Since it is difficult to achieve such high values of $\Sigma\sigma_{CH_n}^-$ without the use of phosphonium substituents, studies were subsequently made on compounds in which a triphenylphosphonium group was located on the central carbon atom together with the phosphoryl group. In this case by varying substituent Y it was possible to obtained cases of $\Sigma\sigma_{CH_n}^-$ ranging from 2.0 to 2.6.

III. Synthesis of phosphoryl compounds

Phosphoryl(triphenylphosphonio)methanes substitueed on the central carbon atom with the general formula (X)

(X)

where Y = $^{+}PPh_3X^{-}$, CN, Ts, COOEt, $CONEt_2$; R and R′ = Et, Bu, Ph, EtO, BuO, PhO in different combinations: X = Cl^{-}, Br^{-}, ClO_4^{-}, BF_4^{-} were synthesised.[57–60] The starting materials used were the respective phosphine-substituted phosphoranes (XII) obtained in accordance with literature data[61,62] from the corresponding monosubstituted triphenylmethylenephosphoranes (XI) and halophosphines or halophosphites in the presence of triethylamine:

$$Ph_3P{=}CHY + RR'PX \xrightarrow{Et_3N} RR'P{-}C(PPh_3)(Y)$$

(XI) (XII)

The phosphinophosphoranes (XII) were then oxidised to the phosphorylphosphoranes (XIII) on treatment with $KMnO_4$ in acetone or H_2O_2 in t-butanol:

$$(XII) \xrightarrow{KMnO_4 \text{ or } H_2O_2} R'P(O)(R)-C(PPh_3)(Y)$$

(XIII)

In many cases, instead of starting from monosubstituted triphenylmethylenephosphoranes (XI), it proved more advantageous to use the corresponding phosphonium salts (XIV), i.e., to treat them with dialkyl- or diaryl-halophosphines (RR′PX) or phosphorohalidites [$(RO)_2PX$] and triethylamine in a solution of dichloromethane under mild conditions (atmosphere of argon, temperature 0–20 °C):

$$\underset{(XIV)}{Ph_3P{-}CH_2{-}Y} + RR'PX + 2Et_3N \rightarrow (XII) + 2Et_3N{\cdot}HX.$$

It subsequently proved possible to carry out the oxidation stage of (XII) → (XIII) without isolation of (XII) from the reaction mixture but to treat it directly with H_2O_2 in t-butanol at 0 °C.

Phosphoranephosphonium salts (XIII), where Y = $^{+}PPh_3X^{-}$, were obtained by addition of diphenyl- or dialkyl-halophosphines to hexaphenylcarbodiphosphorane (XV) with isolation of the intermediate crystalline phosphino derivative (XII), Y = $^{+}PPh_3Cl^{-}$:

$$\underset{(XV)}{Ph_3P{=}C{=}PPh_3} + R_2PCl \longrightarrow (XII) \xrightarrow{KMnO_4} (XIII) .$$

Oxidation of (XII) to (XIII), Y = $^{+}PPh_3Cl^{-}$, was carried out with $KMnO_4$ in acetonitrile. Protonation of phosphoranes (XIII) was carried out in benzene or dichloromethane at 20 °C by treatment with an ethereal solution of halogen halides:

$$(XIII) \xrightarrow{HX} (X) .$$

Crystalline phosphonium salts (X) were generally obtained; their melting points are given below in Table 3.

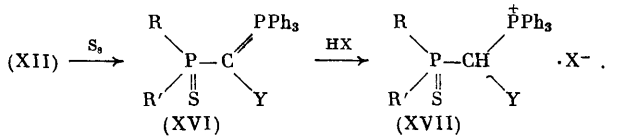


Table 3. Melting points and IR spectra of phosphorylphosphonium salts in the crystalline state.[57–60,65]

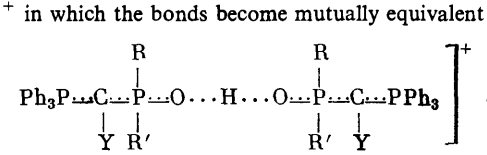
The thiophosphoryl derivatives (XVI) were obtained by addition of sulphur to phosphinophosphoranes (XII) in benzene, acetonitrile, or mixtures of them in the cold for 6–24 h or by boiling for 10–15 min.[63,64]

(XII) (XVI) (XVII)

IV. Phosphaenols (hydroxyl-ylides) in the crystalline state



The crystalline phosphorylphosphonium salts that were studied are listed in Table 3. They are stable compounds that can be recrystallised in air without any special precautions. The conclusion about their phosphoryl CH structure (A) or phosphaenol structure (B) is based on an examination of their IR spectra, and in a number of cases X-ray diffraction analysis was used:

(A) (B)

The IR spectra of the compounds with structure (A) contain a very characteristic band due to P=O in the region 1150–1195 cm^{-1} when alkyl or aryl groups are attached to phosphorus and at 1270–1290 cm^{-1} when RO groups are attached. When structure (B) is formed this band disappears and in its place a band appears at 910–975 cm^{-1} that is typical of the protonated P=O group.[66] At the same time very broad absorption bands appear in these spectra at 1500–3000 cm^{-1} which suggest that OH groups with strong hydrogen bonds OH...X^- are present. As far as the vibrations of groups Y are concerned, these groups are attached to an sp^3-hybridised carbon atom in structures (A) and to an sp^2-hybridised carbon atom in structures (B). As a consequence the frequencies in the first case are higher. Thus, the CO vibration of the carbethoxy group for structure (A) is 1730–1740 cm^{-1} while for structure (B) it occurs at 1660 cm^{-1}. The symmetric SO_2 vibrations in structure (A) are at 1150–1165 cm^{-1} while in structure (B) they occur at 1125–1140 cm^{-1}, the antisymmetric vibrations occur at 1330–1340 cm^{-1} (A) and 1280–1290 cm^{-1} (B) respectively. All of these changes are very uniform, which provides sufficient reliability in the assignment of structures to (A) and (B).

In addition to structures of the type (B) with an OH...X^- hydrogen bond, "dimeric" structures in which the conjugate base acts as an H-bond acceptor were detected. A complex of the type BHB^+ in which the bonds become mutually equivalent is formed:

The IR spectra of the BHB^+ structures are characterised by the absence of bands due to P=O and P–OH and the presence of a broad complex band at 600–1800 cm^{-1}. In this case the vibrations of Y conform to structure (B). Such "dimeric" complexes have been confirmed by X-ray diffraction data.

It should be noted that the X-ray diffraction data very clearly characterise both the phosphaenol forms and BHB^+ structures. Thus, in the structure of the tosyl derivative with form (B) (No. 12, Table 3) (Fig. 1), the central carbon atom [C(1)] has only a slightly distorted planar trigonal coordination with a projection of 0.118 Å from the P(1)P(2)S plane. The C(1)–PPh_2OH and C(1)–PPh_3 have virtually the same length—1.751(4) and 1.764(4) Å—and a multiplicity of one and a half.[67] The phosphaenol form is stabilised in the crystalline state by an OH–Br hydrogen bond of length 3.078 Å.

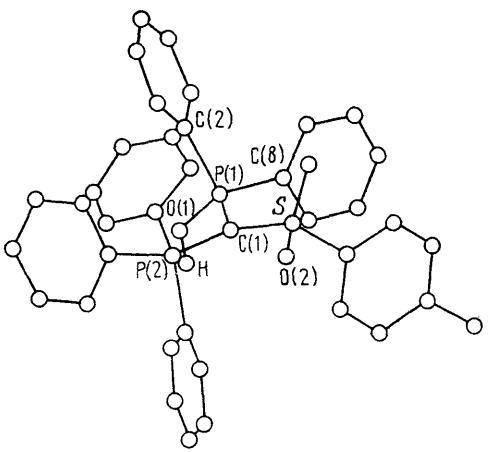


Figure 1. Crystalline structure of the cation component of the bromide salt of (hydroxydiphenylphosphoranylidene)tosyl(triphenylphosphonio)methane $Ph_3P^+C(Ts)=P(Ph_2)O-H...(Br^-)$.[65]

Stabilisation of the phosphaenol structure can, however, be achieved with the assistance of another protophilic species. Thus, in the case of crystals of (dibutylhydroxyphosphoranylidene)cyano-(triphenylphosphonio)methane perchlorate (No. 8, Table 3), structure (B) is unstable, and on recrystallisation from an acetone–ether mixture when air is admitted, it is stabilised by absorption of a single water molecule to form a salt of the type $(BHB')^+$, where B' is the water molecule. In this novel structure the crystal is composed of two crystallographically independent cations. In each of them (Fig. 2) the central carbon atom C(1) is also planar trigonal, the projections from the plane are 0.072 and 0.054 Å, and the sum of the angles about C(1) is 359.4°. The C(1)–PBu_2OH and C(1)–PPh_3 bonds are virtually the same and on average have a length of 1.745(9) Å, which corresponds to a multiplicity of approximately one and a half. The oxygen atoms of the water molecule O(11) act as acceptors of protons from the P–OH group. The O...H...O distances are equal to 2.501(6) and 2.482(7) Å, which corresponds to hydrogen bonds of increased strength.[68] It is interesting to note that in turn the H_2O molecules also participate through their H atoms in the formation of O–H...N bonds with the cyano groups of the neighbouring cations.

The structure of (diphenylhydroxyphosphoranylidene)carbethoxy (triphenylphosphinio)methane borofluoride (No. 4, Table 3) is shown in Fig. 3 as an example of a symmetric BHB^+ complex. The

structure is centrosymmetric. Its two "halves" are identical and joined by a hydrogen bridge. The central C(1) carbon atom is planar trigonal, the sum of the angles is 359.3° and the lengths of the C(1)—PPh_2OH and C(1)—PPh_3 bonds are virtually the same—1.725(8) and 1.735(8) Å—with a multiplicity of about one and a half. The length of the O...H...O hydrogen bond is 2.422(8) Å. The lengths of all the bonds of the "dimer" are mutually equivalent, which suggests that the cation charge is delocalised over both "halves".

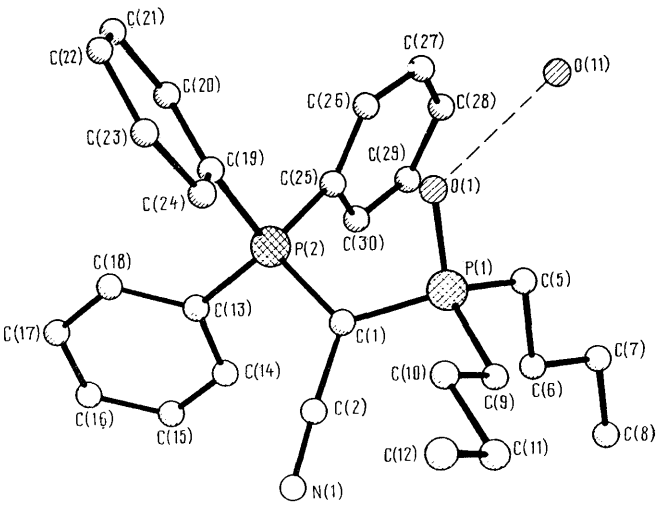

Figure 2. Structure of one of the two crystallographically independent cations of (hydroxydibutylphosphoranylidene)cyano-(triphenylphosphonio)methane perchlorate—a $(BHB')^+$ complex with a molecule of H_2O [the O(11) oxygen atom is shown]; $PH_3P^+C(CN)=(Bu_2)O-H...OH_2(ClO_4^-)$.

It may be concluded from an examination of the data in Table 3 that there are two principal factors that govern the alternative structure. The first is the nature of Y. The phosphaenolising capacity of the Y groups is given by a series that corresponds to the following variation in σ_{CH}^- values:

	$Ph_3\overset{+}{P}$	>CN	>Ts	>COOEt	>$CONEt_2$
σ_{CH}^-	1.08	0.75	0.70	0.60	0.42

The $^+PPh_3$ group has the highest phosphaenolising capacity while $CONEt_2$ has the lowest capacity. The second factor is the nature of the counterion X^-. The OH...X^- hydrogen bond undoubtedly stabilises the phosphaenol. The anions also form the following series of ability to form an H bond: $Cl^- > Br^- > ClO_4^- \approx BF_4^-$. Therefore, with the exception of the compound with a $CONEt_2$ group, all the chlorides and bromides are phosphaenols. The ClO_4^- anion, which has a low tendency to form H bonds, gives rise to the formation of structures (A) or BHB^+ (Table 3). The results can be understood if the combined effect of these two factors is taken into account.

Two phosphonium groups (compound No. 21, Table 3) have such a strong acidifying effect that the proton is not retained on the central carbon atom but is located on the PO group. When Y = CN (bromides Nos. 6 and 7, Table 3), the phosphaenol structure is governed by the fairly strong acidifying effect from the CN group and the stabilising effect from a strong OH...Br hydrogen bond. For the perchlorate this stabilisation is achieved either with a molecule of the conjugate base (No. 9, Table 3) or with a water molecule (No. 8, Table 3)—BHB^+ or $BH-OH_2^+$ complexes are formed. The pattern is quite clear when Y = Ts; the bromides have structure (B) and the perchlorates have structure (A) or BHB^+. As for compounds with the relatively weakly acidifying group Y = COOEt—, although the chloride (No. 1, Table 3) in this case has structure (B), the perchlorates (Nos. 2 and 3, Table 3) have structure (A), and the borofluoride has a BHB^+ structure. Finally, the carbamoyl group (Y = $CONEt_2$, compound No. 5, Table 3) with the weakest effect causes the chloride to have structure (A).

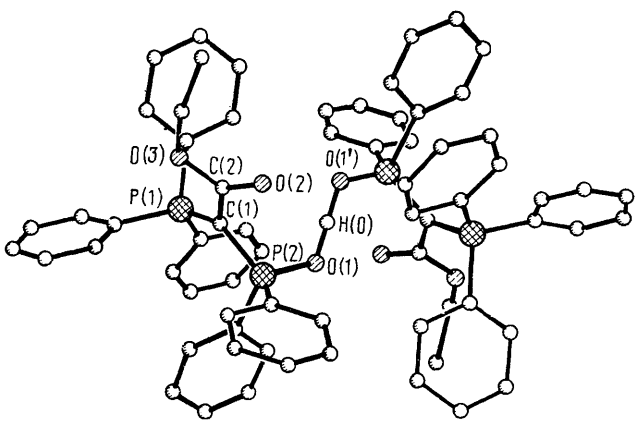

Figure 3. BHB^+ structure of (hydroxydiphenylphosphoranylidene)-carbethoxy(triphenylphosphonio)methane:

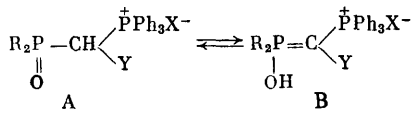

$$Ph_3P^+-C(COOEt)=P(Ph_2)O\cdots H\cdots O=$$
$$=P(Ph_2)P-C(COOEt)=PPh_3(BF_4^-)\ .$$

The relative stability of the phosphaenol forms in the crystalline state naturally depends on the many factors that determine the crystal lattice energy, but it may be assumed that the acidifying effect of groups Y and the strength of the OH...X^- hydrogen bonds are amongst the most important ones.

V. Phosphoryl—phosphaenol tautomerism

Phosphoryl—phosphaenol tautomerism, otherwise known as Phosphoryl—hydroxy-ylide tautomerism, as in (V), is the phosphorus analogue of keto—enol tautomerism, as in (I). Therefore the methods used to study keto—enol systems can be applied to it also.

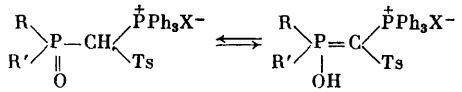
In $MeNO_2$; [2] in CF_3COOH; [3*] two conformers; [4*] in $CHCl_3$.

In the $^{31}P-\{^1H\}$ NMR spectra in solutions of tautomeric phosphonium salts (X) two pairs of doublet signals are generally observed.

(A) (B)

In this case forms (A) display two doublet signals with chemical shifts that are not very different from the initial phosphorylphosphoranes (XIII) but with much smaller spin-spin coupling constants J_{PP} (from 0 to 10 Hz). For forms (B) the chemical shifts of the phosphorus nucleus in the PPh_3 group hardly differ from the above, but the signals due to the nuclei in the P−OH groups are displaced downfield by 20−30 ppm. On the other hand the values of J_{PP} are similar to those of the initial phosphoranes. We should note that the number of signals from forms (B) can double, especially at low temperatures, because of the presence of two conformers in solution or of two diastereoisomers in other cases. On increasing the temperature a number of changes occur in the ^{31}P NMR spectra. There is a redistribution of intensities of the signals due to a change in position of the tautomeric equilibrium and the signals change because of an acceleration of both conformational transitions and proton exchange between the forms. At first the conformational doublets coalesce—a single pair of doublets remains in the spectrum—and these are then converted to broad singlets or even merge into the background noise.[56−60,63−65]



In the PMR spectra, triplet or doublet-doublet signals due to the methine protons of forms (A) with J_{PCH} constants of the order of 13−17 Hz, singlet signals due to the P−OH protons of form (B), and also signals from other groups occur. However, because of rapid proton exchange the signals from CH and OH frequently combine to give a broad singlet. The protons of other groups, such as those from COOEt or $SO_2C_6H_4Me$, on the other hand, appear as separate signals from the tautomeric forms, and they can be used to determine the tautomeric equilibrium constants. However, this is also more suitable to observe at a low temperature.

The tautomeric equilibria are established rapidly and do not change with time. They do not depend on the method of preparing the solution—by dissolving salt (X) or by treatment of phosphorane (XIII) with acid. The results obtained by various methods of studying the tautomeric equilibria are in good agreement. The $^{31}P-\{^1H\}$ NMR data recorded in CH_2Cl_2, the most significant for all of the compounds studied, are given in Table 4 and 5.

It was found that the bis(triphenylphosphonium) salt (X), $Y = {}^+PPh_3$, R and R′ = Ph, exists in solution solely as form (B) (Table 4).[61,62] This applies both to the bromide and perchlorate. Moreover, in trifluoroacetic acid, in which only the (A) forms occur in all other cases, only form (B) occurs in the case of the bis(phosphonium) salt. Evidently because of the strong acidifying capacity of the triphenylphosphonium groups ($\sigma_{CH}^- = 1.08$), the CH acidity of the diphosphonium salt is so high that formation of the CH structure [form (A)] is impossible even in CF_3COOH.

CN-Substituted compounds (X), Y = CN (bromides) with R and R′ = Ph or Bu are in the form of phosphaenols (B), while when R

(98% B); 2 two diastereoisomers; 3* in $CHCl_3$.

and R′ = EtO or PhO (chlorides) at low temperature, they exist as (A). As for perchlorates, both forms occur in solution when R and R′ = Bu, while when R and R′ = Ph a complex of the type BHB^+, in effect form (B), is formed. In contrast to the bis(phosphonium) salt, only for (A) occurs in CF_3COOH.

In the tosyl derivatives (X), Y = Ts (Table 5) when R and R′ = Ph only form (B) occurs in a solution of the bromide and perchlorate. When R = Ph and R′ = ET a tautomeric equilibrium occurs for the perchlorate.‡ There is also a tautomeric equilibrium when R and R′ = Bu (bromide and perchlorate) and when R = Bu and R′ = EtO (X = Br^- and ClO_4^- also), as well as when R and R′ = AlkO (in the bromides). But in solutions of the perchlorates when alkoxy groups are attached to phosphorus, only the (A) forms occur. This also applies, of course, when R and R′ are phenoxy groups.

The carbethoxy derivatives (X), Y = COOEt (Table 4), exhibit a tautomeric equilibrium only when R and R′ = Ph or Bu with X = Cl. In the remaining cases only the (A) forms are present. Finally, if Y = $CONEt_2$, the group that has the lowest acidifying capacity (σ_{CH}^- = 0.42), only form (A) occurs (Table 4). Thus, a decrease in the electron-withdrawing capacity of groups Y leads to a predominance of form (A) and vice versa.

The R and R′ groups attached to phosphorus have a considerable effect on the position of tautomeric equilibrium, as was to be expected. Data on the effect of these groups on the tautomeric equilibrium constants in the series of tosyl derivatives are given in Table 6. These results are correlated with σ^Φ constants, which characterise the effect of the substituents attached to phosphorus on the acidity of phosphorus acids.[69] It can be seen that the content of form (B) increases with a decrease in electronegativity of R and R′. This is quite natural—highly electronegative groups R and R′ increase the strength of P−OH acids, which assists transfer of the proton to carbon.§ A special position is occupied, however, by aromatic derivatives. A phenyl group attached to phosphorus markedly assists phosphaenolisation. The cause of this phenomenon has been discussed more than once in other cases of the "phenyl anomaly". It has been suggested that OH...Ph hydrogen bonds are formed,[70] that there is steric destabilisation of the CH form,[60] that the hydrophoby and rigidity of the benzene rings have an effect, etc. Unfortunately, the origin of this phenomenon is still not clear.

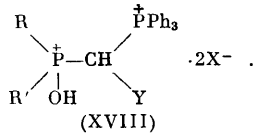
The nature of the anion has a considerable effect on the position of the tautomeric equilibrium (A) ⇄ (B), varying in accordance with its ability to form an H bond that stabilises the phosphaenol: $Cl^- > Br^- < BF_4^- \geqslant ClO_4^-$. The effect of the solvent is also considerable. In aprotic media the percentage content of form (B) decreases with an increase in dielectric constant ε of the solvent.

‡ In this case the signals due to form (A) are split because of diastereomeric anisochronism.

§ This explanation implies that the substituents attached to phosphorus have a greater on effect on the strength of P−OH acids than on P−CH acids, which is very probable.

As an example we can illustrate the effect of solvents on the content of form (B) in $PPh_2(O)CH(\overset{+}{P}Ph_3Cl^-)COOEt$ at −60 °C:

	CH_2Cl_2	CH_2Cl_2+MeCN (4 : 1)	$MeNO_2$
ε	9.14	14.6	38.57
% B	77.0	60.0	<45

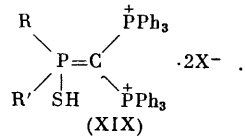


The proton-donating solvent chloroform effectively solvates the P=O group and hence shifts the equilibrium towards from (A). In alcohols, which effectively solvate the OH forms, the equilibrium is shifted towards form (B).

Table 6. Effect of substituents R and R′ on the position of the tautomeric equilibrium A ⇄ B of phosphonium salts (X), Y = Ts, CH_2Cl_2.[58,60,64]

R	R′	$\sum\sigma^{\Phi}$	X=Br⁻ (−80° C)		X=ClO_4 (30° C)	
			% B	K_T	% B	K_T
Bu	Bu	−2.44	75	3.00	29	0.39
Bu	EtO	−1.43	50	1.00	12	0.14
BuO	BuO	−0.82	45	0.82	<2	<0.02
EtO	EtO	−0.42	25	0.33	<2	<0.02
PhO	PhO	−0.12	<2	<0.02	<2	<0.02
Ph	Et	−1.58	95	19.0	60	1.5
Ph	Ph	−1.18	>98	>49	>98	>49

As for the effect of temperature, it depends on the nature of the solvent. In the aprotic solvent CH_2Cl_2 an increase in temperature shifts the equilibrium in favour of the (B) forms, which characterises the (A) forms as more stable. In an alcoholic medium the opposite occurs. The thermodynamic parameters for tautomerism of (X), when Y = COOEt, were calculated from the temperature dependence of the tautomeric equilibrium constants. The tautomers proved to have very similar enthalpies ($\Delta H°$ ranging from −1.5 to +2.5 kcal mol^{-1}). The entropy differences were found to be higher (ΔS ranging from −3.6 to 10.6 E. U.).[59]



The effect of the acidity of the medium on the position of the equilibrium (A) ⇄ (B) is interesting. An increase in acidity of the medium shifts the equilibrium towards form (A). It would appear that protons from the acid compete with the protons of the P−OH group for hydrogen bonding with the anions and thus decrease the stabilising effect of the latter. With a large increase in acid concentration doubly protonated products (XVIII) are formed:

(XVIII)

In the ^{31}P NMR spectra of these acid salts the chemical shifts of the phosphoryl P nucleus occur at lower field. Thus, when Y = COOEt, X = Cl, and R and R′ = Ph, δ_{PO} = 50.1 ppm (as opposed to 28.6 ppm in the monoprotonated (A) form], while when R and R′ = Bu, δ_{PO} = 82.7 ppm [48.8 ppm in the (A) form].

Enethiolisation of the thiophosphoryl group is markedly different from its oxygen analogue.[63] All the phosphonium salts (XVII) have a CH structure in the crystalline state. The salt with two phosphonium groups (XVII), Y = $\overset{+}{P}Ph_3X^-$, cannot be obtained in the crystalline state because of the extremely low basicity of the corresponding phosphorane (XVI), but in solution of CH_2Cl_2 or FSO_3H it has the mercapto-ylide structure (XIX), which is established with certainty from its ^{31}P-{^1H} NMR spectrum:

(XIX)

All of the remaining (XVII) salts, regardless of the nature of Y, R, R′, and X, have a thiophosphoryl structure and do not exist as tautomers. Only in diphosphonium salt does a low value of J_{PP} occur—from 1 to 8 Hz. In all of the remaining salts the value of J_{PP} is in line with that of the thiophosphorylphosphoranes.

Thus, enethiolisation of the thiophosphoryl group only occurs when Y = $\overset{+}{P}Ph_3$. Even the CN group has an insufficient acidifying effect for the enethiol form to occur, and all derivatives with CN and other groups with lower σ_{CH}^- values have the thiosphosphoryl structure (XVII) and do not exist as tautomers. It may be assumed that the region of thiophosphoryl−mercapto-ylide tautomerism must occur when the $\Sigma\sigma_{CH}^-$ values approximately vary from 2.5 to 2.7. Unfortunately, this region remains inaccessible for the time being (cf. Tables 1 and 2).

VI. Enolisation of the phosphoryl group and acidity

It has been known for a long time that the acidic properties of prototropic tautomeric compounds are related in a complex manner to the position of the tautomeric equilibrium. The latter, as is evident from Eqn. (1), is determined by the ratio of the acidity constants but not by the degree of acidity of both forms. Experimentally the given apparent dissociation constant K_{app} of the equilibrium mixture, which is related to the dissociation constants of the individual forms, is determined by ratio (2):[48]

$$K_{app} = K_1.K_2/(K_1 + K_2), \quad (2)$$

where K_1 and K_2 are the dissociation constants of the forms. By measuring the apparent dissociation constant K_{app} and the tautomeric equilibrium constant K_T, it is possible to calculate the dissociation constants of the individual forms:

$$pK_1 = pK_{app} - \lg(K_T + 1), \quad (3)$$

$$pK_2 = pK_1 + \lg K_T. \quad (4)$$

It was of considerable interest to elucidate the acidic properties of phosphoryl CH acids [(A) forms] and phosphaenols [(B) forms] and their structural dependences. It was also suitable to make use of σρ correlation analysis for this purpose. In addition to that it was necessary to test the applicability of the latter for a quantitative representation of the acidity of compounds with these structures on products that were of the same type but not tautomeric. The

thiophosphorylphosphonium salts (XVII) were used as such compounds. The dissociation constants of these compounds in nitromethane and absolute ethanol were determined potentiometrically with a glass electrode.[71] The results of the measurements are given in Table 7.

Table 7. Acid dissociation constants of thiophosphorylphosphonium salts (XVII) $R_2P(S)CH(Y)\overset{+}{P}Ph_3\cdot X^-$ in $MeNO_2$ and absolute EtOH at 25 °C.

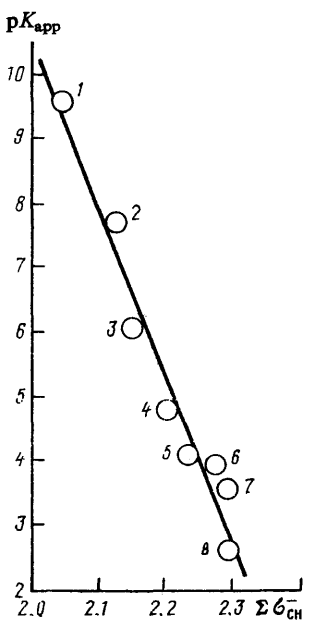

Figure 4. Correlation of pK_{app} with $\Sigma\sigma_{CH}^-$ for $RR'P(S)CH(Y)\overset{+}{P}Ph_3X^-$ in $MeNO_2$; the numbers of the points correspond to the numbers of the compounds in Table 7.

These acids can evidently be classed as fairly strong. We can show for comparison that in $MeNO_2$, pK = 7.05 for CF_3COOH, pK = 11.62 for $ClCH_2COOH$, and pK = 14.41 for CH_3COOH.

On Hammett coordinates with σ_{CH}^- constants they give a good correlation (even an excellent one in absolute ethanol) (Figs. 4 and 5) with the following parameters

In $MeNO_2$: $pK_{app} = 65.82 - 27.410\ \Sigma\sigma_{CH}^-$;

n=8; r=0.980; s=0.52; s_ρ=2.32.

In EtOH: $pK_{app} = 14.94 - 5.052\ \Sigma\sigma_H^-$;

n=7; r=0.998; s=0.03; s_ρ=0.13.

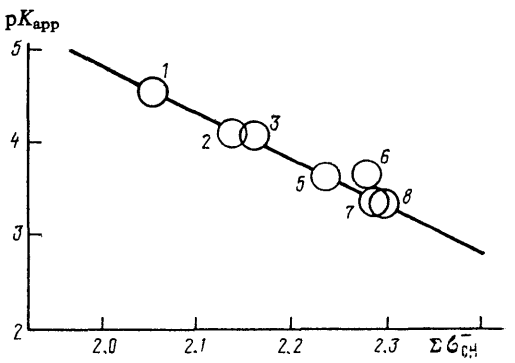

Figure 5. Correlation of pK_{app} with $\Sigma\sigma_{CH}^-$ for $RR'P(S)CH(Y)\overset{+}{P}Ph_3X^-$ in EtOH; the numbers of the points correspond to the numbers of the compounds in Table 7.

In the correlation in $MeNO_2$ two details attract attention. Firstly, the straight line has a very high gradient (ρ = 27.410). This results from the well-known strong differentiating effect of $MeNO_2$; the difference between the strengths of the acids in this case is as high as a factor of 10^7. Secondly, there is a very high value of pK^0 (almost 66). Theoretically this should correspond to the pK of methane in $MeNO_2$. Measurement of this constant is, of course, experimentally impracticable. Ethanol, on the other hand, is a solvent that causes a levelling out; in this case the difference in pK_{app} values does not exceed a factor of $10^{1.25}$. A linear Brønsted relationship occurs between the pK in the two solvents.

$$pK_{MeNO_2} = -15.72 + 5.535 pK_{EtOH},$$

r=0.978; s=0.58; s_ρ=0.52.

The high gradient, which differs markedly from unity, suggests that there are considerable differences in the differentiating capacity of nitromethane and ethanol.

The acid dissociation constants of the tautomeric phosphorylphosphonium salts (X) were determined in a similar manner. The results are listed in Table 8, where the equilibrium content of the phosphaenol forms (B) determined ^{31}P NMR is given for comparison. It can be seen that all the compounds can also be classed as comparatively strong acids. In nitromethane their strength is on average about 0.7 pK units lower than the thiophosphoryl acids (XVII) examined above; in ethanol they are virtually of equal strength. The strong differentiating action of nitromethane occurs here in the same way. The dissociation

constants vary by a factor of 10^{11} in accordance with the substituents attached to phosphorus and carbon, while they vary by a factor of only 10^3 in ethanol, which levels out the differences. With the same substituents on phosphorus the acid strength decreases on changing from Y = CN via compounds with Y = Ts to the carbethoxy and then carbamoyl derivative. These results vary in the same way as the σ_{CH}^{-} constants of the Y groups. Marked variations in the content of the phosphaenol forms occur on changing the substituents in both solvents, and phosphaenolisation does not vary in the same way as acidity. For example, the more acidic compound 2 (Table 8) is only slightly enolised while the less acidic compounds 1 and 4 (Table 8) are almost completely enolised. Relationships of this type are known in the classical chemistry of tautomeric compounds. For example, the more acidic cyclopentanonecarboxylic ester is enolised less than the less acidic cyclohexanonecarboxylic ester. As has already been mentioned, enolisation depends on the acidity ratio of the forms rather than the overall degree of acidity.

The dissociation constants of the (A) forms (pK_{CH}) and the dissociation constants of the (B) forms (pK_{OH}) were calculated using Eqns. (2)–(4). The results are included in Table 8. It can be seen that the value of pK_{CH} increases as $\Sigma\sigma_{CH}^{-}$ decreases. At the same time the Hammett correlation is perfectly satisfactory in nitromethane and good in ethanol (Fig. 6):

In $MeNO_2$: $pK_{CH} = 81.99 - 35.246\ \Sigma\sigma_{CH}^{-}$;

$n=11$, $r=0.977$, $s=0.80$, $s_\rho=2.55$.

With regard to the pK_{CH} in ethanol, only the last four figures in Table 8 are reliable. There is a good correlation between them and $\Sigma\sigma_{CH}^{-}$.

In EtOH: $pK_{CH} = 39.61 - 17.268\ \Sigma\sigma_{CH}^{-}$;

$n=4$; $r=0.996$; $s=0.16$, $s_\rho=1.06$.

In these correlations also there is an unusually high value of pK^0, especially in nitromethane.

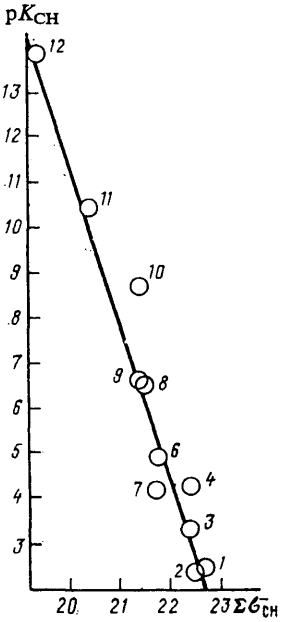

Figure 6. Correlation of pK_{CH} with $\Sigma\sigma_{CH}^{-}$ for $RR'P(O)CH(Y)\overset{+}{P}Ph_3X^-$ in $MeNO_2$; the numbers of the points correspond to the numbers of the compounds in Table 8.

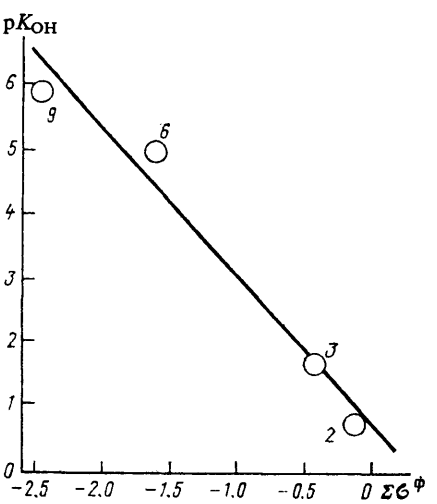

Figure 7. Correlation of pK_{OH} with $\Sigma\sigma^{*}$ for $RR'P(OH)=C(\overset{+}{P}Ph_3X^-)CH(Ts)$ in $MeNO_2$; the numbers of the points correspond to the numbers of the compounds in Table 8.

The dependence of pK_{OH} on structure proves to be quite complex, since in the (B) forms it is not only the substituents on the phosphorus atom that vary but also the nature of the $=C(^{+}PPh_3X)(Y)$ group.

group, which mimics the oxygen atom of the P=O group. When Y is constant, for example, Y = Ts, the pK_{OH} values provide a linear correlation with the σ^{Φ} constants[69] (Fig. 7)

In $MeNO_2$: $pK_{OH} = 0.70 - 2.296\ \Sigma\sigma^{f}$;

$n=4$; $r=0.983$; $s=0.56$; $s_{\rho}=0.30$.

Admittedly in this case the point corresponding to two benzene rings was excluded (see above). With regard to the pK_{OH} values in ethanol, they are virtually equal to pK_{app}, as more than 99% of the (B) form is present in solution. The relationship between pK_{OH} and the nature of the substituents is complex.

Thus, the pK_{app} acidity measurements and calculation of pK_{CH} and pK_{OH} provide a clear definition of the relationship between enolisation of the P=O group and the acidity of phosphoryl compounds.

---o0o---

The main conclusion to be drawn from the above material is that the phosphoryl group *can* undergo enolisation. A high acidity of the phosphoryl CH form (A) is a necessary condition for this to occur. This condition is of course necessary, but it is not sufficient. It is also necessary that the corresponding enol form (B) has a similar acidity to that of the phosphoryl form; this is readily achieved, however, with sufficiently acidic CH forms. The conditions for enolisation of the thiophosphoryl group are more rigorous. The reason for this is the higher acidity of phosphorus thio acids compared to their oxygen analogues. It can be demonstrated that up to the present time it was not possible to observe enolisation of the P=O group because the $\Sigma\sigma^{-}_{CH}$ values of the groups attached to the central carbon atom did not exceed 2, which was naturally a consequence of the fact that the attached groups had an insufficient acidifying effect. Thus, for example, for the "phosphonoacetic ester" of Arbuzov and Razumov[1-9]—$(EtO)_2P(O)CH_2COOEt$—the $\Sigma\sigma^{-}_{CH_2}$ value is 1.28, which is quite insufficient for phosphaenolisation to occur, while the compound used by Kolodyazhnyi[40,41]—$Ph_2P(O)CH(SO_2C_6H_5)_2$—has $\Sigma\sigma^{-}_{CH}$ = 1.97, which is at the limit of enolisability. On introduction of electronegative substituents into the benzene ring, this limit is exceeded and enolisation becomes quite appreciable.

All in all, enolisation of the phosphoryl group fully obeys the laws comprising the theory of prototropic tautomeric acid–base equilibrium.

N-Phosphorylated amides and thioamides

N G Zabirov, F M Shamsevaleev, R A Cherkasov
The V I Ul'yanov-Lenin State University, Kazan

ABSTRACT. The first systematic review is presented on carboxylic and thiocarboxylic acid amides containing a four-coordinated phosphorus atom on the nitrogen atom. The synthesis, structure and certain chemical properties of this compound class have been examined together with their prototropic and phosphorylotropic tautomerism, their dual reactivity, and the structure and properties of some of their metallic and organic derivatives. Particular attention has been paid to the practical application of these compounds.

The bibliography contains 223 references.

III. The structure of *N*-phosphorylated amides and thioamides 1135
IV. Chemical properties 1137
V. Practical applications 1139

I. Introduction

Carboxylic acid amides have been studied thoroughly and are widely used in industry, agriculture, and in various fields of science and technology.[1] Thioamides, however, have become a focus of attention only in the last decade in view of recently discovered practical applications, their diverse reactivity, and their potential value in organic synthesis.[2–5] *N*-Functionalised (including *N*-acylated) amides and thioamides, such as phthalimide, succinimide, and a large number of derivatives, have also proved to be very effective reagents in organic synthesis. Phosphorylated analogues of these polyfunctionalised compounds have also received much attention during the last two decades as a result of the discovery of a broad spectrum of properties of practical value.

The chemistry of *N*-phosphorylated amides and thioamides of type (I) has developed in three stages. After the initial

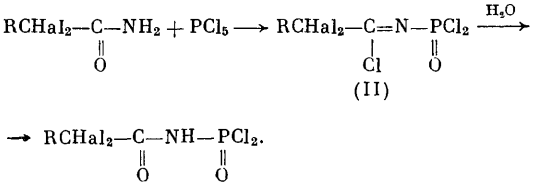
(I)

R = Alk, Ar; R^1 = Alk, Ar, AlkO, ArO, AlkS, ArS, Alk_2N, Ar_2N, etc.,

R^2 = H, Alk, Ar; X, Y = O, or S,

syntheses at the beginning of the 20th century,[6–8] there was a gap of some fifty years during which there was practically no research in this field. Then, during the fifties, A V Kirsanov's "phosphazo reaction" provided a new and simple methodology for preparing this class of compound.[9] Finally, in the 'seventies, with the discovery of their pesticidal activity, *N*-phosphorylated amides again became a focus of renewed interest, specifically with regard to (I, X = Y = O), the *N*-thiophorylated analogues (I, X = O, Y = S), *N*-phosphorylated thioamides (I, X = S, Y = O), and *N*-thiophosphorylated thioamides (I, X = Y = S). In this period, the broad spectrum insecticide, acephate (*O,S*-dimethyl *N*-acetylthiophosphoromonoamidate), was discovered and became commercially available.

In recent years, certain organophosphorus compounds of general formula (I) have proved to be highly effective complexing agents, extractants, and anti-microbial and -tumour agents, etc. This has stimulated the search for simple, convenient, and industrially viable routes to this class of compound, as well as the study of their chemical properties and structure.

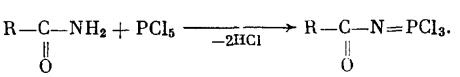


This is the first systematic review on the synthesis, structure and properties of *N*-phosphorylated amides and thioamides. Where possible, analyses have been made of the influence of the structure of these compounds on their reactivity and on other properties.

II. Methods of synthesis

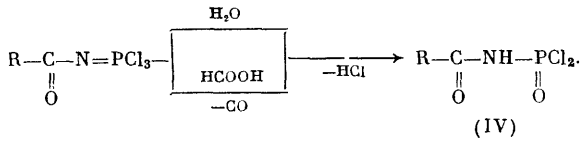
1. Synthesis of *N*-phosphorylated amides

The first *N*-phosphorylated amides of type (I) were obtained by phosphorylation of α-halogeno- and α-nitrocarboxylic acid amides with phosphorus pentachloride.[6–8]



The authors suggested that reaction proceeds via *N*-phosphoryliminochlorides (II) which were converted to the corresponding amides (I, R = Hal, H, NO_2) on exposure to moist air.

(II)



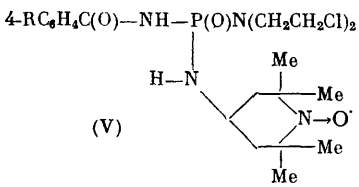
(Ia)

In 1954, A V Kirsanov renewed the study of the reaction between carboxylic acid amides and phosphorus pentachloride, and discovered that a trichlorophosphazo compound (III) was formed initially, rather than an *N*-phosphoryliminochloride.[9]

(III)

The above process was called the "phosphazo reaction". The resulting phosphazo compounds (III) are very hygroscopic and readily converted to the corresponding phosphoryl dichlorides (IV) in the presence of hydroxylic reagents.[10–13]

(IV)



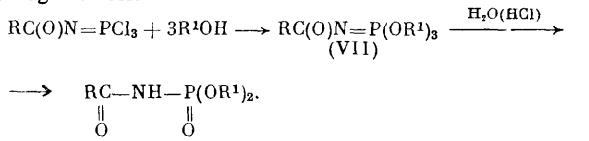
The acylaminophosphoryl dichlorides (IV) can be simply converted to the corresponding diesters on treatment with alkali metal alkoxides or alcohols.[14–20]

$$\underset{\text{(IV)}}{RC(O)NHP(O)Cl_2} \xrightarrow{2R^1OH \text{ or } 2R^1ONa} RC(O)NHP(O)(OR^1)_2.$$

In a similar way, the dichloride (IV) is readily converted into dithioesters,[14,19] bis(ethylenimides),[21] diamides[14,19] and hydrazides[22] of general formula (I).

$$RC(O)NHP(O)Cl_2 + 2HR^1 \rightarrow RC(O)NHP(O)R_2^1,$$
$$R^1 = SR^2,\ NHR^2,\ NHNHR^2,\ \overbrace{NCH_2CH_2}.$$

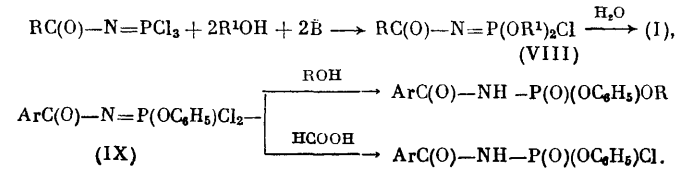
Sequential treatment of aroylaminophosphoryl dichlorides with bis(2-chloroethyl)amine in the presence of triethylamine, followed by 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl, affords the corresponding phosphoric acid triamides (V) which possess antitumour activity.[23] The intermediate monoamide need not be isolated.



(V)

R = H, F, Me.

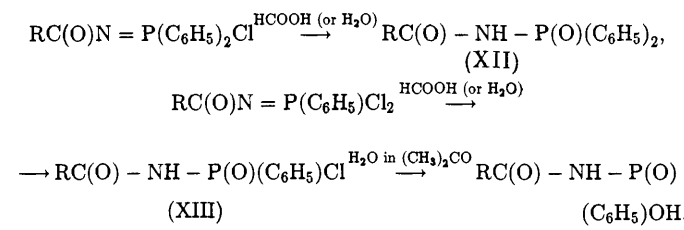
Diarylphosphinic acid *N*-arolyamides (VI) may be prepared from arylmagnesium bromides. These amides resist hydrolysis.[24]



$$\underset{\text{(VI)}}{ArC(O)-NH-P(O)Ar_2}.$$

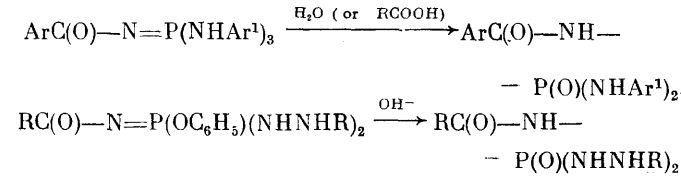
The ultimate stage in preparing *N*-acylphosphoromonoamidates need not involve the conventional displacement of halide. Thus, trialkoxy- or triaryloxy-*N*-acylphosphazenes (VII), obtained by treatment of the corresponding trichlorophosphazo compounds with alcohols and phenols, respectively, are converted to *N*-acylphosphoromonoamidates by action of water, aqueous ethanol, or dry hydrogen chloride.[14,17,20,25,26]

It should be pointed out that triaryloxy-*N*-acylphosphazenes (VII, R^1 = aryl) are very easily hydrolysed. In fact, very high yields of diaryl *N*-acylphosphoromonoamidates are obtained simply by exposing these phosphazenes to moist air, water or 96% ethanol.[26–28]



In another route, *N*-acylphosphoromonoamidates are obtained from trichlorophosphazenes via partial replacement of chlorine atoms, followed by hydrolysis, alcoholysis or acidolysis of the resulting monochloro- or dichlorophosphazenes, (VIII) and (IX).[14,17,26]

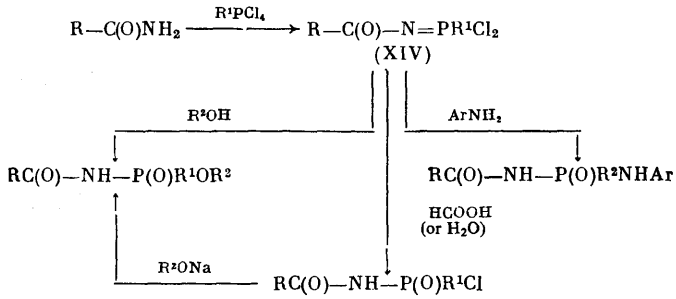
In a similar way, *N*-phosphorylated thioamides of general structure (XI) are prepared from the corresponding phosphazenes (X) (having alkyl, alkoxy, amino or other functionality on phosphorus together with one or two chlorine atoms) on treatment with hydrogen suphide in trifluoroacetic acid.[29,30]



$$\underset{\text{(X)}}{RC(O)-N=PR_n^1Cl_{3-n}} + H_2S \rightarrow \underset{\text{(XI)}}{RC(O)-NH-P(S)R_n^1Cl_{2-n}}$$
$$R^1 = Alk,\ AlkO,\ NR_2,\ NHR;\ n = 1, 2.$$

P-Aryl-substituted *N*-phosphorylated amides, (XII) and (XIII), are obtained by hydrolysis or acidolysis of the corresponding aryl- or diaryl-chloro(*N*-acyl)phosphazenes.[25,31]

The monochlorinated amides (XIII) are readily converted to the corresponding *N*-acyl(phenyl)phosphonamidic acids by vigorous hydrolysis with aqueous acetone.[31]



Acylaminophosphoryl diamides and dihydrazides have been conveniently prepared by hydrolysis or acidolysis of the corresponding triamino- or dihydroazido-phosphazenes, obtained from *N*-acyltrichlorophosphazenes.[22,32]

Structurally varied *N*-phosphorylated amides may be obtained by phosphorylation of carboxamides with halogenophosphoranes, e.g. phenyl-,[33] methyl-[34] and trichloromethyltetrachlorophosphorane,[35] in place of phosphorus pentachloride. Reactions

with these tetrachlorophosphoranes do not proceed as readily as reaction with PCl_5. The initially formed alkyl- or aryl-(dichloro)phosphazenes (XIV) may be easily converted to the corresponding *N*-phosphorylated amides by treatment with water, acid, alcohols or amines, as shown in Scheme 1.

Scheme 1

Methods of preparing *N*-phosphorylated amides via the phosphazo reaction are fairly straightforward and afford the desired product in high yield. However, such routes are not generally applicable. For example, the interaction of aliphatic carboxylic acid amides with PCl_5 proceeds to give both phosphazo compounds and chlorinated amides.[9] As a consequence, this method is not suitable for preparing simple *N*-phosphorylated *N*-acylamides unsubstituted in the acyl fragment, e.g. the pesticide acephate.

As an alternative to the phosphazo reaction the Staudinger reaction, based on trialkyl phosphites and acyl azides, can be applied to the preparation of *N*-acylphosphazenes. The resulting *N*-acyliminophosphates are converted to the desired *N*-phosphorylated amides on treatment with dry hydrogen chloride.[36,37]

$$(RO)_3P + R^1C(O)N_3 \longrightarrow (RO)_3P{=}NC(O)R^1 \xrightarrow[-RCl]{HCl} (I).$$

The synthesis of *N*-phosphorylated amides may also be achieved by another route: acylation of *N*-arylphosphazenes with acetyl chloride. Kabachnik and Gilyarov[39] showed that the trialkyl *N*-phenyliminophosphates formed by the Staudinger reaction are converted to *N*-acetyl-*N*-phenylphosphoromonoamidates on treatment with acetyl chloride. This is one of only a few methods reported in the literature for the preparation of *N*-phosphorylated amides having a tertiary nitrogen atom.

$$(RO)_3P + C_6H_5N_3 \xrightarrow[-N_2]{} (RO)_3P{=}N{-}C_6H_5 \xrightarrow{CH_3C(O)Cl} \longrightarrow (RO)_2P(O){-}N(C_6H_5){-}C(O){-}CH_3 + RCl.$$

A number of routes to *N*-phosphorylated amides are based on the functionalisation of phosphorus(V) acid derivatives in which the phosphorus atom is bonded to an unsaturated nitrogen-containing group. Thus, *N*-phosphorylated iminochlorides (XV, X = Cl), which are isomeric with *P*-chloro-*N*-acylphosphazenes, undergo hydrolysis and alcoholysis to give the corresponding *N*-phosphorylated amides. The latter are also obtained by hydrolysis of *N*-phosphorylated iminoesters (XVI).[16,17,28,39]

$$R{-}C(X){=}N{-}P(O)(OR^1)_2 \xrightarrow{H_2O\ (ROH)} (I),$$

(XV), (XVI)

X = Cl (XV), OR^2 (XVI).

There is also an unusual route to *N*-phosphorylated amides based on the interaction of aryl *N*-(diaryloxyphosphinyl)thioimidates with 25% H_2O_2 in acetic acid or with concentrated nitric acid.[40]

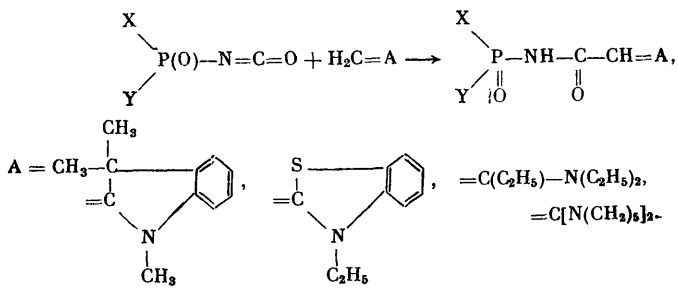
$$Ar{-}C(S{-}Ar^1){=}N{-}P(O)(OAr^2)_2 \xrightarrow{H_2O,\ [O]} Ar{-}C(O){-}NH{-}P(O)(OAr^2)_2.$$

The authors gave no details on this reaction.

A variety of *N*-phosphorylated amides with a functionalised acyl chain can be prepared by reaction of *N*-phosphorylisocyanates with compounds having a labile hydrogen atom. Thus *N*-phosphorylated amides are obtained in 36–61% yield by interaction of isocyanates (XVII) with acetic or propionic acid in the presence of a catalytic amount of sulphuric acid. Evidently, the reaction proceeds via an unstable anhydride (XVIII) which undergoes decarboxylation.[41]

$$(RO)_2P(O) - N = C = O + R^1COOH \xrightarrow{H_2SO_4\ (cat.)}$$

(XVIII)



$$\longrightarrow [(RO)_2P(O){-}NH{-}C(O)OC(O)R^1] \xrightarrow[-CO_2]{} (RO)_2P(O){-}NH{-}C(O)R^1,$$

(XVIII)

R=CH_3, C_2H_5; R^1=C_2H_5.

Benzoic acid, however, does not participate in this reaction.

In another route based on phosphorylisocyanates, nitrogen-containing methylenic compounds add to the latter to give *N*-phosphorylated derivatives of α,β-unsaturated carboxylic acid amides.[42]

The above-described routes to *N*-phosphorylated and *N*-thiophosphorylated amides are essentially based on the intermediate formation and subsequent conversion of compounds with an unsaturated phosphorus atom, such as phosphazo compounds. Since there are limitations in the choice of the acyl group and the

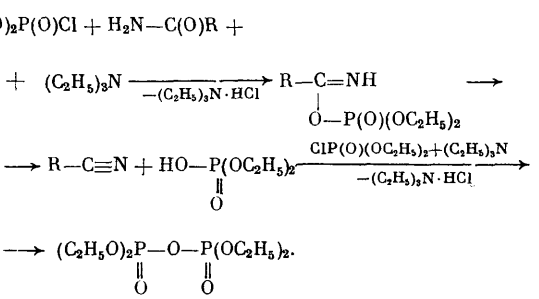
substitution of the phosphoryl residue, the method has certain, and sometimes obvious, limitations. For this reason, there has been interest in the direct phosphorylation of amides and thioamides with phosphorus acid chlorides and in the acylation of phosphorus(V) acid amides with acyl or thioacyl halides:

$$\left.\begin{array}{l} RC(X)NH_2 + ClP(Y)R_2^1 \\ R_2^1P(Y)NH_2 + ClC(X)R \end{array}\right\} \xrightarrow[-HCl]{} R{-}\underset{\underset{X}{\|}}{C}{-}\underset{\underset{H}{|}}{N}{-}\underset{\underset{Y}{\|}}{PR_2^1}.$$



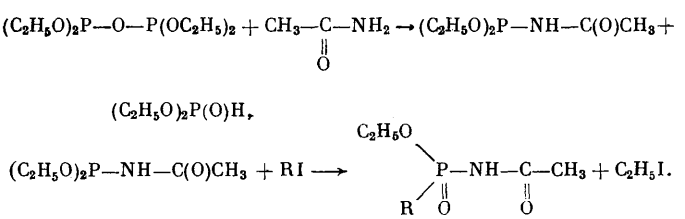
Most success has been achieved by applying the second of these routes. Thus, a whole range of methods is available for preparing (I) based on the interaction of phosphorus(V) and thiophosphorus(V) acid amides with acyl halides. Such reactions have been carried out both in the presence of base (to 'fix' hydrogen chloride)[43–45] and in the absence of base.[46–49] Tertiary *N*-phosphorylated amides have also been prepared by acylation of *N,N*-disubstituted phosphoramidates with acyl halides in the presence of pyridine.[50] These routes are quite suitable for the preparation of oxygen-containing *N*-phosphorylated amides and provide the desired products in an acceptable yield (Table 1).

Various methods involving acylamine metallation have been adapted for the effective preparation of *N*-thiophosphorylated amides. However, the yield of the latter is within a wide range (8 to 87%), depending on the structure of the starting materials.[30,51,52] Only a moderate yield (36%) of *N*-thiophosphorylated amides is obtained by acylation of thiophosphorus(V) acid amides with acyl halides in acetone in the presence of KOH and crown ether,[52] while, in superbasic media (DMSO/KOH), the yield of desired product is 24%. The authors note that under these conditions it is possible to prepare *N*-phosphorylated and *N*-thiophosphorylated amides which cannot be obtained by direct acylation of phosphorus(V) acid amides.[53,54]

Carboxylic acid anhydrides are also effective as the acylating agent. Thus, treatment of phosphorus(V) acid amides with butyllithium at −78 °C, followed by acetic formic anhydride, affords an entire range of *N*-phosphorylated amides and thioamides possessing pesticidal activity.[55] Acylation of thiophosphorus(V) acid amides can also be achieved with acetic anhydride in the absence of catalyst or in the presence of catalytic amounts of sulphuric or phosphoric acid.[56–59] Ketenes may also be used as the acylating agent in acetic acid containing sulphuric acid as catalyst.[59]

It is less convenient to prepare *N*-phosphorylated and *N*-thiophosphorylated amides by phosphorylation of carboxylic acid amides with phosphorus(V) acid halides. Thus, attempts to synthesise *N*-phosphorylated amides by treatment of carboxylic acid amides with dialkyl phosphorochloridates in the presence of triethylamine were unsuccessful. Under these conditions phosphorylation afforded the corresponding tetraalkyl pyrophosphates and nitriles, rather than the desired (I),[45] as shown in Scheme 2.

Scheme 2

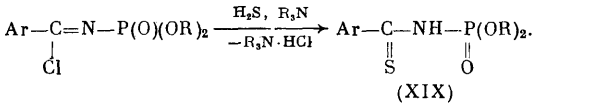


Tetraalkyl pyrophosphates and phenyl isocyanide were obtained by using formanilide.[45] Similar results were obtained on the interaction of amides with phosphono- and thiophosphono-chloridates.[60]

However, if the above phosphorylation is carried out on *N*-metallated acylamines rather than acylamines themselves, the desired displacement takes place in one step. Thus, *N*-sodio derivatives are phosphorylated with thiophosphorochloridates in 46–89% yield[51] (see Table 1). However, thiophosphorylation of amides in the presence of sodium hydride is not very effective (~18% yield), while in superbasic media (DMSO/KOH) the yield of *N*-phosphorylated amides can be increased to 45%.[54]

Phosphorus acid anhydrides are, evidently, also suitable for the phosphorylation of acylamines. Thus, *N*-phosphorylated acetamides may be prepared by using tetraethyl pyrophosphite as phosphorylating agent: the initially formed diethyl *N*-acetylphosphoromonoamidite then undergoes Arbuzov reaction with alkyl iodides to give the corresponding *N*-acetylphosphonamidates,[37] as shown in Scheme 3.

Scheme 3

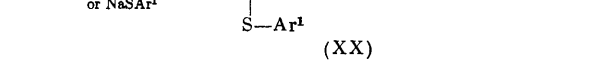


However, this route is more of theoretical than preparative interest, partly because the phosphorylating agent is not readily available and partly because it is difficult to separate the desired product for the diethyl phosphite formed as by-product.

2. Synthesis of *N*-phosphorylated thioamides

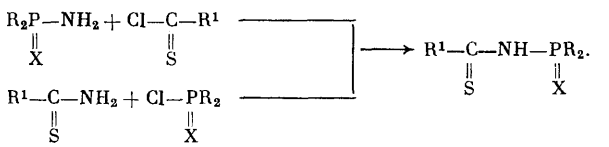
Although *N*-phosphorylated amides and thioamides are structurally similar, it is not always possible to adapt methods developed for the preparation of *N*-phosphorylated amides to the preparation of thioamide analogues. In recent years, a rather specific route has been developed for the synthesis of sulphur-containing *N*-phosphorylated acylamines. It is based on the addition of thio- and dithio-phosphorus acids to compounds containing a carbon-nitrogen multiple bond. The analogous addition of organophosphorus acids has not yet been reported. This highlights the necessity to distinguish the synthesis of *N*-phosphorylated and *N*-thiophosphorylated amides from that of *N*-phosphorylated and *N*-thiophosphorylated thioamides.

Attempts to adapt the phosphazo reaction to the preparation of thioamide derivatives, largely undertaken by Kirsanov, et al. in 1960,[61] met with failure. Thus, it was shown that the interaction of thiobenzamide with PCl_5 under the conditions of the phosphazo reaction leads to a complex mixture of products (HCl, PCl_3, $PSCl_3$, nitriles, thiadiazoles, and other unidentified compounds), rather than to the desired *N*-thioacylphosphazenes.[61]



However, cleavage of *N*-dialkoxyphosphoryl- and *N*-diaryloxyphosphoryl-iminochlorides with H_2S proceeds quite readily to give the corresponding *N*-phosphorylated thioamides (XIX). This is analogous to the hydrolysis of iminochlorides (XV).

(XIX)



The above reaction can be achieved by using a tertiary amine as base, and leads to a high yield of desired product (70–98%).[61]

N-Phosphorylated thioamides (XIX) may also be obtained in 60–90% by treatment of (XV, R = aryl) either with thiophenols (in the presence of tertiary amine) or with sodium arylmercaptides, followed by hydrolysis of the resulting thioiminoesters (XX) in aqueous alcoholic media containing a base.[40]

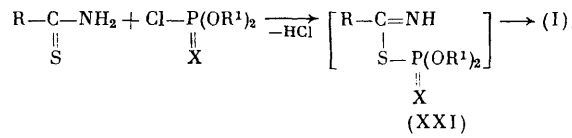
(XX)

For the preparation of *N*-phosphorylated thioamides and *N*-thiophosphorylated thioamides from readily available starting materials, more attention has been focussed on acylation or phosphorylation routes with acid chlorides (see earlier and in Tables 1 and 2), according to the following scheme:

The first of these methods, however, has no preparative value since thiocarboxylic acid chlorides are not readily available and, in many instances, are extremely unstable. The second route, based on the reaction of thioamides with phosphorus(V) acid chlorides is more effective.

In 1967 the synthesis was reported of *N*-(diphenylthiophosphinyl)thioacetamide by interaction of diphenylthiophosphinyl chloride with thioacetamide, as well as by action of methyllithium on diphenylthiophosphinyl isothiocyanate.[62] However, in each instance, acetonitrile and a diphenyldithiophosphinate were formed instead of the anticipated *N*-thiophosphinylthioamide (I, R = Me, R^1 = Ph, X = Y = S). Similar results were obtained for the interaction of diphenylthiophosphinyl chloride with the sodio-derivative of thiobenzamide.[63] However, the latter reaction with dimethyl- and dibenzyl-thiophosphinyl chloride does afford the desired *N*-thiophosphinylthioamide (I, R = Ph, R^1 = Me, $PhCH_2$, R^2 = H, X = Y = S) in 60–67% yield[51,63] (see Table 2).

Table 2. Phosphorylation of thioamides.



Thioamide	Phosphorylating agent	Reaction conditions	Product	Yield, %	Reference
$RC(S)NHNa$	$(CH_3)_2P(S)Cl$	THF, heat	$RC(S)NHP(S)(CH_3)_2$	60–67	[51, 63]

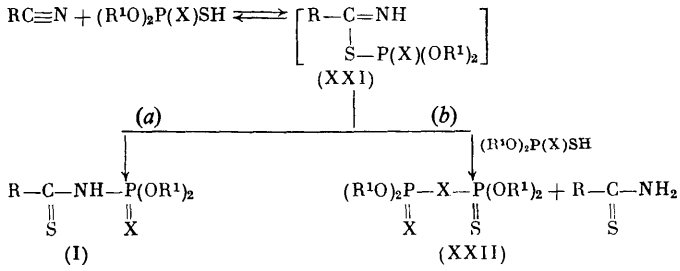
$RC(X)NH_2$	$(R^1O)_2P(Y)Cl$	DMSO, KOH	$RC(X)NHP(Y)(OR^1)_2$	65–80	[53, 54, 66]

The *N*-thiophosphorylthioamide (I, R = Me, R^1 = OPr-*i*, R^2 = H, X = Y = S) was obtained in 15% yield by treatment of diisopropyl dithiophosphorochloridate with the potassium salt of thioacetamide, prepared by treatment of the latter with potassium *tert*-butoxide.[64] The same reaction with thiobenzamide in the presence of sodium hydride gave only a small amount of desired product.[65] Phosphorylation of thioamides with phosphoryl chlorides does not take place in the absence of base or with weak organic bases.

Recently, *N*-phosphorylated thioamides and *N*-thiophosphorylated thioamides were prepared under phase transfer catalysis or in superbasic medium by treatment of thioamides with phosphoryl and thiophosphoryl chlorides (see Table 2). The yield of desired product is 37–45% in 50% KOH containing a quaternary ammonium salt as phase transfer catalyst.[53,54,66] The yield can be increased to 62–66% if solid KOH/crown ether is used in place of the above 2-phase procedure with a quaternary ammonium salt and aqueous base, under which conditions undesired hydrolysis of the phosphoryl chloride takes place to some extent.[53,54,66,67]

In spite of the undoubted advantages of phase transfer catalysis for the phosphorylation of thioamides, the method is not applicable to the reaction of thioacetamide with dialkyl phosphorochloridates or to the reaction of thiobenzamide with dimethyl phosphorochloridate.[64–66] However, these reactions are possible in superbasic media, e.g. solid KOH in dimethyl sulphoxide.[53,54,66] The method can be used for the preparation of all four types of compound (I) with any organic substituent at the (thio)carbonyl or (thio)phosphoryl centre (see Table 2).

By analogy with the reaction of secondary N-sodiothioamides with acyl chlorides, which involve initial formation of *S*-acylthioimidates,[68] it has been proposed that the above phosphorylations proceed with the initial formation of an *S*-phosphorylthioimidate (XXI), which subsequently isomerises to give (I) by 1,3-*S*→*N*-(thio)phosphoryl group migration:

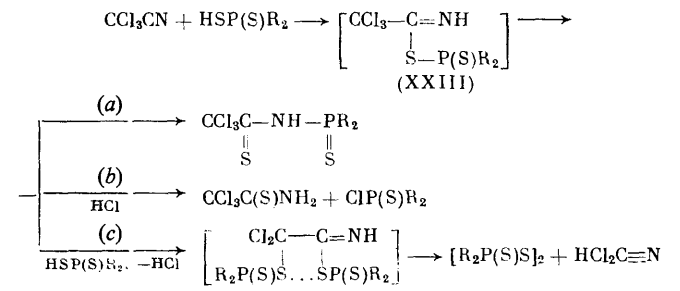


(XXI)

Apparently, the formation of intermediate (XXI) is dependent on a number of factors, which to a large extent compensate one for the other. Thus, in strongly basic media, deprotonation of acylamines is relatively facile, but, on the other hand, strong solvation of the phosphorus atom, bearing an effective positive charge, hinders the S_N2 displacement at phosphorus. It would also appear that the inductive effects of substituents at the carbon atom of the (thio)carbonyl group and at phosphorus on the rate of substitution are in the opposite sense: on the one hand the effect is to increase the acceptor properties of R, thereby facilitating *N*-deprotonation, and on the other hand to decrease the nucleophilic properties of the conjugate amide anion. Thus, structure-reactivity relationships involving phosphoryl chlorides are difficult to interpret. In this context, it is necessary to consider the effect of all the groups linked to phosphorus, both on the phosphorylation step and on the isomerisation of the intermediate (XXI) to give (I). The latter process also involves an S_N2 displacement at phosphorus, again subject to the juxtaposition of various intermolecular and intramolecular forces. Thus, the reaction in question is subject to a fine balance of various factors (electronic, steric, catalytic, medium effects), so that it is critical to select the appropriate method for each particular case.

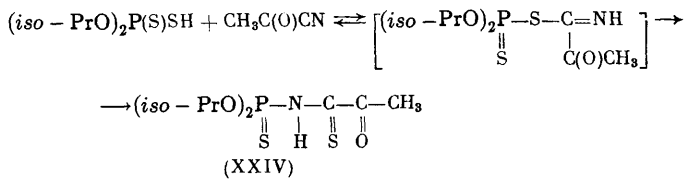
N-Phosphorylated and *N*-thiophosphorylated thioamides may also be prepared by the reaction of monothio- and dithio-phosphorus(V) acids with nitriles.[69–74] This reaction proceeds via addition of the thiophosphorus(V) acid to the cyano group with the initial formation of the corresponding *S*-phosphorylthioimidate (XXI). The latter isomerizes to the corresponding *N*-(thio)phosphorylated thioamides (I, X = S, Y = O; see route (a) of Scheme 4) via 1,3-*S*→*N*-migration of the (thio)phosphoryl group. It should be

pointed out that the *S*-phosphorylthioimidates (XXI), being excellent phosphorylating agents in themselves, also undergo cleavage of the P–S bond by the starting thiophosphoric acid, with the result that carboxylic acid thioamides and (tri)thiopyrophosphates (XXII) are formed as by-products in a concurrent step of the reaction, i.e. path (b).



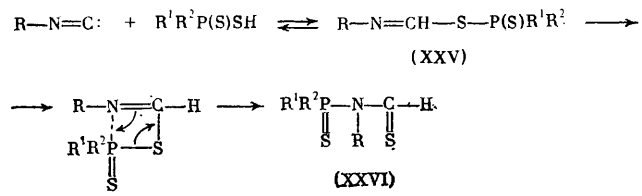
Scheme 4

The yield of phosphoramides (I) depends on the nature of the nitrile, the structure of the thiophosphoric acid, the proportion of the reactants, the reaction conditions, and the presence of impurities. The highest conversion of dithiophosphoric acids to thioamides (I) was achieved with aromatic nitriles.[71,75–78] Aliphatic nitriles either do not react at all or are converted to the corresponding *N*-thiophosphorylated thioamides only in small yield. In this instance, pathway (b) (Scheme 4) is the predominant step.[75] The method is not suitable for preparing *N*-diphenylthiophosphinyl-thioamides since diphenylthiophosphinic acid reacts with nitriles only by pathway (b).[72,79,80]



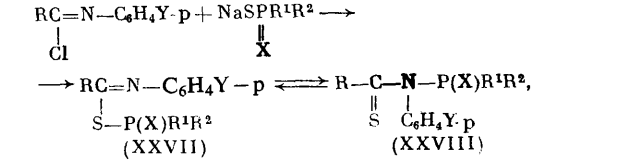
O,O-Dialkyl hydrogen thiophosphates are noticeably less reactive towards nitriles,[65,69,70,74] being converted to *N*-phosphorylated thioamides (I) only in 2.5–12% yield.[65] In no instance has it been possible to isolate the intermediate thioimidates (XXI) by reaction of (di)thiophosphoric acids with nitriles, although there is one publication in which the authors incorrectly assigned an *S*-dithio-phosphorylthioimidate structure to what, in fact, were *N*-thio-phosphorylated thioamides.[72] Only in the reaction with chloroacetonitrile has it been possible to detect the intermediate formation of *S*-dithiophosphorylthioimidates (XXIII) by ^{31}P NMR spectroscopy; in this instance, the intermediates undergo a number of transformations over the course of several hours.[81,82]

Scheme 5



As shown in Scheme 5, only one of the ensuing reactions of (XIII), path (a), leads, via isomerisation, to *N*-thiophosphorylated thioamides, which were isolated in low yield. Decomposition with hydrogen chloride is also an energetically favourable reaction of (XIII), i.e. path (b) and in a third option, the intermediate may react with the starting dithiophosphorus(V) acid, i.e. path (c). This is a redox step which results in the formation of dichloroacetonitrile and a bis(dialkylthiophosphoryl) disulphide.

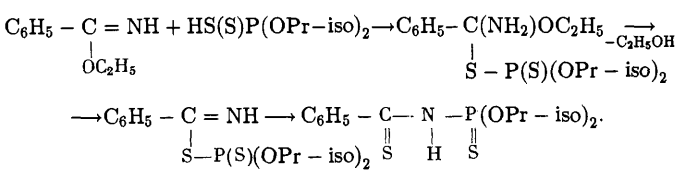
The reaction of dithiophosphorus(V) acids with benzoyl and acetyl cyanide is equally complex.[83,84] In the reaction with acetyl cyanide, it is only possible to isolate an *N*-thiophosphorylthioamide (XXIV) by treatment with *O,O*-diisopropyl hydrogen dithiophosphate. However, the yield of (XXIV) was only 12%.[71,84]



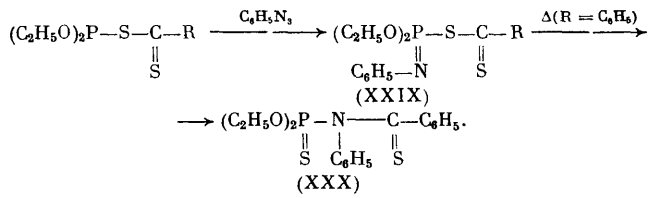
N-Thiophosphorylated thioformamides are readily formed by interaction of dithiophosphorus(V) acids with isonitriles, the method being similar to the reaction with nitriles. Thus, treatment of dithiophosphoric acids with 2,6-dimethyl- and 2,6-diethyl-phenyl isocyanide affords α-adducts (XXV),[84] which isomerise into the corresponding *N*-thiophosphorylthioformamide (XXVI).[71,86]

where R = C_6H_{11}, C_6H_5, 4-$CH_3C_6H_4$, 2,5-$(CH_3)_2C_6H_3$, 2,6-$(CH_3)_2C_6H_3$, 2,6-$(C_2H_5)_2$. C_6H_3; R^1,R^2 = AlkO

It has been established that the rearrangement of (XXV) to (XXVI) is a first-order reaction.[85] By substituting *O,O*-dimethyl dithiophosphate for *O,O*-diethyl dithiophosphate, the rate of the rearrangement is increased. Reaction is clearly slower with acidic dithiophosphonates (as opposed to dithiophosphates), and derivatives of diphenyldithiophosphinic acid do not rearrange at all.[85–87] Isomerisation is enhanced as the nucleophilicity of the nitrogen atom increases.[79,80] Formamides of type (XXVI) were not formed by reaction of isonitriles with dialkyl phosphoric[88] and monothiophosphoric acids or with monothiophosphonic acids.[89]



Tertiary *N*-phosphorylated thioamides and *N*-thiophosphorylated thioamides (XXVIII) may be prepared by reaction of iminochlorides with monothio- and dithiophosphorus(V) acids.[87,90] With acid derivatives having an O–P–S residue, reaction proceeds by attack of the sulphur atom.

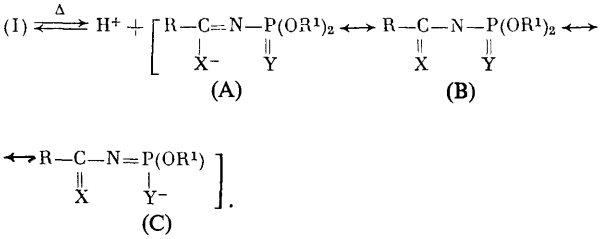


where R = C_6H_5, R^1 = R^2 = AlkO, X = O, S, Y = H, Br, CH_3, CH_3O, NO_2.

In certain instances, the thioamides (XXVIII) are formed as an equilibrated mixture with their thioimidate form (XXVII).

A low yield (3–5%) of *N*-thiophosphorylated thioamides has also been recorded by interaction of dithiophosphoric acids with iminoesters.[71,82,91,92]

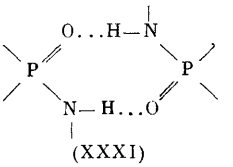
Recently, tertiary *N*-thiophosphorylated thioamides, e.g. (XXX), have been obtained from *O,O*-dialkyl S-thioaroyl thiophosphorimidates (XXIX), which undergo imide-amide rearrangement by S→N-migration of the thiocarbonyl group within the S–P–N residue.[93] The rearrangement also takes place on distillation of the product obtained by Staudinger reaction of *O,O*-dialkyl S-thioacyl monothiophosphites with phenyl azide.



A similar rearrangement, involving migration of a trifluoroacetyl group within the O–P–N residue, has been observed with *O*-acylphosphazo compounds.[94]

III. The structure of *N*-phosphorylated amides and thioamides

Each of the four types of *N*-phosphorylated amide (I) contain three potentially reactive centres—a carbonyl (or thiocarbonyl) group, a phosphoryl (or thiophosphoryl group), and a secondary >N–H group with a labile hydrogen atom. Each of these groups migrates fairly easily, thereby facilitating proto-, acylo- and phosphoro-tropic processes.[36,51,87,95–97] The question of deprotonation and hydrogen migration to the basic centres X, Y and N in (I) has already been addressed quite thoroughly in the literature.[36,37,51,95–97]

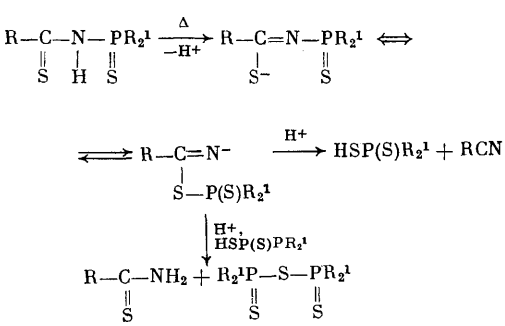


Amides (I) are moderately strong acids. From potentiometric data, it has been calculated that the acid dissociation constants, pK_a, in water[36,96] or aqueous alcoholic media[36,51,95–99] are in the range 4.16–10.7, depending on the nature of the substituent in the acyl and phosphoryl residue.

Numerous and diverse IR-spectroscopic studies on (I) have been carried out, primarily to analyse prototropic shifts and determine the character of hydrogen bonding in these compounds. It has been shown that under normal conditions in solution and in concentrated media, they exist exclusively in the amide form;[36,37,95,97–104] dissociation of the amide hydrogen may only take place at fairly high temperature in solution or on melting. The electronic structure of the resulting anion may be represented by three canonical forms:

On varying the conditions (in solution, in the melt, or on heating), the contribution of each structure may change. The corresponding shifts in the electron density of the anion can be detected in the IR spectrum of the compounds.[104] At the same time, ^1H and ^{31}P NMR spectroscopy indicates the extent of intramolecular hydrogen bonding of the type P=S(O)...H–N and C=O(S)...H–N.[105]

The structures of compounds (I) are dependent to a large extent on the nature of the hydrogen bonding in the various associated amide forms. In *N*-phosphorylated amides, hydrogen bonding of the type C=O...H–N[98,101] or P=O...H–N[36] may be evident. However, in *N*-phosphorylated thioamides, the thioacyl group does not participate in hydrogen bonding; in such compounds, the molecules are associated in the form of cyclic hydrogen-bonded dimers of type (XXXI).



The IR spectra of *N*-thiophosphorylated thioamides indicate that the character of the hydrogen bonding depends on the nature of the acyl group. Derivatives of thioacetamide (I, R = Me, R^1 = OPr-*i*, R^2 = H, X = Y = S) are stabilised in the solid state by intermolecular hydrogen bonding of the type C=S...H–N, which is easily disrupted on dissolving the compounds in carbon tetrachloride. Thiobenzamide analogues (I, R = Ph, R^1 = OPr-*i*, R^2 = H, X = Y = S), however, are characterised by hydrogen bonding of the type P=S...H–N, which is also disrupted on dissolution.[104] Carbonyl analogues of these compounds are associated by intermolecular hydrogen bonding involving the carbonyl oxygen;[104] however, in the solid phase and in solution one cannot exclude the possibility of hydrogen bonding with the thiophosphoryl group. Hydrogen bonding in *N*-phosphorylated thioamides (I, X = S, Y = O) can be simply represented by the dimeric structure (XXXI), the thiocarbonyl group being unassociated. It has been shown[104] that the majority of compounds of type (I) exist in solution or in the melt as an equilibrated mixture of associates each having a distinct electronic structure.

IR- and ^1H or ^{31}P NMR-spectroscopic studies of *N*-(diisopropoxythiophosphoryl)thioacetamide at high temperature (80–170 °C).[104] have provided evidence on the chemical processes which take place under these conditions (Scheme 6).

Table 3. Bond lengths for compounds of general formula $R-\underset{\underset{X}{\|}}{C}-\underset{\underset{R^2}{|}}{N}-\underset{\underset{Y}{\|}}{PR_2^1}$

Compound	R	R^1	R^2	X	Y	Bond lengths, Å							Reference
						C=X	C–N	N–H	P=Y	N–P	N...Y	H...Y

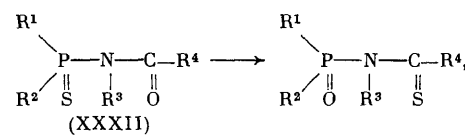
Scheme 6

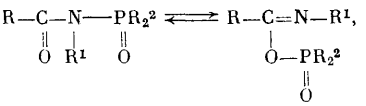


This has been supported by independent studies.[87,97]

The identification of nitriles, thioamides, dithiophosphates and trithiopyrophosphates among the products formed by thermolysis of *N*-thiophosphorylated thioamides provides unequivocal support for the above pathway (Scheme 6), which incorporates a protolytic dissociation and an amidothiophosphate-imidoyldithiophosphate rearrangement. These represent clear examples of 1,3-(N→S)-thiophosphoryl migration in secondary *N*-phosphorylated amides (see Ref. 87 and references cited therein).

Thiophosphoryl group migration in tertiary *N*-thiophosphorylated thioamides also takes place readily. In certain instances, such thioamides exist at room temperature as a tautomeric mixture, in which the proportion of the two forms may reach 1 : 1.[82,87,90] It has been shown that the position of the amide-imide equilibrium depends on several factors and to a large extent on the nature of the substituent on the tertiary nitrogen atom†.

Recently, it has been shown that tertiary *N*-thiophosphorylated amides readily undergo isomerisation wherein the oxygen atom of the carbonyl group and the sulphur atom of the thiophosphoryl group are transposed.[106,135]



(XXXII)

R^1, R^2=CH_3O, C_6H_5; R^3=H, CH_3, C_6H_5; R^4=CH_3, C_6H_5, iso-BuO

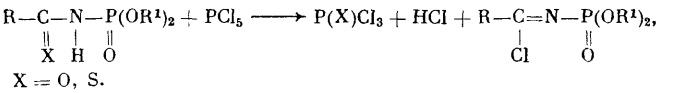
For compounds (XXXII; R^3 = Me or Ph), the isomerisation proceeds even at 40 °C. However, (XXXII); R^3 = H) failed to isomerise. The rate of rearrangement decreases as follows: (XXXII; R^1 = R^2 = MeO) > (XXXII; R^1 = MeO, R^2 = Ph) > (XXXII; R^1 = R^2 = Ph). Benzoylamides (R^4 = Ph) rearrange significantly more readily than acetamide derivatives (R^4 = Me).

† The factors responsible for phosphorylotropic processes in compounds of type (I) have been analysed in more detail in earlier reviews.[82,87] Of necessity, the present review only touches on more recent data in this area.

With oxy-analogues (I, X = Y = O), N→O-phosphoryl migration has been detected under the conditions of electron impact mass spectrometry.[107]

$R = CH_3$, C_6H_5; $R^1 = H$, CH_3; $R^2 = CH_3O$, C_2H_5O, C_2H_5.

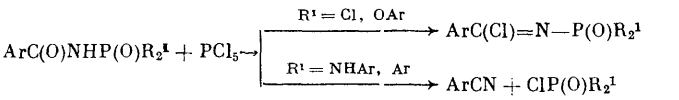
Data obtained from X-ray structural analyses of amides (I) and certain of their metallated derivatives (Table 3) confirm the amido(thio)phosphate structure for these compounds. There was no evidence to support any isomeric structure. From these structural analyses of compounds (I), it is quite clear that the *N*-benzoyl derivative (Ia), its analogues (Ib–e), and compounds (If–i) (studied by ourselves) are associated by intermolecular hydrogen bonding. Compounds (Ig) and (Im) are associated by hydrogen bonding of the type N–H...O=P; in compound (Im) the molecules are linked in the form of a centrosymmetrical dimer, while in the oxygen analogue (Ig) the dimer is associated with other molecules in the crystal lattice. In the *N*-thiophosphorylated thioamide (Ii), hydrogen bonding forces the molecules into uniformly extended spiral chains. The molecules of compound (Ih) also exist as a uniform chain linked by hydrogen bonding of the type N–H...O=C.



The P=S and P=O bond lengths in compounds (I) are as would be anticipated.[120] The nitrogen atom is planar tricoordinated, the P–N bond length being shorter than the norm (1.77 Å) indicative of partial double bond character. All the compounds in the Table contain the atomic grouping, PNHC(Y)C, the planarity of which provides evidence for π-delocalisation of the double bond, O=C=N, as is found in peptides. This is supported by the bond lengths for compounds (Ig) and (Ih).

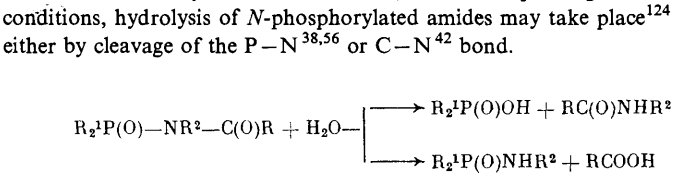
In the thioamide anion (Ij), the P=S and C=S bond lengths are longer than in the neutral molecule (Ii), while the P–N and N–C bond length are shorter. This confirms that the negative charge is delocalised in the fragment XCNPY.[113] In the mercury and lead complexes (Ik, Il), the C=S and P=S(O) bond lengths are even greater, approximating to single bonds, while the P–N and N–C bonds are even shorter.[117–119]

IV. Chemical properties

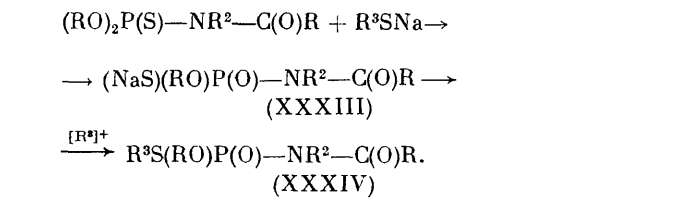


N-(Thio)phosphorylated amides and thioamides participate in a variety of chemical reactions by involvement of one or more of their potentially reactive centres: the labile hydrogen (in secondary amides), the nucleophilic atoms of oxygen or sulphur, and the electrophilic atoms of phosphorus and carbon of the P=X- and C=Y-groups. However, in their reactivity, compounds (I) are markedly different, depending on the nature of atoms X and Y and their bonding, and on the nature of the substituents at the (thio)carbonyl and (thio)phosphoryl centres.

N-Phosphorylated amides (I, X = Y = O) are relatively inert and only a limited number of their reactions have been studied. The replacement of chlorine atoms at the phosphorus centre has been discussed in section II.1. *N*-Acyl- and *N*-thioacyl-phosphoromonoamidates, obtained by alcoholysis of the corresponding dichlorides, react with PCl_5 to give the corresponding *N*-phosphorylated iminochlorides[39,61] which are valuable synthons for the preparation of other derivatives of I.[12,13,17,34,121]

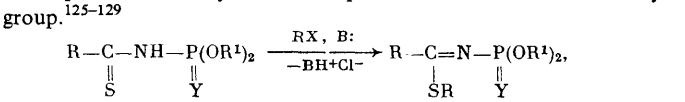


X = O, S.



The reaction of PCl_5 with arylcarboxylic acid *N*-phosphinylamides depends on the nature of the substituents in the phosphinyl group: dichloro- and diaryloxy-phosphinyl derivatives are also converted into iminochlorides, whereas bis(arylamino)- and diaryl-phosphinyl derivatives are cleaved to give the corresponding phosphorus(V) acid chloride and aryl cyanide.[15,24]

As *N*-phosphorylated amides (I, X = Y = O) are weakly acidic, they are readily converted to the corresponding salts on treatment with alkali metal hydroxide or alkoxide;[20,122,123] depending on the conditions, hydrolysis of *N*-phosphorylated amides may take place[124] either by cleavage of the P–N[38,56] or C–N[42] bond.

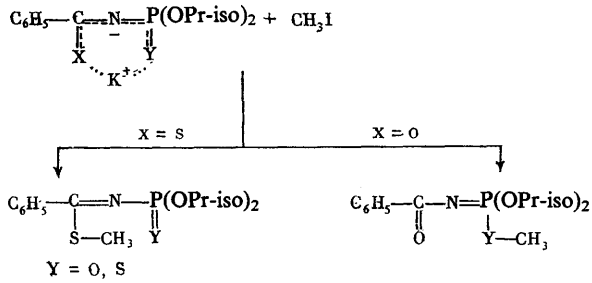


Treatment of tertiary *N*-thiophosphorylated amides with sodium alkylmercaptides effects isomerisation of the thiophosphoryl groups to give the corresponding sodium thiolophosphoramidates (XXXIII) which are readily converted to diesters (XXXIV) with alkyl halide. The products are analogues of acephate.[46]

Attempts to alkylate *N*-phosphorylated amides with alkyl halides in the presence of triethylamine were without success, even on prolonged heating of the reactants,[125] Evidently, the nucleophilicity of the OPNCO group is insufficient for nucleophilic substitution under these conditions.

Amides (I), where either or both of the oxygen atoms (X,Y) are replaced by sulphur, are considerably more reactive. The alkylation of *N*-phosphorylated thioamides (I, X = S, Y = O) and *N*-thiophosphorylated thioamides (I, X = Y = S) with alkyl halides takes place exclusively at the sulphur atom of the thiocarbonyl group.[125–129]

Y = O, S; R = Alk, CH_2COOH, $CH_2COOH \cdot N(C_2H_5)_3$, $CH_2C(O)OCH_3$, CH_2CN.



Complete regioselectivity was observed on alkylation with monochloroacetic acid, -acetic acid ester, -acetonitrile, and -acetic acid triethylammonium salt.[126]

On methylation of (I, X = O, Y = S) with diazomethane, S-methylation of the thiophosphoryl group was preferred over N-methylation by a factor of 9:1.[128] However, on alkylation of dimethylthiophosphinic N-thiobenzoylamide with diazomethane, the sulphur atom of the thiocarbonyl group is marginally more reactive than the sulphur atom of the thiophosphinyl group (by a factor of 6:5).[51]

$$C_6H_5C(S)NHP(S)(CH_3)_2 \xrightarrow{CH_2N_2} C_6H_5C(SCH_3)=N-P(S)(CH_3)_2 + C_6H_5C(S)-N=P(SCH_3)(CH_3)_2.$$

With the *N*-potassio derivatives of (I), the regioselectivity of alkylation is higher[124] (see Scheme 7). Thus. methylation of *N*-phosphorylated and *N*-thiophosphorylated *N*-potassiothioamides takes place exclusively at the thiocarbonyl group, irrespective of the nature of the Y atom (O or S); in contrast, with *N*-phosphorylated and *N*-thiophosphorylated amides, reaction takes place only at the phosphoryl (or thiophosphoryl) centre. The yield of alkylated product is always high (73–86%).[129]

Scheme 7

These studies verify that the regioselectivity of alkylation of (I) is dependent on the nature of the nucleophilic centres present and on the reaction conditions. The sulphur atom of the thiocarbonyl group possesses the highest nucleophilicity and polarisability. Suitably activated thiophosphoryl and phosphoryl groups may also be alkylated, but the carbonyl oxygen is effectively inert under these conditions. Alkylation of the XCNPY function can be promoted by increasing the basicity of the medium: by choosing a stronger base (or superbase), by the addition of crown ethers, or by conducting the reaction under phase transfer catalysis conditions. The nature of the alkylated product depends also on the type of amide: *N*-thiocarbonyl derivatives afford imino(thio)phosphates, whereas *N*-acyl derivatives yield phosphazo compounds (see Scheme 7). The nitrogen atom is relatively inert, presumably for steric reasons

The high nucleophilicity of the thiocarbonyl group in *N*-phosphorylated and *N*-thiophosphorylated thioamides is the salient factor determining their reactivity. In the absence of catalyst, these thioamides add to compounds with a carbon-nitrogen multiple bond. Thus, interaction with *N*-acetyltrichloroacetaldimine under mild conditions leads, exothermically, to adducts (XXXV) in >90% yield. The reaction takes place over several hours.[130]

$$(RO)_2P(X)-NH-C(S)-R^1 + CCl_3CH=N-C(O)-CH_3 \longrightarrow (RO)_2P(X)-N=C(R^1)-S-CH(CCl_3)-NH-C(O)-CH_3$$

X=O, S. (XXXV)

In a similar way, the thiocarbonyl sulphur of *N*-thiophosphorylated thioamides reacts with cyclohexyl isocyanide to give S-iminoformyl derivatives:[131]

$$XC_6H_4-C(S)-NH-P(S)(OR)_2 + \text{cyclo-}C_6H_{11}N=C: \rightarrow (RO)_2P(S)-N=C(C_6H_4X)-S-CH=N-C_6H_{11}\text{-cyclo}$$

Evidently, reactions of thioamides (I) may proceed via an initial isomerisation into an imidoyl thio- or dithiophosphate. Thus, *N*-thiophosphorylated thioformamides (XXVI) interact with aromatic amines by nucleophilic attack at the methine carbon of the intermediate anil (XXXVI) to give the corresponding formamidine salts of dithiophosphoric acid O,O-diesters (XXXVII).

$$H-C(S)-N(Ar)-P(S)(OR)_2 \rightleftharpoons Ar-N=CH-S-P(S)(OR)_2 \xrightarrow{ArNH_2} [Ar-N=CH-NHAr]\cdot[HSP(S)(OR)_2]$$

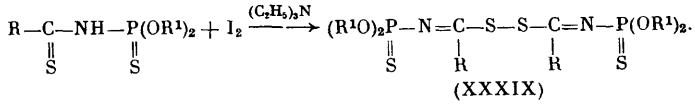
(XXVI) (XXXVI) (XXXVII)

The latter compounds were also prepared independently from a mixture of the appropriate dithiophosphoric acid and anil.[71,86] Acidic cleavage of tertiary *N*-thiophosphorylated thioamides by protic reagents such as water or monothiophosphoric, acetic, thioacetic, and trifluoroacetic acid is thought to proceed in a similar way.[132] It is proposed that this reaction, which takes place even at room temperature, involves an intermediate imidoyl dithiophosphate formed via amide-imidoyl tautomerism. The protic reagent then reacts to give the corresponding thioamide and anhydride (XXXVIII).[132]

$$R-C(S)-N(R^1)-P(X)(OR^2)_2 \rightleftharpoons R-C(S-P(X)(OR^2)_2)=N-R^1 \xrightarrow{HA} R-C(S)NHR^1 + A-P(X)(OR^2)_2$$

(XXXVIII)

A=OH, XP(S)(OR³)₂, OC(O)CH₃, XC(S)CH₃, OC(O)CF₃.

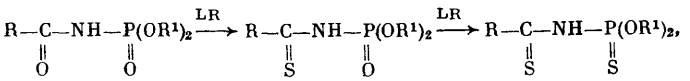


A number of redox reactions of *N*-thiophosphorylated amides and thioamides have also been studied. The outcome depends on the nature of the reagent. Thus, mercuric oxide effects replacement of the thioacyl sulphur atom by oxygen, thereby converting *N*-phosphorylated thioamides to the corresponding amide.[61]

$$ArC(S)NHP(O)(OR)_2 + HgO \rightarrow ArC(O)NHP(O)(OR)_2 + HgS.$$

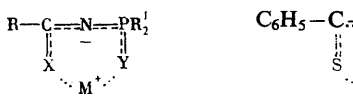
Nitrogen oxides, iodine in ethanolic KOH, and hydrogen peroxide react with *N*-thiophosphorylated thioamides by sequential replacement of the two sulphur atoms by oxygen.[133] The phosphoryl sulphur is replaced initially, followed by the thiocarbonyl sulphur:

$$R-C(S)-NH-P(S)(OR^1)_2 \xrightarrow{[O]} R-C(S)-NH-P(O)(OR^1)_2 \xrightarrow{[O]} R-C(O)-NH-P(O)(OR^1)_2.$$



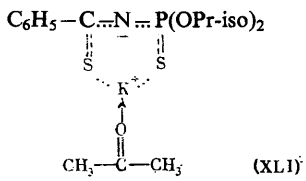
The oxidation of *N*-thiophosphorylated thioamides with iodine in carbon tetrachloride takes a completely different course in the presence of triethylamine:[133,134]

(XXXIX)

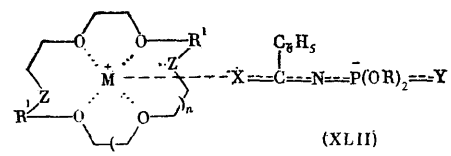


The disulphide (XXXIX) is also formed in small amounts by interaction of *N*-thiophosphorylated thioamides with lead oxide.[119]

There is also the possibility of sequential replacement of the oxygen atoms by sulphur, i.e. the conversion of *N*-phosphorylated amides to *N*-thiophosphorylated thioamides.[133] Lawesson's reagent (2,4-*bis*(*p*-methoxyphenyl)-1,2,3,4-dithiadiphosphetane 2,4-disulphide) is very effective for this purpose.[70]

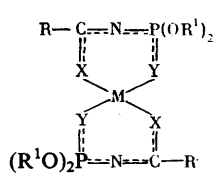


where LR = Lawesson's reagent.



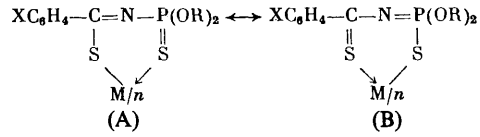
Recently, several publications have appeared (mainly from our own research) on the synthesis and properties of metallic salts of (I),[54,67,97,113,117–119,136,137] Alkali metal salts are formed from (I) by treatment of the amides and thioamides with alkali metal hydroxide or alkoxide. These salts can also be obtained by phosphorylation of amides and thioamides with (thio)phosphorochloridates under phase transfer catalysis conditions in the presence of base and a crown ether.[104,113] Salts of type (XL), their solvate complexes (XLI), and crown ether complexes (XLII) may all be prepared by these routes.

(XL)



(XLI)

(XLII)



X, Y = O, S; Z = O, NH; n = 0, 1; M = Na, K; R = Alk; R^1 = $-(CH_2)_2-$ o-C_6H_4

Both Na^+ and K^+ complexes of type (XL) (X and Y = O or S) have been prepared.[113,117] Amides (I) also form 1:2 complexes (XLIII) with divalent metal cations.[51,66,97,118,119,136,137]

(XLIII)

These complexes are obtainable from both metal salts (M = Co^{2+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, Pb^{2+}, Pd^{2+}, Hg^{2+}, etc.) and metal oxides (M = Hg, Pb). IR-, NMR-, and EPR-spectroscopic studies of [XLIII, M = Ni(II), Cu(II), Hg(II)] have shown that complexes exist as an equilibrated mixture of two isomeric forms, structure (A) predominating.[97,136]

(A) (B)

Spectrophotometric and potentiometric determinations of the stability of these complexes indicate that those with sulphur ligands are more stable. In complexes of the type ML_2, electron-accepting substituents (X) in the benzene ring of the thioacyl fragment tend to destabilise, and electron-donating substituents stabilise the structure. X-Ray analyses have also been performed on the mercury and lead complexes of *N*-phosphorylated thioamides (XLIII),[118,119] the bond lengths [for compounds (Ik) and (Il)] being given in Table 3.

V. Practical applications

As was mentioned earlier, of all the compounds of type (I), most attention has been given to O,S-dimethyl *N*-acetylthiophosphoromonoamidate which is a highly effective insecticide with low toxicity and a broad spectrum of activity. The compound is known under its commercial name, acephate, which is marketed by many companies throughout the world.[138] It is primarily a contact insecticide with limited systemic activity, being degraded in plants relatively quickly to give non-toxic products. In the soil, it is effective, on average, over 15 days, and it is completely deactivated within a year. According to the French company Chevron, which markets acephate under the name of Orthene, its protective action lasts from 7–10 days.[139]

The toxicity of the compound is relatively low: LD_{50} 945 mg/kg (orally in rats); 361 mg/kg (orally in mice); 2000 mg/kg (s.c. in rabbits).[49,139]

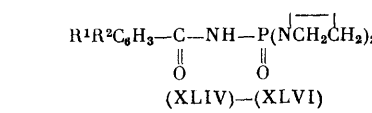
Two reviews on the chemistry and biological properties of acephate have been published[140,141] (the data therein being excluded from the present review). More recent information on the compound is given below. There have been dissertations on a whole range of problems associated with the use of acephate in the battle against pests and crop disease. The compound is very active against ticks and plant lice,[142–148] ants,[149,150] tobacco and maize infestations,[151,152] the larvae of ticks,[153] and termites.[154,155] There are also data on the use of acephate as an antiviral agent in plants,[156] and as a compound which affects the growth and quality of certain floral cultures.[157]

In a number of formulations containing acephate and a second active ingredient, synergism has been observed with a number of compounds: 2,2-dimethyl-1,3-benzodioxol-4-yl methylcarbamate, metoxil or carbaryl; peremetrin, O,O-dimethyl S-[α-(ethoxycarbonyl)benzyl] dithiophosphate, S-(3-phenyl-2(1*H*)-pyrazinon-5-yl) O,O-diethyl thiophosphate (in 1:4 proportion), ethoprophos (in 1:3 to 5:1 proportion), basudin (in 1:4 to 4:1 proportion), and 0.2–4% epoxidised linseed oil.[157–179] These combinations have been used successfully to combat various plant infestations, house flies, mosquitoes, etc.

As acephate is used extensively in agriculture, much attention has focussed on methods of detecting traces of this compound and one of its more toxic metabolites, O,S-dimethyl thiophosphoro-

monoamidate (monitor), in the surrounding soil,[180–182] in various organisms,[183] in biological samples,[184] in pesticidal formulations and commercial products,[185] in water, in food products, and in various agricultural products.[186–191]

A vast amount of research has been devoted to preparing analogues of acephate and diversely functionalised derivatives. The following *N*-acylaminophosphoryl derivatives, $(R^1Y)(R^2S)P(O)-NR^3-C(O)R^4$, have been reported: compounds where R^1 and R^2 = C_1-C_6-alkyl, alkenyl, alkynyl, R^3 = H or C_1-C_{18}-alkyl, R^4 = H, C_1-C_{18}-alkyl, C_3-C_8-cycloalkyl, C_2-C_{18}-alkenyl, C_3-C_{18}-alkynyl, Y = O,S;[48,49,192] compounds of type $(R^1S)(R^2O)P(O)NR^3-C(O)R^4$, where R^1 = Me, Et, $CH_2=CHCH_2$, $HC\equiv CCH_2$, R^2 = Me, Et, R^3 = H, Me, R^4 = H, alkyl, halogenalkyl, alkoxy, alkylthio, alkoxyalkyl, alkylthioalkyl, alkenyl, $(CH_2)_nPh$ (*n* = 1,2), $CH=CMe_2$, $CH=CHPh$, CH_2YPh (Y = O,S);[49,193] compounds of type $(R^1O)_2P(S)-NH-C(O)R$, where R^1 = C_1-C_3-alkyl, R = aliphatic residue with 0–4 halogen atoms, C_6-C_{12}-aryl with 0–2 halogen atoms;[58] compounds of type $(R^1O)_2P(S)-NH-C(O)CH_2R^2$, where R^1 = C_1-C_3-alkyl, R^2 = H, aliphatic residue.[59]



It has been shown that *N*-phosphorylated and *N*-thiophosphorylated halogenocarboxamides possess high herbicidal,[194] fungicidal,[194–197] and antimicrobial[198] activity; furthermore, acetylphosphates and -thionophosphates with halogenalkoxy groups on phosphorus also display the same pesticidal properties as amides (I).[56,57]

Patents have been deposited on pesticidal acephate salts and analogues thereof: $M^{2+}[(R^1O)(R^2S)P(O)-N=C(O^-)R]_2$, where M = Ca, Ba; R^1, R^2 = C_1-C_6-alkyl, R = C_1-C_{18}-alkyl;[122] $MS(R^1O)P(O)-NR_2-C(O)R$, where M = Na, K, NH_4, R^1 = C_1-C_6-alkyl, alkenyl or alkynyl, R^2 = H, C_1-C_6-alkyl, R = H, alkyl, phenyl, aralkyl or alkylaryl which may contain fluorine, chlorine, bromine, or a C_1-C_4-alkylthio group.[199]

It is reported that S-sodio derivatives may be used as starting materials for the preparation of acephate analogues, obtained by alkylation with alkyl halides or alkyl sulphonates[123] (see also Section IV and Ref. 46).

Numerous structure-activity studies have been carried out on acephate derivatives with pesticidal activity (see Ref. 49 and references cited therein). It has been found that it is the environment immediately surrounding the phosphorus atom which largely determines the biological activity of *N*-phosphorylated amides and thioamides. Thus, alkoxy and alkylthio groups on phosphorus impart pesticidal activity to amides (I). However, compounds with ethylenimino groups on phosphorus have another important practical use: as effective antiviral agents.[108–112] Bis(ethylenimino)-phosphoryl derivatives of substituted benzamides are the most active in this respect.[200]

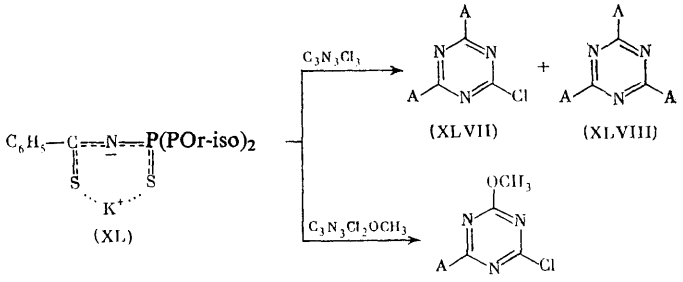
In pharmacological studies of amides (I), most research has been devoted to evaluating the activity of *N*-bis(ethylenimino)phosphoryl-benzamide derivatives, notably benzoTEF (XLIV), fluorobenzoTEF (XLV), and diiodobenzoTEF (XLVI).[108–112]

(XLIV)–(XLVI)

(XLIV): $R^1=R^2=H$; (XLV): $R^1=H$, $R^2=4$-F;

(XLVI): $R^1=R^2=2,5$-I.

Clinically, benzoTEF has proved to be highly effective in the treatment of ovarian and lung cancer, and has also proved to be beneficial in the treatment of breast and stomach cancer, and other malignant diseases.[201] Fluorobenzoyl analogues of this drug have an even broader spectrum of therapeutic activity, having, for example, antiblastic properties.[202] Other analogues of benzoTEF have been synthesised and their toxicity (on s.c. and i.v. administration) measured. These data have shown that *n*-[bis(ethylenimino)-phosphoryl]-arylamines and-acylamines[21,203–209] generally possess lower toxicity than tris(ethylenimino)phosphate (TEF), which, having a relatively high LD_{100} value (30 mg/kg),[200] is widely used medicinally.



In view of the broad application of these compounds medicinally, there have been several reports in the literature on methods of identifying and assaying the drugs quantitatively in pharmacological preparations and in organisms.[210–214]

In recent years, other pharmacological uses of phosphorylated amides (I) have been studied. Their antiviral activity, for example, has been a topic of our researches.[67,215] Notably, it has been shown that acephate, *N*-thiophosphorylated thioamides (I, R = Me, R^1 = OPr-*i*, R^2 = H, X = Y = S), and the thiobenzamide analogue protect animals (white mice) exposed to influenzal pneumonia. The oxygen analogues (I, R = Ph, R^1 = OMe, R^2 = H, X = Y = O) do not possess antiviral properties, but the water-soluble N-sodio derivatives in certain instances do display an effective antiviral action.[67] A comparison of the antiviral activity of thioacetamide with that of the *N*-phosphorylated analogue has shown that there is little pharmacological difference between the two, but the phosphoryl derivative is less toxic.

Metallo-derivatives (XL) and (XLIII),[216] as well as crown ether complexes (XLII),[215] also possess antiviral activity. It has been found that the antiviral properties of these salts depends little on the nature of the organic substituents; it is the metal itself which largely determines their activity. A comparison of the antiviral properties of crown ethers and derivatives of type (XLII)[215] has shown that, whereas activity in the crown ethers is completely absent, the amide complexes (XLII), on the other hand, possess high activity. Effectively, it is the phosphorus-containing residue which is responsible for the biological activity, while the crown ether serves as lipophilic handle thereby facilitating penetration of the active agent across the cell membrane, i.e. enhances the rate of assimilation of the virucide in cells.[215]

In the search for new types of biologically active compound, a variety of functionalised *N*-phosphorylated amides and thioamides have been synthesised and tested. *N*-Substituted amides, obtained by alkylation with chloroacetic acid (see Section II[126,216,217]), are noticeably inferior to *N*-unsubstituted derivatives in their insecticidal and acaricidal properties. Triazine derivatives have also been prepared by treatment of *N*-potassio-*N*-thiophosphorylated thioamides with cyanuric chloride and its methoxy derivative. The former reacts by replacement of two or three chlorine atoms to give, for example, (XLVII) and (XLVIII), while the methoxy-analogue reacts by displacement of only one chlorine to give (XLIX). Compounds (XLVII) and (XLVIII) possess high fungicidal,

herbicidal and insecticidal activities, the former being 2.5 times as active as carbophos against sugar-beet lice.[218]

Among the metallo derivatives (XLIII), complexes with Cu(II), Ni(II), Co(II), Zn(II), Hg(II), Pb(II) and Ag(I) have also been found to possess insecticidal, fungicidal and antiviral properties.[54,216,218]

The synthesis of *N*-metallo derivatives of (I) broadens the potential value of these compounds. Thus, *N*-thiophosphorylated thioamides may be used as highly effective extractants, notably for the separation of copper from iron, zinc, lead, nickel, cobalt and other elements.[54,97,136,137] *N*-(Diisopropoxythiophosphoryl)benzamide, on the other hand, has been used in a liquid ion-exchange electrode for the determination of mercury in the presence of a variety of metal ions: Cu(II), Ni(II), Co(II), Zn(II), Cd(II), Pb(II), Mn(II), Fe(III), Cr(III), Be(III), Al(III), and Ag(I).[219]

In collaboration with others, we have also found new uses for amides (I) and their metallo derivatives (XL). Thus, amides (I) have been found to inhibit the corrosion of steel in concentrated solutions of mineral and carboxylic acids. In this respect, compounds with a P=S or C=S group are more effective than analogues with a P=O or C=O bond. These compounds offer 70–99.5% protection of steel in acids at varying concentration, and can also be used in galvanic systems.[220]

Potassium and sodium salts (XL) possess excellent sorption properties. In this instance, replacement of an oxygen atom in *N*-phosphorylated amides by an atom of sulphur leads (other things being equal) to an increase in chromatographic polarity constants relative to all standard sorbates; the potassium salts are more effective than sodium salts in this respect. The energy of activation of the absorbed molecules was found to be dependent on the nature of the organic substituents in the sorbent which determines their selectivity.[221]

Finally, it should be noted that macrocyclic complexes of structure (XLII) possess liquid crystal properties. On melting, compounds (XLII) are transformed into homogeneous smectic droplets (spherolites). On cooling with exposure to a narrow beam of light from a microscope, the droplets are seen to develop thread-like off-shoots. Smectic phases with structured layers are formed in these complexes. Compounds (XLII) are clearly of interest because they are mesomorphogenic in nature, and form an electrically conducting meso-phase. By contrast with crown ether complexes (XLII), alkali metal salt complexes (XL) do not display liquid crystal properties.[113,222,223]

---o0o---

From the data presented in this review, it is clear to us that studies on the chemistry of phosphorylated amides have proved valuable and should continue to be so. In particular, the practical applications of *N*-phosphorylated amides and thioamides may even be extended to other fields. Even though polyfunctionalised amidophosphates are relatively accessible and display a broad spectrum of reactivity, they have been rarely employed as intermediates in organic synthesis. There are few reactions involving functionalisation of the XCNPY system, especially where the (thio)phosphoryl centre participates. The participation of the nitrogen atom of secondary amides in chemical reactions is an intriguing question. We await quantitative structure-reactivity data on the reactions of (I) which involve functionalisation and tautomerism. Evidently, many new developments will emerge from further studies on the complexation of (I), their extracting properties, and their use as analytical reagents for the determination and separation of heavy metal ion in biological samples, in sewage, and in industrial effluent. It is difficult to foresee what other important and interesting questions will be raised in connection with the chemistry and use of (I) and derivatives thereof.

Ageing and stabilisation of polymers

G E Zaikov
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The most recent information on the kinetic mechanisms of the degradation of polymers and methods of stabilising different classes of polymer materials is presented. Progress in the field of thermal, thermooxidative, ozone, photo-oxidative, radiation, mechanically initiated, hydrolytic, and biological degradation of polymers is reviewed. The problems in predicting the stability of polymers, their blends, and certain composite materials during storage and use are discussed. New methods of studying degradation processes are described. The effect of the specific nature of the solid state on reactions in a polymer matrix is examined.

The bibliography includes 145 references.

I. Introduction

Problems concerning the ageing and stabilisation of polymers still constitute a vital question for research chemists and practical personnel working in the field of macromolecular compounds. Prolongation of the lifetime of polymer products during use and storage is equivalent to increasing the manufacture of these products and improving their quality. A sufficiently accurate prediction of the lifetime of reliable operation enables polymer products to be used to a greater extent without risk of failure.

Problems relating to protection of the environment from polymer waste products have assumed prominence at the present time. The scientific principles of the degradation of used polymers to monomers followed by their polymerisation or the pyrolysis of polymers to low-molecular-weight compounds with recovery of the products obtained have been developed for this purpose. Since up to the present time a significant proportion (in many countries the main part) of polymer waste products has been burnt in special furnaces or on dumps, questions relating to environmental protection have proved to be closely linked to problems in the pyrolysis and burning of polymers. The secondary processing of used polymers to new polymer products is also of considerable importance.

The use of degradation processes for the modification of polymer products in order to improve their performance (principally to change their surface properties) and also the production of polymers with a controlled "lifetime" have once again assumed vital importance.

The question of preventing the degradation of polymers was first raised in our country in the second half of the 1940s.[1–3] It was developed further in studies by M B Neuman, et al.[4–6] Subsequently a strictly quantitative approach was applied to it.[7,8] From 1966 to 1984 studies on this problem were directed in our country by Academician Emanuel',[9,10] who extended the scope of research and established international cooperation.[11,12]

II. Effect of intermolecular interactions on the kinetics of degradation processes in a solid polymer

It was demonstrated in the studies of N M Emanual', et al.[9,10] that a solid polymer has a number of properties that are mainly dependent on the mobility of the polymer chain. The concept of "polychromatic kinetics" of the reactions in the polymer matrix was put forward, where, in addition to the molecular-weight distribution, the dependence of the rate constants of the fundamental chemical reactions on the diffusion properties of the system, the accessibility of the reacting bonds, the optimum nature of the structure of the activated complex, etc., should be taken into account. "Polychromaticity" of the reaction kinetics is mainly caused by energetic factors (quite a wide scatter of values of the energy of activation for a given fundamental reaction).

In recent years a new model has been put forward,[12–15] according to which the polychromaticity of the kinetics of reactions in a polymer matrix is due to a change in the entropy term that forms part of the expression for the rate constant. The number and distribution of the various types of intermolecular bonds (donor-acceptor, electrostatic, Van der Waals, etc.) in a sample of polymer

determine the distribution of unassociated and associated monomer units along the blocks.

Starting from the theory of an activated complex, an expression was obtained for the rate constant of scission of a polymer chain

$$k=k_0 \exp\left[(\alpha_1-\alpha)n\right], \quad (1)$$

where k_0 is the rate constant of reaction without taking into account the change in flexibility of the chain, α and α_1 are coefficients representing the loss in flexibility of the unassociated section of the chain with a length of n monomer units in the initial and transition states respectively. The term $\exp(\alpha_1-\alpha)$ mainly depends on the entropy of the system since α and α_1 characterise the loss in flexibility of the chain.

The constant k_0 usually has a similar value to the rate constant of a reaction involving low-molecular-weight products. It follows from Eqn. (1) that the energy of activation does not depend on the length of the block—the pre-exponential term of the rate constant varies with a change in length of the block. In the initial state the entropy of the system is distributed according to the absence of free rotation of the chain units.

Since in practice there is a distribution of unassociated monomer units with respect to block length, the reaction kinetics can be polychromatic. They depend on the past history of the sample, since block distribution is determined by the conditions of synthesis, processing, and operation of the sample in a stationary but not equilibrium state. With an increase in temperature both the rate constants of the reactions taking place and the ratios of blocks of different lengths change. With these concepts it is possible to interpret in a new way the dependence, which has been recorded by many research workers, of the rate of the process and the apparent energy of activation on temperature.

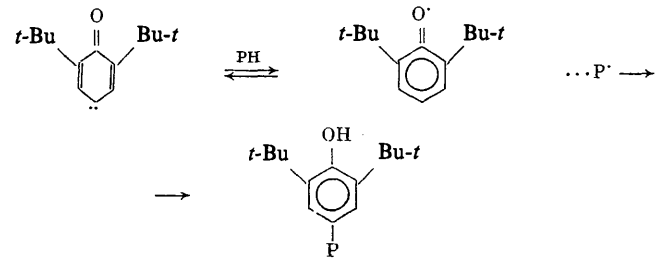
When a block of unassociated monomer units reaches a given length in the system, there is a thermodynamic possibility of chain scission in the middle of the block. From this a different interpretation can be given to the change in the degradation process from scission at the chain ends (low temperatures) to "random" scission (high temperatures), which occurs in a number of cases, and to reactions in cross-linked polymers only starting from a given temperature.

III. Effect of the supermolecular structure of a polymer on thermooxidative processes

The question concerning the nature and role of the supermolecular structure of amorphous polymers is related to the physicochemical behavioural characteristics of polymer products. In recent years quite a large amount of information on the role of supermolecular structures in polymer reactions has been published.

A number of scientists[16–23] have advanced the theory of the role of structural microheterogeneity in chemical reactions that occur in a polymer matrix. A model of heterophase processes in the solid state has been developed. It has been proposed that a polymer consists of a large number of small entities and the reactions in a polymer occur on their surface.

The role of structural microheterogeneity in chemical reactions was examined in studies of a model polymer chain reaction involving benzoyl peroxide. It was demonstrated in the case of vitreous polycarbonate,[16] cellulose triacetate,[17] polypropylene,[18] and molten polyethylene[19] that conversion of the macromolecules may involve successively induced heterogeneous reactions that occur in two structural zones of globular aggregates—in a relatively dense shell and in a looser three-dimensional microphase (the "roe" model).



Studies on the oxidation of poly(ethylene oxide) showed that microheterogeneity predetermines the heterophase conditions for oxidation.[20,21] From the proposed structural kinetic model of reaction it was possible to find a kinetic equation that represents the change in concentration of hydroperoxide [ROOH]

$$d[ROOH]/dt = W_{max}^{ROOH}[ROOH]^{1/2}(C+[ROOH])^{-1/2} - aW_i k_{[ROOH][A]}[ROOH]\,t \quad (2)$$

and the corresponding integral expression for [ROOH]t, which is in agreement with the experimental data. In Eqn. (2) W_{max}^{ROOH} is the maximum rate of formation of [ROOH] attained at the moment of complete loss of the function as branching agent by hydroperoxide; C is a composite constant; W_i is the rate of initiation (initiation occurs by a heterogeneous mechanism at the interface of structural zones); $aW_i t$ is the concentration of aldehyde formed in the melt that reacts with ROOH and ensures that $[ROOH]_{max}$ is reached; $k_{[ROOH][A]}$ is the rate constant of the reaction between aldehyde and ROOH. This result is important in that it stimulates the interest of research workers in the elucidation of the role of supermolecular structures in the autooxidation of polymers. The theories relating to the role of microheterogeneity in the heterophase oxidation of polymers have so far not been recognised by the majority of specialists working in the field of thermooxidative degradation of macromolecules. However, there is clear evidence in favour of this hypothesis. If it is shown in future that the process in a polymer does occur precisely in this manner, it will be necessary to revise the considerable amount of quantitative data obtained previously. For example, many rate constants of processes in a polymer matrix may prove to be only apparent overall constants rather than true constants of the fundamental stage.

IV. A new method for studying features of the physical structure of polymer matrices

Davydov, et al.[24,25] have proposed a new method for studying the structure of polymer matrices using the reactions of triplet carbenes. These reactions occur in a polymer via the formation of intermediate radical pairs as a result of the transfer of a hydrogen atom from the C–H bond of macromolecules to a carbene followed by their recombination

where PH is a macromolecule of the polymer matrix.

The kinetics of the conversion of triplet carbenes reflect the features of the physical structure of a matrix at the level of the effective distances in radical pairs (of the order of 3–5 Å). The effect of an external magnetic field on the rate of this process at low temperatures has recently been detected.[24,25] In the case of poly(methyl methacrylate), for example, at a temperature of 77 K the maximum rate occurs at zero field and at a field of 5000 Oe (Fig. 1).[24] The magnetic effect may be attributed to structural features of PMMA,[24,25] if it is assumed that in this radical process two types of intermediate radical pairs differing in their geometric configuration are formed.

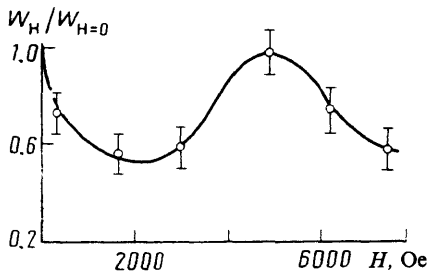


Figure 1. Dependence of the initial rate of conversion of carbenes in PMMA on the strength of the magnetic field.[24] $W_{H=0}$ is the initial rate when $H = 0$.

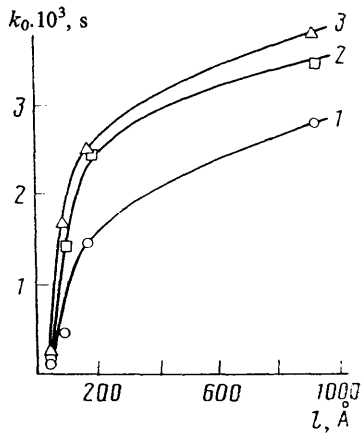

Figure 2. Dependence of the average rate constant for conversion of carbenes on the distance between Aerosil particles in filled PMMA at: *1*, 100; *2*, 113; *3*, 125 K.[25]

Modification of the physical structure of a matrix can be recorded from the change in kinetic parameters of the reaction of carbenes. For example, as the content of an inert filler (Aerosil) increases in PMMA to 65 wt.%, the rate constant of the thermal conversion of carbenes decreases by a factor of 10. The introduction of a filler modifies the physical structure of the polymer in the boundary layer. From kinetic analysis of this lattice reaction it is possible to determine the width of the boundary layer in filled polymers. It is clear from Fig. 2 that with a distance of less than 200 Å between the Aerosil particles, which corresponds to the apparent width of the boundary layer, there is a sharp fall in the rate of reaction.[25]

The method described here can be used to determine the structural features of composite materials (in this particular case—the width of the boundary layer). This has established its future potential.

V. Problems in the stabilisation of polymers during processing. Stabilisation at high temperatures

In recent years there has been increasing interest from research workers in questions relating to the stabilisation of polymer materials during processing, when the main factor causing degradation is mixing (in other words, a rapid shear deformation) of the melt.[11] Two types of stabiliser are recommended for use—amines of the class of sterically hindered piperidines and organic phosphites.[9]

These stabilisers reduce the degree of mechanical degradation processes in the polymers during their processing in an extruder and they considerably reduce the consumption of the principal stabiliser—the antioxidant that is introduced to prevent oxidative degradation of a polymer product during use and storage.

Currently the processing of polymers is being attempted in an inert atmosphere, which considerably reduces the problems related to mechanical oxidative destruction. Because of the high cost of the stabilisers the question has arisen concerning the reduction of their nonrational consumption in evaporation, washing out, bleeding, etc. As a result of this, researchers have shown greater interest in the problems of the solubility of stabilisers in a polymer and the diffusion of additives introduced into a polymer material.[7,26–30]

It was recently shown[27] that the solubility of antioxidants varies in accordance with temperature in a very complex manner and sometimes it even decreases as the tempeature increases. Phase transitions in the polymer constitute the reason for this; on passing through the melting point of the chemical added to the polymer, the heat of solution of the polymer changes and relaxation phenomena occur, leading to an irreversible change in polymer structure at high temperatures (above the glass-transition temperature T_g).

In recent years a property of the solution processes of additives (including stabilisers) such as the dependence of the solubility on the content of polar groups in aliphatic polyamides has been identified. On changing from polyethylene to polyamides-6 and -66 the solubility of the antioxidants usually passes through a maximum. With a small content of amide groups, increasing them leads to an increase in solubility, while when there is a high content, there is a decrease in solubility when they are increased. This is caused by the competition between the increase in solubility due to sorption of the antioxidant (phenol or amine) on the polar groups of the polyamide and its reduction because of the increase in the total compactness of the polymer that is cross-linked by amide–amide hydrogen bonds.[28]

Studies on the high-temperature stabilisation of polymers at $T >$ 200 °C are of considerable interest. Under these conditions conventional stabilisers (phenols, amines) are converted to initiators by thermal and thermooxidative degradation[8,9,11] because of the weakness of the PhO–H or Am–H bonds. Previously it was proposed to use salts of organic acids and metals of variable valence[31] as high-temperature stabilisers. These compounds, being

introduced into the polymer in advance, would decompose at high temperatures to metals or metal oxides in a lower oxidation state. Oxygen reacts with these thermolysis products much more rapidly than with the polymer. Thus, dispersed metals and their oxides protect the polymer from oxidation until they themselves reach a higher oxidation state. However, this method of stabilisation is not always effective, since the transition metal oxides can themselves be catalysts of thermooxidative processes.[8–11]

There may be greater future potential in certain stabilisers of a novel type[30]—polymeric or oligomeric compounds that degrade during oxidation to form free radicals that are free valence carriers. One of these stabilisers is poly(phenylenephenylstibine).[26]

Macroradicals that occur on the polymer chain are virtually immobile. That is why chain termination through recombination of macroradicals occurs extremely slowly even at elevated temperatures.[29,30] The introduction of low-molecular-weight radicals that are capable of migrating in the polymer matrix by diffusion leads to an increase in the rate of quadratic chain termination, i.e. a reduction in the rate of thermooxidative degradation. It is evident from Fig. 3 that small additions of the stibine $-[-C_6H_4Sb(C_6H_5)-]_n-$ reduce the rate of oxidation, whereas at high concentrations of the stibine this rate increases. If the rate of generation of the light radicals that mainly participate in chain termination is less than the rate of formation of the active macroradicals in the oxidation of the polymer, these light radicals will inhibit the reaction. However, an excess of light radicals assists oxidation as a result of their participation in chain propagation reactions. Antioxidants of this type only begin to be effective above a certain temperature—the so-called decomposition temperature.[26]

The proposed method for the stabilisation of polymers at high temperatures[30] is suitable not only during processing but also when heat-resistant polymers are being used.

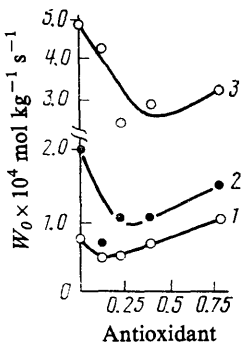

Figure 3. Variation in the rate of oxidation of poly(diphenylphenylene oxide) as a function of the concentration by weight of poly(phenylenephenylstibine) at: *1*, 653; *2*, 673; *3*, 693 K.[26]

Not only the chemical aspect of the reactions leading to inhibition of oxidation processes but also the physical factors related to the distribution characteristics of low-molecular-weight additives in the polymer matrix and the effect of these additives on the structure of the polymer melt have started to be taken into account recently. It is these effects that in a number of cases cause the acceleration of oxidation of a polymer when large concentrations of a reducing agent are introduced. Thus, the dependence of the induction period for the oxidation of polypropylene in the presence of gossypol (a sterically hindered phenol) on the concentration of dilauryl thiodipropionate (a polymer stabiliser) is shown in Fig. 4. The hydrocarbon heptadecane which simulates the hydrocarbon part of the dilauryl thiodipropionate molecule, behaves in a similar way to dilauryl thiodipropionate.[29] The physical aspect of this phenomenon is as follows. When the gossypol dissolves in the polymer its molecules are located in the so-called "potential holes". The number of these holes is limited by the solubility. Therefore, when another additive—dilauryl thiodipropionate (or heptadecane)—is introduced, some of the gossypol molecules are "knocked out" of the potential holes by these additives and are oxidised, resulting in an acceleration of the overall oxidation process.

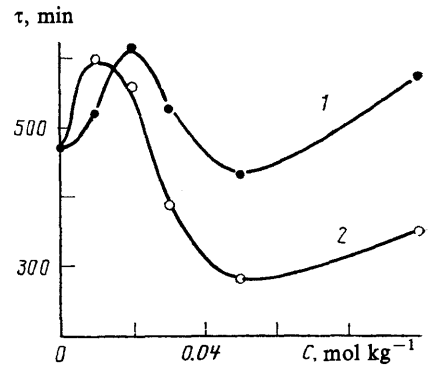

Figure 4. Dependence of the induction period for oxidation of polypropylene in the presence of 0.1 mol kg^{-1} of the natural stabiliser gossypol on the concentration of dilauryl thiodipropionate (*1*) and heptadecane (*2*) (T = 473 K, P_{O_2} = 300 mm Hg).[29]

An elucidation of the mechanism of the high-temperature inhibition of oxidation is one of the most important developments in studies of the chemistry of polymer degradation.[8] Although this process is very inconvenient to study as a considerable number of reactions are taking place simultaneously (several dozen reactions of this type have been identified up to the present time, including oxidation of the stabiliser itself),[32–36] practical requirements demand that increasing attention be given to high-temperature oxidation, since high temperatures are needed not only in polymer processing that is unavoidably accompanied by degradation but also in rapid methods of testing polymers for thermal and thermooxidative stability.

At the present time methods have been developed for the quantitative representation of the high-temperature inhibition of polymer oxidation.[32–36] For this purpose, the absorption of oxygen, accumulation of hydroperoxide (ROOH), and consumption of inhibitor (InH) are recorded and analysed throughout the whole induction period. By using a simple kinetic scheme[34,35] which includes kinetic chain transfer by the inhibitor radical (In$^{\cdot}$), it is

possible to represent the change in concentration of the three key reaction products—oxygen, hydroperoxide, and inhibitor.

Thus, a question that is important for the mechanism of inhibited oxidation of polymers—what happens (how complex do the kinetic mechanisms become) on changing from low temperatures, where the mechanism is quite simple and has already been established quantitatively,[37–42] to high temperatures[32–36]—has been resolved.

Scheme 1

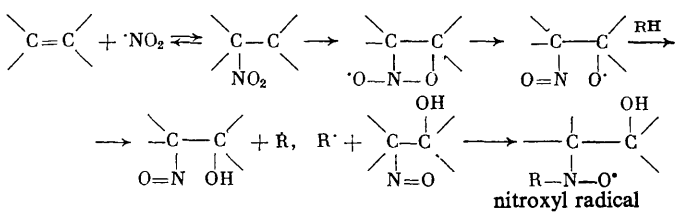
$$R^{\cdot} + O_2 \xrightarrow{k_1} RO_2^{\cdot},$$

$$RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot},$$

$$ROOH \xrightarrow{k_3} RO^{\cdot} + {}^{\cdot}OH \xrightarrow[O_2]{RH} 2RO_2^{\cdot}$$

$$RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_4} \text{molecular products} + O_2,$$

$$RO_2^{\cdot} + InH \xrightarrow{k_6} \text{inactive products},$$



$$In^{\cdot} + RH \xrightarrow{k_7} InH\ (\text{molecular products}) + RO_2^{\cdot}.$$

VI. Reaction between polymers and atmospheric contaminants

In recent years quantitative studies on the effect of components that contaminate the environment on the degradation of polymers have started to appear in the literature. Particular attention has been given to a study of the reaction between nitrogen and sulphur oxides and polymers.[43–46] The kinetics and mechanism of reactions involving nitrogen oxides have been studied in the greatest detail. It has been shown, in particular,[44–46] that the reaction of nitrogen dioxide with the double bonds of macromolecules (including rubbers and vulcanised materials) may be one of the most important ways of initiating the free-radical reactions of polymer ageing in an atmosphere contaminated by industrial waste gases.[44–46]

The reaction between NO_2 and macromolecules containing  bonds has been studied by many methods—EPR, UV and IR spectroscopy, and others. It has been found that nitroxyl radicals are amongst the main reaction products. Usually the two-stage scheme adopted for reactions in solution (the formation of a nitroxyl radical, its conversion to an α-nitro-β-nitroso compound, and acceptance of a second nitroxyl radical by the latter) cannot explain the formation of $(R)_2-NO^{\cdot}$ radicals in the solid state.[44]

A mechanism has now been proposed in which the occurrence of successive "pseudolattice" reactions that have a minimum steric migration of the free valence and which form $(R)_2-NO^{\cdot}$ radicals is assumed.[45]

An $R^{\cdot}$ radical is formed in the immediate vicinity of the nitroso group $(R)_2-N-O^{\cdot}$ and a dialkylnitroxyl macroradical can be a product of the lattice reaction. The formation of $(R'-C=O)-(NO^{\cdot})-R$ radicals in poly(methyl methacrylate) in the presence of NO_2 indicates the decomposition of alkyl macroradicals that is accompanied by cleavage of ester groups with elimination of $(C=O)-OCH_3$.

The reaction of NO_2 with macromolecules containing double bonds is formally given by the kinetic equation[46]

$$\frac{[NO_2]_0}{[NO_2]_t} - 1 = k_{app}t\,, \qquad (3)$$

which reflects the properties of solid-state reactions. The reaction of rubbers with NO_2 is accompanied by a decrease in concentration of C–H groups and the formation of nitro $(R-NO_2)$ and nitrate $(R-O-NO_2)$ groups.

Thus, it has been demonstrated[43–46] that the formation of $(R)_2-NO^{\cdot}$ radicals in reactions between NO_2 and polymers containing double bonds is a free-radical lattice process in which an alkoxyl radical is formed as an unstable intermediate, being highly active in transfer and decomposition reactions with scission of the polymer chain. This leads to ageing of the polymer material.

VII. Ozone ageing of rubbers and vulcanised materials

At the present time considerable progress has been recorded in a kinetic representation of processes involving the ozone cracking of elastomers.[47–50] By improving experimental methods it has been possible to identify the reason for the divergence in experimental results recorded earlier and to elucidate the kinetic mechanisms of the growth of cracks and stress relaxation in samples.[47]

The curves of the dependence of the specific surface area of growing cracks (S_τ) on time τ at difference concentrations of ozone have a similar shape to the well-established characteristics of the rate of autooxidation of hydrocarbons[8] and elastomers.[9] However, in contrast to oxidation by oxygen the ozone ageing of rubbers and vulcanised materials is known to have the characteristics of a nonchain reaction[50] and it does not require an induction period. The chemical reactions that are responsible for its occurrence have molecular mechanisms. The apparent induction period of the dependence of S_τ on τ results from the phenomenon of surface restoration, as first detected by Rzumovskii, et al.[48] In this case the chains ruptured by ozone "escape" towards the interior of the product while the elastomer polymer chains that have not been degraded by ozone appear on the surface. The kinetics of the growth of cracks are satisfactorily represented by the equation for a straight line that is displaced from the origin. From an analysis of kinetic data it was possible to determine the analytical relationship between the surface of the cracks and the experimental parameters at any given moment of time.[49]

$$S_\tau = a + d\,[O_3]^m \left\{\tau - \frac{\gamma\left[\diagup C{=}C \diagdown\right]}{V_r([O_3]_0 - [O_3]_e)}\right\}, \qquad (4)$$

where S_τ is the specific surface of the cracks; a, d, and m are empirical constants; γ is the coefficient of surface restoration; V_r is the rate of introduction of the gaseous mixture into the reaction

volume; $[O_3]_0$ and $[O_3]_e$ are the concentrations of ozone at the entry and exit of the experimental chamber respectively.

A study of the kinetics of the decrease in strength in a sample on ozonisation of different types of rubbers showed[48] that the growth of cracks and stress relaxation essentially constitute two nonconcurrent processes. Induction periods are absent from the curves of the decrease in strength and the rates of decrease in strength are highest at the start of the process, whereas the rates of growth of cracks, on the other hand, increase with time.

It is now generally assumed[47] that the decrease in strength of a sample is a process involving two components—volumetric and surface. The first is dependent on the decrease in cross-sectional area of the sample from the growing cracks. This process is appreciable at the advanced stages of ageing. The second component is related to cleavage of the C=C bonds in the macromolecules of the surface layer. This process predominates at the early stages of reaction.[49]

The quantitative data obtained on ozone ageing of elastomers can be used to improve the accuracy of predicting the lifetime of reliable operation of rubbers and vulcanised materials in an atmosphere of ozone.[11]

VIII. Photodegradation and light stabilisation of a number of polymers

In the field of photodegradation and light stabilisation new data have been obtained on the mechanism of the photoconversion of polyamides,[51–56] and the mechanisms of the principal reactions for photoconversion of polymers such as poly(vinyl chloride) (PVC)[57] and cellulose and its derivatives[58,59] have been established. The effects of physico-structural factors and the acid-base properties of the medium on the light stability of polymers have been analysed in the case of the photooxidation of cellulose.[58]

Recent experimental data have made it possible to amplify and generalise the previously proposed mechanism of the photooxidation of aliphatic polyamides (PA). The general mechanism, as depicted below in Scheme 2, is based on the following arguments. The photooxidation of PA is a chain process whose development is governed by a specific succession of reactions involving peroxide macroradicals $PO_2^{\cdot}$ and low-molecular-weight radicals $X^{\cdot}$ (these would appear to be $HO_2^{\cdot}$ or $^{\cdot}O_2^{-}$).[51] An important route in the conversions of $PO_2^{\cdot}$ radicals is the elimination from them of light $X^{\cdot}$ radicals.[52] In this case an unstable intermediate A (or B) is formed, which is readily oxidised by atmospheric oxygen and converted to a ketoimide (K) and its kinetic analogue (K′) which are kinetic chain carriers and can act as photoinitiators of oxidation.[53]

Scheme 2

1) $PO_2^{\cdot} \xrightarrow{PA,\ O_2} PO_2^{\cdot}$

2) $PO_2^{\cdot} \longrightarrow A + X^{\cdot}$

2′) $PO_2^{\cdot} \longrightarrow B + X^{\cdot}$

3) $X^{\cdot} \xrightarrow{PA,\ O_2} PO_2^{\cdot}$

4) $A \xrightarrow{2O_2} K$

4′) $B \xrightarrow{2O_2} K'$

5) $K + X^{\cdot} \xrightarrow{PA,\ O_2} PO_2^{\cdot}$

5′) $K' + X^{\cdot} \xrightarrow{PA,\ O_2} PO_2^{\cdot}$

} macromolecular scission

6) $PO_2^{\cdot} + X^{\cdot} \longrightarrow$ chain termination

7) $K \xrightarrow{h\nu,\ 2O_2} 2PO_2^{\cdot}$

7′) $K' \xrightarrow{h\nu,\ 2O_2} 2PO_2^{\cdot}$

8) $PA \xrightarrow{h\nu,\ 2O_2} -2PO_2^{\cdot}$

K, K′ — sensitisers

$\sim C(=O)-NH\sim$.

A maximum optical absorption at 360 nm is characteristic of a ketoimide. The nature of its kinetic analogue, which absorbs light in the region of 313 nm, is still unclear. Products K and K′ readily react with $X^{\cdot}$ radicals, which results in macromolecular scission and propagation of the kinetic chain.[54] Chain termination occurs when $PO_2^{\cdot}$ and $X^{\cdot}$ radicals recombine.[55] Chain initiation is achieved by photolytic reactions of products K and K′, the inherent amide groups of the polymer, and the sensitiser introduced into it, the contribution of which varies according to the wavelength of light.[56]

With this proposed mechanism it is possible to represent quantitatively the photooxidation of PA on exposure to UV and longer wavelength radiation. The correlation between the calculated and experimental values of the rate of photooxidation of PA (W_{O_2}) is shown in Fig. 5.

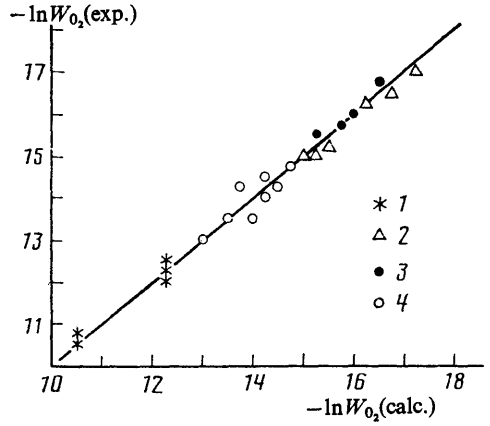


Figure 5. Correlation between experimental and calculated values of $-\ln W_{O_2}$ in the photooxidation of polyimide exposed to light radiation with wavelength: *1*, 254; *2*, 365; *3*, 313 nm; and *4*, in photosensitisation of the process with benzophenone.[51]

Equations have been obtained by Vichutinskaya, et al.[56] which can be used to determine the concentrations of $PO_2^{\cdot}$, K and K′ (the suffices of the rate constants correspond to the numbers of the reactions, W_0 is the rate of chain initiation):

$$[PO_2^{\cdot}] = \sqrt{\frac{k_3}{k_{2'}k_6} k_7 [K] W_0}, \quad (5)$$

$$[K] = \frac{k_2 k_3}{k_{2'} k_5} \frac{k_4}{(k_4 + k_{4'})}, \quad (6)$$

$$[K'] = \frac{k_2 k_3}{k_{2'} k_{5'}} \frac{k_{4'}}{(k_4 + k_{4'})}. \quad (7)$$

Directed research into new light stabilisers is being conducted on the basis of this mechanism. This task continues to be quite urgent as even the best of the known light stabilisers cannot reduce the rate of photooxidation by more than a factor of 5.

Currently it is not completely clear why the overall process according to the scheme given above can be represented in terms of the kinetics of conventional homogeneous reactions. So far no

characteristics of the system related to its solid state nature have been detected, although they evidently must exist.[8] Only in recent studies on chemiluminescence[51,52] were certain charcteristics suggesting the heterogeneous nature of photooxidation identified.

The role of such factors as the structure, molecular mobility, and pH of the medium in the ageing of polymers were revealed in studies on the photoageing of cellulose.[58,59] It was first shown that the rate of photoageing of cellulose is proportional to the content of the accessible amorphous phase. This means that photooxidation does not occur throughout the whole amorphous phase but only in that part which is accessible for low-molecular-weight compounds. On reducing the content of the accessible amorphous phase from 30 to 0%, the rate of photoageing decreases by a factor of 14.[59]

Another important factor in ageing is the molecular mobility. It can vary, for example, by plasticising cellulose with water. An increase in the content of water from 0 to 50% leads to a decrease in the rate of ageing by a factor of 6. This effect, according to Margolin, et al.,[58,59] is due to a sharp increase in the rate of radical recombination (i.e. termination of the oxidation chains) on increasing the molecular mobility of the macromolecules. Another possible explanation[9] is the decrease in reactivity of the peroxide radicals in chain propagation rections when they are hydrated with water molecules ($PO_2^{\cdot}\cdots H_2O$).

The third factor in the photoageing of cellulose—the pH of the medium—is of very considerable significance. It was found[58] that the rate of photodegradation of cellulose can vary by a factor of 10^2-10^3 according to the pH of the medium, and the minimum rate occurs in the region of pH 5. This is due to the catalytic nature of the reactions of radicals and products at the chain propagation stage of the oxidation process.

By varying the structure, molecular mobility, and pH of the medium, it is possible to achieve an increase in the light stability of cellulose by a factor of 100 – 1000. This indicates what practical significance there is in the application of these factors.

Despite the large number of studies on the degradation and stabilisation of PVC,[60] a solution to the question of its photodegradation and light stabilisation still remains very remote. In recent years the basic principles of the photodehydrochlorination and photooxidation of PVC—the main processes that occur during photoageing of this polymer—have been established.[57]

According to a mechanism put forward recently, photodehydrochlorination of PVC is a photochain process with a kinetic chain length of several tens of units, in which chain propagation occurs by photochemical conversion of alkyl and polyene radicals (Scheme 3).

Scheme 3

$$X \xrightarrow{W_0} P^{\cdot} \text{ – chain initiation}$$

$$P^{\cdot} \xrightarrow{k_1} P_1^{\cdot} \text{ – chain propagation}$$

$$\begin{cases} P_1^{\cdot} \xrightarrow{\alpha_2 k_{app}} P_2^{\cdot} + HCl \\ \cdots\cdots\cdots\cdots \\ P_1^{\cdot} \xrightarrow{k_{app}} P_n^{\cdot} + (n-1)HCl \end{cases}$$

$$\begin{cases} P_1^{\bullet} \xrightarrow{k_{1,1}} P_1 + P^{\bullet} \\ \cdots\cdots\cdots \\ P_n^{\bullet} \xrightarrow{k_{n,n}} P_n + P^{\bullet} \end{cases}$$

$$P_1^{\cdot} \xrightarrow{k_r} \text{inactive products}$$

$$P_1^{\cdot} \xrightarrow{k_{r,1}} \text{inactive products}$$

where W_0 is the rate of initiation, α_i is the probability of new radicals being formed, k_{app} is the apparent rate constant of reaction:

$$k_{app} = \varphi\varepsilon I. \tag{8}$$

Here φ is the quantum yield of radical conversion, ε is the extinction coefficient of radical absorption, I is the intensity of light.

From this kinetic scheme for the photodehydrochlorination of PVC, an expression can be readily obtained[57] from which the rate of dehydrochlorination can be calculated from known kinetic parameters.

$$W_j = \gamma\eta\alpha_j W_0, \tag{9}$$

where

$$\eta = \frac{k_1 k_{app}}{k_r + (k_1 + k_r)k_{r,1}k_{app}^{-1}}, \tag{10}$$

$$\gamma = \sum_{j=1}^{n}[R_j^{\cdot}]_{pl} \Big/ \sum_{j=1}^{n}[R_j^{\cdot}]_{rig}. \tag{11}$$

In this case the subscripts "pl" and "rig" refer to plasticised and rigid PVC respectively.

According to the proposed mechanism, the key parameters are the values of the extinction coefficient ε, the quantum yield φ of radical conversion, and also the intensity of light I. Moreover, with a knowledge of the proportion of the rigid regions in plasticised PVC, where radicals R_j are stable, the dependence of the rate of dehydrochlorination on the content of plasticiser can be given.

The photooxidation of PVC occurs as a process with a very short chain length and formally linear termination.[57] The possibility of migration of the free valence for considerable distances in solid PVC has been demonstrated by means of low-molecular-weight radicals. The results suggest the possibility of using light-stable antioxidants and also quenchers of excited states for the light stabilisation of PVC, which opens up new ways of increasing light stability.

In recent years a considerable number of studies have been published on the photoradical ageing of polymers,[61–67] namely, on the change in functional composition and structure of high-molecular-weight compounds as a result of the chemical reactions of electronically excited radicals and radical ions.

A considerable amount of data has been obtained on the quantum efficiency of photochemical reactions of macroradicals in various carbon-chain and heterochain polymers and on the effect of photon energy on the quantum efficiency of these reactions.[68–77] The efficiency of photodissociation processes of macroradicals can be represented satisfactorily in terms of a free-volume model. The mechanism and kinetics of the photoradical ageing of polycaproamide and poly(acrylic acid) at 77 K have been studied in detail. It has been established that the principal route of the reactions of electronically excited radical anions in these polymers is the ejection of an electron, the quantum yield of which increases with an increase in photon energy. Neutral macroradicals (median and terminal) are active sites of the photoradical ageing of poly(acrylic acid) and polycaproamide. In this case excited median macroradicals only undergo dissociation. Photoradical chain reactions involving median macroradicals have been identified in the degradation of a large number of different polymers, including poly(acrylic acid) and polycaproamide. In the case of poly(acrylic acid), for example, photodecomposition of median radicals can occur by two routes—with scission or without scission of the main polymer chain.

The second of these two reactions, which is the photochemical stage of chain propagation, is also accompanied by efficient rupture of the functional groups and the formation of a product (a ketene) whose subsequent reactions cause cross-linking of the polymer chains.

$$\sim CH_2\dot{C}(COX)CH_2\sim \xrightarrow{h\nu} \begin{cases} \longrightarrow \sim CH_2C(=C=O)CH_2\sim + X^{\cdot} & (I) \\ \longrightarrow \sim CH_2\dot{C}(COX)\dot{C}H_2 + \dot{C}H_2(COX)CH_2\sim & (II) \end{cases}$$

$$X^{\cdot} + \sim CH_2CH(COX)CH_2\sim \longrightarrow \sim CH_2\dot{C}(COX)CH_2\sim + HX, \quad (III)$$

$$\sim CH_2C(=C=O)CH_2\sim \longrightarrow \sim CH_2\ddot{C}CH_2\sim + CO. \quad (IV)$$

The quantum yields of these reactions have been determined.

By using the above results together with the experimentally determined apparent rate constants for macroradical recombination, it was possible to represent with considerable accuracy the kinetics of the change in concentration of the initial, intermediate, and final products of the photoradical ageing of poly(acrylic acid).[61–67]

An important fact which is consistent with the scheme given above has been established experimentally: by changing the dose of absorbed light radiation it is possible to produce a directed change in the molecular weight distribution of the polymer in which median macromolecules occur. With small doses the molecular weight distribution is determined by reaction (II), while with large doses it is determined by reaction (IV) and the subsequent formation of cross-links as a result of reactions involving the ketene.

In addition to the already well-established phenomenon of kinetic nonequivalence which was observed previously[57] during photoradical processes in different polymers, the levelling effect of the photon energy on the kinetic nonequivalence of sulphonyl macroradicals has recently been detected.[52,53]

A study of the photochemistry of macroradicals involved in forbidden transitions (the possibility exists for considerably extending the region of spectroscopic sensitivity) and an investigation of photoradical chain reactions, in particular the steric distribution of their products, should evidently be considered the most interesting developments of future research into the photoradical ageing of polymers.

IX. Kinetics and mechanism of oxidative reactions of stressed polymers

Studies of the effect of mechanical stresses on the structure, dynamics, and reactivity of polymers led to a number of unexpected new results.[78–83]

Structural stresses of an energetic nature increase or reduce the rate of a chemical reaction depending on the change in linear dimensions of the reaction site during reaction.[79]

$$\ln \frac{k_\sigma}{k_0} = \frac{\gamma\sigma}{RT}, \quad (12)$$

where k_σ and k_0 are the rate constants of the chemical reaction of the polymer in stressed and unstressed states respectively: σ is the stress; γ is the coefficient of sensitivity of the reaction to stress, equal to the product of a constant γ_a, which is inherent to each specific reaction, and a coefficient β, which takes into account the nonuniform distribution of stress on the bond ($\beta \geqslant 1$).

By establishing a quantitative relationship between the rate constant of reaction and the stress it was possible to classify different chemical reactions according to their sensitivity to the application of stress and also to study the supermolecular structure of the polymers.[78,79,81,82]

All chemical reactions can be divided into three groups in accordance with their sensitivity to deformational stresses.

1. Processes that are insensitive to applied stress; for these $\gamma_a = 0$.

2. Chemical reactions that are highly sensitive to stress; these have $\gamma_a \geqslant (0.5-1.0) \times 10^{-29}$ m^3. These include processes that are accompanied by scission of the main macrochains, for example, the hydrolysis of polyamides. Treatment of the results of Popov[79] using Eqn. (12) gives an estimated value of $\gamma_a \approx 2 \times 10^{-29}$ m^3.

3. Reactions having low sensitivity to stresses; for these $0 < \gamma_a < 0.5 \times 10^{-29}$ m^3. These include reactions of ozone with saturated polyolefins ($\gamma_a = 0.33 \times 10^{-29}$ m^3) and polyaminoimides ($\gamma_a = 0.05 \times 10^{-29}$ m^3).

By studying the supermolecular structure of polymers using Eqn. (12), it was possible to determine quantitatively the nonuniform distribution of stress on the bonds in oriented polyolefins—low- and high-density polyethylene and polypropylene ($\beta = 2-6$).

The supermolecular structure of isotropic polyamidoimides containing a fluorene ring (PAI-1), a nitrile group (PAI-2), and a *para*-phenylene group (PAI-3) were studied in particular detail with this method. In this case the coefficient β varies from 40 to 120 according to the chemical structure of the polyamidoimide. PAI-1 has the most ordered structure, and it is characterised by the lowest value of β and the lowest density, which provides the greatest opportunity for the formation of intermolecular hydrogen bonds.

Irreversible rearrangement of the supermolecular structure of polymers affects the dependence of the rate of their ozone oxidation on stress.[81] A particularly marked effect of this type of rearrangement occurs in the ozone oxidation of oriented polyolefins subjected to tension under conditions of stress relaxation. The additional orientation leads to an improvement in the fibrillar structure and a decrease in the rate of ozone oxidation.[82]

The physical and performance properties of polymers and the rate and mechanism of the chemical reactions occurring in them are determined to a considerable extent by the relaxation properties of the macromolecules and the mobility of low-molecular-weight additives,[78] since polymer products are generally used under conditions of mechanical stress and by the effects of temperature and oxidation. In order to resolve many scientific and practical problems, it is important to elucidate the effect of these factors on the molecular mobility of oriented polymers.

At the initial stage of stretching previously oriented samples (ε is about 6% for polyethylene and about 10% for polypropylene), the molecular mobility of the chains in the amorphous regions increases, with the magnitude of these changes depending on the molecular weight distribution, degree of orientation stretching, and degree of oxidation.[79] Deformation of samples with an average molecular weight and narrow molecular weight distribution at high degrees of stretching is accompanied by a decrease in molecular mobility.

Ozone oxidation produces a considerable increase in the rigidity of the amorphous regions,[81] which leads (at low degrees of oxidation) to an improvement in the mechanical properties of the polymer material.

A study of the effect of the orientation temperature (T_{or}) on the structure and strength of films of mixtures of polypropylene and high-density polyethylene (HDPE) showed that when T_{or} is higher than the melting point of the crystallites of HDPE, considerable changes occur in the polymer matrix. A new crystalline modification of PE is formed, the tensile strength decreases sharply, and the

melting point of the crystallites of PE and its degree of crystallinity are reduced. The combined experimental data suggest that the T_{or} of polyolefins should be close to the melting point of the more readily melting component of the mixture but should not exceed it.[78]

Ozone-oxygen oxidation of polymers substantially alters such characteristics of the physical structure of a polymer matrix as the melting point of crystallites of components of the polymer mixture, the polydispersion, and degree of crystallinity of the components.[82,83] As a result of oxidation there is a small decrease in the melting point and an increase in polydispersion of polyethylene and also a substantial decrease in melting point and polydispersion of polypropylene. When a mixture of polypropylene and polyethylene is treated with ozone, only the crystalline structure of the former is rendered amorphous to the extent of complete loss of crystallinity.[79]

Recently, unexpected effects relating to the action of mechanical stresses on the kinetics of oxidation of polyolefins have been revealed.[60] The oxidation of oriented polyethylenes, and particularly oriented and stressed polyethylenes, occurs in separate spatial zones of the reaction. The number of the latter and the characteristics of their distribution in space provide a basis for the assumption that they are formed around particles of contaminants that initiate the oxidation of the polymer.[82] Products of the conversion of polymerisation catalysts present in trace amounts in the polymer and also metal ions that have penetrated the polymer as a result of corrosion of the equipment (the polymerisation reactor, for example) can act as these particles. This in particular governs the variable thermooxidative stability of the same polymer synthesised using different catalytic systems.[8,9]

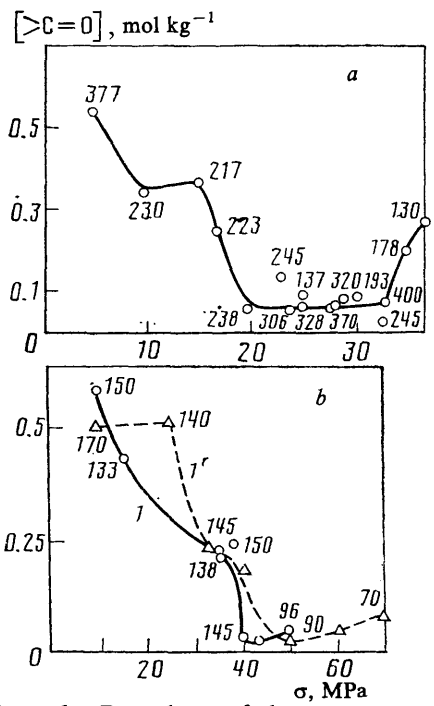

Figure 6. Dependence of the average concentration of carbonyl groups formed up to the moment of sample fracture on stress in the oxidation of oriented polypropylene: *a*, degree of stretching λ = 7.5, temperature of oxidation 120 °C; *b*, λ = 8.5, temperature of oxidation 130 °C.[78]

Mechanical stresses during oxidation primarily alter the permeability of the matrix. With low stresses the rate of translational diffusion of the low-molecular-weight radicals that are carriers of free valence from initiation "points" through the matrix falls (Fig. 6).[78] This leads to a marked decrease in the overall rate of oxidation under load. However, on increasing the stress above a given limit, mechanical radical initiation that is distributed throughout the polymer much more uniformly than initiation on contaminants starts to predominate.[82] At the same time the rate of oxidation of the polymer starts to increase again. With an increase in mechanical stress, not only the rate but also the oxidation conditions are altered. There is a change from a branched-chain process to a nonchain oxidation of the terminal macroradicals. These effects have the result that the criterion of rupture as a fixed average concentration of scissions or terminal oxygen-containing groups is not applicable to stressed polyolefins undergoing oxidation.[78]

Models for the rupture of stressed polyolefins undergoing oxidation which can be used in a number of cases to predict the longevity of various grades of polymers under various operating conditions have been proposed.[78–84] Analytical expressions that relate the longevity of a polymer to the number of initiation sites in samples and their growth rate have been obtained. The number of sites depends on the conditions of polymerisation, purity, and formation and their growth rate depends on the polymer structure and the oxidation conditions. All this makes it possible to develop new principles for increasing the stability of polymers without the use of traditional stabilisers. Careful removal of contaminants, increasing the degree of initial stretching, etc., are required for this purpose.

X. Radiation ageing of polymers

Bykov, et al.[85–87] have studied in detail the phenomena of shrinkage and cracking in polyolefins, in particular polyethylene, during radiative oxidation.

A well-defined sandwich structure consisting of an external oxidised layer and an internal unoxidised layer will be formed in thick films (plates, cable insulation) as a result of the diffusion-controlled flow of oxygen. The oxygen-containing compounds formed in the oxidised layer alter the conformation of the initial molecules. In this case mechanical stresses develop, leading to cracking of the polymer to the depth of the oxidised layer. The thickness of the oxidised layer and hence the depth of the cracks depends on the strength of ionising radiation.

In thin films that are oxidised to a uniform depth (oxygen permeates a sample quite rapidly) cracking does not occur, but shrinkage that is related to the accumulation of polar groups during oxidation is observed. The shrinkage of thin films and the cracking of thick films are governed by the same structural reorganisation processes—cracking starts at the moment when shrinkage reaches a given critical magnitude.[85–87]

A post-effect that is not related to post-radiative oxidation is characteristic of both the phenomena studied—shrinkage and cracking. The structural reorganisation processes that give rise to shrinkage and cracking are delayed relative to oxidation. The characteristic time lag is ~1 month.[88]

A kinetic model was developed, making it possible on the basis of common arguments to represent the phenomena of shrinkage and cracking as the result of radiation oxidation.[85–88] Using this model a

method was developed for determining the guaranteed operating lifetimes of cable insulation made of polyethylene. At the present time this method is being tested in the cable industry.

XI. Hydrolytic degradation of heterochain polymers

All heterochain polymers undergo degradation by reacting with water.[89–91] The hydrolysis reactions are catalysed by acids and bases. In dilute solutions of acids and bases (the so-called pH region) the rate of these reactions increases in proportion to the concentration of solvated H^+ and OH^- ions.[89] In more concentrated acid and base solutions the dependence of the rate of hydrolysis on the composition of the medium is more complex. Thus, for example, the rate of hydrolysis of amides increases with an increase in concentration of $H_5O_2^+$ ions and reaches a maximum value for aliphatic amides when the concentration of H_2SO_4 is 15% (for aromatic amides this occurs at about 50% H_2SO_4) and then decreases. The decrease in the rate of degradation at higher concentrations of sulphuric acid is related to the formation of an unreactive protonated form of the amide bond.[91] Because of this, the view was expressed[89] that solutions of polyamides in concentrated sulphuric acid should be stable.

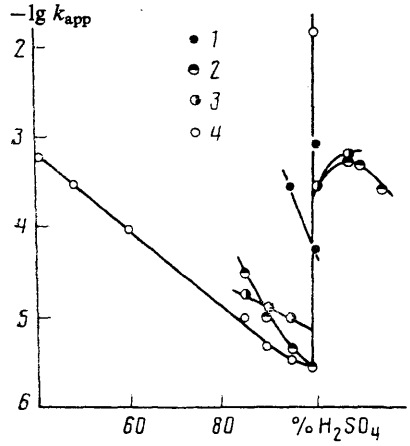

Figure 7. Dependence of the rate constants for degradation of polyamide on the concentration of H_2SO_4 at 80 °C:[89] *1*, polybenzamide; *2*, poly(*p*-phenylene terephthalamide); *3*, poly(*m*-phenylene terephthalamide); *4*, polycaproamide.

However, it was recently shown[90,91] (Fig. 7) that the rate constants for degradation of aliphatic and aromatic polyamides decrease as the content of H_2SO_4 increases up to 99.5%, while when it rises further to 100% they increase sharply. This change in reactivity has no analogies in the chemistry of low-molecular-weight amides. This is believed[91] to occur because the polymer state of the material assists the development of high local concentrations of protonated amide bonds in solution, with the result that the properties of the medium are changed in the immediate vicinity of the polycation.

The results obtained are important for the chemistry of aromatic fibre-forming polyamides since concentrated sulphuric acid is the only readily available solvent for these polymers.

It was recently demonstrated at a quantitative level that mineral acids act as catalysts of the polycyclodehydration of poly(*o*-hydroxy-amides) in solution. When mineral acids (hydrochloric, sulphuric, phosphoric) are introduced into a mixture containing poly(*o*-hydroxyamides) in dry *N*-methyl-2-pyrrolidone, two reactions—hydrolysis and cyclodehydration—occur simultaneously.[91] By changing the conditions of the reaction it is possible to direct it along a given route. With these data it is possible to predict the stability of poly(*o*-hydroxyamides) in aggressive media. They are of potential benefit in terms of the synthesis of these polymers, since they can be used to alter the reaction conditions (reduce the temperature, for example) so as to direct it on the cyclodehydration route.

Similar results have been obtained for a large number of polyamides, polyimides, polybenzoxazoles, and other polymers.[90,91]

XII. Interaction of polymers with biological media

Recently a complex analysis of the structure properties, and stability of poly(ether–urethanes) for medical use was carried out.[92–95] The use of block copolymers for the manufacture of artificial organs (cardiac chambers, cardiac valves, etc.) and a number of medical products (for example, catheters) makes it necessary to develop a scientifically based system of requirements to be imposed on these materials. A comprehensive approach has been developed for studying materials and products used as membranes, diaphragms, and certain other elements of an artificial heart, involving the application of a number of spectroscopic and diffusion methods.[92]

In virtually all of the materials of this type there is an intermedite (mixed phase) that consists of polyether and polyurethane residues, and this is responsible to a considerable extent for a whole set of physicochemical and mechanical properties of the material (and products made from it).[93] A correlation has been established between the degree of structural heterogeneity and the adsorption properties of the surface of poly(ether–urethanes) relative to blood plasma proteins (formation of blood clots on the polymers),[94] which is extremely important in relation to the specific conditions of using the products.

A comprehensive approach has been suggested[95] for studying the kinetics of adsorption of blood plasma proteins on the surface of the block copolymers, including the development of a kinetic diffusion model for the process, a method of determining the physicochemical parameters of the system polymer–protein, and a prognosis of the composition and structure of the adsorbed layer as a factor that is of definite significance in determining the thrombosis-resistant properties of segmented poly(ether–urethanes).[92–95]

A diffusion method and an H–D isotope exchange method specially developed for this class of polymers were used to determine their essential properties (water adsorption capacity, coefficients of diffusion and permeability) which it was necessary to take into account during use and storage of the materials.[94]

In recent years a new problem concerning the production of substitute materials for various biological tissues and systems has arisen on the borderline between mechanics, biology, and medicine. Polymer materials are increasingly being used for this purpose.[96–101]

For a polymer implant, not only the biological compatability but also the rheological compatibility is of considerable importance. Rheological incompatibilty, i.e. a lack of correspondence between the biochemical properties of the transplant material and the redesigned organ or tissue, results in very severe stresses developing at the points where they are connected. Therefore, in developing synthetic materials for medical application, the question of predicting their deformations and strength and structural characteristics is a vital one as is a determination of these properties after prolonged exposure of the material to an aggressive medium under conditions of continuous cyclic stress.

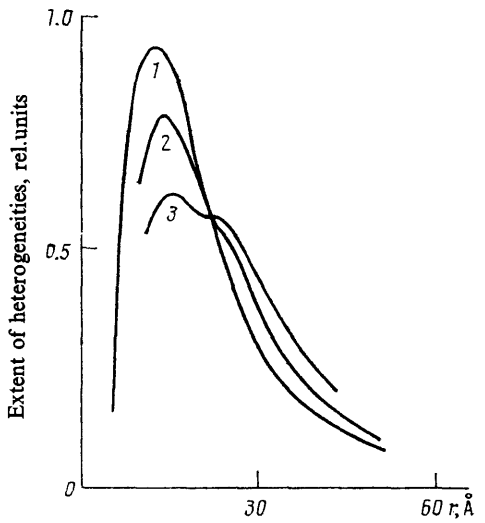

Figure 8. Distribution by size of microheterogeneities in PET fibres at different periods of implantation:[96] *1*, initial material; *2*, 3 months; *3*, 8 years.

In this connection studies were made on poly(ethylene terephthalate) (PET) that was subjected to biomechanical stresses in the transplantation of ligaments and tendons.[96–99] Braided tissue bands made of PET fibres were used with perpendicular interweaving of filaments. The residence of such fibres in an organism leads to irreversible changes in the structural characteristics of the material (Fig. 8), for example, a redistribution of microheterogeneities (the proportion of small pores decreases).[96] The number of small pores on the surface can decrease through an increase in their size as a result of the hydrolysis of PET[89] and also through penetration of the pores by collagen tissues of the organism.[97]

The change in structure of the fibres has an effect on their creep, which increases as the residence time of the PET material in the organism increases (Fig. 9).[97] The increase in deformation mainly occurs because of sorption of tissue liquid by the material.[97] As a result of the sorption of liquid under a continuous load (for example, the operation of a ligament in a living organism, an orientation strengthening of PET fibre occurs.[98]

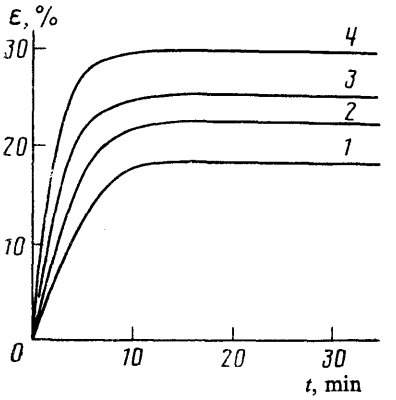

Figure 9. Creep of PET fibres at different periods of implantation:[97] *1*, initial material; *2*, 3 months; *3*, 1 year; *4*, 8 years.

A general prediction of the possible changes that occur in Lavsan (PET) substitute materials for ligaments and tendons can be made (Fig. 10).[89,96–98]

$$P = P_0(1 - k_{app} t d d_0^{-1} \rho^{-1})^2, \quad (13)$$

where P_0 and P are the initial and continuing tensile strengths respectively; k_{app} is the apparent rate constant for degradation; t is the residence time in the organism; d_0 and d are the initial and continuing average diameters of a simple filament of PET; ρ is the density of the PET fibre. This equation can be used to determine the average time taken for the ligaments and tendons to lose 50% of their strength. This time is estimated to be 30 ± 2 years.[96]

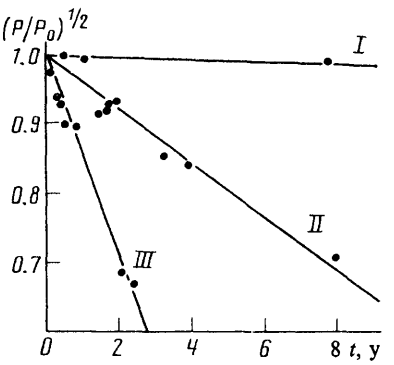

Figure 10. Dependence of the relative tensile strength of materials made of PET on the residence time of an implant in the human organism (*I*, PET ligaments and tendons, *II*, PET gauze) and rabbit (*III*) PET gauze.[98]

There is considerable interest in recent studies[99,100] related to the use of polymers subject to biodegradation in equipment for the controlled release of drugs. Drugs are released in proportion to the

surface erosion of these polymers. This usually occurs with zero-order kinetics, which corresponds to the therapeutical requirements of the supply of drugs to the organism.

The kinetic principles for representing the process of drug release from polymers undergoing bioerosion have recently been developed.[99,100] The molecular weight distribution of the initial polymer affects the kinetic parameters of drug release. The case where residues of a drug are connected to a polymer chain has been examined in terms of the kinetics. From the integral kinetic equations obtained it is possible to determine all of the required kinetic parameters. There is also the possibility of the nonuniform release of drugs due to the formation of soluble biodegradation products throughout the whole polymer.[100]

In general the following processs can occur in biodegraded polymer products:[89]

– adsorption of substances present in tissues of a living organism or of microorganisms on the surface of the material;

– destruction of the material either as a result of the specific action of living organisms that can use the polymer material as a nutritional source or by the action of an aggressive medium, including the action of metabolic products from microorganisms.[101–106]

When the first process occurs, the chemical structure does not change as a rule; the material acts as a support on which the adhesion and growth of colonies of microrganisms occur or collagen-like capsules are formed (when the material is used as an implant).

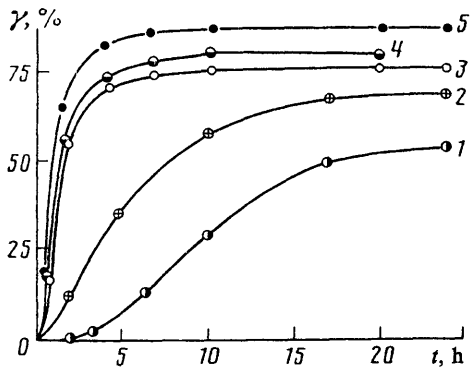

Figure 11. Kinetic curves for adhesion of colonies of spores of *Aspergillus niger* to the surface of different polymers: *1*, polyethylene; *2*, epoxy resin; *3*, poly(methyl methacrylate); *4*, cellophane; *5*, acetylcellulose (25 °C, 90% relative humidity).[105]

The second process leads directly to ageing of the polymer material through the action of chemically active agents. In this case the "bulk" operating properties are changed.

The kinetics curves of adhesion are satisfactorily given by the equation[105]

$$\ln(\gamma/\gamma_0) = -kt, \qquad (14)$$

where γ and γ_0 are respectively the proportion of particles remaining on the polymer surface after adhesion over a period t and the proportion of particles irreversibly adhering under these conditions; k is the rate constant for formation of adhesive bonds between the spores of microorganisms and the surface of the material.

The kinetic curves for the growth of biomass are satisfactorily given by the exponential function[106]

$$m/m_\infty = 1 - \exp(-kt), \qquad (15)$$

where m and m_∞ are respectively the continuing and final quantities of biomass on the surface of the polmer. In this case m_∞ is greater, the higher the solubility of water in the polymer. To illustrate this, the kinetic curves for adhesion and growth of biomass on different polymers that have been plotted according to Eqns. (14) and (15) are shown in Figs. 11 and 12.

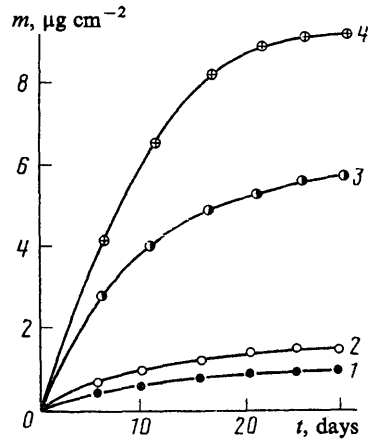

Figure 12. Dependence of the accumulation of biomass consisting of spores of *Aspergillus niger* on residence time on the surface of different polymer films (25 °C, relative humidity 90%): *1*, polyethylene; *2*, fluoropolymer; *3*, poly(ethylene terephthalate); *4*, cellulose.[106]

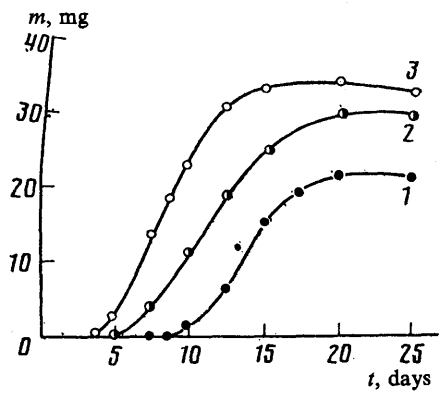

Figure 13. Kinetic curves for growth of *Aspergillus niger* biomass on canvas subjected to thermal humid ageing.[106] Ageing time, h: *1*, zero (initial material); *2*, 400; *3*, 1000 (25 °C, relative humidity 90%).

Under real conditions, degradation and biodegradation of the polymer material can occur simultaneously. The kinetic curves for the accumulation of biomass on canvas consisting of flax and cotton that has undergone thermohumid ageing followed by the growth of fungal spores are given in Fig. 13. It is clear that an increase in the time of ageing leads to an increase in the growth of biomass.[106]

Thus, the biological stability of a polymer material is governed by a combination of complex physicochemical processes involving adhesion, biological growth, and biodegradation which occur under certain external conditions.

XIII. Protection of materials with polymer coatings

One of the methods of protecting materials from the effect of aggressive media is to deposit protective polymer coatings on their surface. However, since the polymer coating itself is also degraded on contact with aggressive media, its service life is finite if it is a question of protecting a metal, and the aggressive medium, on reaching the metal surface, causes it to corrode.[9,11,89,91,94] Therefore, there is still considerable interest in studying ways of reducing the rate of penetration of aggressive media through protective polymer coatings.

A method of protection that is related to the introduction of additives which absorb oxygen and thus inhibit its participation in the thermooxidative degradation of polymers[107] is effective if the concentration of the aggressive medium (ozone, oxygen) is of the order of thousandths of a percent.[11] When the pressures of the aggressive medium are close to atmospheric, this method of protection is ineffective.

An experimental study of the efficiency of binding fillers such as oxides of beryllium, cadmium, magnesium, calcium, and alkaline earth metals and alkali metal hydroxides in the inhibition of diffusion of solutions of hydrochloric, hydrofluoric, and nitric acids in foamed plastics, polyarylate, polypropylene, and other polymers showed that the inhibitory effect depends in a complex manner on the nature of the polymer and the acid as well as on the concentration of the aggressive medium.[108]

The simplest model of the inhibitory effect of protective additives involves two possible mechanisms.[108] A diffusing molecule A binds with additive B in the polymer either reversibly as in

$$A + B \overset{K_e}{\rightleftharpoons} (AB),$$

where K_e is the equilibrium constant, or irreversibly as in

$$A + B \xrightarrow{k_1} (AB),$$

where k_1 is the rate constant of reaction. In both cases the diffusion coefficient (D_0) of molecules A in the initial polymer decreases after introduction of the additive as a result of these reactions, which immobilise a proportion of the diffusing molecules. Specially introduced low-molecular-weight compounds as well as certain functional groups of macromolecules, such as amide and amine groups in a polyamide, can act as additives in relation to diffusing HCl and H_2O molecules.[109]

The calculated curves for distribution of the diffusing component A throughout the coating at the same moment in time with reversible and irreversible binding and in the absence of binding are shown in Fig. 14, while the kinetics of formation of the "free" diffusing component A at the polymer–metal interface are displayed in Fig. 15. In this case the inhibitory effect with irreversible binding is equal to 30, while with reversible binding it is equal to 5.

The calculations demonstrate that under certain conditions the introduction of absorbents into the polymer can slow down the progress of the front of an aggressive medium towards a metal surface by a factor of several tens.

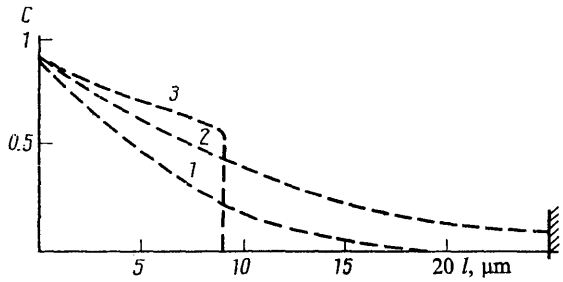

Figure 14. Calculated curves for distribution of the diffusing species throughout the coating 2 min after diffusion has started when $D_0 = 7 \times 10^{-13}$ m^2 s^{-1}:[109] *1*, reversible binding; *2*, absence of binding (no additives); *3*, irreversible binding.

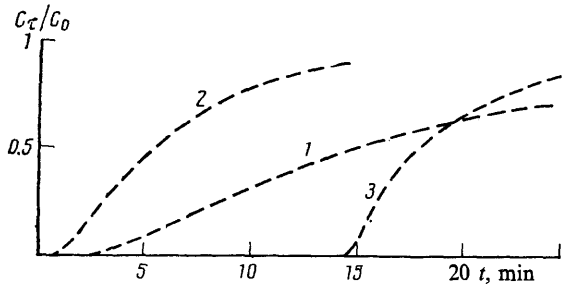

Figure 15. Accumulation of "free" diffusing species at the polymer–metal interface[109] (C_0 is concentration of diffusing species at the interface between coating and medium, C_τ is the continuing concentration of diffusing species at the metal interface: *1*, reversible binding; *2*, absence of binding (no additives); *3*, irreversible binding.

XIV. Predicting the properties of polymer products

The problems of polymer ageing are inseparably linked to a prediction of the change in their properties under real operating conditions.[9–11,89,91] It has been demonstrated in practice that predictions based on exiting rapid test methods frequently give erroneous results, since the mechanisms that are typical of real operating conditons are not reproduced during rapid testing. In order to determine to what extent the effects are equivalent, it is first of all necessary to make a detailed study of ageing mechanisms under natural climatic and artificial conditions.[110–122]

In order to conduct systematic studies on polymer materials for ageing under natural conditions in a warm humid climate, an experimental unit was developed and produced for determination of

molecular mobility, relaxation and phase transitions, viscoelastic properties, and the structure of polymers based on the use of current high-sensitivity methods.[110–122]

The information already collected at this stage can be used to classify the mechanisms of physicochemical reactions of different classes of polymers during atmospheric ageing in a moist subtropical zone. Data are currently being collected on the link between the physicochemical reactions and the change in macroscopic properties of the polymers and on the role of individual climatic factors in the ageing of polymer materials. An interactive information system that is designed for processing the results of kinetic tests and predictions has been developed.[123–126] In order to represent data, the user can select a suitable function from a suggested library of standard models. Unknown parameters are determined by maximum probability based on prior information. Statistical treatment of the results with determination of the accuracy of the parameter estimates and a check of the statistical hypotheses are carried out. Provision is made for planning the experiment, transforming the results using different anamorphisms, and presenting the results in the form of graphs, tables, and storing them. This program forms the basis of the first machine-readable standard in the country.

A method for predicting the photochemical response to a given polychromatic effect on a polymer with an unknown spectroscopic sensitivity has recently been developed.[123,124] The necessary and sufficient conditions for correctness have been determined and an original regularisation method has been developed. The results are presented in the form of a corridor of admissible response values.

The proposed method has already found practical application in solving problems in applied photochemistry, and it can be used to determine much more effectively the photosensitivity of polymer materials being used under real conditions. A package of computer programs has already been developed for putting this method into effect. An investigation of the mechanism of action of classical inhibitors such as phenols and amines is in progress, in order to provide a prediction of their efficiency as stabilisers for polymers.[127,128]

carbonised polyimides (Fig. 16) with a maximum coking value is achieved with a quasi-isothermal heat regime, a statistical inert atmosphere, a relatively high content of nitrogen atoms in the main polyimide chain, and by orientation of the sample.[130]

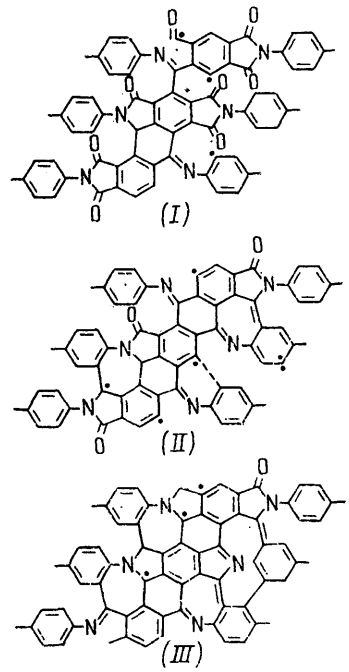

Figure 16. Structural scheme for carbonisation of polypyromellitimide at: *I*, 525; *II*, 575; *III*, 625 °C.[129]

XV. Ageing and stabilisation of heat-resistant polymers

The ageing and stabilisation of heat-resistant polymers can be suitably studied at temperatures above 300 °C, and in a number of cases above 400 °C.[127–139] Polyimides constitute the best known examples of this class of polymers. Two approaches to the stabilisation of heat-resistant polymers have already been examined above in Section V.[26,30,31]

Recently there has been a considerable growth of interest in studying thermochemical reactions that occur at temperatures of 500 °C and above. This is related not only to the problems of thermal and thermooxidative stability of polymers but also to research into their combustion processes, the primary stage of which is pyrolysis of the polymer to gaseous products.[140] At these temperatures thermal degradation is characterised by substantial rearrangement of the whole macromolecular structure (of the polyimide in this case) with the formation of carbonised products that are more or less ordered and mainly consisting of condensed aromatic and heterolytic species.[127,128] One of the aims of these studies is to establish the optimum conditions for obtaining polyimide materials that have a maximum "cooking value" and at the same time acceptable mechanical properties. The preparation of

An effective way of stabilising heat-resistant polymers, in particular polyimides, is to refine their methods of synthesis[131] with the aim of substantially reducing the cyclisation temperature of the prepolymers. This trend, which is not related to classical stabilisation methods,[132] can be used in a number of cases to perfect the structure of the polyimides and improve their thermal stability and other important properties.[133]

The use of polyimides for the heat stabilisation of other so-called large-tonnage polymers should be regarded as having future potential.[134] The use of a polyimide in combination with poly(vinylpyrrolidone), furfuryl alcohol, and epoxy resins results in the formation of composite materials in which the polyimide structure acts as a unique heat-resistant framework, substantially increasing the heat stability of polymer fillers.[135–139] According to thermal analysis data,[134–139] the heat resistance increases by 100–150 °C in the case of poly(vinylpyrrolidone) and by approximately 200 °C for furan and epoxy resins. The second component in turn imparts a number of valuable properties to the polyimide such as thermohydrolytic stability and high-temperature adhesion to metals and graphite materials.

At the present time this is the most promising development in research into ageing processes and in seeking ways to stabilise heat-resistant polymers.

XVI. Conclusion

The ageing of polymers and the stabilisation of polymer materials remains, as before, a vital problem. At the present time the accent of research has shifted from individual polymers to polymer blends and composites.[121] The transition to multicomponent systems complicates the task, since in this case additivity does not usually occur. It was demonstrated back in the 1960s that even in the co-oxidation of two hydrocarbons,[142] each of which is separately oxidised under given conditions, cases are possible where only one compound (R_1H) is oxidised in the mixture, and the other (R_2H) is not oxidised. In essence this occurs because hydrocarbon R_2H is regenerated by R_1H according to Scheme 4.

Scheme 4

$$R_1H + O_2 \longrightarrow R_1^{\cdot} + HO_2^{\cdot}$$
$$R_1^{\cdot} + O_2 \longrightarrow R_1O_2^{\cdot}$$
$$R_1O_2^{\cdot} + R_1H \longrightarrow R_1OOH + R_1^{\cdot}$$

$$R_2H + O_2 \longrightarrow R_2^{\cdot} + HO_2^{\cdot}$$
$$R_2^{\cdot} + R_1H \longrightarrow R_2H + R_1^{\cdot}$$
$$R_2^{\cdot} + O_2 - \times \longrightarrow$$

Investigations are continuing into the specific nature of the polymer state with regard to the reactivity of interacting species in the polymer matrix[143,144] and the mobility of molecular chains and low-molecular-weight compounds in polymers under different conditions. Particular attention is being given to the effect of structural relaxation of vitreous polymers on the kinetics of chemical reactions. A model that has been proposed[143,144] can be used to represent qualitatively the majority of known kinetic effects of structural relaxation of vitreous polymers.

There is no doubt that studies to establish cases of synergism and antagonism in the stabilisation of polymers in the presence of several stabilisers and other chemical additives will be continued. Multifunctional stabilisers that contain a number of functional groups in the same molecule, acting by different mechanisms and thus creating a synergistic effect, are of increasing interest. The application of polymeric stabilisers for the stabilisation of polymers operating at high temperatures is expanding. At high temperatures they are quite mobile (and therefore effective), while at the same time they are not washed out and do not bleed like low-molecular-weight stabilisers. The development of new, more sensitive methods has been proposed[145] for studying polymer degradation processes that would allow the conditions of testing to approximate to real operating conditions and hence markedly increase the accuracy of predicting the lifetime of reliable operation and preservation of polymer products.

Degradation processes are starting to be used more extensively for the modification of polymer products in order to improve their properties.

Enzymic methods of resolving racemates of amino acids and their derivatives

M A Verkhovskaya, I A Yamskov
Institute of Foodstuffs, Academy of Sciences of the USSR, Moscow

ABSTRACT. The review is devoted to modern methods of resolving racemates of amino acids and their derivtives by the action of enzymes. Processes of enantioselective enzymic hydrolysis are considered for both *C*- (esters, amides, amino acid nitriles) and *N*-derivatives (acyl- and alkoxycarbonylamino acids) and also for their cyclic derivatives. Examples are given of the catalytic preparation of optically active derivatives from racemic amino acids.

The bibliography contains 119 references.

Contents

I. Introduction 1163
II. Enantioselective enzymic hydrolysis of amino acid derivatives 1164
III. Enantioselective enzymic derivatisation of amino acids and their derivatives 1175

I. Introduction

Optically active amino acids are used widely in various branches of the national economy, including agriculture (food additives, herbicides), the food industry (sweeteners, aroma-producing agents, products for dietary foods), and medicine (infusion solutions, therapeutic agents). The precipitate growth of the industrial manufacture of optically active amino acids is linked primarily with the discovery of new opportunities for their use. For example, the introduction into manufacture of the artificial sweetening agent aspartame has caused a multiple increase in the volume of manufacture of L-phenylalanine and L-aspartic acid in the last five years (Table 1).[1]

Table 1. Manufacture of L-phenylalanine and L-aspartic acid.[1]

Year	Amino acid	Main area of use	Total cost (millions of dollars)
1979	*L*-Phe	Infusion solutions	7.4
1984	*L*-Phe	Aspartame	~100.0
1979	*L*-Asp	Therapy, aroma-producing agents	1.2
1984	*L*-Asp	Aspartame	~15.0

The improvement of methods of obtaining amino acids using new achievements in biotechnology has enabled a significant reduction in the cost of optically active amino acids which, in its turn, has opened up possibilities for using them in new areas and has significantly extended market salts. The manufacture of lysine is a graphic example of the effect of such technology on the price and volume of manufacture of this amino acid (Table 2).[1]

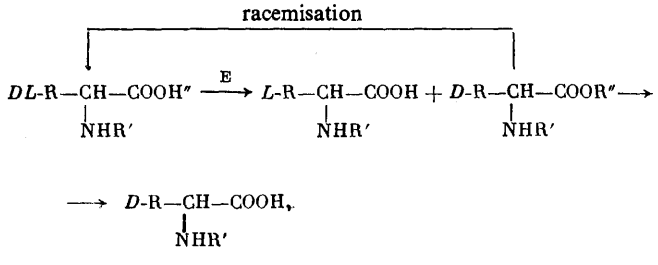
Table 2. Manufacture of L-lysine.

Year	Manufacturing efficiency (arbitrary units)	Mean cost (dollars pound^{-1})	World production (millions of pounds)	Total cost (millions of dollars)
1956	1	23.7	0.2	5
1969	4	4.45	7.0	31
1980	8	2.10	90.0	189

As a rule chemical synthesis of amino acids leads to a racemic product, the preparation of enantiomers requires an optical resolution step. Existing methods of resolving racemates of amino acids may be divided into three main groups, 1) physicochemical methods, 2) chemical and 3) biotechnological (with the participation of enzymes or cells of microorganisms). Physicochemical methods include mechanical separation, selective crystallisation and chromatographic separation. Chemical separation of a racemic amino acid or a derivative is effected with a chiral compound and one of the diastereomers is removed by crystallisation, chromatography, etc.

The first two methods are suitable for solving analytical problems and for the large scale separation of a limited number of amino acids (for example L-glutamic acid using selective crystallisation), but they are not suitable for the industrial preparation of a large selection of optically active amino acids.

The most widespread methods of obtaining enantiomeric amino acids at the present time are those using enzymes or microbial cells. Work published before 1982 is not considered in the present review, this was included in the review by Shvyadas and Galaev.[2] A high reaction rate and stereospecificity are the features of enzymic reactions. The significant acceleration of the reaction when using enzymes may be demonstrated by the following example. The rate



constant for the non-enzymic hydrolysis of urea is 4.15×10^{-5} sec^{-1} at 100 °C while the rate constant for the reaction catalysed by urease is 3×10^{4} sec^{-1} at 20 °C. Another no less important feature of enzymes is their specificity in reaction and in substrate. The specificity may be absolute or almost absolute since some enzymes act on molecules of only one substrate while others act on molecules with marked differences in structure, such as on a whole class of compounds. As a rule enzymes display high reaction specificity but some of them are capable of catalysing 'foreign' reactions. For example the majority of hydrolases catalyse reactions typical of transferases. In addition some groups of enzymes catalyse different types of reaction, i.e. they display a multicatalytic function. In the majority of cases enzymes 'correctly' demonstrate absolute stereospecificity in catalysis when they act on part of a molecule linked with a chiral centre in the substrate or form chiral products from achiral substrates. Racemases and isomerases are exceptions in this respect. Even enzymes possessing wide specificity in relation to substrate structure may display absolute stereospecificity. For example D-amino acid oxidases (EC 1.4.3.3.) catalyse the oxidation of a wide range of primary and secondary D-amino acids while not affecting L-amino acids. L-Amino acid oxidases (EC 1.4.3.2.) act in a similar manner. Stereospecificity is not an obligatory property of enzymes acting on groups distant from a chiral centre in a substrate. Carboxyesterase (EC 3.1.1.1.) catalyses the hydrolysis of the ethyl esters of L- and D-tyrosine at the same rate. On the whole stereospecificity, which is natural for enzymes, is difficult to achieve by chemical means in spite of the fact that asymmetric synthesis has developed significantly in recent years.

By virtue of these factors the enzymic methods of obtaining optically active amino acids have been at the centre of attention of investigators for several decades. They may be divided into two groups, 1) enantioselective enzymic hydrolysis of amino acid derivatives and 2) the enantioselective enzymic derivatisation of amino acids and their derivatives.

II. Enantioselective enzymic hydrolysis of amino acid derivatives

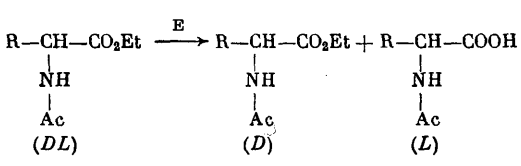
1. Esters of amino acids

The enantioselective enzymic fission of esters as a method of obtaining optically active amino acids was already known at the beginning of the century.[3]

E – enzyme.

The reaction products are the L-amino acid and the ester of the D-isomer which is subjected to non-enzymic hydrolysis of racemisation for subsequent reintroduction into the process for resolving the racemate. Many enzymes of animal and microbial origin are known which possess esterase activity. The best studied of them is α-chymotrypsin, distinguished by high activity and enantioselectivity of action primarily in relation to specific substrate, viz. esters of aromatic *N*-acylamino acids. Its high cost and non-availability in large quantities hinders the application of this enzyme for the separation of racemates in practice. Immobilisation of the enzyme enables the cost of the biocatalyst to be reduced. At the present time the investigation of the chymotryptic hydrolysis of specific substrates is directed mainly towards the development of continuous processes for obtaining optically active amino acids.[4,5] *N*-Acetyl-L-phenylalanine is obtained from its racemic methyl esters in a membrane-reactor (capacity 1.3 $kg\ m^{-2}\ d^{-1}$).[4]

Another way to reduce the cost of biocatalyst is to use cheaper enzymes such as proteases of microbial origin or whole cells. Glaenzer and collaborators[6,7] studied the use of bakers' yeast *Saccharomyces cervisiae* for the enantioselective hydrolysis of raemic *N*-acetylaminoacid esters. It was known previously[4] that the cells of *S. cerevisiae* possess oxido-reductase activity. They catalyse the enantiospecific reduction of ketones, but there are very few data on their hydrolytic activity. It turned out that they are capable of hydrolysing esters of *N*-acetylamino acids with an unbranched chain with a high degree of enantioselectivity (Table 3).



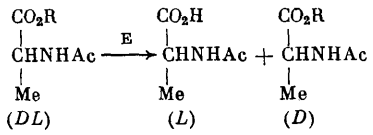


Table 3. Enantioselective anaerobic hydrolysis of *n*-acetylamino acid esters [DL-AcNHCH(R)COOEt] by cells of *Saccharomyces cerevisiae*.

Substrate No.	R	Yield of D-AA ester, %	Enantiomeric excess, %	Substrate No.	R	Yield of D-AA ester, %	Enantiomeric excess, %
1	Me	47	100	4	CH_2CHMe_2	48	92
2	Et	48	96	5	CH_2Ph	38	97
3	iso-Pr	75	13	6	CH_2CO_2Et	49	86
3	iso-Pr	38	80 *	7	$CH_2CH_2CO_2Et$	46	89

* Aerobic hydrolysis.

Substituents in the β-position inhibit the reaction (Table 3, substrate 3), γ-substituents do not show this negative effect (Table 3, substrate 4). Hydrolysis does not occur in the case of substrates with an *N*-acetylamino group in the β-position. When two chemically different ester groups are present (Table 3, substrates 6 and 7) reaction occurs only at the α-ester group, not affecting the ω-group of esters of *N*-acetyl-L-aspartic and -glutamic acids. The hydrolytic action of α-chymotrypsin has similar characteristics.

Changes in the ester component do not as a rule display a significant effect on the course of the hydrolysis of *N*-acetylalanine ester.

R is methyl, ethyl n-propyl, iso-propyl, n-butyl, n-octyl, benzyl, cyclohexyl, t-butyl.

The t-butyl ester is not hydrolysed, the methyl ester is hydrolysed somewhat more slowly than the remaining esters of primary and secondary alcohols, the rates of fission of which are approximately the same and the enantiomeric excess is at least 96%.

Since the esterase actions of *S. cerevisiae* cells and of α-chymotrypsin have much in common it has been suggested that proteinases are the main active principle. To confirm this the hydrolysis of substrate 1 was catalysed by mutant strain ABYS1 of the yeast, which is characterised by a lack of non-specific proteases and carboxypeptidases, and also by the wild strain X-2180-Ia (Table 4).

Table 4. Enzymic hydrolysis of *N*-acetyl-DL-alanine ethyl ester.

Reaction time, h	*S. cerevisiae*		Wild strain X-2180-1 A		Mutant strain ABYS1	
	Enantiomeric excess, %	Yield of D-ester, %	Enantiomeric excess,%	Yield of D-ester, %	Enantiomeric excess, %	Yield of D-ester,%
24	92	not determined	89	52	1	95
48	100	47	100	43	2	81

In many cases the use of enzymes and microbial cells for the fission of racemic esters is limited by the low water solubility of the substrates. The use of two-phase systems of 'water–immiscible organic solvent' is not always possible. For example, on adding chloroform or ethyl acetate to the aqueous system containing the enzyme and substrate, the hydrolysis of esters of *N*-acetylamino acids (alanine, phenylalanine, phenylglycine) is not observed.[8] This is evidently linked with a shift in the direction of ester synthesis in the 'hydrolysis–synthesis' equilibrium of the given system. To solve this problem Fadnavis and collaborators[8] have proposed carrying out the enzymic hydrolysis of esters in reverse micelles. The authors considered that cells of microorganisms, possessing enzymic activity, may in principle be considered as a system containing an enzyme immobilised by inclusion in or addition to the cell wall. To confirm this hypothesis the hydrolysis of esters of *N*-acetylamino acids has been carried out with cells of *S. cerevisiae* crosslinked with glutaraldehyde in an aqueous medium and in reverse micelles [organic phase was chloroform–isooctane (1 : 9 by volume), the detergent being bis(2-ethylhexyl)sulphosuccinate, sodium salt] (Table 5).

Table 5. Hydrolysis of *N*-acetyl-DL-amino acid methyl esters of bakers' yeast in aqueous medium and in reverse micelles.

Note. A is the extent of conversion, %; B the excess of L-enantiomer, %.

No enzymic hydrolysis of the D-enantiomer was observed, spontaneous hydrolysis in the reverse micelles was less than 1.5% in 72 h (less than in aqueous medium). The advantages of using reverse micelles are evident in the case of substrates with low solubility, such as in the hydrolysis of 5 g substrate 1 (Table 5) in 200 ml in 72 h. The enantiomeric excess of unreacted D ester was 30% in aqueous medium and 75% in the reverse micelle medium.

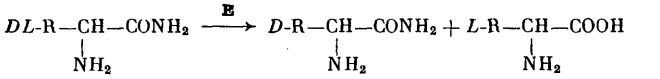
The search for enzymes capable of hydrolysing esters of racemic amino acids led to the discovery of the esterase activity of lipases.[9,10] It is known from the literature that lipases are capable of the fission

of esters of racemic alcohols and carboxylic acids, they are also readily available, inexpensive and stable. Investigation of the hydrolysis of the substrate *N*-Z-α-amino-DL-heptanoic acid ester with lipase from six microorganisms showed that the best results were obtained with the lipase from *Aspergillus niger* and satisfactory results with the lipase from *P. fluorescens* and *C. cylindracea*. Using these three enzymes and a porcine pancreas lipase (PPL) the ester hydrolysis has been effected for a series of natural and synthetic acids (Table 6).

In the general case the enantioselectivity of lipase action decreases in the series PPL ≈ *A. niger* lipase > *P. fluorescencs* lipase > *C. cylindracea* lipase. Three types of unnatural amino acids: 1) with unbranched hydrocarbon chain (Table 6, substrates 2–6), 2) with an unsaturated bond (Table 6, No. 8) and 3) with a heteroaromatic ring (Table 6, No. 10) in the side chain R were separated with high values of the enantiomeric excess (85–95%) by lipases from *A. niger* and from pancreas (except for substrate 6) although the reactions were not optimised. The good result was particularly important in the case of substrate 10 (Table 6) since other enzymic processes (such as the use of acylase I) do not lead to resolution of the racemate of this heteroaromatic amino acid.

It is known that transferring from esters of amino acids with an *N*-acylamino group to esters of amino acids with a free amino group leads to a reduction in the enantioselectivity of enzymic hydrolysis.[11] However in many cases the selectivity is sufficiently large and it is possible to separate enantiomeric amino acids with a free amino group by enzymic enantioselective hydrolysis of their esters. One of the most widely used biocatalysts for this purpose is α-chymotrypsin. Investigations of recent years in this direction may be separated into two main groups. The first group contains work on the development of efficient continuous processes using immobilised α-chymotrypsin.[12,13] The cost of the process may be reduced by racemising the D-isomer and subsequently reintroducing it into the separation process.[14] Such processes may be effected in two-phase 'water–immiscible organic solvent' systems.[15,16]

The second group comprises work devoted to the chymotryptic fission of racemic amino acids containing substituents in the side chain R[17] or at the α-carbon atom.[18] The methyl (or ethyl) esters of *ortho*-(*meta*-, *para*-)fluoro-DL-phenylalanine may be separated into enantiomers in high yield and enantiomeric purity.[17]



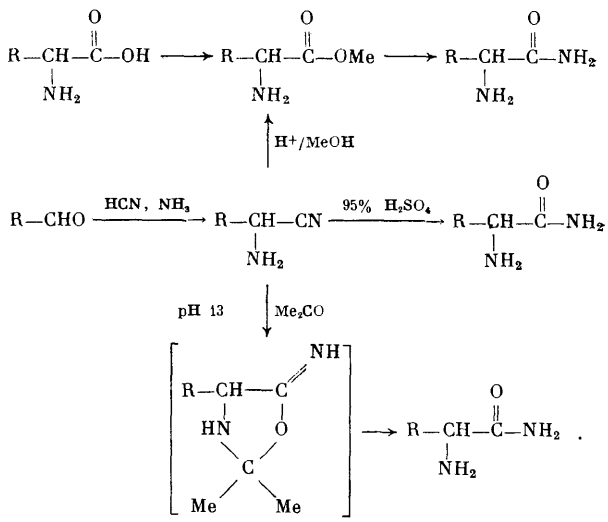
It is known that the introduction of an α-substituent significantly reduces the rate of enzymic hydrolysis. For example, on introducing an α-methyl group into the *N*-acetyltyrosinamide molecule the hydrolysis rate is reduced 10^5 times which is seemingly linked with the incorrect orientation of the bond being hydrolysed.[19] The effect is less significant for amino acid esters. However there is a need for optically active α-aminoacids. They are used in investigations of the link between structure and activity in peptide hormones, conseqently the enzymic separation of their racemic derivatives is of significant interest. The resolution of the methyl esters of α-methyl-DL-amino acids (tryptophan, phenylalanine and *para*-fluorophenylalanine) has been effected (37 °C, pH 5.0, time 30–40 h).[18]

The high enantioselectivity of enzyme action enables the preparation of L-isomers in good yield (33–36%) and optical purity (96% for α-methyl-L-tryptophan). Contamination by the isomer was attributed to spontaneous non-enzymic hydrolysis since no hydrolysis of D-esters by chymotrypsin was observed.

The use of enzymes (or enzyme complexes) from microorganisms or whole cells is an alternative to the use of expensive enzymes of animal origin for esters of amino acids with a free amino group as for esters of *N*-acylamino acids. The fission of the methyl esters of DL-phenylalanine and DL-tyrosine and the benzyl ester of DL-alanine has been effected on a preparative scale (25 g).[20] The scope for ester hydrolysis by the alkaline protease from *Bacillus licheniformis*, the main component of which is subtilisin A (Carlsberg subtilisin), was investigated. The enzyme is stable and active at room and higher temperatures (the half-live for inactivation at 60 °C is about 5 h) and over a wide pH range (6–12). The enantioselective hydrolysis of a racemate leads to the preparation of the product in high yield (L-phenylalanine 48%, D-phenylalanine methyl ester 42.5%) and enantiomeric purity (L-enantiomer 90%, D-enantiomer 100%). Subtilisin 8350, obtained by replacing six amino acids in the protein chain of subtilisin BPN′ from *Bacillus amiloliquefaciens*, has been used for the separation of the esters of several amino acids with a free amino group and also of *N*-acylamino acids.[21] The modified enzyme proved to be 50 times more stable than the initial enzyme in water and 100 times more stable in anhydrous dimethylformamide. Practically 50% conversion was achieved in the resolution of racemic esters. The yields of product and unreacted substrate were more than 40% and the enantiomeric excess was more than 91% (the initial enzyme possessed low selctivity).

2. Amino acid amides

In the general case the enantioselective enzymic hydrolysis of amino acid amides proceeds by the scheme.



Enzymes possessing amidase activity are encountered in many microorganisms. Both purified enzymes and their complexes[22] and whole cells[23–25] may be used for the resolution of racemates. The possibility of using the proteolytic complex pronase from *Streptomyces griseus*, containing serine proteases and aminopeptidases, for the separation into enantiomers of the racemic amides of leucine, phenylalanine and tryptophan has been studied.[22] The hydrolysis of amino acid amides catalysed by pronase is characterised by high values of the rate, enantioselectivity and degree of conversion of the L substrate. DL-Leucine amide may also be separated into antipodes in 50% yield by whole cells of *Enterobacter cloacae*, *Pseudomonoas sp.* etc.[23] The L-aminopeptidase from *Pseudomonas putida* enabled separation of Met and Phg amides into optical antipodes.[24] Enzymes are encountered possessing an enantioselective action in relation to a D substrate.[26–28] DL-Valine amide may be separated into antipodes using either cells of *Pseudomonas rasea*, which hydrolyse L-amino acid amides (yield of L-valine was 50%, 40 °C, time 5 h),[25] or cells of *Rhodococcus erythropolis*, which hydrolyse D-amino acid amides (yield of D-valine 38–47%, 40 °C, time 2 h).[27] The D-amidase from a strain of *Ochrobactrum anthropi*, isolated from soil, has been partially purified and characterised.[28] Data on substrate specificity are given in Table 7. In addition the rates of hydrolysis for L-substrates (with the exception of norvaline and norleucine) have been determined and were less than 0.1% of the hydrolysis rate of the D-enantiomer.

Among the few studies devoted to the enzymic separation of amino acid amides some[29–33] occupy a special place. Regarding the industrial enzymic separation of amino acids to be promising and fully competitive with asymmetric synthesis and chemical separation, the authors have carefuly developed all the stages of obtaining optically active amino acids from racemic amides, beginning with the preparation of the starting materials. It is known that amides may be obtained from amino acids through the corresponding esters. It is probably more expedient to use as starting materials the α-aminonitriles which are intermediates in the synthesis of amino acids from aldehydes by the Strecker reaction. The conversion of α-aminonitriles into the corresponding amides may be effected by various routes. A promising method[29] has been proposed which is a one-stage conversion of an aminonitrile into the amide through an intermediate oxazolidine in alkaline medium in the presence of catalytic quantities of acetone (yield of product was over 90%).

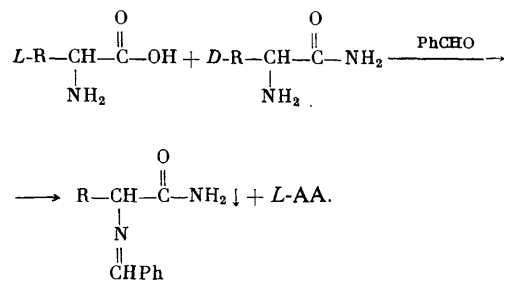


Table 7. Amidase activity of the enzyme from *Ochrobactrum anthropi.*

Substrate D-AA amide	V_{rel}*, %	Substrate D-AA amide	V_{rel}*, %	Substrate D-AA amide	V_{rel}*, %
Phe	100	Norleu	40	Phg	15
Tyr	97	Ala	33	Pro	9.7
Trp	96	Met	28	Lys	2.5
Leu	46	Norval	15	His	1,5

* V_{rel} is hydrolysis rate.

Many microorganisms are known which produce aminopeptidases (such as *Aspergillus* etc.). However, their use for separating amino acid amides, in the authors' opinion, is limited by low activity, narrow substrate specificity and undesirable side effects. A search carried out showed that the enzyme preparation of aminopeptides from *Pseudomonas putida* possessed the best characteristics. The high (almost 100%) enantioselectivity was combined with a very broad substrate specificity. The relative activity varied from 20% (L-phenylalanine amide) to 100% (D-phenylglycine amide), substrate concentration may be as high as 20% without affecting the activity of the enzyme. A considerable virtue is that the reaction may be conducted over a wide pH range. Traditional methods such as ion exchange chromatography or extraction are used for the separation of the L-amino acid and the D-amino acid amide. In those cases when the D-amino acid is required the authors suggest using one of the other methods developed by them. The first consists of the use of biocatalysts possessing no enantioselective action. Such a biocatalyst was found which was an enzyme with amidase activity towards L and D substrates from cell preparations of *Rhodococcus erythropolis.* The yields of the D-amino acids obtained by this method were very high in comparison with the usual chemical hydrolysis. Another method is based on the formation of a Schiff's base, from benzaldehyde and the D-amino acid amide, which is practically insoluble in water (and therefore readily isolable).

Acid hydrolysis at temperatures below 100 °C of the compound obtained give the D-amino acid without racemisation. The D- and L-amino acids obtained in this way possess high optical purity (99% and more).

In those cases when the D-enantiomer is not widely used it is expedient to subject the D-substrate to racemisation for subsequent reintroduction into the separation process. For this purpose a racemisation process was developed for the Schiff's base, i.e. for an *N*-(or un)substituted benzilidene-amino acid amide, in aqueous organic medium in the presence of base.[31] The racemate of the Schiff's base obtained was hydrolysed to the DL-amino acid amide which was subjected to enantioselective hydrolysis by an enzyme from *Pseudomonas putida.* The method[29–32] developed has enabled separation of racemates of phenylglycine, *p*-hydroxyphenylglycine, valine, phenylalanine, tryptophan, methionine, lysine, thienylglycine and their derivatives. The structural elements for the amino acids required for the development of the enzymic activity from *Pseudomonas putida* are an unsubstituted amino group and an α-hydrogen atom. Since α-alkylated amino acids are of significant scientific and commercial interest a new biocatalyst has been developed from *Mucobacterium neoarum* which possesses amidase activity towards α-alkylated amino acids.[33] The enantiomers of α-methylvaline, -leucine, -phenylalanine, -4-methoxyphenylalanine and α-ethylphenylalanine have been separated in high yield and enantiomeric purity (for example, the yield of α-methyl-L-leucine was 49.5% and of α-methyl-D-leucine amide 48.7%).

3. Amino acid nitriles

It is known that many strains of microorganisms such as *Corynebacterium sp., Nocardia rhodochrous, Pseudomonoas sp., Pencillium sp., Escherichia coli* and several others are capable of catalysing the hydrolysis of nitriles to the corresponding amides or acids and because of the variety of microorganisms the substrate spectrum is extremely broad. This comprises aliphatic and aromatic nitriles, α-hydroxy and α-aminonitriles.[34,35]

Many strains have been investigated[36] and among them was *Brevibacterium sp.* R312 which hydrolyses practically every water soluble nitrile to the corresponding acid but the reaction does not occur enantioselectively. The selection of strain R312 was effected in a medium containing fluoroacetamide, which is toxic for it, since hydrolysis to fluoroacetic acid occurs by the action of the non-specific amidase. Screening enabled selection of several mutants not carrying out this reaction and one of them A_4 was chosen for subsequent investigations. The spectrum of nitrilase activity of A_4 and R312 proved to be absolutely identical which confirmed the hypothesis that the enzyme system causing the hydrolysis of nitriles comprises two enzymes, a nitrilase and an amidase. Investigation of the amidase activity of whole cells and cell extracts showed that R312 hydrolyses practically all amides investigated with the exception of acrylamide, methacrylamide, L- and D-asparagine and D-glutamine, though the latter is hydrolysed by cell extracts. The amidase activity of A_4 is appreciably less. It hydrolyses only formamide, urea, nicotinamide, L-glutamine and amides of α-amino acids, although on hydrolysis of amides of DL-amino acids the yield did not exceed 50% and the hydrolysis product was the L-amino acid.

Additional investigations confirmed the enantioselectivity of the action of the enzyme. D-Aminopropionamide is not a substrate but the D-enantiomer is converted quantitatively into L-alanine. The use of strain A_4 enabled separation of the racemate of α-amino-γ-methylthiobutyronitrile quantitatively in 2–3 h. The hydrolysis products are L-methionine and D-methionine amide, the latter may be subjected to racemisation or hydrolysis to the D-amino acid by strain R312. Similar processes enabled the preparation of L-alanine, L-α-aminobutyric acid, L-phenylalanine, L-valine and L-leucine.

In the process of separating racemic aminonitriles with a strain of *Pseudomonas MY-1*[37] it was evident that two enzymes were participating, a DL-aminonitrilase and an enantioselective amidase. Separation of the enantiomers of DL-phenylglycine nitrile to the L-amino acid and the D-amino acid amide occurs quantitatively in 0.5 h at 15 °C. Optically active L-Phe may be obtained from the whole mass of racemic derivative as a result of a combined process in which hydrolysis of the DL-aminonitrile occurs to the DL-amino acid amide under the action of cells of *Acinetobacter calcoaceticus* with subsequent hydrolysis of the amino acid amide and racemisation of the D-phenylalanine amide by cells of *Arthrobacter* ATCC 31652.[38]

There are however data indicating that the participation of enantioselective amidases in the hydrolysis process is not the sole route for the resolution of racemic nitriles. It has been shown[39] that optically active amino acids and their amides (such as L-leucine amide) may be obtained from racemic nitriles by the enantioselective action of a nitrilase (strain 311).

4. Acylamino acids

The enantioselective hydrolysis of *N*-acylamino acids by acylase is the most widespread method for the large scale separation of enantiomers of amino acids.

$$\underset{\substack{|\\ \text{NHCOR}'\\ (DL)}}{\text{R—CH—COOH}} \xrightarrow{\text{E}} \underset{\substack{|\\ \text{NH}_2\\ (L)}}{\text{R—CH—COOH}} + \underset{\substack{|\\ \text{NHCOR}'\\ (D)}}{\text{R—CH—COOH}}.$$

The industrial development of this method, including the process of racemising the D-enantiomer for subsequent reintroduction into the separation process, was effected in the fifties and sixties by Tanabe Seijaku Co. Ltd.

At the end of the sixties a fermentor was built containing acylase immobilised by ionic binding to DEAE-Sephadex for the continuous production of amino acids. This was the first industrial application of immobilised enzymes. Since 1969 several types of fermentors have been developed for obtaining L-methionine, L-valine, L-phenylalanine and other amino acids from their racemic *N*-acyl derivatives.[40,41]

Enzymes possessing acylase activity are isolated from animal, plant and microbial sources. The most studied acylase of animal origin is the enzyme from porcine kidney, viz. acylase I, which is specific for aliphatic amino acids.

Acylases from animals belonging to four classes have been investigated.[42] These are fish (silver carp), amphibians (frog), birds (pigeon) and mammals (mouse, rat, cat, dog, cow, pig) in addition to human acylase. Freshly prepared kidney homogenates served as the enzyme source. Substrates used are the *N*-acetyl derivatives of DL-amino acids (norvaline, norleucine, valine, leucine, glutamic acid, phenylalanine and tryptophan) and *N*-chloroacetyl-DL-phenylalanine and *N*-formyl-DL-methionine. The character of the substrate specificity proved to be similar for the majority of animals. The maximum rate was displayed in the hydrolysis of *N*-formyl-methionine. The specific activity of the enzymes varied more than 16 times (from 4.2 for frog to 65.5 μmole min^{-1} mg $protein^{-1}$ for cow) so assessment of substrate specificity was carried out in relative units (for *N*-formylmethionine V_{max} = 100%). The rate of hydrolysis for the unnatural amino acid *N*-acetylnorleucine was 30–49%. Comparison of the hydrolysis rates of amino acids with branched and unbranched side chains (leucine, valine and norleucine, norvaline) showed that the latter were more suitable substrates (the difference in rate was 1.2–4.0 times). The *N*-acetyl derivatives of aromatic and dicarboxylic amino acids were poor substrates ($0.5\% \leqslant V_{rel} \leqslant 10\%$). As might have been expected replacement of the acetyl group by chloroacetyl leads to a 2–3-fold increase in rate. The substrate specificities of porcine acylase (PA) and human acylase (HA) differed somewhat. The maximum hydrolysis rate was observed for *N*-acetylnorleucine (V_{rel} = 208% for PA, 124% for HA), *N*-acetylnorvaline was in the second place (181% for PA, 110% for HA) and *N*-formylmethionine in third place (100%). The remaining substrates behaved in a similar manner with the other acylases. The data obtained are in good agreement with the previously proposed structure for the active centre as a narrow hydrophobic cleft of length five methylene units,[43] and suggest that the original and main role of the enzyme is the hydrolysis of *N*-formylmethionine.

Enzymes possessing acylase activity are encountered in many microorganisms.[2] They are inexpensive, available in large quantities and are used widely for the resolution of racemates of acylamino acids.[44–53] Up to the present time development has been conducted

on the application of free enzymes and microbial cells,[44–47] however the advantage of using immobilised enzymes was demonstrated indisputably even in the late sixties (the efficiency of using an immobilised enzyme for three months was more than 10 times greater than for the free enzyme).[54] The various methods of immobilising aminoacylases have been discussed.[55] The substrate specificity of microbial acylases is appreciably broader than that of acylase I. Substrates were not only the aliphatic amino acids but also derivatives of aromatic and dicarboxylic acids.[2] An investigation has been carried out of specificity in relation to the acyl group of phenylalanine for fungal acylase (for which aromatic amino acids are good substrates) and for acylase I.[56] The relative rate was studied at the pH optimum determined for each acyl group for fungal acylase (pH 6–7.5) and at pH 7 for acylase I. The hydrolysis rate fell in the series formyl > chloroacetyl > acetyl > propanoyl > butanoyl > pentanoyl > hexanoyl > ethyloxycarbonyl ⩾ benzyloxycarbonyl (Z) [t-butyloxycarbonyl (Boc) ≈ 0] on catalysis with fungal acylase and in the series butanoyl > chloroacetyl > propanoyl > pentanoyl > acetyl > hexanoyl > formyl > ethoxycarbonyl ⩾ benzyloxycarbonyl (t-butyloxycarbonyl ≈ 0) on catalysis with acylase I. Derivatives of the urethane type were significantly less reactive than the usual acyl derivatives, neither t-butyloxy nor benzyloxycarbonyl derivatives were subject to hydrolysis in practice. The correlation between the chain length of the hydrocarbon fragment of the acyl group [$H-(CH_2)_n-C(O)$, n = 0 to 5] and the relative rate of hydrolysis is shown in Fig. 1. The hydrolysis of N^{α}-formyl-N^{ε}-t-butyloxycarbonyl-DL-ornithine was effected by acylase (yield of L-amino acid was 48.5%, of D-amino acid derivative 44%) which confirms the suitability of the formyl group for practical separations.

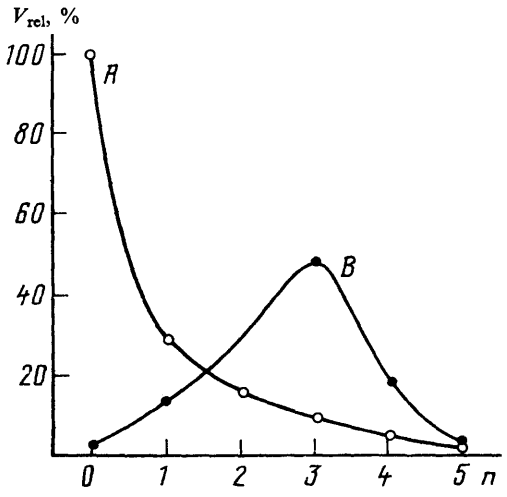

Figure 1. Dependence of the relative hydrolysis rate of *N*-acylphenylalanine by *A*, fungal acylase and *B*, acylase I on the number of methylene units (*n*) in the acyl group.

The kinetics of the enantioselective hydrolysis of *N*-acetyl-DL-amino acids (methionine, leucine, alanine, valine, serine, tryptophan, phenylalanine and phenylglycine) by acylase from *Aspergillus oryzae*, free and immobilised on DEAE-Filtradex R50, have been investigated.[57,58]

With the aim of broadening the application of acylase for obtaining optically active amino acids a search for new enzymes possessing acylase activity has been carried out[59,60] as has a clarification of such activity for enzymes of other classes.[61,62] The acylase from *Comamonas testosteroni* specific for acyl-L-proline was discovered in this way.[59] The high enantioselectivity enables resolution of *N*-acetyl-DL-proline into enantiomers. Replacement of the acetyl group by chloroacetyl accelerates the rate of hydrolysis of the *N*-derivatives of L-proline 3.6-fold. No reaction took place in the case of the benzoyloxycarbonyl and t-butyloxycarbonyl derivatives, the activity in relation to the derivative of other amino acids was one to two orders of magnitude less than for *N*-acetyl-L-proline. An acylase from *Bacillus thermoglucosidius* has been investigated.[60] The enzyme is specific for aliphatic amino acids (V_{rel} = 100% for *N*-acetyl-L-methionine), the hydrolysis rate for aromatic amino acids was approximately one order of magnitude less.

The majority of *N*-acetyl derivatives of acidic and basic L-amino acid and the *N*-acetyl-D-amino acids investigated (methionine, leucine, valine) were inert to the action of this enzyme (V_{rel} < 1%). Replacement of the acetyl group by chloroacetyl leads to an increase in rate V_{rel} of approximately 10-fold. The benzoyloxycarbonyl and t-butyloxycarbonyl derivatives were inert. The enzyme investigated has much in common with acylase I and with the acylase from *Asp. oryzae*. They all contain Zn^{2+}, are activated by Co^{2+} ions, have pH optima 8.0–8.5 and have similar amino acid compositions. However the activity of the acylase from *Bacillus thermoglucosidius* was approximately two orders of magnitude greater with the *N*-chloroacetyl derivative of DL-alanine and DL-norleucine. In addition the enzyme is distinguished by a high stability under extreme conditions. On heating to 70 °C for 10 min its activity was fully preserved, to 80 °C 90% was retained. It was stable to organic solvents (ethanol up to 50%, isopropanol up to 30%). The activity (80%) was retained in the presence of 5% sodium dodecyl sulphate and 85% in 8 M urea at 37 °C for 30 min. These special features of the acylase from *B. thermoglucosidius* suggest it may have promise in the preparation of optically active amino acids.

The same authors detected acylase activity towards acylamino acids in the purified dipeptidase from *B. stearothermophilus* which was 3–30% of its activity in the hydrolysis of dipeptides.[61] However this enzyme displayed higher specificity towards aromatic amino acids (V_{rel} = 100% for *N*-acetyl-L-methionine, 110% for *N*-acetyl-L-tyrosine and 160% for *N*-acetyl-L-phenylalanine). As in the previous case replacement of the acetyl group by chloroacetyl leads to an increase in V_{rel} of at least 10-fold. The ability of polymixin acylase to hydrolyse *N*-acyl derivatives of amino acids, although with low enantioselectivity has been shown.[62] Of all the acyl groups investigated containing from 2 to 16 carbon atoms the decanoyl (C_{10}) derivatives were most readily subject to hydrolysis. It must also be mentioned that when preparing the enzyme under specific conditions it is able to remove a Z protecting group (although with a low rate).

D-Amino acids are being used more widely in recent years. Communications on the presence of D-acylase activity in certain microorganisms is of special interest in this respect. D-Aminoacylases from microorganisms of *Pseudomonas*[63,64] and *Streptomyces*[65,66] species were known previously. Low enantioselectivity was a disadvantage of these enzymes which limited their use for the manufacture of D-amino acids. An investigation has been carried out[67] of 800 strains of microorganisms isolated from soil and

one strain *Alcaligenes dentrificans* DA 181 was found to be a source of D-aminoacylase, possessing high activity and enantioselectivity towards *N*-acyl-D-amino acids. The enzyme, expressed under optimum conditions, possesses an activity of 250 μmol h^{-1} ml^{-1} (D-acylase from *Pseudomonas Sp.* has 10 μmol h^{-1} ml^{-1},[64] and from *Streptomyces olivaceus* 84 μmol h^{-1} ml^{-1} [65]). The maximum specific activity, 108 600 μmol h^{-1} ml^{-1}, was displayed in the hydrolysis of *N*-acetyl-D-methionine (*Pseudomonas sp.* 6.8 μmol h^{-1} ml^{-1} and *Str. olivaceus* 571 μmol h^{-1} ml^{-1}). The enzyme catalyses the hydrolysis of L substrates to an insignificant extent (Table 8).

Table 8. Relative hydrolysis rate of D- and L-substrates by the aminoacylase from *A. dentrificans*.

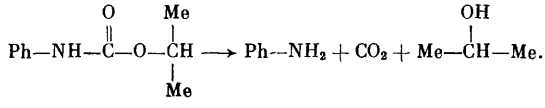
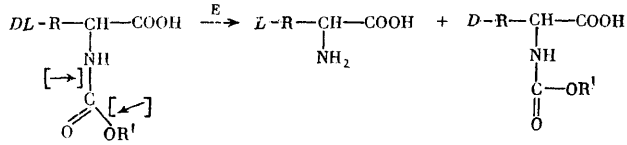
*AI is acylase I, AA is acylase from *Aspergillus sp.*

** The free amino acid was not isolated.



*** *N*-Acyl derivatives of α-methyl-AA.

The use of aminoacylases for the separation of enantiomers enables rarely encountered and unnatural optically active amino acids to be obtained. The racemic acyl derivatives of such amino acids and also of α-methylamino acids are separated into enantiomers by acylase I and by the acylase from *Aspergillus sp.* in preparative quantities (Table 9).[68]



The values for the enantiomeric purity given in Table 9 characterise the significant enantiospecificity of the action of the enzyme (the amino acids isolated were not recrystallised). In the case of *N*-acyl-α-methyl-AA, the activity in relation to which was low (V_{rel} < 1%, for *N*-acetylmethionine V_{rel} = 100%), hydrolysis was effected with acylase I enclosed in a membrane which made it possible to use large quantities of protein many times in small reaction volumes. It was not expedient to use the acylase from *Asp. oryzae* since its specific activity was two orders of magnitude lower than that of acylase I.

5. Carbamates of amino acids

Many pesticides contain carbamate groups, such as NH(CO)OMe. It was shown previously that breakdown of *N*-phenylcarbamates occurs in soil under the action of microorganisms.[69]

With the development of an efficient method for the chemical synthesis of carbamates of amino acids[70] the possibility arose of obtaining optically active amino acids by enzymic breakdown of these derivatives. With this aim Kula and collaborators attempted to effect the hydrolysis of carbamates of several amino acids with an esterase from porcine liver, a hydantoinase from *Pseudomonas fluorescens* DSM 84, the urease from black beans, an acylase from porcine kidney and an acetylcholinesterase from porcine and human erythrocytes.[71,72] Enantioselective enzymic hydrolysis of the carbamates of amino acids occurs according to the following scheme.

Enantioselective removal of the *N*-alkoxycarbonyl group was observed only in the case of acylase and acetylcholinesterase. Of the three *N*-substituted DL-amino acids investigated, the alkoxycarbonyl derivatives of alanine, valine and *N*,*N*′-α,ε-disubstituted DL-lysine, acylase hydrolysed the carbamates of alanine and valine with both methoxy- and with ethoxycarbonyl (EOC) substituents. In the case of the alkoxycarbonyl derivative of lysine complete hydrolysis occurred but only with a methoxy carbonyl (MOC) group. Acetylcholinesterase effected the decomposition of the *N*-MOC derivatives of all three amino acids but in the case of lysine hydrolysis occurred regioselectivetly at the α substituent. The *N*-EOC derivatives were not hydrolysed. The pH optimum for the action of acetylcholinesterase was 7.5–8 and for acylase 7.5. The Michaelis constant (K_M) for the hydrolysis of *N*-MOC-DD-alanine was 68 mM for acetylcholinesterase and 8.2 mM for acylase. The activity of each of the enzymes in the hydrolysis of valine and lysine

derivatives was approxitimately the same but was one order of magnitude less in the hydrolysis of α,ε-bis(MOC)-DL-Lys. The activity of acetylcholinesterase was 15–20 times less than the activity of acylase but the size of the latter in the hydrolysis of *N*-MOC-DL-Val(Ala) was less than 1% activity of acylase in the hydrolysis of *N*-acetylmethionine (values of K_M are of the same order) (Table 10).

Table 10. Hydrolysis of amino acid carbamates by acylase from porcine kidney (temperature 37 °C).

Carbamate of DL-AA	α, μmole min^{-1} mg^{-1}	K_M, mM	Time, h	L-AA detected, %	
				A	B
N-MOC-Ala	0.63	8.2	78	47.5	43.0
N-EOC-Ala	0.56	8.2	70	45.5	44.0
N-MOC-Val	0.45	9.1	70	45.5	44.5
N-EOC-Val	0.40	9.1	76	42.5	34.5

Note. α is specific activity; A before chromatographic separation; B after chromatographic separation.

When considering the mechanism of the enzymic hydrolysis reaction of carbamates of amino acids the authors suggested two possible routes for the reaction.[72] The first was fission of the ester bond of the carbamate. The products of this reaction would be an alcohol and a substituted carbamic acid. Derivatives of carbamic acids are unstable and the intermediate obtained is spontaneously decomposed into an amino acid and carbon dioxide. Enzymic attack at the carbonyl atom with fission of the amide bond is a more probable route. The products of this reaction are the amino acid and a monoester of carbonic acid which decomposes to an alcohol and CO_2. In either case two volatile products are formed which may readily be removed from the reaction. This enables the reaction to proceed to completion and simplifies the isolation of the amino acid.

However the low values of the carbamates activity of acylase and acetylcholinesterase exclude the possibility of using these enzymes for the large scale resolution of amino acid racemates. In this situation there are two next steps, 1) a search for new sources of enzymes possessing high activity and 2) the selection of mutant strains. Kula and Sambale chose the first route.[73,74] They investigated 42 strains of microorganisms isolated from soil, which had previously been subjected to treatment with pesticides containing carbamate structures, and 36 strains from the German Microorganism Collection (from *Agrobacterium rodiobacter, Agrobacterium rhizogenes, Arthrobacter globiformis, Bacillus coagulans, Corynebacterium sepedonicum, Enterobacter cloacae, Mucobacterium spegmatis, Pseudomonas fluorescens, Pseudomonas putida*). Seven strains from the German Collection displayed low activity towards the alanine derivative and four towards the lysine derivative. The greatest activity was shown by the strain of *Pseudomonas fluorescens* DSM 50124 at 2.3 nmol min^{-1} mg^{-1} for *N*-MOC-Ala and 1.6 nmol min^{-1} mg^{-1} for *N*-MOC-Val.

The strains of microorganisms isolated from soil were cultured in media enriched with one of the substrates *N*-MOC-Ala, *N*-MOC-Val or *N,N'*-α,ε-bis(MOC)-Lys and the presence of carbamatase activity was then determined. It turned out that such activity was possessed by significantly fewer strains cultured in media enriched with the valine derivative than in the case of the alanine and lysine derivatives. This may be linked with the bacteriostatic properties of valine.[75] The majority of strains possessing carbamatase activity effected the hydrolysis of all three substrates but the activity towards the lysine derivative was the least. It is interesting to note that strains cultured on a medium enriched with *N*-MOC-DL-Ala possessed higher activity towards valine and lysine derivatives than those cultured on media enriched with *N*-MOC-DL-Val or *N,N'*-α,ε-bis(MOC)-DL-Lys. Six samples were isolated for further investigation (Table 11). The D-enantiomers of the substrates investigated were stable to the action of the enzyme. The hydrolysis of racemic substrates led to a product containing contamination by the D-isomer only in the case of alanine, but this is apparently linked with the presence of an alanine racemase.

Table 11. Hydrolysis of *N*-methoxycarbonyl-DL-amino acids by various strains of microorganisms isolated from soil.

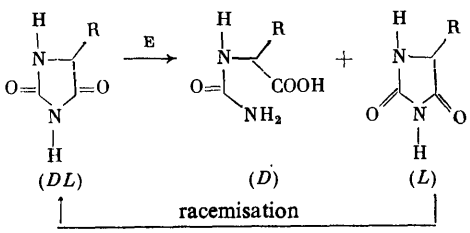
Strain	α, nmole min^{-1} mg^{-1}			Hydrolysis of *N*-Moc-DL-Val				
	N-MOC-*DL*-Ala	N-MOC-*DL*-Val	*N,N'*-α,ε-bis(MOC)-DL-Lys	[protein], mg ml^{-1}	[substrate] mM	Time, h	[product], mM	Yield, %
A3 Xanthomanas maltophilia	166	126	96	0.2	180	65.5	18.5	10.6
A4 Methylobacterium extorques	318	81	45	1.2	180	65.0	29.5	16.9
L8 (not determined)	19.5	4.1	8.9	1.5	180	63.5	9.2	5.4
L10 Pseudomonas putida	59.0	8.8	0.0	0.5	180	67.0	46.0	26.3
L12 not determined	8.3	6.1	0.0	4.0	180	64.0	74.7	42.7
L18 Alcaligenes sp.	20.9	51.8	0.0	1.4	350	64.5	162.5	46.5

In the majority of cases the hydrolysis of *N,N'*-α,ε-bis(MOC)-Lys led to *N*-ε-MOC-LYs, *N*-α-MOC-Lys was not detected in the reaction products. Four strains gave unsubstituted lysine, two others a mixture of lysine and *N*-ε-MOC-Lys.

In the course of further investigations a strain was found possessing DL-carbamatase activity (121 nmol min^{-1} mg^{-1} for the alanine derivative, 170 nmol min^{-1} mg^{-1} for valine and 6.0 nmol min^{-1} mg^{-1} for lysine).[74] Two enzymes were isolated by purification, an L-carbamatase (MW 160000) and a D-carbamatase (MW 90000). Their substrate specificities towards the amino acid side chain and the alcohol component of the carbamate group were investigated (Table 12). The L-carbamatase displayed the greatest activity towards *N*-MOC-L-Phe while the best substrate for the D-carbamatase proved to be *N*-MOC-D-Ala. An increase in the number of carbon atoms in the alcohol component of the carbamate group causes a change in activity, which is extremely marked in the case of the L-carbamatase and insignificant in the case of D-carbamatase.

The stereoselective hydrolysis of *N,N'*-α,ε-bis(MOC)-DL-Lys occurs only at the α-amino group. Such a regioselective enzyme might play an important role in peptide synthesis for removing *N*-α-protecting groups.

Table 12. Specific activity of purified enzymes.

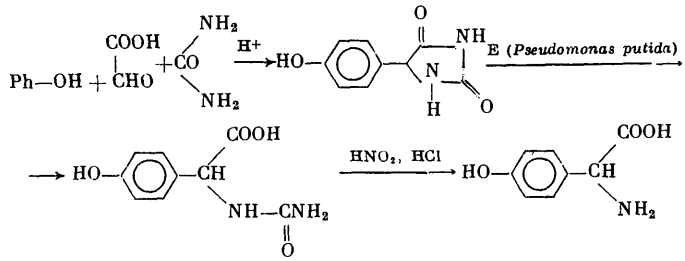


DL-Amino acid carbamate	L-Carbamatase activity, μmole min^{-1} mg^{-1}	D-Carbamatase activity, μmole min^{-1} mg^{-1}
N-(MOC)-*DL*-Val	12.1	4.5
N-(EOC)-*DL*-Val	1.1	2.1
N-(MOC)-*DL*-Ala	25.6	51.3
N-(EOC)-*DL*-Ala	8.9	26.7
N-(MOC)-*DL*-Phe	42.6	0.1
N-(MOC)-*DL*-Leu	3.3	1.0
N,N'-αε-bis(MOC)-DL-Lys	1.0	0.5

In conclusion it must be recorded that the specific activity of the strains found in the primary selection were inadequate for the development of an enzymatic process. However the fact that many microorganisms belonging to different species possess carbamatase activity raises hopes that further search and investigations will lead to the obtaining of enzymes suitable for the industrial resolution of amino acid carbamates.

6. Cyclic derivatives of amino acids

a) 5-Monosubstituted hydantoins



Enzymes possessing hydantoinase activity are mainly encountered in the microorganisms *Hansemula sp.*,[76] *Pseudomonas*,[77–79] *Agrobacterium*,[80] *Arthrobacter*,[81,82] *Corynebacterium*,[83] *Bacillus*,[84] etc. They catalyse the fission of hydantoins into *N*-carbamoyl-α-amino acids.

Hydantoins are intermediate compounds in the synthesis of α-amino acids from aldehydes, KCN and urea or ammonium carbonate.[85] They have an important advantage in comparison with other derivatives of amino acids. They racemise spontaneously under the conditions of the enzymic reaction and make it possible to convert practically 100% of a racemate into one of the enantiomers.

Removal of the *N*-carbamoyl group is possible chemically with an equimolar quantity of sodium nitrite in acidic medium. Complete retention of configuration was observed and the degree of conversion was close to 100%.[86]

This method enabled development of one of the most economic processes for the large scale manufacture of such amino acids as D-*p*-hydroxyphenylglycine used in the preparation of the semi-synthetic penicillin amoxicillin and the cephalosporins cephadroxil and cefatriazine.[86] Development of the process included the design of a simple and economical method for the chemical synthesis of the substrate DL-5-(*p*-hydroxyphenyl)hydantoin from phenol, glyoxylic acid and urea in an acidic medium.

The manufacture of D-phenylglycine and D-valine, which are used to the synthesis of antibiotics and pesticides, was developed in a similar manner.

The catalytic conversion of DL-5-(*p*-hydroxyphenyl)hydantoin also occurs by the action of cells of *Pseudomonas sp.* AJ-11220 however in this case the product is not the *N*-carbamoyl-D-amino acid but D-*p*-hydroxyphenylglycine.[87,88] Other similar processes have been studied.[89,90]

Yokozeki and collaborators have investigated strain AJ-11220, have optimised the conditions of expression of cells and of carrying out the enzymic hydrolysis (pH optimum 8.0, optimum T = 43 °C) and determined the substrate specificity of the enzyme (Table 13).[87]

Table 13. Substrate specificity of the enzyme from *Pseudomonas sp.* AJ-11220.

Hydrolysis produce	V_{rel}, %	Hydrolysis produce	V_{rel}, %
D-cyanoethylglycine	100	*D*-His	33
D-Met	80	*D*-Trp	21
Gly	80	*D*-Ile	19
D-Gln	72	*D*-Lys	18
D-Phg	62	*D*-Val	15
D-*p*-hydroxy-Phg	61	*D*-Glu	12
DL-Ala	58	D-3, 4-methylenedioxy-Phe	11
D-Phe	41		

All the products with the exception of glycine and alanine have the D configuration. In the case of alanine the authors linked the formation of a racemic product with the presence of alanine racemase in the cells, which was confirmed by subsequent experiments.

The possibility of obtaining D-lysine from its hydantoin precursor has been demonstrated for the first time.[87] It must also be noted that dihydrouracil is hydrolysed to a very insignificant extent by

AJ-11220 cells although it is the best substrate for the enzyme from *Pseudomonas putida*.[86] All these data suggest that the enzyme participates in the catalytic process with a different substrate specificity. To investigate this a partial purification was carried out and the substrate specificity of the fractions isolated was determined.[88] Cells of *Pseudomonas sp.* AJ-11220, suspended in 0.02 M tris HCl buffer (pH 7.5) containing either 10 mM $CoCl_2$ and $CaCl_2$ (variant I), or 10 mM dithiothreitol (variant II), were subjected to the action of an ultrasonic oscillator with subsequent fractionation on a column of DEAE-Toyopearl 650 M previously equilibrated with the appropriate buffer. Isolation by the first variant led to a 27-fold purification of the enzyme, viz. D-hydantoin hydrolyase (D-HH), with an overall activity yield of 63% (Table 14). No L-hydantoin hydrolase was detected. The hydrolase of *N*-carbamoyl-AA (CH) found in the unpurified extract was also not detected after fractionation on DEAE-Toyopearl.

Table 14. Partial purification of D-hydantoin hydrolase.

Fraction	Total quantity of protein, mg	Formation			
		D-enantiomer		L-enantiomer	
		A*, nmole min^{-1}	α, nmole min^{-1} mg^{-1}	A*, nmole min^{-1}	α, nmole min^{-1} mg^{-1}
Unpurified extract	540	36 000	67	0	0
DEAE-Toyopearl	13	22 620	1795	0	0

*A is total activity.

Purification according to variant II led to the observation that D-hydantoinase activity, found in the unpurified extract, was not detected after fractionation on DEAE-Toyopearl. The results of purifying the D and L hydrolases of *N*-carbamoyl-AA are shown in Table 15.

Table 15. Partial purification of *N*-carbamoyl-L- and D-amino acid hydrolases.

Fraction	Total quantity of protein, mg	Formation			
		D-enantiomer		L-enantiomer	
		A, nmole min^{-1}	α, nmole min^{-1} mg^{-1}	A, nmole min^{-1}	α, nmole min^{-1} mg^{-1}
Unpurified extract	475	7200	15	2290	5
DEAE-Toyopearl	10	2600	261	0	0

The data obtained enable certain conclusions to be drawn as to the mechanism of the asymmetric hydrolysis of DL-hydantoins of amino acids by *Pseudomonas sp.* AJ-11220. Only the D-isomer of the hydantoins is converted into the corresponding *N*-carbamoyl-D-amino acid by D-HH (pH optimum 8.0, optimum T 55 °C). *N*-Carbamoyl-D-amino acids are hydrolysed to the D-amino acid by D-CH (pH optimum 7.0, optimum T 50 °C). The L-hydantoins of amino acids racemise spontaneously and the D-isomers obtained are introduced into the hydrolysis process. When using preparations of D-HH and D-CH, obtained by fractionation on DEAE-Toyopearl, in the hydrolysis of DL-5-(*p*-hydroxyphenyl)hydantoin (pH 8.0) the product D-(*p* hydroxyl)phenylglycine, was obtained quantitatively. The substrate specificity of the three partially purified enzymes was also determined (Table 16).

Table 16. Substrate specificity of enzymes (D-hydantoin hydrolases and hydrolases of *N*-carbamoyl-D- and L-amino acids).

Substrate, hydantoin derivative of AA	V_{rel}, % (D-HH)	Substrate, *N*-carbamoyl-D- or L-AA	V_{rel}, %	
			D-CH	L-CH

DL-3,4-Dimethoxy-Phe	4
L-Met	2
Gly,L-Ala,L-Ile,L-Asp,L-Glu	0

The strain *Flavobacterium sp.*-3912 was investigated in a similar manner. This enzyme hydrolyses DL-5-indolylmethylhydantoin to L-tryptophan in fairly high yield. The mutant strain AJ-3940, in which the routes decomposing tryptophan are blocked (yield of L-tryptophan was almost 100%), was also investigated.[91–93] The pH optimum for strain AJ-3940 was 8.5 and optimum T about 50 °C. Data on the substrate specificity are shown in Table 17.

Hydantoin hydrolyase activity towards both L and D substrates was observed at all stages of purifying the enzyme from strain AJ-3912 (ratio of specific activities L/D = 2.6 to 2.7). The *N*-carbamoyl-AA hydrolase activity was also detected at all stages of the purification but only towards the L substrate. Since no *N*-carbamoyl-AA racemase was detected in the strain, the following mechanism is proposed for the enzymic conversion of hydantoins of DL-amino acids into L-amino acids.[93]

The pH optimum for the hydrolysis of the hydantoin derivative was 9.7, the reverse reaction proceeds at a pH close to neutral values (7–8). The pH optimum for the action of L-CH is 8.0 and the optimum temperature for the purified enzymes is 40 °C. Data on the substrate specificity of L-CH are shown in Table 18.

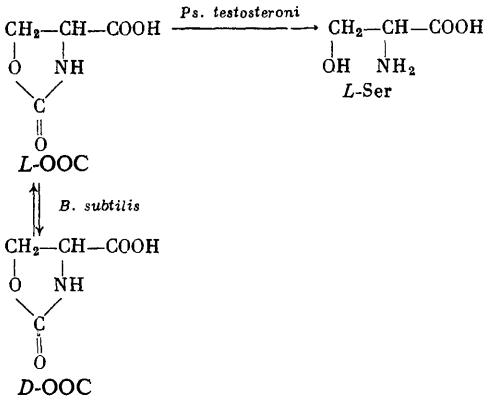

Table 18. Substrate specificity of *N*-carbamoyl-L-amino acid hydrolase.

Substrate, *N*-carbamoyl-AA	V_{rel}, %
DL-3,4-Methlenedioxy-Phe	100
L-Phe	82
L-Tyr	59
L-Trp	55
DL-3,4-Dimethoxy-Phe	24
L-Met	24
Gly	5
L-Ile	2

Another strain, *Arthrobacter sp.* DSM 3747, has been investigated.[94] This strain is able to catalyse the hydrolysis of DL-5-indolylmethylhydantoin to L-tryptophan, which showed that the conversion proceeded according to a scheme similar to that proposed previously,[93] but the racemisation of 5-indolymethylhydantoin in the presence and absence of cells of *Arthrobacter sp.* occurs in a different way (Fig. 2). This formed the basis for proposing that a third enzyme participates in the process, a hydantoin racemase, which was isolated during subsequent work.[95]

b) DL-2-Oxooxazolidine-4-carboxylic acid

A method is known for the quantitative preparation of L-cysteine from DL-2-aminothiazolin-4-carboxylic acid (ATC), an intermediate in the chemical analysis of DL-cysteine, by a combined enzymic process of hydrolysis of L-ATC and racemisation of D-ATC by cells of *Pseudomonas thiazolinophilum* AJ-3854.[96,97] The process was applied industrially and subsequently attempts were made to develop a similar process to obtain L-serine from DL-2-oxooxazolidine-4-carboxylic acid (OOC), which is an intermediate in the synthesis of DL-serine.[98] It is necessary to effect two reactions for the complete conversion of the racemic derivative into the optically active amino acid, viz. the hydrolysis of L-OOC to L-serine and the racemisation of D-OOC. In all 849 strains were investigated 12 of which proved to be capable of catalysing the first reaction and 8 the second. The strain of *Pseudomonas testosteroni* AJ-2770 was the best source of hydrolysis activity and *Bacillus subtilis* AJ-1996 of racemisation. By the combined process L-Ser was obtained from D-OOC in 30% yield with cells of *Ps. testosteroni* and *B. subtilis*. When using L-OOC as substrate the reaction proceeded in a similar manner. This enabled the conclusion to be made that racemisation is not the rate-limiting stage. L-Ser was not obtained from D-OOC if cells of one of the strains was not present. The combined process occurs according to the scheme:

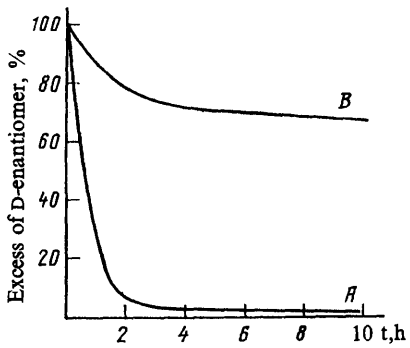

Figure 2. Racemisation of D-indolylmethylhydantoin *A*, in the presence and *B*, in the absence of cells of *Arthrobacter sp.*

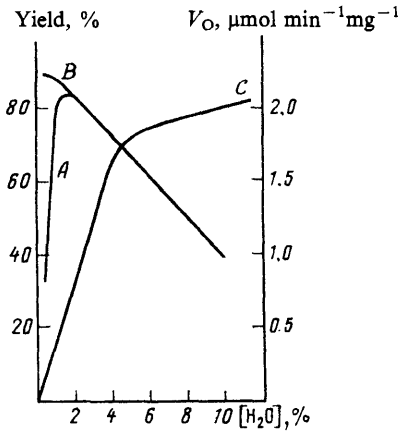

Figure 3. Effect of water content on the yield of *N*-acetyl-L-tryptophan ethyl ester (*A*, reaction time 24 h; *B*, at low H_2O concentrations the reaction time was increased to 15 d) and *C*, on the reaction rate. *N*-Ac-L-Trp 0.05 g (0.02 mmole), α-chymotrypsin 0.01 g, 0.1 M phosphate buffer pH 6.8, 30 °C.

III. Enantioselective enzymic derivatisation of amino acids and their derivatives

Reactions catalysed by enzymes are, as a rule, reversible. However by creating particular conditions (for example varying reagent concentration, removing one of the products from the reaction) it is possible to secure a shift in the equilibrium in the direction required. In practice this is achieved by carrying out the reaction in media containing significant quantities of organic solvent, such as in aqueous organic media (including alcohol–water), in two-phase systems (water–immiscible organic solvents), in systems of reverse micelles and in two-phase aqueous polymeric systems. The enzymic synthesis of aminoacid derivatives is in the development stage. The greatest number of studies in this area is devoted to the synthesis of α-amino acid esters.

1. Synthesis of amino acid esters

One of the first reports on the ability of enzymes to catalyse the synthesis of amino acid esters was made in 1965.[99] The rate of the enzymic reaction and the yield of product depends on many factors, among which are the decisive role played by the state of the enzyme, the properties of the carrier (including the specific surface) when using immobilised catalysts, the composition and pH of the aqueous phase, the concentration of amino acid and alcohol, the composition of the organic phase, the rate of the volumes of the organic and aqueous phases, etc. The synthesis of *N*-acetyl-L-tyrosine ethyl ester using immobilised α-chymotrypsin in a two-phase system has been optimised with respect to these parameters (yield of product was 85–90%).[100] *N*-Acetyl-L-tryptophan ethyl ester was obtained in 86–95% yield under similar conditions (two-phase water–chloroform system, time 2–8 h),[101] which enabled the process to be used for separating racemic *N*-acetyltryptophan (time 48 h, yield of L-enantiomer 45%).[102] The esterification of acyl derivatives of aromatic amino acids in two-phase systems and in aqueous organic media has been investigated.[103,104] The ratio of aqueous and organic phase proved to have a significant effect on the extent of conversion. On changing this ratio from 1:10 to 1:80 the yield was increased from ~38 to ~92%. In a water–chloroform system at constant V_{aq}:V_{org} ratio (1:40) the effect of ethanol concentration on the yield of product was fairly weak (Table 19). The yield of product in ethanol was satisfactorily high. The reaction system was a suspension of hydrated α-chymotrypsin which may easily be removed by filtration. Another important virtue of the one-phase system was considered to be the significantly less noticeable inhibition by the substrate concentrations (Table 20).

Table 19. Effect of ethanol concentration on yield of product.

[EtoH] in $CHCl_3$, M	Yield of *N*-Ac-L-Trp ethyl ester, %
1	83 *
3	86 *
5	77 **
8.6 (50 об.%)	79 **
17.1	78 **

* Two-phase system.
** One-phase system.

Table 20. Effect of substrate concentration.

N-Ac-L-Trp	Reaction time, h	Yield of *N*-Ac-L-Trp ethyl ester, %	
		EtOH	$CHCl_3$ (1 M EtOH)
0.05	24	81	78
0.10	24	86	78
0.15	24	75	78
0.20	24	70	78
0.20	48	85	78
0.20	72	83	78
0.20	96	85	4.4
0.25	96	58	3.0

The dependence of the ester yield on the water content of the system when carrying out esterification for 24 h has a maximum in the region of 2–4% H_2O (Fig. 3, curve *A*), however the shape of the curve is changed on increasing the synthesis time (at these and lower H_2O concentrations) to 15 d (Fig. 3, curve *B*). This is seemingly linked with the significant reduction in reaction rate (Fig. 3, curve *C*) due to the reduction in the extent of hydration of α-chymotrypsin. It is possible that the negative effect may be reduced by using the modified enzyme, hexylchymotrypsin, for the synthesis of esters.[105] The size of V_{max} for such an enzyme is increased.

Another possible method of increasing the reaction rate at low H_2O concentrations is immobilisation of the enzyme, such as the adsorption of α-chymotrypsin into chitin.[106] When carrying out

esterification in ethanol containing 3.4% water the yield of *N*-acetyl-L-tryptophan ethyl ester was 28% for the free enzyme (reaction time 24 h) and 85% for α-chymotrypsin adsorbed onto chitin (reaction time 12 h). The use of other polysaccharides, such as microcrystalline cellulose and aminoethylcellulose, led to a lower yield (20 and 23% respectively after 24 h) than for the free enzyme. It is known that α-chymotrypsin in solutions containing hydrophilic solvents at high concentration loses its catalytic activity to a significant extent due to partial unfolding of the polypeptide chain. The enzyme bound to chitin probably retains the native conformation at H_2O concentrations below 5%. It is possible that a significant portion of the water in such solutions is also adsorbed by the chitin and contributes to the stabilisation of the native conformation.

Investigation of the esterification at various temperatures showed that the yield was practically unchanged in the temperature range 10–35 °C and at higher temperatures it fell sharply.[104] Under the conditions described above esterification was effected for aromatic *N*-acetyl-L-amino acids (tryptophan, tyrosine and phenylalanine), the analogous derivatives of L-alanine and L-leucine did not react. The yields of the ethyl esters of *N*-acetyl-D-tryptophan and -phenylalanine were extremely insignificant. This indicates the retention of substrate specificity and enantioselectivity under the given conditions. However the specificity towards the alcoholic component of the reaction was other than in the case of hydrolysis. Methanol and 2-methylpropan-2-ol (t-butanol) did not react, the other primary and even secondary alochols investigated gave a product in high yield (Table 21).

Table 21. Effect of structure of the alcohol component on the synthesis of *N*-acetyl-L-tryptophan esters.

Alcohol	Yield after 24 h, %	Alcohol	Yield after 24 h, %
Methanol	0	Butan-2-ol	83
Ethanol	81	Butan-2-ol	65
Propan-1-ol	83	2-Methylpropan-1-ol	80
Propan-2-ol	78	2-Methylpropan-2-ol	0

Table 22. Initial esterification rate (V_0) and yield of acetylamino acid ester.

Solvent	*N*-Ac-L-Trp-OEt		*N*-Ac-L-Tyr-OEt

Ethanol	12	81	15	82

Attempts were also made to conduct the synthesis in other hydrophilic solvents containing 1.7 M ethanol (Table 22).[107] Esterificaiton of *N*-acetyl-L-tryptophan did not take place in dimethylformamide, dimethylacetamide and dimethylsulphoxide.

An investigation was also conducted on the effect of aqueous phase composition, buffer concentration and pH (Table 23) which showed that the yield was extremely insignificant (5%) in pure H_2O. When using phosphate buffer the optimum concentration was 0.1 M. At higher concentrations the activity of the enzyme was reduced. This may be linked with a reduction in the quantity of water available for the stabilisation of the enzyme due to the increase in the quantity bound to phosphate. It is interesting that other buffers at the same molar concentration at other pH (5.0 and 9.0) gave results (70 and 74%) similar to that obtained when using phosphate buffer (pH 6.8). The minimal effect of pH may be explained by the inorganic salts playing the role of adsorbents of the enzyme after mixing the solution of α-chymotrypsin with a large excess of organic solvent.

Table 23. Effect of buffer on the synthesis of *N*-acetyl-L-tyrosine ethyl ester.

Buffer	pH	*M*	$V_0 \cdot 10^2$, μmole $min^{-1} g^{-1}$	Yield, % (24, h)

* Benzyl alcohol was used as the alcohol component.

Papain is another enzyme widely used for obtaining optically active esters.[108–113] Attempts were undertaken to separate enantiomers of *N*-t-butyloxycarbonylamino acids by the enzymic synthesis of esters. Methylene chloride was used as the organic phase and 1 M citrate–phosphate buffer (pH 4.2) as the aqueous phase. By varying the ratios of buffer : methylene chloride : alcohol, esters were obtained for the majority of amino acids in high yield (Table 24). Yields were not high in the case of sterically hindered valine, isoleucine, threonine) and basic (lysine, arginine, histidine) amino acids.

As is seen from Table 24 the optimum ratio of organic and aqueous phases $\beta = V_{org}/V_{aq}$ varied from $\beta = 17$ for hydrophilic amino acids (aspartic and glutamic acids) to $\beta = 0.3$ for the hydrophobic (phenylalanine, leucine, tryptophan and methionine). Esterification of the dicarboxylic acids occurred at the α-carboxyl group to the monoester. The possibility of using enzymic synthesis for the separation of amino acid racemates was demonstrated by the synthesis of *N*-t-butyloxycarbonyl-L-aspartic acid from the racemic *N*-protected amino acid and benzyl alcohol. No D-ester was detected in the product and it was shown that the D-enantiomer was not esterified by papain. In subsequent investigations the possibility was shown of obtaining esters from the analogous *N*-derivatives of alanine and aliphatic alcohols $C_nH_{2n+1}OH$ (n = 2, 4, 6) and diols $HO(CH_2)_{2m}OH$ ($1 \leqslant m \leqslant 5$).[109] Immobilisation of papain itself on XAD-7 (neutral cross-linked polymethylacrylate) or Sepharose enabled the reaction to be carried out for n = 8, 10, 12, 16 and m = 6 as well. When using the immobilised enzyme the amount of alcohol was reduced 5-fold and the enantioselectivity of papain action towards α-amino acids was retained. The process may be used for resolving racemic *N*-t-butyloxycarbonylamino acids (alanine and aspartic acid).[110] As in the cases of α-chymotrypsin the enzymic synthesis using papain may be conducted in an aqueous alcoholic medium.[111–113] Esterification of *N*-benzyloxycarbonylamino acids catalysed by papain was carried out in an alcohol–water system with a minimum quantity of water (4–5 eq. H_2O/eq. AA). Ethyl, methyl, n-propyl and n-butyl alcohols were used as the alcohol component of the reaction (Table 25).[112]

Table 25. Synthesis of *N*-protected amino acid esters.

N-Protected-DL-AA	Product, *N*-Z-L-AA-OR		*N*-Protected-DL-AA	Product, *N*-Z-L-AA-OR	
	R	Yield, %		R	Yield, %
Ala	Et	48.5	Ser	Et	26.5
Ala	Me	42.5	Met	Et	47.5
Ala	n-Pr	37.5	Asp	Et	31.5
Ala	N-Bu	40.0	Gln	Et	44.5

Leu	Et	45.0	3,4-Cl_2-Phe	Et	45.5

Note. Reaction conditions in example 1: 50 °C, 10.7 g Z-DL-Ala in 80 ml abs. EtOH containing 2 ml citrate buffer (pH 4.5), time 24 h. Yield of Z-D-Ala was 42.5% (enantiomeric excess > 95%).

* *N*-Boc-L-Ala-OEt.

** *N*-Fmoc-L-Ala-OEt.

Immobilised papain was used in another study for esterification.[113] Of eight carriers investigated the best proved to be Sephadex G-50 (yields of esters of *N*-t-butyl- and *N*-benzyloxycarbonylamino acids were 40 to 93%). Investigation of the effect of volume, concentration and pH of the aqueous phase showed that the maximum yield was achieved at a water content of about 5%. The dependence of yield on pH had a sharp maximum at pH 4.2 and on increasing the concentration of citrate buffer from 0 to 3 M the yield was increased from 0 to 93%.

Some studies have appeared recently demonstrating the possibility of carrying out enzymic reactions in anhydrous organic solvents.[114–116] It has been shown[117] that α-chymotrypsin precipitated from n-propanol is capable of catalysing the synthesis of *N*-acetyltryptophan ethyl ester in cyclohexane with a high enantioselectivity which may be adjusted by varying the precipitation conditions. On precipitating in the presence of *N*-acetyl-D-tryptophan the ratio of the initial rates of the enzymic reactions $V_0^L/V_0^D = 70$ (V_0^L = 0.5 μmol mg^{-1} h^{-1}, V_0^D = 7.1 mmol mg^{-1} h^{-1}). When precipitating in the presence of *N*-Ac-L-Trp the enantioselectivity was strongly increased (V_0^L = 2.7 μmol mg^{-1} h^{-1}, no synthesis of D-ester was observed after 120 h).

2. Synthesis of amino acid amides

It was found that the D-enantioselective aminopeptidase from *Ochrobactrum anthropi*, which is able to hydrolyse the amides of D-amino acids and the *p*-nitroanilides and esters of amino acids and certain peptides, catalyses the aminolysis of D-amino acid esters under certain conditions.[118,119] D-Alanine-3-pentylamide was synthesised quantitatively in 1 h from D-alanine methyl ester and 3-aminopentane in various organic solvents saturated with water (Table 26).

Table 26. Enzymic aminolysis of alanine methyl ester by 3-aminopentane.

Substrate	Solvent	Yield, %
D-Ala-OMe	n-Butyl acetate	98
DL-Ala-OMe	n-Butyl acetate	48
L-Ala-OMe	n-Butyl acetate	0
D-Ala-OMe	Benzene	98
D-Ala-OMe	1,1,1-Trichloroethane	91
D-Ala-OMe	Toluene	67

When using a DL-substrate the product contained no L-amino acid amide. The enzyme possesses a wide specificity towards the acceptor of the acyl group. Products were syntheised in high yield from D-alanine and n-butylamine, benzylamine and neopentylamine in a similar manner. At the same time the specificity of the enzyme towards the acyl group proved to be appreciably worse. Only esters of D-alanine, glycine and D-α-aminobutyric acid gave a product in high yield (98, 80 and 40% respectively). The methyl esters of 19 other D-α-amino acids, β-alanine and various carboxylic acids were not substrates in this enzymic reaction. In water the aminolysis of

D-alanine methyl ester occurs in 78% yield after 7.5 min with subsequent complete hydrolysis to D-alanine in 30 min.

The information presented in the review on the enzymic methods of resolving racemic amino acids and their derivatives demonstrates the intense development of the sphere of science and manufacturing activity. The widespread use of enantioselective enzymic processes together with processes for the enzymic synthesis of amino acids from achiral substrates enables the need for optically active amino acids to be satisfied to a significant extent.

The role of chemical factors in the evolution of natural systems (chemistry and ecology)

S F Timashev
Karpov Physicochemical Institute

ABSTRACT. Certain trends in the development of chemical and related sciences as regards the solution of ecological problems are described. Apart from the discussion of traditional chemical problems associated with the development of resource-saving and low-waste technologies and sensor systems for the monitoring of the natural environment, the physicochemical aspects of the dynamics of a wide variety of natural systems are analysed and the role of the chemical factor in their evolution is elucidated. The idea of parameters defined as limiting permissible amount of waste and limiting permissible concentrations, characterising respectively the self-protecting properties of the environment and individual organisms was introduced on the basis of non-linear models of non-equilibrium thermodynamics. The dynamic equations describing the states of eco-systems in the presence of external stochastic chemical factors are discussed. Problems concerning the influence on the evolution of natural communities of mass transfer processes in the interior of the Earth and in various layers of the atmosphere are analysed. The idea that the Earth–atmosphere system as thermodynamically open is developed and the possible role of anthropogenic factors in the initiation of natural catastrophies is discussed.

V. The influence of mass transfer processes in the Earth–atmosphere system on the state of the biosphere 1194
VI. Conclusion 1200

I. Introduction

The Earth's biosphere, which embraces the lower part of the atmosphere, the hydrosphere, and the upper part of the lithosphere with its rich and wide variety of ecological localised regions and eco-systems, was formed under conditions where the Earth was strongly acted upon both from space (electromagnetic radiation over a wide frequency range, solar and stellar wind, gravitational effects of the sun, the moon, and the planets, and collisions with macroscopic objects—asteroid fragments and comets), and from the inner regions of the Earth (terrestrial magnetism, movements of the lithospheric plates and of the Earth's core, material ejected in major volcanic eruptions). The unity (physicochemical, biochemical, geochemical, and cosmochemical) between eco-systems and their environment arising under these conditions[1–5] was responsible for the modulating and modifying variability[6] of organisms subjected to variations in the intensity and form of extraneous factors. The evolution of terrestrial communities provided examples of the stability of living matter accompanied by the variability of its forms even under the conditions of global catastrophies. Since the 30's of the present century and especially during the last decades, the biosphere has been subjected to the influence of anthropogenic factors having anomalously high (compared with those obtained previously) local intensities and sometimes exhibiting new essential features. According to Matros and Noskov,[7] in terms of the amount of sulphur dioxide (~150 million tonnes annually) and hydrocarbons (~70 million tonnes annually) evolved, industry has already become comparable to natural sources and as regards carbon monoxide (~300 million tonnes annually) it surpasses them. The parameters of other types of anthropogenic contaminants ejected into the natural environment and their amounts are also not encouraging.[8] The greatest risk associated with anthropogenic contaminants and influences (in contrast to the natural ones) involves their locally high concentrations, harmful to living matter, or their locally enhanced levels (for example, radioactive and elecromagnetic radiation). Indeed, despite the large integral radiation dose received by the biosphere from cosmic rays and the natural breakdown of radioactive elements in the Earth's core, the overall background of damaging radiation is low and is not dangerous to eco-systems. Whereas the material ejected by volcanoes contains large amounts of harmful components (for example, SO_2), it is usually scattered over large areas because, these components reach an extremely great height. Thus, the relationship between the appearance of silvery clouds at a height of approximately 80 km and the powerful eruption of Vesuvius preceding this phenomenon led to the conclusion that large amounts of water vapour are ejected into the mesopause by the eruption.[11] Sulphur compounds have also been detected in the silver clouds.[12]

In the anthropogenic evolution of harmful components, their scattering in the atmosphere, the hydrosphere, and in the soil does not occur on such a scale and the local concentrations (or harmful radiation) can exceed by many orders of magnitude the natural background. An even greater danger is associated with the ejection into the biosphere of substances foreign to living organisms—xenobiotics, including those which did not exist previously in nature. Such substances are dioxins, formed in the manufacture of organochlorine derivatives.[13] They already constitute a global risk to humanity and civilisation as a result of the possibility of the long term contamination of the entire biosphere by these substances.

Under these conditions, ecology and other sciences which may participate in the solution of complex ecological problems assume first class importance.[14] In this communication, an attempt is made to present the principal relationships through which such interaction between chemistry and ecology can occur and is already occurring. However, before proceding to the discussion of the essential features of the problems, certain general explanations are necessary.

In connection with the development of acute ecological problems, during the last decade the concept of "ecology" has been extended and it is now regarded as an interdisciplinary synthetic science and protection of the environment from pollution, the development of low-waste resource-saving technologies, the construction of purifying equipment, and planned utilisation of the Earth's resources are included in it. Naturally, ecology employs data from most varied disciplines, but this refers to the methodological and not the idealogical aspects of the science.[15,16]

Ecology is a component of biological science, dealing with the study of the structure and functioning of systems at a superorganism level (eco-systems or biogeocenoses) as regards their relationship with one another and with the environment.[1-5,15-17] This means that any ecological development should include the analysis of the state or dynamics of biological communities in their living environment. Separate components are traditionally investigated in this connection within the framework of genetics, physiology, and anatomy; the level of individual cells is investigated in cell biology; the mechanisms of the interaction of molecular components in the environment and various types of radiation with submicroscopic elements of living systems (biological membranes and their fragments), a wide variety of enzymes, parts of the heredity apparatus, etc. are studied in biochemistry and molecular biology; the state of the environment, including the effects of radiations and particles of different kinds on such environment (liquid, gaseous) is investigated in various branches of chemistry (analytical, inorganic, organic, chemistry of macromolecular compounds, colloid, physical, and radiation), physics (chemical, the physics of the condensed medium, nuclear, molecular, biological), and mathematics.[18] Thus the effecive solution of ecological problems implies that specialists in adjacent disciplines possess the necessary professional knowlege and that each executes his own concerted "manoeuvre".

In particular, in the construction and analysis of models of the evolution of eco-systems—ecological modelling,[19] there arises, together with the formulation of the problem and the elucidation of the main factors to be taken into account in the model (the ecological problem), a set of physicochemical, physical, and biochemical problems associated with the determination of the essential features (genesis) of the parameters in the equations and their dependences on the state of the environment, which may change, as well as mathematical problems associated with the necessity to analyse the corresponding systems of equations (in the general case non-linear), the determination of stationary states of the eco-system and the conditions of bifuraction transitions,[20] etc.

The aim of the present article is to present in a general form (accompanied by specific examples with which the author is most familiar) the possible relations between chemistry and ecology in order to elucidate the aspects of chemical science, of greatest current interest, which assist in the solution of ecological problems. Evidently in such formulation of the problem the role of chemical science should consist primarily in the development of nature-protecting and resource-saving technologies with analytical monitoring of the composition of the entire industrial waste and of the quality of the final products and articles. The ecological problems then involve the study of the influences of such waste on eco-systems with the elucidation of the possible ecological modulations and modifications[6] to prevent the possible eco-system degradation process. Naturally, it is essential to describe adequately the self-protecting possibilities of the eco-systems themselves, the buffer properties of their environment, the ecological resources of the biosphere as a whole, and its "tolerance of abuse".[21,22] This is particularly important bearing in mind the objectively existing tendencies to expand industrial manufacturing processes, to develop further the exploitation of useful mineral products, and to influence actively the biosphere.

The ecological resources are usually estimated empirically and are characterised by experimental (for the given region, a specific season, etc.) limiting permissible amount of waste (LPW) and limiting permissible concentrations (LPC). However, the discovery of the genesis of these parameters and the elucidation of the responses to various anthropogenic influences of the living systems themselves as well as the purifying possibilities inherent in inorganic nature make it possible to forecast on a sounder basis and more comprehensively the consequences of harmful influences of anthropogenic factors on eco-systems and to prevent these influences. As shown below, chemical science can analyse successfully and partly solve such problems.

II. Nature-protecting chemical technologies

The scale and nature of man's industrial activity has to be interrelated with the possibilities of modern science and technology and cannot permit a disturbance of the state of the environment of the planet's eco-system. This means that technological waste (gaseous, liquid) from industry must be sufficiently diluted as regards corrosive components and components harmful to living systems, so that, despite the wide variety of substances of anthropogenic and non-anthropogenic origin constantly ejected into the natural environment, the "buffer capacity" of the environment is maintained, i.e. the rates of degradation or elimination from turnover cycles (accompanied by irreversible "storage") should ensure the conversion of harmful substances into safe ones, which participate in natural turnovers. At the same time certain stationary concentrations of corrosive components not exceeding the LPC should be established in the environment (see Section IV).

The discovery of the mechanisms of the binding, detoxification and transformation (chemical, radiochemical, photochemical, microbiological) of harmful substances in the environment and also their elimination (filtration, micro-and ultra-filtration, reverse osmosis[23,24]) or their decomposition products constitutes an important problem in the protection of nature, since requirements as regards the LPW and the anthropogenic contaminants of the environment (LPC) in each specific region must be worked out on precisely this basis.

High local pollution of the environment by heavy metals, in the first place lead, cadmium, mercury, and arsenic,[25] accumulating in living organisms, is especially dangerous. Metals and metalloids enter the atmosphere with aerosol and vapour-phase industrial waste, as a result of dust rising from the soil, as a consequence of the arrival of dust from space, during volcanic eruptions, etc.[26] At the same time the metals present in rain water enter the soil and open water containing areas where the vast majority of heavy metal ions are adsorbed on microscopic suspensions of mineral origin which form part of the composition of medium and fine silt particles

0.05–0.005 μm in size (up to 70–80% of the total content in water).[27]

There are a wide variety of technological processes for the elimination of heavy metals from industrial aqueous waste and water in open water containing areas. Membrane (including membrane-sorption[23,24] and membrane-extraction[28]) and radiation-sorption methods for the detoxification of contaminated waters are effective. Such procedures are frequently used in combination with traditional chemical treatments with active agents (Cl_2, NH_3, O_3) and physical treatment (heating, UV radiation). There is now a possibility of synergism in the action of the above factors.[29] Irradiation alters the chemical (microbiological) composition of the system, i.e. leads to the disruption or conversion of the contaminants in water, which makes it possible to remove them subsequently from the medium being purified.

The solutions of the problem of the detoxification of aqueous waste by the removal of heavy metals may also be based on the use of the characteristic features of their complex formation reactions with a wide variety of ligands in the given medium. The formation of the so called secondary bonds,[30] whose strength is intermediate between covalent and van der Waals bonds, frequently plays an important role in such complex formation. The formation of secondary bonds by heavy organometallic cations with the functional groups of biopolymers is responsible for the poisoning of living organisms by heavy metals [for example, Hg(II)]. At the same time, the secondary bonds between Au(I) and organic ligands are formed in many medicinal drugs exhibiting a high therapeutic effect.

Other examples of the use of modern advances in chemical science for the detoxification of natural and technological waters may be found in other reviews of the present issue (see also Refs. 31 and 32). Naturally the number of unsolved problems is still very large. Cellulose-paper industries, non-ferrous metallurgical undertakings, power engineering, and the industrial manufacture of caustic soda and chlorine are serious sources of the pollution of the environment. The ejection into the atmosphere of Freons, which help to disrupt the Earth's ozone layer protecting the biosphere against the harmful effects of UV radiation, is a well known ecological danger.[33,34]

It is important to note that the advances achieved in chemical technologies makes it possible to reduce the amount of waste and achieve a saving of energy and materials in many industries. In particular, the harmful components discharged into the atmosphere (under conditions where they become highly concentrated during the purification process) may become sources of a valuable raw material for other industries. At the present time, large streams of effluent gases, containing admixtures of harmful components (SO_2, NO_x, HF, H_2S, CO) are ejected into the atmosphere in many industries.[35] In particular, the amount of sulphur dioxide discarded into the atmosphere in individual copper-zinc undertakings exceeds 1000000 tonnes per year. Nevertheless in the processes involving the neutralisation of gaseous waste containing SO_2, H_2S, and HF in small amounts (<1%) the sulphur- and fluorine-containing waste is hardly utilised.

One of the possible schemes (Fig. 1) for the detoxification of local gaseous waste (their volume is relatively small), which contains harmful components (SO_2, HF, HCl, NO_x, CO, H_2S), is described below. It involves their neutralisation with ammonia and the utilisation of the useful components, using a membrane unit whereby the excess ammonia is returned to the cycle. In the presence in the initial gaseous stream of the least reactive components (NO_x, CO, H_2S), it is necessary to introduce a catalytic reactor into the scheme[35] in order to neutralise these components with ammonia.

This scheme provides for the absorption of the excess ammonia (usually the amount of the excess ammonia may be approximately 10–20% of that supplied for neutralisation) by dilute aqueous ammonia solutions followed by the extraction of the absorbed ammonia and its return (with regulated amounts of water vapour) to the neutralisation reactor. Ammonia is extracted from the ammonia solution by passing a small proportion αI ($\alpha \ll 1$)

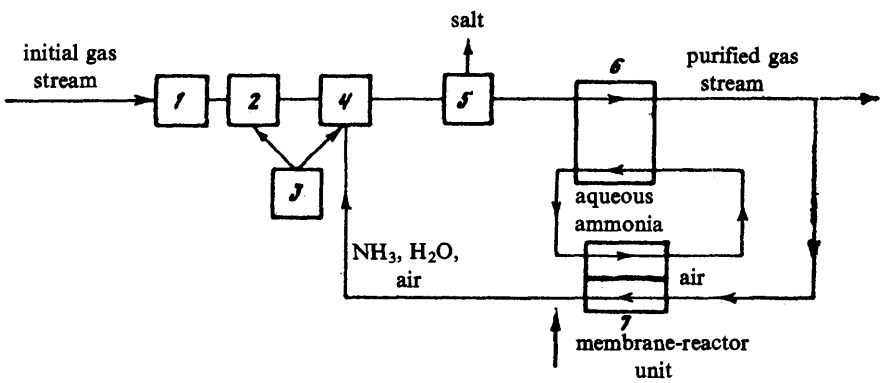

Figure 1. Schematic illustration of the process involving the neutralisation with ammonia of the corrosive components of gaseous waste in the membrane unit for the return of ammonia to the cycle.[36] The principal components of the block scheme: *1*, filter for preliminary purification of the gas mixture; *2*, catalytic purification unit (in the presence of NO_x, CO, and H_2S in the gas); *3*, source of ammonia; *4*, turbulent reactor for the neutralisation of corrosive components with moist ammonia supplied in stoichiometric excess; *5*, system for the trapping of the aerosol formed with isolation of the salt product; *6*, system for scrubbing with water to remove excess ammonia from the effluent gas stream, including a water absorber with supply to the latter of dilute aqueous ammonia (2–4%) (at the outlet the ammonia concentration is 4–5%); *7*, membrane unit (aqueous ammonia at a concentration of 4–5% is supplied to the interfibre space).

of the purified gas stream *I* through hollow fibres,[36–38] the ratio of the concentrations of ammonia and water at the outlet from the membrane unit being regulated by the gas-dynamic gas flow regime within the fibre.[36,37] For gas flow rates of approximately 10^2-10^3 $m^2\ h^{-1}$ and for a content of acid components of about 1 vol. %, the membrane elements should return ammonia in an amount $\lesssim 1.0$ m^3 $NH_3\ h^{-1}$, which is an entirely acceptable task in view of the functional characteristics of the hollow fibre membranes developed for this purpose on the basis of a perfluorinated sulphonic acid cation-exchange material of the Nafion type.[38]

The salt compounds removed from the mixing reactor (trapped in the form of aerosols) may be of interest as a raw material. In particular, the neutralisation of sulphur dioxide with ammonia in the presence of water vapour results in the formation of salts of sulphurous and sulphuric acids, which can be used either for the preparation of mineral fertilisers or for the liberation of ammonia (on thermal decomposition of the salts, on electrolysis of their solutions) with return of the ammonia to the cycle. This imparts to the given technology a low-waste character. Naturally, problems associated with the development of the optimum design of the mixing reactor with a system for the trapping of aerosols and for the removal of solid or highly concentrated liquid products arise in the application of this type of technology.

In fact, each liquid or gaseous industrial waste can be and should become a source from which valuable components can be extracted (or returned to the cycle): scarce heavy metals (Cu, Cr), organic components, acids, and alkalies. The advances in chemical science give grounds for the hope that new highly effective nature-protecting and resource saving technologies will be achieved:[39,40]

In discussing problems associated with the ejection of harmful components into the environment, it is important to discover whether these components are scattered uniformly throughout space (as molecular or ionic impurities) or are concentrated on some type of carriers (for example, aerosols, a wide variety of submicroscopic colloid particles, etc.). It is well known that simple knowledge of the chemical composition of the environment does not permit the understanding of many of the phenomena in inorganic nature. The combination of even small fractions of certain components of the environment (water molecules, other inorganic molecules or atoms, organic molecules) into colloid formations influences fundamentally a wide variety of physicochemical processes in the environment. Aerosols, the amount of which (in terms of weight) in the atmosphere is small (microgramme amounts in a cubic metre of air) and are at the level of the content of rare gases (xenon, krypton), determine not only many properties and phenomena (including the generation of sky glow, rainbows, and false suns as well as the climate in different regions of the Earth) but also the forms and rhythms of life on our planet, which we are witnessing.[41]

Furthermore, aerosols as well as colloid impurites in aqueous media can sorb harmful components in the environment, giving rise thereby to their anomalously high concentration: the concentrations of these components averaged over the volume of the aerosols can exceed by many orders of magnitude the corresponding average values in the environment. Such concentration processes play a dual role. On the one hand, the environment is freed from harmful components (including carcinogenic, radioactive, etc. components) with their "storage" in a relatively small number of macroparticles. On the other hand, these "depositories" represent a serious danger to individual persons so that development of methods for the individual protection of organisms against the harmful effect of active aerosols[42] and other colloid particles has acquired great importance as regards the protection of nature.

The development of methods for exerting controlled chemical, physical, and physicochemical influences on the environment in order to initiate such processes leading to the storage of individual components of the environment in a colloid-chemical depository is extremely urgently required. One can, for example, spray into the atmosphere special aerosols or introduce into an aqueous medium specific complex forming agents, after which the resulting complexes can be concentrated by ultrafiltration.[43] Various flocculation,[44] coagulation, etc. procedures are effective.

One of the methods whereby aqueous systems can be specifically acted upon may be the so called "magnetic treatment". Although this type of preparation of water for use in steam boilers in order to diminish the amount of scale formed during their functioning has long been known,[45] the attitudes to various procedures for the magnetic treatment of aqueous systems (the establishment of a flow of water through a permanent magnet with an induction of approximately $1-10^3$ Oe,[46,47] exposure to a variable electromagnetic field in the frequency range $1-10^3$ Hz [24]) have been extremely cautious in view of the controversial nature of the theoretical interpretations of the effects of such treatments.

Nevertheless, certain ideas about the results of the action of magnetic fields on real aqueous systems have already been formulated. According to Michelson,[46] when a moving solution supersaturated with hard salts is exposed to a magnetic field, crystallisation results in the formation of particles with a crystallographic structure differing (looser) from that arising in the absence of the magnetic field, so that there is a change in the ratio of the rates of crystallisation in the bulk of the solution and on the inner surface of the thermal apparatus (the latter is undesirable).

Further progress in the discovery of the mechanisms of the action of magnetic fields on aqueous systems will be associated with the formulation of experiments with the necessary analytical backup, including the monitoring of the content of ionogenic impurities (starting from water with a specific resistance of 18 N Ω cm) and of the number of colloid particles (for example, when microfiltration membranes with a pore size of approximately $0.1-0.2$ μm are used) in the aqueous medium.[48] Various hypothetical models of the mechanisms of such influences can have undoubted heuristic value in this connection.[49]

III. Chemical membrane sensors

The application of nature-protecting and resource-saving technologies is possible only when special systems for the industrial monitoring of the quality of the products and waste and also for continuous monitoring of the environment with analysis of specific industrial gaseous and liquid waste (for chlorine-containing hydrocarbons, organic solvents, pesticides, heavy metals, etc.) are present at all the stages and cycles of the manufacturing processes. A wide variety of systems for the detection of chemical signals are usually employed; traditional, analytical systems (based on specific chemical reactions, in particular colour reactions) and modern sensor systems which permit high-speed and continuous monitoring of the chemical composition of the medium up to the determination of the lowest possible concentrations of the components.[50–52] The sensitive elements in the recording system of the sensor are usually sputtered layers of metal oxides (ZnO, TiO_2, NiO, etc.) whose

resistance changes on chemisorption of electron-donating or electron-accepting components,[53] field transistors sensitive to chemisorption processes on the locking valve,[50] ceramic layers formed from mixtures of oxides ($Cr_2O_3-Al_2O_3-V_2O_3-Ti_2O_3$, α-$Fe_2O_3-SnO_2$, etc.)[54] whose electrical conductivity changes on sorption of certain components, light guides where conditions for total internal reflections are altered on sorption of specific components on the surface which thereby influences the propagation of the light signal,[55,56] and thin metallic layers (Al, Cu) in which surface plasmons, sensitive to the adsorption of specific components, may be excited in the IR range.[57]

The characteristic concentrations of the components measured by the above procedures depend on the type of molecules, the method of measurement, and the composition of the medium and lie in the range $10^{-8}-10^{-4}$ M. In individual cases, a higher sensitivity can be attained: antigen concentrations of approximately 2.5×10^{-9} M have been measured[57] with the aid of an IR biosensor; proteins in solution at a concentration of approximately $10^{-11}-10^{-12}$ M have been detected using opto-biosensors with excitation of surface plasmons;[58] using in the recording system sensitive bioelements (of the blue crab) in which electrical pulses are generated during the "recognition" process, an aminoacid concentration of approximately 10^{-13} M has been measured.[59] For comparison, we may point out that insects can distinguish the molecules of sex attractants when their content relative to other molecules in air is in the proportions $1:10^{17}$.[60]

The use of solid state systems for chemical sensors makes it possible to diminish greatly the size of the latter by accommodating on a single crystal or transistor several sensitive elements together with electronic circuits for the preliminary treatment of the signal and the storage and processing of information. Highly sensitive electrochemical sensors,[61,62] in which electrocatalytic reactions of components adsorbed on the electrodes take place, are widely used.

The progress in the creation of chemical and electrochemical sensors is at present very appreciable.[50-52] Sensors for the determination of the concentrations of ions (H^+, K^+, Na^+, Ca^{2+}, Ag^+, NH_4^+, Fe^{2+}, Cu^{2+}, Ni^+, Cd^+, Pb^+, F^-, Cl^-, Br—, NO_3^-), gas molecules (H_2, O_2, NH_3, CO_2), and biologically active substances (glucose, urea, quaternary ammonium compounds, sucrose, lactose, lysine, ethanol, penicillin, pyruvate, lactate, organophosphorus compounds, carbolates, psychotropic substances) have been developed and are widely used.[63-66] Thus semiconductor sensors based on metal oxides (ZnO, TiO_2, NiO) make it possible to measure microamounts of oxygen in gases ($10^{-5}-10^{-1}$ vol. %), to determine the concentrations of organic and inorganic gases and vapours (alcohol, acetone, ammonia, nitrogen oxides, carbon monoxide), and to detect free atoms and radicals (H, O, N Cl, OH, CH_3, C_2H_5, NH, NH_2) with a sensitivity up to 10^6-10^8 of active species in 1 cm^3.[53] Nevertheless the requirements (decrease in the levels of measurable concentrations of the components in liquid and gaseous media, greater selectivity, high speed, stability of characteristics) which must be met by such systems are continuously becoming more stringent, which is associated with the creation of new industries where components dangerous to eco-systems may be synthesised and also with some progress in establishing the harmful influence of components which had been previously regarded as safe. This entails the appearance of new virtually uninvestigated problems associated with the possible observation of synergistic effects when the eco-system is acted upon simultaneously either by a mixture of harmful components or by individual components against the background of fields of different nature (electromagnetic fields in different frequency ranges, low-frequency sonic fields).

The study of effects of this type will probably lead to a revision of the established values of the LPC (for different regions of the Earth and for different times of the year). This means that work on the improvement of chemical sensors should continue and chemical science should help in progress in this field. Together with the problem of the chemical composition of the environment (in the first place the determination of the content of harmful components), it is necessary to formulate the problem of the adequate description of the state of the environment—the provision of a more complete set of its characteristics influencing the evolution of an individual person and the eco-system as a whole. Therefore, apart from purely chemical sensors which permit the determination of the chemical composition of the environment as well as temperature and pressure sensors, it is necessary to employ other procedures for monitoring the state of the environment (for example counters for aerosol particles and radioactive radiation, sensitive receivers for electromagnetic radiation).

In this section, we shall discuss only problems associated with the increase in the sensitivity of the action of chemical sensors. Problems involving an increase in the selectivity of the detection of individual mixture components by solid state sensors are of extremely great current interest because the selectivity of many of the existing systems is low. Thus the change in the resistance of semiconducting oxide films depends only on the electron-donating or electron-accepting properties of the chemisorbed components. Therefore the overall change in resistance on sorption of several components makes it difficult to reach unambiguous conclusions about the contributions of individual components. The causes of the change in the charge on the gate of a field transitor on chemisorption of several components simultaneously are also difficult to analyse. The selectivity of such sensor devices can be significantly increased using as one of the elements special layers, partitions, or coatings which separate the medium being analysed from the recording system. Such composite devices are usually referred to as membrane sensors. If the partition (in particular, a porous one) contains biologically active compounds, enzymes, fragments of individual cells, immobilised antigens for the detection of the corresponding antibodies, fragments of membranes with chromophoric groups, etc., one refers to membrane biosensors.[55,56,67]

Coatings modifying the surface of the recording system increase the efficiency of the analysis in cases where the transfer of the components through the membrane layer is the rate-limiting stage of the overall irreversible process involving the detection of these components, namely in the appearance of stationary currents associated with electrochemical reactions of the components of the mixture analysed (O_2, H_2, alcohols, etc.),[68] in transient processes during the establishment of the state of equilibrium on sorption of components by the sensitive elements of the device, in enzyme-catalysed chemical and biochemical reactions,[66] in the generation of photocurrents whose magnitude may depend on the sorption of the components of the medium,[69] on irreversible "storage" or chemical binding of the permeating components in information accumulating systems, etc. Materials (organic and inorganic) usually employed in the membrane technology can be used for the formation of membrane coatings on the surfaces of sensor elements. The main difficulty then consists in the deposition of membrane coatings with an optimum thickness: sufficiently thin so that the response time does not exceed a certain required value and at the same time sufficiently thick so that the transfer through the coating (or the

transient processes in it for non-stationary analytical methods) should remain the rate-limiting stage of the entire irreversible process leading to the detection of the component with its chemical or electrochemical transformation. One of the optimum solutions apparently involves the creation of fairly compact submicroscopic barrier membrane layers with $d \simeq 0.01\,\mu m$.[70]

In this case it is possible to achieve anomalously high selectivities with respect to the target components for a relatively short delay time τ ($\tau \simeq d^2D \simeq 1$ s for diffusion coefficients D characteristic of vitreous polymeric materials) in the detection of a chemical signal. The possibility of attaining high selective detection parameters will be demonstrated on a model example.[71] We shall assume that the barrier layer is formed on the basis of a film with a thickness d and consisting of a material with a permeability constant $\Pi_{0i} = \gamma_{0i}D_{0i}$ in which repelling (for the permeating component i) force centres are distributed at random. We shall represent the repulsion potential of this species i, at a distance r from the centre, by the expression

$$U_i(r) = U_{0i}(b_i/r)^{m_i},$$

where b_i is the characteristic distance and m_i is a numerical parameter. Suppose that n is the concentration of such centres, whereupon, under conditions such as $d \ll d_{0i}$,

$$d_{0i} = [(U_{0i}/k_BT)^{1/m_i} b_i n^{1/3}]^{m_i-2} n^{-1/3},$$

we have the following expression for the permeability constant:[71]

$$\Pi_i \simeq \Pi_{0i} \exp\left[-\pi\Gamma\left(1-\frac{2}{m_i}\right)(U_{0i}/k_BT)^{2/m_i} b_i^2 nd\right]. \qquad (1)$$

A similar situation occurs also in other model representations of the potentials of the repelling centres.

The case considered corresponds to the transfer process (below the permeation threshhold) of the components i.[24] For a lower density of the scattering centres, where the transfer process "above the permeation threshold" obtains (for further details, see Refs. 24 and 71), we have the following features:

(1) for $d \lesssim L_i$ (L_i is the correlation length characterising the topology of the path followed in the transfer of the species i in the given material[24]), we have $\Pi_i \simeq d^{3-D_{fi}}$ — fractal transfer (D_{fi} is the fractal dimension);

(2) for $d \gg L_i$, we have $\Pi_i = \text{const.}$ — diffusional transfer.

The significance of the theoretical relations (1) for low values of d is that at high repulsion potentials the species effectively pass through the membrane only in those regions where the fluctuating force field is weakened by the lower local concentration of repelling centres (in the region of a "defect" in the packing of the centres. Since the parameters of the repulsion potentials for species of different nature are different, the selectivity of such a membrane depends exponentially on its thickness. Therefore it is possible, in principle, to achieve for the target component an anomalously high selectivity combined with a high (owing to the small thickness) permeability. So far this is merely a theoretical prediction of the unique possibilities for the selective isolation of mixture components with the aid of submicroscopic barrier membrane structures. These may be layers of organic or inorganic (for example, polyphosphazenes) materials obtained in different ways (the Langmuir–Blodgett method, plasma-chemistry, photochemistry, electrochemistry, alkoxo-technology, etc.). The Langmuir–Blodgett method, which makes it possible to achieve in the layer a specified array of individual molecules (for example, the formation of alternating oriented donor and acceptor layers separated by a distance of 2–3 nm) is especially promising.[72–75]

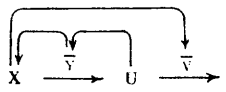
The technology used for the creation of such barrier structures and ultrathin layers should be at the highest level of sophistication. Such ultraclean technology (as regards materials and the concentrations of impurities and aerosols in the preparation chamber) should employ the experience and methods of the electronic industry. The sensitivity of such membrane systems with respect to the component being detected can probably be increased if the signal is recorded with one-sided excitation of the recording system (on photoexcitation of a semiconductor film, on transition of the membrane to the conductivity switching state,[24] etc.).

In the case of electrochemical sensors, the electric field behaves as an additional controlling factor, which determines the transfer of species, by altering its strength in the layer, one can apparently regulate the "permeation" regime for individual components — below or above the threshhold. Analysis of the voltage–current characteristics of such electrochemical systems with barrier membrane layers over a wide range of potentials can therefore yield exhaustive information about the impurities present in the electrolytic medium.

IV. Physicochemical principles of the modelling of the state of eco-systems

One of the main tasks in ecology consists in the discovery of the dynamic changes in the eco-systems taking into account the wide variety of life cycles, complex interactions, and internal controls (including positive and negative feedback) in food chains.[76] The classical deterministic models characterise the simplest of the situations, such as the dynamics of the growth of population in a closed environment, taking into account the fertility parameters, the real living area, etc., described by a logistic equation,[77–79] the dynamics of the mutual relations between the predator and prey taking into account the "search efficiency", the "successful" encounters between the predator and the prey, etc., described by the Lotka–Volterra equation.[76,80]

Such models make it possible to discover the main principles governing the existence and coexistence of consumers in eco-systems and to understand in what way and how rapidly anthropogenic factors can interfere in the natural characteristic features of the development of populations. The possibilities of modern computers have made it possible to expand significantly and increase the sophistication of deterministic models and to introduce into the latter various functional relationships, including a wide variety of food chains,[81,82] and to elaborate the interactions between consumers and the environment, including the situation when the latter contains toxicants.[83–85] There has also been a growth of the spatial scale of eco-systems susceptible to modelling: from levels corresponding to individual lakes[86] to the level corresponding to large regions (with dimensions up to 500 km).[84] The results of such model calculations make it possible to plan and prosecute more purposefully on a well-founded basis man's economic activity and to develop a strategy for saving ecologically endangered regions.



However, a number of fundamental problems arise in such modelling.[78] Each investigator is faced by the necessity to select certain arbitrary boundaries of eco-systems and boundary conditions, which influences the characteristic features of the evolution of the system, its stationary states, and naturally

introduces elements of subjectivity. The second more fundamental problem consists in the non-linearity of deterministic equations for the dynamics of eco-systems, which gives rise to the virtual unpredictability and the pseudo-random nature of the behaviour of such systems over a long time interval owing to the exceptional sensitivity of the solutions to the selection of the initial conditions, which can never be fixed or measured with sufficient accuracy. High-dimensional systems, such as the real eco-systems with a wide variety of internal feedbacks (positive and negative, including feedbacks with lag) and external influences, exhibit a random behaviour to a large extent with transitions between various stationary states. An impression is created that the greater the number of real factors underlying the model, the greater the chance of a transition during analysis to chaos or at least to instability.[78]

All the foregoing means that the very formulation of the model must be designed not so much to discover the multifactor influences on eco-systems but rather to establish the possibilities of the eco-system (with all its complex inter-relationships) as regards its preservation and its reponse to individual factors. In particular, these can be the response of eco-systems to changes in the state of the environment, for example, under the influence of electromagnetic radiation and on introduction of toxicants and sources of radioactive contamination. In the latter cases, the analysis of ecological models makes it possible to represent more effectively the physicochemical and biochemical significance of the LPC and LPW, including the nature of the change in the states of consumers at concentrations of harmful substances exceeding the LPC and of the "ecological reserves" of the system which determine the values of the LPW. Evidently the equations describing the evolution of eco-systems must take into account the possibility of the transfer of consumers to new states with altered properties (in particular with an altered content of harmful substances). We shall examine all these problems in somewhat greater detail.

1. Models of the evolution of eco-systems subjected to the action of toxic substances. The limiting permissible amounts of waste

To illustrate the general principles governing the allowance for the effect of toxic components on the evolution of eco-systems, we shall examine, following Kreikenbohm and Bohl,[83] a model example of a system comprising two interacting populations Y and V of microbions in the food chain:

Here X is the substrate of the organism Y which is a toxicant of the organism V, this being reflected in the above scheme by the direction of the arrow from X to V. It is assumed that, at low concentrations of the substrate, the latter undergoes degradation (consumption by the organism Y), i.e. the "environment is purified" by the removal of the substance X. However, with increase in its concentration, the substrate suppresses the functional activity of Y and thereby limits the formation of the product U, which in its turn inhibits the activity of Y. The scheme presented can, for example, describe the functioning of the phenol degrading bacteria (X = phenol, toluene, unsaturated hydrocarbons, aliphatic acids),[83] which are inhibited by the substrate X itself at its elevated concentrations (in the case examined by the above workers,[83] for $x \gtrsim 5$ mM). Their metabolic partners—the bacteria V (methanogens)—completely cease to form the products of the conversion of their substrate U (methane) at concentration $x \gtrsim 20$ mM.

The evolution of such microbiological populations can be described by the following dynamic system of formal chemical kinetic equations:[83]

$$\dot{x} = -\frac{\mu_1(x, u)}{\gamma_1} y + \tilde{D}(x_R - x), \tag{2a}$$

$$\dot{y} = [\mu_1(x, u) - \tilde{D}]y, \tag{2b}$$

$$\dot{u} = \frac{\mu_1(x, u)}{\gamma_1} y - \frac{\mu_2(x, u)}{\gamma_2} v - \tilde{D}u, \tag{2c}$$

$$\dot{v} = [\mu_2(x, u) - \tilde{D}]v, \tag{2d}$$

$$\gamma_1 > 0,\ \gamma_2 > 0,\ \tilde{D} > 0,\ x_R > 0,$$

where x and u are respectively the concentrations of the substrates X and U in the given medium, x_R is the concentration of the substrate on the surface of the source (we postulate that the substrate enters the medium by dissolving at a rate $\tilde{D} = \alpha S$, α being the rate constant for the dissolution of the substrate X and S the surface area of the substrate), y and v are respectively the densities of the populations of Y and V in the culture medium, $\mu_1(x, u)$ and $\mu_2(x, u)$ are parameters (for their model representation, see Kreikenbohm and Bohl[83]) which determine the rates of change of the densities of the populations of Y and V, and γ_1 and γ_2 are parameters relating the changes in the concentrations of the populations of Y and V to the concentrations of the substrates X and U. The second terms in Eqns. (2b) and (2d) model the effects of inhibition by the substrate X. We may draw attention to the fact that in the scheme described by Eqns. (2a)–(2d) purely concentration effects are considered without taking into account the possible changes (see below) in the functional parameters of the kinetic scheme in an evolutionary dynamic process.

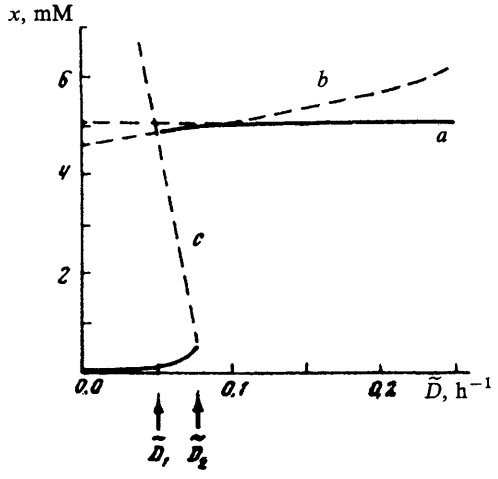


Figure 2. Bifurcation diagram for Eqns. (2a)–(2d).[83] The continuous lines along branches *a*, *b*, and *c* characterise the stationary states of the substrate.

Kreikenbohm and Bohl[83] analysed the stability of various stationary states of the system of non-linear equations (2a)–(2d). The rate of introduction of the substrate-toxicant X into the medium was examined as the controlling parameter. Fig. 2 presents the bifurcation diagram in the plane $(\tilde{D}, x)$ corresponding to the system (2a)–(2d) and constructed using a certain set of parameters.[83] The continuous lines on all three branches *a*, *b*, and *c* characterise the stationary states of the substrate X attained for any evolution of the system beginning in the vicinity of these states (stable states). The range $\tilde{D}_1$, $\tilde{D}_2$) represents the region of bistability. From the ecological point of view, the "bacteriological reactor" described functions well, provided that the system is in the region of stability of the branch *c*. The magnitude of the perturbation forcing the system components to evolve to the standard state on the branch *b*, in which the system is no longer capable of ensuring to the required extent the degradation of the toxic substance X, is thereby determined in the model.

Evidently, in a comparative analysis the parameter $\tilde{D}$ may characterise different types of toxicants added to the medium by sources with the same area of dissolving surface but with different rates of dissolution. At the same time, the differences in the value of $\tilde{D}$ can be caused by the different amounts of a definite toxicant present in the medium, i.e. by different areas of the source adding the toxicant at a specific rate. When the medium contains only one kind of toxicant, this provides grounds for relating the parameter $\tilde{D}$, for which there is a transition from the stable branch *c* to the stable branch *b*, to LPW—the limiting permissible amount of waste component injected into the medium, which is determined by the area S_{lim} injecting the toxicant. When the output of the source of the harmful component exceeds the limiting value, so that $S > S_{\text{lim}}$, the bacteria Y are no longer able to cope with the "processing" of the toxicant. In this case irreversible changes may occur in the eco-system (see below).

2. Models of the functioning of protetcing systems of the organism. Limiting permissible concentrations

As mentioned in the Introduction, living systems have been subjected throughout the entire course of evolution to powerful one-sided influences of different kinds. Under these conditions, specific protecting systems should have arisen in organisms, preventing the lethal effect of at least low concentrations of xenobiotics and other harmful components and small doses of a wide variety of harmful radiation.

Evidently such stability of biosystems in relation to changes in the parameters of the environment is possible up to a certain limit. When this is exceeded, the functional stage of the organism changes and there is then a possibility of ecological consequences for the entire eco-system owing to the existing interrelations, including food chains. Such deviations of the states of individuals from the norm can be naturally attributed to structural rearrangements in individual components or systems of the organism (enzymes, membranes, respiratory or photosynthetic chains). The Ageev–Vershubskii model,[87] proposed previously to describe the cooperative phenomena associated with the rearrangement of the polymer matrix in uptake–release processes in binary media containing surface-active and inactive components, may prove useful in this instance.

We shall consider the evolution of the structural changes in certain components of the living system occurring on uptake of a toxicant by this component. In conformity with Ageev and Vershubskii,[87] we shall consider the equations governing the evolution of two coupled quantities characterising the state of the component being examined: the concentration $c(t)$ of the toxicant component taken up by the component and the structural parameter $a(t)$ defined as the current values of the fraction of the total volume V_0 of the component undergoing structural rearrangements on uptake. We assume that $0 \leqslant a(t) \leqslant a_{\max} < 1$, where $a_{\max}$ is the fraction of the volume of the component in which the given structural changes can occur on uptake of the toxicant. We assume further that the volume $(a_{\max} - a)V_0$ which has still not been transformed and the volume $V_0(1 - a_{\max})$ which does not undergo structural rearrangements participate in the uptake process (the rate constants for the corresponding uptake processes will be designated by γ and η), while the release of the toxicant into the medium takes place via the volumes $(a_{\max} - a)V_0$ and a_0V_0 with release rate constants β and α respectively. Let k be the rate constant for the structural rearrangements which may occur in the volume $a_{\max}V_0$ of the component on uptake of the toxicant. Evidently the physical significance of the constants α, β, γ, η, and k can be discovered by constructing models at a more elementary level, taking into account the nature of the influence of the toxicant molelcules on components of the living system and specifying in detail the characteristics of the mechanism of the structural transformations occurring in the components.

According to Ageev and Vershubskii,[87] the system of equations for the evolution of the parameters $c(t)$ and $a(t)$ can be expressed as follows:

$$\dot{c} = \gamma\left[1 - \left(\frac{c}{c_s}\right)^n\right](a_{\max} - a) + \eta(c_{0s} - c)(1 - a_{\max}) - \\ - \beta c(a_{\max} - a) - \alpha c a, \tag{3a}$$

$$\dot{a} = -ka\left[a^2 - a_{\max} \cdot a + \frac{1}{4}a_{\max}^2 \frac{c_{\max} - c}{c_{\max} - c_{\min}}\right] \\ \text{when } c \leqslant c_{\max}, \tag{3b}$$

$$\dot{a} = 0, a \equiv a_{\max} \text{ when } c > c_{\max}, \tag{3c}$$

where c_s and n are respectively the uptake saturation concentration and the parameter of the dynamics of the uptake of the toxicant by components of the system which can undergo a change in their structure on uptake, c_{0s} is the uptake saturation concentration of the fragments whose structure does not change on uptake of the toxicant, and $c_{\max}$ and $c_{\min}$ are the critical concentrations of the toxicant at which abrupt transitions of the system to the state with a rearranged structure (from the initial non-rearranged state) and to the state with the initial structure (from the state with a rearranged structure) respectively begin.

In order to determine the entire set of the possible stationary states of the system (3a)–(3c), it is necessary to analyse the phase diagram of the model (Fig. 3) in the states space (a, c).[87] The intersection of a zero isocline $c = 0$, which is unique for the specified system of parameters α, β, γ, and η family of the possible curves I–IV of this type with various branches of the zero isocline $a = 0$ (the equation of state of the structure) corresponds to the stationary solutions on the phase plane. There is a possibility of the intersection of the three stable branches of the equation of state MA, GB, and BE with curves I, III, and IV respectively. An unstable solution of the system with the generation of the limiting cycle DABG and the appearance of an auto-oscillatory state in the alteration of the structure corresponds to the intersection of curve II with the unstable branch GA. Fig. 4 illustrates the kinetics of the attainment of a stationary state in the regions MA, GB, and BE by the toxicant concentrations.

Within the framework of this model, the contact between the component of the living system and the environment does not alter its structure provided that the uptake concentration of the toxicant does not exceed c_{max}. Following the dynamic attainment of the critical concentration of the toxicant taken up ($c = c_{max}$), processes inolving a rearrangement of the structure of the component begin and either reach an oscillatory state (for system parameters giving rise to the type II zero isoclines) with periodic variation (from 0 to a_{max}) of the structure of the component and of the concentration of the toxicant taken up (from c_{min} to c_{max}) or are completed by the establishment of a stationary state (a_{st}, c_{st}) of the system. For parameters giving rise to the zero isocline I, the system returns to the initial non-rearranged structural state (0, c_1), in the case of the zero isocline (III) the state (a_3, c_3) is generated, while in the case of the zero isocline (IV) the state produced is a_{max}, c_4).

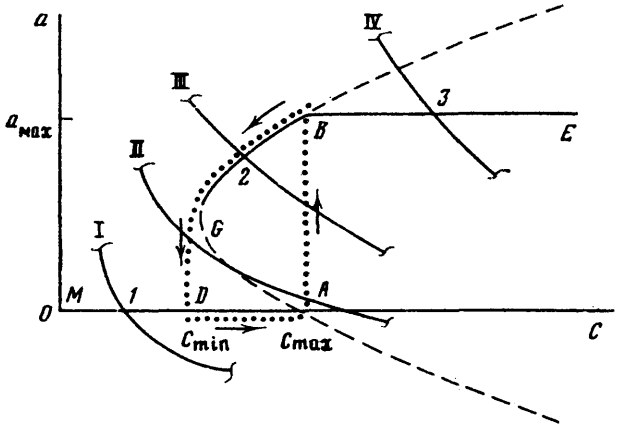

Figure 3. Phase portrait of the model.[87] Dashed lines—unstable or non-realised branches; circles—possible location of limiting cycle. The arrows indicate the direction of motion of the representative point. The numbers of solutions *1*–*3* correspond to the numbers of the regions of existence of the stationary regimes (see also text).

Thus, if the concentration c_{max} is attained in the component of the system considered for certain concentrations ρ_{lim} of the toxicant in the external environment, then it is natural to relate ρ_{lim} to the limiting permissible concentration LPC. In other words, the LPC for different individuals may be defined as the concentrations of harmful components of the external environment for which the organism undergoes a transition to another state which is different from the normal state. Such changes in states can be either reversible or irreversible depending on whether the state returns or does not return to the initial state when the harmful components are removed from the medium. In the former case, one may speak of ecological modulations, while in the latter we have ecological modifications and degradation of the system.[6] The state of the organism can then be characterised in terms of different features (the contents of the harmful component, the rate of metabolic processes, the changes in the functional activities of various systems of the organisms, disturbances in the hereditary apparatus), etc. Evidently the deviations of the states of individuals from the norm give rise to general changes in the evolution of eco-systems. In particular, an increase in the content of the harmful component (carcinogen) in certain individuals can constitute a risk to predators feeding on the given individuals, etc. This should be reflected in the system of equations for the evolution of the eco-system as a change in the "level of quality" of the predator's food. A possible scheme for the construction of equations for the evolution of eco-systems taking into account the modulating or modifying changes occurring in them under the influence of fluctuating external factors is presented below.

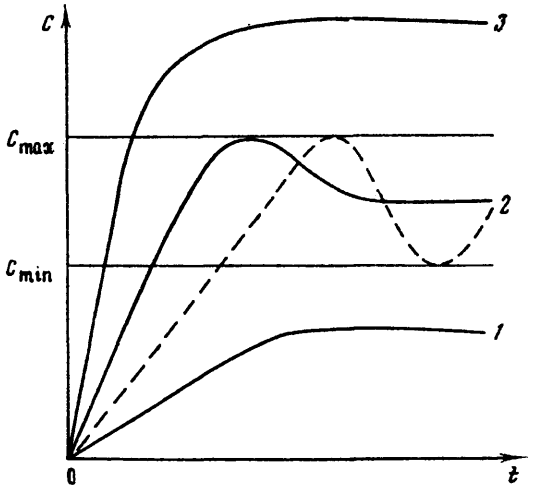

Figure 4. Characteristic form of the kinetic curves for the attainment of a stationary regime by the toxicant concentrations.[87] The numerals opposite the curves correspond to the numbers of the regions of existence of the stationary regimes; the possible occurrence of oscillatory kinetics is indicated by the dashed line.

3. Equations of the dynamics of eco-systems with allowance for various states of individuals

A general approach to the modelling of ecological modifications can be formulated on the basis of kinetic equations for space–time distribution functions of the subsystems in the overall space of the characteristic parameters with introduction of functions of random sources and sinks modelling the characteristics of the changes in state both as a result of the internal activity of the above subsystems and due to factors external to the systems.[20] The deterministic nature of the kinetic equations makes it possible to determine beforehand the nature of the possible states and to estimate their relative stabilities, while the fluctuation influences on the system determine the occurrence of one of several possible states in the vicinity of the bifurcation point.[77]

Since biological systems are highly non-equilibrium and open systems, in the analysis of their evolution it is necessary to take into account two fundamental factors. Firstly, the probability of the transition of the system to one of the stable states beyond the bifurcation threshhold of the thermodynamic branch when some

kind of controlling parameter λ is altered depends on the specific state of the system in the given time interval. The population of the species, the solar activity, the ionisating radiation dose, the amount of dissolved organic matter of allochthonous or autochthonous origin (if one is dealing with aqueous systems) etc. may be considered as the controlling parameter.

Secondly, the evolution of the highly non-equilibrium eco-systems can be effectively acted upon by weak external factors. In principle, without exerting any effects on equilibrium systems, such factors can determine the preferred selection of a particular stationary state beyond the bifurcation point ("forced bifurcation"[20]). Such factors may be, in particular, electromagnetic radiation in different frequency ranges (starting from weak low-frequency influences[88]), changes in the qualitative composition of the environment, etc. The accumulation of the changes occurring under these conditions and the subsequent fluctuation influences of diffeent kinds may lead either to slight but fundamental changes in eco-systems or to new bifurcation transitions.

Evidently the modelling of the evolution of eco-systems involves major fundamental and mathematical difficulties. Each eco-system is a multicomponent object with a multiplicity of internal feedbacks (including negative feedbacks) and subjected to multifactor influences of a wide variety of different types. The state of each system can be described by the distribution function $f(t, \mathbf{r}, \Gamma)$, where t is the time, $\mathbf{r}$ the radius-vector, and Γ the set of parameters determining the state of the given system. For a quantitative analysis of the equations for the evolution of the system (kinetic equations for the function f), complicated in many instances *a priori* by the uncertainty and the ambiguity in the overall parameters Γ, it is convenient to employ characteristics introduced in the mathematical description of random motion in mechanical and hydrodynamic systems.

Conservative systems are usually considered for which an element of the phase space undergoes a change in shape after a time but retains its volume, and dissipative systems for which the volume of the element of the phase space contracts during motion, i.e. structure formation in the system takes place as a result of an external excitation with increase in the controlling parameter. Dissipative systems are coherent. They behave as a single whole as if each species were "informed" about the state of the system as a whole. Under these conditions, a decrease in the controlling parameter in classical dissipative systems leads reversibly to the initial state of the conservative system.

In eco-systems the situation may be fundamentally different. The changes occurring in communities under conditions of the reversible alteration of certain controlling parameters may be reversible and irreversible, i.e. may be characterised by a kind of "hysteresis". The irreversible changes in eco-systems, including those characterised by a decrease in the volume of elements of a generalised phase state $(\mathbf{r}, \Gamma)$ will be defined here as ecological modulations. The irreversibility of the changes occurring in the eco-system shows that the magnitude of the controlling parameters has exceeded the adaptive possibilities of the biocenosis. Here one should refer to ecological modifications and, when metabolic and ecological regression processes have developed,[6] to eco-system degradation processes. Evidently in each specific case it is necessary to determine in addition the minimum level of irreversible changes, indicating the occurrence of ecological modulations and modifications and of ecological regression. In particular, one can detect changes in the genetic apparatus.

So far several systems are known (mechanical, hydrodynamic, etc.) for which it is possible to describe analytically the phenomena involving the appearance of dissipative structures under the influence of controlling factors (the constraining force on excitation of the motion of a pendulum, the temperature difference in the Benard system, the energy introduced into the Henon–Hales system,[77] etc.). In ecological systems one cannot even be certain about the adequacy of the description of stationary states and difficulties arise even in the modelling of the deterministic behaviour of such systems. We shall therefore refer only to qualitative analysis of the characteristics of the evolution of communities.

The nature of the transition to bifurcation points and the factors which determine such transitions to new levels of organisation of communities are of interest. In this case, it may prove sufficient to analyse a relation for the correlation function of fluctuations ("correlator") which is simpler than for the distribution functions $f(t, \mathbf{r}, \Gamma)$:

$$\delta g_a = \int \langle \delta f_a(t_1; \mathbf{r}_1, \Gamma_1) \delta f_a(t_2; \mathbf{r}_2, \Gamma_2) \rangle \mathrm{d}\Gamma_1 \, \mathrm{d}\Gamma_2 \,, \tag{4}$$

where $\delta f_a = f_a - \bar{f}_a$, where $\bar{f}_a$ is the stationary distribution function for the subsystem a. The symbol $< \ldots >$ denotes averaging over all possible states of the subsystem. In the case of spatially homogeneous systems, the averaging involves integration with respect to one of the radius-vectors and one of the times. Here one introduces the variables $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$ and $\tau = t_1 - t_2$. In particular, the average residence time of substances in a flow reactor is the external controlling parameter for the classical Belousov–Zhabotinskii reaction—the oxidation of malonic acid in the presence of cerium sulphate and potassium bromate where spectroscopic methods detect oscillations in the concentrations of Ce^{3+} and Ce^{4+} as a function of time. In this case the function $\delta g(\mathbf{r}, \tau) = \delta \bar{g}(\tau)$ introduced is a measure of the correlation between the successive changes in the Ce^{4+} concentration detected from the selective light absorption by these ions. For a regular motion, the function $\delta \bar{g}(\tau)$ is constant or oscillates, while in the chaotic regime $\delta \bar{g}(\tau)$ decreases rapidly (frequently exponentially) with time.[77,89]

Naturally the equations describing the evolution of the function $\delta g(\tau)$ are in general complex and difficult to analyse but the use of the phenomenological approximations to the correlation times, usually employed for such equations, may become a basis for the qualitative analysis of the models of eco-systems. Indeed, solutions of the equations for the function f when the system is acted upon by stochastic factors should be treated either in terms of generalised functions[90] or, following the Langevin method,[91] in terms of probabilities—as functions of the density of the probability of the occurrence of various values of f. At the same time, analysis of the relaxation equations, which are naturally not as informative as the equations for f, may prove an easier task. Here it is more convenient to analyse the equations for the Fourier components:

$$\delta \varphi_a(\mathbf{k}, \omega) = \int_{-\infty}^{+\infty} \int \delta g_a(\mathbf{r}, t) \exp[-i(\mathbf{kr} - \omega t)] \, \mathrm{d}\mathbf{r} \, \mathrm{d}t. \tag{5}$$

This is partly associated with the simple analytic form of the Fourier components of external stochastic influences.

We shall now quote the simplest example of the introduction of relaxation equations for correlators in a linear approximation, where the "equation of motion" for the function $\delta \tilde{f}_a(t)$ assumes the form

$$\frac{\mathrm{d}}{\mathrm{d}t} \delta \tilde{f}_a = -\sum_b \lambda_{ab} \delta \tilde{f}_b, \tag{6}$$

where λ_{ab} are constant coefficients. Correlators of the quantities $\delta\tilde{f}_a$ satisfy the same linear equations:[92]

$$\frac{d}{dt}\langle\delta\tilde{f}_a(t)\delta\tilde{f}_c(0)\rangle=-\sum_b\lambda_{ab}\langle\delta\tilde{f}_b(t)\delta\tilde{f}_c(0)\rangle,\quad t>0 \quad (7)$$

(the subscript c in this system of equations is of arbitrary significance). When the system departs appreciably from equilibrium and also when it is acted upon by random factors capable of displacing it from the initial stationary state, the equations describing the devleopment of the system prove to be non-linear.

The simplest non-linear equations with feedback,[76,93,94] in which account is taken of interspecies interactions and also of influences of abiotic factors on the system, are usually analysed in relation to the evolution of eco-systems. A way of describing the state of the system, differing somewhat from that in the literature,[76,93,94] is described below. It makes it possible to use the above synergistic approaches[20,77] for the analysis of the evolution of eco-systems taking into account all the existing internal interrelations (including positive and negative feedbacks) and external factors.

The state of eco-systems may be characterised by the presence of a definite number of trophic levels. We shall attribute to each organism of the given eco-system two numbers (ij). The order of the trophic level will be designated by the index i ($i = 1, 2, \ldots, l$), starting from the highest-order level of consumers ($i = 1$) and ending with the level of producers ($i = l$). The numbering of individuals in each trophic level i will be specified by the index j ($j = 1, 2, \ldots, N_i$), where N_i is the number of individuals in the level i. We shall assume that each individual is in one of several possible states (these states s may be characterised from the standpoint of physiology, biochemistry, etc. depending on the formulation of the problem and the level of the problem considered).

Let θ_{ij}^s represent the relative populations of each of the states $s(ij)$ for individuals (ij) subject to the normalisation condition

$$\sum_s\theta_{ij}^s=1.$$

Under these conditions, certain stationary states of the population $\theta_{ij}^{s_0}$ correspond to the state of the eco-system in the norm. The states s_0 and the corresponding values of $\theta_{ij}^{s_0}$ depend in the general case on the natural age of the entire eco-system and on its previous history and vary with fairly large characteristic times in conformity with the programmed most probable evolution of the given eco-system up to its significant modification with transition to a climatic state. Since we are interested in evolutionary changes associated with the influence of external factors of the community and occurring over a much shorter time than that of natural succession, we shall consider the evolution of an eco-system as a quasi-stationary process and shall not introduce explicitly the time variation of s_0. We shall represent the equations for the evolution of the eco-system in the form

$$\frac{d\theta_{ij}^S}{dt}=\sum_{i'j';s'}\hat{D}[\theta_{ij}^s|\{\theta_{i'j'}^{s'}\}]+$$

$$+\sum_{s'}\hat{L}[W(ij;s'\to ij;s)\theta_{ij}^{s'}-W(ij;s\to ij,s')\theta_{ij}^s]+(g_{ij}^s-r_{ij}^s), \quad (8)$$

where $\hat{D}$ is a non-linear operator defining the evolution of the eco-system as a consequence of the internal interrelations present in it under standard external conditions ensuring natural evolution. The second term, characterised by the action of the linear operator $\hat{L}$, defines the influence on the evolution of the system by the fluctuations of external factors in time and the influence of factors of a new kind (for the given eco-system) expressed in terms of the probabilities W of the transition of the system from the state s to adjacent states s' and the reverse transition from the possible state s' to the state s.

For example, when biocidic ionogenic additives are introduced into the environment, ionic impurities are incorporated into a wide variety of components of the organism, in particular into the active ion transport systems, which can influence fundamentally the kinetics of their functioning as a consequence of changes in the initial distributions of local electrostatic fields in the vicinity of ionic channels in a biological membrane and also the possible conformational rearrangements in the protein–lipid complexes.[24] This factor may be taken into account by altering the probabilities $W(ij;\ s\to ij,\ s')$ in Eqn. (8) and it should influence the populations θ_{ij}^s and hence the evolution of the entire eco-system. Evidently the influence of ionising radiation on the structural elements of biological systems can be described similarly [in terms of the change in the probabilities $W(ij;\ s\to ij,\ s')$].

The time-variable quantities such as the pH, intensity of the thermal and UV radiations, concentration of nutrient substances (if one is dealing with aqueous cenoses), etc. may behave as the fluctuating factors in Eqn. (8). The inclusion of "new" factors in the second term implies the possibility of a significant influence by the latter on the evolution of the eco-system. The third term in Eqn. (8) characterises the rate of change of the population θ_{ij}^s as a consequence of external sources (g_{ij}^s) and sinks (r_{ij}^s) and contains a component rapidly fluctuating in time. Therefore, in the second and third terms it is sometimes convenient to differentiate fluctuation components and to represent them by generalised functions, for example:

$$g_{ij}^s-r_{ij}^s=\sum_k a_{ij;k}\theta(t-t_k),\quad \theta(x)=\begin{cases}1 \text{ when } x>0\\ 0 \text{ when } x<0\end{cases} \quad (9)$$

or

$$g_{ij}^s-r_{ij}^s=\sum_k b_{ij;k}^s\delta(t-t_k). \quad (10)$$

Here $\delta(x)$ is a delta-function.

Assuming that the second and third terms are perturbing factors, it is possible to analyse the devleopment of the eco-system under the conditions where these factors operate, provided that the evolution of the unperturbed system, expressed in a general form by a system of non-linear equations for the populations $\overline{\theta}_{ij}^s$, is assumed to be known, i.e. the relations $\overline{\theta}_{ij}^s=\overline{\theta}_{ij}^s(t)$ are known. In order to obtain these relations in each specific case, it is necessary to set up and solve the corresponding model system of non-linear equations whose parameters can be obtained in the course of special studies. As pointed out above, we shall be interested in the variation of the differences $\delta\theta_{ij}^s=\theta_{ij}^s-\overline{\theta}_{ij}^s$ as a function of time. We do not assume that these changes are small in the general case ($\delta\theta_{ij}^s\lesssim 1$). As a consequence of the non-linear inter-relations in the system, the change in the populations of states s (with the transition $s_0\to s_1$) for the individuals (ij) may influence significantly the evolution of the entire system as a consequence of the influence of "weak" factors.

Evidently a fully defined state s_0^ξ should correspond to each set ξ of external factors (natural for the given eco-system). If one may formulate the concept of a mutually unambiguous correspondence between the states s_0^ξ and the state of the environment, then the

changes in the values of s_0^{ξ} (transition to adjoining states s from the state s_0) will be qualified as a modulation transition. On the other hand, if irreversible changes in the states s_0 take place (for example, there is a transition to the state s' accompanied by a change in hereditary structures), then we shall refer to the modification or degradation of the states of (ij). In this case fundamental changes may occur in the entire eco-system owing to the existence in the latter of internal interrelations. The problems of the evolution of the eco-systems involve precisely the discovery of the possibilities of such irreversible changes detected via the functions $\delta\theta_{ij}^{s}(t)$. As mentioned above, it is more convenient to analyse the evolution of correlators

$$\delta g_{ij}^{ss'}(t)=\langle\delta\theta_{ij}^{s}(t)\delta\theta_{ij}^{s'}(0)\rangle,$$

where s' is any of the possible states or components of the specific spectrum $\delta\varphi_{ij}^{ss'}(\omega)$.

V. The influence of mass transfer processes in the earth–atmosphere system on the state of the biosphere

The preservation of life on Earth under the conditions of continuing intense anthropogenic influences may depend to a large extent on a series of global factors influencing the evolution of large eco-systems (seas and oceans and part of the continents). Here we have in mind the phenomena occurring not only in the Earth's biosphere but also in the upper layers of the atmosphere and in the deep layers of the Earth. These are in the first place the turnover of water and of biologically important elements (C, O, N, P, and certain others) in nature. The occurrence of the corresponding cycles is varied and, apart from the movements of water in the atmosphere and streams of subterranean waters carrying a wide variety of inorganic and organic components, it may involve the circulation of water in the oceans[95,96] and the turnover of the oceanic crust (its formation from melts in the reservoir in the Earth's mantle accompanied by their partial degassing with subsequent subduction of the oceanic lithosphere[97]).

1. Processes in the upper layers of the atmosphere

In this Section we shall discuss the possibility of the existence of fairly intense flows of water, the molecules and cluster of which can entrain also other inorganic and organic components in the upper atmosphere, into the stratosphere and further into the ionosphere and space. The discovery and quantitative analysis of the magnitude of such directed fluxes of substances is essential for the construction of models of the evolution of large eco-systems and for the understanding of the evolution of the entire biosphere as a whole.

The evident influence of the upper layers of the atmosphere on the evolution of biological communities is demonstrated by the ozone layer, which protects biocenoses against the harmful effects of intense UV radiation.[33] The conclusion of international agreements limiting the manufacture and large-scale employment of Freons, which, without reacting with the tropospheric radicals, enter freely the stratosphere, has in fact been associated with the global nature of the danger of the breakdown of the ozone layer on photodissociation of the Freons in the stratosphere.

Many inorganic and organic compounds have been detected in the upper atmosphere at heights of approximately 100 km,[98–100] which indicates the unsuitability of equilibrium barometric ideas for the determination of the density and composition of the atmosphere. At the heights indicated, water may be present in anomalously large amounts, forming silvery clouds, and the sources of this water are by no means always associated with volcanic eruptions. Seasonal changes in the relative concentrations of sodium and potassium in the silvery clouds have been detected, agreeing in the summer with the ratio characteristic of sea water.[99] This shows that sodium and potassium enter the silvery clouds with the wind-driven sea water spray and points to terrestrial rather than cosmic (as a consequence of the interaction of the solar wind and the ionosphere) causes of the appearance of silvery clouds at the heights indicated.

The rate of supply of a wide variety of components from the troposphere to the upper layers of the atmosphere is determined primarily by the turbulent mixing of the atmosphere at least up to heights of approximately 110 km.[101] Evidence for the existence of intense migrations of air masses at heights of 80–90 km (the rate of the wind-induced displacements is approximately 1–2 km h^{-1}) was obtained, in particular, by analysing the form of the silvery clouds and also on the basis of spectroscopic data.[102] A possible source of the turbulence, ensuring the transport of components indicated, is internal gravitational waves propagated from the regions of active meteorological processes occurring in the lower atmosphere (fronts, zones of increased activity) and also from mountainous regions.[101]

The transport of water to the upper atmosphere can be effected by charged water clusters in the electric fields arising between storm clouds in the ionosphere.[98] According to estimates,[98] approximately 1 g of H_2O can be transported with ionic clusters containing 10 H_2O molecules from an area of 1 km^2 per hour with a characteristic overall current of approximately 0.1 A. This corresponds to the water content in a silvery cloud with a volume of approximately 1 km^3 and made up of ice particles approximately 0.12 μm in diameter at a concentration of ~0.1 of a particle per cm^3. Evidently such "upward rain" or "rain on the ionosphere" should eliminate aerosol particles and gaseous components dissolved in water from the atmosphere.

The subsequent transfer of the water molecules and the impurity species, which partly dissociate and ionise, to the upper layers of the ionosphere can occur under the influence of convective plasma streams developing in the ionosphere–magnetosphere system as it drifts through crossed electric and magnetic fields. The electric fields in the boundary regions of the ionosphere arise regardless of the possible fields between powerful storm clouds and the ionosphere.[103,104] Analysis has shown[105] that various types of distribution of the large-scale electric field may arise in the ionosphere–magnetosphere system. A definite type of convective movement of the plasma corresponds to each distribution. The characteristic inhomogeneities existing under these conditions, whose extent in space is approximately $10-10^3$ km,[106] may influence strongly the kinetics of the removal of the components to the upper layers of the ionosphere, including the region of the exosphere (above 500 km) where processes involving the thermal heating of the species as a result of the absorption of UV quanta by oxygen and nitrogen molecules from sunlight take place vigorously. A proportion of the molecules and atoms then acquire thermal velocities exceeding 11.2 km s^{-1}, which is sufficient to drive the species outside the limits of the Earth's atmosphere.

The removal of components of the Earth's atmosphere (predominantly water molecules and the oxygen atoms and ions formed as well as nitrogen atoms and molecules) outside the limits of the Earth's gravitational field occurs also on interaction of the solar wind—the stream of charged particles (predominantly protons,

helium nuclei, and electrons) emitted by the sun—with the external layers of the ionosphere, which form the boundary of the magnetosphere and are turned towards this stream.[103] In the transition layers, formed at the boundary of the region of the strong magnetic field (magnetosphere) and the rapidly moving plasma, strong electric fields arise.[107,108] These fields can induce magnetospheric convection—the acceleration of plasma streams, which promote the removal of neutral and charged components into the region of the direct influence of the solar wind, which "blows off" the atmospheric species into space. The high energy components of the solar wind penetrate the atmosphere down to heights of 40–60 km, so that the processes involving the "blowing off" of species can proceed with different efficiencies as a function of the thickness of the atmosphere—from the mesosphere up to heights exceeding approximately 1000–1500 km, where appreciable concentrations ($\sim 10^2$ cm^{-3}) of oxygen and nitrogen ions have been detected by modern instruments.[109] The possibility of the operation of this mechanism of the removal of atmospheric species into space is indicated by data concerning the effect of the solar wind on cosmic rays. Under conditions where the Earth crosses part of the recurrent high-speed stream of solar wind, part of the stream of cosmic rays "intended" for the Earth is driven off and does not reach the Earth.[110]

The efficiency of the "blowing off" effects increased with increase in the velocity of the particles in the solar wind, provided that their energy is sufficient for the generation of secondary particles and the formation of particle showers, since large overall momenta can then be transmitted to the species (ions, molecules, and clusters) in the atmosphere. It has therefore been of interest to analyse the phenomena occurring on the sun and responsible for the increase in the velocity of the particles of the solar wind. It has come to be assumed that the high-speed streams of the solar wind arise in the coronal holes or in unipolar magnetic regions with an open configuration of the magnetic field.[111] Another possibility for the generation of high-speed streams of the solar wind may be associated with the non-stationary processes in the active regions of the sun or in the vicinity of active formations.[111–113] The acceleration of the protons emitted by the sun is induced, in particular, by the formation at distances of approximately 2000 km from the sun's surface, where the temperature and density decrease sharply, of magnetohydrodynamic Alfven waves,[114] into which the non-linear acoustic waves generated by the layers of the sun's photosphere are transformed.

The generation of streams of the solar wind having anomalously high energies, up to relativistic values, has in fact been attributed to the Alfven waves arising in powerful solar eruptions. The fact that the energies E_p of the protons emitted by the sun can be $E_p \lesssim 3000$ MeV is indicated by the streams of neutrons (these are formed in the atmosphere together with π-mesons) having energies up to 1000 MeV after certain solar eruptions (for example on 21st June, 1980 and on 3rd June, 1982).[115,116]

Since the high speed streams of the solar wind can intensify the "blowing off" of the components of the atmosphere into space, the elucidation of adequate mechanisms of the formation of such streams and of the relation with the visible phenomena and processes on the sun (see also the footnote on p. 1197 below) is important for the analysis of the processes involving the partial "replacement" of the components of the atmosphere and its purification (see below), which influence the evolution of the Earth's biosphere. This is of particularly great current interest in connection with the intensification of the anthropogenic influences on the Earth's ionosphere by powerful electromagnetic radiations, by chemical substances emitted during the flights of ultrasonic aeroplanes, and by the ignition of powerful rockets[117,118] and also in connection with the possibility of stimulating the processes in the ionosphere (for example, on excitation in the latter of plasma-wave discharges[119]).

Naturally, the fluxes and composition of the components carried away from the Earth vary with time and depend on many factors. The discussion in the present Section of the entire set of problems of the "upward mass transfer" beyond the limits of the Earth's gravitational influence appears essential, because it is not clear *a priori* which of the stages of the transport of the components of the atmosphere (primarily water, oxygen, and nitrogen) into space is rate-limiting. It might be thought that each of the stages considered above may under certain conditions prove to be rate-limiting. In the next Section, we shall discuss the range of problems associated with the discovery of the processes occurring in the inner regions of the Earth, which are responsible for the current stable state of the atmosphere despite the processes involving the "cleaning" of the atmosphere by the removal of its components into space, described above.

2. Processes in the inner regions of the Earth

The deep layers of the Earth exert not only a direct influence on the eco-system (during earthquakes or on emission into the atmosphere of the products of volcanic activity) but also an indirect influence, determining the Earth's magnetic field. The influence of the magnetic field on the evolution of eco-systems is exerted when it acts on the functioning of biological objects[24,88,120] and also on the state of aqueous systems as living environments.[24,48,49]

It will be shown below that processes associated with the generation of the Earth's magnetic field can also lead to ecological consequences. According to existing ideas,[121–125] the observed magnetic field is caused by the convective movement, arising in the course of the Earth's rotation, of the conducting medium—the Earth's liquid metal core enclosed in a spherical layer with dimensions $0.19\ R_0 < R < 0.57\ R_0$ between the mantle and the solid inner core (R_0 is the Earth's radius). An obligatory condition for the functioning of this mechanism ("the dynamo-mechanism") is the gyrotropic nature (reflecting non-invariance) of the convective streams in which either right-hand screw or left-hand screw motions should predominate. Mathematically this is expressed by the non-zero value of the average helicality of the streams generated: $\langle \mathbf{v}\,\mathrm{rot}\,\mathbf{v}\rangle \neq 0$, where $\mathbf{v}$ is the local flow rate vector. The Earth's magnetic field has a poloidal (meridional) component with lines of force in the meridional plane and a toroidal (azimuthal) component in which the lines of force run along the latitudes. Under these conditions, only the meridional field has a radial component and extends into the environment. The convective movements in the liquid-metal core, with different angular velocities of the rotation of its different layers, lead to the transformation of the magnetic field indicated, including the interconversions of the components specified above.[121,122] The energy consumed under these conditions on dissipation in the functioning of the dynamo is evolved in the gravitational separation processes in the Earth's liquid core—in the precipitation of heavy substances, in the first place iron, at the lower limit of the liquid core and of light substances, containing the elements S, O, and Si, at its outer limit.

It is important to emphasise that the dynamo-mechanism is merely a mechanism of the intensification of certain seeding magnetic fields, which are generated in the Earth's liquid core. According to Dolginov,[122] the most probable mechanisms of the

generation of such fields are associated with galvanoelectric phenomena, in particular with the "battery" effect. The latter is characteristic of the Lorentzian plasma[92] when the electron concentration and pressure gradients are not parallel. Under the conditions on Earth, the battery field is naturally associated with the large-scale irregularities in the temperature and chemical composition at the interface between the mantle and the liquid core. The changes in the magnitude and sign of the geomagnetic field which occurred in the course of geological epochs (such data are obtained from the analysis of the magnetisation of ancient rocks) are associated, according to Dolginov,[122] with the change in the composition of the interface as a result of the exchange of material between the mantle and the core (cf. Ruzmaikin et al.[124]).

Despite the comprehensive development of the theory of terrestrial magnetism, the question of the nature of the convection in the Earth's core, the nature of the seeding magnetic fields, has still not been unambiguously solved. We shall consider below one of the possible hypotheses[24] concerning the nature of the seeding geomagnetic field, from which follow a series of global consequences related to the evolution of the Earth's eco-systems and to the characteristic features of the formation of a number of useful minerals, the optimum search for and the rational employment of which constitute an important aspect of man's nature-protecting activity.

It has been postulated[24] that in the region of the boundary between the outer part of the Earth's liquid metal core and the lower mantle, where high pressures are combined with shift deformations and the breakdown (regrinding) of rocks, endothermic chemical reactions take place. One of the initial reactants (hydrogen) is dissolved at high concentrations ($\sim 10^{24}$ cm^{-3}) in the Earth's liquid metal core (this hypothesis does not conflict with the possible ideas concerning the formation of our planet).[126]† According to this hypothesis, the Earth's core is a fairly capacious source of hydrogen, which has been active in the course of more than two billion years, i.e. throughout the existence of the hydrosphere. For the densities of the hydrogen dissolved in the Earth's core indicated above, its mass ($\sim 2 \times 10^{26}$ g) exceeds the overall mass of hydrogen in the hydrosphere (1.8×10^{23} g) by three orders of magnitude. This hypothesis is justified by the multiplicity of the consequences arising from it (see below), some of which are apparently susceptible to direct tests. Under the conditions indicated, the hydrogen, which is present in the atomic ionised state in a melt of catalytically active iron-group elements and other heavy elements, can effectively reduce the metal oxides MO_x in the lower mantle with formation of water:

$$MO_x + xH_2 \dashrightarrow M + xH_2O, \qquad (11)$$

and can interact with the metal carbides in the lower mantle, forming methane:

$$M_pC + 2H_2 \dashrightarrow CH_4 + pM. \qquad (12)$$

Water arises also on interaction of hydrogen with the oxygen approaching the core–mantle interface. The products formed as well as the helium and nitrogen emerging from the core are removed to the upper layer of the mantle and then into the Earth's crust.

†Another consequence which may follow from the above model[126] is that helium, nitrogen, and oxygen are dissolved (in smaller amounts than hydrogen) in the Earth's core.

Presumably the interface between the Earth's core and the mantle is not an ideal sphere. It is more likely to be "indented" in a radial direction from the centre and is non-uniform as regards the composition of the rocks at the boundary with the liquid core. In view of the high rates of the catalytic processes indicated, convective mass streams may be initiated in a number of regions of such a non-uniform boundary in the liquid phase of the core. They may be responsible for the transfer of hydrogen to the reaction zones and the temperature gradients generated in endothermic chemical reactions [in the first place on occurrence of reaction (11)] may give rise to certain spatially fixed dissipative structures. Owing to the establishment of non-uniform (with respect to the interface) temperature jumps

$$\Delta T(\mathbf{r})|_{s_i} = T_{s_1}(\mathbf{r}) - T_0 < 0,$$

where $T_{S_i}(\mathbf{r})$ is the local temperature of the lower mantle–liquid core interface (the surface S_i) and $T_0 \equiv T_{S_0}$ is the temperature "at the bottom" (the surface S_0) of the convective zone considered, structures of a mixed type can be formed—Benard[77] and Marangoni[127] structures. Evidently, owing to the non-uniformity (chemical, temperature-dependent) of the surface, asymmetric irregular dissipative structures (humps, eddies) should arise. Such irregularity gives rise to a non-zero average helicality of the streams of the liquid-metal medium generated, which is essential for the generation of the seeding magnetic field.

Owing to the presence of a temperature gradient in the radial direction in such convective structures the temperature in each section parallel to the interface varies within the limits of the cell[77] from a certain maximum quantity at the cell boundary S_u, where the convective stream is directed from the bulk of the core upwards towards the interface, to the minimum value at the boundary S_d, where the stream is directed downwards—into the bulk of the core. Conditions are thereby created for the occurrence of thermodiffusion streams (the Soret effect) of the highly mobile electronic component in the direction from the boundary S_u to the boundary S_d. As a result of this, electric fields $\mathbf{E}_c$, compensating the thermal diffusion electron stream, arise in the region between the above boundaries. These fields must be characterised not only by the components $E_c^{\perp}$ normal to the S_u and S_d surfaces (as a consequence of the Soret effect) but also by the components $E_c^{\parallel}$ parallel to the above surfaces (owing to the variation of the average temperature in the radial direction). Under these conditions, double electrical layers are formed at the boundaries S_u, S_d, S_i, and S_0 and also in the sections S_m through the convective zone where the quantities $T(\mathbf{r})|_{S_m}$ are characterised by local minima or maxima.

It is to be expected that the redistribution of the labile electron density as a consequence of the Soret effect and the generation of the electric fields $\mathbf{E}_c$ lead to additional stabilisation of the dissipative structures. In addition, owing to the appearance of the electric field component $E_c^{\parallel}$, closed circuits L are formed in each dissipative cell, in which eddy currents flow:

$$\oint_L \mathbf{E}_c \, d\mathbf{l} = -\frac{1}{c}\frac{d}{dt}\int_S \mathbf{B} \, d\mathbf{S} \neq 0,$$

where $\mathbf{B}$ is the electromagnetic induction vector, $d\mathbf{l}$ a differential element of the closed circuit L, and S the surface resting on the circuit L.

Evidently in the dissipative cell adjoining the cell under consideration an eddy current flowing in the opposite direction is generated. However, owing to the non-uniformity, mentioned above, of the convective structures formed, in the system investigated the induced resultant magnetic field can be regarded, together with other fields analysed,[122] as a seeding field. The orientation of the circuits L will depend on the geometrical characteristics of the chemical non-uniformities of the interface and on the differential rate of rotation of the liquid-metal phase of the core in the region of the formation of the dissipative structures considered.‡

Evidently the geomagnetic field (when the model considered is adequate) must be associated with the convective mass streams in the Earth's core, of maximum spatial extent, which are generated on reduction of oxides (the commonest compounds in the mantle) accompanied by the formation of water. In a critical analysis of this hypothesis, it is essential to take into account the available data concerning the distribution of water in the Earth's crust and in the hydrosphere during different geological eras and the stochastic changes in the Earth's magnetic field occurring in the given model as a consequence of the decrease in the rate of the chemical reaction (either as a consequence of the exhaustion of the oxides at the core–mantle interface or due to the limitation of the product removal stages). At the same time, data concerning the stochastic nature of the changes in the geomagnetic field apparently give rise to conclusions about the structure of the liquid core–lower mantle interface and about the kinetics of the endothermic reactions occurring in this region and initiating the formation of dissipative structures in the Earth's liquid core. This makes it possible in its turn to predict further changes in the geomagnetic field, which is of undoubted importance for ecological modelling.

A further series of consequences with an ecological and nature-protecting bias follow from the foregoing and refer to problems of the formation of useful minerals. The discovery of the mechanisms of the formation of deposits of ores, petroleum, gas, and coal is useful not only from the standpoint of an effective search for them but also for the rational mining and exploitation of these deposits, which is particularly important since the Earth's resources are already to a large extent exhausted. A theory of the mixed inorganic and organic nature of the formation of petroleum can be established on the basis of the hypothesis that processes (11) and (12) occur.

The methane generated in reaction (12) may participate in the chain of further catalytic incomplete oxidation (with participation of water and oxygen molecules) and hydrogenation processes. These reactions, occurring in the submicropores of the rocks in the Earth's lower mantle at more moderate temperatures than those corresponding to the formation of methane, lead to the synthesis of alkanes (possibly via the formation of CO,[129] alkenes, alkadienes, alkynes, arenes, and acenes,[130–134] which are the simplest components of petroleum.

The subsequent pathway leading to the conversion of the above components into more complex and heavier petroleum fractions involves the transfer of the components via a system of transport channels under the influence of static pressure gradients into regions where their organic (possibly in the presence of fossil residues of organic and bio-organic nature "stored" in these regions) and microbiological transformation takes place under the conditions of diagenesis.

Numerous special studies have been devoted to the problems of the biochemistry and geochemistry of petroleum formation.[135–141] The proposed scheme apparently makes it possible to reconcile the theories of the organic and inorganic origin of petroleum. Firstly, it incorporates naturally organic and microbiological reaction stages,[138–140] including those discovered in the study of petroleum biomarkers.[140] Secondly, the scheme developed here makes it possible to understand the inorganic origin of petroleum and gas in deep deposits.[141] It is regarded as established[142] that the existence of petroleum and gas deposits requires that the deposit be provided with an additional supply of natural gases, in the first place methane, from deeper regions with their partial outflow and scattering in the Earth's troposphere ("ascending mass transfer"), where the hydrocarbons are oxidised to CO_2 in photochemical reactions. The inflow of gaseous hydrocarbons together with hydrogen and helium into bore holes driven into a crystalline foundation has been detected at depths of 2–12 km.[130,143]

Analysis of maps of known petroleum and gas deposits (with discrimination between them as regards type and age) with the aim of their possible inclusion in a single system of "pores" (sites where petroleum and gas have accumulated) and "channels" (transport ways) would be of undoubted heuristic interest from these standpoints. Such systems of pores and channels should begin in the region of the interface between the liquid-metal core and the lower mantle, should pass through the mantle and the Earth's crust, and should terminate in the deposits. The transport pathways may include channels with submicroscopic dimensions and also macrocracks (fluid breaks),[144] through which the continuous hydrcarbon phase is transported. It is evidently necessary to analyse maps on different scales in order to discover the "self-resembling" scale-invariant fractal rules.[145]

Naturally the specification of the proposed scheme in a more concrete form must reflect the genetic relation between the latest shifts of the Earth's crust and the formation of various types of accumulations of petroleum and gas and also the dependence of the phase and chemical compositions of the hydrocarbon deposits on the direction and activity of the latest displacements and on the intensity of the heat flux. Data obtained by deep seismic probing in tectonic studies have shown (this does not conflict with the model) that the Earth's crust is subdivided into blocks of differnt shape and size as a consequence of the formation of vertical and inclined zones with breaks and cracks, many of which can be traced as far as the upper mantle.

Ore formation processes can be considered similarly. They are known to depend largely on the distribution in the Earth's crust of convective fluxes of geothermal waters and on the mineral composition of the rocks through which water is transported to the core-forming zones. When water interacts with the rocks, the composition of the fluid, including the isotope composition of the oxygen in water, evolves. The latter factor provides an effective instrument for the analysis of the ore formation processes. In particular, conclusions have been reached for specific deposits concerning the nature of the structure of the fluid fluxes on the way to the ore formation zones, about the amount of water which has passed through a wide variety of rocks during specific periods of time, about the rate of cooling of rocks, about the features of the

‡ Electric fields of the type indicated can also be generated in the convective region of the sun and in the relatively stable convective structures of the solar atmosphere.[128] These fields not only ensure an additional stability of the structures in the solar plasma but also act as a factor accelerating charged particles (protons, electrons), causing an increase in the energy of the particles of the solar wind (external effect) and non-isothermal nuclear synthesis in the region of the lower boundary of the convective zone (internal effect).

spatial distribution of temperature in the ore formation zones for different times, and about the sequence of the formation of various sections of the deposits.[146–148]

In the general case, the picture of the formation of ore deposits must be supplemented by ideas concerning the genesis of geothermal sources and about the features of the water–rock interaction, which determines, in particular, the rates of filtration, microfiltration, ultrafiltration, and reverse-osmotic penetration of water streams into the Earth's mantle. Subterranean waters are usually considered in terms of a single system of the natural water turnover: evaporation from the surfaces of open water-containing areas—accumulation in the atmosphere—precipitation—stages involving the transport of water incident on soils to subterranean storage areas and further to open water-containing areas, etc. In conformity with Eqn. (11), the water turnover system must be expanded by including in it the sources of water active in the region of the liquid core–lower mantle interface and the systems of transport channels in the Earth's mantle.

As already mentioned, a branched network of pores and channels with different characteristic dimensions, used for the ascending transport of water under the influence of internal pressure gradients, may be formed in the mantle, which is inhomogeneous as regards composition, structure, and the extent of cracks and breaks. Such water is included in the region of the Earth's crust in the normal system of the water turnover.[130,131] The topology of such waterways from the Earth's core can be characterised by the correlation length L_E, which is comparable to the Earth's radius. Conclusions, of heuristic value, about the location of subterranean water streams[149] and the principal breaks through which the hydrosphere is additionally supplied with water follow from the fractal nature of the transport of liquid fluid through the Earth's mantle.

Such analysis, supported by experimental research, may prove useful not only for the rational utilisation and preservation of natural resources already discovered but also for the more effective search for new useful minerals and for the development of general concepts concerning the rational utilisation of natural resources in the future. Indeed, the very processes involved in the search for useful minerals and the mining of deposits already discovered cause harm to nature, damaging local ecological areas. In the initial stages of the utilisation of natural resources, these features exert a lesser influence. The present exploitation of the depths of oceans in order to collect iron–manganese concretions[150,151] as a rich source of copper, nickel, cobalt, and other metals does not constitute a danger to the natural environment. On the other hand, the continuation of the vigorous exploitation of coal and petroleum and gas deposits leads to the breakdown of the natural balances in terms of the solid, liquid, and gaseous components in major subterranean reservoirs, which is riddled with serious consequences, primarily owing to the disturbance of local natural ecological areas.

As regards petroleum and gas as well as fresh water, humanity has approached the stage where it has become necessary to curtail the extraction of these substances to amounts which can be made good under natural conditions. The development of the concept of the "limiting permissible utilisation" (LPU) and the introduction of the corresponding norms as regards the restoration of the given substance in nature has become a matter of urgency. For the solution of such problems, it is necessary to specify adequately the mechanisms of the formation and "ripening" of useful minerals and to approach an understanding of the conditions governing the initiation and acceleration of these processes under natural conditions. One cannot rule out the possibility that it is already necessary to think about "laying down" petroleum and gas deposits for our descendants using for this purpose the deposits which have already been "worked out" but which have retained the entire natural system of "subterranean communications", including the transport systems in the Earth's mantle. It may be that for this purpose it is necessary to introduce into the remaining bore holes certain substances and micro-organisms and to employ other methods involving chemical, biochemical and physical influences.

3. The Earth as a thermodynamically open system

We shall consider yet another important comment. If it is supposed that the formation reactions of water and certain organic chemical compounds from inorganic components are still continuing, then the quasi-stationary level of the World oceans is achieved owing to the existence of a definite flux of water molecules and oxygen atoms and ions from the Earth into space. These molecules entrain other components of the atmosphere, including larger organic molecules (urea, aminoacids, nucleotides, etc.) and clusters (the possible mechanisms of the "blowing off" of such molecules into space were discussed in Section V.1). Evidently the experimental observation of such quasi-stationary fluxes, provided that they exist, would make it possible to refine certain conceptual ideas about the turnover of water and other biologically important elements (N, C, P, etc.) in nature and also the models of the evolution of eco-systems on a global scale [for example, from a study of the purification processes in the atmosphere after major volcanic eruptions, especially since the components of the eruptions can reach the stratosphere (see Section I), in the analysis of the consequences of global radioactive contaminations, in the nuclear winter scenarios,[152] etc.].

It was emphasised above that the directed streams of the molecules of water and other substances into the stratosphere and then into space should serve as an additional (acting together with the turnover of the given substances, processes leading to the degradation and photodegradation of harmful substances, etc.) factor cleaning the atmosphere, because, together with such streams, harmful components can also be carried away outside the limits of the Earth's gravity.

In order to estimate the amounts of water lost by the Earth, we shall assume that throughout the existence of the hydrosphere (2 billion years) the content of hydrogen in the Earth's core diminished by 0.1%, i.e. that the loss of hydrogen per year was approximately 10^{14} g. The average amount of water carried away into space is then about 10^{15} g per year (the flux is $\sim 10^{11}$ H_2O molecules cm^{-2} s^{-1}) for an overall mass of the hydrosphere of approximately 1.6×10^{24} g and of the atmosphere of approximately 0.5×10^{22} g. We may note that the average fluxes of solar wind particles incident on the Earth are $\sim 10^{10}-10^{12}$ particles cm^{-2} s^{-1}. The generation on the sun of ultrafast streams of protons and electrons leads to an increase of the above quantities by 2–3 orders of magnitude with evident consequences for the process involving the "blowing off" of the particles of the atmosphere.§

When the Earth is considered as a thermodynamically open system involved in energy and material exchange with cosmic space, a number of theoretical problems, requiring model justification, arise. In particular, it is necessary to establish the mechanism of the

§ Bearing in mind the ecological problems considered in this article, we may point to the possible analogy between the brief intense external influences purifying the Earth's atmosphere and the cleaning effect of large precipitations of water in St. Petersburg.

generation of the addition momentum ΔM in the Earth–atmosphere system in order to compensate for the difference between the flux of material ΔM_{out} lost from the Earth into space and the flux ΔM_{in} of material (flowing from space to the Earth)—meteor streams and components of the solar wind. There exist also other mechanisms "perturbing" the dynamic behaviour of the Earth–atmosphere system. One of the factors is associated with the position of the Earth in its orbit, since the overall vector of the Earth's orbital velocity and the velocity of the solar system in the Galaxy and the Metagalaxy change in the course of the year. This leads to seasonal variations in the rate of rotation of the Earth about its axis, which is the reason for changes in the elastic stresses within the Earth's crust.[153] One should also note the variable nature of the tidal forces associated with the inconstancy of the moment of the lunar and solar gravitational forces, which leads to oscillations in the Earth's axis (nutation).[153] Fluctuating influences on the Earth's motion are also exerted by processes on the sun, some of which have definite cyclic features.

The dynamic equations describing the Earth–atmosphere system must take into account the entire set of the perturbing external factors indicated and must include terms corresponding to the "sources" and "sinks" of the momentum in order to ensure stable motion of the Earth as a thermodynamically open system. Under these conditions, the entire solar system must be regarded as a complex hierarchy of self-organising subsystems saturated by energy sources and involve a surprisingly large number of collective processes.[154] The stable states of the Earth–atmosphere system occur in the vicinity of local minima in certain generalised functionals with stabilisation of the overall momentum of the Earth and the atmosphere in the vicinity of the mean value. Apparently such local minima characterise the overall stage of the entire solar system as well as the "resonance" stabilisation of the moon, the exotic "reverse" rotation of Venus,[155] and the rings in the satellite systems of the giant planets.[154]

It is important to note that the momentum of the sun (about 2% of the momentum of the entire solar system corresponds to the sun, while the mass of the latter is 99.9% of the total mass) as well as the momentum of each planet in the solar system as a single whole do not remain unaltered during the changes in the relative positions of the sun and the planets.[156] The centre of gravity of the solar system can shift from the central regions of the sun almost by $2R_{\odot}$, where $R_{\odot}$ is the radius of the sun, i.e. outside the limits of the sun. The stability of the states of the Earth and other elements of the solar system indicated above can therefore be partly due to entirely deterministic (in terms of location, in terms of the time of inclusion) internal local rearrangements in each of the celestial bodies, manifested for planets by "planet-quakes", by local rearrangements in the ionosphere ("ionosphere-quakes"), and by volcanic activity, and for the sun of the local processes in its surface region. The latter may include the generation of sunspots, leading to the necessary correction of the intrinsic momentum of the sun and its atmosphere. From this standpoint, numerical calculations of the variations in solar activity (of the relative number of sun spots—the Wolf number or the "indices of solar activity", determined by the flux of the wave type radiation from the sun in the radiowave ranges from metres to centimetres—usually at a wavelength of 10.7 cm[156]) merely as a consequence of a change in the relative positions of the sun and the planets and also the discovery of the sun—planet contribution to the initiation of natural catastrophes on our planet (as a consequence of the effects due to the changes in the momentum of the Earth in the Solar System and the attractive forces from other celestial bodies) may be of definite heuristic value.

It is noteworthy that the changes in the water regime within large regions, in particular the oscillations in the levels of large lakes without outflow (the Caspian and Aral seas and the Balkhash and Chany lakes), associated with natural long-period variations in the rate of rotation of the Earth,[157] as well as the movements of the tectonic plates in the course of the Earth's geological evolution may lead to a spatial rearrangement of the sources and sinks of the momentum i.e. to a change in the location of the regions with the highest seismic and volcanic activities. There is a possibility of a simultaneous "switching on" of atmospheric and intraterrestrial sources and sinks of the momentum, leading to major natural catastrophes, which have been described since ancient times: "... there was a violent earthquake and the sun went black... and the stars of the sky fell onto the Earth... and all the mountains and islands were shaken from their places" (Book of Revelation by John the Evangelist: **6**, 12–6, 14).

It is important to note that external influences leading to catastrophes can also be anthropogenic. One should probably consider major nuclear tests, the ignition of powerful rockets, and sharp changes in the hydrological regions associated with the construction of large dams. Furthermore, unsystematic and extravagant development of the Earth's resources (water, useful minerals) disturbs the complex system of natural hydrothermal and other communications which govern the mass transfer processes (the transport of water and simple inorganic and organic compounds) in the Earth's crust, which is essential for natural processes leading to the formation of new and the long term existence of present deposits of natural resources. The mass redistributions occurring may influence also the geological activity of individual regions and can also initiate natural catastrophes.

In view of the objective necessity for the further utilisation of natural resources and the expansion of the scale of industrial and agricultural products, humanity is forced to develop a strategy for its existence. The prediction of possible situations, including natural catastrophes, on the basis of mathematical models describing the changes in the Earth–atmosphere system under the influence of stochastic external factors becomes important in this connection. In the future, it will actually be possible to refer to a system of measures directed to weaken undesirable natural phenomena and their partial regulation or even complete elimination—by launching special powerful rockets or by nuclear explosions in deep bore holes.

The development of such approaches requires an adequate analysis of the existing and new data concerning the relationships[158] between anthropogenic activities in various regions, supported by experimental justification of the proposed concept—by the study of chemical processes at high temperatures, pressures, and shear deformations, by the study of mass transfer processes in the upper layers of the atmosphere, etc. We may note that direct experimental information about the mass fluxes blown off from the ionosphere into space, characterising the additional purifying capacity of the atmosphere, may be obtained from a comparative analysis of the components of the solar wind incident on the Earth after interaction with the Earth's atmosphere. The mass fluxes carried away from the Earth into space contain definite information about our planet since their composition includes fragments of organic and bioorganic molecules.

It may be thought that all planets with liquid metal cores in all the star systems of the Universe are thermodynamically open (naturally to different extents) systems "breathing" into space.[21,22]

One could imagine also exceptional situations—occurring in explosions of "nova" or "supernova" stars—where instead of "breathing" the corresponding planetary systems are destroyed with ejection of the contents of their atmospheres into space. Admittedly, such a fate does not threaten our planet. The detection in space of regions with an increased concentration of fragments of organic molecules may be an indication of the catastrophes which occurred on other worlds.

Thus one may speak of a dynamic unity of the Earth and the surrounding cosmic space, which means that the enigmas concerning the appearance of living organisms on Earth shift from a purely terrestrial level to a cosmic level. Life, having arisen (or having been created) anywhere, might have embraced those regions of the Universe where the necessary conditions for their development existed. We thus arrive at a more concrete specification of Vernadskii's general ideas[1] concerning the interaction of the inorganic matter of the planet and of the living matter at all the space-time levels of the organisation of the material world, the constant interaction of cosmic organic matter with the living matter on planets, and the wide-scale distribution of living matter throughout the Universe and its cosmic importance.

VI. Conclusion

The efforts of chemical science in connection with problems of ecology have been traditionally directed to current developments in the resource-saving and low-waste technologies and towards an improvement of the efficiency of the system of monitoring of the natural environment. At the same time, the possibilities of chemistry and related sciences in the solution of ecological problems may be expanded. In this section we shall deal with one class of hitherto poorly developed problems whose ecological importance is apparently not fully recognised. This concerns the electromagnetic pollution of the natural environment.[88,159] As a consequence of the experimental theoretical complexities in the problems arising, many of the postulates described below have still not been fully formulated in modern science and should be regarded as controversial.

At the present time, the spectral density of anthropogenic sources of electromagnetic radiation (EMR) within many frequency ranges, primarily in the radio-frequency ranges, exceeds by several orders of magnitude the natural background (generated by the radio emission from the sun, the planets, and other cosmic sources, by phenomena in the Earth's atmosphere, etc.) and by the intrinsic spectral noise in natural radiation receivers (native biological systems, including the human brain and nervous system).

At the same time, many effects on biological systems by the EMR in various frequency ranges, starting from fractions of Hz and up to SHF (wavelength $\lambda \simeq 1 - 10$ cm) and EHF ($\lambda \simeq 0.1 - 1$ cm) ranges. Together with therapeutic effects of EMR in different ranges on man,[88,159] specific (non-thermal) negative effects have been observed after prolonged irradiation, so that limiting permissible levels (LPL) of exposure to EMR have been established. The LPL for irradiation by radiowaves under industrial conditions is 10 μW cm^{-2} in the USSR, 1 mW cm^{-2} in Canada, 10 mW cm^{-2} in the USA and a number of other countries.[159] The existing scatter in the established norms (by up to 3 orders of magnitude in terms of power!) indicate an inadequate level of the current understanding of the specific features of the effect of EMR in different ranges on biological systems—on the human brain and nervous system. On the other hand, the discovery of all the factors influencing the state and functional activity of man, in the first place the functioning of his brain, constitutes a fundamental condition for the existence of civilisation. It is not fortuitous that the United States Senate and Congress have declared the decade starting on 1st January, 1990 as the "decade of the brain".

The human brain, being a non-equilibrium system of the organism, is most capable of "switching over" its state ("forced bifurcation") under the influence of weak external (light, sonic, etc.) signals. The brain is apparently the most highly organised multiparameter dynamic system, each state of which is established as a coherent (concerted) set of ensembles comprising ten and more neurons and characterised by a definite set of metastable levels. The transitions between such generalised states occur via a system of alternatives[77] under the influence of weak signals. The wide variety of states of the brain system is indicated by the virtually "non-deletable" and readily recalled memory, including visual images, manifested by man's creative activity during normal life and in dreams.

Man's light and sound receptor systems, which transmit information to the brain, as well as the olfactory biochemical reception systems, possess a uniquely high sensitivity. It has been shown experimentally that the radio frequency EMR also exerts a direct influence on the sensitive highly non-equilibrium systems of the brain.[159] In biological systems there are no specialised receptor organs for radio signals (in contrast to light signals). One may therefore think that the primary mechanisms of the reception of radio waves are fairly non-specific and are the same for all biosystems.

These influences can be exerted either through a change in the state of the aqueous component of the biosystems, in which the activity of free, non-bound water may be altered under the influence of the radio frequency EMR [49] or through a change in the functional state of the ionic channels in biological membranes as a result of an increase in the degree of hydration of the channels and the consequent loss of selectivity relative to the transfer of ions of different kinds.[24] Further studies should establish with a greater certainty not only the primary mechanisms of the effect of EMR at different frequencies on man but also the systems for further processing in the brain of the information carried by such radiation.

This is of particularly great current interest, since negative influences on man can be exerted not only by anthropogenic sources of EMR but also by major fluctuations in the natural radio frequency EMR background. In particular, the increase in solar activity with increase in the relative number of sun spots and eruptions on the sun, responsible for the increased intensity of the solar wind and streams of plasma clouds away from the sun, leads not only to an increase in the intensity of the intrinsic solar EMR in the radio frequency ranges (type I–V radio waves) but also to the generation of magnetospheric holes and subholes with strong variations in the geomagnetic field on interaction of the streams of solar plasma with the Earth's magnetosphere and ionosphere. A broad spectrum of electromagnetic waves is then excited in the Earth's magnetosphere: "holes" and "swellings" ($\sim 10^5 - 10^2$ Hz); stable and irregular geomagnetic pulsations ($\sim 10^{-2} - 10$ Hz); atmospheric noise ($\sim 1 - 10^2$ Hz); low-frequency radiation ($\sim 10^2 - 10^4$ Hz). This is a consequence of a wide variety of phenomena in magnetospheric holes and subholes: turbulent movements in the magnetospheric plasma, the development of plasma instabilities, the generation of intense electric currents amounting to tens of thousands of amperes in the ionosphere (at heights of approximately 100 km), etc.[109,156] The negative

influences of such magnetic holes on the state of human beings are well known. Although solar activity can be partly associated with the relative positions of the sun and the planets (see Section V), each planet is a source of its characteristic radiation in the ultralong radio frequency range, generated on interaction of the solar wind and the streams of solar plasma with the planet's magnetosphere and atmosphere. Presumably, further progress in the science of the brain, the discovery of the mechanisms of the reception of weak information-containing electromagnetic signals by the organism, will make it possible to understand better all the influences exerted by cosmic space and the environment on man.

We shall make yet another comment. The history of science has shown how difficult it is to predict the true course of scientific progress. It is sufficient to recall the classical statement by Lord Kelvin on the eve of the XXth century, concerning two "small clouds" (the negative results of Michelson's experiments, anomalies in the absorption spectrum of an absolutely black body) which at the time precluded the formulation of physical science in a "final form". The theory of relativity and quantum mechanics were created on this basis. The century coming to its conclusion involved the formulation of its own problems and puzzles. One of the "little clouds" as regards physicists has already been specified: the fact that the measured flux of "solar" neutrinos is smaller almost by a factor of three than the value predicted within the framework of the standard model of the sun. The paradox of the situation consists in the fact that, together with brilliant astrophysical discoveries of the nature of many stellar and quasi-stellar objects separated from the sun by billions of light years, we have the state of affairs where the processes in our Star are still not fully understood!

Here one would wish to mention two other major "clouds" (which arose many centuries before Lord Kelvin's "little clouds"), whose internal essential features have so far been poorly understood, so poorly that many scientists do not consider them seriously. This concerns astrology as the science of relations between the state and evolution of individual living organisms (including man) and eco-systems, on the one hand, and the relative disposition of celestial bodies, on the other, as well as telepathy as the science of processes involving the transfer of information without special signals and technical means (including "thought transfer") at a distance in which the organism makes use of his own memory system and the system for the reproduction of visual images.

We have already discussed above the possible relation between solar activity and the relative positions of the sun and the planets. The fairly well established influence of the state of the sun on the functioning of living systems should be effected primarily through the low-frequency variable magnetic field and different radio frequency ranges generated by the EMR. The problem of how the above radio emissions influence the human psyche and state of health remains, however, unsolved. As regards information signals from bio-objects, including man, if one does not introduce into consideration new postulates (in conformity with Occam's principle), in particular the hypothesis of the existence of "hitherto unknown biofields",[160] one may assume that the transmission and reception of such signals are effective also at radio frequencies, most probably in the centimetre and decimetre ranges.[159] At the present time the thermal radio emission by man (in the ranges indicated and at longer wavelengths — in the decametre, kilometre, etc. ranges), the intensity of which is rigorously related to the temperature of the emitting internal organs, is used effectively for diagnosis at a distance. This also applies to the equilibrium emission by the body in the IR range ($\sim 8-14$ μm).[161] The latter is characterised by a high power (~ 10 mW cm^{-2}) so that the power of the radiation emitted by the entire human body in the IR range exceeds 100 W.[162]

Evidently, for the transmission of information signals by the human brain in radio frequency ranges as well as the establishment of the highest sensitivity for the reception of weak signals, it is necessary that macroscopic ($\sim 1-10$ cm) domain structures, all the neurons of which function in a coherent regime, be formed in the brain. In this case the power of the transmitting signals may exceed by several orders of magnitude the equilibrium thermal background. There are no fundamental prohibitions of the existence of such "telepathic communication" — neither as regards energy characteristics nor as regards the possible highly specific individual sensitivity of natural systems. Naturally, there are major difficulties in the experimental location of the signals transmitted by the brain, which is partly associated with the fairly random character and virtual non-controllability of the most striking manifestations of spontaneous telepathy. There exist also fundamental difficulties in the understanding of the mechanism of the coding of information in the domains of the active medium of the brain capable of being stimulated, the transformation of information into radio wave signals, the reception of the signals in the receiving systems, etc.

In such hypothetical approaches to astrology and telepathy, the problems of these sciences acquire the same essential features and should be solved by discovering the mechanisms of the reception by man of weak information signals in different radio frequency ranges. The question arises whether the "clouds" mentioned above will develop and whether astrology and telepathy will become established as natural scientific disciplines or whether they will still remain for a long time *terra incognita* which will excite the imaginations of impressionable investigators and laymen.

Enigmas in nature have always existed and will exist. Furthermore, the level of the recognised lack of knowledge increases (or at least does not diminish) as reliable knowledge accumulates. Scientific progress is partly effected through this process involving the recognition by man of the depth of his lack of knowledge. However, even regardless of the difficulties concerning astrology and telepathy discussed above, the discovery of information communication, manifested in the reception by living organisms of low-frequency variable magnetic fields and radio frequency EMR, is one of the new and important aspects of ecological science.

This review represents an attempt to analyse the wide variety of problems arising in the formulation of the concept of the survival of humanity combined with the choice of ecological priorities and the aim is to draw the attention of chemists as well as specialists in other fields (ecologists, medical practitioners, biochemists, physicists, and mathematicians) to the possibilitiy of a joint search for and solution of general and what are apparently the most important problems to everyone at the present time — the problems involved in saving the home.

What future awaits us? "Then I saw a new heaven and a new earth; the first heaven and the first earth had disappeared now and there was no longer any sea" — wrote John the Evangelist (Book of Revelation: **21**, 2). What was the new world seen by the Evangelist? After all, the New Testament is threaded by the idea of the multivariability of the future, the understanding of the world as a subject with which humanity has a dialogue and as an open system with an "open future".[163] Not only destructive but also creative, cleansing forces are active in the world (the "white horse", Book of Revelation: **6**, 2, 19, 11) and the scales in the hands of the rider on the "black horse" (Book of Revelation: **6**, 5) can serve as a

symbol of the uncertainty of the ways in which man and humanity as a whole will develop.

This view on the world is adequate, especially now that wide use is made of technologies which can do irreparable harm to the biosphere and when nuclear and chemical weapons have accumulated in amounts sufficient for the complete annihilation of civilisation. The visions of John the Evangelist may prove to represent reality, as already demonstrated by the Chernobyl catastrophe: "... and a huge star fell from the sky, burning like a ball of fire, and it fell on a third of all rivers and streams; this was the star called wormwood and a third of all water turned to bitter wormwood, so that many people died from drinking it." (Book of Revelation: **8**, 10; **8**, 11).

Humanity stands at the crossroads and the face of the "new" Earth will in fact depend on the choice of priorities (ecological, social, ideological etc.) in the development of a survival strategy: either a path will be found and followed to the convergence of world social-political systems, so that the history of humanity does not break off, or civilisation will be destroyed and will be reborn after many thousands or millions of years (possibly "without a sea"?).

Certain physicochemical principles of eco-systems and their expression in the form of material inequalities for different levels of initial information

N V Sokolov
Institute of the Problems of Water, USSR Academy of Sciences

ABSTRACT. The usefulness of estimates of the contents of various components of ecological systems and subsystems in the form of material inequalities is demonstrated with the aid of the principle of the threshold nature of the action of chemical substances on producers and consumers. The principle of the coupled material-characteristic imbalance is formulated, according to which the unknown part of the mass of the ecological system can be estimated with the aid of inequalities expressing the relations between the masses of the components and their contributions to the overall characteristics of the system as a whole. The possibilities of using material inequalities for different levels of initial information for the monitoring of eco-systems and for the planning of physicochemical nature-protecting measures are demonstrated.

The bibliography includes 40 references.

I. Introduction

Monitoring on the global and regional scale and prediction of the changes in the state of eco-systems and planning of nature-protecting measures necessitates the large-scale and operative estimation of the contents of various components, phases, fractions, and constituents of ecological systems and subsystems and also the determination of the rules governing their compositions.

An ecological system represents a territorially (spatially) isolated integral elementary unit of the biosphere all the components of which are closely related to one another, or a certain assembly of such units.[2]

By an ecological subsystem, we shall understand a part of the eco-system which is imagined to be isolated or which has real physical boundaries and which can contain or not contain producers, consumers, and substrates. Ecological subsystems defined in this way can include waste water before and after purification, liquids contained in closed water supply systems, solid waste stored on military proving grounds and contaminating the lithosphere, various solutions and heterogeneous mixtures undergoing chemical changes in industrial and natural processes, as well as individual living organisms and their components. Under these conditions, one of the features of ecological subsystems is the possibility of their ultimate interaction with the environment and the living organisms present in it. Thus, various substances can enter natural water-containing areas even from a closed water supply system when its hermetic seal fails, while waste aerosols and industrial waters in general lead to daily contamination of the atmosphere and hydrosphere. It is seen from the definition that, in contrast to the eco-system itself, its ecological subsystem can be both homogeneous and heterogeneous, can consist of one component or of a very large number of components, and can be part of nature or an artificially produced mixture.

The principle of the threshold nature of the effect of chemical substances on producers and consumers[1–14] is in the first place the reason why it is useful to estimate in the form of material inequalities the liquid and gaseous waste entering the environment. Secondly, the methods for the large scale monitoring of the states of the atmosphere, the hydrosphere,[15–22] and the lithosphere should not themselves promote additional anthropogenic contamination by chemical substances. Thirdly, when they are applied, one must achieve the most effective utilisation of the initial information collected at considerable material expense. Fourthly, these methods should not entail the destruction or negative changes in biological objects.

The difficulty of collecting detailed information about the state of ecological systems and subsystems and of its subsequent utilisation[23,24] necessitates the establishment of universal characteristics of the compositions of such systems. These characteristics must be suitable for practical use even in the absence of complete data and in the presence of different levels of the initial information.

Thus large scale monitoring and prediction of the state and chemical evolution of ecological systems and subsystems as well as the planning of nature-protecting measures[24-30] require the discovery of the principal rule governing the composition which is applicable to the entire wide variety of information conditions encountered in practice. The specific features of ecological requirements (the principle of the threshold nature of the effect of chemicals contaminating the environment) indicates the suitability of the inequalities in the search for such a rule.

II. Universal rules for the compositions of ecological systems and subsystems in the form of inequalities

The chemical processes in ecological subsystems frequently take place under the conditions of random oscillations in temperature, pressure, the concentrations of reactants, the activity of the catalyst and inhibitors, the magnetic field strength, and other parameters. Furthermore, as already mentioned, there is frequently no exhaustive information about the ecological subsystem. These features necessitate the establishment of new general rules which determine the relations between the amounts of reactants and products in chemical reactions in both homogeneous and heterogeneous ecological subsystems.

Bearing in mind the specific features of ecological subsystems and the principle of the threshold nature of the influence (of various factors), we shall attempt to compare, under the conditions of incomplete initial data, the unknown amount of the system component with a quantity which can be readily calculated theoretically or determined experimentally. We shall explain the idea of this approach by a simple example. Evidently, the overall mass of substances with a molecular weight not less than the specified value cannot be greater than the mass of the entire system. Having divided the left-hand and right-hand parts of the trivial inequality corresponding to this claim by the specified molecular weight and having taken into account the fact that one then obtains on the left-hand side a quantity which exceeds the total number of moles of such substances, we obtain as a result a new relation according to which the total number of moles of substances with a molecular weight not less than the specified value, existing in a certain ecological subsystem (isolated volume), cannot be greater than the ratio of the total mass of the system to the specified molecular weight at any instant during chemical reactions.

Using the definition of the concentration and of the average density, it is easy to demonstrate with the aid of the above rule that the molar concentrations of substances in a certain volume of space where chemical reactions take place cannot be greater at any instant than the ratio of the average density of the entire system at this instant to the molecular weights of the corresponding substances.

The possibility of applying this rule can be illustrated in relation to the industrial synthesis of sulphuric acid by the contact method.[31] This substance exerts a powerful negative effect when it enters the environment. Suppose that an aqueous solution of sulphuric acid with a density of 1841 kg m^{-3} is introduced into the absorption tower. Then, according to the rule established, the concentration of sulphuric acid in the solution entering the tower is $\leqslant$18.79 kmol m^{-3}. If after the reaction with SO_3 and cooling of the liquid phase, the density of the resulting solution is 1838 kg m^{-3}, then, on the basis of the assertion formulated above, we find that the concentration of sulphuric acid in the resulting solution is less than or equal to 18.76 kmol m^{-3}. If the initial sulphuric acid solution contains 98.2% H_2SO_4, then the concentration of sulphuric acid was 18.45 kmol m^{-3}. The final solution with the density indicated at 15 °C can represent 99.3% sulphuric acid and its concentration will be 18.62 kmol m^{-3}. As can be seen from the values obtained, the results are in full agreement with the rule established above.

Thus the general rules postulated above make it possible to estimate at each instant the amounts of both the starting materials and the products present in any isolated volume even for a minimal amount of information available about the chemical reactions and about the influence of numerous random factors and mass-exchange processes.

In order to obtain an expression whereby the weight fractions of the substances in ecological subsystems can be estimated, we write

$$\frac{m_k(t)}{M_\Sigma(t)} \leqslant \sum_{i=k}^{i=l(t)} \frac{n_i(t)\mu_k}{M_\Sigma(t)} \leqslant \mu_k n_{sp}^{\cdot}(t), \qquad (1)$$

where $M_\Sigma(t)$ is the mass of the entire ecological subsystems at time t, $n_i(t)$ and $m_i(t)$ are the number of moles and the mass of the ith substance in the ecological subsystem at time t, μ_k the molecular weight of the kth substance, $l(t)$ the number of substances present in the subsystem at time t, i the summation index such that at a fixed time t the inequalities

$$\mu_1 \leqslant \mu_2 \leqslant \mu_3 \leqslant \ldots \leqslant \mu_{i-1} \leqslant \mu_i \leqslant \mu_{i+1} \leqslant \ldots \leqslant \mu_{l(t)}, \qquad (2)$$

hold, k a fixed value of i, and $n_{sp}^{\cdot}(t) = \left[\sum_{i=1}^{i=l(t)} n_i(t)\right] \Big/ M_\Sigma(t)$, the specific number of moles (the average characteristic of the ecological subsystem) equal to the ratio of the total number of moles of all the substances present in the ecological subsystem to their overall mass.

Eqn. (1) makes it possible to formulate the following theorem:

Theorem 1. *For any chemical reactions in ecological systems and subsystems, the weight fraction of a given substance at any instant cannot exceed the product of the specific number of moles at the given instant and the mole fraction of the given substance.*

Having multiplied the terms of the inequalities (1) by the average density† of the entire ecological subsystems $\bar{\rho}(t)$, we obtain an expression which makes it possible to estimate the concentrations of the components of the ecological subsystem from a minimal amount of data. It permits the formulation of the following rule.

The weight concentration of any reactant cannot be greater than the product of the specific number of moles, the average density of the system at the given instant, and the mole fraction of the substance.

Having used the idea of the material imbalance in relation to the mole fractions of the components of an ecological subsystem, we set up a sequence of inequalities:

$$\frac{n_k(t)}{\sum_{i=1}^{i=l(t)} n_i(t)} \leqslant \sum_{i=1}^{i=k} \frac{n_i(t)\mu_i}{\mu_k \sum_{i=1}^{i=l(t)} n_i(t)} \leqslant [\mu_k n_{sp}^{\cdot}(t)]^{-1}, \qquad (3)$$

where $n_i(t)$ is the number of moles of the ith substance and μ_i is the molecular weight (the weight of one mole) of the ith substance.

† The average density of the ecological subsystem is equal to the ratio of the mass of the entire subsystem to its volume.

Using Eqn. (3), we formulate the second theorem.

Theorem 2. *The mole fraction of a given substance in any reactions in ecological subsystems and subsystems at any instant cannot be greater than the reciprocal of the product of the specific number of moles and the mole fraction of the given substance.*

Since the weight and mole fractions of a substance cannot be greater than unity, their estimates are limited by the values of the products: for the weight fractions $\mu_k n^{\circ}_{sp}(t) \leqslant 1$ and for the mole fractions $\mu_k n^{\circ}_{sp}(t) \geqslant 1$. The expressions for their estimation can therefore be usefully combined into a single universal inequality:

$$\frac{|1-\mu_k n^*_{sp}(t)|+\mu_k n^*_{sp}(t)-1}{2[\mu_k n^*_{sp}(t)-1]} n \frac{n_k(t)}{\sum_{i=1(t)}^{i=t} n_i(t)} + \frac{|1-\mu_k n^*_{sp}(t)|+1-\mu_k n^*_{sp}(t)}{2[1-\mu_k n^*_{sp}(t)]} \frac{m_k(t)}{\sum_{i=1(t)}^{i=t} m_i(t)} \leqslant \leqslant \frac{\mu_k n^*_{sp}(t)[|1-\mu_k n^*_{sp}(t)|+1\mu_k n^*_{sp}(t)]}{2[1-\mu_k n^*_{sp}(t)]} + [\mu_k n_{sp\cdot}(t)]^{-1} \frac{|1-\mu_k n^*_{sp}(t)|+\mu_k n^*_{sp}(t)-1}{2[\mu_k n^*_{sp}(t)-1]}. \quad (4)$$

Consequently the contents of the components in ecological subsystems can be estimated from minimum amounts of physicochemical data when the specific number of moles in the system is known. The new average characteristic introduced here—the specific number of moles—can be fairly readily determined in the case of homogeneous liquid ecological subsystems from the decrease in the freezing point of the solution, or the increase in its boiling point, or osmometrically; for gaseous solutions, this quantity is unambiguously expressed in terms of the pressure, density, and temperature.

A series of practical problems concerning the protection of the environment necessitate the estimation of the content of substances with a molecular weight greater (smaller) than the specified value. For this purpose, using the principle of material imbalance, we shall set up similarly a sequence of inequalities replacing the unknown masses and numbers and moles of the components by larger quantities. As a result, we obtain the third and fourth theorems which are formulated as follows.

Theorem 3. *The sum of the weight fractions of substances with molecular weights smaller than or equal to the specified value at any instant in eco-systems and ecological subsystems cannot be greater than the product of the specific number of moles at this instant and the specified molecular weight.*

Theorem 4. *The sum of the mole fractions of substances with molecular weights greater than or equal to the specified value in ecological systems and subsystems at any instant cannot be greater than the reciprocal of the product of the specified molecular weight and the specific number of moles.*

Thus an objective relationship has been established between the content of the component in the system, the specific number of moles, and the molecular weight. These rules make it possible to differentiate the space of the values of the possible weight and mole fractions of the components constituting the ecological subsystems (Figs. 1 and 2).

Situations are frequently encountered where, apart from the average characteristic of the ecological subsystem (the specific number of moles), data concerning its quantitative composition at a given instant are also known. In order to establish the general rules for the compositions of multicomponent systems applicable for this level of initial data, we shall again make use of inequalities. The method of achieving this aim is expressed in the form of the principle of the coupled material-characteristic imbalance; *the unknown part of the mass of the ecological subsystem can be estimated by comparing the inequalities expressing the relations between the masses of the components and their contributions to the overall characteristic of the entire subsystem.*

We shall write the inequality relating the number of moles of the kth component to the total number of moles in the subsystem:

$$m_k(t)/\mu_k + [M_\Sigma(t) - m_k(t)]/\mu_{max} \leqslant N_\Sigma(t), \quad (5)$$

where μ_{max} is the maximum molecular weight of the component and $N_\Sigma(t)$ the total number of moles of all the substances constituting the system.

We supplement Eqn. (5) by the expression relating the mass of the component to the overall mass of the system through the number of moles of the remaining substances multiplied by the minimum molecular weight, namely

$$m_k(t) + [N_\Sigma(t) - m_k(t)/\mu_k]\,\mu_{min} \leqslant M_\Sigma(t). \quad (6)$$

By dividing inequalities (5) and (6) by the mass of the entire system, we obtain, after algebraic rearrangements, relations which make it possible to estimate in the following manner the contents of the components in ecological systems from the specific number of moles when the qualitative composition is known:

$$\frac{m_k(t)}{M_\Sigma(t)} \leqslant \begin{cases} \mu_k \dfrac{n^*_{sp}(t)\mu_{max} - 1}{\mu_{max} - \mu_k} \\ \text{when} \quad \mu_k n^*_{sp}(t) \leq 1, \\ \mu_k \dfrac{1 - \mu_{min} n^*_{sp}(t)}{\mu_k - \mu_{min}} \\ \text{when} \quad \mu_k n^*_{sp}(t) > 1. \end{cases} \quad (7)$$

The regions where the estimating inequalities, constituting formula (7), are applicable were determined on the basis of the condition $m_k(t)/M_\Sigma(t) \leqslant 1$.

In order to derive relations between the mole fractions of the components and an average physicochemical characteristic of the entire system, we shall take into account the fact that $n_k(t)/N_\Sigma(t) = m_k(t)/[\mu_k n^{\circ}_{sp}(t) M_\Sigma(t)]$. We then obtain from formula (7)

$$\frac{n_k(t)}{N_\Sigma(t)} \leqslant \begin{cases} \dfrac{n^*_{sp}(t)\mu_{max} - 1}{n^*_{sp}(t)(\mu_{max} - \mu_k)} \\ \text{when} \quad \mu_k n^*_{sp}(t) \leq 1, \\ \dfrac{1 - \mu_{min} n^*_{sp}(t)}{n^*_{sp}(t)(\mu_k - \mu_{min})} \\ \text{when} \quad \mu_k n^*_{sp}(t) \leq 1. \end{cases} \quad (8)$$

With the aid of inequalities (4), (7), and (8), it is possible to estimate the weight and mole fractions of the components for two levels of incomplete information.

Calculations based on the universal rules established for the compositions of ecological systems in the presence and absence of qualitative analytical data, carried out with the aid of a computer by

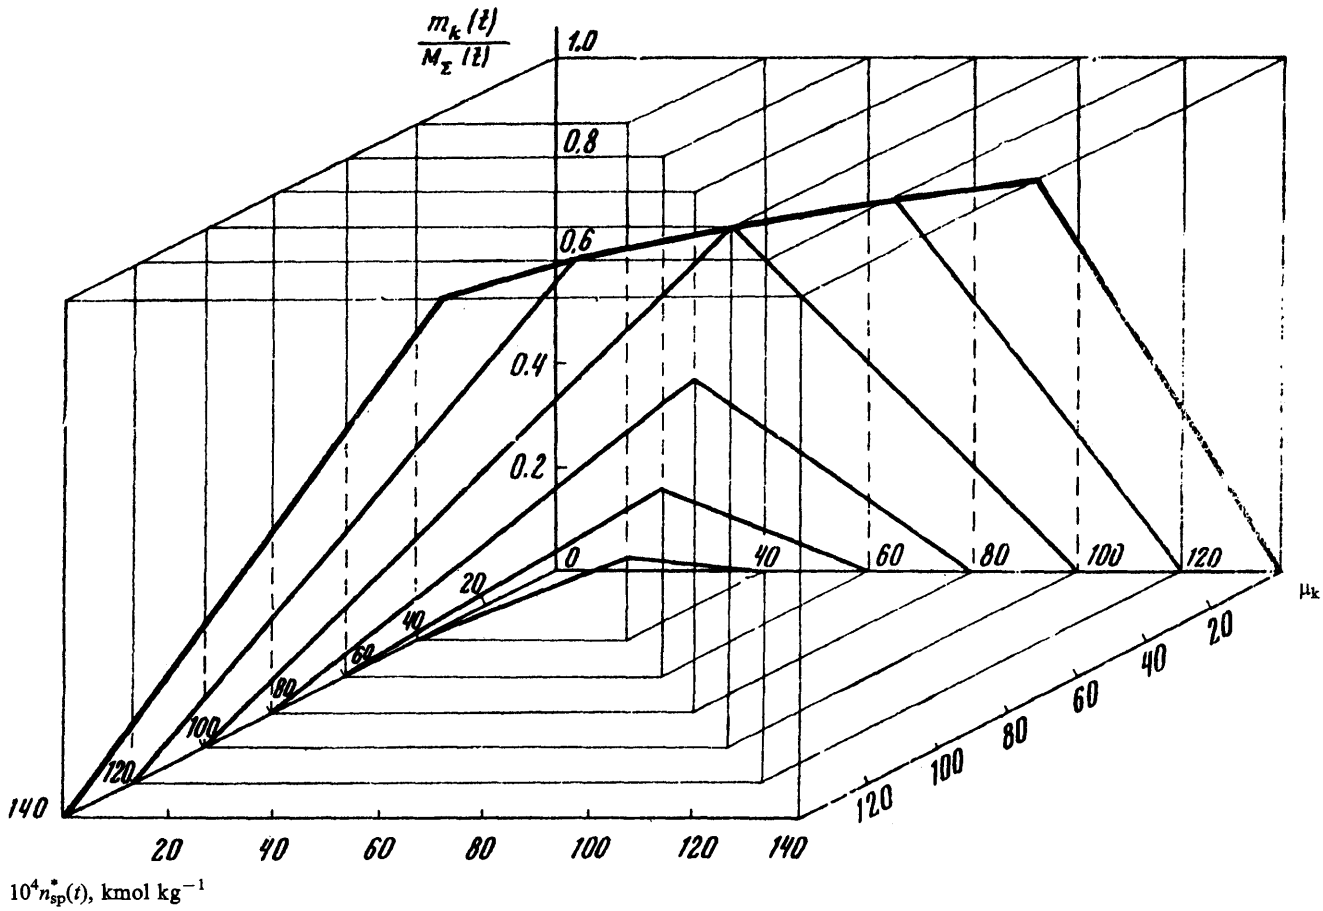

Figure 1. The space of the possible weight fractions of substances constituting eco-systems.

means of a specially developed algorithm and a program written in the BASIC language and based on it, confirmed the possibility of their practical employment. The high degree of generalisation of the above inequalities makes it possible to take into account any chemical, physical (including nuclear) and physicochemical changes in open, closed, and isolated ecological systems and subsystems, taking into account the effects associated with mass-exchange processes. Yet another important feature of these expressions is their low information requirement, i.e. the possibility of their practical application for a small amount of initial data.

Since in certain cases it is simpler for homogeneous and heterogeneous systems to measure experimentally the specific heat and the specific volume than to determine the specific number of moles of the ecological subsystem, we shall find inequalities relating the partial molar quantities and composition for these levels of information.

For this purpose, applying the principle of the coupled material-characteristic imbalance, we set up an inequality for heat capacities using the partial molar heat capacity of the kth component in the following form:

$$C_k^m \frac{m_k(t)}{\mu_k} + [M_\Sigma(t) - m_i(t)] \left(\frac{C^m}{\mu}\right)_{min} \leqslant C_\Sigma(t), \qquad (9)$$

where C_k^m is the partial molar heat capacity of the kth component, $C_\Sigma(t)$ the overall heat capacity of the entire ecological subsystem at time t, and $(C^m/\mu)_{min}$ is the minimum ratio of the partial molar heat capacity to the molecular weight (the minimum partial specific heat).

The inequality coupled with formula (9) is obtained by expressing the mass of the components with the aid of infinitesimal amounts of heat absorbed by them on raising the temperature of the entire ecological subsystem by an infinitesimal amount. Thus,

$$\frac{\mu_k \delta Q_k}{\delta T C_k^m} + \frac{(\delta Q_\Sigma - \delta Q_k)}{\delta T} \left(\frac{C^m}{\mu}\right)^{-1}_{max} \leqslant M_\Sigma(t), \qquad (10)$$

where δQ_Σ is the infinitesimal amount of heat absorbed by the entire ecological subsystem, δQ_k the infinitesimal amount of heat absorbed by the kth component, δT the infinitesimal rise in the temperature of the system on absorption of heat, and $(C^m/\mu)_{max}$ the maximum ratio of the partial molar heat capacity to the molecular weight of the given system (the maximum partial heat capacity).

On dividing inequalities (9) and (10) by the mass of the system and taking into account the fact that

$$\delta Q_\Sigma = M_\Sigma(t) \delta T \overline{C}_{sp}(t) \text{ and}$$

$$\overline{C}_{sp}(t) = C_\Sigma(t)/M_\Sigma(t),$$

we obtained a relation between the specific heat of the entire system

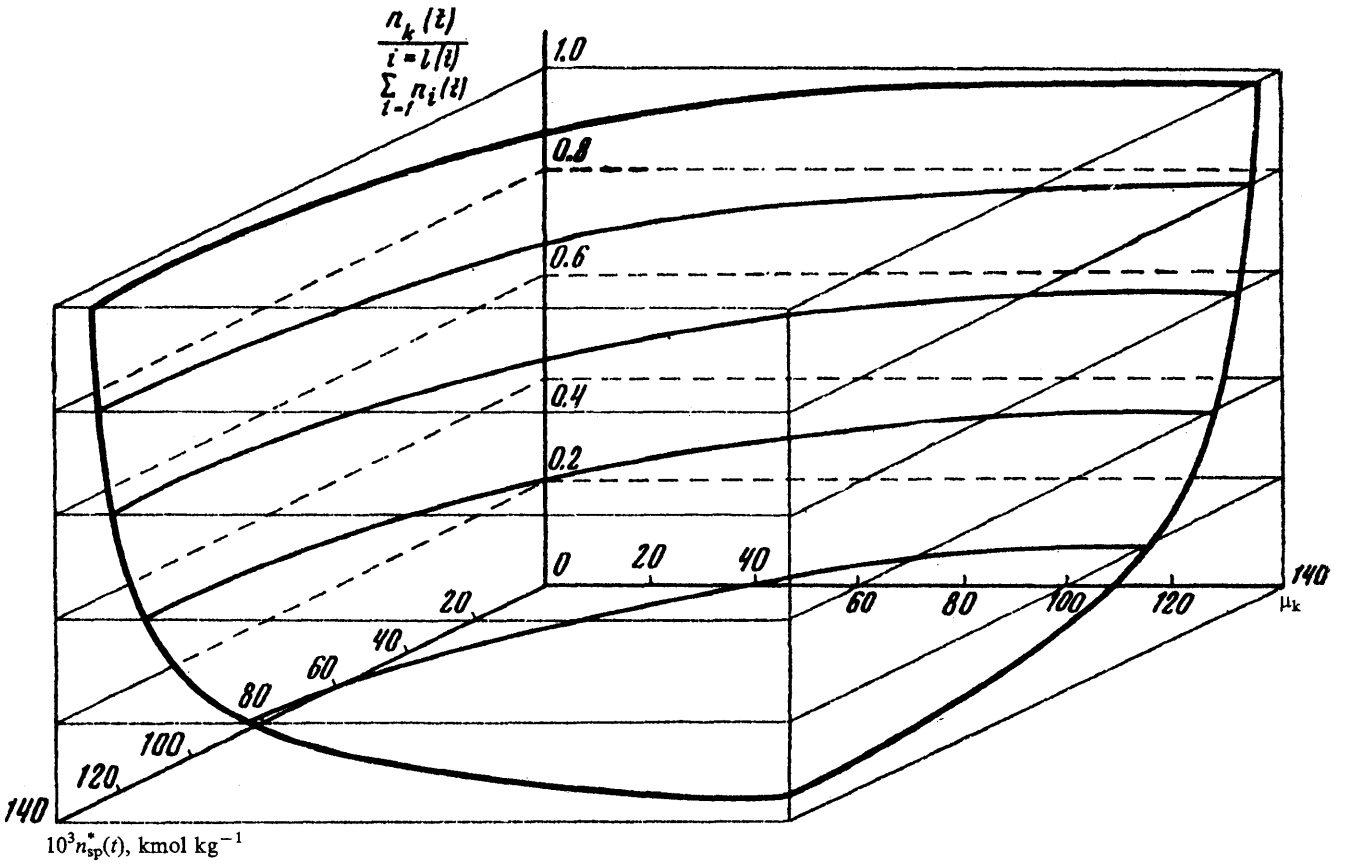

Figure 2. The space of the possible mole fractions of the substances constituting ecological systems. The surface of the maximum possible mole fractions of the substances in the eco-systems is differentiated.

$\bar{C}_{sp}(t)$ and the partial molar heat capacity and the content of the given component:

$$\frac{m_k(t)}{M_x(t)} \leqslant \begin{cases} \dfrac{\bar{C}_{sp}(t) - (C^m/\mu)_{min}}{C^m_k/\mu_k - (C^m/\mu)_{min}} \\ \text{when } \bar{C}_{sp}(t)\mu_k/C^m_k < 1, \\ (C^m/\mu)_{max} - \bar{C}_{sp}(t) \\ (C^m/\mu)_{max} - C^m_k/\mu_k \\ \text{when } \bar{C}_{sp}(t)\mu_k/C^m_k \geq 1. \end{cases} \tag{11}$$

The following rule follows from Eqn. (11):

The weight fraction of any component in a differentiated ecological system (subsystem) at a given instant cannot be greater than the ratio of the product of its molecular weight and the specific heat of the entire system (subsystem) to its partial molar heat capacity.

It can be used when the partial molar heat capacities of the other components constituting the ecological system are unknown. For example, the average specific heat of a human being, constituting a complex ecological subsystem, is 3.59 kJ kg K^{-1}.[32] Consequently, on the basis of this value of the specific heat of the ecological subsystem, one can conclude that the human organism contains not more than 86% of water. This result corresponds to the real situation, since according to Lightfoot,[32] the weight fraction of water in the human organism is 0.75.

We shall make use of the concept of the partial molar volumes of the components in order to obtain new relations. By setting up an inequality with the partial molar volume, we obtain a relation implying that *the weight fraction of any component at a fixed instant cannot be greater than the ratio of its molecular weight to the product of its partial molar volume and the average density of the entire system at this instant.*

For the case where the range of variation of the partial molar volumes is known, we set up two coupled relations for the imbalance of the volume and mass and, on combining them, we obtain, after algebraic rearrangements,

$$\frac{m_k(t)}{M_x(t)} \leqslant \begin{cases} \dfrac{1/\bar{\rho}(t) - (v^m/\mu)_{min}}{v_k{}^m/\mu_k - (v^m/\mu)_{min}} \\ \text{when } \nu^m_k/\mu_k > 1/\bar{\rho}(t), \\ \dfrac{(v^m/\mu)_{max} - 1/\bar{\rho}(t)}{(v^m/\mu)_{max} - v_k{}^m/\mu_k} \\ \text{when } \nu^m_k/\mu_k < 1/\bar{\rho}(t), \end{cases} \tag{12}$$

where $\bar{\rho}(t)$ is the average density of the ecological subsystem at

time t, $(v^m/\mu)_{min}$ and $(v^m/\mu)_{max}$ are the minimum and maximum ratios of the partial molar volume to the molecular weight, and v_k^m is the partial volume of the kth component.

Inequalities which make it possible to express under conditions of incomplete data a relation between the numbers of the components, their specific heats of combustion, and the specific heat of combustion of the entire ecological system can be set up similarly by establishing material inequalities for the imbalances in the masses of the components and in the heat of combustion. It is then possible to demonstrate, in particular, that *the weight fraction of any substance in the ecological subsystem at a given instant cannot be greater than the product of the specific heat of combustion of the system and the ratio of the molecular weight to the molar heat of combustion of the given substance.*

In order to discover the relation between the specific radioactivities of physicochemical systems and their content of radioactive isotopes when incomplete data are available, inequalities were set up expressing the imbalance in the overall radioactivity in terms of the weight fractions of the substances and the masses. It was then shown that the *weight fraction of the radioactive isotopes cannot be greater than the ratio of the specific radioactivity of the physicochemical system at a given instant to the specific radioactivity of the isotopes.*

III. Specific rules for the compositions of homogeneous ecological subsystems

We shall find the general relations for a series of readily determined mean statistical characteristics of homogeneous systems such as refractive index, the radiation attenuation factor, etc., on the one hand, and their contents of the components, on the other.

With the aid of the generalised Debye equation, a relation was found between the refractive index of a homogeneous system n and the content of the kth component:

$$\frac{m_k(t)}{M_\Sigma(t)} \leqslant \begin{cases} \left[r_{max} - \dfrac{n^2-1}{(n^2+2)\bar{\rho}(t)}\right] \Big/ (r_{max}-r_k) \\ \text{when } r_k \leqslant (n^2-1)/[(n^2+2)\bar{\rho}(t)], \\ \left[\dfrac{n^2-1}{(n^2+1)\bar{\rho}(t)} - r_{min}\right] \Big/ (r_k - r_{min}) \\ \text{when } r_k > (n^2-1)/[(n^2+2)\bar{\rho}(t)], \end{cases} \tag{13}$$

where r_k is the specific refraction of the kth component and r_{max} and r_{min} are the maximum and minimum specific refractions of the substances constituting the homogeneous system.

With the aid of the equations set up for the imbalance of the molecular refraction and the number of atoms, it proved possible to estimate the maximum possible number of atoms in the molecules from the relative refractive index under the conditions of incomplete information.

The fact that the fraction of radiation absorbed can be readily measured for homogeneous systems makes it possible to compare it with the contents of substances in multicomponent systems under the conditions of incomplete information. A relation which makes it possible to formulate the following rule can be obtained from the Lambert–Bouguer–Beer Law.

The molar concentration of each component in solution cannot exceed the ratio of the logarithm of the attenuation factor for incident radiation attenuated by a layer of solution of unit thickness to the molar extinction coefficient.

By applying the principle of the material-characteristic imbalance to cases of the absorption of radiation, it is possible to establish the following relation:

$$\frac{m_k(t)}{M_\Sigma(t)} \leqslant \begin{cases} \left[\dfrac{1}{\rho(t)L}\ln\dfrac{I_0}{I} - \varepsilon_{min}^{sp}\right] \Big/ (\varepsilon_k^{sp} - \varepsilon_{min}^{sp}) \\ \text{when } \varepsilon_k^{sp} \geqslant [\bar{\rho}(t)L]^{-1}\ln I_0/I, \\ \left[\varepsilon_{max}^{sp} - \dfrac{1}{\bar{\rho}(t)L}\ln\dfrac{I_0}{I}\right] \Big/ (\varepsilon_{max}^{sp} - \varepsilon_k^{sp}) \\ \text{when } \varepsilon_k^{sp} < [\bar{\rho}(t)L]^{-1}\ln I_0/I, \end{cases} \tag{14}$$

where L is the thickness of the layer through which radiation passes, I_0 and I are the intensities of the incident and transmitted radiation, ε_{max}^{sp} and ε_{min}^{sp} are the maximum and minimum specific extinctions, and ε_k^{sp} is the specific extinction of the kth component.

Setting up similarly the inequality for electrical conductivity, we note that *the number of equivalents in a unit volume of any substance, dissociating into ions in solution, cannot be greater than the ratio of the specific conductance of the homogeneous system to the equivalent conductance of the given substance at infinite dilution.*

For systems containing high-molecular-weight compounds, we find, by setting up material imbalance inequalities, the relation between the viscosity-average, number-average, and weight-average molecular weights, on the one hand, and the distribution of the fractions of the macromolecules, on the other. It has been possible to show that *the weight fraction of macromolecules with a molecular weight greater than or equal to the specified value cannot be greater than the ratio of the viscosity-average molecular weight to the specified value raised to the power equal to the parameter of the Mark–Houwink equation, while the numerical fraction of macromolecules with a molecular weight greater than or equal to the specified value cannot be greater than the ratio of the viscosity-average molecular weight to the specified molecular weight.*

IV. Specific rules for compositions of heterogeneous ecological subsystems

When heterogeneous systems are examined, new tasks, involving the determination of their phase and fractional composition and also of the measure of the fragmentation of phases arise. Therefore, in order to establish the general characteristics of the phase composition of heterogeneous systems, we shall set up relations for the imbalance of the volume and mass, expressing them with the aid of the average density of the entire system and the minimum and maximum densities of its constituent phases. As a result, we obtain a relation between the volume fraction of a particular part of the system and the average density of the heterogeneous system in the following form:

$$\frac{V_k^p(t)}{V_\Sigma(t)} \leqslant \begin{cases} [\bar{\rho}(t) - \rho_{min}]/(\rho_k - \rho_{min}) \\ \text{when } \rho_k > \rho(t), \\ [\rho_{max} - \bar{\rho}(t)]/(\rho_{max} - \rho_k) \\ \text{when } \rho_k \leqslant \bar{\rho}(t), \end{cases} \tag{15}$$

where $V_k^p(t)$ is the volume of the kth phase (fraction), $V_\Sigma(t)$ the volume of the entire heterogeneous system, and ρ_k the density of the kth phase.

Consequently, *the volume fraction of the phase (fraction) of the heterogeneous system cannot be greater than the ratio of the deviations*

of the average density of the entire heterogeneous system and the density of the given phase (fraction) from the minimum or maximum density of the heterogeneous system.

From the inequalities expressing the material-volume imbalance, we obtain

$$\frac{m_k^p(t)}{M_\Sigma(t)} \leqslant \begin{cases} \dfrac{1/\bar{\rho}(t)-1/\rho_{max}}{1/\rho_k-1/\rho_{max}} \\ \text{when } \rho_k < \bar{\rho}(t), \\ \dfrac{1/\rho_{min}-1/\bar{\rho}(t)}{1/\rho_{min}-1/\rho_k} \\ \text{when } \rho_k \geqslant \bar{\rho}(t), \end{cases} \tag{15a}$$

which makes it possible to formulate the following rule:

The weight fraction of the phase (fraction) of an ecological heterogeneous subsystem cannot be greater than the ratio of the deviations of the average specific volume of the entire ecological heterogeneous subsystem and the specific volume of the given phase (fraction) from the minimum or maximum specific volume of the subsystem.

As an example, we shall consider the application of this rule to the determination of the weight fraction of one of the components of DNA from the crab *Cancer borealis*. The average density of this DNA in CsCl solution is $\bar{\rho}(t)$ = 1694 kg m^{-3}, while its maximum density is 1700 kg m^{-3} or the density of the satellite band is 1681 kg m^{-3}. We shall estimate from Eqn. (15a) the weight fraction of the satellite band. Here $m_k^p(t)/M_\Sigma(t) \leqslant 0.313$, which corresponds to the real situation (according to experimental data for centrifugation in a density gradient,[32] the relative amount of the minor component of the DNA of the crab *Cancer borealis* in 0.3). The average density of mouse DNA is 1700 kg m^{-3}, while the maximum density is 1701 kg m^{-3}. Then, according to the rule, the weight fraction of the part with the density of 1690 kg m^{-3} is $\leqslant$0.09 and according to experimental data[33] it is approximately 0.08. Thus the experimental results indicate that the relations established can be applied in practice to heterogeneous ecological subsystems.

In the special case where the maximum and minimum specific volumes of phases constituting the system are unknown, it follows from Eqn. (15a) that *the weight fraction of the phase (fraction) of the ecological heterogeneous subsystem cannot be greater than the ratio of its density to the average density of the entire ecological heterogeneous subsystem.*

We shall use the latter postulate to predict the content of water in an ecological subsystem—an active silt representing a complex heterogeneous system containing micro-organisms and solid disperse particles with the aqueous dispersion medium surrounding them. Comparison of the high-speed estimates of the moisture contents of the active silt with the water contents found as a result of drying (Table 1) shows that in all cases the deviation of the high-speed estimates of the moisture content of the active silt from the exact value hardly exceeds 1.21%. The slightly greater moisture content determined by drying compared with the maximum possible value specified by the high-speed estimates in two cases out of 19 can be explained by errors of the measurement.

Consequently one may assume that the relation established between the weight fraction of the phase (fraction) of the ecological heterogeneous system and the ratio of its density to the average density of the entire system does indeed hold in practice and permits high-speed estimates of the moisture content of the active silt—a specific ecological subsystem used in purification plant for the protection of the environment against substances dissolved in waste water.

Table 1. High-speed estimates of the moisture content of an ecological subsystem (active silt) obtained under the conditions of incomplete information and the moisture contents found by a drying procedure*.

* The experiments were performed under the author's supervision in the Academy of Communal Economy.

We now set up the inequality for the imbalance of specific heats:

$$m_k^p(t)C_{p_k} + [M_\Sigma(t) - m_k^p(t)]C_{p_{min}} \leqslant M_\Sigma(t)\bar{C}_{sp}(t), \tag{16}$$

where $m_k^p(t)$ is the mass of the kth phase, $C_{p_k}^{sp}$ the specific heat of the kth phase, and $C_{p_{min}}^{sp}$ the minimum specific heat of the phases. The mass imbalance can be formulated as follows with the aid of the specific heats:

$$m_k^p(t) + [M_\Sigma(t)\bar{C}_{sp}(t) - m_k^p(t)C_{p_k}^{sp}]/C_{p_{max}} \leqslant M_\Sigma(t). \tag{17}$$

After rearrangements and combination of formulae (16) and (17), we arrive at the following postulate:

The weight fraction of a given phase, in a heterogeneous system, cannot be greater than the ratio of the deviations of the specific heat of the entire heterogeneous system and of the partial specific heat of the given phase from the minimum or maximum specific heats of the phases of the heterogeneous system.

Using the principle of the material-characteristic imbalance, we shall establish the general characteristics of the fragmentation of phases and of the size distribution of particles. By solving this problem with the aid of a sequence of inequalities, we obtain relations equivalent to such assertions.

The weight fraction of a part (fraction) of a heterogeneous system cannot be greater than one third of the product of the specific surface

of the entire system, the density of the disperse phase, and the maximum radius of the particles of the given part; the weight fraction of any part (fraction) of particles of a fragmented phase cannot be greater than the product of the specific number of the particles and the mass of the particle of maximum size in the given part (fraction).

Analysis of the adsorption of a multicomponent mixture can also be carried out under conditions of incomplete information with the aid of the idea of material imbalance. It was found that

$$\Gamma_k(t) \leqslant \begin{cases} (V_\Sigma(0)\bar{\rho}(0) - \bar{\rho}(t)V_\Sigma(t)]/(\mu_k S_{sp} M_\Gamma), \\ \text{provided that the qualitative composition of the mixture of adsorbates is known;} \\ \dfrac{[N_\Sigma(0) - N_\Sigma(t)]\mu_{max} - [V_\Sigma(0)\bar{\rho}(0) - V_\Sigma(t)\bar{\rho}(t)]}{M_\Gamma S_{sp}(\mu_{max} - \mu_k)}, \\ \text{when the qualitative composition of the mixture adsorbate is known if} \\ \mu_k < [V_\Sigma(0)\bar{\rho}(0) - V_\Sigma(t)\bar{\rho}(t)]/[N_\Sigma(0) - N_\Sigma(t)]; \\ \dfrac{\bar{\rho}(0)V_\Sigma(0) - \bar{\rho}(t)V_\Sigma(t) - \mu_{min}[N_\Sigma(0) - N_\Sigma(t)]}{M_\Gamma S_{sp}(\mu_k - \mu_{min})}, \\ \text{when the qualitative composition of the mixture adsorbate is known if} \\ \mu_k \geqslant [V_\Sigma(0)\bar{\rho}(0) - V_\Sigma(t)\bar{\rho}(t)]/[N_\Sigma(0) - N_\Sigma(t)]. \end{cases} \quad (18)$$

Here M_Γ and S_{sp} are the mass and specific surfaces of the adsorbent and $\Gamma_k(t)$ is the degree of adsorption of the kth component from the mixture of adsorbable substances at time t. Thus it is possible to analyse the adsorption process under conditions of a small amount of initial data.

V. Analysis of the deviation from the limiting possible contents of substances and rates of chemical reactions

For a number of problems of the protection of the environment, it is necessary not only to indicate the ranges of the possible contents of substances but also to achieve point predictions of all the quantities and to estimate the possible deviations. Theoretical analysis led to the derivation of formulae demonstrating that, for any prespecified absolute or relative deviation of the content of a component from its maximum possible value, there may exist ecological subsystems such that the real deviation is equal to the specified deviation. This means that the points corresponding to the different ecological subsystems can continuously fill the space of the possible contents of the components determined by the ratio of the average characteristic of the system to the isotypical measure of the properties of the components.

We shall make use of the universal characteristics of the compositions for the point estimates of the contents of the components in ecological subsystems. For a minimum amount of initial data, it is useful to postulate that the point estimate x_{est} of the weight fraction of components with $\mu_l > \mu_k$ is given by

$$x_{est} = 1 - n^*_{sp}(t)\mu_k/2. \quad (19)$$

The relative error of this estimate is

$$\frac{|x_{est} - \sum_{\mu_i > \mu_k} m_i(t)/M_\Sigma(t)|}{\sum_{\mu_i > \mu_k} m_i(t)/M_\Sigma(t)} \leqslant \frac{n^*_{sp}(t)\mu_k}{2[1 - n^*_{sp}(t)\mu_k]}. \quad (20)$$

In the case where qualitative analytical data are also available, the point predictions are refined. It follows from the relations established that in this situation the point estimate of the weight fraction of substances with specific heats greater than or equal to the specified value C^{sp}_k can be obtained with the aid of formula

$$x^c_{est} = 1 - (1/2)[\bar{C}_{sp}(t) - C^{sp}_{min}]/(C^{sp}_k - C^{sp}_{min}), \quad (21)$$

subject to the relative error

$$\frac{|x^c_{est} - \sum_{c_i^{sp} \geq C_k^{sp}} m_i(t)/M_\Sigma(t)|}{\sum_{c_i^{sp} \geq C_k^{sp}} m_i(t)/M_\Sigma(t)} \leqslant \frac{\bar{C}_{sp}(t) - C^{sp}_{min}}{2[C^{sp}_k - \bar{C}_{sp}(t)]}. \quad (22)$$

The non-equilibrium concentrations of reactants and products in the system can also be estimated with the aid of the equilibrium constants for closed homogeneous systems. For this purpose, the equilibrium value of the chemical variable is determined from the solution of the equation containing the equilibrium constant and the initial concentrations of the products and reactants of the chemical reaction.[33] With the aid of this variable, the point predictions of the concentrations of reactants and products and *a priori* estimates of their errors are found.

Table 2. ***A priori*** **estimates of the absolute errors of the point estimates of the rates of chemical reactions for a known ratio of the reactant concentrations.**

Reaction	Order of reaction	Rate constant for reaction	Overall concentration of reactants, kg m^{-3}	Absolute error of the point prediction of the rate of reaction kmol m^{-3} s^{-1}	*A priori* absolute estimate of the error of the prediction of the rate of reaction, kmol m^{-3} s^{-1}

In order to predict the results of the change in the compositions of ecological systems and subsystems under the conditions of incomplete information, it is essential to analyse the possible deviations of the rates of chemical reactions from their maximum values. As a result of a theoretical study, it has been shown that, by virtue of the limitations to the densities of solutions and to the overall pressure of the mixture of gases, under real conditions the rates of chemical reactions have a relative maximum. It was found that, when account is taken of the first limitation, the rate of the chemical reaction reaches its relative maximum value for molar concentrations of the reactants directly proportional to the ratio of the kinetic orders with respect to these substances to their molecular

weights and, for a limited maximum total pressure of the gas mixture in the reactor, the rate of a chemical gas-phase reaction reaches its maximum value in the case where the partial pressures of the reactants are in the same proportions relative to one another as the kinetic orders with respect to these substances.

The possible ranges of the rates of chemical reactions thus established permitted point predictions of their values and the estimation of the absolute errors of such predictions under conditions of incomplete information. Table 2 presents the results of such predictions. The rate constants for the calculations were taken from Emanuel' and Knorre.[34] In all the cases analysed, such predictions proved justified.

Formulae for the estimation of the concentrations and mass of the products formed as a result of the reactions in ecological subsystems and also inequalities for the *a priori* estimation of their accuracy were derived with the aid of the maximum possible rates of chemical reactions.

In all cases of practical importance, parallel chemical reactions occur when measures are taken for the protection of nature and in respiration, digestion, and other processes where the organisms interact with the components of the environment. Under such conditions, a sequence of the following inequalities can be written for the estimation of the weight fractions of the reactants forming a monotonically non-decreasing sequence of reactivities:

$$\sum_{i=1}^{l_s} m_i(t) \leqslant \sum_{i=1}^{j-1} m_i(0) + [1-\varkappa_j(t)] \sum_{i=j}^{l_s} m_i(0) \leqslant$$

$$\leqslant [1-\varkappa_j(t)] \sum_{i=1}^{l_s} m_i(0) + \varkappa_j(t)\mu_{j-1} \sum_{i=1}^{j-1} m_i(0)\mu_i^{-1} \leqslant$$

$$\leqslant \left\{1-\varkappa_j(t)\left[1-\mu_{j-1}\sum_{i=1}^{l_s} n_i(0) \Big/ \sum_{i=1}^{l_s} m_i(0)\right]\right\} \sum_{i=1}^{l_s} m_i(0), \quad (23)$$

where $\varkappa_j(t)$ is the degree of conversion of the jth substance at time t; $1 \leqslant j \leqslant l_s$; l_s is the number of reactants forming the reactivity sequence.

The following rule follows from Eqn. (23):

The weight fraction of the substances in the mixture, which form a series with monotonically non-decreasing reactivities and which have not entered into parallel chemical reactions, cannot be greater than the sum of the quantity supplementing the degree of conversion of any one substance in the given mixture up to unity and the product of this degree of conversion, the molecular weight of the preceding substance in the reactivity series, and the specific number of moles of the initial mixture of substances forming the given series.

In the case where there is a monotonically non-increasing reactivity, another sequence of inequalities is valid:

$$\sum_{i=1}^{l_s} n_i(t) \leqslant [1-\varkappa_j(t)] \sum_{i=1}^{j} n_i(0) + \sum_{i=j+1}^{l_s} n_i(0) \leqslant$$

$$\leqslant \sum_{i=1}^{l_s} n_i(0)[1-\varkappa_j(t)] + \varkappa_j(t) \sum_{i=j+1}^{l_s} n_i(0) \leqslant$$

$$\leqslant \left\{1-\varkappa_j(t)\left[1-\sum_{i=j+1}^{l_s} n_i(0)\mu_i \Big/ \left(\mu_{j+1}\sum_{i=1}^{l_s} n_i(0)\right)\right]\right\} \sum_{i=1}^{l_s} n_i(0) \leqslant$$

$$\leqslant \left\{1-\varkappa_j(t)\left[1-\sum_{i=1}^{l_s} m_i(0) \Big/ \left(\mu_{j+1}\sum_{i=1}^{l_s} n_i(0)\right)\right]\right\} \sum_{i=1}^{l_s} n_i(0). \quad (24)$$

On the basis of Eqns. (24), we formulate a new rule:

The overall mole fraction of substances which have not entered into parallel chemical reactions by time t and which form a series with monotonically non-increasing reactivities cannot be greater than the sum of the quantity supplementing up to unity the degree of conversion of any of the substances constituting the reactivity series and the ratio of this degree of conversion to the product of the molecular weight of the next substance, after the chosen one, and the specific number of moles of the initial mixture of substances constituting the reactivity series.

We shall make use of the rules established for the occurrence of parallel chemical reactions in order to obtain point estimates of the results of chemical reactions of this type. Here one can write

$$\frac{m_{re}^{est}(t)}{\sum_{i=1}^{l_s} m_i(0)} = 1 - \frac{1}{2}\{1 - x_j(t)[1 - \mu_{j-1}n_{sp}^{s}(0)]\}, \quad (25)$$

where $m_{re}^{est}(t)$ is the point estimate of the overall mass of the substances constituting the reactivity series and entering into chemical reactions and $n_{sp}^{s}(0)$ is the specific number of moles of these substances at $t = 0$.

It follows from Eqns. (23) and (25) that the relative error of such a point estimate must satisfy the inequality

$$\frac{|m_{re}^{est}(t) / \sum_{i=1}^{l_s} m_i(0) - \sum_{i=1}^{l_s}[m_i(0) - m_i(t)] / \sum_{i=1}^{l_s} m_i(0)|}{\sum_{i=1}^{l_s}[m_i(0) - m_i(t)] / \sum_{i=1}^{l_s} m_i(0)} \leqslant$$

$$\leqslant \frac{1 - \kappa_j(t)[1 - \mu_{j-1}n_{sp}^{s}(0)]}{2\{\kappa_j(t)[1 - \mu_{j-1}n_{sp}^{s}(0)]\}}. \quad (26)$$

A point estimate of the mole fraction of the substances which have reacted is obtained similarly using Eqns. (24).

Various mixtures of petroleum products, members of genetic and homologous series, etc., entering the environment and present in various ecological subsystems, belong to the set of substances forming series with monotonically non-increasing or monotonically non-decreasing reactivities in parallel chemical reactions.

Point estimates of the results of parallel chemical reactions in ecological system can be refined, provided that data for μ_{min}^{s} and μ_{max}^{s}—the minimum and maximum molecular weights of the substances constituting sequences with monotonically non-decreasing or monotonically non-increasing reactivities—are available. Since

$$\sum_{i=1}^{j-1} m_i(0) \leqslant \mu_{j-1} \sum_{i=1}^{j-1} n_i(0),$$

it follows that, on the basis of the imbalance of the number of moles in the mixture, we obtain

$$\sum_{i=1}^{j-1} m_i(0)/\mu_{j-1} + \left[\sum_{i=1}^{l_s} m_i(0) - \sum_{i=1}^{j-1} m_i(0)\right] \Big/ \mu_{max}^{s} < n_{sp}^{s}(0) \sum_{i=1}^{l_s} m_i(0).$$

Consequently,

$$\sum_{i=1}^{j-1} m_i(0) \Big/ \sum_{i=1}^{l_s} m_i(0) \leqslant \frac{n_{sp}^{s}(0) - 1/\mu_{max}^{s}}{1/\mu_{j-1} - 1/\mu_{max}^{s}}.$$

On the basis of the latter expression, we find the relation for the case of a monotonically non-decreasing reactivity of a mixture with known values of μ^s_{max} and μ^s_{min}:

$$\sum_{i=1}^{l_s}[m_i(0)-m_i(t)] \Big/ \sum_{i=1}^{l_s} m_i(0) \geqslant \varkappa_j(t)\left[1-\frac{n^s_{sp}(0)-1/\mu^s_{max}}{1/\mu_{j-1}-1/\mu^s_{max}}\right].$$

This makes it possible to obtain the point estimates

$$m^{est}_{re}(t)/\sum_{i=1}^{l_s} m_i(0) = 1-\frac{1}{2}\left\{1-\kappa_j(t)\left[1-\frac{n^s_{sp}(0)-1/\mu^s_{max}}{1/\mu_{j-1}-1/\mu^s_{max}}\right]\right\},$$

and an *a priori* estimate of the modulus of the relative error:

$$\frac{|m^{est}_{re}(t)-\sum_{i=1}^{l_s}[m_i(0)-m_i(t)]|}{\sum_{i=1}^{l_s}[m_i(0)-m_i(t)]} \leqslant \left\{1-\kappa_j(t)\left[1-\frac{n^s_{sp}(0)-1/\mu^s_{max}}{1/\mu_{j-1}-1/\mu^s_{max}}\right]\right\} \Big/$$

$$\Big/ 2\kappa_j(t)\left[1-\frac{n^s_{sp}(0)-1/\mu^s_{max}}{1/\mu_{j-1}-1/\mu^s_{max}}\right].$$

For the case of the monotonically non-increasing reactivity of the mixture, we obtain after similar steps

$$\sum_{i=1}^{l_s}[n_i(0)-n_i(t)]\Big/\sum_{i=1}^{l_s} n_i(0) \geqslant \kappa_j(t)\left(1-\frac{1/n^s_{sp}(0)-\mu_{min}}{\mu_{j+1}-\mu^s_{min}}\right).$$

Consequently the number of moles of the reactive substances constituting a mixture with monotonically non-increasing reactivity can be estimated with the aid of the expression

$$n^{est}_{re}(t)\Big/\sum_{i=1}^{l_s} n_i(0) = 1-\frac{1}{2}\left\{1-\kappa_j(t)\left[1-\frac{1/n^s_{sp}(0)-\mu^s_{min}}{\mu_{j+1}-\mu_{min}}\right]\right\},$$

subject to the guaranteed relative error

$$\frac{|n^{est}_{re}(t)-\sum_{i=1}^{l_s}[n_i(0)-n_i(t)]|}{\sum_{i=1}^{l_s} n_i(0)} \leqslant \left\{1-\kappa_j(t)\left(1-\frac{1/n^s_{sp}(0)-\mu^s_{min}}{\mu_{j+1}-\mu^s_{min}}\right)\right] \Big/$$

$$\Big/ 2\kappa_j(t)\left(1-\frac{1/n^s_{sp}(0)-\mu^s_{min}}{\mu_{j+1}-\mu^s_{min}}\right).$$

VI. Specific features of the estimation of the changes in disperse ecological subsystems when nature-protecting measures are taken

The disperse particles entering the environment, formed as a result of man's industrial activity, exert an appreciable negative influence on consumers and producers. In order to predict the amount of disperse contaminants entering the hydrosphere and the atmosphere together with waste water and gaseous waste, it is necessary to establish the efficiency of the purification of such waste water and gaseous waste as a result of nature-protecting measures. A characteristic of the process involving the removal of disperse particles from an ecological subsystem is the degree of separation (purification) $\varkappa_s$ — a quantity indicating the weight fraction of the disperse phase trapped by means of technical nature-protecting procedures. Another parameter — the relative loss ε — is equal to the weight fraction of the residual disperse phase particles in the liquid or gas after purification. There exists a simple relation between the degree of separation (purification) and the relative loss:

$$\varkappa_s = 1-\varepsilon.$$

If after the completion of the application of nature-protecting measures, no compression or rarefaction of the purified liquid and gaseous media occurred, then the relative loss is equal to the ratio of the output and input weight concentrations of the disperse phase.

Taking into account the specific features of the disperse systems and using a probability (statistical?) treatment of the separation process, we formulate an expression for the degree of separation $\varkappa_s$ in the form

$$\varkappa_s = \int_o^\infty P_{11}(r,t|\mathrm{B})dF_1(r), \tag{27}$$

where $F_1(r)$ is the integral size distribution function of the particles of the disperse phase at the instant when the disperse system is introduced into the separation apparatus and $P_{11}(r,\ t|\mathrm{B})$ is the conventional probability of the separation (of entry into the collector designed for the disperse phase) by time t of a molecule present in particle having a radius r on entry into the apparatus subject to the condition that all the particles and molecules of the disperse medium enter the collectors for the phases undergoing separation.

In the separation of heterogeneous systems in continuous operation apparatus, the particles may become dispersed owing to the presence of velocity gradients in the streams and their impact against the inner surfaces of the apparatus and against one another. The fine particle fragments formed (other characteristics remaining unchanged: density and charge) are in most cases more difficult to separate than the whole particles. If the comminution takes place only at the instant when the particles are introduced into the apparatus, then the efficiency of the separation will be smaller than for gradual dispersion to the same extent. Therefore

$$\varkappa_s > \int_o^\infty P_{11}(r,t|\mathrm{B}\cap\mathrm{Con})dF^{fr}_1(r), \tag{28}$$

where $F^{fr}_1(r)$ is the integral size distribution function of the particles after grinding and $P_{11}(r,\ t|\mathrm{B}\cap\mathrm{Con})$ is the conventional probability of the separation of particles which have retained their initial dimensions subject to the condition that they enter one of the separation zones (one of the collectors).

For further exposition, we introduce the concept of the quasi-size of the separation of order α. We shall define the quantity r_{s_α} as the radius of a particle such that the relation

$$P_{11}(r,\ t|\mathrm{B}\cap\mathrm{Con}) \geqslant 1-\alpha,$$

is valid for $r \geqslant r_{s_\alpha}$. It follows from this definition that in the general case r_{s_α} depends on the current time t. The application of the concept of the quasi-size of the separation makes it possible to take into account the experimentally observed effects involving the loss of individual large particles owing to random influences, eddies, and streams of dispersion media, while finer particles are fully separated.

Using r_{s_α}, we can formulate the following inequality:

$$\int_o^\infty P_{11}(r,t|\mathrm{B}\cap\mathrm{Con})dF^{fr}_1(r) \geqslant (1-\alpha)\int_{r_{s_\alpha}}^\infty dF^{fr}_1(r). \tag{29}$$

Then

$$\varkappa_s \geqslant (1-\alpha)[1-F^{fr}_1(r_{s_\alpha})]. \tag{30}$$

In its turn, we have

$$\int_o^{r_{s_\alpha}} dF_1^{\text{fr}}(r) \leqslant r_{s_\alpha}^n \int_o^{r_{s_\alpha}} r^{-n} dF^{\text{fr}}(r) \leqslant r_{s_\alpha}^n \int_o^{\infty} r^{-n} dF_1^{\text{fr}}(r), \tag{31}$$

whereupon

$$\overline{r_{\text{fr}}^{-n}} = \int_o^{\infty} r^n dF_1^{\text{fr}}(r) \text{ and } \int_o^{r_{s_\alpha}} dF_1^{\text{fr}}(r) = F_1^{\text{fr}}(r_{s_\alpha}). \tag{32}$$

Ultimately, we have

$$F_1^{\text{fr}}(r_{s_\alpha}) \leqslant \overline{r_{\text{fr}}^{-n}} r_{s_\alpha}^n. \tag{33}$$

Consequently,

$$\varkappa_s \geqslant (1-\alpha)(1-\overline{r_{\text{fr}}^{-n}} r_{s_\alpha}^n). \tag{34}$$

The universal relation for the degree of separation thus demonstrated is valid for any form of the size distribution function of particles. This inequality is applicable to both continuous and periodic heterogeneous system separation processes. For its practical employment, it is essential to determine the quantity $\overline{r_{\text{fr}}^{-n}}$ for any positive value of n. For this purpose, we express $\overline{r_{\text{fr}}^{-3}}$ in terms of the particle concentration ν_{fr} after fragmentation. In the case of particles of arbitrary shape, the particle concentration is

$$\nu = \frac{C_o}{\beta_s \rho_1} \int_o^{\infty} \frac{dF_1(r)}{r^3} = \frac{C_o \overline{r^{-3}}}{\beta_s \rho_1}, \tag{35}$$

where β_f is a coefficient equal to the ratio of the volume of the particle to that of the cube having its characteristic dimension (for spherical particles, $\beta_f = 4/3\pi$) and C_0 is the concentration of the particles of the disperse phase.

If the particles of the disperse phase are insoluble in the dispersion medium, then the particle concentration after fragmentation can be found from the formula

$$\nu_{\text{fr}} = \beta_p C_o \overline{r^{-3}}/(\beta_f \rho_1), \tag{36}$$

where β_p is the fragmentation coefficient indicating by what factor the number of particles has increased on dispersion.

It follows from Eqn. (36) that $\nu_{\text{fr}} = \beta_p \nu$. On the other hand,

$$\nu_{\text{fr}} = C_o \overline{r_{\text{fr}}^{-3}}/(\beta_f \rho_1).$$

Hence

$$r_{\text{fr}}^{-3} = \beta_p \beta_f \rho_1 \nu / C_o. \tag{37}$$

We shall refer to the ratio ν/C_0 as the specific number of particles and shall denote it by n_{sp}. We may note that the product $\beta_f \rho_1 | r_{s_\alpha}^3$ is none other than $m_p(r_{s_\alpha})$—the mass of a particle whose radius is equal to the quasi-size of the separation. Then on substituting Eqn. (37) in the inequality (34), we obtain

$$\varkappa_s \geqslant (1-\alpha)[1-\beta_p m_p(r_{s_\alpha})\nu/C_o]. \tag{38}$$

We express $\overline{r^{-1}}$ with the aid of the specific surface. For particles of arbitrary shape,

$$S_{\text{sp}} \geqslant 3\rho_1^{-1} \int_o^{\infty} r^{-1} dF_1(r). \tag{39}$$

This inequality is converted into an equality in the case of spherical particles with an ideally smooth surface. Therefore

$$\overline{r^{-1}} \leqslant S_{\text{sp}} \rho_1 / 3. \tag{40}$$

For $\overline{r_{\text{fr}}^{-1}}$, one can also write

$$\overline{r_{\text{fr}}^{-1}} < S_{\text{sp}}^{\text{fr}} \rho_1/3 \text{ or } \overline{r_{fr}^{-1}} < \beta_s S_{\text{sp}} \rho_1/3,$$

where $S_{\text{sp}}^{\text{fr}}$ is the specific surface after dispersion and β_s is a coefficient showing by what factor the specific surface has increased owing to the fragmentation of the particles. With the aid of the latter inequality, we obtain from Eqn. (34)

$$\varkappa_s \geqslant (1-\alpha)[1-\beta_s S_{\text{sp}} \rho_1 r_{s_\alpha}/3]. \tag{41}$$

When the separation process is effected as a result of the work performed by external forces A, the particles may undergo deformation and fragmentation and an amount of heat Q may be evolved. We denote by $m_1^+(t)$ the mass of the disperse phase entering the apparatus at time t; ΔH_{def} is the change in the internal energy of the heterogeneous system on deformation of the particles. For systems which do not contain highly disperse fractions, one can write for the process under stationary conditions

$$A = \Delta U_{\text{def}} + Q + m_1^+(t)[S_{\text{sp}}^{\text{fr}} - S_{\text{sp}}]\sigma. \tag{42}$$

Hence

$$S_{\text{sp}}^{\text{fr}} = (A - \Delta U_{\text{def}} - Q)/[\sigma m_1^+(t)] + S_{\text{sp}}. \tag{43}$$

Subsequently

$$\beta_s = (A - \Delta U_{\text{def}} - Q)/[\sigma S_{\text{sp}} m_1^+(t)] + 1. \tag{44}$$

Thus the coefficient β_s, taking into account the phenomenon of dispersion during separation, can be found from simple energy relations. It is seen from Eqn. (44) that, other conditions being equal, the coefficient β_s diminishes with increase in the specific surface of the heterogeneous system entering the apparatus, i.e. the intensity of the comminution diminishes with increase in dispersity.

In the absence of dispersion, the coefficient $\beta_p = \beta_s = 1$ and formulae (38) and (41) assume the following form:

$$\varkappa_s \geqslant (1-\alpha)[1-n_{\text{sp}} m_p(r_{s_\alpha})], \tag{45}$$

$$\varkappa_s \geqslant (1-\alpha)(1-S_{\text{sp}} r_{s_\alpha} \rho_1/3). \tag{46}$$

The quantities r_{s_α} can be determined not only theoretically but also experimentally. A suspension (emulsion or aerosol) resistant to aggregation and having a known grain size distribution must be used for the experiment.

When random influences are negligible, for example, when coarsely disperse particles are deposited in the gravitational field, one can assume that all the particles larger than a certain radius r_{s_o}, called the size of the separation, are fully separated. When this condition holds, we find from the inequalities (45) and (46), having put $\alpha = 0$ in the latter,

$$\varkappa_s \geqslant 1 - n_{\text{sp}} m_p(r_{s_o}), \tag{47}$$

$$\varkappa_s \geqslant 1 - S_{\text{sp}} r_{s_o} \rho_1/3. \tag{48}$$

In the analysis of separation processes, the concept of the relative loss (breakthrough) ε is frequently employed. By definition, $\varepsilon = 1 - \varkappa_s$. From the inequalities (47) and (48), we obtain

$$\varepsilon \leqslant n_{\text{sp}} m_p(r_{s_o}), \tag{49}$$

$$\varepsilon \leqslant S_{\text{sp}} \rho_1 r_{s_o}/3. \tag{50}$$

The results of the theoretical study, expressed by the inequalities (45) and (46), can be usefully formulated in the form of the following theorems:

Theorem 5. *The relative loss (the ratio of the output and input weight concentrations) of the disperse phase cannot be greater than the sum of the specified probability and the product of the quantity supplementing to unity the specified probability, the specific number of particles, and the mass of the particle which is not separated with the specified probability.*

Theorem 6. *The relative loss (the ratio of the output and input weight concentrations) of the disperse phase cannot be greater than the sum of the specified probability and one third of the product of the specific surface, the quantity supplementing to unity the specified probability, the density of the disperse phase, and the radius of the particle which is not separated with the specified probability.*

In order to estimate the maximum possible degree of separation, we introduce the concept of the quasi-size of the loss r_{e_α} of order α. The quantity r_{e_α} will be defined as the radius of the particles such that the probability $P_{11}(r, t|\mathrm{B}\cap\mathrm{Con}) \leqslant \alpha$ for $r < r_{e_\alpha}$.

Taking into account the possibility of the fragmentation of particles, we obtain with the aid of r_{e_α}

$$\varkappa_s \leqslant \int_0^\infty P_{11}(r, t \mid \mathrm{B} \cap \mathrm{Con})\, dF_1(r) \leqslant$$
$$\leqslant \alpha \int_0^{r_{e\alpha}} dF_1(r) + \int_{r_{e\alpha}}^\infty P_{11}(r, t \mid \mathrm{B} \cap \mathrm{Con})\, dF_1(r). \qquad (51)$$

Since $P_{11}(r, t|\mathrm{B}\cap\mathrm{Con}) \leqslant 1$, it follows that

$$\int_{r_{e\alpha}}^\infty P_{11}(r, t \mid \mathrm{B} \cap \mathrm{Con})\, dF_1(r) \leqslant \int_{r_{e\alpha}}^\infty dF_1(r). \qquad (52)$$

We therefore have

$$\int_0^\infty P_{11}(r, t|B\cap\mathrm{Con})\, dF_1(r) \leqslant 1 - F_1(r_{e_\alpha}) + \alpha F_1(r_{e_\alpha}). \qquad (53)$$

Since

$$F_1(r_{e_\alpha}) \geqslant 1 - \int_{r_{e\alpha}}^\infty (r/r_{e_\alpha})^n\, dF_1(r) \geqslant 1 - r_{e_\alpha}^{-n} \int_0^\infty r^n\, dF_1(r), \qquad (54)$$

it follows that

$$F_1(r_{e_\alpha}) \geqslant 1 - \overline{r^n}/r_{e_\alpha}^n. \qquad (55)$$

Consequently

$$\varkappa_s \leqslant \alpha + (1-\alpha)\overline{r^n}/r_{e_\alpha}^n. \qquad (56)$$

On the basis of the results obtained, we formulate the following theorem:

Theorem 7. *The degree of separation of a disperse system cannot be greater than the sum of the order of the quasi-size of the loss and the product of the quantity supplementing to unity the order of the quasi-size and the ratio of the initial nth order moment of the random particle radius to the quasi-size of the loss raised to the nth power.*

With the aid of the relations demonstrated, one can also obtain point estimates of the degree of separation of disperse systems with an improved accuracy. Bearing in mind that, when $\alpha = 0$, the relative loss $\varepsilon \leqslant \overline{r^{-n}} r_{s_0}^n$, we can write expressions for the point estimate of the degree of separation:

$$\varkappa_{\mathrm{est.}} = 1 - \overline{r^{-n}} r_{s_0}^n/2, \qquad (57)$$

and for the *a priori* estimate of the modulus of its relative error:

$$\frac{|\varkappa_s - \varkappa_{\mathrm{est.}}|}{\varkappa_s} \leqslant \frac{r_{s_0}^n \overline{r^{-n}}}{2\varkappa_s} \leqslant \frac{r_{s_0}^n \overline{r^{-n}}}{2(1 - r_{s_0}^n \overline{r^{-n}})}, \qquad (58)$$

where $n = 1$, we obtained from the last two relations

$$\varkappa_{\mathrm{est.}} = 1 - S_{\mathrm{sp}} \rho_1 r_{s_0}/6 \text{ and}$$

$$\frac{|\varkappa_s - \varkappa_{\mathrm{est.}}|}{\varkappa_s} \leqslant \frac{S_{\mathrm{sp}} \rho_1 r_{30}}{6 - 2 S_{\mathrm{sp}} \rho_1 r_{s_0}}, \qquad (59)$$

and, when $n = 3$, they assume the following form:

$$\varkappa_{\mathrm{est.}} = 1 - n_{\mathrm{sp}} m_{\mathrm{p}}(r_{s_0})/2 \text{ and}$$

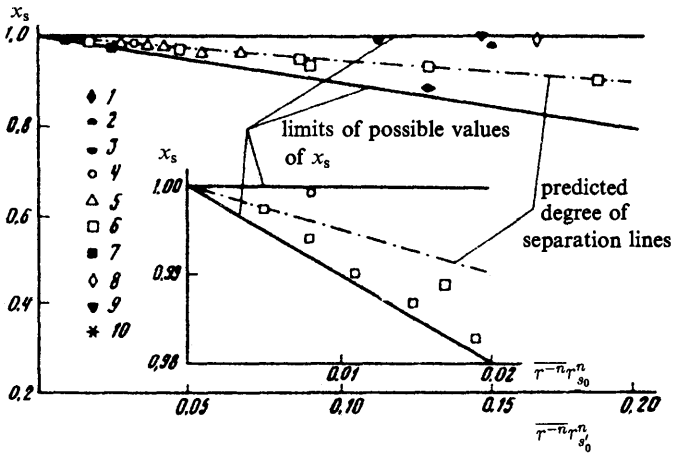
$$\frac{|\varkappa_s - \varkappa_{\mathrm{est.}}|}{\varkappa_s} \leqslant \frac{n_{\mathrm{sp}} m_{\mathrm{p}}(r_{s_0})}{2[1 - n_{\mathrm{sp}} m_{\mathrm{p}}(r_{s_0})]}. \qquad (60)$$

As was in fact to be expected, all the experimental points obtained by different workers[35–38] lie close to the line of the predicted degrees of separation and none fall into the cross-hatched regions of impossible values (Figs. 3 and 4). The closer were the points in Fig. 4 plotted from the experimental values to the abscissa axis, the more accurate was the *a priori* point estimate of the degee of separation of the disperse systems.[38]

VII. The rule for the compositions of simple and complex two-component and multi-component ecological systems and subsystems

Comparison of the rules established above for the compositions of homogeneous and heterogeneous ecological subsystems makes it possible to discover their general features and to proceed to the solution of the problem of the discovery and formulation of the main rule for the compositions of ecological systems and subsystems, generalising the results obtained in the theoretical study.

All the inequalities for the contents of substances, demonstrated for both homogeneous and heterogeneous systems, can be reduced to the following form provided that qualitative analytical data are available:



$$\mathfrak{D}_i(t) \leqslant (\overline{\mathrm{S}}(t) - \mathrm{S_b})/(\mathrm{S}_i - \mathrm{S_b}), \qquad (61)$$

where $\mathfrak{D}_i(t)$ is the fraction (weight, mole, or volume fraction) of the component, phase, or part (fraction) of the ecological subsystem, $\overline{\mathrm{S}}(t)$ is an average physicochemical characteristic of the system, $\mathrm{S_b}$ is the boundary value (minimum or maximum) of the isotypical measure of the property of the given substance of the system, and S_i is a measure of the property of the ith component.

The inequality (61) is equivalent to the following formulation of a theorem:

Theorem 8. *The fraction of any component [phase, part (fraction)] of ecological systems and subsystems cannot be greater than the ratio of the deviations of the average characteristic of the entire system (subsystem) as a whole and the isotypical measure of the property of the component, phase, or part (fraction) from their maximum or minimum value.*

Varieties of the expression for the fraction are unambiguously related to the method of averaging the physicochemical characteristic of the ecological system (subsystem). For example, if this is the specific number of moles, then $\mathfrak{D}_i(t)$ will be the weight fraction and if it is the average density $\bar{S}(t)$ then $\mathfrak{D}_i(t)$ will be the volume fraction.

Point	System being separated (purified)	Separation apparatus
1	Aqueous oil emulsion	Ultracentrifuge
2	Tobacco dust	Sleeve filter, No. 2 cloth fabric
3	Tobacco dust	Sleeve filter, No. 5114 nitron fabric
4	Water drops	Cyclone
5	Kaolin suspension	Centrifugal "Plava-E" separator
6	Suspension of poly (vinyl chloride)	Tubular centrifuge
7	Kaolin suspension	Tubular centrifuge
8	Quartz glass suspension	Cup-type centrifuge
9	Suspension of Ammophos sludge	Settling tank
10	Coal powder	Sifting screen

Figure 3. Point estimates of the degree of separation (purification) of disperse systems.

On combining the entire set of relations established, we obtain the following equation:

$$\mathfrak{D}_i(t) = K_i(t)\bar{S}(t)/S_i, \qquad (62)$$

which reflects the principal rule for the compositions of multicomponent ecological subsystems and eco-systems:

The relative amounts (contents) of substances, phases, fractions, parts, and subsystems in any ecological systems (subsystems) can be numerically estimated at any instant by comparison with the ratios of the average (overall) characteristic of the system (subsystem) to the isotypical measures of the properties of the substances, phases, fractions, parts, and subsystems multiplied by coefficients which are always smaller or equal to unity and do not increase by discrete increments together with the uncertainty of the estimate with increase in the level of the reliable initial information.

For the practical employment of the principal rule for the compositions of ecological subsystems and systems, it proved necessary to calculate the coefficients in Eqn. (62). An algorithm was therefore developed for the calculation of these coefficients for different levels of the initial data and a block scheme was set up. For cases of incomplete information, it proved possible to derive formulae permitting the calculation of the coefficients of the principal rule. The possibility of determining the coefficients $K_i(t)$ from thermodynamic and kinetic parameters for higher levels of initial data was demonstrated.

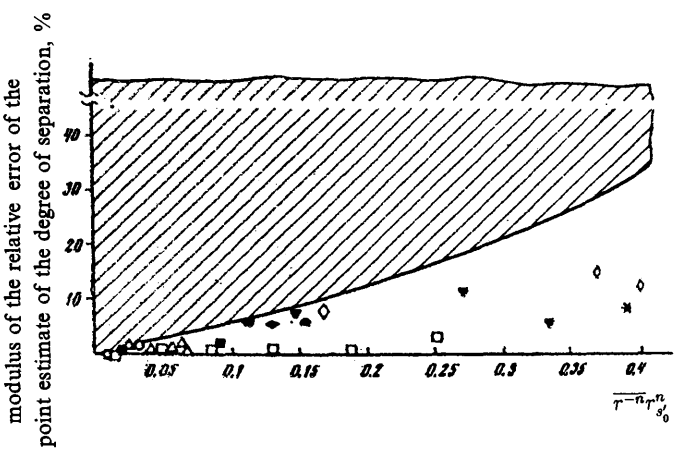


Figure 4. The region of the possible values of the modulus of the relative error of the point estimates of the degree of separation of disperse systems with an improved accuracy. For the designations of the points, see Fig. 3. The cross-hatched region represents the impossible values of the modulus of the relative error (of the points estimates of the degree of separation with an improved degree of accuracy).

On the basis of the principal rule established for the compositions, it was found possible to represent graphically the changes in the compositions of multicomponent ecological systems and subsystems in terms of their variables $\bar{S}(t)$, S_i, and $\mathfrak{D}_i(t)$.

With the aid of the main rule established for the compositions, it has been shown that *the overall (average) characteristic of the entire system (specific heat, specific number of moles, density, specific volume, specific heat of combustion, etc.) is equal* to the product of the isotypical characteristics of the components, their weight fractions, and the reciprocals of the coefficients of the principal rule governing compositions.

The principal rule for the compositions of ecological systems and subsystems can be used not only for the determination of the compositions of the eco-system but also for the solution of certain problems of the protection of the environment, including the organisation of the monitoring and measures ensuring that the limiting permissible concentrations of toxic substances are not exceeded.

Using the author's own experimental data for the specific heats of solution of two- and three-component powders and the specific volume of a specific ecological subsystem (active silt) as well as the literature data,[39,40] the coefficients of the principal rule for the

compositions of eco-systems and ecological subsystems have been found for zero uncertainty in the estimates of the contents of the components. The results of the calculations are presented in Table 3, from which it is seen that, in conformity with the principal rule for the compositions established, all the coefficients are not more than unity.

Table 3. The coefficients of the principal rule for the compositions of ecological systems and subsystems for zero uncertainty in the estimates of the contents of the components.

Ecological subsystem	Components	Average characteristic	Content, weight fraction	$K_i(t)$
Three-component powder	KNO_3,	Specific heat of solution	50.0	0.64
	$CuSO_4 \cdot 5H_2O$,		33.3	0.07
	KCl		16.7	0.17
Two-component powder	KNO_3,	Ditto	33.3	0.94
	$CuSO_4 \cdot 5H_2O$		66.7	0.31
Aqueous solution of methanol	H_2O,	Specific volume of solution	45.8	0.40
	CH_3OH		54.2	0.60
Aqueous HNO_3 solution	H_2O,	Specific heat of solution	80.0	0.95
	HNO_3		20.0	0.05
Gas mixture	$H_2+O_2+H_2O$	Specific number of moles	3.0	0.29
			47.0	0.28
			50.0	0.55
Man	H_2O	Specific heat	75	0.87
Active silt	H_2O	Specific volume	99.12	0.996
	H_2O	Ditto	98.35	0.988

VIII. Measures ensuring that the limiting permissible amounts of liquid and gaseous waste polluting the environment are not exceeded for different levels of initial information

The increasingly acute ecological crisis makes it essential that the following requirement is rigidly adhered to: that the limiting permissible norms as regards gaseous and liquid waste products[2,12] contaminating the hydrosphere and the atmosphere must not be exceeded. The existence of different levels of initial information makes it much more difficult to satisfy this requirement.

According to the definition of the limiting permissible amounts of liquid and gaseous waste, the condition that the limiting permissible concentration of the ith toxic substance in the eco-system is not exceeded is specified by the relation

$$C_i^-(t) \leqslant (\mathrm{LPLW}_i \text{ or } \mathrm{LPGW}_i)/Q(t), \tag{63}$$

where $Q(t)$ is the productivity of the apparatus for the detoxification (purification) of liquid or gaseous waste, $C_i^-(t)$ the concentration of the toxic ith component at the outlet from the detoxification apparatus to the environment, LPLW_i and LPGW_i are the limiting permissible amounts of liquid and gaseous waste, and t is the current time.

For further exposition, we shall make use of the concept of the protection factor (PF_i) for the environment introduced by the present author.[12] By definition, this quantity shows by what factor the weight fraction of the ith toxic component has diminished during the detoxification process as a result of separation and chemical reactions.

The concentration of the ith toxic component at the inlet to the detoxification apparatus can be represented in the following form with the aid of the principal rule for compositions:

$$C_i^+(t) = K_i(t)\bar{\rho}_+(t)\bar{S}_{sp}(t)/S_i^{sp}, \tag{64}$$

where $\bar{\rho}_+(t)$ is the average density at a given instant t of the liquid or gaseous mixture subjected to detoxification.

Using the concept of the protection factor, we shall represent the condition that the limiting permissible concentration is not exceeded in the following way:

$$\frac{K_i(t)\bar{\rho}_-(t+t_r)S_{sp}(t)}{S_i^{sp}PF_i} \leqslant \frac{(\mathrm{LPLW}_i \text{ or } \mathrm{LPGW}_i)}{Q(t+t_r)}, \tag{65}$$

where $\bar{\rho}_-(t + t_r)$ is the average density of the mixture (for example, water or air being purified) entering the environment at time $t + t_r$ after detoxification and t_r is the residence time of the mixture in the detoxification apparatus.

We shall call the ratio $\mathrm{LPLW}_i/[Q(t + t_r)\bar{\rho}_-(t + t_r)]$ the dimensionless limiting permissible amount of liquid waste and $\mathrm{LPGW}_i/[Q(t + t_r)\bar{\rho}_-(t + t_r)]$ the dimensionless limiting permissible amount of gaseous waste. We shall designate them by DLPLW_i and DLPGW_i. The physical significance of the quantities introduced is fairly simple: they indicate the maximum permissible weight fraction of the toxic substance in the liquids and gases entering the environment after detoxification (purification).

Using the concept of DLPLW_i and DLPGW_i, one can write on the basis of Eqn. (65)

$$PF_i \geqslant \frac{K_i(t)\bar{S}_{sp}(t)}{(\mathrm{DLPLW}_i \text{ or } \mathrm{DLPGW}_i)S_i^{sp}}. \tag{66}$$

The last relation proves the following theorem.

Theorem 9. *The protection factor for the environment not less than the product of the reciprocal of the dimensionless limiting permissible amount of liquid (gaseous) waste, the coefficient of the principal rule for compositions, and the ratio of the average specific characteristic of the homogeneous or heterogeneous mixture being detoxified to the isotypical measure of the properties of the toxic component guarantees that the limiting permissible concentration (LPC) is not exceeded.*

Thus, on the basis of the theorem formulated, it is possible to determine the protection factors for the environment which guarantee *a priori* that the limiting permissible concentration is not exceeded for different levels of initial information.

In particular, in the presence of a minimal amount of data, when only the values of $\bar{S}_{sp}(t)$ and S_i^{sp} are known, we have the following expression according to the sequence of inequalities for the detoxification of waste waters and bearing in mind that $K_i(t)$ is always less than or equal to unity:

$$C_i^-(t) \leqslant \frac{K_i(t)\bar{\rho}_-(t+t_r)\bar{S}_{sp}(t)}{S_i^{sp}PF_i} \leqslant \frac{\bar{\rho}_-(t+t_r)\bar{S}_{sp}(t)}{S_i^{sp}PF_i} \leqslant \frac{\mathrm{LPLW}_i}{Q(t+t_r)}. \tag{67}$$

According to the analogous sequence of inequalities for the detoxification of gaseous waste, we obtain a relation for the estimation of the protection factor (in the presence of a minimal amount of information) guaranteeing that the limiting permissible concentration is not exceeded:

$$PF_i \geqslant \frac{\bar{S}_{sp}(t)\bar{\rho}_-(t+t_r)Q(t+t_r)}{(\mathrm{LPLW}_i \text{ or } \mathrm{LPGW}_i)S_i^{sp}}. \tag{68}$$

If S^{sp}_{max} and S^{sp}_{min}, the maximum and minimum specific partial measures of the properties (characteristics) of the components, are known, then it follows from formulae (61) and (62) that the coefficient of the principal rule for compositions $K_i(t)$ can be estimated as follows:

$$K_i(t) \leqslant \begin{cases} \dfrac{\bar{S}_{sp}(t) - S^{sp}_{min}S^{sp}_i}{S^{sp}{}_i - S^{sp}_{min}\bar{S}_{sp}}(t) \\ \text{when } S^{sp}_i \geqslant \bar{S}_{sp}(t), \\ \dfrac{S^{sp}_{max}\bar{S}_{sp}(t)S^{sp}{}_i}{S^{sp}_{max} - S^{sp}{}_i\bar{S}_{sp}(t)} \\ \text{when } S^{sp}{}_i < \bar{S}_{sp}(t). \end{cases} \tag{69}$$

For this level of information, we obtain from formula (69) the relation ensuring unconditionally that the LPC is not exceeded:

$$PF_i \geqslant \begin{cases} \dfrac{\bar{\rho}_-(t+t_r)Q(t+t_r)[\bar{S}_{sp}(t) - S^{sp}_{min}]}{(LPLW_i \text{ or } LPGW_i)(S^{sp}_i - S^{sp}_{min})} & \text{for } S^{sp}_i \geqslant \bar{S}_{sp}(t) \\ \dfrac{\bar{\rho}_-(t+t_r)Q(t+t_r)[S^{sp}_{max} - \bar{S}_{sp}(t)]}{(LPLW_i \text{ or } LPGW_i)(S^{sp}_{max} - S^{sp}_i)} & \text{for } S^{sp}_i > \bar{S}_{sp}(t). \end{cases} \tag{70}$$

Formulae (69) and (70) are special cases of the more general formula (66).

The protection factor can be expressed as a function of temperature, the concentration of added reagents, the residence time, the length of the apparatus, and other technological and design parameters of the detoxification process and apparatus. Therefore, expressing one of such quantities as a function of the reciprocal of the protection factor, it is possible to determine from the inequality (66) the values of the technological or design parameter guaranteeing the satisfaction of the ecological requirement that the limiting permissible amounts of liquid or gaseous waste are not exceeded. For example, if the detoxification of the ith toxic component is described by a first-order chemical reaction equation, then the following expression holds for the protection factor:

$$PF_i = \phi(T) = \exp[At_r \exp(-E_a/RT)], \tag{71}$$

where A is the pre-exponential factor, E_a the activation energy, R the gas constant, T the temperature and $\varphi(T)$ a function of temperature.

Having expressed the temperature T as a function of the reciprocal of the protection factor $\varphi^{rec}(PF_i)$ and then using the inequality (66), we obtain a relation for the determination of the absolute temperatures which must be maintained in the chemical waste water detoxification reaction in order to guarantee that the limiting permissible amount of liquid waste is not exceeded:

$$T \geqslant -E_a/R \ln\left[\frac{1}{At_r}\ln\frac{K_i(t)\bar{S}_{sp}(t)}{DLPLW_iS^{sp}_i}\right]. \tag{72}$$

In another special case, for the detoxification of disperse contaminations with an unknown distribution of grain sizes (by the separation of the disperse particles), using the inequality already established

$$\varepsilon \leqslant \alpha + (1-\alpha)\overline{r^{-n}_{fr}}r^n_{s_\alpha},$$

and theorem 9, we can formulate a sequence of inequalities guaranteeing that the limiting permissible concentration of the disperse phase is not exceeded:

$$\frac{1}{PF_{i_d}} \leqslant \alpha + (1-\alpha)\overline{r^{-n}_{fr}}r^n_{s_\alpha} \leqslant \frac{LPGW_{i_d} \text{ or } LPLW_{i_d}}{Q(t+t_r)C^+_{i_d}(t)} \leqslant$$

$$\leqslant [(DLPGW_{i_d} \text{ or } DLPLW_{i_d})S_{i_d}]/[K_{i_d}(t)\bar{S}_{sp}(t)]. \tag{73}$$

Here the subscript d indicates that the corresponding characteristics refer to the disperse phase. Consequently

$$r_{s_\alpha} \leqslant \sqrt[n]{\left[\frac{[DLPGW_{i_d} \text{ (or } DLPLW_{i_d})]S^{sp}{}_{i_d}}{K_{i_d}(t)\bar{S}_{i_d}(t)} - \alpha\right] \Big/ [(1-\alpha)\overline{r^{-n}_{fr}}]}. \tag{74}$$

Eqn. (74) makes it possible to find the quasi-sizes of the separation which guarantee that the limiting permissible concentration of the disperse phase is not exceeded. After this, it only remains to select the apparatus for the purification of waste water or a dust trapping device with r_{s_α} satisfying this expression.

For known values of the input concentrations (weight and particle concentrations) of the disperse phase and in the absence of effects associated with the fragmentation of particles, the inequality (74) (for $n = 3$) assumes the following form:

$$r_{s_\alpha} \leqslant \sqrt[3]{\left[\frac{LPGW_{i_d} \text{ (or } LPLW_{i_d})}{Q(t+t_d)C^+_{i_d}(t)} - \alpha\right] \Big/ [(1-\alpha)\beta_f\rho_1 n_{sp}]}. \tag{75}$$

Thus the successive employment of the principle of the coupled material-characteristic imbalance has made it possible to obtain a series of inequalities for the estimation of the contents of substances in ecological systems and subsystems for different levels of initial information and to formulate the principal rule for the compositions of such systems. The results obtained can be applied both for high-speed large-scale monitoring and for the design and technical measures to protect the environment, whose aim is to reduce the amounts of different toxic substances entering the hydrosphere, atmosphere, and lithosphere.

Membranotropic autoregulatory factors in methane oxidising bacteria

E S Babusenko, G I El'-Registan, N B Gradova, A N Kozlova, G A Osipov
Mendeleev Moscow Institute of Chemical Engineering

ABSTRACT. It is possible that the methane oxidising bacteria *M. capsulatus* synthesise in the course of their development and secrete into the culture liquid extracellular metabolites—membranotropic autoregulatory factors d_1 and d_2 the synthesis of which had been observed earlier in other groups of microorganisms. It is shown that the physiological effect of the factor d_2 is due to the influence of the fraction comprising free aliphatic acids and containing mainly palmitic palmitoleic acids. One of the manifestations of the effect of the specific autoregulatory factor d_1 as its concentration increases in the culture medium is the transition of the vegatative cells to a hypometabolic state. The active principle of the factor d_1 is the lactone of 3-deoxypentonic acid. A practical use for the chemical analogues of the autoregulatory factors d_1 and d_2 is suggested.

The increased ecological requirements as regards the safety of the technologies used in the national economy necessitates the development of new or an improvement of the efficiency of the already available technological solutions subject to the obligatory condition of their ecological cleanliness. One of the most vigorously developing branches of world economic practice is biotechnology, which has acquired the status of one of the priority fields in developed countries. The recognition of the leading role of biotechnology is not fortuitous. The intensification of agriculture and industries satisfying man's immediate needs is associated with the employment of biotechnological processes. Furthermore, the recovery of the environment subjected to anthropogenic influences should not only involve specific solutions based on biotechnological processes but also solutions based on the fundamental knowledge of the reactions and turnover of substances effected with participation of natural biological factors. A special role is attributed in this connection to microorganisms whose activity is associated with conversion cycles of the elements and whose use in numerous industrial processes can provide a basis for the ecologically safe preparation of the required products. The discovery of the characteristics of the vital activity of microorganisms and of the general physiological principles of microbial synthesis and the study of their trophic relations and their resistance and adaptation to environmental factors are therefore of fundamental importance.

Studies of the regulation of the growth and development of methane oxidising bacteria constitute one of the examples emphasising the necessity for extensive study of the characteristics of the vital activity of microorganisms. Methane oxidising bacteria are widely distributed in natural media, they play a major role in the transformations of carbon in nature,[1] and they participate in the formation of hydrogen sulphide in the petroleum stratum waters as a result of the trophic links between methane oxidising bacteria and sulphate reducing bacteria.[2] In national economic practice, methane oxidising bacteria are treated as a promising object for the ecologically clean manufacture of bacterial biomass from natural gas in order to employ it as feed additives, for the isolation of biologically active components from the biomass,[3] for use in mine shafts in order to reduce the concentration of methane in air to diminish the risk of explosion,[4] and as part of the composition of technolgenic biocenoses used in various biological methods for increasing the extraction of petroleum from the given geological stratum.[5] However, one should note that, despite the fairly widescale investigation of the physiology of the bacteria of this group, the characteristics of their development have been little investigated, which creates difficulties in obtaining them for large scale industrial processes. It is known that under unfavourable conditions certain methanotrophic organisms give rise to resting forms: exospores, lipid, cysts, and ripe and unripe cysts of the *Azotobacter* type.[6] For other methanotropic organisms, the resting forms are unknown. The causes of the uncontrolled change in metabolic activity under the conditions of periodic and chemosatic cultivation of methane oxidising bacteria have not been investigated. The instability of the process is frequently observed in the continuous cultivation of *M. capsulatus*, which is accompanied either by a spontaneous increase in the cell population, or a decrease in metabolic activity, or processes involving the lysis of the culture. However, the factors which determine the direction of the processes towards the transition of the cells to a hypometabolic (anabiotic) state or the state of cell autolysis remain unelucidated.

In modern theoretical microbiology, there exists a concept according to which a developing microbial culture represents a self-regulating system, its behaviour being determined both by the action of external factors and by the influence of autoregulatory metabolites, which control the rate and the stages in the develoment of the culture.[7]

In recent years, the elucidation of the role of the autoregulatory metabolites involved in the control of the physiological states of the cells of microorganisms and in the development of their cultures has become a vigorously investigated field. In the most general definition, the autoregulatory factors are understood as physiologically active compounds of different chemical nature, secreted by the microbial population or its components into the surrounding medium, not used for the purposes of constructive and energetic metabolism, and playing in the cell community the role of a signal in relation to the alteration of the quantitative (rate of growth) or qualitative (cytodifferentiation) state of the microbial culture.[8] The principal biological function of the extracellular autoregulatory metabolites is to ensure the occurrence of the intercellular interactions and also the interactions of the microorganisms with the medium, directed towards the active growth of the population and the self-preservation of the species.

The extensive data obtained in the study of low-molecular-weight autoregulatory metabolites, synthesised by organisms at different

levels of development (prokaryotes and eukaryotes and unicellular and multicellular organisms), made it possible to formulate this field of knowledge as a separate science—chemical ecology.

We have discovered[8,9] membranotropic autoregulatory factors participating in the control of the structural state and physiological activity of membranes and hence regulating the metabolic activity of the cell, which is expressed by a change in the intensity of cell proliferation processes and/or the differentiation of the microbial cell. In conformity with the last activity among those listed above, they have been called factor d.[8] It has been shown that microorganisms belonging to various taxonomic groups synthesise in the course of the development of their periodic or non-periodic cultures and secrete into the surrounding (incubation) medium autoregulatory metabolites—factors d_1 and d_2 differing in their chemical nature and physiological activity.[9]

This review presents data concerning the discovery of a specific autoregulatory mechanism of the development of the methane oxidising bacterium *M. capsulatus*, effected with the aid of the membranotropic factors d_1 and d_2, and the study of the chemical nature and biological activity, which is important both for the characterisation of the growth and development of the methane oxidising bacteria in natural populations and for ensuring the stability and improving the productivity of the processes involved in their continuous cultivation.

The following biological tests have been adopted in the isolation and purification of the factors d: (1) the change in the intensity of the respiration of the intact cells and isolated membranes (index of membranotropic activity); (2) the change in the rate of growth of the proliferating culture of the producer (integral index of the metabolic activity of the cells); (3) stimulation of the growth of the resting forms of the producer; (4) induction of the autolysis of the cells and (biological activity of the factor d_2); (5) induction of the transition of the vegetative cells to a hypometabolic or anabiotic state (biological activity of the factor d_1).

The isolation, purification, and identification of the factors d_1 and d_2 are based on the methods of modern lipidology:[10] extraction of the autregulators from the culture liquid by lipophilic solvents, their partitioning in a solvent system as a function of the polarity of the molecules, fractionation on columns and plates with adsorbents using selective eluents and solvent systems, rechromatography for the preparative isolation of chromatographically homogeneous fractions, and gas-chromatographic separation for the determination of the component composition and possible identification.[8,11-13]

The membranotropic autoregulatory factors were isolated from the culture liquid separated from the cells by extraction with 1-butanol (2:1) and the residue, remaining after distilling off the solvent, was separated into two fractions in which the activity of the factor d_1 or the factor d_2 predominated. After the separation on a silica gel column of the "crude" preparation of the factor d_2 (chloroform–alcohol fraction in the chloroform–methanol–water two-phase system in proportions of 2:2:1), the neutral lipids, capable of being eluted with chloroform, exhibited the activity of the factor d_2. On separation of the active fraction by preparative thin-layer chromatography, the activity was observed mainly in the fraction comprising free aliphatic acids (FAA) (Table 1), which was inferred from the ability of the preparation both to inhibit the respiration of the membranes and cells and to induce the autolysis of the latter. The FAA fraction of the factor d_2 as well as the "crude" preparation of this autoregulator stimulated at low concentrations and inhibited at high concentrations the respiration of the producer cells. The degree of inhibition of the cell respiration and of the oxidase activities of the isolated membranes increased with increase in the concentration of the FAA introduced, with decrease in the pH of the incubation medium, and with decrease in the amount of the biological material in the measuring cell. It developed as a function of time and also depended on the physiological age of the culture (Figs. 1 and 2).

Table 1. The change in the rate of the endogenic respiration of the cells under the influence of fractions of the extracellular *M. capsulatus* lipids.

No. of fraction	50 μl ml^{-1} fraction	TLC, R_f*	Rate of consumption of oxygen			OD of cell suspension, % relative to control***
			Control μmol O_2 min^{-1}	expt.** μmol O_2 min^{-1}	expt.** % relative to control

* The spots on the chromatogram were identified by analogy with mono-, di-, tri-glyceride oleates.

** Data obtained by the polarographic method; the measurements were performed 3 min after introducing the preparation into the measuring cell.

*** OD = optical density of the cell suspension determined 3 h after introducing the preparations of the fractions into the culture.

Gas-chromatographic analysis of the composition of the FAA fraction (of the factor d_2), isolated from the culture liquid in the course of the stable cultivation of *M. capsulatus* in a chemostatic regime, made it possible to determine a wide range of aliphatic acids: with an even and odd number of carbon atoms ranging from C_{12} to C_{18}, saturated acids, and mono-, di-, tri-, and poly-unsaturated acids (Table 2).[14] Palmitic and palmitoleic acids, whose contents reached 36 and 25% respectively, were the main components. Other components present were 6% of stearic acid, 8% of oleic acid, and 6.5% of linoleic acid. Biological tests of the commercial preparations of the individual aliphatic acids, forming part of the composition of the factor d_2 in dominant amounts, established that unsaturated aliphatic acids are responsible for the physiological activity of this autoregulator (Table 3).

Model experiments designed to determine the biological activity of the components of the factor d_2 showed that oleic and palmitoleic acids induce the active lysis of the cells of the culture *M. capsulatus* in the linear growth phase. Thus in the presence of oleic acid, considered as a chemical analogue of the factor d_2, introduced into the cell suspension at a concentration of $(4-70) \times 10^{-2}$ μg ml^{-1}, vigorous lysis of the culture (70%) was observed after only 1 h of incubation, reaching virtually 100% with increase in the incubation time to 4 h (the autolysis of the cell was inferred from the fall in the optical density of the cell suspension and also from the amount of

soluble protein released from the cells into the incubation medium, the level of which amounted to 37% in the given instance). This conclusion agrees with the earlier results of the study of the chemical nature of the factor d_2 in the bacteria *Pseudomonas carboxydoflava* and *Bacillus cereus*.[11]

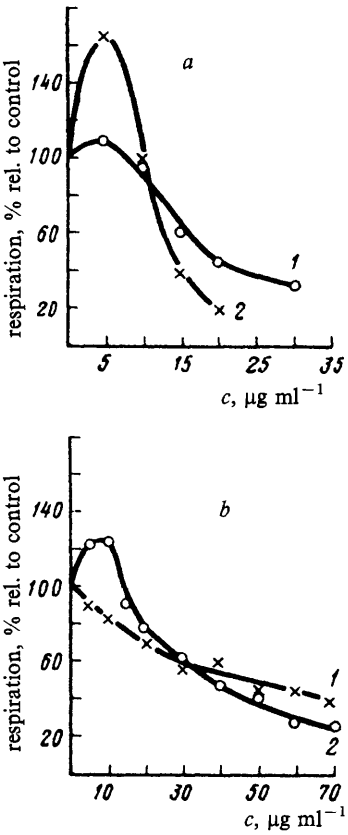

Figure 1. The influence of the factors d_1 (*a*) and d_2 (*b*) of a culture *M. capsulatus* on the endogenic respiration of the producer cells as a function of the concentration *c* of the autoregulator and the physiological state of the cells in the exponential (curve *1*) and linear (curve *2*) growth phases.[13]

The mechanism of the action of FAA (the factor d_2) on cells is based on their ability to be incorporated in membranes without the participation of acyl-transferring proteins.[15] The stimulation of the respiration of the cells of ageing cultures under the influence of low FAA concentrations, which has been demonstrated, can be accounted for by the ability of unsaturated aliphatic acids to increase the liquidity of the membrane lipids, which increases the activity of the electron-transport chain enzymes integrated in the membrane.[16] The stimulation of respiration by saturated aliphatic acids is probably based on their ability to uncouple respiration and oxidative phosphorylation.[17] This effect is more pronounced when the medium is acidified, whereupon the FAA are fully protonated. The introduction of high concentrations of the factor d_2 (20–80 μg ml^{-1}) or of its active principle—unsaturated aliphatic acids, in the given instance oleic and palmitoleic acids (200 nm ml)—into the profilerating bacterial culture leads to a supercritical increase in the liquidity of the membranes, which induces the inhibition of the respiration of the cells and stimulates the autolysis of the cells. This conclusion does not conflict with the available literature data showing that saturated aliphatic acids exert a destabilising influence on membranes.[18]

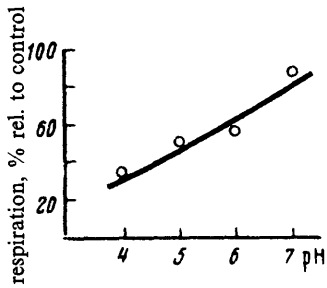

Figure 2. The influence of the factor d_2 of a culture of *M. capsulatus* (20 μg ml^{-1}) on the endogenic respiration of the linear growth phase cells suspended in 0.15 M phosphate-citrate buffer as a function of the pH.

Table 2. The aliphatic acid composition of the extracellular lipids of a *M. capsulatus* culture.[14]

Acids	Content oflipids under chemostatic conditions (D* = =0.21 h^{-1}, *t*=41 °C)%	Content of lipids under lysis conditions, %
12:0	0.63	0.22

*** The acid was not detected.

It is essential to note that the autolytic degradation of microorganisms induced by the influence of high concentrations of the factor d_2 or its chemical analogue, which has been chosen as the

biological test, represents the response of the cells to the extreme effect of autoregulators. In the course of the development of cultures of microorganisms, the change in the structure and functional activity of membranes under the influence of physiological FAA concentrations ensures that the metabolic processes (katabolic and anabolic), which play an important role throughout the entire life cycle of the microorganisms, remain in balance.

Table 3. The influence of aliphatic acids on the endogenic respiration of the cells of a *M. capsulatus* culture.

Acid concentration nmol ml^{-1}	Cell respiration (% relative to 100% in the control 3 min after the introduction of the acid)			
	palmitic	palmitoleic	stearic	oleic
20	140	150	120	160
200	110	5	115	5
400	85	5	120	5

Thus the biological role of the factor d_2 or microorganisms consists, in the case of the methane oxidising bacteria, in maintaining the liquidity of the cell membrane lipids within the limits ensuring the optimum and necessary lipid–protein interactions through which the functional activity of the membrane is controlled. At the limiting permissible concentration of the factor d_2 in the culture, the latter destabilises the membranes, which induces the development of autolytic processes.

These data can be used to develop procedures for the autolysis of methane oxidising bacterial cells with the aid of the factor d_2 or its chemical analogue in order to obtain the cell protein in a soluble form, which increases significantly the assimilability and digestability of the microbial biomass used as a protein feed additive in protein-balanced feed for agricultural animals and birds.

The results obtained in the determination of the chemical structure and biological activity of the factor d_2 have been used to analyse the data on the stability of the technological process for the preparation of the methanotrophic bacterial biomass under experimental-industrial conditions. In elucidating the causes of the spontaneous autolysis of a chemostatic culture of *M. capsulatus*, we began with the following hypothesis. It may be that under conditions considered the synthesis of the extracellular factor d_2 was increased and hence the balance between the activities of the factors d_1 and d_2 was disturbed in favour of the latter, which stimulated the developing autolysis of the cell. Comparative analysis of the level of the factor d_2 in the versions involving a stably growing chemostatic culture and an autolysing culture showed that in the latter case there was a significant increase both in the activity of the factor d_2 (12.3 units litre^{-1} for the stable culture and 19.6 units litre^{-1} for the autolysing culture) and in the specific content of unsaturated aliphatic acids (Table 1). It is noteworthy that the increase in the sum of unsaturated aliphatic acids in the autolysing culture compared with the stably growing culture is not correlated with the corresponding increase in the activity of the factor d_2. However, the observed fact can be explained by taking into account data showing that the greater destabilising effect of polyunsaturated aliphatic acids on membranes compared with monounsaturated acids. It follows from Table 1 that significant amounts of C_{18} polyunsaturated acids appear in the autolysing culture. Thus the instability of the production of the *M. capsulatus* biomass associated with the autolysis of the cells in the chemostatic culture may be caused by the increase in the level of activity of the factor d_2. On this basis, a possible practical recommendation involves the necessity to achieve balanced levels of the activities of the factors d_1 and d_2, which can be achieved by the artificial introduction of a chemical analogue of the factor d_1.

The question arises what is the autoregulatory factor d_1 of *M. capsulatus*? As shown above, the autoregulatory factors d_1 detected in certain bacteria[9] exhibit a membranotropic activity, a test for which involes a change in the endogenic respiration of cells and in the exogenically stimulated respiration of the membranes. The biological activity of the factors d_1 is manifested by their ability to induce the transition of vegetative cells to the anabiotic state, a test for which involves the formation of refractile resting forms of microorganisms under the influence of the factor d_1.[19]

In the course of the purification of the factor d_1 of a culture of *M. capsulatus*, it was established that the sought type of activity was exhibited by the acetone fraction obtained in the separation of the "crude" preparation of the factor d_1 (aqueous alcohol fraction in the chloroform–methanol–water two-phase system in proportions of 2:2:1) on a silica gel column. Subsequent separation of this fraction by thin layer chromatography in the chloroform–methanol–acetic acid–ethyl ether solvent system (in proportions of 35:5:5:45) revealed that the activity of the factor d_1 was observed in the fraction with R_f = 0.67. After rechromatography, a chromatographically homogeneous preparation was obtained, its individuality being demonstrated by chromatography on Silufol and Merck plates in the initial solvent system and also in the chloroform–acetone–methanol (12:4:1) and the chloroform–methanol (85:15) systems. The chromatographically individual fraction of the factor d_1 had all the properties of the autoregulators of this type described previously. At concentrations of 7–40 μg mol^{-1}, the preparation inhibited the endogenic respiration of the cells and the respiration of the isolated membranes stimulated by NADH and malate or succinate. The degree of inhibition of the respiration depended on the concentration of the factor introduced and the pH of the medium, developing as a function of time (Figs. 3 and 4). The individual isolated fraction of the factor d_1 of a culture of *M. capsulatus* did not exhibit species specificity in relation to both other species of methane oxidising bacteria and bacteria of other genera, but the extent of their effect on the cells was different. The specific biological activity of the factor d_1 of a *M. capsulatus* culture was similar to the activity of the autoregulators of this type in previously investigated bacteria.[8,9] In doses of 20–80 μg ml^{-1}, the factor d_1 induced the formation of refractile anabiotic forms of *M. capsulatus*. It follows from the adopted definition of the resting forms of microorganisms, that specialised cells, whose formation is a natural event in the cycle of the development of microbial cultures, may be included among them.[20] On the basis of the foregoing, conditions were selected for the cultivation of *M. capsulatus*, where provision was made for the possible increase in the synthesis of the factor d_1 in the culture, as a consequence of which the cycle of its development terminated with the formation of refractile forms similar to those obtained when the bacterial cells were acted upon by the pure preparation of the factor d_1. The refractile forms of *M. capsulatus*, both obtained on treatment with the factor d_1 and formed in the

natural cycle of the development of these bacteria, exhibited all the characteristics of the resting forms of the microorganisms: the absence of an experimentally determined metabolic activity, an increased refraction of light by the organisms as a consequence of the dehydration of the cell protoplast, prolonged survival, and the characteristic features of their ultrastructural organisation which are different from those of vegetative cells.

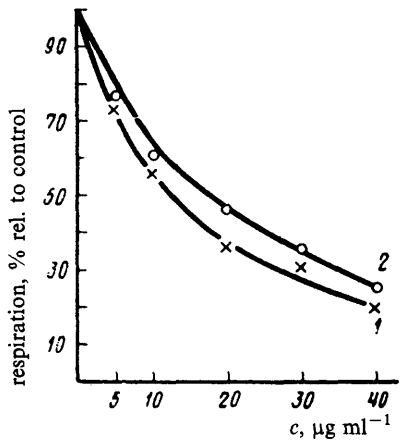

Figure 3. The suppression of the NADH-oxidase (curve *1* and malate oxidase (curve *2*) activities of the isolated membranes of *Micrococcus lysodeikticus* by the factor d_2/[13]

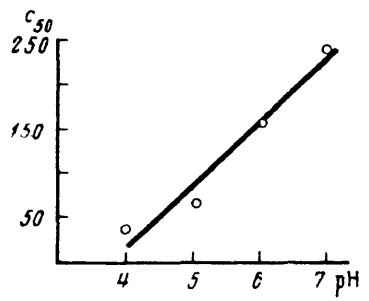

Figure 4. The influence of the pH of the incubation medium (0.2 M phosphate-citrate buffer) on the inhibition by the factor d_1 of the endogenic respiration of the *M. capsulatus* cells; c_{50} = amount of the factor d_1 (μg ml^{-1}) causing 50% inhibition of the respiration of the cells.

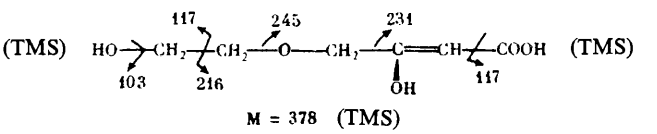
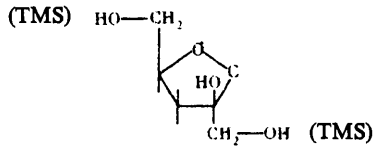


Thus the anabiotic cells, whose formation is induced by the activity of the factor d_1, can be classified as cyst-like anabiotic forms designed to preserve the bacterial species under conditions unfavourable for growth.

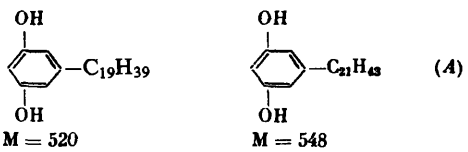
The authors suggest that the resting forms described for certain methane oxidising bacteria are apparently formed with participation of their factors d_1 and the differences, mentioned by Gal'chenko et al.[6] and Whittenburg and Dalton,[21] between the structures of their envelopes and their refractile properties are caused by the conditions which determine the activity of the above autoregulator and its concentration. The complete analogy in the manifestation of the biological activity of the factor d_1 of the *M. capsulatus* bacteria and the previously described factor d_1 of the *P. carboxydoflava* and *B. cereus* bacteria suggests also the identity of the mechanisms of their action on the structural organisation of the membranes.[22,23] The mechanism of the action of the factor d_1 on the lipid bilayer of the membrane is apparently based on the formation of a network of intermolecular hydrogen bonds between the functional groups of the autoregulator molecule and the lipid molecules, which leads to the immobilisation of the lipid matrix. A consequence of the structural reorganisation of the membrane (polycrystallisation) is a change in the functional activity of the enzymes integrated in it (in particular inhibition of the enzymes of the electron-transport chain), a change in the permeability of the membrane to univalent ions, and the associated dehydration of the cell (the increase in refractility). Thus the factors d_1 are capable of modifying the structure of the lipid phase of the membrane, increasing its microviscosity, in contrast to the action of the factors d_2, which increase the liquidity of the membrane.

Finally, one should note yet again that the regulatory function of the factors d_1 and d_2 of microorganisms depends not only on their concentration in the developing culture but also on the external cultivation conditions, in particular on the pH and ionic composition of the growth medium. In this connection, they can be regarded as mediators of the transmission of the external signal to the cell.

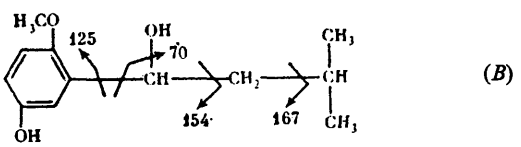


Having described the biological activity of the factor d_1 of a *M. capsulatus* culture, we shall turn to the problem of the identification of its chemical structure. The determination of the structure of the factors d_1 was based on the results of spectroscopic and mass-spectrometric analyses and proton magnetic resonance spectra. It had been shown previously[12] that, as regards their chemical nature, the factors d_1 of the *P. carboxydoflava* and *B. cereus* bacteria are alkoxybenzenes, which are present in the bacterial cultures in the form of a mixture of isomers or homologues differing in the positions of the hydroxy-groups in the ring and the configuration of the alkyl group.

It has been demonstrated by chromatograph-linked mass-spectrometric analysis under the conditions indicated by Svetlichnyi et al.[11] that two substances enter into the composition of the active principle of the factor d_1 of a *M. capsulatus* culture. These substances cannot be identified by computer from the Wiley and NBS libraries. However, their retention times are in the region of linear C_{10} aliphatic acids, C_6 polyfunctional acids, and deoxypentoses. Mass-fragmentation analysis revealed that the spectra of both compounds contain common ions characteristic of carboxylic acids (the ions 117, 129, 135, and 145) and a hydroxy-group (alcohol group) (the ion 103). This shows that the above substances are related—isomers or molecules with small structural differences. The structures of the test molecules are the same as far as the ion 261. On the basis of a computer search catalogue, the following structure of the molecules, which explains the mass-spectrometric data for these compounds, can be put forward according to the details of the fragmentation of the molecules (under the influence of electron impact at 70 eV):



M = 378 (TMS)



The closest version suggested by the computer in the identification process indicates that these substances are lactones of pentonic acids.[24] They give rise to many of the ions present in the alcoholic derivatives of the test substances, namely 103, 117, 129, 131, 133, 147, 217, 245, and 235. The lactone of 3-deoxypentonic acid (M = 378, trimethylsilyl derivative) is closest to the test substances:

M = 378 (TMS)

The chemical structure of the factors d_1 isolated from the *P. carboxydoflava (A)*, and *B. cereus (B)* cultures is as follows:[12]

M = 210

Thus investigations have shown that the chemical nature of the factor d_1 of a *M. capsulatus* culture, inducing the formation of anabiotic forms of the producer, differs from that established previously for the factor d_1 of the *P. carboxydoflava* and *B. cereus* bacteria. The very fact of the observation of differences between the chemical structures of compounds exhibiting the same type of biological activity is very interesting. Studies on the final identification of the chemical structure of the factor d_1 of a *M. capsulatus* culture as well as the determination of the nature of the factors d_1 of other microorganisms appears to be extremely significant. Firstly, these data can provide an idea about what general structure or functional groups are responsible for the biological activity associated with membrane polycrystallisation processes, the changes in the functional activity of the membranes, and the dehydration of cells in the course of the development of the anabiotic state. Secondly, the expansion of knowledge about the structures of compounds exhibiting the type of activities investigated is essential for the selection of cheap and readily available chemical analogues for their practical application in the development of technologies associated with the employment of stabilised cells in order to produce bacterial preparations for different purposes.

In conclusion, one must emphasise yet again that the data described constitute only a special example of the large field of biological knowledge concerning the nature and action of low-molecular-weight metabolites, whose function is to control the changes in the qualitative state of the organism, the physiological activity of the cells, and their interaction with one another and with the surrounding medium. One should note the necessity for the study of the biological activity of autoregulators strictly in relation to changes in the external conditions in the surrounding medium, in the given instance the conditions in the cultivation of microorganisms. The combination in one system of our ideas about the role of external and endogenic (autoregulatory) factors in cell proliferation processes (the growth of the culture) and cytodifferentiation will promote the acquisition of fundamental knowledge about the features of the vital activity of microorganisms in their environment. In addition progress in studies on the mechanisms of the regulation of the growth and development of microorganisms may serve as a basis for a theory of controlled cultivation and may help in the solution of specific biotechnological problems.

The role of hydrogen peroxide in natural aquatic media

E V Shtamm, A P Purmal', Yu I Skurlatov
N N Semenov Institute of Chemical Physics, Academy of Sciences of the USSR, Moscow

ABSTRACT. Chemical and biochemical processes defining the H_2O_2 cycle in natural waters and in biological subjects are examined. Assessments are given of the inflow of H_2O_2 into surface waters from the atmosphere, data are collated on the H_2O_2 content of sea and fresh water. Photochemical, catalytic and biochemical processes make the main contribution to H_2O_2 formation. The interaction between intracellular redox processes of aquatic microorganisms and the redox state of aquatic media is discussed. Biotic and abiotic processes for the decomposition of H_2O_2 in natural waters and the role of free radicals connected with the H_2O_2 cycle in the self-purification of natural aquatic media are examined. Data are presented which indicate the important role of H_2O_2 in the formation of the biological wealth of natural waters.

I. Introduction

Truisms of the type "water is life" and "without oxygen the living world cannot exist" are well-known. Water is contained not only in the hydrosphere but is also one of the essential components of the atmosphere and is present in the lithosphere in large quantities and in the free state. In its turn molecular oxygen exists not only in the form of an atmospheric gas but is also partially dissolved in water and is contained in ground gases. The effects of water and oxygen on living processes are different. Organic life without water is impossible in principle, and strictly it originated on the Earth without oxygen.

It is known that oxygen is formed in photosynthesis by a 4-electron oxidation of water. In its turn oxygen is converted back into water by a 4-electron reduction. However in nature single-event 4-electron processes are only effected in specific biological and catalytic systems.[1,2] As a rule various intermediates are formed as a result of the oxidation of water or the reduction of O_2, among which is hydrogen peroxide, the stable intermediate product of 2-electron conversions of oxygen and water.

Even on the basis of such general considerations it may be proposed that hydrogen peroxide must accompany the oxidation–reduction conversions of oxygen and water. Even more, it is fairly difficult to purify water from traces of H_2O_2 without using special measures. The overall question is, in which processes and in what amounts is it formed and decomposed, and what is the "purpose" of hydrogen peroxide in the life processes of aerobic organisms and in the environment? The present review is devoted to the examination of these questions and their application to the problem of setting the quality of natural waters.

II. Methods for detecting hydrogen peroxide

The content of hydrogen peroxide in the environment is not large, so special, highly sensitive methods are required for its detection. Such methods have been developed only comparatively recently due to the recently awakened interest in studying the role of H_2O_2 in the environment. Methods of titrating H_2O_2 using the iodometric procedure[3] have a lower limit of sensitivity at the 10^{-5} M level. Sinel'nikov[4] has successfully reduced the level of sensitivity of the iodometric titration to 10^{-6} M, however the method is extremely laborious and is not widely used. Electrochemical methods of analysis of H_2O_2 are also not widely used at present, although the highly sensitive chromatographic method of analysis for the content of H_2O_2 in aqueous media is based on the use of an electrochemical transducer. Spectral methods, such as chemiluminescent, fluorometric and photometric methods, are the most widespread.

1. Chemiluminescent methods

Chemiluminescent methods have the greatest sensitivity. The oxidation reaction of luminol and other substances with hydrogen peroxide is used in these essentially kinetic methods for generating electronically excited species emitting quanta of light. The intensity of the chemiluminescence is proportional to the H_2O_2 concentration in the sample being analysed. The methods using luminol are the most widespread.[5] Luminol is very soluble only in a medium of pH $\gtrsim$ 10 so reaction is effected in an alkaline medium in the majority of chemiluminescent methods using it. Cobalt salts, haematin, potassium ferricyanide, etc. are used as catalysts of H_2O_2 decomposition in alkaline medium.

Various dissolved organic and inorganic compounds are present in natural aquatic objects. Some of them participate in the catalysis of H_2O_2 decomposition in alkaline medium (in which the analysis is carried out), others react with reactive intermediate particles or affect the properties of the catalyst used and the reaction kinetics. Because of this the chemiluminescent procedure does not always give correct results. It is necessary to construct calibration graphs of 'added

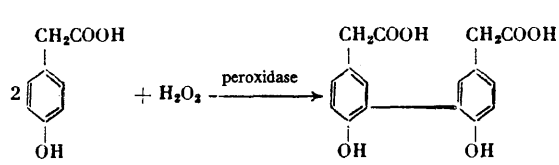
hydrogen peroxide *vs.* signal observed' for each new sample investigated. In addition, control analyses of water samples where hydrogen peroxide would be completely decomposed are necessary for background information. Catalase is usually used as the additive to decompose H_2O_2.

The enzyme peroxidase also serves as catalyst of the chemiluminescent emission of luminol when it is oxidised with hydrogen peroxide.[6] This reaction is effected in neutral or weakly alkaline media with an optimum in the region of pH 8–8.5. Impurities in natural waters may prove to have a marked inhibiting action because of the low solubility of luminol in neutral media.

Comparatively recently several sensitive chemiluminescent procedures for determining hydrogen peroxide in solution have been developed which are based on the luminescence of peroxyoxalates, which are the oxidation products of oxalate esters with hydrogen peroxide.[7–9]

Fluorimetric and photometric methods of determining H_2O_2, based on the peroxidase oxidation of specific substrates, are widespread. In the absence of kinetic chemiluminescent methods, the fluorescence and photometric methods may be regarded as stoichiometric. The decrease in the initial reagent or the concentration of final product of the peroxidase reaction are recorded. It is necessary to be confident that the stoichiometry of the reaction of H_2O_2 with the substrate is retained over a fairly wide range of conditions of carrying out the analysis.

The selective peroxidase oxidation of hydrogen donors with hydrogen peroxide and other organic peroxides has been known for a long time. Substrates include phenols, aromatic amines, triarylmethanes and certain heterocyclic compounds.



2. Fluorimetric methods

Fluorimetric methods of determining trace amounts of H_2O_2 have been carried out in two ways.

The first comprises oxidation of an H donor substrate, possessing marked fluorescent properties, with hydrogen peroxide into a non-fluorescent product. In this case the concentration of H_2O_2 is measured by the decrease in fluorescence intensity. Scopoletin (a fluorescent phenol) has been used as a donor for horse radish peroxidase when determining the H_2O_2 content of cell cultures.[10–12]

Zika and collaborators,[13–15] Kieber and Helz[3] and Holm and collaborators[16] have modified this procedure to be suitable for the analysis of the H_2O_2 content of natural waters. The procedure enables continuous automated measurements to be carried out.

In the second variant *p*-hydroxyphenylacetic acid is used as substrate for the peroxidase reaction. Oxidation of this substrate leads to the formation of a product possessing fluorescent properties.[9,17–26]

Fluorescence analysis is suitable only for relatively pure water since fresh and coastal sea waters contain a large quantity of interfering organic components.[27] An advantage of the method is the possibility of extended storage of the fluorescent product in the water sample being analysed.

3. Photometric methods

The photometric methods of determining H_2O_2 are the most widespread.[28,29]

In 1970 Motolla and collaborators[30] were the first to use the peroxidase oxidation of the leuco form of the dyestuff Crystal Violet to develop a highly sensitive analytical method for determining hydrogen peroxide.

This method was later used for the analysis of natural samples.[31] The procedure proposed[31] was inadequate due to the non-linear character of the dependence of the absorption of the oxidised form on H_2O_2 concentration in the sample and the extended (about an hour) time to carry out the analysis at a comparatively low sensitivity (10^{-5} M).

Optimisation of that method[30,31] has been carried out[25] by varying reagent concentrations, the order of mixing and the conditions of conducting the analysis. Overall the optimisation successfully increased significantly the sensitivity (10^{-7} M), reduced the time to carry out the analysis (3 min), reduced the consumption of reagents and secured linearity for the calibration graph. It became clear, in particular, that the growth rate and level of dyestuff coloration achieved (Malachite Green, Crystal Violet) depended on the relative content of peroxidase and humic compounds in the water. This is seemingly linked with the formation of a complex of the peroxidase with humic compounds and the participation of the reactive residues of the humic compounds in the reaction with the peroxidase–peroxide complex.

Under optimum conditions, using leuco-Crystal Violet (LCV) in the analysis of water samples for H_2O_2 content, 5 mg litre^{-1} leuco base and 20 mg litre^{-1} horse radish peroxidase were taken. Reaction was carried out in pH 4.5 acetate buffer (0.05 M). When carrying out serial measurements it is possible to prepare a "developing" solution containing a 10 times more concentrated mixture of leuco base and peroxidase in acetate buffer. In this way the analysis reduces to adding 1 ml mixture to 9 ml water sample to be analysed.

The advantages of the photometric methods of analysing samples of natural waters for H_2O_2 content are the simple design of the apparatus, the possibility of visual control (of Crystal Violet), the possibility of extended storage of "developed" test samples (F-substituted Malachite Green[32]) and the possibility of increasing the sensitivity of the method by the use of liquid chromatography.[23]

Among the disadvantages of the method are the need to conduct the reaction in weakly acidic media and the possible consequent appearance of unexpected factors affecting the results of analysis and the effect of turbidity of the water samples being analysed on the results of the photometric measurements (the need to filter or centrifuge test samples with a high content of suspended particles). In addition the need to construct calibration graphs for determining the apparent extinction coefficient of the dyestuff and the usually low solubility in water of the leuco base of the dyestuff lead to competition of the peroxidase–peroxide complex from H donors contained in the water sample being analysed.

Recently *N,N*-diethyl-*p*-phenylenediamine has been proposed as a peroxidase substrate. It possesses favourable analytical properties and a high solubility in water.[33]

As has been shown[31,34,35] when analysing natural waters using leuco Crystal Violet, the characteristic blue colour is determined by the presence in the water test sample of H_2O_2 exclusively and not organic peroxides. Nevertheless it is necessary to carry out experiments with catalase added to the water being analysed in order to allow for the possible contribution of organic peroxides to the observed colour and to determine the background absorption.

The emergence of coloured forms of leuco bases in the water samples may arise not only from the peroxidase reaction but also from the possible content of other oxidising agents in the medium. In order to verify such a possibility it is necessary to carry out a "cold" experiment without addition of peroxidase to the sample being analysed.

The photometric method of analysing low concentrations of H_2O_2 may be used in the kinetic mode. This is determined by the formation of a coloured compound (I) on reaction of H_2O_2 with peroxidase. In the presence of H_2O_2 and a suitable substrate the stationary concentration of compound (I) is determined by the rate of its formation (proportional to the H_2O_2 concentration in the medium) and its apparent transformation constant (proportional to substrate concentration). By measuring the concentration of compound (I) and knowing the rate constant for the reaction of H_2O_2 with peroxidase, it is possible to calculate the concentration of hydrogen peroxide in the medium.

Table 1. Content of H_2O_2 in natural waters.

Water sample	Place of sampling	$[H_2O_2]$, 10^7 M	Reference
Snow	Japan	20–40	[36]
Rain	Japan	100–250	[36]
	USA, California	3–40	[37]

III. Distribution of hydrogen peroxide in the environment

Up to the middle sixties the attention of investigators was mainly drawn to hydrogen peroxide because of its practical use and as a convenient model reagent for studying mechanisms of catalytic oxidation–reduction processes. Even in the forties it was known that H_2O_2 was contained in rainfall in fairly large concentrations. Much work has appeared recently devoted to the detection of H_2O_2 in various natural waters. The results of some of these investigations are collected in Table 1.

1. Hydrogen peroxide in the atmosphere

The presence of H_2O_2 in the atmosphere was known even in the XIX century. The main mass of hydrogen peroxide is roughly in the thirteen kilometre layer of the troposphere. Hydrogen peroxide is present in the atmosphere in the gaseous state and in solution in drops of atmospheric moisture such as clouds, rain, mist and haze.

The ratio of the quantities of H_2O_2 in these forms is determined by three factors. Clouds occupy ~0.1 portion of the volume of the troposphere,[51] the coefficient of filling a cloud volume with drops of moisture is $\sim 10^{-6}$,[51] and the Henry constant, characterising the distribution of H_2O_2 between the aqueous and gaseous phases, is 1.2×10^5 mole litre^{-1} atm^{-1}.

$$[H_2O_2]_{(dis)} = K_H P_{H_2O_2}$$

It follows from these characteristics that

$$M_{H_2O_2(g)}/M_{H_2O_2(dis)} \simeq 1/(0.1 \times 10^{-6})(1.2 \times 10^5),$$

i.e. the main mass of H_2O_2 is in the gaseous phase.

The total quantity of atmospheric H_2O_2 in our estimation based on the vertical profile of H_2O_2 distribution in the troposphere is ~2 megaton.

The formation of H_2O_2 in the atmosphere is photochemical in nature.[52]

$$O_3 + h\nu \rightarrow O_2 + O('D), \text{ at } \lambda < 310 \text{ nm};$$

$$O(^1D) + H_2O \rightarrow 2OH, \; k_2 = 2.2 \times 10^{-10} \text{ cm}^3.\text{sec}^{-1}$$

Both species $O(^1D)$ and OH react with methane.

$$O(^1D) + CH_4 \rightarrow OH + CH_3, \; k_3 = 1.4 \times 10^{-10} \text{ cm}^3.\text{sec}^{-1},$$

$$OH + CH_4 \rightarrow H_2O + CH_3, \; k_4 = 2.3 \times 10^{-12} \exp(-1700/T) \text{ cm}^3.\text{sec}^{-1}.$$

In the subsequent chain of conversions the first stable oxidation products of methane, viz. CH_2O, H_2O, O_3 and H_2O_2, are formed.[52]

$$CH_3O + O_2 \rightarrow CH_2O + HO_2, \; k_5 = 3.9 \times 10^{-14} \exp(-900/T) \text{ cm}^3.\text{sec}^{-1},$$

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2, \; k_6 = 2.3 \times 10^{-13} \exp(-600/T) \text{ cm}^3.\text{sec}^{-1},$$

$$HO_2 + HO_2 \xrightarrow{M} H_2O_2 + O_2, \; k_7 = 1.7 \times 10^{-33} \exp(-1000/T) \text{cm}^6.\text{sec}^{-1},$$

where M is any particle in the medium (N_2, O_2, H_2O etc.) participating in the termolecular reaction to draw off the excess energy.

The oxidation of other hydrocarbons in the atmosphere leads to the formation of H_2O_2 by side reactions. Since methane is the main organic compound in the atmosphere the photoinitiated oxidation of methane may be considered to be the main source of H_2O_2.

The consumption of gaseous hydrogen peroxide in the atmosphere occurs by three routes.[52]

$$OH + H_2O_2 \rightarrow H_2O + HO_2, \; k_8 = 1.9 \times 10^{-12} \exp(-160/T) \text{ cm}^3.\text{sec}^{-1},$$

$$H_2O_2 + h\nu \rightarrow 2\dot{O}H, \; \lambda \leqslant 400 \text{ nm},$$

$$H_2O_{2(g)} \rightarrow H_2O_{2(dis)}.$$

Within the framework of a one-dimensional model of the atmosphere the following equation holds true for each height.

$$[H_2O_2] = \frac{k_7[H^{\cdot}O_2]^2}{k_3[OH] + a_9 I_\lambda + \varkappa_{10}},$$

where a_9 is the capture cross section for a photon with a defined λ,

I_λ is the intensity of solar radiation of wavelength λ at height H, $\varkappa_{10}$ is the apparent rate constant of "rain out" hydrogen peroxide by its absorption into atmospheric moisture and removal from the atmosphere with rain.

The significance of the terms in the denominator can be determined as a function of height. The last of the components has the greatest significance for tropospheric conditions, i.e. $[H_2O_2]_g$ is high in the troposphere if $[HO_2^{\cdot}]$ or $[\dot{O}H]$, which is linked linearly with $[HO_2^{\cdot}]$, are large and the content of atmospheric moisture is low. Since the formation of OH occurs at a rate proportional to $[O_3]$, $[H_2O]$ and the intensity of UV irradiation, then the greater these factors are the greater will be $[H_2O_2]$. $[H_2O_2]$ will be greatest in a well-illuminated and humid atmosphere with minimum aerosol content. The presence of aerosols of natural or anthropogenic origin may lead to a reduction of $[\dot{O}H]$ and correspondingly of $[H\dot{O}_2]$.[53] As is evident from the equation a 3–5 fold reduction of $[HO_2^{\cdot}]$ occasions a 10–25 fold reduction of $[H_2O_2]$.

The overall quantity of hydrogen peroxide passing from the atmosphere with precipitation to the surface of the oceans and land in a year may not exceed the quantity of $O(^1D)$ atoms generated in that time. However a global calculation of that sort is fairly complex. It is possible to estimate the maximum quantity of H_2O_2 falling onto the Earth from the atmosphere by proceeding from an average figure for precipitation of ~1000 mm in a year and the concentration of H_2O_2 in the precipitation. The latter figure varies within wide limits, from zero to 10^{-4} M[55] (see also Table 1). Taking a value of $[H_2O_2]$ ~10^{-5} M as being characteristic, we find ~200 g H_2O_2 falls each year on each square metre of land and ocean surface. To this figure must be added the hydrogen peroxide dissolved in natural waters and moisture of the soil. To make any global estimate of the quantity of H_2O_2 passing into water in this way is impossible since this quantity will be determined by the mixing layer renewing the contact surface of water and air. The problem of the dynamics of gases dissolving in water has been specially considered.[56] The time for H_2O_2 to reach the equilibrium concentration $[H_2O_2]_{dis}$ in drops of atmospheric moisture is several seconds.[56] Taking a value of $K_H = 1.2 \times 10^5$ mole litre^{-1} atm^{-1}, we obtain $[H_2O_2]_{dis} \sim 10^{-4}$ M. However this value characterises $[H_2O_2]$ in a thin surface layer. Diffusion transfer even in a metre thick water layer would require ~10^7 sec at a diffusion coefficient of ~10^{-5} cm^2 sec^{-1}. A more effective mechanism for the transfer of H_2O_2 from the surface is wind and wave mixing of the surface layers of the water. In order to assess the maximum quantity of H_2O_2 which may pass into natural waters by solution from the atmosphere it is possible to use the expression

$$\frac{dN}{dt} = \frac{\bar{v}n}{4} S\alpha,$$

where $\bar{v}$ is the root mean square velocity of gaseous particles, n their concentration, S the contact surface of gas with liquid and α the coefficient of accommodation.

Putting the values $t = 3.15 \times 10^7$ sec (1 yr), $S = 10^4$ cm^2 (1 m^2), $n = 2.2 \times 10^{10}$ cm^{-3},[51] $\bar{v} = 4.2 \times 10^4$ cm sec^{-1} and $\alpha = 0.18$[57] into the integrated form of this equation, we obtain $N = 1.23 \times 10^{24}$ ~2 mole, i.e. 70 g m^{-2}, a number comparable with the estimate given above for the quantity of H_2O_2 passing into natural waters with rainfall. One must not overlook the hypermaximal character of the given estimate made using the maximum concentration of H_2O_2 in the gas being absorbed by a constantly renewed water surface. Seemingly it is reasonable to speak of two channels, close in scale, for the inflow of H_2O_2 from the atmosphere, viz. with rainfall and by dissolving gaseous H_2O_2. It is interesting to note that if decomposition and other chemical conversions of hydrogen peroxide do not occur in natural waters then $[H_2O_2]$ of ~10^{-4} M, i.e. of the order of a saturating H_2O_2 concentration, would have accumulated in a stirred surface layer of thickness 20 m in a year.

Both fluxes of hydrogen peroxide from the atmosphere into natural waters, as already mentioned above, are highly sensitive to anthropogenic contamination of the atmosphere by aerosols and are reduced ten-fold by serious contamination. This is linked with the chemical origin of H_2O_2, viz. its formation on recombination of $HO_2^{\cdot}$ radicals. The reduction in the quantity of H_2O_2 in precipitation may be even greater due to autocatalytic oxidation of sulphite ions by hydrogen peroxide taking place in the droplets of clouds.

$$H^+ + HSO_3^- + H_2O_2 \rightarrow 2H^+ + SO_4^{2-} + H_2O.$$

Analysis of the various processes for oxidising HSO_3^- with oxygen or ozone and the catalysis of these processes by ions of iron and manganese showed that the oxidation of HSO_3^- with hydrogen peroxide is more significant.[58,59] It was noted previously,[60] that as $[SO_2]_g$ increased then $[H_2O_2]$ in raindrops was reduced. In other investigations an inverse proportional relationship was noted between the concentrations of sulphate ions and of hydrogen peroxide in rain water.[61,62] There are also other data obtained in aerochemical investigations of the chemical composition of cloud droplets,[63] in which such a correlation was not detected.

The problem of relating the compositions of raindrops and cloud droplets is not simple. There are differences in their lifespans (~1 h for clouds and ~100 sec for rain) and dimensions, the radius of a cloud droplet is 10 μm and of a raindrop is 300–1000 μm. A change in the composition of a falling raindrop compared to cloud occurs through absorption of various gaseous constituents and capture of aerosol particles. However in the lifespan of a raindrop the equilibrium concentrations of absorbed substances are reached only in the thin surface layers of a drop due to the low rate of diffusion. We are unaware of a quantitative solution to the problem of relating the composition of a raindrop to the composition of a cloud allowing for the absorption of gases in the atmosphere near the ground. There is considerable interest in the investigation of the H_2O_2 content in fossil ice in Greenland and Antarctica.[8] It turned out that in the Northern Hemisphere H_2O_2 was detected in significant concentrations in ice, the age of which was estimated at tens of thousands of years. This observation is the basis for the statement that hydrogen peroxide is an inherent component of atmospheric precipitation, a natural "companion" of O_2 and H_2O.

It also follows from these data,[8] that in the ice of Antarctica, in contrast to the Arctic, the H_2O_2 content falls rapidly with the age of the ice. It is not excluded that this is linked with a fall of H_2O_2 under the influence of solar UV radiation. The results of measuring H_2O_2 in the fossil ice of Antarctica indicates indirectly the natural occurrence of an "ozone hole" over Antarctica in times past. Attention has primarily been paid to these "holes" only since the early eighties.[64,65] The changes in UV radiation in the troposphere affect the photodissociation reaction which leads to a change in the equilibrium concentrations of the atmospheric oxidising agents, viz. O_3, $\dot{O}H$, $HO_2^{\cdot}$, H_2O_2.[66]

Measurements of the H_2O_2 content of snow revealed the correlation that the greater the atmospheric contamination by smoke the lower was the H_2O_2 concentration in melted snow.[67] This observation is in agreement with the hypothesis given above that an increase in aerosol contamination is associated with a reduction in the stationary concentration of $\dot{O}H$ and of $HO_2^{\cdot}$ and a large

reduction in H_2O_2 concentration in the gaseous phase. When the atmosphere is contaminated by both aerosols and sulphur dioxide it is possible that the oxidation of HSO_3^- remains incomplete in drops due to the decrease of $[H_2O_2]_g$ and correspondingly of $[H_2O_2]_{dis}$. In this event rainfall may contain unreacted oxidation substrates, such as sulphite ion and formaldehyde. This leads to the fact that in many areas substances which react efficiently with H_2O_2 are discovered in the water instead of H_2O_2. Nevertheless it can be proposed that the flux of oxidation equivalents in the form of hydrogen peroxide dissolved in water is reduced depending on the industrial development of a region. Moreover, it is possible for predominantly reduction equivalents (metal ions in the reduced form, sulphite ions, other reduced forms of sulphur) to reach the Earth's surface. This problem has not been studied adequately.

2. Hydrogen peroxide in the sea

The content of H_2O_2 in natural waters was determined for the first time in 1966 by Van Baalen and Marler[12] in the Gulf of Mexico. These investigations stimulated authors to study the ecological role of blue-green algae. The H_2O_2 content of the sea proved to be $\sim 10^{-7}$ M. It was suggested that atmospheric precipitation, metabolites of aquatic organisms and photochemical processes are the sources of H_2O_2.

After a long interruption the study of the H_2O_2 content of the sea was continued in the eighties by Zika and collaborators.[45,68] It was shown that the H_2O_2 content of the water of the Gulf of Mexico fell from $(1.2-1.4) \times 10^{-7}$ M in the surface layer to 5×10^{-9} M at a depth of 100 m.[43,69]

A detailed study of the distribution of hydrogen peroxide in the waters of the Gulf of Mexico was undertaken in 1985.[44] In oligotrophic regions weakly saturated with organic substances the H_2O_2 content in the water varied within the limits $(1.2-1.6) \times 10^{-7}$ M, while at a depth of 40 m, in a layer of convective mixing, the H_2O_2 concentration remained approximately constant, and below this it was reduced. In the coastal zone insignificant diurnal changes of H_2O_2 concentration were observed, viz. from 1.7×10^{-7} M at 8 am to 1.9×10^{-7} at 2 pm in May and from 1.9×10^{-7} M at 6 am to 2.9×10^{-7} M at 6 pm in August. Below the 20 m layer of efficient mixing the concentration was reduced to 0.3×10^{-7} M and did not undergo diurnal variations.

A tenfold and greater increase in concentration in layers at depths up to 50 m and over was shown after rain.[40]

An investigation of the H_2O_2 content in the ocean along the coast of Peru has been described.[46] A correlation was recorded between the H_2O_2 content of the water and biological activity and photochemical reactions.

The possible role of microorganisms in the formation of H_2O_2 in sea water has been established.[70] The ability to produce H_2O_2 not only by the action of sunlight but also in the dark was discovered in certain forms of algae. Not all algae possess this property. The sea diatom *Thalassiosira weissflogii* does not produce H_2O_2 in the dark or in the light.

The distribution of H_2O_2 in estuarine water has been studied.[47] The investigation was carried out in November. A diurnal variation was detected in the H_2O_2 content of water, the maximum hydrogen peroxide concentration of 9×10^{-7} M being reached at 6 pm. Seasonal variations were detected in the H_2O_2 content of the water from 0.35×10^{-7} M in February to 1.3×10^{-6} M in July.

The H_2O_2 content of water in the northwest portion of the Black Sea has been measured.[71] The H_2O_2 concentration did not exceed 1.5×10^{-7} M. Substances with a reducing nature, reacting efficiently with H_2O_2, were recorded in certain samples in place of H_2O_2.

The distribution of H_2O_2 concentration in the water of the White Sea has been studied using chemiluminescent methods.[72] Colleagues of the Pacific Ocean Oceanological Institute of the Far Eastern Division of the USSR Academy of Sciences have carried out investigations in many regions of the world's oceans.[73] The H_2O_2 concentration in these investigations varied within the limits 20 to 470 nM.

Methods for modelling mathematically the H_2O_2 distribution in sea water in time and space have been discussed.[74]

3. Hydrogen peroxide in inland fresh water

The first measurements of the H_2O_2 content of inland natural waters were made by V E Sinel'nikov using chemiluminescent and iodometric methods.[4,48,49,75–77] The investigations were mainly carried out on the Volga over several years at the end of the sixties and the beginning of the seventies. The H_2O_2 content in Volga water varied within the limits of 3×10^{-7} to 3×10^{-6} M. As a result it was concluded that 10^{-6} M was a typical value for the H_2O_2 content of uncontaminated sections of the water.[48]

According to these investigations microorganisms, particularly algae, play a major role in the formation of H_2O_2 in natural waters.[78] A significant increase (up to 10^{-5} M[79]) in H_2O_2 concentration was detected in the zone of contamination of reservoirs by domestic effluent, containing readily oxidisable organic compounds. The content of organic peroxides accompanying H_2O_2 was measured by iodometric titration using catalase to destroy hydrogen peroxide. Their concentration did not exceed 10% of the H_2O_2 concentration.

Later, in the early eighties, a study was undertaken of hydrogen peroxide in fresh natural waters.[31,34] Samples of water which were used for farm irrigation, samples of river water, drainage from fields and unpurified sewage were taken. They were irradiated under laboratory conditions with an artificial light source simulating sunlight. The concentration of H_2O_2 formed was $(2-7) \times 10^{-6}$ M for the majority of samples studied, while in water samples taken from biologically clean ponds it was 3×10^{-5} M.

A diurnal variation was detected in the H_2O_2 content of the surface water layer of a pond on a sunny day of 2.9×10^{-7}, 8.8×10^{-7} and 1.5×10^{-8} M at 8 am, 1 pm and midnight respectively.[8]

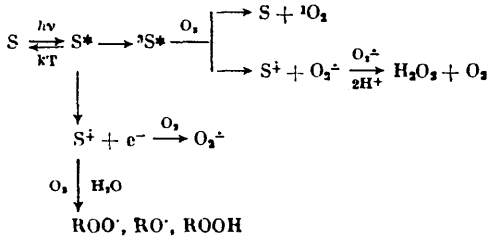
Many measurements of the H_2O_2 content of various water samples were carried out in this country in the eighties. The main results of these measurements have been collated.[80–83] Investigations were carried out using chemiluminescent and peroxidase photometric methods.

In the same regions of the Volga where Sinel'nikov had carried out measurements 10–15 years previously, an intensification of the diurnal variation and the initiation of seasonal variations were detected[82] in the H_2O_2 content of the water. In May the H_2O_2 concentration in Volga water near Volgograd varied between 10^{-6} and 3×10^{-6} M. Towards the middle of June the H_2O_2 content of the water began to undergo sudden diurnal changes. In sunny weather the maximum H_2O_2 content occurred at 4 pm and the minimum in the early morning hours. In overcast weather hydrogen peroxide was, in general, not detected. Shortly afterwards a period arrived when H_2O_2 generally disappeared from Volga water. On the contrary, titration of natural water with small additions of hydrogen peroxide enabled the detection of the presence in it of compounds of a reducing nature which reacted efficiently with H_2O_2. The authors thereby recognised a change in the state of the medium from normal

oxidising, when H_2O_2 was present in the water, to quasi-reducing, when a reducing agent was recorded in place of H_2O_2 and was titrated by adding H_2O_2. This change of the "sign" of the redox state of the medium was apparently produced for the first time in the mid-seventies and led to the catastrophic change in the ecosystem of the Volga (see Section VIII, No. 2).[80]

The results of measuring the H_2O_2 content of the waters of the Volga,[82] the Dnieper[84] and other waters of this country show that the seasonal change of the dynamic redox state of aquatic media has in recent years become the rule and not the exception.

IV. Processes forming hydrogen peroxide in natural waters



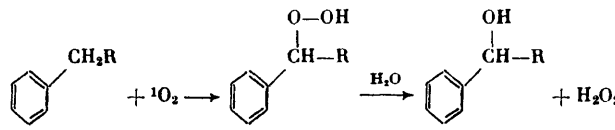
The fact that part of the H_2O_2 concentration in water undergoes diurnal changes correlating with solar activity suggests that hydrogen peroxide is formed predominantly by photochemical reactions. At the same time the formation of H_2O_2 in aquatic media is linked with the activity of algae and bacteria. The general considerations expressed at the beginning of the review also indicate the possible role in the formation of hydrogen peroxide of catalytic oxidation processes of readily oxidisable compounds with oxygen. We will discuss the most probable channels of introduction into aquatic media in more detail.

1. Photochemical processes in natural waters leading to the formation of H_2O_2

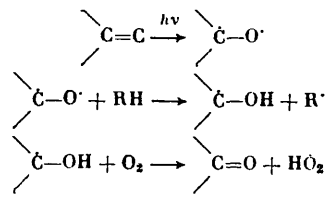
The photochemistry of natural waters is one of the most successfully developed areas of studying chemical processes occurring in the environment.[85,88]

Electronically excited species are formed by the action of solar radiation ($\lambda \geqslant 300$ nm) in water as primary products. These include S*, $^1O_2$ (S are organic compounds, photosensitisers, dissolved in water),[89–92] free OH radicals,[87,93–97] $O_2^{\cdot-}$,[14,34,98–101] peroxy radicals ROO·[93,102] and solvated electrons.[92,103–106] The reaction of the reactive intermediates with one another and with compounds dissolved in water may lead to the formation of H_2O_2 in an aerobic medium.[15]

The general scheme for the photochemical conversions of organic substances (S) in natural waters as a result of direct photolysis may be represented as follows.[107,108]



Organic substances dissolved in natural waters are mainly humic compounds. The efficiency of forming H_2O_2 in aquatic solutions containing humic and fulvic acids, and also various amino acids, has been studied and it was discovered that the rate of forming H_2O_2 was greater in humic than in fulvic acids.[31,34] Tryptophan was the most productive of the amino acids, absorbing light in the longest wave region of the UV spectrum.



Test samples of surface and ground water with various contents of humic compounds have been irradiated with sunlight[14] and it was discovered that the rate of H_2O_2 formation correlated with the concentration of compounds absorbing light in the near UV region.[15]

The presence of $O_2^{\cdot-}$ in natural waters has been confirmed by adding superoxide-dismutase and also acceptors of $O_2^{\cdot-}$ such as dichlorophenolindophenol, cytochrome C and nitrotetrazolium blue.[14,34,98,99,109]

It was shown that $O_2^{\cdot-}$, as a precursor of H_2O_2, is also formed on photolysis of tryptophan.[34,110,111] Flavins also differ from other compounds of biological origin by having a high efficiency of H_2O_2 formation.[112] The generation of H_2O_2 is accelerated in the presence of electron donors. A high rate of hydrogen peroxide formation through the intermediate formation of $O_2^{\cdot-}$ radicals was observed in photochemical conversions of pyruvate, glyoxalate and other keto-acids especially in the presence of H donors. The accelerating effect of electron donors (H atom) on the rate of formation of H_2O_2 may be linked with their participation in reaction with $^1O_2$ [113] with the formation of $O_2^{\cdot-}$ radicals or with oxidising agents S^+ with subsequent oxidation of the resulting radical–donor by molecular oxygen. Hydrogen peroxide may be formed as the product of the reaction of $^1O_2$ with certain organic compounds avoiding the step of forming $O_2^{\cdot-}$ radicals.[114]

Carbonyl compounds readily take part in a photochemical reaction of a different type. In particular, humic acids form reactive biradicals in the excited state.[115,116]

Many of the resulting radicals undergo various conversions in an aerobic medium in the presence of variable valency metal ions, often with the intermediate formation of H_2O_2 (see Section VII).

Both organic and inorganic compounds may undergo photochemical conversion in natural waters and as a result various reactive intermediates are formed. In an aerobic medium this may lead to the initiation of radical processes of oxidation of the organic compounds dissolved in the water with the accompanying formation of H_2O_2.

Free radicals, chiefly $\dot{O}H$, are the primary products of photochemical conversions of inorganic compounds as a rule.[117–119]

$$NO_3^- \xrightarrow{h\nu,\,H^+} NO_2 + \dot{O}H,$$

$$NO_2^- \xrightarrow{h\nu,\,H^+} NO + \dot{O}H.$$

In addition $O_2^{\cdot-}$ radicals may be formed on photolysis of certain oxides of a semiconductor type.[42,120,121]

$$TiO_2^{2+} \xrightarrow{h\nu} TiO_2^+ + e^- \xrightarrow{O_2} O_2^{\cdot-}$$

Transition metal complexes are subject to photochemical conversion, being decomposed by the action of light with the formation of a metal ion in the reduced form. These processes occur

with the highest efficiency in the case of iron complexes, which absorb light in the near UV region.[122,127]

$$FeOH^{2+} \rightarrow Fe^{2+} + \dot{O}H,$$
$$FeHO_2^{2+} \rightarrow Fe^{2+} + H\dot{O}_2,$$
$$FeC_2O_4^{+} \rightarrow Fe^{2+} + CO_2^{\pm} + CO_2 \text{ etc.}$$

Some copper complexes are reduced in sea water by sunlight.[69]

$$CuX^{+} \rightarrow Cu^{+} + X,$$

where X^- is an anionic ligand.

Manganese[128,129] and chromium[130,131] ions also participate in photochemical conversions.

The role of metal ions in H_2O_2 formation in aquatic media will be discussed in more detail below.

2. The formation of H_2O_2 by redox catalytic processes

Most reactions in natural systems are effected with the participation of dissolved oxygen and variable valency metal ions.

It has been shown that copper ions participate in H_2O_2 formation in sea water.[132] Hydrogen peroxide at a concentration of 10^{-7} M affects the Cu^+/Cu^{2+} ratio and the autoxidation of chloride complexes of Cu^+ and Cu^{2+} leads to the formation of H_2O_2. This process has been studied in detail.[133,134] The mechanism of the process includes the intermediate formation of copper-oxygen complexes.[135]

$$Cu^+ + O_2 \rightleftharpoons (CuO_2)^+ \rightleftharpoons Cu^{2+} + O_2^{\cdot-},$$
$$O_2^{\cdot-} + Cu^+ \xrightarrow{2H^+} Cu^{2+} + H_2O_2,$$
$$CuO_2^+ + Cu^+ \xrightarrow{2H^+} 2Cu^{2+} + H_2O_2.$$

In addition to autoxidation reactions of transition metal ions, oxidation reactions of various readily oxidisable organic compounds, catalysed by metal ions, may contribute to H_2O_2 formation.

Ascorbic acid[136] and dihydroxyfumaric acid[67] are typical examples of reducing compounds which form stoichiometric quantities of H_2O_2 on oxidation by oxygen of the air. These redox ligands (DH^-) react with metal ions, with copper ions in particular, with the formation of the reduced form which participates in the activation of O_2.[138]

$$\left.\begin{aligned} &Cu^{2+} + DH^- \rightleftharpoons CuDH^+ \underset{-H^+}{\dashrightarrow} Cu^+ + D^{\cdot},\\ &CuDH^+ + Cu^{2+} \underset{-H^+}{\longrightarrow} 2Cu^+ + D, \end{aligned}\right\} \text{reduction of metal}$$

$$\left.\begin{aligned} &Cu^+ + O_2 \rightleftharpoons CuO_2 \dashrightarrow Cu^{2+} + O_2^{\cdot-},\\ &CuO_2^+ + DH^- \underset{-H^+}{\longrightarrow} Cu^+ + D + H_2O_2. \end{aligned}\right\} \text{activation of } O_2$$

A radical mechanism forming H_2O_2 is also possible by the catalytic oxidation of reducing agents which are efficient electron donors (H atom).[137,138]

$$O_2^{\cdot-} + DH^- \rightarrow HO_2^- + D^{\cdot-},$$
$$D^{\cdot-} + Cu^{2+} \rightarrow Cu^+ + D.$$

Chain processes are in essence similar reactions, the termination of which occurs by destruction of the chain propagators ($O_2^{\cdot-}$, Cu^+, D^-) on heterogeneous impurities or by recombination with one another.

The catalytic oxidation rate of ascorbic acid and related reducing agents with oxygen is far higher than with hydrogen peroxide, which also leads to the accumulation of H_2O_2 in the medium.

3. The role of microorganisms in the formation of hydrogen peroxide

Van Baalen and Marler[12] and Sinel'nikov[78] were the first to reach the conclusion that the role of algae in the process of forming H_2O_2 is important. Even earlier Mehler[139–141] had demonstrated in classical studies the ability of chloroplasts to produce H_2O_2 under the action of light. It was later shown that, in the process of forming H_2O_2, oxygen may oxidise reduction equivalents in the electron transport chain of photosynthesis.[142–146]

The photochemical formation of H_2O_2 was demonstrated for the first time in 1973 by Patterson and Meyers on irradiating the blue-green alga *Anacystis nidulans* with light of wavelength 620–675 nm.[147]

By adding 3-(3,4-dichorophenyl)-1,1-dimethylurea (DCMU) to block Photosystem II, it was shown that the photosynthetic apparatus was the source of reduction equivalents for the formation of H_2O_2 when reducing O_2. The rate of forming H_2O_2 grew on adding to the medium either inhibitors of the Calvin cycle (PCMB, iodoacetamide) or an inhibitor of phosphorylation (carbonyl cyanide *m*-chlorophenylhydrazone) and also under conditions of CO_2 deficiency. Components of the Calvin cycle suppress H_2O_2 formation.

The conclusion was reached[147] that reduction equivalents, for which O_2 and CO_2 compete, are produced in algae cells by the action of light. It was proposed that the centre of H_2O_2 formation was localised in the final reducing step of Photosystem I.

In addition to *Anacystis nidulans* a large number of fresh water[148] and marine[70] algae were discovered to be capable of producing H_2O_2 in the external medium in the process of photosynthesis. No correlation was noted between the morphological features or the accepted nomenclature differentiation of the algae and their ability to produce H_2O_2. The kinetic characteristics of the process of forming H_2O_2 for the various algae species differed markedly.

It was also discovered[70,148] that certain types of algae are able to produce H_2O_2 not only by the action of light but also in the dark. This shows that the H_2O_2 formation by algae may not be linked solely with photosynthesis.

Palenik and collaborators[149,150] have shown the role of intracellular L-aminoacid oxidases (deaminases) in the formation of H_2O_2 by the reaction:

$$R{-}CHNH_3COO + H_2O + O_2 \rightarrow R{-}CHOCOO^- + NH_4^+ + H_2O_2.$$
(L-aminoacid) (α-ketoacid)

The ammonium ion liberated in the reaction is captured by algae cells (*Pleurochrysis carterae*) and used as a source of nitrogen.

Other surface deaminases are known which participate in the transformation of nitrogen in seawater. These include amino-oxidases, which oxidise primary amines (ethanolamine, putrescine) in the presence of phytoplankton and the polyaminooxidase of the diatom *Thalassiosira weissflogii*, which uses spermine and spermidine as substrates with the formation of H_2O_2 as a side product.[151]

The activity of the surface deaminases is usually large when the growth of phytoplankton is limited by nitrogen. For this reason these processes are usually effected in regions with a low content of inorganic forms of nitrogen (for example in the open ocean).

The quantitative contribution of processes involving deaminases has not been established. The formation of H_2O_2 in abiotic processes occurs at a greater rate than in biotic processes in surface water while at depth the biotic contribution becomes dominant.[15] Palenik and collaborators[149] have established that the

rate of H_2O_2 formation by *Pleurochrysis carterae* reaches $(1-2) \times 10^{-9}$ mole litre^{-1} h^{-1}. Since aminoacid oxidases are widely distributed among microalgae and other deaminase reactions may lead to the formation of H_2O_2, the biological production of H_2O_2 in the dark may be significant in several cases.

It has been shown[152,153] that non-photosynthetic photochemical processes for H_2O_2 formation are also effected efficiently in algae cells by the action of the UV component of sunlight, as a result of the photolysis of water-soluble intracellular components. A portion of the resulting hydrogen peroxide is decomposed by intracellular enzymes (catalase, peroxidase, see below) but a portion of it is eliminated into the external medium. The rate of photoproduction of H_2O_2 and its stationary concentration in the medium depends on both the species of algae and on the age of the culture.[109] The precursor of H_2O_2 in algae cells is the $O_2^{\cdot-}$ radical.

It has been shown[154] that H_2O_2 is formed on autoxidation of ferredoxin. On the other hand the formation of H_2O_2 was detected in membrane preparations from blue-green algae *Anabena* with the ferredoxins washed away.[146]

V. The role of hydrogen peroxide in the formation of a single "cell–medium" redox system

The hydrogen peroxide cycle in natural waters is closely linked with the exchange of oxidation–reduction equivalents between the aquatic organisms and the surrounding medium. It is possible to draw conclusions on the principles of such a redox exchange both within the limits of a cell and between a cell and the external medium which have a bearing on the general principles of the functioning of the living cell.[155]

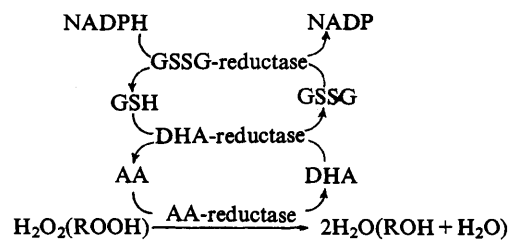
1. Intracellular redox processes involving H_2O_2

The redox state of the intracellular medium is determined by the interconnected distribution of the oxidised and reduced forms of variable valency metal ions entering the active centres of oxidation–reduction enzymes and labile redox metabolites, such as NADP/NADPH, cytochrome C (Fe^{3+}/Fe^{2+}), ATP/ADP + P (P is phosphate), etc. The oxidation state of cytochrome C determines the respiration rate of a cell and accordingly the rate of phosphorylation processes. Phosphate plays a regulatory role in maintaining the intracellular redox state, its exchange with the external medium is regulated by the cell.

The interaction of intracellular redox systems implies the exchange of oxidation–reduction equivalents between the cell structures. In other words, a system exists for the regulation of the intracellular redox state on which the occurrence of such complex biochemical processes as cell respiration, protein synthesis and the secretion of hormones and neurotransmitters depend.

Hydrogen peroxide together with O_2 play a special role in the redox processes in the cell.

The intracellular content of H_2O_2 in algae cells is determined not only by photochemical processes but also by other oxygen-dependent processes in the cell. Among them a central place is occupied by biological oxidation processes involving O_2, viz. the oxidase (oxygen acts as an electron acceptor), oxygenase (oxygen acts as a donor of an O atom) and the peracid oxidation of lipids occurring with the participation of O_2 and free radicals. The enzymes known to form H_2O_2 in metabolic processes involving O_2 are glycolate oxidase, α-gulonolactone oxidase, aldehyde oxidase, xanthine oxidase, D-aminoacid oxidase, monoamine oxidase, galactose oxidase, prostaglandin synthetase, dihydroorotate dehydrogenase and certain others.



Hydrogen peroxide is formed in the living cell in the mitochondria, microsomes and in peroxysomes.[156–158] The formation of H_2O_2 also occurs on oxidation of NADPH in the endoplasmic reticulum. It was shown[159] that up to 15% of the total oxygen required by a cell for life is converted into H_2O_2.

The H_2O_2 content of different cells under dark conditions varies within wide limits, from 10^{-9} to 10^{-6} M.[159,160] In the case of algae the stationary H_2O_2 concentration reached in the medium on illumination with sunlight varies, depending on the species of algae and their functional state, within the limits 3×10^{-6} to 3×10^{-5} M.[109] It is probable that such high H_2O_2 concentrations are also reached in algae cells. Many algae express H_2O_2 to the external medium which indicates that processes using peroxide oxidation equivalents are weakly developed in them.

The enzymes superoxide dismutase, catalase and peroxidase serve as physiological regulators of the intracellular hydrogen peroxide content.[161,162] In a comparative study of the catalase activity of various species of blue-green and green algae, it was discovered that the blue-green were far less active.[163] In addition the catalase of blue-green algae proved to be more sensitive to the action of solar UV irradiation than did that of green algae.[164]

The deficiency of catalase activity in many algae is compensated by glutathione- and ascorbate-dependent peroxidases.[164] A high glutathione reductase activity and high concentration of glutathione (3×10^{-3} M) were discovered in the blue-green algae *Nostoc muscorum*[165] which is characterised by a high rate of H_2O_2 formation both in the dark and in the light.[148] This alga does not contain glutathione peroxidase,[166] but displays high dehydroascorbate reductase and ascorbate oxidase activity.

An overall scheme has been suggested for regulating H_2O_2 content in the cells of blue-green algae.[166]

where GSH (GSSG) and AA (DHA) are the reduced (oxidised) forms of glutathione and ascorbic acid respectively.

According to such a mechanism relatively large quantities of the H_2O_2, which passes into a cell at a rate up to 30% of the photosynthetic transport of electrons, may be destroyed.

In mammalian cells glutathione has a leading role in maintaining the stationary H_2O_2 concentration. This compound is the main stock of mobile sulphydryl groups and the dependence of the rate of the glutathione peroxidase reaction on hydrogen peroxide concentration complies with an equation of zero order.[167] Up to 70% glutathione peroxidase is found in the cytosol and 30% in the mitochondria. A feature of glutathione peroxidase is the ability to use fatty acid hydroperoxides as oxidising agents. This plays a decisive role in the regulation of peroxide oxidation of lipids. A supply of reduction equivalents in the form of NADPH is necessary for glutathione peroxidase to function.

Various amines and phenols are typical substrates for the peroxidase reaction.[168] The mechanism of action of peroxidase has

been discussed in detail.[134] A peroxidase function is possessed not only by the peroxidases themselves but also by other haem-containing proteins, particularly cytochrome P-450.[169] Chloroperoxidase occupies a special place among the peroxidases as it catalyses the decomposition of H_2O_2 as well as substrate oxidation.[170]

In its turn catalase also possesses peroxidase activity in relation to certain substrates.[171] Thus catalase participates in the peroxidase oxidation of ethanol,[162] causing the development of an unbalance in the redox state of the cell.[172]

The kinetic feature of catalase, in contrast to the peroxidases, is its absence of substrate saturation. When exogenous hydrogen peroxide passes into the cell, on average 40–60% of its metabolism is linked with catalase and the remaining peroxide participates in peroxidase oxidation processes.[173]

In addition to direct H_2O_2 formation in enzymic processes a large portion of the intracellular hydrogen peroxide is formed by the disproportionation of O_2^-.[153] According to one estimate,[160] the stationary concentration of O_2^- in liver mitochondrial membranes is 10^{-11} M. The O_2^- radicals formed in the cell participate both in dismutation reactions, catalysed by superoxide dismutase, and in the initiation of free radical processes.[174,175] In spite of the fact that the O_2^- radical is a natural metabolite of the cell, it is toxic in excess.[174,176]

Hydrogen peroxide may display a toxic effect at concentrations significantly exceeding the physiological.[177,178] At high concentrations hydrogen peroxide inactivates the transformation of DNA[179] and also induces chromosomal aberrations in ascites tumour cells.[180] Other physiological changes by the action of H_2O_2 are known.[178]

On the other hand the physiological concentration of H_2O_2 is not only non-toxic but is also necessary for normal cell activity.[155] It has been shown[172,181–183] that hydrogen peroxide participates in the regulation of cellular respiration. It was also shown that by itself H_2O_2 does not induce the peroxide oxidation of lipids,[184] it does not destroy mitochondria[185] but it is used by plant cells to induce intracellular reduction processes.[186]

It is known that a normal (stationary) level of peroxide oxidation of lipids is inherent for the cell membrane.[169] This is necessary for the regulation of the various cell functions and for the whole organism such as the setting of the metabolic state of the respiratory chain, changes of membrane permeability, etc. It is also known that lipoperoxides are obligatory intermediates in hormone biosynthesis (prostaglandin, progesterone), and participate in the hydroxylation of the cholesterol group of steroids.[175]

Under hyperbaric conditions a simultaneous increase occurs in the concentration of H_2O_2 and of free radicals in the cell which leads to a reduction in the NADPH/$NADP^+$ ratio. In its turn this causes a reduction in the content of reduced glutathione in the cell and correspondingly to the activation of peroxide oxidation of lipids. The reaction of O_2^- with H_2O_2, catalysed by metal complexes, may participate in the initiation of peroxide oxidation of lipids.[187,188] It was shown[184] that this reaction is also responsible for the inactivation of algae cells under the action of solar UV radiation.

This same reaction seemingly serves as a basis for the phenomenon of "photooxidising death", the sudden cessation of the "bloom" of blue-green algae in a deficiency of CO_2.[189,190] Under these conditions both hydrogen peroxide and its precursor, the O_2^- radical, are formed in the cell. The cells become sensitive to the action of light not only in the absence of CO_2 but also by the action of DCMM, the inhibitor of Photosystem II.[190] "Photooxidative death" is accompanied by decolourisation of the photosynthetic pigments, but this process is not linked with cell death.

The source of CO_2 in the "bloom" process of blue-green algae is not so much atmospheric carbon dioxide gas as the activity of bacteria. The more extended and stable bloom of eutrophated reservoirs in particular is linked with this circumstance.[191] The high sensitivity of blue-green algae to photooxidative inactivation explains why algae of this type are better able to function under conditions of oxygen deficiency, in a quasi-reducing medium and under weak illumination.

2. Exchange of oxidation–reduction equivalents between a cell and the external medium

Isolation of a cell from the extracellular medium is essential to preserve the continuity of the intracellular redox state. The presence of exchange with an extracellular redox system increases the possibility of a cell changing the direction of the intracellular redox processes but the danger of an adverse action of the external medium on the internal redox state of the cell is contained.

Many intracellular metabolic processes are linked with the transmembrane transfer of oxidation–reduction equivalents from the cell to the external medium and *vice versa*.

Hydrogen peroxide, together with O_2, serves as a carrier of oxidation equivalents in nature. Consequently the problem of H_2O_2 transport within the limits of the cell and through the cell membrane is important. It has been shown[155] that the mitochondrial membrane is weakly permeable to H_2O_2 while other biological membranes are fairly readily permeable. So from hyperoxic conditions, where large quantities of H_2O_2 are formed,[192] 10–40% hydrogen peroxide penetrates the cytosol and may then pass from the cytosol to the external medium[157] The high permeability of cell membranes for H_2O_2 also follows from the data on the kinetics of the formation and destruction of hydrogen peroxide in cultures of algae.[84,153]

Many intracellular metabolic processes are linked with the transmembrane transfer of reduction equivalents from the cell into the external medium. The obvious role of such exchange is displayed in the vital activity of microorganisms. Thus the initial stage of the multiplication of many bacteria is linked with the formation of a reducing medium.[193] If a substance having a reducing nature is introduced into the culture medium then the induction period in the multiplication of bacterial cells disappears but on introducing an oxidising agent it is increased.[193] In the growth process of bacterial cultures the redox potential of the medium is reduced and anaerobic strains are characterised by large shifts of potential in comparison with aerobic.

It has been shown[194] that ferricyanide is reduced in yeast cultures. Addition of citrate, a component of the Krebs cycle, accelerates this process, although citrate itself does not react with ferricyanide. This experiment shows that reduction equivalents formed in the Krebs cycle are partially eliminated into the external medium. The flux of reduction equivalents is determined by the intracellular redox system and is increased on inhibiting the processes transferring them to O_2.

Transfer of reduction equivalents to the external medium serves as one of the main processes securing the optimum redox state of the cell. An essential role in transmembrane transfer of reduction equivalents is assigned to the ascorbate/dehydroascorbate redox system.[155]

The available data show that a close interconnection exists between the metabolic activity of microorganisms and the redox state of the surrounding aqueous medium. The existence of a single

redox system for the intra- and extracellular media is in agreement with the ideas of Skadovskii,[195] who considered a reservoir to be a biological individual, and also with the hypothesis of Academician Vernadskii that natural water is a bioinert body.[196] In fact a natural aquatic medium like a monoculture of microalgae, must be considered as a specific organism possessing an insignificant integration of cells. In this "organism" extrametabolites of hydrobionts may play the role of "media hormones" regulating the composition of cenoses.[197] A decisive role in setting the qualitative state of an aquatic medium under natural conditions belongs to the smallest forms of hydrobionts, since, as emphasised,[195] the margin between physicochemical and biological processes is eroded as the dispersity of the hydroecosystem is increased.

Possible mechanisms for the participation of microorganisms in the redox systems within reservoirs include the following five main types of reaction:[151]

1) the excretion of a compound of a reducing nature into the external medium,

2) transmembrane electron transfer to an extracellular electron acceptor,

3) catalysis of extracellular redox reactions by an enzyme localised on the external surface of the cell,

4) catalysis of redox reactions by an extracellular enzyme bound to the cell surface with the participation of a reducing agent excreted by the cell,

5) catalysis by the cell surface of non-enzymic redox reactions with the participation of extracellular redox factors.

The expression of soluble organic compounds into the external medium is a characteristic of growing cells. According to one estimate[198,199] 5–10% of the total carbon of phytoplankton is expressed into the medium and serves as a source of reduction equivalents for carrying out chemical and biological reactions. Many of the excretions participate in complex-forming reactions with metals[200–202] and thereby affect their redox catalytic activity. Thus, certain aquatic microorganisms are capable of producing siderophores binding iron ions.[203] Other bacteria using sulphate as a source of electrons eliminate sulphides which participate in the reduction of metals.[204]

Electrons formed in the cell in photoreactions (or in respiratory processes) may be transferred to the outside of the cell surface and used in the reduction of various cellular substrates. These electron-transfer processes are effected by trans-plasma membrane reductase, which transports electrons from the intracellular donor (NADH, NADPH) to an extracellular electron acceptor. Such membrane-impermeable oxidising agents as ferricyanide, cytochrome C and copper complexes are reduced directly on the cell surface.

Microorganisms may also catalyse extracellular redox reactions (and hydrolysis reactions) through ectoenzymes immobilised on their outer surfaces. A whole class of surface enzymes exists, such as deaminases, typical of phytoplankton which catalyse the elimination of NH_4^+ on oxidation of nitrogen-containing organic compounds[151] with simultaneous reduction of O_2 to H_2O_2 (see Section IV).

In contrast to the intracellular enzymes functioning in strictly controlled conditions (ionic strength, pH, content of Ca^{2+}, Mg^{2+}, etc.) the ectoenzymes are closely dependent on the state of the external medium. In particular metal ions contained in the aqueous medium may lead to inactivation of ectoenzymes. For example, alkaline phosphatase in a phytoplankton culture or in full-scale samples are inhibited by copper(II) ions even at very low concentrations in the medium.[205] The high sensitivity of the ectoenzymes to the presence of metals may determine the ecotoxic properties of the latter, differing from their toxicity towards metabolic processes such as photosynthesis or respiration, which are integrated with a large number of biochemical reactions.

The reduction of extracellular substrates may also occur directly on the reduced parts of the cell surface without the participation of enzymes. Such reactions may proceed both in the dark and in the light. The reactions are non-enzymic and require regeneration of the reducing agent. The reduction of ions of copper and iron by microalgae cells may serve as an example of such reactions.[151]

Many forms of microalgae, including diatoms,[150] pyrophytes[206] and blue-green algae[207] reduce intracellular electron acceptors. Using *Thalassiosira weissflogii* as an example it was shown[208,209] that three types of reducing agents participate in these processes:

1) reducing agents eliminated by cells and not regenerated in the absence of microalgae,

2) reduced parts of the cell surface which may be inactivated by pretreatment of the algae with oxidising agents,

3) surface reductases, the activity of which does not depend on illumination.

There are compounds dissolved in the culture medium of *T. weissflogii* after filtration of the algae which reduce complexes of copper(II)[208] and iron(III).[209] The chemical nature of the reducing compounds is unknown. It has been suggested that they may be polysaccharides forming part of the cell wall (polygalacturonic acid) or a sulphydryl-containing protein or amino acid.[208]

Two types of reduction centre are encountered on the surface of cell membranes. In the alga *T. weissflogii* such centres are not regenerated, but are oxidised on preliminary treatment with copper(II) ions and such treatment does not affect the ability of cells to reduce metal complexes by the enzymic route. The surface redox reactions of cells are catalysed by reactive groups in the case of *Dunaliella tertiolecta*.[208]

The reduction of copper(II) occurs only in light (>425 nm) and the copper(I) ions formed are oxidised by molecular oxygen. Regeneration of the reduced groups on the cell surface is effected by extracellular photochemical processes. Intact cells of *T. weissflogii* reduce membrane-permeable copper(II) and iron(III) complexes with a potential in the range from −10 to +100 mV both in the light and in darkness by enzymic processes involving transmembrane reductases.[151] Plasma membrane redox activity is linked with the consumption of nitrate by the algae,[210] such that the rate of formation of reduction equivalents by the cell reaches 10% of the rate of reduction of nitrate.[15]

Transmembrane reductases are also present in other microalgae and macrophytes and probably in water bacteria. The evidence for this is the oxidation and reduction by cells of various membrane-permeable compounds. Plasma membrane redox systems also participate in the reduction of variable valency metal ions in cells of higher plants and mammals.[211]

Plant cells are able to reduce iron(III) chelates, including Fe EDTA.[212] This occurs in two ways. The first is by the action of ectoenzymes bound to the cell surface, forming NADH under the action of malate dehydrogenase and using the NADH in the reduction of iron(III) chelates by ferri-NADH oxidoreductase.[213] The second route is the formation of a superoxide radical in the plasma membrane redox system, this radical then participates in the reduction of Fe(III).[214] The extracellular reduction of iron is closely linked with its consumption by phytoplankton cells.[215–217] The subsequent oxidation by hydrogen peroxide of metal ions reduced by ectoenzyme action serves as an important link in the cycling of variable valency metal ions in aquatic media.

A numerical assessment has been made of the rate of formation of Cu(I) in coastal sea waters by the action of cellular water-soluble reducing agents.[69] This rate was 2 nmole litre^{-1} d^{-1} which proved to be 10 times greater than the rate expected for plasma membrane reductase of algal cells at a population of 10^7 per litre water. The conclusion was drawn that it was necessary to allow for the contribution of bacterioplankton and also of abiotic processes for a complete estimate of the reduction rate of copper.[151]

Confirmation has been obtained in the case of manganese of the participation of ectoenzymes both in its oxidation and in reduction. The manganese cycle in the illuminated zone of natural waters includes a redox transition between dissolved Mn(II) and particulate Mn(IV).[218–223] The oxidation of Mn(II) is effected by the photosynthetic activity of fresh water algae.[219] The resulting Mn(IV) forms part of the composition of extracellular carbonic anhydrase which catalyses the conversion of bicarbonate to CO_2. In oxygenated[220] and anaerobic[219] sea water the oxidation of Mn(II) by aquatic microorganisms is effected by a different mechanism. The measured rate of Mn(II) oxidation is 100 times greater than the rate of uptake of manganese by phytoplankton[220] and far greater than the rate of abiotic oxidation of Mn(II) in a sterile medium.

Two processes make the main contribution towards maintaining manganese in the reduced state in water close to the surface. These are the photoreduction of manganic oxide[222] and the reductive dissolution of MnO_x by hydrogen peroxide[224] produced particularly by phytoplankton aminooxidase.

Hydrogen peroxide is also implicated in the intra-algal iron cycle, participating in both the oxidation of Fe(II)[225,226] and in the reduction of Fe(III) in the light. Biota may promote these reactions through the activity of their own extracellular enzymes.

VI. Processes decomposing hydrogen peroxide in natural waters

The formation of H_2O_2 in natural waters by photochemical and catalytic processes is accompanied by processes decomposing it. Judging by the diurnal dynamics of the H_2O_2 content of aquatic media the processes forming and decomposing H_2O_2 are balanced and one may speak of the stationary (or quasi-stationary) concentration of hydrogen peroxide. This concentration depends not only on the rate of H_2O_2 formation but also on the kinetic characteristics of the decomposition process.

The decomposition of H_2O_2 in natural waters has been discussed many times.[31,80,82,152,227–230] The half-conversion time of H_2O_2 in eutrophic waters is about 1 h.[31] It has been shown[229] that in oligotrophic waters in the dark the half-conversion time for decomposition of hydrogen peroxide is 130 h and 10 h in fresh water. These data show that, as in the process of formation, abiotic and biotic processes may participate in the decomposition of H_2O_2.

1. Abiotic processes for the decomposition of H_2O_2 in natural aquatic media

The whole data accumulated on the catalysis of H_2O_2 decomposition by transition metal ions may be used to describe the abiotic processes of H_2O_2 breakdown in natural media.[134,231] Natural waters are characterised by a low metal ion concentration, neutral pH value, indefinite composition and low ligand concentration. Several monographs and reviews have been devoted to the study of the forms in which metal ions exist in natural waters.[200,201,232,233]

It may be concluded on the basis of the data available that of the metal ions, which are potential catalysts of H_2O_2 decomposition, only copper ions and chelate complexes of iron are found in a homogeneous state in natural aquatic media.[234]

The relative contribution of the various metal ions to H_2O_2 decomposition has been studied.[235] It was shown that the catalytic breakdown of hydrogen peroxide in neutral aqueous solution is effected mainly by microcolloidal iron hydroxide and by copper ions. In the first case the process is effected by a nonradical mechanism and in the second through the formation of free radicals.[132,236]

$$CuOH^+ + HO_2^- \rightarrow Cu^+ + O_2^{\cdot-}.$$

The reaction of Cu^+ and H_2O_2 has been studied in detail.[133] The primary product of this reaction is the CuO^+ species which may be considered as a hydrolysed Cu^{3+} ion.[1] In the absence of extraneous reactive substrates this species oxidises water (and is decomposed) with the formation of an OH radical.[133,237]

$$Cu^+ + H_2O_2 \xrightarrow[-H_2O]{} \begin{array}{c}(OH^-)CuO^+\\ \uparrow\downarrow -H^+\\ CuO^+\\ \uparrow\downarrow H^+\\ CuOH^{2+}\end{array} \xrightarrow[H_2O]{} CuOH^+ + \dot{O}H$$

In a similar manner the OH radical appears in the reaction of Fe^{2+} and H_2O_2 in neutral medium as a result of the conversion of a first-formed particle of the type of $FeH_2O_2^{2+}$ or FeO^{2+}.[1]

In the presence of an H donor species such as CuO^+ and FeO^{2+} react with the donor by a two-electron mechanism.[237]

$$CuO^+ + DH_2 \xrightarrow[-H_2O]{} Cu^+ + D.$$

In this case hydrogen peroxide is consumed in the catalytic oxidation of the donor without the formation of intermediate free radicals.

The H donors themselves (redox ligands) may participate in the formation of free radicals[239] by virtue of the specific property of partial charge-transfer of the complexes.[1,238]

$$Cu^{2+} + DH^- \rightarrow CuDH^+,$$
$$CuDH^+ + H_2O_2 \xrightarrow[-H_2O]{} Cu^{2+} + D^{\cdot} + \dot{O}H.$$

It must be emphasised that the metal ion in this reaction remains in the oxidised state. The introduction of redox ligands into an aqueous medium containing H_2O_2 and copper ions may initiate the formation of OH radicals in it, which play an important role in processes of self-purification of natural waters.[240] On the other hand the introduction of H_2O_2 into a medium containing the H donor DH_2 may lead to the oxidation of this reducing agent without the formation of free radicals.

$$Cu^+DH_2 + H_2O_2 \xrightarrow[-2H_2O]{} Cu^+ + D.$$

Strictly speaking these two extreme cases also illustrate the difference in principle between the two redox situations which may occur in natural waters, viz. an oxidative and a quasi-reductive state of the aquatic medium (see below). In the first case reducing agents initiate the breakdown of H_2O_2 into free radicals, in the second hydrogen peroxide is consumed in the oxidation of a reducing agent introduced into the medium.

In addition to catalytic breakdown, the decomposition of H_2O_2 into free radicals by solar radiation is important under natural conditions.[96,241,242]

2. The role of microalgae in H_2O_2 decomposition

The separation of the biotic and abiotic contributions to the kinetics of H_2O_2 decomposition[230] observed in natural waters is extremely arbitrary since natural water is in principle a catalytic oxidation–reduction system of an open type. As a result of the activity of microorganisms there is a constant exchange in it of oxidation–reduction equivalents between the biota and the aquatic medium. It is possible to interrupt this flux by filtration of water samples through a fairly fine porous filter (usually 0.22 μm). However, stopping the flux changes the observed kinetic picture in an appreciable manner. Consequently more adequate information may be obtained by combining full-scale investigations on H_2O_2 decomposition in natural waters[80,82] with the investigation of model systems in cultures of algae and bacteria.

A detailed study of the kinetics of H_2O_2 decomposition by microalgae has been carried out.[152,153] The main conclusion of the investigations was the existence of two basic types of biotic processes of H_2O_2 decomposition which differed in the dependence of reaction rate on the initial hydrogen peroxide concentration.

For young cultures of algae the reaction is first order with respect to H_2O_2 concentration and its rate (w_1) is proportional to the biomass of the microorganisms (chlorophyll concentration).[152] In the case of natural algocenoses and old cultures there is in addition a contribution from a reaction of zero order with respect to H_2O_2 concentration,[84,153] the rate of which (w_0) is also proportional to the biomass of algae. The relative contributions of the first and zero order reactions depends on the initial hydrogen peroxide concentration (the greater its concentration, the greater the contribution of the first order reaction) and also on the state of algocenosis or of the alga culture.

Investigations carried out with whole and powdered algae and adding inhibitors of various reactions showed[84] that the first order reaction is caused by the action of catalase, while peroxidase processes make the main contribution to the zero order reaction. The catalase reactions are localised in the cell membrane fractions and the peroxidase in the water soluble fraction (not separated on centrifugation for 5 min at 10000 rpm).

Kinetic saturation of the peroxidase reaction at relatively low H_2O_2 concentrations is linked with the limited rate of intake (w_r) of peroxidase substrates (H donors). Experiments with an added dehydrogenase inhibitor (*m*-cresol) showed[84] that substrates of the peroxidase reaction pass into the medium as a result of the action of dehydrogenases.

It was shown[82] that reducing agents, H donors, react efficiently with H_2O_2 and are not only formed in algae cells but are also eliminated from them to the external medium. The rate of formation of reducing compounds (w_r) is proportional to the algal biomass and depends on the ecological situation in algocenosis. Blue-green algae are the most efficient producers of reducing agents.

The rate of decomposition of hydrogen peroxide in natural waters (w_d) is determined by the rate of formation of reducing compounds and the rate of their catalytic decomposition (w_1).

$$w_d = w_0 + w_1 = w_r + \varkappa_1 [H_2O_2],$$

where $\varkappa_1$ is the observed first order rate constant.

In a quasi-stationary state the rate of decomposition of H_2O_2 coincides with its rate of formation (w_f).

$$w_d = w_f = w_r + \varkappa_1 [H_2O_2].$$

From which it is obvious that

$$[H_2O_2] \simeq (w_f - w_r)/\varkappa_1.$$

In other words, the content of hydrogen peroxide in a natural aquatic medium is determined by the difference in the rates of flux within the reservoir of H_2O_2 and reducing agents which react with O_2 far less efficiently than with H_2O_2. The two redox states of the aquatic medium, which differ in principle, are distinguished by the ratio of these rates (see above).

As was indicated, a change in the redox state of the medium accompanies the bloom of blue-green algae and is caused by their ability to produce reducing compounds in the external medium which react efficiently with H_2O_2.

VII. Radical processes for self-purification linked with the hydrogen peroxide cycle

As is seen from the data given in Sections IV and VI the processes of forming and breaking down H_2O_2 in natural waters are accompanied by the formation of free radicals in the medium. Of the other processes leading to free radicals mention must be made of the possible role of radiochemical processes, collapse phenomena (effects of cavitation of gaseous microbubbles in deep tanks[243,244]), acoustic phenomena,[245,246] uptake of reactive atmospheric gases[94,247–249] and biological processes.[250]

Radiochemical processes are only effected after radiation contamination of a locality,[249] since the natural radiation background is small. The contribution of collapse and acoustic phenomena to the formation of free radicals has not been studied quantitatively. The uptake by water of atmospheric ozone may make a significant contribution.[249,251]

In the absence of contamination, O_3 dissolved in water breaks down by a radical chain mechanism with the participation of $\dot{O}H$, and $O_2^{\dot{-}}$ radicals in chain propagation reactions.[248,252–254] Ozone reacts with reducing agents (H donors), when present in the water, with subsequent breakdown into radicals.[248]

$$O_3 + DH^- \rightarrow HO_3 + D^{\dot{-}},$$
$$HO_3 \rightarrow \dot{O}H + O_2.$$

Quantitative assessment of the contribution of the various routes to the formation of free radicals is difficult.[96] For practical purposes it is important to have an estimate of the stationary concentration of free radicals. It is possible to obtain this assessment both by direct measurements and by calculation, determining independently the rate of formation of radicals and the observed rate constant of their destruction in the medium in question.

1. Free radicals in natural waters

The methods of detecting free radicals in natural waters are based on the use of various types of radical "trapping". Depending on concentration, the "trap" may intercept either all the radicals formed in the medium or only a small proportion of them. In the first case the rate of formation of radicals in the system is determined from the rate of supply of the trap or the rate of accumulation of its reaction product with the radical. In the second case, knowing the

rate constant for the reaction of the trap with a given radical, it is possible to assess the stationary concentration in the medium.

Mill and collaborators[93] applied the trap method to the assessment of the free radical content of natural waters for the first time. They used toluene to intercept ȮH radicals and pyridine to intercept RO_2 radicals.

The dye *p*-nitrosodimethylaniline (PNDMA), which is widely used for the same purpose in radiation chemistry, was used as a trap.[81] This dye is gradually decolourised in samples of natural waters, chemical–biological processes making a decisive contribution. The rate is sharply reduced in filtered samples.

The trapping method has been significantly improved in recent years. The use of stable nitroxyl radicals for trapping gives the best results.[255–262] The stable product formed with this or with any radical may be identified chromatographically and the nature of the initial radical is thereby clearly established. Using such traps data have been obtained on the stationary concentrations and formation rates of free radicals and of other reactive intermediates in various natural waters (Tables 2 and 3).

Table 2. Typical values for the concentrations of reactive intermediates in natural surface waters.[107,261,262]

measured by the rate of decolourisation of PNDMA in distilled water. The proportion of radicals participating in the reaction with inhibitors of radicals contained in a water test sample is determined by the rate of decolourisation of PNDMA in natural water. Since the values of k_i for the overwhelming majority of traps lie in the range 10^8 to 10^{10} M^{-1} sec^{-1},[264] it may be assumed that $k_i \sim 10^9$ M^{-1} sec^{-1} and, depending on the size of the $\Sigma k_i[S_i]$ parameters, the observed concentration in aqueous medium of the trap for ȮH radicals (S_e) is assessed from:

$$S_e = \Sigma[S_i] \approx 10^{-9}.(\Sigma k_i[S_i]).$$

Table 3. Measured and estimated stationary concentrations and production rates (w) of ȮH radicals under the action of sunlight in samples of sea and fresh water.[96]

2. Kinetic methods of assessing the stationary concentration of radicals and their role in the self-purification of natural aquatic media

As has been indicated it is necessary to know the rate of formation and the observed rate constant for disappearance in order to assess the stationary concentration of free radicals.

The last of these parameters is determined fairly simply for ȮH radicals using PNDMA. A method has been developed[81,240] for measuring the "inhibiting ability" parameter in an aqueous medium, viz. $\Sigma k_i[S_i]$ sec^{-1} where S_i is the trap for ȮH radicals contained in the water, k_i the rate constant for the reaction of ȮH with the trap S_i. The essence of the method is that ȮH are formed by the photolytic decomposition of H_2O_2 and the rate of formation is

If H_2O_2 is added to natural waters and the change in S_e is followed as H_2O_2 is decomposed, then it is possible to estimate the fraction of H_2O_2 decomposing into radicals.

$$\alpha = \Delta S_e/\Delta[H_2O_2].$$

According to one estimate[265] this fraction varies for different natural waters from 0.1 to 0.5 and is 0.3 on average. Thus about 30% hydrogen peroxide is decomposed into ȮH radicals in natural waters.

The process of forming H_2O_2 also proceeds through the intermediate formation of radicals. As was shown in Section IV, $O_2^{\cdot-}$

radicals serve as precursors of H_2O_2. The disproportionation of two $O_2^{\cdot-}$ radicals in neutral medium occurs with low efficiency,[266] and at low formation rates the catalytic processes involving copper ions are more probable.

$$O_2^{\cdot-} + Cu^{2+} \rightleftharpoons CuO_2^{+} \rightleftharpoons Cu^{+} + O_2,$$
$$O_2^{\cdot-} + Cu^{+} \rightleftharpoons CuO_2^{+} \xrightleftharpoons{2H^+} Cu^{2+} + H_2O_2.$$

The magnitudes of the rate constants for the reactions of $O_2^{\cdot-}$ with Cu^{2+} and Cu^{+} are close[267] so that the ratio of the rates of these reactions is determined by the redox ratio $[Cu^{2+}]/[Cu^{+}]$. In an oxidising medium the reaction of Cu^{+} with H_2O_2 leads to a reduction in the H_2O_2 yield due to the reaction of $O_2^{\cdot-}$ with Cu^{+}. This is reflected in the observation that in the presence of the enzyme superoxide dismutase (SOD) the rate of H_2O_2 formation in natural waters is usually increased.[98,99] If the rate of H_2O_2 formation is half the formation rate of $O_2^{\cdot-}$ radicals in the presence of SOD then in its absence a portion of the $O_2^{\cdot-}$ radicals participate in the reduction of H_2O_2 to OH radicals.

$$O_2^{\cdot-} + H_2O_2 \xrightarrow[H^+]{Cu^{2+}/Cu^{+}} O_2 + \dot{O}H$$

Correspondingly, it is possible to assess the extent of transformation of initially formed $O_2^{\cdot-}$ radicals into OH from the difference in the rates of the photochemical formation of H_2O_2 in the presence and absence of SOD. This fraction varies depending on the chemical composition of the aquatic medium, but is usually about 50%.

In the quasi-stationary approach the rates of formation and breakdown of H_2O_2 are therefore equal to one another and in these processes the rate of OH radical formation is an appreciable fraction of the hydrogen peroxide formation or decomposition. For a rough assessment of the rate of formation of OH it is possible to take the rate of the photochemical formation of H_2O_2 in the aquatic medium:

$$w_i \approx w_f.$$

Knowing w_f and the parameter $\Sigma k_i[S_i]$, it is possible to assess the stationary OH concentration and the apparent rate constant for the radical oxidation of any contaminating substance P (k_p):

$$[OH] = w_i/\Sigma k_i[S_i],$$
$$k_p = k_{(OH+P)}[OH] = k_{(OH+P)}w_i/\Sigma k_i[S_i],$$

where $k_{(OH+P)}$ is the bimolecular rate constant for the reaction of OH with P.

Various peroxidase self-purification processes are efficiently brought about in the presence of H_2O_2 in aquatic media in addition to the radical reactions.[152] Thus 3,4-dichloroaniline undergoes practically no conversion in a state of natural algocenosis in the dark in the absence of added H_2O_2 and is rapidly consumed if hydrogen peroxide is added to the algae.[265] In a similar manner various amines, which are peroxidase substrates, are oxidised on storing with algal cultures.[152]

The rate of the H_2O_2 cycle within reservoirs thereby reflects the efficiency of radical (and peroxidase) processes of self-purification of aquatic media. This enables assessment of the potential for chemico-biological self-purification of aquatic media, which is essential for assessing the acceptable loading of organic contaminants in natural reservoirs both in combination with and in relation to individual compounds.[71] The quantity of hydrogen peroxide formed (and decomposed) in natural waters gives an idea of the quantity of dissolved organic compounds which may be oxidised in extracellular chemico-biological processes (the chemico-biological self-purification potential). Under actual conditions a portion of the H_2O_2 is formed without the formation of reactive intermediates and the breakdown of H_2O_2 may be effected by a catalase mechanism, also without the formation of intermediates.

VIII. The hydrogen peroxide cycle within reservoirs and the biological wealth of aquatic media

On a global scale the fluxes of oxidation and reduction equivalents in the biosphere are balanced in the processes of photosynthesis and respiration. In addition to this global redox system there also exists in natural waters quasi-stationary redox subsystems comprising hydrogen peroxide and reduction equivalents of biotic origin. In view of the diversity and complexity of the mechanisms of H_2O_2 reactions with indigenous reducing agents under natural conditions, useful information for describing them adequately may be obtained from a study of model catalytic redox systems.

1. Modelling redox processes involving hydrogen peroxide within reservoirs

Ascorbic acid, hydroquinone and glutathione stand out among the most widely distributed reducing agents in nature as peroxidase substrates.[155] The redox catalytic reactions involving ascorbate ion have been studied in most detail.[268] As was indicated above, ascorbic acid is oxidised more efficiently by oxygen than by hydrogen peroxide. Another feature of ascorbic acid is the initiation of coupled processes of radical oxidation of various compounds difficult to oxidise.[239] A third feature is that ascorbic acid is an efficient H donor, for example in relation to organic radicals,[137] preventing the oxidation of organic substances. At the same time ascorbic acid radicals, stabilised by a system of double bonds, are kinetically extremely inert.[138]

Hydroquinone is a precursor of aquatic humus. In spite of its wide practical use in various investigations the mechanism of the redox catalytic reactions of hydroquinone are still unclear. A detailed kinetic investigation has been carried out of the catalytic oxidation of hydroquinone by hydrogen peroxide in the presence of copper ions.[269] It was found that in addition to non-radical processes hydroquinone participates in coupled radical oxidations of compounds difficult to oxidise. Hydroquinone thereby serves as the most suitable reducing agent to put into the medium in the presence of H_2O_2 to model the radical self-purification process induced by reducing compounds of biogenic origin.

Thiol compounds form part of proteins, humic compounds and metabolic products of water organisms, particularly micro-algae.[270,272] However the mechanism of the catalytic redox reactions involving thiols, and glutathione in particular, has been insufficiently studied. This gap has been partially closed.[269] It was shown that glutathione possesses extremely important features.

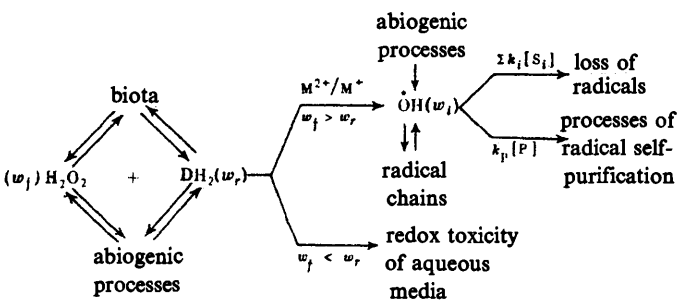
First of all glutathione readily reduces copper ions and forms stable (covalent) mono and less stable bis complexes with Cu^{+}.

$$2Cu^{2+} + 2GSH \xrightarrow[-2H^+]{} 2Cu^{+} + GSSG,$$
$$Cu^{+} + GSH \rightleftharpoons CuGSH^{+},$$
$$CuGSH^{+} + GSH \rightleftharpoons Cu(GSH)_2^{+}.$$

The complexes $CuGSH^+$ and $Cu(GSH)_2^+$ reversibly add O_2 (see Ref. 273) but are not decomposed to electron transfer products. The reduction of O_2 is effected directly to water by reaction of the oxygenated complex with a second glutathione copper complex, avoiding the formation of intermediate hydrogen peroxide.

$$Cu(GSH)_2^+ + O_2 \rightleftharpoons (GSH)_2CuO_2^+,$$

$$(GSH)_2CuO_2^+ + Cu(GSH)_2^+ \xrightarrow[-2H_2O]{} 2Cu^+ + 2GSSG.$$



Evidently the oxidation of glutathione will proceed extremely slowly at low natural concentrations of copper.

The glutathione Cu^+ complexes react far more efficiently with hydrogen peroxide.

$$Cu(GSH)_2^+ + H_2O_2 \xrightarrow[-2H_2O]{} Cu^+ + GSSG.$$

Glutathione and seemingly other thiol compounds bind copper ions in the form of unreactive, biologically inaccessible complexes. Glutathione may thereby work as a reducing agent, modelling the onset of toxicity and the inhibition of self-purification processes of natural aquatic media by reducing toxicants.

Generalised results of full-scale and laboratory investigations[274] have enabled us to propose a dynamic chemico-biological redox model for natural aquatic media.

The gist of the model is as follows. In a natural aquatic medium biotic and abiotic processes are in constant operation forming oxidation and reduction equivalents, which react with one another. The results of these interactions are determined by the ratio of the fluxes within reservoirs of reactive oxidation equivalents, hydrogen peroxide (w_f) and the reducing compounds (DH_2) reacting efficiently with them (w_r). If the flux of oxidation equivalents predominates ($w_f > w_r$), an oxidative state is set up in the medium. Reducing agents entering the medium are either oxidised by hydrogen peroxide or initiate conjugated radical processes of self-purification of the aquatic medium from the contaminating compounds (P). If the flux of reducing agents exceeds the H_2O_2 flux ($w_r > w_f$) then a quasi-reductive redox state is set up in the aquatic medium (on increasing the flux the reducing agents will be gradually oxidised by oxygen dissolved in the water). Under these conditions various toxic effects arise in the water.[82]

2. Hydrogen peroxide and the biological wealth of an aquatic medium

The participation of H_2O_2 in the self-purification of an aquatic medium is closely linked with maintaining its biological wealth. However there is another aspect to biological wealth connected with the hydrogen peroxide cycle within reservoirs. One speaks of the redox-toxicity factor of a medium which arises when quasi-reductive conditions become established in an aquatic medium.[80,82]

It has been shown[275] that the presence of H_2O_2 is necessary in an aquatic medium for the development of fish in the early stages. This is linked with the possible participation of peroxy oxidation equivalents in bringing about metabolic redox processes. In fact a certain optimum H_2O_2 content exists in a natural aquatic medium, at which the chemico-biological redox processes within the reservoir are balanced. Unbalance of these processes may lead to two specific situations.

As was indicated in Section VII, in an aquatic medium the H_2O_2 cycle is closely linked with the free radical cycle. At the same time (see Section V) the H_2O_2 cycle is closely linked with the microelement cycle (particularly manganese ions). On increasing the free radical processes the oxidation of Mn(II) may be accompanied by the formation of metastable microcolloidal particles with mixed valency Mn(III,IV)[276,277] possessing strongly expressed oxidative properties. This is linked with the fact that the Mn(IV) ion, although having a high oxidation potential, is extremely inert in reactions of ligand substitution by virtue of the particular features of its electronic structure (d^3). Correspondingly the reduction of Mn(IV) by reducing compounds is brought about comparatively slowly. The Mn(III) ion (d^4), on the other hand, has a labile coordination sphere and is an efficient oxidising agent, possessing a high oxidation potential. The Mn(III) ion in microcolloidal particles of mixed valency is reduced to the Mn(II) ion which readily disproportionates with a neighbouring Mn(IV) ion with the formation of two more Mn(III) ions, i.e. particles with even more marked oxidative properties. The formation of such particles is particularly characteristic of aquatic media subjected to radiation contamination.

The hyperoxidising state of the medium, when metastable microcolloidal particles of bound or adsorbed Mn(III,IV) are present in the water, proves to be toxic for fish, a disease of the gills is observed. The factors controlling the emergence of the hyperoxidising state of the medium have not yet been clarified. Another, more completely studied phenomenon linked with the unbalancing of oxidation-reduction processes is the formation of a quasi-reducing state of an aquatic medium (see Section VI). Under these conditions a whole range of negative factors arise.

There is seemingly a reduction in the ability of the medium towards self-purification which leads to the accumulation of a whole series of toxic agents in the water.

Since the emergence of quasi-reducing conditions is usually accompanied by vigorous development of blue-green algae in the water, the majority of negative consequences are linked with precisely this factor. Blue-green algae occupy a special position in the ecosystem of modern reservoirs. In summer months they frequently become the dominant species in the phytoplankton.

The combination of an ability to photosynthesise, to consume organic compounds from the external medium[278] and to fix atmospheric nitrogen[279] causes the high adaptability of these microorganisms. In comparison with green algae and diatoms, blue-green algae effect photosynthesis at far lower light intensities and in the dark respiration consumes far less energy. The inhibitory effects of elimination and breakdown products of blue-green algae have great importance for other representatives of the algoflora.[280] Blue-green algae are most suited to living in reducing conditions. In the bottom layers of water they may vigorously assimilate sulphur in its sulphydryl form.[281]

The massive development of blue-green algae leads to many negative consequences. At bloom in a reservoir the pH of the medium increases, sometimes to values of 10–12. This creates

pathogenic microflora and of stimulants of intestinal illnesses, including cholera bacillus.[281] The situation is very dangerous when, in their life cycle, many forms of blue-green algae eliminate into the aquatic medium compounds which possess a strong toxic action.[280,282–285] Cases of mass destruction of animals and diving birds linked with the bloom of blue-green algae have been recorded in many regions of the Earth since the middle of this century.[286]

---o0o---

The combination of literature data and our investigations indicates the important role of hydrogen peroxide in the aquatic component of the environment. Seemingly the evolution of aerobic life in the ocean also proceeds with the participation of H_2O_2 as the basic form of activated oxygen.[287] The oxidising character of the medium is also a condition for the rich functioning of the water ecosystem.

Under the influence of anthropogenic factors the content of H_2O_2 in natural aquatic media may be increased or decreased. An increased concentration of H_2O_2 into the overshoot zone is recorded on dropping unpurified domestic effluent into a reservoir. A sudden reduction of hydrogen peroxide concentration is possible on dropping biologically purified effluent into the reservoir due to reaction with reducing compounds introduced with the effluent.

The content of H_2O_2 in the air and in atmospheric moisture may be reduced (with SO_2 overshoot) or increased (with overshoot of organic substances) in a similar way. When the air is contaminated with sulphur oxides, sulphuric acid and incompletely oxidised sulphite will enter the soil ecosystem in place of oxidation equivalents such as H_2O_2. Such a substitution has an unfavourable action on the functioning of the soil ecosystem.[288]

In addition to its effect on the oxidation-reduction state of aquatic media, hydrogen peroxide makes an appreciable contribution to the formation of free radicals and participates in the self-purification of waters from difficultly oxidisable organic compounds. Free radicals may also have a significant effect on the biological richness of aquatic media, participating in the oxidation of compounds involved in biochemical cycles, in the initiation of peroxide oxidation of lipids, etc. Seemingly in natural waters, as in the cell, there is a physiological optimum both in H_2O_2 content and in the stationary concentrations of active intermediates.

The effect of anthropogenic factors on the H_2O_2 content of natural waters may be compensated by artificial addition of oxidation equivalents (H_2O_2, soluble peroxy compounds) to water or to the soil ecosystem (in irrigated farming). By varying the H_2O_2 content it is possible to regulate the biological richness of aquatic media, to suppress the development of undesirable microorganisms, blue-green algae in particular, and to intensify self-purification processes. The practical application of such measures to large bodies of water and areas requires large quantities of H_2O_2. Consequently a promising direction for investigation is the design of heterogeneous systems (with combined photo-sensitisers) generating H_2O_2 efficiently under the action of sunlight. The manufacture of small scale electrochemical generators of H_2O_2 based on the cathodic reduction of O_2 would also be promising.

An absolute requirement is the putting into practice of prophylactic measures to prevent the introduction of reducing compounds into reservoirs together with effluent which has passed biological purification. Water-submersible sources of UV irradiation may be used for this purpose. Under the action of hard UV radiation H_2O_2 is formed in waste water, radical chain oxidation processes are initiated, pathogenic microflora perish, aromatic compounds are hydroxylated, organochlorine compounds are dechlorinated and the overall content of dissolved organic compounds is reduced.

Regrettably the solution of many ecological problems encounters a shortage of H_2O_2. In practice H_2O_2 is not used in the purification of waste water, in spite of the fact that there is a multitude of patents to that effect and hydrogen peroxide is applied widely worldwide in the purification of domestic and industrial waste water.[289]

Supercritical extraction and prospects for the creation of new waste-free products

A A Pichugin, V V Tarasov
Mendeleev Moscow Institute of Chemical Engineering

ABSTRACT. The principal ideals underlying a new separation procedure—supercritical extraction—are described and its advantages and disadvantages are considered. The properties of supercritical gases such as solvent power and selectivity are discussed. The possibilities of supercritical extraction in the solution of applied problems in the protection of the environment are demonstrated: purification of waste waters, regeneration of sorbents, detoxification of toxicants.

The bibliography includes 32 references.

I. Introduction

The tasks faced by modern chemical engineering in connection with the problems concerning the protection of the environment can be performed only on the basis of the ecological optimisation of the existing and the creation of new low-energy low-waste chemical processes. One of the promising aspects of the creation of such processes, which has been attracting increasing attention by investigators and technologists during the last decade, is based on the use of supercritical gases as extractants and solvents for the extraction, separation, and purification of substances and also as a medium for various chemical reactions.[1] Although the first studies on the application of supercritical gases as solvents were published as early as the past century,[2] systematic fundamental and applied research in this field dates back to the 1970s, which is associated with the increasing urgency of energy saving and environmental protection problems. Among studies carried out hitherto on these lines, the vast majority are devoted to supercritical extraction (SE) of various substances both from the standpoint of the investigation of the physicochemical features of supercritical extraction and from the standpoint of its chemical-analytical and technological applications.

Supercritical extraction is a method for the extraction of components of solid or liquid mixtures into a supercritical gas phase, which plays the role of an extractant in this case. The supercritical gas (*supercritical fluid*) is a substance in a supercritical state, i.e. at a temperature and pressure above its critical point. By virtue of their low critical temperatures, carbon dioxide, ethane, ethylene, propane, sulphur hexafluoride, etc. have found the greatest number of applications in research and technological practice as extractants. Among them the greatest popularity is enjoyed by supercritical CO_2 because of its high solvent power in relation to many organic substances, ready availability, low cost, non-combustibility, and non-toxicity. A significant advantage of supercritical gases (SG) compared with the usual liquid solvents (extractants) is that the solvent power of such gases exhibits a marked dependence on temperature and pressure, which makes it possible to regulate extremely (i.e. by varying the temperature T or the pressure p) the selectivity of the supercritical extractants and also to achieve the complete regeneration of the extractant without resorting to reagent methods or distillation. Another attractive aspect of the application of supercritical gases is that high molecular diffusion coefficients (higher by 1–2 orders of magnitude than for the usual liquids) and low viscosities (approaching the usual gases in terms of order of magnitude) are characteristic of such substances.

Although supercritical extraction is a new and relatively expensive process, the results of a whole series of resarch studies have already found industrial applications and have been commercialised. For example, certain new technological processes based on supercritical extraction in the USA include the regeneration of the adsorbents and catalysts, the extraction of certain toxic organic substances from aqueous solutions and the soil, the elimination of asphaltenes from heavy petroleum fractions, the removal of sulphur from coal, the extraction of caffeine from coffee grains, the extraction of certain biologically active substances from plant raw material, etc. The range of industrial applications of supercritical extraction has been gradually expanding.

Supercritical extraction has been finding increasing applications in analytical chemistry as a selective method for the separation and concentration of components of complex mixtures of organic substances.

Bearing in mind that it is impossible to cover fully in a single article the present state of research into the field of supercritical extraction, which has recently acquired an interdisciplinary character, and also the fact that no reviews have so far been published on this topic in Russian scientific literature, the aim of the present study is to give an account of the main ideas underlying supercritical extraction and its practical importance and in addition to reflect certain latest tendencies in the development of this promising field.

II. The properties of supercritical gases as extractants

Supercritical gases occupy, as it were, an intermediate position between the usual gases and the usual liquids, combining the properties of both and possessing at the same time their own intrinsic properties. The supercritical state is a qualitative state of

matter in which the gaseous and liquid state become indistinguishable.[3] It is shown on the phase diagram (Fig. 1) that, on moving along the path (indicated by an arrow in Fig. 1) passing through the supercritical region, it is possible to achieve a transition from the liquid to the gaseous state and conversely without first-order phase transitions (in this instance this would be evaporation and condensation).

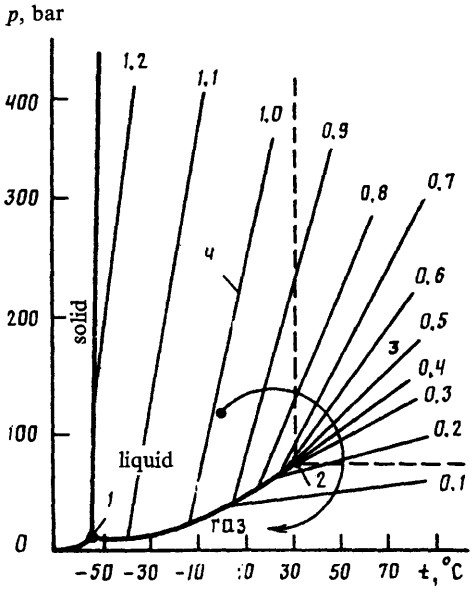

Figure 1. Temperature–pressure diagram for CO_2 with an indication of constant density lines: *1*, triple point; *2*, critical point (critical temperature −31.06 °C; critical pressure 73.8 bar); *3*, supercritical region; *4*, density lines.

One of the most important qualities of a supercritical gas as an extractant is its solvent power. It is determined by the molecular structure and density of the supercritical gas and can be characterised qualitatively by the solubility parameter δ (the square root of the cohesion energy density). This quantity can be rigorously calculated from thermodynamic properties by using the Hildebrandt theory.[3] The solvent power of a supercritical gas increases with increase in temperature at a constant density and with increase in density (pressure) at a constant temperature. The pressure dependence of the solubility parameter is illustrated in Fig. 2 for gaseous, liquid, and supercritical CO_2. Evidently δ for gaseous CO_2 is close to zero and at a temperature below the critical value (in the given instance $t = -30$ °C) the entire variation of δ with increasing pressure consists in an abrupt rise of δ until the attainment of a certain pressure p, which is caused by the condensation of CO_2. The parameter δ for liquid CO_2 differs only slightly from the value for organic solvents, for example solvents such as toluene, hexane, etc.[3,4] At a temperature exceeding the critical value (the cases corresponding to 32 and 70 °C are illustrated), increase in p does not induce a first-order phase transition and there is a possibility of a smooth regulation of the solvent power (δ) within wide limits by means of relatively small changes in temperature or pressure. The greatest changes in δ (as well as in the density—see Fig. 1) are observed in the vicinity of the critical point, since the compressibility becomes virtually unlimited at the critical point. The possibility of regulating the solvent power of a supercritical gas and hence the solubility of the components being extracted by varying the pressure or temperature is a unique characteristic quality of supercritical gases from the standpoint of their use as extractants.[5]

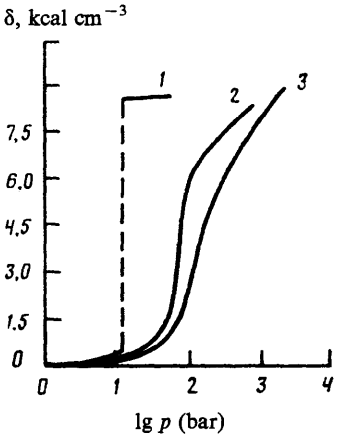

Figure 2. Dependence of the solubility parameter (δ, kcal$^{1/2}$ cm$^{-3/2}$) on pressure for CO_2 at different temperature (°C); *1*, −30; *2*, +32; *3*, +70.[1]

The solubility of the extracted components in a supercritical gas is determined by the characteristics of their partition between the phases in contact at equilibrium. Modern thermodynamics makes it possible to describe fairly reliably and in many instances with a high degree of accuracy the phase equilibria in various systems involving a supercritical gas. A detailed description of such problems may be found in the literature.[5–10] Here we shall deal only with the fundamental features important for the understanding of which factors determine the solubility of substances in a supercritical gas and the selectivity of the supercritical extraction.

We shall consider the relatively simple case of the equilibrium distribution of the components i between the solid (s) and supercritical (sp) phases. The equality of the fugacities of the ith component in the phases corresponds to the state of equilibrium:

$$f_i^s = f_i^{sp}. \quad (1)$$

The fugacities of the components can be determined using the fugacity coefficients ϕ_i:

$$f_i = y_i \phi_i p. \quad (2)$$

In Eqn. (2), p is the pressure and y_i the mole fraction of the component i in the supercritical phase or the vapour. For the

simplest case, where the solid phase consists of the component i, one can write[8]

$$y_i^{sp}\phi_i^{sp}p = \phi_i^s p_i^s \exp\int_o^p (V_i^s/RT)dp, \quad (3)$$

where p_i^s is the vapour pressure of the component i at a temperature T, ϕ_i^s the fugacity coefficient of the component i corresponding to the pressure p_i^s, V_i^s the molar volume of the component i, and ϕ_i^{sp} the fugacity coefficient in the supercritical phase. If the molar volume V_i^s is independent of p, then Eqn. (3) becomes

$$y_i^{sp}\phi_i^{sp}p = \phi_i^s p_i^s \exp\left(\frac{V_i^s(p-p_i^s)}{RT}\right). \quad (4)$$

Hence it is possible to find the solubility of the component i in the supercritical phase:

$$y_i^{sp} = \frac{p_i^s}{p}\left[\frac{\phi_i^s}{\phi_i^{sc}}\exp\left(\frac{V_i^s(p-p_i^s)}{RT}\right)\right]. \quad (5)$$

The multiplier in square brackets in Eqn. (5) is the intensification factor E, which shows by what factor the real solubility of the component i in the supercritical phase (y_i^{sp}) is greater than in an ideal gas (p_i^s/p):

$$E = \frac{\phi_i^s \exp\left(\frac{V_i^s(p-p_i^s)}{RT}\right)}{\phi_i^{sp}}. \quad (6)$$

The numerator in Eqn. (6) characterises the influence of pressure on the fugacity of the compound i, while the denominator (ϕ_i^{sp}) reflects the influence of the intermolar interactions in the supercritical phase and of the density. The quantity ϕ_i^{sp} may be found from equations of state such as the Soave–Redlich–Wang or Penn–Robinson equations.[3] It follows from Eqn. (6) that a component with a greater molar volume V_i^s is characterised also by a greater factor E for the same p and T and for identical intermolecular interactions in the supercritical phase. In terms of order of magnitude, the factor E is usually in the range 10^4-10^7 for substances of different types. Fig. 3 presents the dependences of E on the density of the supercritical CO_2 for a series of polar organic compounds with different functional groups.[11] Evidently the factor E varies in the series of these compounds approximately within the limits of one and a half orders of magnitude. At the same time, it has been shown[11] that the range of solubilities in the series of these compounds is much greater and corresponds to several orders of magnitude because the solubility is determined not only by the intensification factor, characterising the solvent–solute interactions, but also by the vapour pressure [Eqn. (5)]. The influence of the vapour pressure on the solubility and hence on the selectivity is illustrated in Fig. 4, which shows the dependence of the solubility of tetracyclic sterols having similar properties in supercritical CO_2 on the density of the latter. The solubility of cholesterol is greater by two orders of magnitude than that of ergosterol. This finding can be explained by the fact that the two compounds, having similar values of E, have very markedly different (by approximately two orders of magnitude) vapour pressures, that of cholesterol being higher, although they are both very low ($<10^{-10}$ bar).[12] Thus the selectivity of the supercritical extraction is proportional to the ratio of the vapour pressures although, the latter can in fact be negligibly low. With increase in p_i^s, the solvent–solute interactions, i.e. the factor E, make an increasing contribution to the selectivity.

The initial addition to the supercritical gas, for example to CO_2, of hydrocarbons and polar organic solvents is an extremely effective procedure for increasing the solubility of the extracted components in the supercritical phase and of the selectivity of the extraction.[5,13] This method has been widely used in research and technology because it significantly extends the limits of the applicability of supercritical extraction.[14] The most frequently employed additives (modifiers) of this kind in CO_2 are propane, hexane, alcohols (methanol, ethanol, octanol), acetone, tributyl phosphate, etc.[14] Such modifiers not only make it possible to increase the solubility and selectivity but in the vast majority of cases increase the dependence of the solvent power of the extractant on the pressure and temperature and make it possible to reduce the working pressure p and temperature T and also to reduce the amount of extractant consumed. The mechanism of the action of modifiers varies and depends on their nature. For example, propane, which has a high solvent power in relation to petroleum products, sharply increases their solubility in a CO_2–propane mixture compared with pure CO_2.[14] In contrast to supercritical CO_2, which is a lipophilic solvent with a very low dielectric constant ($\varepsilon = 0.5$ at $t = 50$ °C and $p = 250$ bar), polar organic substances are capable of forming donor–acceptor complexes of the extracted components, which affect the solubility and selectivity to a much greater extent than might have been expected on the basis of their fugacities alone.[13] Certain examples of an increase in solubility in the presence of polar modifiers are presented in Table 1. The last two rows of the table are noteworthy. They show that even ionic surfactants, in the given instance sodium 2-ethylhexyl sulphosuccinate, can be used as modifiers. Even ethanol-modified supercritical CO_2 is incapable of dissolving large amounts of hydrophilic substances. However, as can be seen from Table 1, in the presence of surfactants CO_2 is able to solubilise hydrophilic molecules as a result of the formation of reverse micelles or microemulsions.[1]

In many cases components entering into the composition of a complex mixture treated by the supercritical gas can play the role of modifiers. In this instance, being dissolved in the supercritical phase, some components increase the solubility of others, as happens, for example, on treatment of a naphthalene–benzoic acid mixture with supercritical CO_2.[15] A synergistic effect is observed in this case (Fig. 5), i.e. the solubility in the ternary system (two solutes, one solvent) exceeded the solubility in the binary system (one solute, one solvent).

III. Organisation of the supercritical extraction process

The organisation of the supercritical extraction process is illustrated schematically in Fig. 6.[16] The extractant (supercritical gas) passes in a continuous stream through the extractor (a mixer or a column apparatus), where it comes into contact with the solid or liquid mixture to be treated, extracting the soluble components. After emerging from the extractor, the extractant containing the dissolved target components is then subjected to a treatment, the main purpose of which is to isolate the target product from the extract and hence regenerate the extractant. This is achieved by a controlled decrease in temperature or pressure. Subsequently the parameters (p and T) of the regenerated extractants are adjusted to the required values and the extractant is again directed to the extractor, the circulation of the extractant being thereby achieved. Fig. 7 illustrated schematically the separation of components A and

B when component A is completely miscible with the supercritical gas. Evidently the complete separation of A and B can be achieved only when the extractant and component B are not infinitely miscible. A number of principal advantages and disadvantages of supercritical extraction as a technological process are presented below.[14,17,18]

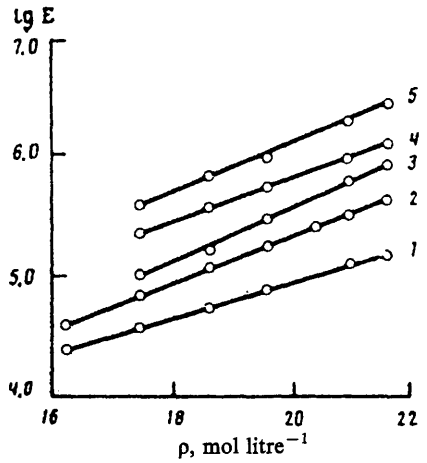

Figure 3. Dependence of the intensification factor E on the density (ρ) of supercritical CO_2 (t = 35 °C) for various substances: *1*, hexamethylbenzene; *2*, naphthol; *3*, phthalic anhydride; *4*, anthracene; *5*, acridine.[11]

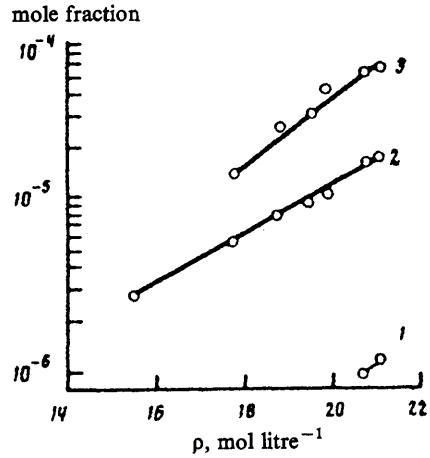

Figure 4. Dependence of the solubilities of various sterols in supercritical CO_2 (t = 35 °C) on its density: *1*, ergosterol; *2*, stigmasterol; *3*, cholesterol.[12]

Advantages: in terms of solvent power, supercritical gases are comparable to liquid organic solvents; the solvent power of supercritical gases and the solubility of the extracted components can be varied by altering p or T; it is possible to regenerate the extractant fully by altering p or T; high diffusion coefficients and low viscosities of supercritical gases; low working temperatures; low energy consumption in the process.

Table 1. The influence of modifiers on the solubilities of the extracted components in supercritical CO_2 at 35 °C.[13]

Extracted component	Modifier	F*
Acridine	Methanol (3.5%)	2.3
2-Aminobenzoic acid	Methanol (3.5%)	7.2
Cholesterol	Methanol (3.5%)	100
Hydroquinone	tri-n-butyl phosphate (2%)	300
ditto	Ethanol (5%)+surfactant** (0.5%)	>200
Tryptophan	Ethanol (5%)+surfacant (0.5%)	>100

* F is a parameter showing by what factor the solubility increases in the presence of the modifier.

** The surfactant employed was sodium di-2-ethylhexyl sulphosuccinate.

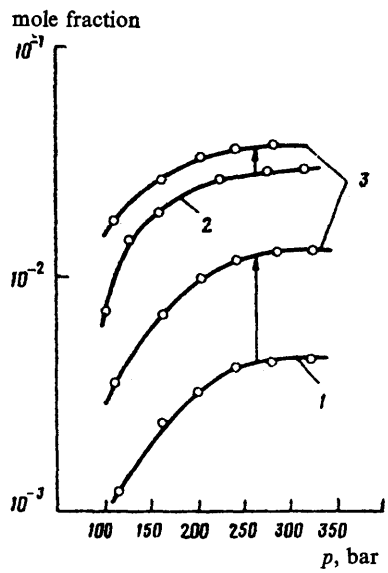

Figure 5. Mutual influence of naphthalene and benzoic acid in their extraction by supercritical CO_2 (t = 35 °C); dependence of the solubility in supercritical CO_2 on pressure in different systems: *1*, benzoic acid–CO_2; *2*, naphthalene–CO_2; *3*, (naphthalene + benzoic acid)–CO_2.[15]

Disadvantages: increased working pressure; high cost of equipment; unusual process conditions for many undertakings; complex character of the phase equilibrium in systems with supercritical gases.

IV. Applications of supercritical extraction

As shown by the analysis of the literature, among the wide variety of aspects of the technological applications of supercritical extraction, the aspects concerned with the protection of nature are nowadays of perhaps greatest interest because in this field the advantages of supercritical extraction make it extremely attractive for the solution of a wide range of applied problems.

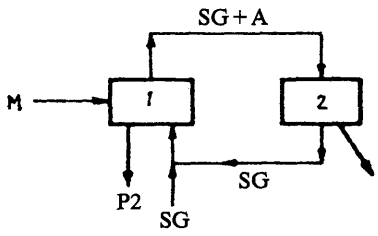

Figure 6. Schematic illustration of the supercritical extraction process: *1*, extraction; *2*, regeneration of the extractant and isolation of the products; M—mixture of components A and B undergoing separation: P1—product enriched in component A; P2—product enriched in component B.

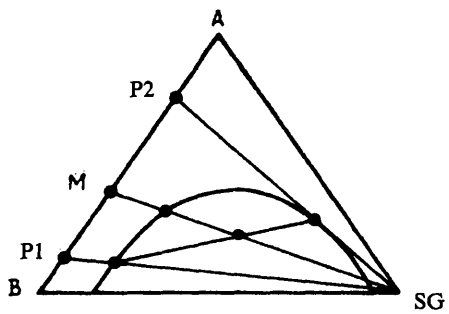

Figure 7. Schematic illustration of a binary mixture M of components A and B by supercritical extraction in conformity with the scheme presented in Fig. 6.

The processes based on the application of supercritical gases can be arbitrarily divided into three categories: single-stage separation, two-stage separation, and separation with simultaneous chemical conversion of the extracted components. In the single-state separation, the initial treated material is brought directly into contact with the supercritical gas, for example, in order to remove toxicants or to extract valuable components. In the two-stage separation, the initial treated material, for example water contaminated by organic toxicants, is brought into contact not with the supercritical gas but with an extracting phase of another type, usually a sorbent. Next, the sorbent is regenerated by being treated with the supercritical gas. In processes of the third category, the initial treated mixture is brought into direct contact with the supercritical gas, which functions not only as a solvent (extractant) but serves at the same time as a medium for the occurrence of chemical reactions, for example, such as oxidation of organic toxicants.

The single-stage separation is most suitable in those cases where the concentration of the extracted components in the mixture is relatively high. For example, processes involving the extraction of phenol, alcohols, aldehydes, and ketones from aqueous waste solutions by supercritical CO_2 and hydrocarbons have been developed for such cases.[19–23,27] The extraction of pyrethrin, for example, from plant raw material by means of supercritical CO_2 has proved extremely effective. Pyrethrin is extremely toxic to insects and is almost harmless to warm blooded animals. This substance is unstable and does not accumulate in the environment, in contrast to pesticides. The use of supercritical extraction for such purposes has made it possible to reduce almost by a factor of two the capital and operating costs compared with the usual multistage liquid extraction.[24,25] Another example of a single-stage process is the extraction of highly toxic organic substances, such as chlorine-containing pesticides and polychlorinated biphenyls from the soil and solid waste by supercritical CO_2.[24,26] The efficiency of the single-stage separation increases significantly when modifiers, increasing solvent power, are introduced into the supercritical gas.

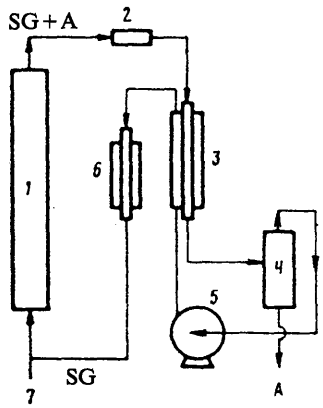

Figure 8. Schematic illustration of the sorbent regeneration process with the aid of supercritical extraction: *1*, apparatus in which the adsorbate is extracted from the sorbent by the supercritical gas; *2*, reductor; *3*, heat exchangers; *4*, separator; *5*, compressor; 6, heat exchanger; *A* = adsorbate.

The two-stage separation is extremely effective at low concentrations of the contaminant. In this case, supercritical extraction provides excellent possibilities for the regeneration of widely used sorbents such as activated charcoals and synthetic polymeric sorbents.[28–30] The usual regeneration methods, such as treatment with live steam and heat treatment, involve an extremely high energy consumption and are expensive. Compared with these methods, the use of supercritical extraction makes it possible, for example, to reduce by a factor of two the cost of regeneration of the sorbent in the purification processes for the waste waters from the industrial manufacture of pesticides involving the removal of contaminants such as atrazine, dinitrobutylphenol, alachlor, etc.[29]

An extremely important advantage of supercritical extraction is also the many-fold increase in the useful life of the sorbent, because it does not lose appreciably its properties even after many regeneration cycles. Fig. 8 illustrates schematically the regeneration of the sorbents by supercritical CO_2.[28]

The use of supercritical gases as a medium for chemical reactions has great potential possibilities. Supercritical water has attracted increasing attention of investigators and technologists in this connection. On passing to the supercritical state, the properties of water are radically altered and it becomes similar to non-polar organic solvents in terms of its solvent power. Supercritical water hardly dissolves in organic ionic substances and is completely miscible with hydrocarbons.[31] In supercritical water ($t > 374$ °C, $p > 218$ atm), organic toxicants can be oxidised by atmospheric oxygen to simple products such as CO_2, etc.[31] The study of the properties of supercritical water had made it possible to develop an effective process for the removal from waste waters of toxic organic components such as chlorine-containing pesticides, polychlorinated biphenyls, trichloroethane, perchloroethylene, etc.[31,32] The only reagent used in this process is compressed air. The degree of conversion of all the toxicants investigated into simple products as a result of oxidation was more than 99.99%, which exceeds significantly the degrees of conversion achieved in the combustion of toxic waste. The fact that, in contrast to combustion, the oxidation of, for example, chlorinated aromatic hydrocarbons in supercritical water does not involve the formation of dangerous toxicants such as dioxins and dibenzofurans is also important. Technical-economic estimates have shown that the cost of combustion exceeds significantly the cost of the process involving the use of supercritical water, which is associated with the lower consumption of fuel in the latter case. Fuel is necessary only in the initial stages of the process in order to establish the required temperature, which is then maintained as a result of the exothermicity of the oxidation reaction.

Another important example of the use of supercritical gases both as solvents and as reactants is the desulphurisation of coals by supercritical ethanol. Suphur-containing organic compounds are extracted into supercritical ethanol and are reduced there to products such as ethyl sulphide, and ethyl disulphide, thiophene, etc. Such treatment makes it possible to reduce the sulphur content in coal by a factor greater than 2.[24]

Extracting emulsions for the extraction of substances from aqueous media

E V Yurtov, M Yu Koroleva
Mendeleev Moscow Institute of Chemical Engineering
EKOSPEKTR NPP

ABSTRACT. The characteristic features of the extracting emulsions used to extract and concentrate substances from aqueous solutions are examined. The influence on the properties of the extracting emulsions of the conditions in their preparation, of the properties of the disperse phase (the ionic strength and the pH of the aqueous solutions), the properties of the dispersion medium (viscosity, dielectric constants), as well as the presence of polar organic substances in the emulsions is discussed. The influence of the nanodispersion formed on mass transfer through the interface and on the properties of the extracting emulsions is demonstrated. The approaches to the mathematical description of the kinetics of the processes in extracting emulsions are discussed and it is shown that extracting emulsions with various properties designed for a wide variety of applications can be developed on the basis of the study of the physicochemical properties of such disperse systems.

Examples of the use of extracting emulsions in chemical engineering for the extraction of substances from aqueous media by membrane extraction into a multicomponent emulsion, for preliminary concentration in analysis, for therapeutic and prophylactic purposes in medicine, and for the protection of the environment are considered.

The bibliography includes 102 references.

I. The membrane extraction method and extracting emulsions

Considerable interest in extracting emulsions, i.e. emulsions extracting or concentrating various substances, arose in connection with the first publications on membrane extraction into a multicomponent emulsion.[1,2]

Nowadays, together with the overall increased interest in liquid membranes,[3,4] a method of membrane extraction into a multicomponent emulsion has been developed for applications in various fields: for the isolation and concentration of substances from technological solutions, in analytical practice, in the solution of problems concerned with the protection of the environment, and for the detoxification of biological liquids involving the removal of harmful substances of exogenic and endogenic origin.[5–12]

The extraction and re-extraction stages in the membrane extraction process occur simultaneously in a system comprising three liquid phases. One of the phases (the liquid membrane) separates two solutions of different composition and immiscible with it: the initial solution (to be exhausted) and the re-extracting solution (the recipient) (Fig. 1). The membrane usually consists of an organic liquid, but systems are known with an aqueous membrane, used mainly for the separation of organic compounds.[13–19]

The membrane extraction method has many advantages compared with the usual extraction. One of the main ones is the reduction of the number of stages in the process. The combination of extraction and re-extraction makes it possible to achieve in a single stage the maximum possible, for the given system, differences between the concentrations of the extracted substance between the extracted and receiving phases. If the extracted substance in the phase F1 (Fig. 1) is bound in a weakly dissociating complex or forms an insoluble compound, then this ensures the most complete extraction from the initial phase F1.

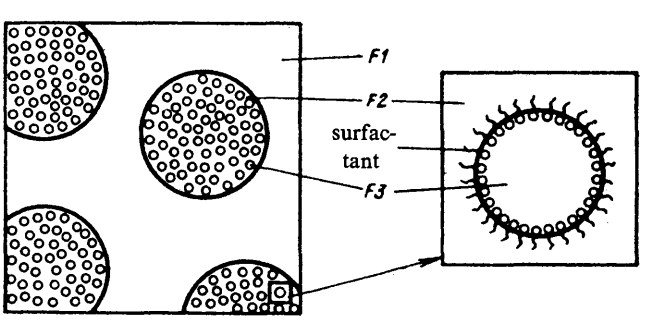

Figure 1. A multiple emulsion: F1 = solution to be extracted; F2 = liquid membrane (dispersion medium of the extracting emulsion); F3 = recipient solution (disperse phase of the extracting emulsion).

The degree of extraction in the membrane extraction process depends mainly only on the compositions of the initial and receiving solutions. The extractant in the phase F2 (Fig. 1) is merely a transferring agent, which interacts with the extracted substance

during its transport from the phase F1 to F3. Therefore the liquid membrane does not as a rule have to meet the requirements of a high capacity and high partition coefficients. The extractant-transferring agent determines mainly the rate and selectivity of the process. Thus in membrane extraction it is possible to use low concentrations of the transferring agents in the liquid membrane or to employ extractants which are relatively ineffective from the standpoint of two-phase extraction as transferring agents. This factor is attractive not only because of its economic aspect but also because of its ecological aspect.

Membrane extraction is a promising procedure for correcting the homeostasis and detoxification of biological liquids[8-11,20,21] and also for the extraction of metabolic products from enzyme solutions.[22,23] In this case, membrane extraction has an additional advantage associated with the possibility of preventing (or reducing to a minimum) the direct contact between the substances contained in the internal phase with the biological medium by virtue of the presence of the liquid membrane, consisting in the given instance of inert substances and, if necessary small amounts of the transferring agent. The amount and type of transferring agent are chosen to ensure, on the one hand, an acceptable rate of transport of the extracted substance through the liquid membrane and, on the other hand, so as not to traumatise the biological medium from which extraction takes place.

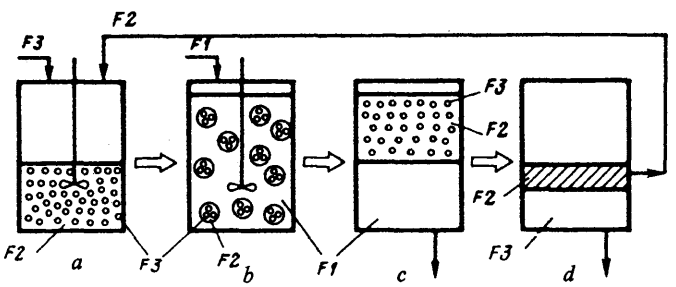

Figure 2. Schematic illustration of the membrane extraction process in a multiple emulsion: *a*, preparation of the extracting emulsion; *b*, bringing of the extracting emulsion into contact with the solution to be extracted; *c*, separation of the refined solution; *d*, separation of the extracting emulsion into layers.

In the case of extraction in a multiple emulsion, the process takes place in a system consisting of the extracting emulsion dispersed in the solution F1 to be extracted. The dispersion medium of the extracting emulsion F2 is the liquid membrane. The extracted solution F3 is dispersed in the liquid membrane F_2 with the aid of a surfactant (Fig. 1). The entire process consists of four stages (Fig. 2). In the first stage, the re-extracting aqueous solution is vigorously dispersed ($\omega = 200-2000\ s^{-1}$) in the organic phase containing the transferring agent and the emulsifier and an emulsion of the "water in oil" type is obtained (Fig. 2*a*). It is then brought into contact with the solution to be extracted under the conditions of "gentle" stirring ($\omega = 10-50\ s^{-1}$). This extracting emulsion is dispersed into individual globules and a multiple emulsion of the "water–oil–water" type is formed (Figs. 1 and 2*b*). At the end of the mass transfer, the extracting emulsion is separated from the refined product by means of gravitational separation into layers (Fig. 2*c*) and in the final stage the aqueous phase enriched in the target component and the organic phase are separated (Fig. 2*d*).

One of the characteristic features of the membrane extraction process in a multiple emulsion is the possibility of the constant renewal of the interface in the extracting emulsions during stirring, which is a positive factor in the extraction of substances in systems where interfacial films are formed. Such interfacial films, which retard the rate of diffusion of substances between phases, can be produced into systems containing both inorganic substances[24,25] and organic (protein) compounds.[26]

In analytical practice, the extracting emulsions can be used for the preliminary concentration of substances. Here not only the stability of the emulsions but also the distribution of water in the system, frequently leading to the "swelling" of emulsions (the transport of water into the extracting emulsion), which lowers the rate of concentration of the extracted substance, is very important. The use of kinetic factors for optimising the extraction time makes it possible, as will be shown below, to reduce to a minimum the negative effect of the swelling of extracting emulsions.

The region of possible applications of extracting emulsions is much wider than merely in the process involving membrane extraction in a multiple emulsion. Extracting emulsions can be used for the detoxification of various surfaces and media in the solution of ecological and medical problems. In particular, the employment of extracting emulsions as protective-prophylactic ointments, protecting (and cleaning) the skin against the action of harmful substances of different origin, in the first place the toxic substances present in industry, is a very promising application.[10,27] Extracting emulsions used for this purpose consist of thin films in which the contribution of the heterocoagulation resulting from the effect of the surface of the skin is enhanced.

II. Properties of extracting emulsions

The extracting emulsions must meet a number of requirements which are essential for their effective utilisation. These are stability throughout the period of application of extracting emulsions and minimal water transfer to the inner phase of the emulsions. It is also essential that the emulsions should be fairly stable throughout the long period of their storage before use. The emulsions must have definite properties depending on the specific process in which they are applied. Thus in technological processes, where the extracted component is concentrated in the inner aqueous phase, and the emulsions must then be separated into layers, the latter must be fairly stable throughout the extraction process, but after extraction they must be capable of separating rapidly into layers with the aid of the available methods. The emulsions used in medicine must be highly stable in order not to release the inner phase of the emulsion into the biological fluid.

In order to increase the capacity of the extracting emulsions, use is usually made of concentrated disperse systems, close to highly concentrated systems, with a volume fraction of the inner phase $\varphi = 0.6-0.7$. The view has been expressed in the literature that extracting emulsions with $\varphi > 0.5$ have a comparatively low stability,[28] but under certain conditions not only systems with $\varphi > 0.5$ but also highly concentrated emulsions with $\varphi > 0.74$ proved to be stable.[29]

An increase in the fraction of the inner phase above the theoretically possible value (φ_{theor}) for spherical particles of the same size (φ_{theor} is 0.741 for hexagonal packing, 0.686 for cubic centred packing, 0.524 for cubic packing, 0.340 for tetrahedral packing, and 0.64 for random packing[30,31]) involves the deformation of the drops of the disperse phase. Furthermore, real emulsions are polydisperse, which makes it possible to obtain stable emulsions with a high fraction of the disperse phase. The size distribution of the drops is an important characteristic of the extracting emulsion, which influences the stability of the system, its rheological properties, and other technological characteristics. The difference between the size distributions of the drops in emulsions having the same composition is one of the main causes of the discrepancies sometimes observed between the results of studies on membrane extraction in a multiple emulsion.

The properties of the extracting emulsions and in particular their stability are in many respects determined by the degree of dispersion of the inner phase.[28,32–34] The smaller the drop size, the higher the stability of the emulsion obtained. The influence of factors such as the type of stirring device,[28,38] the intensity of stirring, surfactant concentration,[33,34] etc. on the degree of dispersion has been noted.

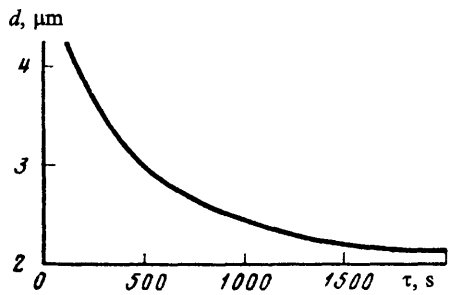

Figure 3. The effect of the emulsification time on the size of the drops of the inner phase of the emulsion of water in xylene (volume fraction of the inner phase $\varphi = 0.5$).[34]

Stirring for a period longer than the optimum time gives rise to little improvement in the quality of the emulsions.[33,34] The average drop size diminishes rapidly in the course of the first seconds of the emulsification process (Fig. 3).[34] With decrease in the size of the drops, their rigidity also increases and their size becomes comparable to the size of the eddies in the apparatus and there is no further dispersion. The viscosity of the emulsion diminishes during dispersion (Fig. 4).

The influence of the rate of stirring and of the surfactant concentration on the inner phase drop size is similar to the influence of the emulsification time (Fig. 3).[34]

As the temperature in the mixer is altered, there is a change in the surface tension, viscosity, and adsorption of the emulsifier. The decrease in viscosity and surface tension with increase in temperature improves the emulsification but under these conditions there is a sharp diminution in the degree of adsorption of the surfactant, which lowers the stability of the emulsions.

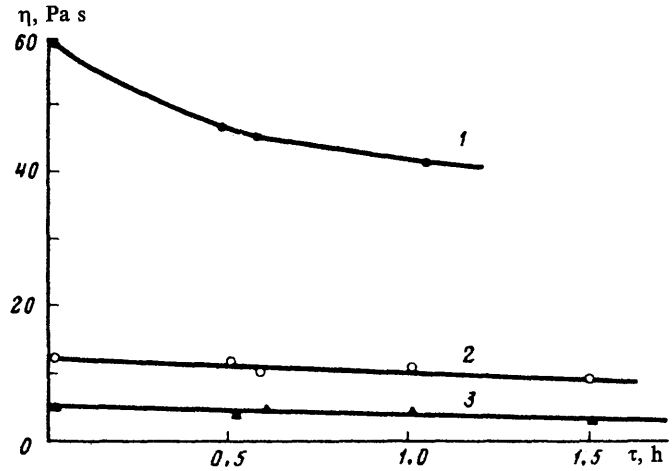

Figure 4. Dependence of the viscosity of the emulsion (η) on the dispersion time after the addition of the inner phase has ended;[34] temperature 25 °C; volume fraction of the inner phase: *1*, 0.65; *2*, 0.50; *3*, 0.40. Rate of displacement 3 s^{-1}.

With increase in the surfactant concentration, the stability of the adsorption layer is known to increase and hence there is an increase in the resistance of the emulsions to coalescence.[33] The dependence of the stability of the emulsions on the surfactant concentration show a maximum at 0.02 M (C_1) for hostacerin DGO and 0.45 M (C_2) for sorbitan oleate (Fig. 5).

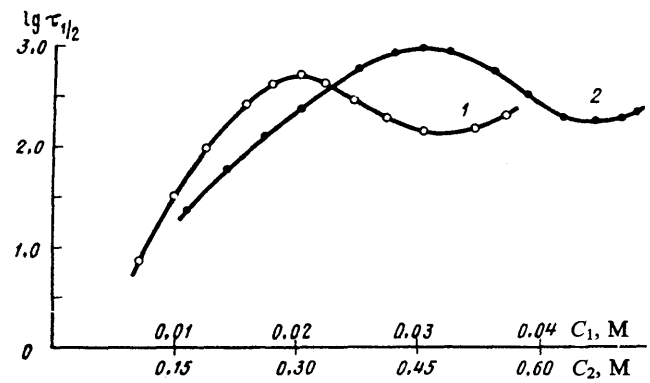

Figure 5. Dependence of the half-separation period ($\tau_{1/2}$) of the aqueous phase of the emulsion at 25 °C on the concentrations of hostacerin DGO (C_1, curve *1*) and sorbitan oleate (C_2, curve *2*). Fraction of inner phase 0.65. Isotonic buffer solution at pH 7.4 in liquid paraffin.

As mentioned above, the radius of the inner phase drops in emulsions initially diminishes with increase in the surfactant concentration and then remains constant,[34] which is associated with

the fact that the disperse system tends to the minimum interfacial energy possible for the given amount of the surfactant, so that, despite the high degree of dispersion of the inner phase, the drops coalesce until the attainment of an emulsifier content at the interface close to the limiting degree of sorption. When the surfactant is present in an amount sufficient for the stabilisation of all the drops of the interface formed as a result of the dispersion, the maximum stability of the emulsion is attained (under the given dispersion conditions).[35]

The increase in the viscosity of the emulsion is also associated with the decrease in the inner phase drop size (for φ = const.) (Fig. 6). After the attainment of the limiting degree of adsorption, the excess surfactant dissolves in the liquid membrane, the viscosity of the emulsions remaining virtually constant under these conditions.

At surfactant concentrations in the dispersion medium exceeding the critical concentration for the formation of non-spherical micelles (CCM-2), structure formation takes place in the organic phase and the viscosity of the emulsions increases with increase in the emulsifier concentration (Fig. 6).

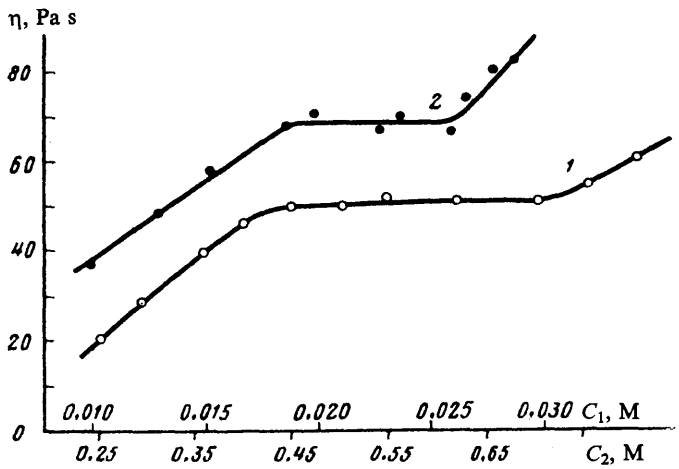

Figure 6. The influence of the concentrations of hostacerin DGO (curve *1*) and sorbitan oleate (curve *2*) on the viscosity of the emulsions at a rate of displacemnt of 3 s^{-1}. Fraction of inner phase 0.65; temperature 25 °C.

The study of the ξ-potential of the inner phase drops showed that, with increase in surfactant concentration above the value necessary for the complete saturation of the adsorption layer at the interface in the emulsion, the ξ-potential of the inner phase drops is seen to decrease. This lowers the repulsion energy between the disperse phase drops, which increases the rate of their coalescence and hence leads to a decrease in the stability of the emulsions.

Some increase in the stability of the emulsions at surfactant concentrations exceeding the CCM-2 in the liquid membrane is apparently associated with the formation of a heteroadsorption layer owing to the adsorption of the surfactant micelles at the interface.[36] When the repulsion energy of the adsorbed micelles exceeds their attraction energy, there is some increase in the stability of the emulsions.

Variation of the fraction of the inner phase in the emulsion leads to the variation of the specific interface. A definite position of the maximum in the dependence of the stability of the emulsion on the fraction of the disperse phase corresponds to each surfactant concentration (Fig. 7). The maximum stability corresponds to the complete saturation of the adsorption layer. For higher fractions of the inner phase at a specified surfactant concentration, the adsorption layer proves to be unsaturated and the stability of the emulsion is therefore diminished; for small fractions of the inner phase, when the interface in the emulsion is saturated to the maximum extent with surfactant molecules, the stability diminishes owing to the presence of an excess surfactant in the dispersion medium, i.e. an effect analogous to the dependence of the stability of emulsions on the surfactant concentration is observed (Fig. 5).

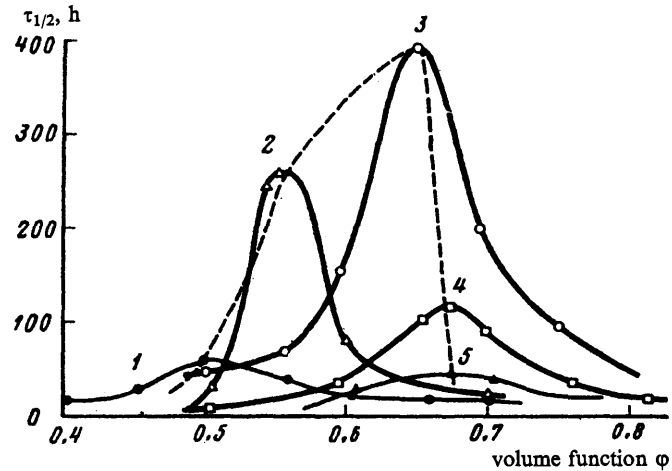

Figure 7. Dependence of the half-separation period of the inner phase of the emulsions at 60 °C on the initial fraction of the inner phase at different molar concentrations of sorbitan oleate: *1*, 0.24; *2*, 0.35; *3*, 0.45; *4*, 0.50; *5*, 0.55.

With increase in the surfactant concentration, the maximum in the stability of the emulsion shifts towards higher fractions of the inner phase.[37] At a surfactant concentration exceeding 0.02 M for hostacerin DGO and 0.45 M for sorbitan oleate, the stability maximum shifts towards higher fractions of the inner phase, but the absolute stability diminishes, the amount of surfactant necessary for the limiting degree of adsorption increasing sharply. For higher fractions of the inner phase, the shape of the drops deviates from the spherical and the drops are distorted, which reduces the stability of the extracting emulsions.

Thus in order to determine the quantitative composition of the most stable emulsion with the given qualitative composition, it is essential to take into account the interrelated influence of the fraction of the inner phase and the surfactant concentration.

The properties of the extracting emulsions can be varied by altering the composition of the dispersion medium, its viscosity, and its polarity. An increase in the viscosity of the outer phase of the emulsions can evidently ensure a certain kinetic stability of the

emulsion as a result of the decrease in the rate at which the thickness of the liquid film between the two surfaces diminishes as the drops of the inner phase approach one another. This fact can play a significant role in reverse emulsions. Fig. 8 presents the dependence of the half-separation time of the aqueous phase of the emulsion on the viscosity of the dispersion medium μ in the range of viscosities of hydrocarbon oils. Fig. 8 shows that the variation of the viscosity of the dispersion medium in the given range exerts an insignificant influence on the stability of the emulsions, but does influence appreciably their viscosity.[38] By altering the ratio of different oils in the organic phase of reverse emulsions, it is possible to alter the viscosity and other properties of the compositions without impairing the stability of the extracting emulsions.

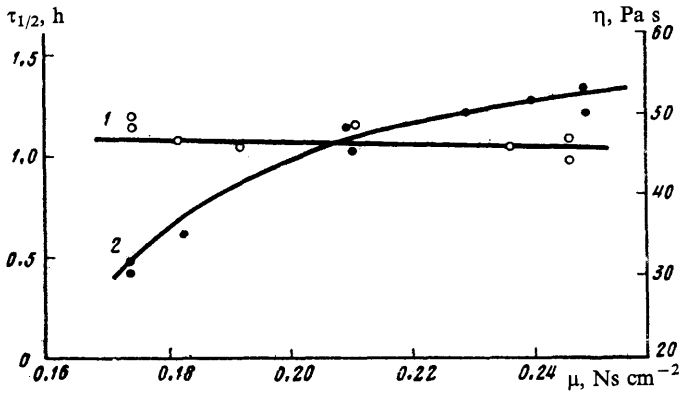

Figure 8. Dependence of the half-separation period of the aqueous phase (curve *1*) and of the viscosity of the emulsion (curve *2*) on the viscosity of the dispersion medium (μ).[38]

However, when the range of viscosities of the dispersion medium is widened, for example, by adding a hydrocarbon with a lower viscosity (decane), the stability of the emulsion is seen to decrease. Although in concentrated emulsions, close to highly concentrated ones, the thickness of the layers of organic phase is small (~20 nm), the hydrodynamic factor plays a fairly considerable role in the stability of the emulsions. Therefore, from the standpoint of the stability of the emulsions, it is useful to employ dispersion media with a fairly high viscosity and account must be taken of the fact that under these conditions the rate of diffusion of the target component falls in membrane extraction in a multiple emulsion.

The extractant-transferring agent forming part of the composition of the dispersion medium exerts a significant influence on the stability of the extracting emulsions. The extractants-transferring agents possess as a rule surface-active properties[24,39] and they therefore reduce the stability of the emulsions as a result of competitive adsorption at the interface. However, as shown previously, in the case of membrane extraction there is no need for high concentrations of the extractants-transferring agents in the liquid membrane and therefore in each specific case it is possible, as a rule, to select the necessary concentrations of the transferring agents both from the standpoint of the rate of extraction of the target component and from the standpoint of the stability of the extracting emulsion.

Apart from the above factors, the stability of the extracting emulsions is influenced significantly by the composition of the disperse phase. Among the factors playing the greatest role in their stability, mention may be made of the pH of the disperse phase, the ionic strength, and the presence of organic substances, which influence the polarity of the inner phase and the properties of the interface.

Fig. 9 presents the dependences of the half-separation period of the aqueous phase and of the viscosity of the emulsions on the NaCl concentration in the inner phase. With increase in the ionic strength of the solution constituting the disperse phase of the emulsions, both the stability and the viscosity of the emulsions increase. This is a positive factor in membrane extraction, since it makes it possible to increase the capacity of the emulsions with respect to the target component by increasing the content of the binding reagent in the inner phase.

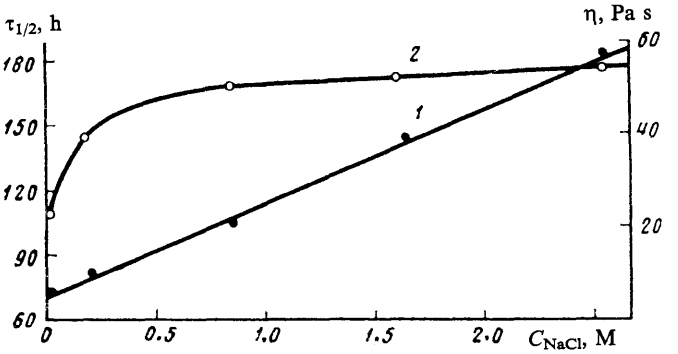

Figure 9. Dependence of the half-separation period of the aqueous phase at 60 °C (curve *1*) and of the viscosity of the emulsions at 25 °C (curve *2*) on the NaCl concentration in the inner phase of the emulsions.

Emulsions containing in the inner phase compounds creating alkaline or neutral media are frequently employed in membrane extraction. Fig. 10 presents the dependences of the stabilities and viscosities of the emulsions on the pH of the inner aqueous phase. In the region of neutral media, the half-separation time of the aqueous phase and the viscosity of the emulsions are virtually constant. The emulsions with alkaline and acid inner phases are characterised by a lower stability and viscosity. This has been attributed to the protonation of the emulsifier in the acid solutions and its hydrolysis in highly alkaline and acid media, which increases the hydrophilic–lipophilic balance (HLB) of the emulsifier and hence lowers the stability of the extracting emulsions.

Apart from other factors, the properties of the extracting emulsions may be appreciably influenced by the presence of organic substances which affect the polarity of the disperse phase. Figs. 11*a* and 11*b* illustrate the influence of the overall concentration of ethanol and diethyl ether ($C_{\text{alcohol+ether}}$), present in molar proportions of 4:1, on the stability and viscosity of emulsions.[35]

The increase in the overall concentration to ~3.0 M diminishes slightly the half-separation period of the emulsions. At concentrations of 3.5 M, there is a sharp fall in stability. This is associated with the fact that an increase in the content of ethanol and diethyl ether in the emulsion entails a decrease in the amount of the surfactant in the adsorption pair at the interface owing to the increase in the solubility of the surfactant in the phases. As a result, the stability of the emulsions falls sharply. Furthermore, an increase in the concentrations of ethanol and diethyl ether in the organic membrane diminishes the difference between the polarities of the phases so much that it becomes difficult to stabilise the system. Therefore at high concentrations of ethanol and diethyl ether in emulsions, an increase in the amount of the surfactant does not lead to an appreciable increase in the stability of the emulsions.

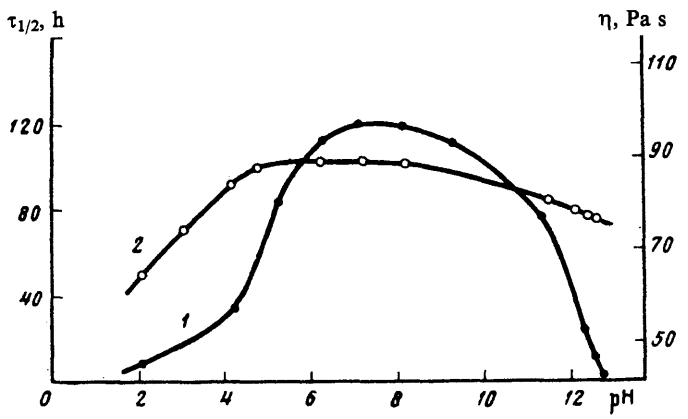

Figure 10. Dependence of the half-separation period of the aqueous phase at 100 °C (curve *1*) and of the viscosity of the emulsions at 25 °C (curve *2*) on the pH of the disperse phase.

It is noteworthy that, with increase in the contents of ethanol and diethyl ether (in the given concentration range), the viscosity of the emulsions decreases linearly (Fig. 11*b*).

Thus, depending on the type and concentration of the surfactants used to stabilise the system and also on the composition of the dispersion medium and the disperse phase, it is possible to obtain emulsions with different properties for each specific application.

III. The nanodispersion in the extracting emulsion

One of the most important phenomena which may occur at the interface in the extracting emulsion is the formation of a secondary emulsion made up of small particles of the order of 10–100 nm. The formation of such an emulsion is promoted by the presence of a surfactant and a cosurfactant in the system[40–42] and by the disequilibrium between the phases of the extracting emulsion, i.e. by the mass transfer of the components of the phases and the solvents through the interface. The formation of such dispersions in the presence of mass transfer has been investigated[25] in two-phase non-emulsion systems.

The spontaneous formation of an emulsion at the interface is possible when chemical reactions occur, including the formation of new surfactants, and also in the presence of aliphatic alcohols.[43–46] However, in the given instance, the authors observed the formation of larger drops—more than 200 nm in diameter.

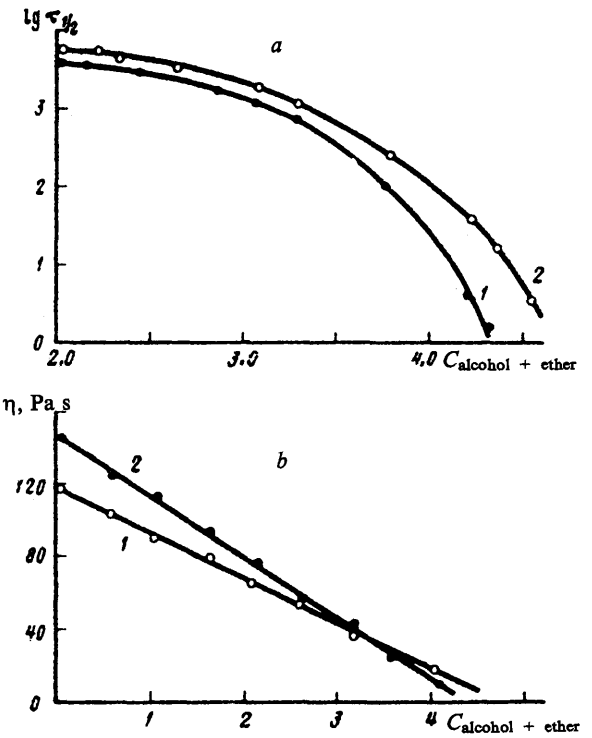

Figure 11. The effect of the overall concentration of ethanol and diethyl ether on the half-separation period of the aqueous phase (*a*) and of the viscosities (*b*) of emulsions stabilised by hostacerin DGO (line *1*) and sorbitan oleate (line *2*) at 25 °C.[35]

The formation of a secondary emulsion has been frequently referred to as microemulsification and the resulting emulsion was called a microemulsion. However, the term microemulsion has come to imply only thermodynamically stable disperse systems comprising particles 10–100 nm in diameter.[47,48] Furthermore, the diffusion coefficients of the microemulsion are much lower than those of the monomers—individual surfactant molecules. As the equilibrium shifts towards a decrease in the concentration of the surfactant monomer, there is no decomposition of the microemulsion drops.[49]

Thus, to solve the problem of classifying a particular emulsion, formed in the presence of diffusion of the substances in the heterogeneous system, as a microemulsion, one requires information about the particle size, the diffusion coefficients, and the thermodynamic stability of the system.

In the case of membrane extraction, the hypothesis of the formation of a microemulsion has been put forward mainly in connection with the transport of water.[50–52] However, the lack of

direct evidence enabled the authors to conclude that the hypothesis of the solubilisation of water by micelles or microemulsions in the course of its transport is invalid and they explain this phenomenon by the transport of water by individual surfactant molecules.[53,54]

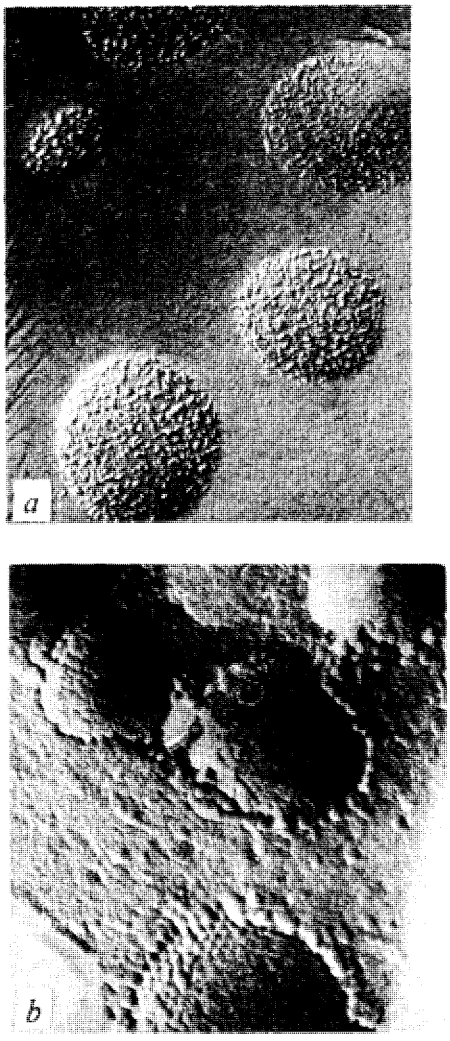

Figure 12. Photomicrographs of an emulsion containing an aqueous solution of ethanol and diethyl ether suspended in liquid paraffin and stabilised with sorbitan oleate: *a*, before extraction (×100 000); *b*, after extraction (×130 000).[57]

Data concerning the size distribution of drops in the emulsion before and after the membrane extraction of cholesterol have been published.[55,56] Photomicrographs of the Pt/C replicas of the cleavage plane of the emulsion, obtained by the freezing-cleavage method,[57] are presented in Fig. 12. The data obtained indicate the absence of a microemulsion from the initial emulsion before extraction and the subsequent formation of drops 17–25 nm in size in the course of the extraction process. The calculated effective diffusion coefficients of the substances forming part of the composition of such drops exceed by 2–3 orders of magnitude the molecular diffusion coefficients. Thus the small drops formed in the course of mass transfer in the extracting emulsion have two features of a microemulsion. The study of the thermodynamic stability of such systems is difficult since extracting emulsions are non-equilibrium systems.

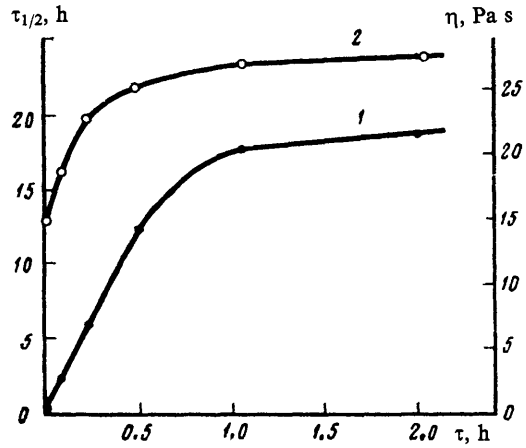

Figure 13. Dependence of the half-separation period at 70 °C (curve *1*) and of the viscosity of the emulsions at 20 °C (curve *2*) on the duration of the extraction of cholesterol.

In our view, for particles with diameters ranging from tens to hundreds of nanometers, one can use the term "nanodispersion", which implies both thermodynamically stable disperse systems (microemulsions) and thermodynamically unstable systems (solubilised micelles). The application of the concept of the "nanodispersion" makes it possible to designate clearly the fraction of small drops formed as a result of emulsification at the interface caused by the mass transfer.

The formation of the nanodispersion drops can influence significantly the kinetics and the quasi-equilibrium in processes occurring in extracting emulsions. The nanodispersion drops are distributed in the bulk of the liquid membrane and are concentrated at the interface, forming a structural-mechanical barrier (Fig. 12). This results in an increase in the stability of the extracting emulsions during extraction (Fig. 13) accompanied by an increase in their viscosity, apparently owing to structure formation in the emulsions and an increase in the cooperative interaction of the drops of the disperse phase. Fig. 14 presents kinetic curves for the separation of such emulsions into layers. The plots are characterised by the presence of two sections: rapid separation of a definite fraction of the inert phase slightly stabilised by the nanodispersion and slow separation of the remainder.

The formation of the nanodispersion is a positive factor when it is necessary to have emulsions which remain stable for a long time, for example, in medicine, in analytical methods, and in the preparation

of protecting creams, since the stability of the emulsions increases appreciably under these conditions. On the other hand, in the organisation of a technological process, where rapid separation of the extracting emulsion into layers is necessary in order to regenerate the extracted substance, the formation of nanodispersion is undesirable, since it entails an additional expenditure on the decomposition of the disperse system. An increase in the viscosity of the extracting emulsions increases the probability of paste formation (the coalescence of the globules), which prevents the normal operation of the technological equipment.

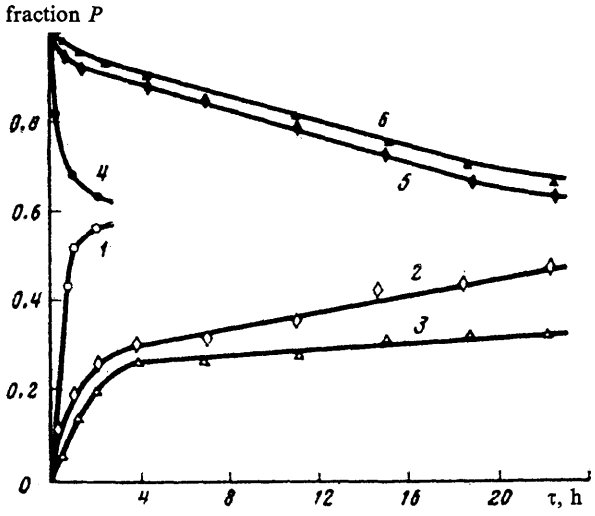

Figure 14. Kinetic curves for the separation of the extracting emulsions into layers (*1*–*3* aqueous phase; *4*–*6* organic phase) at 70 °C as a function of the duration of extraction of cholesterol. Extraction time (h): *1* and *4*, 0 (initial emulsion); *2* and *5*, 0.25; *3* and *6*, 1.

The formation of a nanodispersion is a positive factor also in the extraction of substances with surface-active properties, since the capacity of the extracting emulsions increases as a consequence of the increase in the degree of adsorption of the target component at the interface in the emulsion. The presence of a cosurfactant in the emulsions, for example, of ethanol and diethyl ether in the emulsions for the extraction of cholesterol (see Section V.3), promotes the formation of a nanodispersion as a result of the additional decrease in interfacial tension. By varying the type of cosurfactants and their concentration, the composition of the emulsions for the extraction of cholesterol was selected. For this emulsion composition, the specific interface increases by 55–65% and more,[56] which helps to increase the degree of extraction. The contribution of the adsorption of the target component at the interface to the overall capacity of such emulsions exceeds 50%.

The drops of the nanodispersion and the surfactant micelles can act as transferring agents in the liquid membrane of the extracting emulsions. A number of studies[58–60] have been devoted to the use of nanodispersions in the liquid membrane for the extraction of sodium and potassium picrates and proteins. The dodecyl ether of tetraethylene glycol is used as the surfactant and aliphatic alcohols are used as cosurfactants.

When extracting emulsions containing concentrated aqueous solutions in the inner phase are used, the drops of the nanodispersion can play the role of transferring agents for the solvent, leading to the transmembrane transfer of water to the inner phase (i.e. the swelling of the emulsions), which is an undesirable process. Some of the main factors which determine the rate of transfer of water are the type and concentration of the surfactants in the liquid membrane.[50,54,61] From the standpoint of the intensity of the formation of the nanodispersion, the use of sorbital ethers is undesirable,[54] since a high rate of transfer of water in emulsions stabilised by sorbitan oleate has been noted.[61]

The direction of the transmembrane transfer of water in a multiple emulsion is determined by the sign of the water activity gradients; when the sign is reversed, there is a corresponding change also in the direction of the transport of water.[38] It is noteworthy that the transmembrane transport of water to the inner phase of the extracting emulsions can be effected not only by the drops of the nanodispersion; the transport of water by the molecules of the surfactant and the transferring agent can also make a definite contribution.

In practice, when the extracted component is concentrated in the inner phase, use is made of extracting emulsions whose disperse phase contains concentrated aqueous solutions. For this reason, the swelling of the emulsions is the preferred process.

The emulsion swelling process does not as a rule reach equilibrium, since, as a result of the large difference between the osmotic pressures in the outer and inner aqueous solutions, the swelling of the extracting emulsions may be considerable. This leads to the breakdown of the emulsions in the extractor owing to the rapid coalescence due to the decrease in the degree of adsorption of the surfactant at the interface.

Thus the optimisation of the residence time of the extracting emulsion in the apparatus in order to concentrate the target component in the inner phase to the maximum extent is important.

IV. Mathematical description of the kinetics of the processes in extracting emulsions

An extensive literature has been devoted to the mathematical description of the mass transfer processes in heterophase liquid systems in both diffusional and kinetic regimes (see, for example, Refs. 3 and 62–64).

The description of the mass transfer in a multiple emulsion involves a number of characteristic features associated with the instability of the geometrical shape of the globules of the extracting emulsion and hence of the liquid membrane, the hydrodynamic set up in the latter, and the structure of the emulsion globules. The large specific interfaces in the extracting emulsions are responsible for the appreciable influence of adsorption not only on the extraction equilibrium but also on the rates of the processes in both diffusional and kinetic regimes.

The diffusion in a multiple emulsion is described using approaches based on the consideration of the non-stationary or quasi-stationary transport of the substances.

When quasi-stationary models are used, it is assumed that convective streams of the drops of the disperse phase arise in the liquid membrane owing to the sharp changes in the rate and

direction of the motion of the globules of the extracting emulsion caused by its dispersion in the solution being extracted. It has been noted that the mobility of the drops depends on their number and size and is fairly clearly correlated with the apparent viscosity of the emulsions.[65] Thus it has been suggested that the concentrations of the extracting component in each drop of the inner phase are equal at each instant.

In the given case, the globule of the extracting emulsion can be represented approximately by a hollow sphere (Fig. 15*a*), whose nucleus consists of the re-extracting solution, its composition being averaged over all the drops of the inner phase. Since concentrated emulsions, close to highly concentrated emulsions, are as a rule used for membrane extraction, the curvature of the liquid membrane is frequently neglected and the latter is treated as flat. The curvature factor can be taken into account with the aid of the relation

$$f_{int}/j=2\delta/d\ln[1/(1-2\delta d^{-1})],$$
$$j_{ext}/j=1-2\delta/d,$$

where j, j_{int}, and j_{ext} are the calculated fluxes through the flat membrane and through the inner and outer surfaces of the spherical membrane respectively, d is the diameter of the globule of the extracting emulsion, and δ is the thickness of the liquid membrane.

The coefficients of the mass transfer from the extracted solution, where it is effected by convective diffusion, into the globule of the extracting emulsion can be determined experimentally or estimated with the aid of the correlation equations published by Ivakhno et al.[66]

Molecular diffusion predominates in the drops of the disperse phase. Although this is a slower process, the mass transfer in the re-extracting solution is rarely the rate-limiting stage of the process, since the interface of the inner phase drops is large (10^6-10^8 ml^{-1}) and the re-extraction constants are usually small.

The models of the quasi-stationary transport do not always describe adequately the mass transfer in a multiple emulsion, especially during the final period of such mass transfer, although they may serve as a convenient mathematical approximation, adequate only along individual sections of the kinetic curves.[67]

Another version of the modelling of the extracting emulsion is based on the hypothesis that all the particles of the disperse phase have negligibly small dimensions, are uniformly distributed, and are fixed within a spherical globule with a radius R at specific reaction points (Fig. 15*b*). The target component or its complex with the transferring agent diffuses from the outer boundary of the extracting emulsion globule to its centre and, as soon as the diffusion front reaches the negligibly small drops of the inner phase, they are instantaneously saturated by the target component owing to extraction. Thus, at a distance r_f from the centre of the spherical globule of the extracting emulsion, there is a boundary between zones containing the inner phase saturated and unsaturated with the target component. The mathematical description includes the solution of the equation for the non-stationary diffusion in terms of spherical coordinates:

$$\frac{\partial C}{\partial \tau}=\frac{D}{r}\frac{\partial}{\partial r}\left(r^2\frac{\partial C}{\partial r}\right); \quad r_f(\tau)\leqslant r\leqslant R.$$

The moving front (of reaction points) model was first proposed and a solution was obtained for one-dimensional diffusion by Marr and co-workers.[68] Later Ho and Li[69] solved numerically the equation with the aid of the perturbation method. The moving front model has been used to describe the transport of substances in multiple emulsions.[19,70–79]

A number of workers have noted the necessity to take into account the resistance to mass transfer in the boundary layer of the outer phase, particularly at the beginning of the process and in the case of a high concentration of the reactants in the inner phase.[80,81] This is apparently valid only in the case of liquid membranes with a low viscosity. For extracting emulsions based on viscous hydrocarbon oils in the absence of slow reactions, the rate-limiting stage of the process is as a rule diffusion in the liquid membrane. Thus in the extraction of lysine in a multiple emulsion (see Section V.1), the resistance to mass transfer in the bulk of the globule exceeds by a factor greater than 500 the resistance in the outer boundary layer.[38]

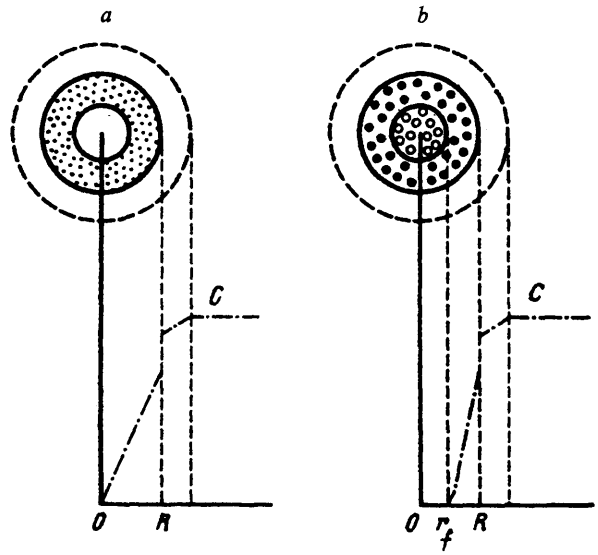

Figure 15. Models of the globules of extracting emulsions: *a*, hollow sphere; *b*, moving front. The dot-dash line represents the profile of the variation of the concentration (C) of the diffusing substance; R = radius of the extracting emulsion globule; r_f = radius of the reaction front in the globule.

The moving front model describes adequately the kinetics of membrane extraction in the case of highly viscous emulsions where the intraglobular convection is suppressed. In practice mainly concentrated emulsions, close to highly concentrated ones, are used, i.e. disperse systems with a high viscosity (see Section II) and therefore in such cases the moving front model is preferred.

The concentrations of the target component $C(t)$ in the solution being extracted have been calculated[38,82] for the membrane extraction of lysine using a model of a moving front with quasi-stationary diffusion (Fig. 16). It was shown that the non-stationary model describes adequately the experimental kinetic curve throughout the process, whereas the quasi-stationary model describes it only in the initial instants.

The mathematical adequacy of the linear functions arises because the complex functions can be fitted by a linear relation along the initial sections of the kinetic curves regardless of the real nature of the mass transfer. The main difference between the non-stationary and stationary models is observed far from the points used for the identification of the model parameters. In the mathematical description of the kinetics of membrane extraction in a multiple emulsion, it is therefore necessary to consider the kinetic curve from the initial instant up to the attainment of quasi-equilibrium in the system.

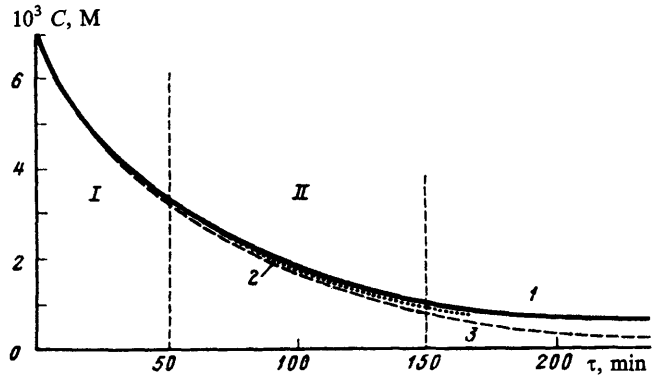

Figure 16. Comparison of the experimental kinetic curve (*1*) with relations calculated on the basis of the moving front (curve *2*) and stationary diffusion-controlled transport (curve *3*) models; *I*, tabulated value of the Fisher statistic f_t = 9.55; calculated Fisher statistics—f_2 = 0.23, f_3 = 0.23; *II*, f_t = 9.12; f_2 = 0.32; f_3 = 1.13; *III*, f_t = 9.12; f_2 = 0.23; f_3 = 13.83.

Information about the nature of the diffusion processes in the liquid membrane can be provided by the "physicochemical probing" method proposed by Frank-Kamenetskii and consisting in the determination of the degree of the power relation between the mass transfer coefficient β and the diffusion coefficient D.[82,83]

The moving front model describes mainly the membrane extraction process in the diffusion regions of the reaction. Special difficulties arise in the transitional region of the reaction, where it is necessary to take into account the influence of the rates of not only diffusion but also of chemical reactions. The analytical solution of the equations for the mathematical description of the kinetics narrows the range of their applicability, since the adoption of certain assumptions is frequently required.

In the given instance, it is best to use a universal, numerical method, which, in contrast to the analytical solutions, makes it possible to obtain an adequate description of the process with constants having a definite physical significance.[84]

In the development of the given model, the following assumptions were made: the diffusion of the components in the liquid membrane is non-stationary; the chemical reactions in the extracting emulsion globule take place at a finite rate and may be both reversible and irreversible; the globule of the extracting emulsion is spherical and is regarded as a pseudohomogeneous medium. For each system component, the following equation is valid:

$$\varepsilon \frac{\partial C_i}{\partial \tau} = D_i\left[\frac{\partial^2 C_i}{\partial r^2} + \frac{2}{r}\frac{\partial C_i}{\partial r}\right] + R_i(\mathrm{C}),$$

where i = 1, ..., N, N is the number of system components, and r = 0, ..., R.

The solution of the above system of equations yields the distribution of the concentrations at any instant and at any point in the system. The system may be solved by employing the method of matrices in combination with the run-through [machine pass] and linearisation methods. In the dimensionless form, we have

$$\hat{\varepsilon}\frac{\partial \bar{C}_i}{\partial T} = \frac{\partial^2 \bar{C}_i}{\partial X^2} + \frac{2}{X}\frac{\partial \bar{C}_i}{\partial X} + R_i(\mathrm{C}),$$

where $X = r/R$, $\bar{C}_i = C_i/C_0$, and $T = (D/R^2)\tau$ for the following initial and boundary conditions:

$$X=1,\ \bar{C}_i=1 \text{ when } T=0,$$
$$d\bar{C}/dX=k\Delta\bar{C} \text{ when } X=1,$$
$$d\bar{C}/dX=0 \text{ when } X=0.$$

The given differential equation is converted into a system of algebraic equations:

$$AC_{i+1}^{k+1} + BC_i^{k+1} + EC_{i-1}^{k+1} = F,$$

where A, B, E, and F are the coefficients of the system of equations which are solved by the run-through method requiring a minimal amount of calculations.

It is noteworthy that, when the specific interface is large and the thickness of the liquid membrane is small, the presence of a surfactant can alter the diffusion coefficient of the target component in the liquid membrane, the partition coefficient between the phases, the reaction rate constant, etc. compared with the corresponding values obtained for a two-phase system of similar composition. The nanodispersion, formed on mass transfer through the interfaces in the multiple emulsion, can also exert a significant influence on the given quantities. This must be taken into account in the determination of the parameters of the mathematical models in independent experiments.

The mathematical description of the kinetics of membrane extraction in a multiple emulsion can include the optimisation of the process either from the standpoint of the attainment of a high degree of concentration (since the molecular diffusion of the target component or of its complex with the transferring agent is appreciably faster than the transmembrane transfer of water leading to the swelling of the emulsion) (see Section III) or from the standpoint of a more effective separation of the substances.[85] Harrington's method, using the so called desirability function as the optimisation parameter, may be used for these purposes.[86]

In the extraction of lysine in a multiple emulsion,[38,82] it has been shown that the maximum efficiency of the lysine concentration process is obtained at time τ_{opt}, which is not the same as the time of attainment of quasi-equilibrium in the system (Fig. 17), since, at times exceeding τ_{opt} in the membrane extraction process, the

concentration of the target component in the inner phase begins to fall because the swelling of the emulsion predominates.

The optimisation of the mass transfer process in extracting emulsions makes it possible to achieve best results in the concentration or extraction of the target component.

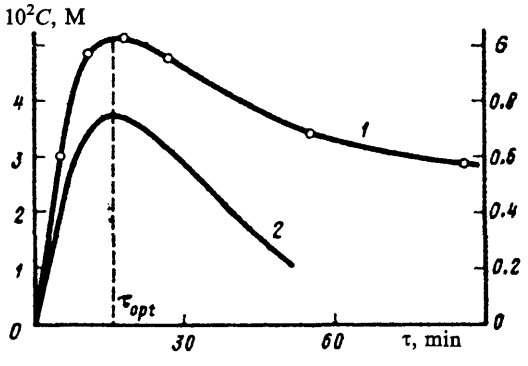

Figure 17. Dependence of the concentration of lysine in the inner phase of the emulsion (curve *1*) and of the generalised desirability function (curve *2*) on the duration of extraction with optimisation of the process.

V. Examples of the practical use of extracting emulsions

1. Application of extracting emulsions in technological processes

Various practical applications of the membrane extraction method in the extraction of numerous metals have been described in the literature: Cu, Ni, Co, Zn, Cr, U, and Hg as well as organic compounds. Detailed reviews of these studies in recent years may be found in the literature.[3,87–89]

Fig. 18 presents as an example a schematic illustration of the experimental-industrial apparatus for the extraction of copper.[5] This process makes it possible to extract more than 99% of the metal. The residual concentration does not exceed 2–7 g m^{-3}, i.e. is 20–30 times lower than in the single-step liquid extraction under comparable conditions. The concentration factor varies from 10[66,90] to 500 and above.[91–94] The emulsifier is usually sorbitan oleate and, more rarely, sorbitan stearate, polyamines, etc. Various hydroxyoximes, β-ketones, and carboxylic or alkylphosphoric acids are used as transferring agents.[66] The inner phase of the emulsions contains 0.5–2.5 M sulphuric acid solution, while the concentration of the sulphuric acid in the extracted solution is not more than 10^{-2} M.

As an example of the extraction of organic substances, one may quote the membrane extraction of aminoacids from enzyme solutions in the microbiological industry.[38,95,96] The extraction of aminoacids proceeds most effectively from weakly concentrated aqueous solutions, especially from dilute liquid waste and wash solutions. Thus the above process can assist in a more complete extraction of aminoacids, in the reduction of their losses, and in the creation of almost waste-free technologies. In one contact step, it is possible to achieve residual concentrations of the order of hundredths of a gram per litre.

The process is of special interest for the extraction of aminoacids sparingly soluble in water, for example tryptophan, since in practice one deals with relatively low concentrations of such aminoacids in aqueous solutions.

A technological scheme has been developed for the recovery of aminoacids (lysine, tryptophan) from their aqueous solutions with the aid of membrane extraction in a multiple emulsion (Fig. 19). The scheme includes the following stages: the preparation of the extracting emulsion, membrane extraction in the multiple emulsion, decomposition of the extracting emulsion after extraction, the evaporation of the solution of the inner phase of the emulsion, and the crystallisation of the aminoacid from the concentrate followed by its washing and drying and the preparation of the commercial product. The ethanol used to wash the aminoacid is periodically redistilled. When the process is carried out in accordance with the above scheme, the aminoacid is freed from other substances present in biological waste: pigments, inorganic salts, etc.[38]

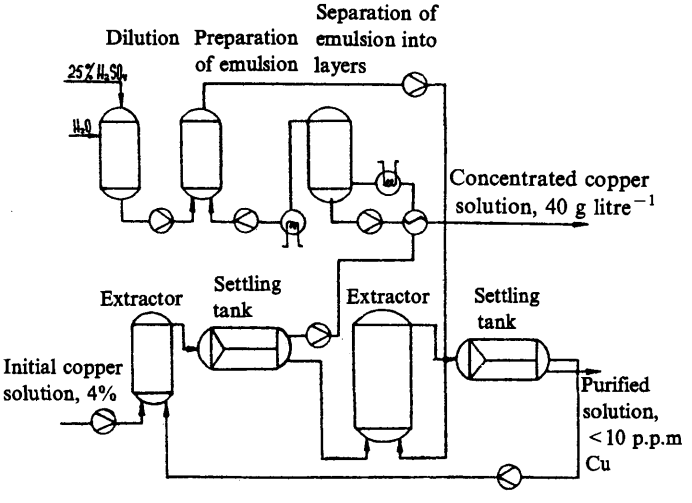

Figure 18. Schematic illustration of the apparatus for the extraction of copper in multiple emulsions.[5]

2. The use of extracting emulsions in analysis

Extracting emulsions can be used for the preliminary concentration of substances for the purpose of their subsequent analysis.[12] These processes may be of special interest in the analysis of the state of the environment, where the test substances are present at very low concentrations unsuitable for traditional analytical methods. Concentration is achieved by allowing a large volume of the test liquid to flow through the cell with the extracting emulsion. Problems of stability are then solved as a rule by selecting the appropriate composition of the extracting emulsion. The situation is more complex as regards the diffusion of water into the extracting emulsion. The swelling of the extracting emulsion impairs the efficiency of the concentration, particularly in extraction from media with low concentrations of the solutes.

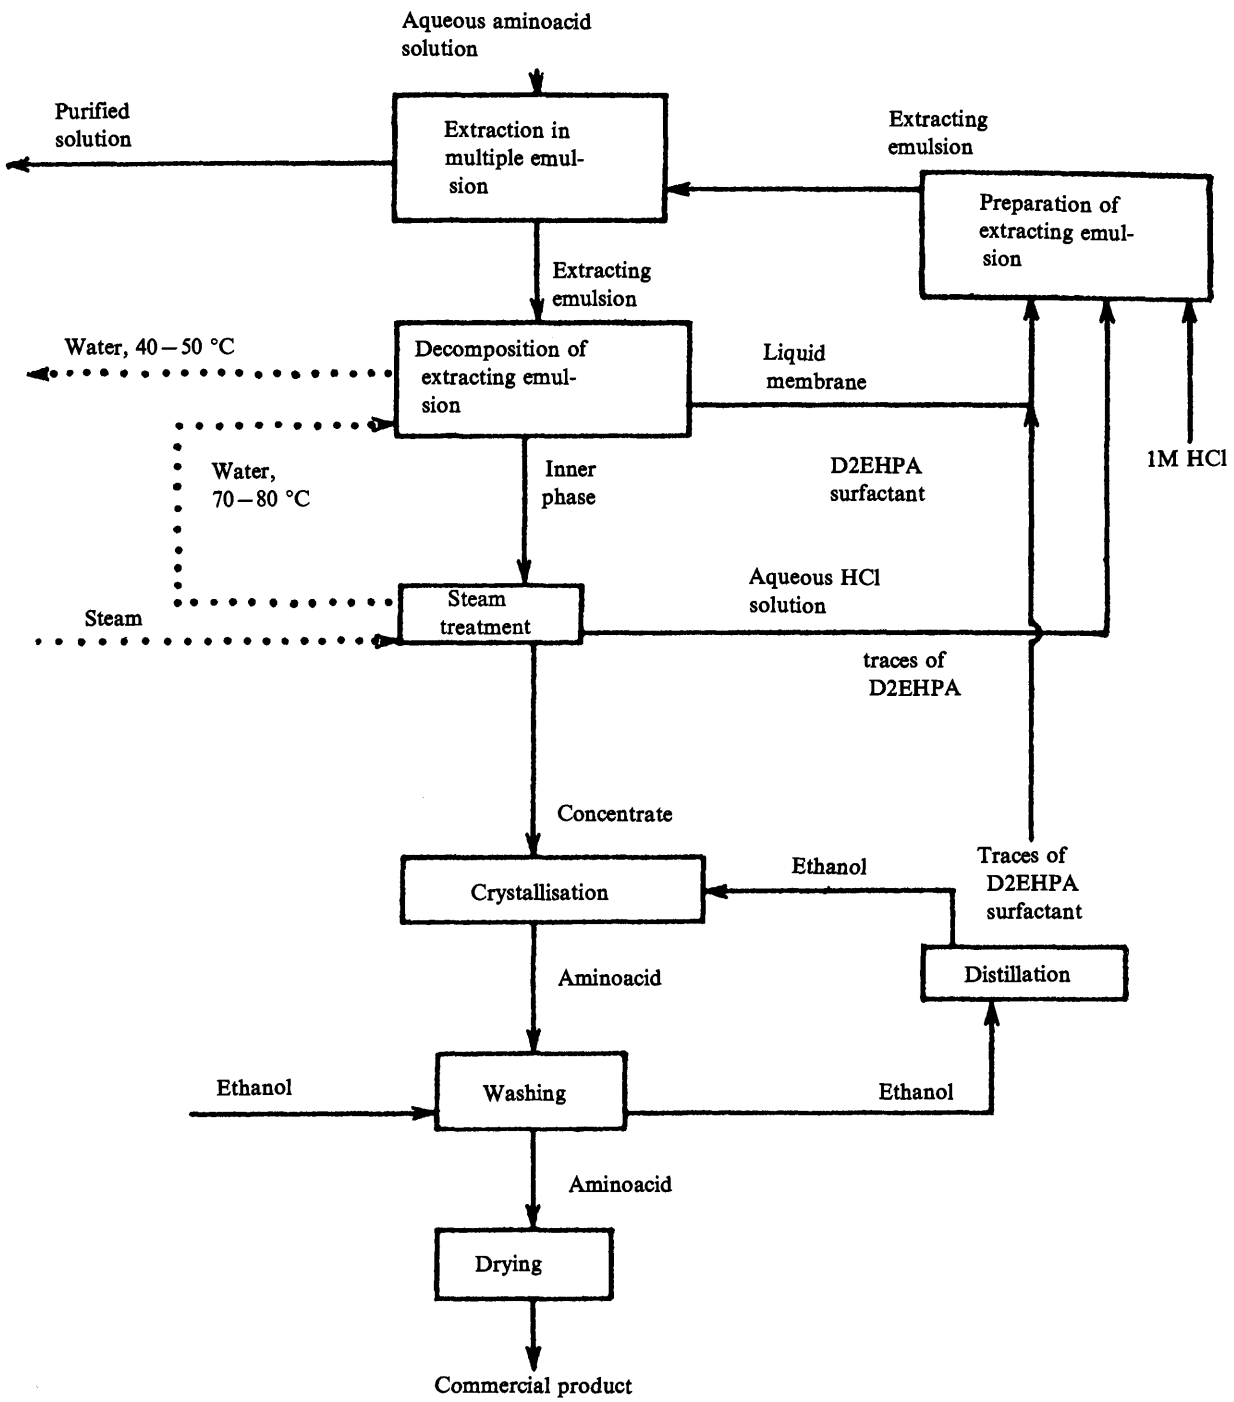

Figure 19. Technological scheme for the isolation of aminoacids (lysine and tryptophan) from their aqueous solutions.

The effect of swelling can be reduced by optimising the contact time on the basis of kinetic relations, as stated above, and also by employing polymeric surfactants. Examples of the use of extracting emulsions in analysis can be found in the literature[12,97] and the use of the extraction of mercury,[98] lead, and cadmium[12] for analytical purposes has been described.

3. The use of extracting emulsions for the detoxification of biological media

Extracting emulsions can find applications in the detoxification of biological media—for the extraction of poisons of exogenic and endogenic origin.[8–10,21,99,100] When inert liquids are used as the

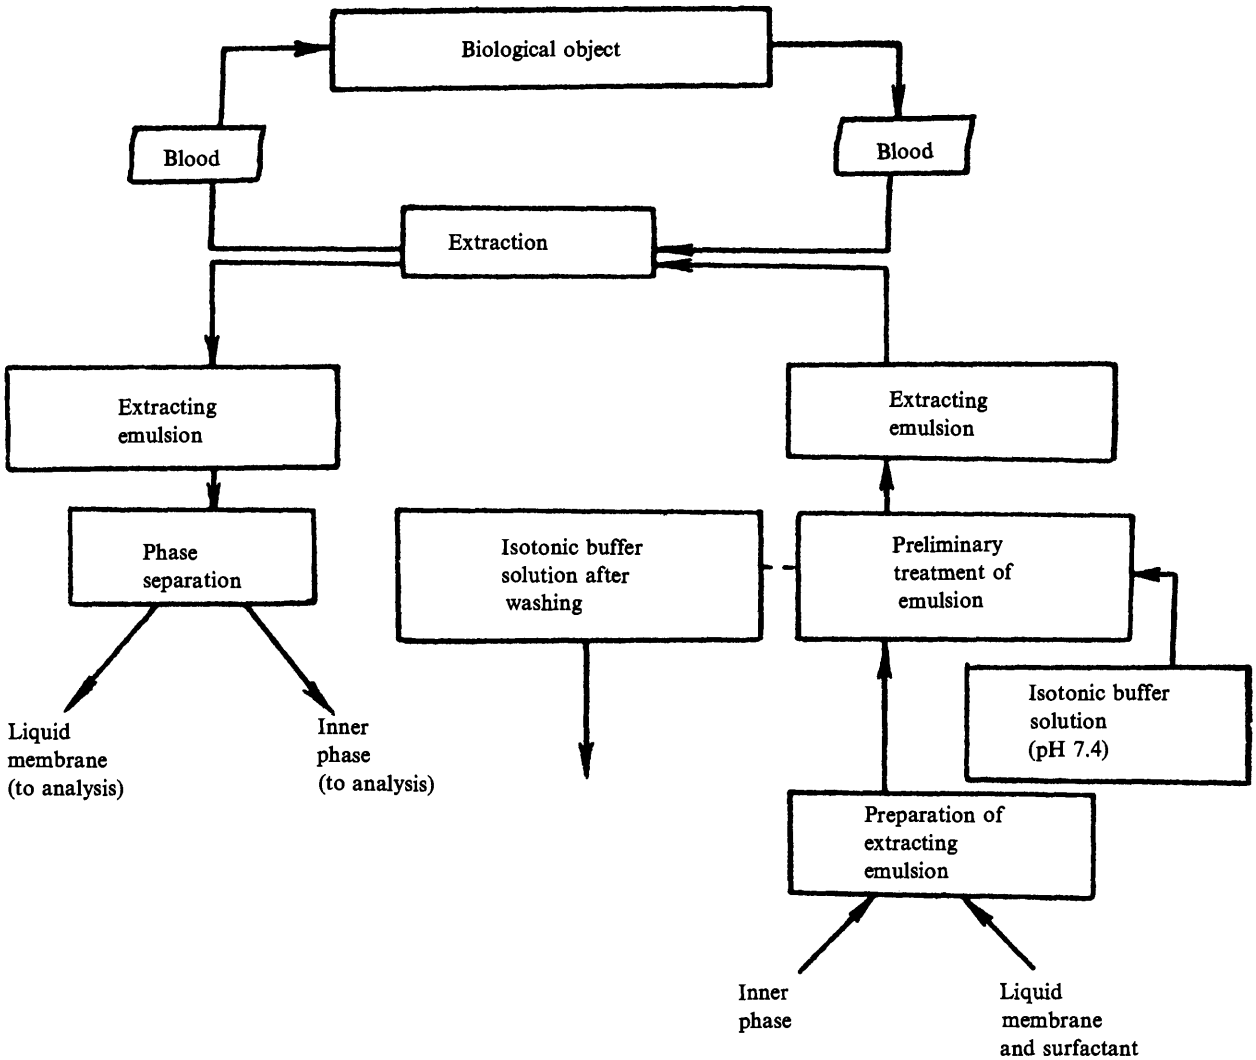

Figure 20. Schematic illustration of membrane extraction from blood using extracting emulsions.

dispersion medium (liquid membrane), it is possible to carry out extraction directly from the blood.

It is noteworthy that many components of biological liquids possess surface-active properties and the contribution of the adsorption component to the capacity of the emulsion can therefore be fairly large; for example it exceeds 50% in the extraction of cholesterol. From this standpoint, membrane extraction in a multiple emulsion has an additional advantage, since extracting emulsions are characterised by a large specific interface (10^6-10^8 m^{-1}). There exist various procedures for increasing the interface, for example as a result of the formation of a nanodispersion, which increases the capacity of the extracting emulsions in the extraction of substances with surface-active properties.

Emulsions containing ethanol and diethyl ether have been developed for the extraction of lipids, including cholesterol and its ethers.[21,35,99] Such emulsions extract cholesterol and lipids into the liquid membrane and sorb them at the interface. In emulsions of this kind, the mass transfer of ethanol and diethyl ether across the interface entails the formation of a nanodispersion. The conditions under which the formation of a nanodispersion is a maximum were selected by varying the concentrations of ethanol and diethyl ether as well as their ratio. The specific interface then increased by 55–65% which resulted in an increase of the degree of extraction of cholesterol owing to adsorption on the interface in the extracting emulsion.[56]

Emulsions containing saponins have been developed for the extraction of non-etherified cholesterol from biological liquids in order to reduce its content in the organism under the conditions of atherosclerosis.[9,21] A water-insoluble equimolecular complex of cholesterol and the saponin is formed in the inner phase of such emulsions. It is almost totally insoluble in water and precipitates. Owing to the haemolytic activity of saponins, preliminary washing of the extracting emulsions with an isotonic buffer solution before extraction from the blood is necessary. After such treatment, the emulsions have no toxic activity since the liquid membrane reliably isolates the saponins present in the disperse phase.

Fig. 2 illustrates schematically the membrane extraction from the blood using extracting emulsions. Blood circulates between the organism and the apparatus in a manner similar to the haemodialysis or haemosorption processes.[10,101] After extraction, the emulsion can be separated into phases in order to determine the concentrations of the substances extracted from blood.

4. Application of extracting emulsions as protection-prophylactic creams

The method of membrane extraction in a multiple emulsion can serve as a basis for the creation of prophylactic creams to protect the surface of the skin against various toxic substances.[11,27,102] Such creams are in many cases more effective than the traditional ones. The difference between them and the existing ointments consists in the fact that the creams extract the sensitisers from the surface of the skin and fix them within their bulk. Traces of the sensitiser on the surface of the skin can also be absorbed by the cream which prevents their accidental incidence on the unprotected sections of the skin.

A process analogous to membrane extraction in a multiple emulsion then takes place. Here the solution of the sensitiser or the upper layer of the skin constitutes the external phase being extracted. Irreversible or reversible reactions involving the binding of the toxic substance may occur in the inner phase. In the latter case, it is necessary to endeavour to make sure that the equilibrium constant of the reversible reaction is as large as possible in order to maintain a minimal concentration of the extractant-transferring agent in the liquid membrane. A fairly wide range of reagents can be used in the inner phase of the emulsion cream, since they are separated from the skin by an inert liquid membrane and do not therefore come into direct contact with the skin.

It is noteworthy that the cream can be not only protecting but also therapeutic and prophylactic, since it can be deposited on the skin already containing a sensitiser, which is extracted from the skin into the emulsion cream.

An important condition for the efficacy of the cream is the maximum extraction of the toxic substance from the organic membrane in contact with the skin into the inner aqueous phase or its fixation in the bulk of the liquid membrane. This is achieved by the strong binding of the sensitiser in a weakly dissociating complex in the inner phase and also by employing low concentrations of the extractant-transferring agent in the organic membrane. Creams whose action is based on this principle prevent the penetration into the skin of not only sensitisers (i.e. substances including dermatitis) but also of other harmful substances (i.e. substances leading to damage of the organism on penetration into the latter through the skin), which is of increasing interest owing to the impairment of the ecological situation.

An important characteristic of the protecting cream is its stability. In this case the emulsions obtained must be even more stable than those employed in technological processes and even in extraction from blood, since in the application of the cream the emulsion is present as a thin layer on the surface of the skin and under such conditions the role of heterocoagulation processes becomes more marked.

A similar approach to the creation of extracting protecting creams served as a basis for the development of a number of specific compositions of prophylactic creams designed against harmful organic and inorganic substances, in the first place sensitisers: heavy metals, chromium, antibiotics, aldehydes, ketones, etc.[11,27,102]

The current state of the problem of the elimination of boron from waste waters

A I Rodionov, O M Voitova, N Ya Romanov
Mendeleev Moscow Institute of Chemical Engineering

ABSTRACT. The advances in the extraction of boron-containing substances from waste waters and natural brines are examined and surveyed. The current prospects for the solution of the problem of creating an ecologically clean technology for the purification of industrial liquid waste with recovery of valuable components are described. The results of studies on the problem, obtained under experimental and industrial conditions, are discussed.

The bibliography includes 78 references.

I. Introduction

The disturbance of ecological equilibria in the biosphere has raised at the present time a series of fairly acute questions associated with the protection of the environment, which necessitates more stringent requirements as regards the protection of water, soil, and the atmosphere. The requirements have become more stringent both as regards the purity of the liquid waste discarded into water-containing areas and their amount.

The industrial waters, sludge, and mother liquors in modern factories processing boron-containing raw material contain an appreciable quantity of boron. This fact poses a serious problem in many industries concerning the extraction and utilisation of boron-containing products.

The use of modern methods for the extraction of boron from waste waters makes it possible to improve the technological processes and to solve problems of the recovery of boron and of the preservation of natural resources.

In nature, boron is encountered in the form of more than 80 independent materials. In the dissolved state in water, boron is present as salts of boric and polyboric acids and also as free orthoboric acid.

The data concerning the toxicity of boron compounds are fairly contradictory and the toxicities of many boron-containing substances have been hardly investigated. Soluble boron compounds are classified as polytropic poisons, prolonged action of which can induce chronic intoxification and diseases of the nervous system.

The limiting permissible concentrations (LPC) in water-containing areas used in fish farming are 0.1 mg litre^{-1} in terms of B_2O_3 and 0.017 mg litre^{-1} in terms of boron and in sanitary-domestic water it is 0.5 mg litre^{-1} in terms of boron. A norm for the LPC of boron in drinking water has not been laid down, but a concentration of 1 mg litre^{-1} has been recommended in the USA.

Thus the current interest in the problem of the extraction of boron from waste waters is associated, among others, with economic problems and the protection of human health.

The methods for the processing of natural types of boron-containing raw material involve a series of a wide variety of technologies for the extraction of boron from aqueous solutions, such as precipitation of boron in the form of sparingly soluble compounds, coprecipitation, extraction with organic solvents, sorption on selective sorbents, separation by electro-ion-exchanger membranes, etc. These methods are at present being developed.

II. Reagent methods for the extraction of boron from waste waters

The reagent methods for the purification of waste waters are based on the precipitation of boron in the form of sparingly soluble compounds and are fairly effective in the case of high concentrations of boron-containing substances in the treated liquid waste.

Treatment of the waste waters obtained in the processing of boron-containing raw material with lime water makes it possible to reduce appreciably and stabilise the concentration of boron. In this case it is possible to reduce the concentration of boron trioxide from 2.5–2.7 to 0.20–0.25%. When lime water is added, calcium borate crystallises from boron-containing solutions. The composition of the borate $x\mathrm{CaO}.y\mathrm{B_2O_3}.z\mathrm{H_2O}$ depends on the precipitation conditions. Thus borates with the ratios $x:y:z$ = 2:3:13 and 1:1:6 are formed at 25 °C, borates with the ratios 2:3:9 and 1:1:4 are formed at 80 °C,[1–3] while at 95 °C borates with the ratios 2:1:1, 2:3:7, and 1:3:5, and, after the introduction of a seed, also 4:5:7, 2:3:5, and 2:7:8 were isolated.[4] From the standpoint of subsequent use, calcium diborate hexahydrate $\mathrm{CaO}.\mathrm{B_2O_3}.6\mathrm{H_2O}$ (1:1:6) is of greatest interest. The borate is preciptiated via the reaction:

$$2\mathrm{H_3BO_3} + \mathrm{Ca(OH)_2} + \mathrm{aq} \rightarrow \mathrm{CaO}\cdot\mathrm{B_2O_3}\cdot n\mathrm{H_2O} + \mathrm{aq}.$$

It is essential to note that the precipitation process is influenced significantly by the temperature, the amount of lime water, and the pH.[5,6] In order to obtain the borate with the 1:1:6 composition, it is essential that the temperature should be not higher than 25–30 °C. The optimum temperature is 22–27 °C. In order to obtain a borate with a stable composition and involving the maximum extraction of boron from the solution, the pH of the reaction medium should be in the range 11.4 ± 0.20.[3] Furthermore, it has been found that the range of grain sizes and the chemical composition of calcium diborate depend on the content of impurities in the solution being purified and in the lime water. The purification of the lime water should ensure the content of the inadequately slaked component not greater than 0.2% and 0.015% Fe_2O_3 for an overall 10% content of active CaO.

In the course of the precipitation of the 1:1:6 borate, a small amount of amorphous variable-compositon calcium borate is produced. The amount of B_2O_3 in the amorphous component of the precipitate is relatively constant and the B_2O_3:CaO weight ratio is in the range 0.85–1.05. In the crystalline product, this ratio is always close to the theoretical value of 1.24.[6] The yield of the boron obtained in the amorphous phase is up to 10–15% of its content in the solution.

In the course of the preparation of commercial calcium diborate, the crystal growth stage is rate-limiting, the maximum size of the crystals not exceeding as a rule 50 μm. The concentration of boron oxide in the liquid phase diminishes from 1.5 to 0.15–0.17% after mixing the reactants for 1–3 min at 25 °C, i.e. it is reduced virtually to the equilibrium value.

It is notable that, in the purification of waste waters with a high B_2O_3 content, the precipitate contains, other conditions being equal, a greater amount of the crystalline phase. A similar effect has been obtained also in the presence of a definite amount of a seed in the reactor.

A reactor design ensuring the separation of finely disperse impurities from the crystalline phase during the synthesis of calcium diborate has been developed.[4] The yield of the commercial borate is in this case 96.8 ± 0.5%, the calcium borate being homogeneous in its chemical composition and in terms of its grain size.

The presence of boron-containing kerosene and polyacrylamide (PAA) hydrocarbons in waste waters does not affect the efficiency of the extraction of boric acid.[7] However, the crystals of calcium borate preciptiated from a solution containing these organic impurities are acicular in shape and a tendency towards the agglomeration of the crystals and loss of the regular form corresponding to the internal structure of the crystal is observed. This can be accounted for by the fact that the impurities influence the crystallisation process through a change in the structure of the solution and through adsorption on the faces of the crystals, inducing a change in the rate of their growth.

The coprecipitation of calcium and copper borates makes it possible to isolate up to 93–95% of boron from a solution containing 0.2–0.4% B_2O_3. After preciptiation, the solution contains 0.03% B_2O_3 and the precipitate contains 22.4% B_2O_3, 18.3% CuO, 36.3% CaO, and 23.1% H_2O. Somewhat poorer results are obtained in the coprecipitation of calcium borate with other microimpurities—manganese and cobalt.[8]

A decrease in the content of boric acid in the water being purified can be achieved by isolating at 95 °C dicalcium borate $2CaO.B_2O_3.H_2O$, the solubility of which is low. For this purpose, waste waters containing up to 0.25% B_2O_3 are treated with lime water, the measured amount of the latter, recalculated in terms of CaO, amounting to 130–170% of the stoichiometric amount[9] according to the reaction equation:

$$2Ca(OH)_2+2H_3BO_3=2CaO\cdot B_2O_3\cdot H_2O+4H_2O.$$

The residual content of B_2O_3 in the waste water is 0.03–0.04%.

It is essential to note that the extraction of boron from waste water by precipitating sparingly soluble calcium borate is widely used on the industrial scale.

The mother liquors in the boric acid industry, containing 1.3–1.6% B_2O_3, 21–23% $MgSO_4$, and 0.2–0.6% H_2SO_4, are also treated with magnesium oxide.[10] In this case, magnesium borates having the composition $xB_2O_3.yMgO.zH_2O$ are precipitated. At 95 °C, for a MgO norm amounting to 4.5 mol per mole of B_2O_3 and for a stirring time of 2 h, more than 90% of the boron is precipitated and the filtrate contains 0.26% B_2O_3 after separating the precipitate. Treatment of the mother liquors with ammonia and carbon dioxide or ammonium carbonate makes it possible to obtain ammonium borosulphate and magnesia:

$$4H_3BO_3+(NH_4)_2CO_3=(NH_4)_2B_4O_7+CO_2+6H_2O,$$

$$4MgSO_4+4(NH_4)_2CO_3+10H_2O=$$

$$=3MgCO_3Mg(OH)_2\cdot 9H_2O+4(NH_4)_2SO_4+CO_2.$$

The precipitated magnesium carbonate is separated from the solution and the latter is neutralised with H_2SO_4 and dried, which affords ammonium borosulphate containing 6% B_2O_3, 70% $(NH_4)_2SO_4$, and 20% $MgSO_4$.

It is essential to note that the magnesium and manganese borate precipitates can be used to prepare boric acid. Calcium borate is employed as a substitute for boric acid in many chemical processes. It has also been suggested that the precipitate, formed when boron-containing waste waters having the composition 7% B, 15% B_4C, 60% B_2O_3, and 18% of carbon black are allowed to stand, be subjected to a high-temperature treatment in order to obtain boron carbide.[7]

Waste waters containing 40–50 g $litre^{-1}$ of boric acid can be used in the manufacture of boron dyes.[11] For this purpose, they are treated with sodium carbonate in an amount necessary for the formation of the tetraborate:

$$4H_3BO_3+Na_2CO_3=Na_2B_4O_7+CO_2+6H_2O,$$

and for the formation of a product in which the ratio $Na_2CO_3:Na_2B_4O_7.10H_2O$ does not exceed 10.

In aqueous solutions, boric acid forms complexes with tartaric and trihydroxyglutaric acids. Thus boron can be isolated from very dilute solutions by precipitation in the form of salts with these acids.[12]

The methods for the extraction of boron from waste waters by precipitating sparingly soluble borates are fairly simple to apply and are widely used on the industrial scale. However, the use of these methods is justified in weakly mineralised systems in which the concentration of B_2O_3 is at least 0.3–0.5%. The presence of alkali metal chlorides and sulphates in the solution lowers the qualitative parameters of the process. One of the deficiencies of the method is the impossibility of attaining a high degree of elimination of boric acid from the liquid waste.

III. Extraction of boron from aqueous solutions on inorganic sorbents

On precipitation of certain metal hydroxides from aqueous solutions, boron ions are entrained to some extent. Coprecipitation is explained by the formation of the corresponding metal borates.

The limits of the practical applicability of the given method are between 1 and 3 g litre^{-1} in terms of B_2O_3. The upper limit is set by the duration of the protecting effect of the sorbent and the lower by the formation of eluates dilute in boron on regeneration of the sorbent, which hinders the extraction of boron from them on further treatment.

The sorbents employed are the alkali metal hydroxides $Al(OH)_3$, $Fe(OH)_3$, $Sn(OH)_4$, $Ti(OH)_4$, $Mn(OH)_4$, $Ni(OH)_2$, $Mg(OH)_2$, and $Zn(OH)_2$.[13–16] The degree of coprecipitation of boron with these hydroxides increases with enhancement of their basic properties. Thus, at a boron concentration of 0.31 g litre^{-1}, the amounts of boron coprecipitated are 90% by $Ni(OH)_2$, 60% by $Mg(OH)_2$, $Al(OH)_3$, and $Fe(OH)_3$, and 25% by $Zn(OH)_2$. This suggested the following exchange mechanism: borate ions$\rightleftarrows OH^-$ ions of the hydroxides. However, $Zn(OH)_2$ sorbs much less boron than had been suggested and $Cu(OH)_2$ does not sorb it at all. This can be accounted for by the occurrence, together with ion exchange, of a chemical interaction involving the formation of borates, which is confirmed by studying the influence of the concentration of borate ions on the sorption of boric acid. When the boron concentration in solution was altered from 0.31 to 31 g litre^{-1}, the amount of boron coprecipitated changed from 0.037 to 0.806 g litre^{-1} for $Zr(OH)_4$ and from 0.099 to 3.534 g litre^{-1} for $Ni(OH)_2$. The IR spectra of the hydroxides precipitated from boric acid solutions at different concentrations permit the conclusion that the interaction of a nickel salt with boric acid involves the formation of nickel borate, which is coprecipitated together with $Ni(OH)_2$, the structure of the borate resembling that of ulexite $CaNa[B_5O_6(OH)_6].5H_2O$, while in the case of the hydroxides $Al(OH)_3$ and $Zr(OH)_4$ ion exchange takes place.

Data have been published[5,6] concerning the preparation of borate concentrates from petroleum waters (0.25–0.46 g litre^{-1} in terms of B_2O_3) with the aid of $Mg(OH)_2$, MgO, and heat-treated dolomite ($MgCO_3$ + $CaCO_3$). When boron was extracted with magnesium hydroxide, the sorption capacity was 0.3% in terms of B_2O_3, which is of virtually no practical interest. Using magnesium oxide and heat-treated dolomite as sorbents under static conditions with a sorbent : solution ratio of 1 : 100 and for 8 h contact, it is possible to extract 50–70% of B_2O_3, the degree of extraction being independent of the degree of mineralisation of the brines. Under dynamic conditions, it is possible to achieve almost complete extraction of boron (up to a residual content of 20 mg litre^{-1} of B_2O_3). However, the cost of magnesium oxide is fairly high and it is therefore desirable to use heat-treated dolomite. The process parameters have been established:[17] ratio of solid and liquid phases S : L = 1 : 100, temperature 30–45 °C, pH 9. Under these conditions, the degree of elimination of boron is 90%.

A method has been developed for the elimination of boron from highly mineralised natural solutions,[18] involving their treatment with chromium hydroxide in an amount of 2–12 g per 100 ml of the solution at pH 8.5. The sorbent is supplied in two lots in equal portions, after which the solution is stirred for 30 min. For a settling time of the suspension of 30 min, the efficiency of the extraction of boron reaches 65%. The nature of the anion in the initial chromium salt and its concentration have almost no effect on the extraction of boron in the pH range 6.8–12.[19]

A sorbent consisting of granulated magnesium-nickel hydroxide (MNH) has been synthesised.[20] Its comparison with zirconium hydroxide shows that under static conditions the rates of equilibration on the MNH sorbent are almost twice as high but the capacity of the zirconium hydroxide is greater. The experiments carried out under dynamic conditions shows that, in the sorption of boron from concentrated brines, preference should be given to zirconium hydroxide.

A technology has been developed for the extraction of boron by a sorbent based on zirconium and magnesium-nickel hydroxides, involving a multicycle procedure, in which the solutions are brought into contact with the sorbent, the sorbent is regenerated with an alkaline solution, and boron is isolated from the eluates by means of compounds of univalent or divalent metals with formation of sparingly soluble borates and the mother liquor.[21] The mother liquor from the preceding cycle is brought into contact with the sorbent before its regeneration in the next cycle.

Zirconium hydroxide, obtained directly in the boron-containing solutions, was proposed as the sorbent.[23] This hydroxide gives rise to a fairly high degree of precipitation of boron. Thus, after a fourfold precipitation, the degree of extraction of boron from a solution containing about 1 g litre^{-1} of B_2O_3 in 98.5%. The boron is extracted from the residue by being converted into borax with sodium hydroxide and by leaching the deposit with warm water. The sorption properties of granulated zirconium hydroxide (GZH) have also been investigated[23] by freezing and by the gel-sol methods. Boron was extracted from waste waters with an overall degree of mineralisation of 4.2 g litre^{-1} and a high concentration of boric acid at pH 5. The capacities of the sorbents obtained by the above procedures are 44.9 and 38.2 mg g^{-1} respectively.

Stable polynuclear derivatives of zirconium nitrate exhibit an enhanced ability to react with borates.[24] H_3BO_3 is sorbed under static conditions, the equilibration time being 30 min. The ratio of the solid and liquid phases is 1 : 30. For a H_3BO_3 content in the liquid waste between 0.5 and 2.5 g litre^{-1}, the percentage extraction of the acid is independent of its concentration. The greatest sorption effect is observed at pH 9 and reaches 90% in one cycle. It has been established that heating assists sorption.

Studies on the sorption of boron by granulated metal hydroxides from boric acid solutions and natural magnesium chloride brines under static conditions at boron concentrations between 0.05 and 0.25% in terms of B_2O_3 have shown that[25] the optimum sorption conditions are attained at pH 3.5–4.0 and temperatures in the range 35–40 °C. In terms of their equilibrium sorption capacity, the metal hydroxides can be arranged in the following sequence: Zr^{4+} (in NaCl solution) > Al^{3+} > Zr^{4+} > Fe^{3+}.

Zirconium hydroxide has the maximum capacity and this sorbent has been tested also under dynamic conditions. The maximum capacity is attained at a flow rate of the solution being purified of 0.2–0.5 ml min^{-1}, at 25–30 °C, and at pH 3.5–4.0.

According to Nikolaev's study,[26] the efficiency of the capture of boron from water by different hydroxides at pH 8.2–8.3 is characterised by the following sequence:

$$ZrO_2 > La_2O_3 > SiO_2 > TiO_2 > Fe_2O_3,\ Al_2O_3.$$

The presence of certain ions has a fairly appreciable influence on the extraction of boron by metal hydroxides. For example, the presence of sodium and lithium chlorides promotes an increase in the capacity of zinc, nickel, iron, aluminium, and tin hydroxides with respect to borate ions. This can be accounted for[27] by the influence

of the above electrolytes on the structure of the boron ions in solution. At the same time, the absorption borate ions diminishes in the presence of anions in the following sequence: $NO_3^- > Cl^- > SO_4^{2-}$. With increase in the boron concentration in the initial solution, the influence of anions diminishes appreciably.[28–32]

The extraction of boron by aluminium and iron hydroxides has been investigated in fair detail.[33] The concentration and nature of the hydroxides, the contact time, and the pH of the reaction medium were adopted as the principal factors governing the process. Aluminium hydroxide has been obtained by adding aluminium sulphate to a sample of the waste water and iron hydroxide was prepared by adding iron chloride. The maximum boron extraction effect is observed at pH 7.0–9.0 and is attained at the instant of the formation of the hydroxides, i.e. the separation of the suspension in order to extract the spent hydroxide is best performed in a contact clarifier or on a contact filter. With increase in the hydroxide concentration, the coprecipitation effect also increases, but such relations are not highly linear and the copreciptiation effect increases up to a certain limit.

The removal of boron from natural brines[34] is most effective when the Al_2O_3 sorbent is used in an amount corresponding to 0.5–20% relative to the mass of the brine. The suspension containing the sorbent is heated to 60–80 °C and stirred at this temperature for 30–60 min. The residual boron content in the brine is less than 50 mg litre^{-1} and the degree of extraction reaches 87–97%. The sorbent is separated from the solution by allowing it to settle, after which the boron is desorbed with a 10% mannitol solution. Solutions of glycerol, sorbitol, and a number of other substances can be used as desorbing agents. A procedure for the elimination of boron compounds from magnesium chloride brines with activated alumina or activated bauxite has been proposed.[55] When the ratio of the Al_2O_3 content to the mass of the brine is 1:4, the degree of purification is 91%.

Studies[36] on the sorption properties of the ash formed after the combustion of coal are of interest. Since the ash contains sodium, potassium, calcium, magnesium, aluminium, and iron ions, the hydroxides of the above metals are formed at elevated pH and bind the borate ions.

Thus we may note that the most effective inorganic sorbent is zirconium hydroxide, which, however, suffers from a serious deficency—low mechanical strength, which is an obstacle to its employment in industry. Aluminium hydroxide also exhibits a high efficiency in extracting boron.

The method involving the coprecipitation of boron with metal hydroxides makes it possible to attain high degrees of elimination of boron from waste water, but it is less critical as regards the content of dissolved alkali metal salts. However, one must add that the above method is technologically complex: the rates of filtration are low and a constant regeneration of the carrier deposit is required, which involves the consumption of acids and alkalies. The deposits as a rule contain boron at a low concentration, their composition is not constant, and they require additional processing. The process has not been applied widely on an industrial scale.

IV. Sorption of borate ions on anion-exchange resins

The methods for the extraction of boron with the aid of ion-exchange materials are applicable mainly to weakly mineralised aqueous solutions with a fairly low content of B_2O_3 (up to 2–3 g litre^{-1}).[9] The need to apply ion-exchange methods arises in the extensive purification of waste waters and also in the extraction of boron for analytical and chromatographic purposes and for the separation of isotopes.

The studies on the sorption properties[37,38] of anion-exchange resins of neutral and weakly basic types in relation to the extraction of boron from waste waters have shown that weakly basic anion-exchangers of the polycondensation type, containing hydroxy-groups as well as primary, secondary, and tertiary amino-groups, are more selective with respect to boron. Up to 80% of boron is extracted from pure solutions of boric acid containing 0.28% B_2O_3, but the attainment of this degree of purification requires a long contact time.

The presence of metal salts in the solutions lowers the degree of extraction of boron. This fact as well as the low exchange capacity of the sorbents suggest that mixed and highly basic sorbents may be more promising, but these do not exhibit selectivity with respect to borate ions.

There are insufficient literature data and recommendations concerning the application of USSR-produced ion exchangers. For example, the AV-17 anion-exchange resin has been suggested for the isolation of boric acid from heat exchangers, aqueous salt solutions, and waste waters.[39–42] The AV-17 anion-exchange resin in the OH-form has been used for the extraction of boron from heat exchangers of the power reactor of an atomic power station.[43] The degree of purification reached 99.5% and the dynamic capacity of the resin was 100–120 g litre^{-1}. It has been established[44] that, with increase in the concentration of boric acid by a factor of 10, the degree of sorption of boron increases by a factor of 2–4, while a temperature rise from 18 to 50 °C lowers the degree of extraction of boron, especially for dilute solutions. The resin is regenerated with a potassium hydroxide solution and the eluate is treated in an electrodialysis cell with cation-exchange and dipolar membranes, which results in the extraction of 98% of borate ions.

The sorption capacity of the AV-29 anion-exchange resin with respect to boron is 507 mg litre^{-1} when the resin comes into contact with a solution whose pH is 6.[45] Compared with the AV-17 anion-exchange resin the efficiency of the AV-29 resin is higher by a factor of 1.7.

According to the data of Samberskii, et al.,[46] the capacity with respect to boron increases in the following sequence of anion-exchange resins: AV-17 × 8, AV-29, AN-2F, EDE-10P, AN-31, i.e. with increase in the content of hydroxy-groups in the resin. In the presence of salts, the capacity of the sorbents falls sharply (especially that of the AV-17 anion-exchange resin) owing to the high ion-exchange affinity for the Cl^- and SO_4^{2-} ions. The influence of cations on the sorption of boron diminishes in the sequence $K^+ > Na^+ > Zn^{2+} > Mg^{2+}$, which is apparently caused by the different capacities of the cations for hydration. Thus the presence of even small amounts of NaCl and $ZnCl_2$ diminishes sharply the capacity of the resins with respect to boron.

The complex-forming sorbents ANB-11 and ANB-11m are highly effective in the extraction of boron from mineralised waters.[47,48] The static capacity of the above anion exchangers is 80 mg litre^{-1} and the optimum pH at which the boron-containing waters and the sorbents are brought into contact is 7. The presence of salts hardly affects the sorption process. Sorbents distinguished by a satisfactory kinetic parameter, which are readily regenerated with HCl, have undergone industrial tests.[49] In order to increase the degree of purification, the sorption is carried out on anion-exchange resins subjected to preliminary treatment with methanol.

Studies directed towards the search for ion-exchange materials selective with respect to borate ions are of practical interest.

In order to increase the sorption capacity with respect to boron, anion exchangers of the aminoepoxide type have been modified chemically which increased the concentration of hydroxy-groups.[50] Anion exchangers of the aminoepoxide type[51] and the epoxyamino-type, B-8, B-257,[52] and SB-1[53] have been obtained in this way. The experimental data for the extraction of boron from natural concentrated magnesium chloride brines, obtained under static conditions, showed that B_2O_3 concentrations in excess of 1 g litre^{-1} and a solution temperature of 40 °C are optimum for the sorption of boron. The equilibrium capacity of ion exchangers under these conditions is 110 mg h^{-1}. However, at a B_2O_3 concentration below 1 g litre^{-1}, the sorbent capacity falls sharply and the ion-exchange purification becomes inefficient.

For example, the SB-1 ion-exchange resin, containing in its structure hydroxy- and amino-groups which are selective with respect to boron, can be used for the effective extraction of boron from solutions at a concentration of 2–3 g litre^{-1} of B_2O_3, but, owing to the instability of the borate ions, boron cannot be extracted as far as the limiting permissible concentrations (LPC). The study of the pH dependence of the sorbent capacity with respect to boron showed that the maximum occurs at pH 7.4–8.8 and the total dynamic exchange capacity of the resin is 160 mg of B_2O_3 per gram of the resin. The degree of extraction of boron is 82% for an initial B_2O_3 content of 1.2–3.22 g litre^{-1}.[54] When the SB-1 ion-exchange resin is compared with the zirconium-hydroxide based inorganic sorbent GZH, whose properties were discussed in the previous Section, it is noteworthy that the latter sorbent permits a more extensive purification of the solutions, while the SB-1 sorbent has a higher mechanical strength by an order of magnitude.[55] The equilibrium pH depends on the content of salts in the solution. In the presence of a high salt content, the sorption pH differs from the initial value by more than 1–2 units, while in the presence of a low salt content the pH is 8.5–9.5, which is attributed to the "buffer" capacity of the impurities.

Resins with active catechol groups exhibit a fairly high capacity with respect to borate ions. On this basis, the ANPK-31 sorbent has been synthesised. It consists of the AP-31 anion-exchange resin modified with catechol.[56] At pH 7.5, this resin extracts 60 mg of boron per gram of the resin.

A technology has been developed for the preparation of a sorbent.[57] It is based on the use of chitosan (a chitin hydrolysis product), which is a glucosamine polysaccharide. Fe_3O_4 grains coated by the chitosan solution bind boron into complexes with chitosan. The efficiency of the purification is 70%. This method of purification has been validated by industrial tests.

The interaction of boric acid with polyhydroxy-compounds, which include aliphatic and cyclic diols and triols and polyhydric alcohols and phenols, has been fairly thoroughly investigated hitherto. One of the sorbents exhibiting a high selectivity is poly(vinylene glycol) (PVG),[58] which is a linear insoluble powdered polymer. Its capacity is 91.4 mg of B_2O_3 per gram of the sorbent, an increase in the pH of the solution from 3.5 to 8.5 increasing the degree of extraction of boron. An increase in the content of alkali metal and magnesium salts also improves the sorption of boric ions. However, PVG has not come to be widely used owing to its operating properties and also because it is impossible to obtain concentrated solutions in the desorption process.

Much attention has been devoted to the preparation of polymerised sorbents with aminopolyol groups capable of extracting selectively boron compounds from aqueous solutions at B_2O_3 concentrations from 0.5 to 1 g litre^{-1} and above.[59] An example of such a sorbent is the Amberlite XE-243 resin, which exhibits a high selectivity with respect to boron in neutral and alkaline media. In an acid medium, the resin capacity falls sharply. These capacities are 1.74, 1.5, and 0.7 mequiv. litre^{-1} respectively. The presence of NaCl and $MgCl_2$ does not affect the efficiency of the process, which is carried out in weakly alkaline medium. The resin has been recommended for the extraction of borates from natural brines.

Sorbents have been synthesised using tris(hydroxymethyl)amino-methane as the aminopolyl.[60] The capacity of these sorbents reaches about 70 mg of H_3BO_3 per gram of the resin for sorption from solutions containing 1 g litre^{-1} of boric acid and 50 mg per gram of the resin for sorption from solutions with a high solvent content. The optimum sorption pH is 7. The presence of salt hardly affects the capacity of the sorbents with respect to boron, so that it is useful to use them for the extraction of boron from solutions against a strong salt background. The character of the interaction of borate ions with the sorbent based on *N*-methylglucosamine is similar. However, when these sorbents are used in chloroform, the sorption maximum shifts to a more alkaline region. The resins are readily regenerated with hydrochloric acid and less effectively with hard water and alkali. The sorption process takes place less effectively in the presence of magnesium sulphate. The presence of $MgCl_2$ increases the capacity of the resin with respect to boron which is apparently associated with the salting-out of boron into the sorbent phase. The presence of NaCl, KCl, and LiCl hardly affects the resin capacity. It has been established that the process kinetics depend very significantly on the boric acid concentration in the solution.

It is noteworthy that the capacities of all the sorbents based on phenol-containing resins are lower than those of Amberlite XE-243 and its analogues. The optimum complex-forming sorbent is the resin based on *N*-methylglucosamine. Furthermore, a major advantage of polymerisation sorbents compared with the poly-condensation phenol-containing resins is their high chemical stability.

The suggestion that an activated charcoal impregnated with the Methylene Blue dye be used for the purification of boron-containing waste waters is of interest.[61–63] A fairly high efficiency of the purification of boron-containing waste waters has been achieved using Filtrasorb activated charcoal. The degree of purification was 90% for an initial boron concentration of 5–30 mg litre^{-1}.

The extraction of boron with a mixture of organic and inorganic sorbents merits attention.[64] The method involves the treatment of the anion-exchanger with a solution of zirconium oxalate and then with ammonia at pH 9–10. The sorbents prepared on the basis of the AV-17–12P, AN-2F, and PD7-10G anion-exchange resins are fairly effective in the removal of boron-containing substances from water (65%). However, the technology of their preparation is complex.

Thus one may conclude that the sorption method has a number of evident advantages and permits a fairly extensive purification of the solution without its secondary contamination. The disadvantages of the sorption technology, which complicates its practical application, are the absence of the industrial production of sorbents with the required qualities, low rates of sorption, and low economic parameters of the process.

V. Extraction of boron with organic solvents

The extraction of boron with organic solvents is one of the highly effective and selective procedures. Studies have shown that the most effective extractants for borate ions are hydroxylated organic

compounds. In the general case, the greater the number of hydroxy-groups in the structure of the organic substance, the greater its efficiency. The concentration of hydroxy-groups can be increased either by diminishing the molecular weight of monohydric alochols or by increasing the number of hydroxy-groups in the molecule by going over to polyols. As a consequence of this, two main trends have arisen in the study of the extraction of boron—extraction with monohydric and polyhydric alcohols.

Studies on a series of alcohols have shown that the efficiency of the extraction of boron with alcohols falls with increase in their moelcular weight. In terms of decreasing efficiency of the extraction of boron by alcohols, the latter can be arranged in the following sequence: 1-butanol, isobutyl alcohol, 1-pentanol, isopentyl alcohol,..., 1-octanol,..., isododecyl alcohol.

With increase in the concentration of the salting-out agent, for example $MgCl_2$, in the aqueous phase, the above sequence is in general retained, but alcohols with the iso-structure become much more effective than the alcohols with the normal structure. In concentrated $MgCl_2$ solutions, the efficiency of the alcohols with a branched structure then increases with increase in the length of the carbon chain. The alcohol efficiency sequence changes: iso-octyl alcohol,..., isopentyl alcohol, isobutyl alcohol, 1-pentanol, 1-butanol, 1-nonanol.

Thus, in the extraction of boron from bischofite brines, the most effective organic extractants are iso-octyl and isopentyl alcohols. In order to increase the efficiency of the isolation of boron, a mixture of several organic compounds is frequently used. For example, a boron extractant consisting of a mixture of aliphatic alchols (60–70% of isopentyl alcohol, 20–25% of isobutyl alcohol, and 5–10% of propylbutyl alcohol) has been proposed[65] for the extraction of boric acid. The extractant is selective with respect to boron and is immiscible with water. The maximum degree of extraction of boron is 99% and it can be attained for a boron content in the initial solution of 1 g litre^{-1}.

Table 1. The partition coefficients of boric acid in extraction with 2-substituted β-diols.

No of extractant	K_p		
	pure boric acid solution	boric acid solution saturated with NaCl	boric acid solution saturated with $MgCl_2$
(I)	13.8	39	14.9
(II)	14.6	–	58
(III)	20	40	30
(IV)	31	42	–
(V)	30	37	53

A fair amount of attention is being devoted to studies on the extraction of boric acid from aqueous solutions of diols. A fairly high degree of extraction of boron is attained[66] using 2-propylheptane-1,3-diol (I), 2-butyloctane-1,3-diol (II), 2-isopropyl-6-methylhexane-1,3-diol (III), 2,2,4-trimethylpentane-1,3-diol (IV), and 2,2,5-trimethylhexane-1,3-diol (V).

The best diluents for extractants (I) and (II) are chlorohydrocarbons, toluene, (kerosene can also be used), while the best diluent for extractants (IV) and (V) is chloroform. Table 1 presents the equilibrium partition coefficients K_p of boric acid in extraction with 0.5 M solutions of extractants (I)–(V) in chloroform for a 0.1 M solution of boric acid without electrolytes and against the background of saturated sodium and magnesium chloride brines at 20 °C. With increase in the extractant concentration in the diluent, the degree of extraction rises. The maximum partititon coefficient is observed for a tenfold molar excess of the extractant. A decrease in the boric acid concentration in the solution extracted to 0.31 g litre^{-1} does not diminish the degree of extraction when extractants (I)–(IV) are used, but the degree of extraction falls somewhat (from 96.78 to 90.26%) in the case of extractant (V). The extractants investigated extract boric acid over a wide pH range. However, at pH values in excess of 8, the degree of extraction of boron falls sharply, especially in the case of extractants (IV) and (V). The organic solvents are re-extracted with a solution of alkali.

A promising extractant, Yarrezin-B, which is an aminophenol-formaldehyde polymer, has been developed[67] for the extraction of boron. The extractant has undergone industrial tests.

Alkylcatechols and hydroxymethyl derivatives of alkylphenols have been proposed as extractants.[68] In the presence of added aromatic amines, these substances extract boron from neutral and weakly acid solutions. They are re-extracted with solutions of inorganic acids.

Studies directed towards the search for effective boron extractants are being continued. It is noteworthy that extraction is a promising method for the removal of boron from brines, having advantages such as ease of automation, high rate of the process, continuous operation, and high purity of the product obtained. However, the method also suffers from serious disadvantages, which limit its application: complexity of the equipment and partial solubility of the organic extractants in water, which leads to the loss of expensive reagents and create an ecological problem.

VI. Thermal methods for the elimination of boron-containing substances from waste waters

Thermal methods for the extraction of boron from industrial liquid waste are of definite interest in some cases. We shall consider below some of them.

The method based on evaporation ensures the complete utilisation of boron-containing compounds and the liquidation of boron-containing liquid waste. After evaporation, the cooled solutions are treated with seeding crystals, increasing thereby the degree of salting-out of boric acid. This technology has been developed for the etching and moulding of a foil, where the content of boric acid is 10 g litre^{-1}.

The waste waters from electroplating industry, containing fluoroborates, are also treated by evaporation. The improvement of this method compared with that described above consists of the fact that the waste waters are treated beforehand with an alkali metal hydroxide until the attainment of pH 8 and the precipitated metal hydroxides are separated. This prevents encrustation of the apparatus.

Evaporation is frequently used in the purification of boron-containing waste waters from atomic power stations.[69] Radioactive waste waters containing boric acid at a concentration less than 2.4% are treated with soda-lime until the attainment of pH 6.8–7.7. The

liquid waste is then concentrated by evaporation until a boric acid concentration of 25–54% is reached. The distillate is cooled and discarded into a water-containing area, while the concentrated liquid waste is directed to a settling tank where boric acid crystallises on cooling. In order to reduce the pH and intensify the crystallisation process, the still residue is treated with oxalic acid. The supernatant liquid is treated with a solution of potassium permanganate and is directed to the evaporation apparatus.

A procedure for the purification of waste waters containing boron compounds and organic substances has been proposed.[70] It consists of the fact that the water is heat-treated in the presence of steam in an amount permitting the conversion of a major proportion of the boron into H_3BO_3. The method makes it possible to regenerate heat and boric acid, but is highly energy consuming.

In the general case, thermal purification methods are energy consuming, while in combination with other methods they greatly complicate the technology.

VII. Other methods for the isolation of boron from aqueous solutions

A fairly considerable amount of attention has been devoted to the extraction of boron from aqueous systems by electrochemical methods and by reverse osmosis. These procedures are of interest for the preparation of highly pure boron-containing products and also when it is necessary to eliminate boron compounds thoroughly from aqueous systems.

Liquid membranes based on β-diols, placed between two semiconducting partitions, have been proposed[71] for the extraction of boric acid. The β-diols employed were 2-butyloctane-1,3-diol, 2-propylheptane-1,3-diol, and nonane-1,3-diol dissolved in heptane, benzene, chlorobenzene, and isopentyl alcohol. The degree of extraction of boric acid from solutions increases linearly from 45 to 87% with increase in the concentration of the diols in the liquid membrane from 10^{-3} to 10^{-1} M and the current density is 0.5–10 mA cm^{-2}. In all cases, the highest percentage extraction of borate ions through the membrane is observed when isopentyl alcohol is used as the solvent for the liquid membrane, while the smallest effect is obtained when benzene is employed. Studies[72] on the influence of the pH in the electrodialysis of boron-containing waters showed that the optimum pH for the process is in the range 9.1–9.6.

By varying the composition of the liquid membrane, it is possible to achieve fairly complete extraction and concentration of boric acid from aqueous salt solutions. Electrochemical purification is also carried out with the aid of ion-exchange diaphragms, consisting of films of an ion-exchange resin and a filler. The diaphragms have a low hydrodynamic permeabilty and in water their intrinsic electrical conductivity is also low.[9] Apart from concentrating boron-containing solutions, electrolysers with ion-exchange membranes can find applications in the selective electrochemical decomposition of a boron-containing raw material.

A technology has been proposed[73,74] for the purification of boron-containing waste waters formed in the nickel-plating process. It involves reverse osmosis. In the first stage at pH 6, nickel is separated, after which the second purification stage is carried out. The boric acid concentrate obtained in the second stage is utilised.

Heterocyclic polymeric materials, including fluorinated and modified polyamides, are used[75] as the membrane material in the elimination of boron from waste waters by reverse osmosis. Thus, when a polypiperazineamide membrane is used at a pH of the medium of 8.4, the degree of extraction of boron is 83%, while at pH 11 the efficiency increases to 95%.

A cascade of reverse osmosis apparatus has been used for the extraction of boric acid from the waste waters generated by atomic power stations.[76] The process is carried out at pH 5–6.5 and at the ambient temperature.

A membrane, obtained by depositing a cellulose acetate film on a polyamide film, has been developed.[77,78] The active surface of the polyamide film was subjected to preliminary treatment with compounds selected from the $CaMoO_4$, $CoWO_4$, $PbWO_4$, $CaWO_4$, etc. group. The selectivity of this membrane is higher by 11.3% and its productivity is higher by 14.5% than those of the usual double membrane.

The employment of the electrochemical method as well as the reverse osmosis method for the extraction of boron compounds from aqueous solutions requires further study and improvement of the design of the electrolysers and of the quality of the membranes.

---o0o---

As can be seen from the data presented above, boron is extracted from aqueous systems by means of a series of methods. The choice of the method of purification depends significantly on the concentration of boric acid in the waste water.

The elimination of boron from water by coprecipitation with gel-like metal hydroxide deposits entails costs associated with the regeneration of the deposits. This method has not been applied widely in technology.

The extraction of boron by organic compounds is a fairly effective and selective method when the boric acid content is in excess of 3 g $litre^{-1}$ and has a number of advantages. However, the method suffers at the same time from serious disadvantages, which limit its application: complexity of the equipment and partial solubility of the organic extracts in water, which creates an ecological problem.

The procedure based on evaporation is energy consuming and when combined with other methods appreciably complicates the technology.

The methods for the extraction of boron with the aid of ion-exchange materials of different kinds have been developed mainly for aqueous solutions with a relatively low (up to 2–3 g $litre^{-1}$) boric acid content. The low exchange capacities and the lack of selectivity of the majority of resins in relation to boron compounds make their practical use fairly complicated.

The commonest method for the extraction of boric acids from waste waters is the reagent method involving the precipitation of boron by lime water in the form of the sparingly soluble calcium borate. The method has proved itself in aqueous systems with concentrations of 1.3–1.5% in terms of B_2O_3.

It is essential to note that the usefulness of a method for the extraction of boron from waste waters must be considered for each specific case.

Micellarly enhanced (reagent) ultrafiltration

A A Svittsov, T Zh Abylgaziev
Mendeleev Moscow Institute of Chemical Engineering

ABSTRACT. The few data available in the scientific and technical literature on a new method for membrane separation—micellarly enhanced or reagent ultrafiltration (RUF)—are presented. Three versions of reagent ultrafiltration are considered in which sols are separated on a membrane. Data are presented concerning the influence of the characteristics of the disperse phase on the ultrafiltration process.

The bibliography includes 17 references.

Membrane separation and the usual filtration are frequently regarded as identical technological processes. The series of procedures filtration, microfiltration, ultrafiltration, and reverse osmosis are outwardly similar because of the presence of a partition and a common driving force—the pressure gradient. However, in this series the size of the retained particles diminishes (from micrometres to angstroms), the pressure gradient increases, and the specific productivity of the partition falls rapidly. Furthermore with increase in dispersity, for example, in the sequence coarse suspensions/emulsions–sols/microemulsions–lyophilic colloid systems (polymer and surfactant solutions), the influence of the sieve effect diminishes and the role of the aggregative behaviour of the disperse phase in the solution (its interaction with the surface of the membrane) increases appreciably.

The objects to be separated, for example industrial waste waters, very often consist of inhomogeneous mixtures containing a vast amount of an indifferent inorganic electrolyte and the contaminant proper, the amount of which can be very low but is nevertheless much greater than the limiting permissible amount. In particular, liquid radioactive waste consists of aqueous solutions of salts with an overall ionic concentration amounting to hundreds of milligrams per litre. Under these conditions, the contaminating components (radionuclides) cannot be determined in terms of weight concentrations and only the radioactivity is measured. Such systems can be conveniently separated by micellarly enhanced or reagent ultrafiltration (RUF). This membrane separation method, which can combine a high productivity with a low working pressure and the ability to eliminate ionic components from water with selective separation of the components, is based on the conversion of dissolved low-molecular-weight components into a new associated molecular or colloid state with subsequent separation on a macroporous membrane of the associated species produced.

Reagent ultrafiltration can be applied in several versions.[1]

1. The addition to the solution of a water-insoluble organic compound which interacts with the required component according to the extraction mechanism. The resulting emulsion is separated on a porous membrane subject to appropriate requirements.

2. The addition to the solution of surfactants which lead to additional purification at a concentration above the critical concentration for micelle formation (CCM) as a consequence of the physical adsorption of the contaminant on the surfactant micelles.

3. The addition to the solution of water-soluble polyelectrolytes with functional groups which are able to combine with the required components via an ion-exchange complex formation, etc. mechanism. The solution remains homogeneous and its separation is achieved in accordance with the laws governing the ultrafiltration of solutions of high-molecular-weight compounds.

4. The addition to the solution of a freshly prepared sol on the particles of which the required component is bound as a result of physical adsorption.

5. The conversion of the dissolved ionic species of the components into a molecular and subsequently a colloid phase in the course of the hydrolysis as a result of the addition of alkali to the solution. The electromembrane method of hydrolysis is a variety of this version.

6. The addition to the solution of chemical reagents whose interaction with the reqired component converts the latter into an insoluble form. The formation of a deposit should be stopped at the colloid phase formation stage.

We should like to emphasise that there may not in fact be a distinct boundary between the above versions, i.e. the solution of the given problem may require different versions to supplement one another.

At the present time, certain versions of the RUF have already undergone a far reaching theoretical development and have even found industrial application, whereas others are only being investigated.

This review deals with the application of the last three versions, where sols are subjected to membrane separation and it is therefore necessary to take into account the stability of the system and the size of the colloid particles in the concentration process.

It is known[2,3] that a deposit begins to be formed on supersaturation of the system and that the process can be divided arbitrarily into three stages: (1) the formation of nuclei of critical size; (2) the growth of particles (the particles are aggregates of the nuclei); (3) precipitation and ageing of the deposit.

The precipitation reaction in the colloid range of dispersity can be stopped in different ways: by introducing into the reaction mixture various stabilisers (surfactants, polymers), which on being sorbed on the surfaces of colloid particles prevent their further aggregation, by altering the temperature, pH of the reaction medium, etc. The choice of specific conditions and additives for controlling the dispersity of the colloid system is determined by the nature of the disperse phase and the solvent.

The ultrafiltration process is greatly influenced by the particle size, which depends on its turn on the mechanism and kinetics of the process leading to the formation of the new phase. The formation of the new phase begins either as a result of the fluctuation generation of a nucleus of critical size (homogeneous fluctuation of crystallisation centres) or following the introduction into the system of ready made nuclei from outside (heterogeneous formation of crystallisation centres).

According to the Gibbs–Thomson equation, we have for a critical nucleus of spherical shape

$$r_{cr} = \frac{2\sigma V}{RT \ln \gamma},$$

where r_{cr} is the critical radius of the nucleus, σ the interfacial tension, V the molar volume of the new phase, R the gas constant, T the temperature, and γ the critical degree of supersaturation. For non-electrolytes, $\gamma = c/c_0$, c is the concentration of the test substance in the supersaturated solution, and c_0 the equilibrium solubility of the macrocrystals. For strong electrolytes, $\gamma = ab/L$, where a and b are the activities of the cations and anions and L is the solubility product. It follows from this equation that the lower the degree of supersaturation, the higher the values of r_{cr} and the appearance of the critical nucleus therefore becomes increasingly more difficult with decrease in the degree of supersaturation of the system.

Depending on the conditions, there is a possibility of both homogeneous and heterogeneous formation of nuclei.[2,4,5] Furthermore, depending on the degree of supersaturation, the process can proceed in the same system via both the nucleus formation mechanisms. This has been demonstrated by Mikhnevich.[3] When the degree of supersaturation in the system diminishes, crystallisation becomes possible only on increasingly larger particles. Finally, if r_{cr}, defined by the Gibbs–Thomson equation, becomes greater than the size of the impurity particles, "spontaneous" formation of nuclei on the latter begins. The energy necessary for such a heterogeneous process is then found to be lower than the energy of the homogeneous formation of nuclei of the same size.

The next stage of crystal growth is determined by two processes:[6] the supply of the substance from the bulk of the solution to the surface of the crystal (diffusion) and incorporation of molecules in the crystal lattice (surface reaction). The growth rate is determined by the rate of the slower of the two processes. Crystal growth processes controlled by either diffusion or the surface reaction are therefore distinguished. The rate of the surface reaction is independent of the hydrodynamic conditions and is determined by the state of the surface of the growing crystal. Experiments have shown that, when small amounts of other substances, capable of being sorbed on the surface, are added, they may influence significantly the rate of growth and shape of the crystals. As regards the rate of supply of the substance, one may claim that it depends on the stirring. As the stirring becomes more intense, the rate of crystallisation increases but only up to a certain limit, at which the rate-limiting factor is the surface reaction.

Between the establishment of supersaturation in the system and the appearance of the first traces of the new phase which can be distinguished in one way or another, there is a definite time interval called the induction period. During this period, crystallisation centres are formed vigorously. The duration of the induction period τ_i varies markedly depending on the nature of the deposit and for a given deposit is a function of the initial degree of supersaturation.[7] Thus, for $BaSO_4$ and AgCl deposits having approximately the same molar solubilities, we have, for equal initial concentrations,

$$\tau_i(BaSO_4) \gg \tau_i(AgCl).$$

According to Nielsen's studies,[8] where the crystallisation of $BaSO_4$ was investigated, the induction period τ_i, the total number of grown crystals N, and the average rate of formation of nuclei N/τ_i were determined, the number of crystals N remains approximately constant up to a concentration $c \simeq 0.01$ M and then increases sharply: N/τ_i increases in proportion to the concentration raised to the power 18. Evidently in this case there is a change from the heterogeneous to the homogeneous mechanism of the formation nuclei. The size of the nucleus (18 ions or 9 molecules), the critical degree of supersaturation ($\gamma_{cr} = 630$), and the interfacial tension ($\sigma = 90$ erg cm^{-2}) were calculated from the data presented.[9]

Thus, on the basis of the foregoing, one may postulate that, by altering the degree of supersaturation of the system, the rate of supply of the test substance, and the rate of the surface reaction, it is possible to achieve control of the induction period and the dispersity of the colloidal phase and hence also of the particle size. Then, having stabilised the system obtained, the ultrafiltration process can be carried out. The barium chromate colloid system has been obtained by this method. It is important to note that sometimes, when the precipitation process is carried out without satisfying the technological requirements, colloid systems are formed in settling tanks.[10] In this respect, a result which is undesirable for a given process may prove positive for reagent ultrafiltration.

It has been suggested[11] that sodium sulphide, forming disperse systems with contaminants, be used as the reagent for the isolation of mercury, lead, and cadmium ions. As a result of the formation of colloid systems, it became possible to remove them by means of ultrafiltration.

When the fourth version of reagent ultrafiltration is carried out, satisfactory results are achieved at low concentrations of the contaminant, which is sorbed on the colloid particles. This can naturally limit the application of the given method. However, it proved effective for the elimination of caesium-137 from liquid radioactive waste from atomic power stations.[12] Copper ions Cu^{2+} and the $[Fe(CN)_6]^{4-}$ ions were introduced into the caesium-containing liquid waste. The reaction resulted in the formation of a colloid system in which caesium was sorbed on the colloid particles retained by subsequent ultrafiltration. The degree of extraction of caesium-137 was 99% and the consumption of the reagents was 2% of the amount required for the precipitation.

The fifth version of reagent ultrafiltration, where the colloid particles are obtained by hydrolysis, can find extensive application if it proves possible to shorten the hydrolysis time, i.e. to increase the rate of reaction. It is known that, at a concentration of the component isolated in excess of 10^{-3} M, the hydrolysis proceeds with formation of polynuclear complexes in several stages, including the formation of monomers and dimers, their polymerisation, the appearance of amorphous colloid particles, and their subsequent transformation into a crystalline form. Any of the atoms forming part of the polymer chain can be hydrolysed twice and three times, which leads to the branching of the chain. The identification of the species formed is exceptionally difficult, but for practical applications only one parameter is important—their size, which after the addition of alkali has ceased may increase owing to coagulation and may lead to the loss of resistance to aggregation by the colloid system. There are several methods for preventing this phenomenon: the addition of surfactants and a change of temperature.[13]

The results achieved in the removal of iron and chromium from solutions are presented in Figs. 1 and 2 and the influence of surfactants on this process is illustrated in Fig. 3.

Hydrolysis with the aid of electroadjustment of the pH of the solution, i.e. the gradient-free micellarly enhanced ultrafiltration method, is a variety of the fifth version. In this procedure, the question of the resistance of the system to aggregation is even more

acute, but at the present time the method has not yet been investigated.

Membrane separation is evidently determined in many respects by the stability of sols as regards an increase in concentration, by the size and charge of their particles, and by the hydrodynamic conditions in the apparatus. The creation of optimum hydrodynamic conditions is especially important for diminishing the phenomenon of concentration polarisation.

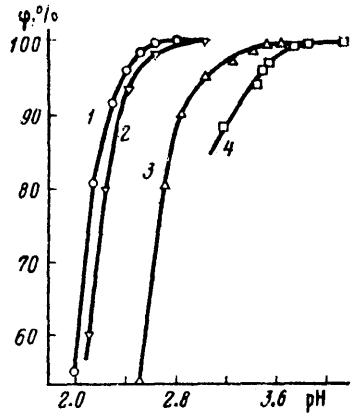

Figure 1. Dependence of the selectivity of the purification (φ) on the pH of the medium for an iron solution; [Fe] (mg litre^{-1}) in the initial solution:[1] *1*, 1000; *2*, 300; *3*, 60; *4*, 25.

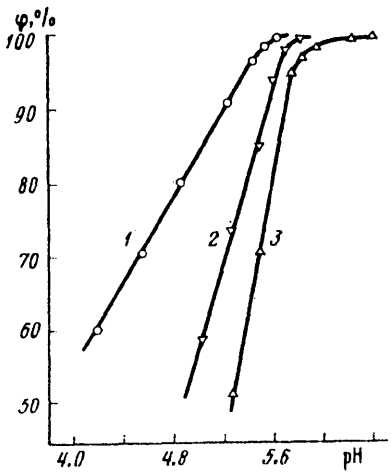

Figure 2. Dependence of the selectivity of the purification on the pH of the medium for chromium solutions; [Cr] in the initial solution (mg litre^{-1}):[1] *1*, 500; *2*, 350; *3*, 100.

The change in the properties of hydrosols during their concentration from 3.5 to 43% has been investigated[14] by the ultrafiltration method. It was noted that during concentration there is an increase in the viscosity of the sol, which exerts an appreciable influence on the rate of ultrafiltration, especially on increasing the concentration above 35%. This is explained by the fact that, for a given size of the particles and taking into account their hydration shells, the closest packing is attained under these conditions. The shells of the stabilising counterions begin to overlap, so that a slight increase in the concentration of the sol entails an appreciable increase in viscosity. Ultimately this leads to a lower stability of silica sols in relation to gel formation.

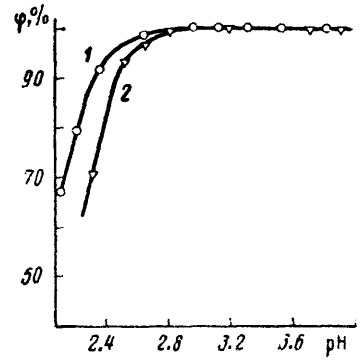

Figure 3. Dependence of the selectivity of the purification on the pH of the medium for the iron–surfactant system; [Fe] in the initial solution (mg litre^{-1}):[1] *1*, 1000; *2*, 100; the surfactant concentration was 100 mg litre^{-1} in both cases.

Studies[15] of the influence of hydrodynamic conditions and of the diameter of the SiO_2 sol particle on the rate of ultrafiltration showed that, on vigorous stirring of the disperesions, whereupon a gel layer made up of the sol particles is not formed on the surface of the membrane, the rate of filtration is constant and independent of the particle diameter. A highly concentrated sol (106 kg m^{-3}) is an exception. In the absence of stirring, the rate of filtration increases with increase in the particle diameter, which can be explained by the increase in the porosity of the gel layer. An increase in pH diminishes the resistance of the gel layer as a consequence of the increase in the repulsion between the sol particles. In these experiments, the size of the colloid particles was less than the size of the membrane pores. However, in practice one may encounter opposite cases where the colloid particles, penetrating into the pores, irreversibly contaminate the membrane. In order to solve this problem, it has been suggested[16] that the particles capable of penetrating into the membrane pores be aggregated until particles which are retained on the surface of the membrane are obtained. An increase in the size of the particles and the presence of a charge on their surface have positive influence on the rate of filtration.

Certain aspects of the ultrafiltration of colloid systems have been described by Bryk and Tsapyuk.[17]

Studies in the field of the ultrafiltration of colloid systems are just being activated, but it is already possible to formulate preliminary results: (1) the irreversible contamination of the membrane is caused by particles whose size is smaller than the pore size; (2) the charge on the colloid particles, by virtue of which there is a possibility of

their electrostatic repulsion from the membrane, is very important; (3) by controlling the conditions in the formation of the colloid system, it is possible to achieve the best ultrafiltration conditions by an appropriate combination of the size and charge of the particle; (4) it is important to set up the optimum hydrodynamic situation over the membrane, the elimination of stagnant zones being of primary importance.

Reagent ultrafiltration increases markedly the applications of the membrane separation methods. It becomes possible to use highly productive processes for the purification of liquid industrial waste, which could be achieved previously only by reverse osmosis, and to eliminate selectively contaminating components from the waste without involving the salt ballast, which is especially important in the handling of radioactive and electroplating waste. A new method has arisen for the fractionation of components of liquid mixtures which may become analytical after appropriate further developments. Finally, new approaches to the utilisation and processing of toxic concentrates are appearing.

ABSTRACT. The influence on the eco-system of the products of the large-scale technology for the preparation of ultra-pure water required for the electronic and radiotechnical industries is examined. The distillation, ion-exchange, and membrane methods are subjected to a comparative analysis. It is shown that the membrane method for the extreme purification of water is ecologically the most desirable. The methods for the elimination of nitrates from drinking water are examined.

I. Introduction

The preparation of ultrapure water has become one of the most urgent problems in chemistry and chemical engineering in connection with its definite role in the manufacture of electronic devices, integrated circuits, microprocessors, and specially pure substances.

The construction of transistors, integrated circuits, and microprocessors involves a multiplicity of operations with chemical treatment, after which the articles have to be washed with water of the highest purity. There is a direct relationship between the purity of water and the information capacity of integrated circuits. In particular, in order to obtain 64 kbytes of information, the content of organic carbon must not exceed 500 μg litre^{-1} and the attainment of 4 Mbytes requires the use of water in which the concentration of organic carbon is not more than 30 μg litre^{-1}. Even more stringent requirements must be met as regards the content of inorganic substances and micro-organisms. It is therefore not fortuitous that the widely familiar study by Shockley, who first obtained a transistor in 1951, was published simultaneously with the work of Reents and Kahler, who were the first to use a mixed bed of cation-exchange and anion-exchange resins for the extreme purification of water.[1]

The progress in electronic engineering and the synthesis of specially pure chemical and pharmaceutical preparations have helped to convert the ion-exchange technology for the manufacture of specially pure water into a large-scale process. With the aid of this technology, the problem of the conditioning of water for industry can be solved fairly easily. However, it was found subsequently that the ion-exchange method and the ion-exchange technology based on it constitute an "ecological boomerang", since the waste waters from ion-exchange apparatus contain a mass of mineral substances which exceeds by an order of magnitude the mass of impurities extracted from natural waters.

The return to the method of multistage vacuum distillation, developed by Kohlrausch,[2] did not lead to success, although the first impression was that the method and the technology based on it do not involve the discarding of substances into the environment. The paradox of the purification of water by distillation consisted in the fact that the high energy consumption leads to the contamination of the environment not in the region of the operation of the given apparatus but in the regions where there are thermal electric power stations whose gaseous waste is emitted into the atmosphere and spreads over long distances. The results of the ecological analysis of these methods have led to the alarmist attitude for our time.

At the same time, a new aspect of the solution of the ecological problems in the preparation of high purity water has arisen. This is associated with the use of membrane methods for the separation of substances and the membrane technology based on them. Hitherto many specialists have been sceptical about the possibility of replacing distillation and ion-exchange methods for the purification of water by membrane methods, pointing out at the same time the limitations of the baromembrane methods (microfiltration, ultrafiltration, and reverse osmosis), which do not permit the preparation of water purer than distilled water, or of electromembrane methods (electrodialysis with ion-exchange membranes) in view of its limited possibilities in the elimination of organic non-electrolytes with low dissociation constants. However, they failed to take into account the fact that, firstly, there exists a mechanism of the electroosmotic transport of molecules through ion-exchange membranes as a result of the forces arising from the coupling with fluxes of ions (ion–dipole interaction) and, secondly, that there is a possibility of combining various baromembrane and electromembrane methods whereby one can set up a sequence of operations leading to the preparation of ultrapure water. A feature distinguishing membrane purification methods from other procedures is the approximate equality of the mass of the substances entering the liquid waste and the mass of the substances extracted from natural waters when the latter are purified. The ecological usefulness of a particular membrane method also depends on the operating costs, among which the cost of the electrical energy is of main importance. At the present time there are membrane methods, applied under laboratory or even industrial conditions, which permit intensive purification of water with a very low electrical energy expenditure. In the immediate future, there will be a need to increase the information capacity of the integrated

circuits and microprocessors and this will entail both an extensive and an intensive growth of the production of ultrapure water, which has already reached a large scale. The ecological blunders in this kind of technology have therefore become completely inadmissible and this has determined the aim of the present publication. Furthermore, while the problem of the preparation of ultra-pure water is specific, at the same time it has significant general features in common with the solution of other problems in ecological chemistry.

II. The distillation method for the intense purification of water

The purification of water by distillation has been known since ancient times,[3] but interest in the preparation of ultrapure water did not arise until the past century. After G Kwinke observed that the specific conductance of pure water increases on storage, Kohlrausch and Heidweiler[2] applied in the concluding purification stage consecutive vacuum distillations using vessels made of old Jena glass. After 60 days of successive vacuum distillations, water with a specific conductance of 4.2×10^{-8} S cm^{-1} (specific resistance 23.8 MΩ cm) at 18 °C and 6.09×10^{-8} S cm^{-1} (specific resistance 16.4 MΩ cm) at 25 °C was obtained. The preliminary purification was carried out using the freezing out method proposed by Nernst. The principal physical parameters of the water obtained in these experiments are quoted in monographs and textbooks of physical chemistry, although Kohlrausch himself believed that he had not obtained ultrapure water. However, he discovered how to estimate the electrical conductivity of ideal water on the basis of the van't Hoff theory. Calculation showed that ideally pure water should have a specific conductance of 3.8×10^{-8} S cm^{-1} (specific resistance 26.4 MΩ cm) at 18 °C. A novel method for the determination of the physicochemical parameters of ultrapure water without its purification was developed by Harned and Hamer.[4] They measured potentiometrically the ionic product of water using a hydrogen indicator electrode and a silver/silver chloride reference electrode. The electrolyte was a standard solution of potassium hydroxide and potassium chloride. By extrapolating the electrode potentials obtained to zero ionic strength, Harned and Hamer[4] obtained the following numerical value of the ionic product of water:

$$K_w\ (25^\circ\mathrm{C}) = [\mathrm{H^+}][\mathrm{OH^-}] = K\cdot[\mathrm{H_2O}] = (1.008+0.001)\cdot 10^{-14}, \quad (1)$$

where K is the dissociation constant of water. With the aid of the Ostwald dilution law

$$K = c\alpha^2/(1-\alpha), \quad (2)$$

where α is the degree of dissociation of a weak electrolyte and C its concentration, it is possible to calculate the degree of dissociation from which the equivalent molar conductance can then be evaluated by means of the familiar Arrhenius relation:

$$\alpha = \Lambda/\Lambda_\infty \quad (3)$$

The values obtained are sufficient to calculate the specific conductance $\varkappa$ and the specific resistance ρ:

$$\varkappa = 1/\rho = \Lambda\cdot c \quad (4)$$

It was found[5] that the specific resistance of ideally pure water at 18 °C is 26.6 MΩ cm^{-1}, while at 25 °C it falls to 18.25 MΩ cm. We shall now introduce the dimensionless specific resistant ρ^*, which is equal to the ratio of the experimental specific resistance ρ to the calculated specific resistance of ideally pure water ρ_{lim}:

$$\rho^* = \rho/\rho_{\mathrm{lim}} \quad . \quad (5)$$

Using calculated resistances for the temperatures at which the experimental measurements were made as ρ_{lim}, we are able to estimate the degree of purity of water which is independent of the temperature of the measurement. In particular, Kohlrausch[2] was able to obtain water having $\rho^* = 0.8947$, which is 89.47% of the specific resistance of ideally pure water.

At the present time the distillation method is used widely to desalinate sea and ocean waters, using various evaporators of the thin-film type improved to achieve instantaneous ebullition, hygroscopic and hydrophobic evaporators, and distillation on membranes. The water obtained by single distillation has an intrinsic cost between 3 and 13 roubles per m^3. A relatively high consumption of metals accompanied by a relatively low quality of the purified water (the content of inorganic impurities is approximately 1 mg litre^{-1} and that of organic substance is approximately 4 mg litre^{-1}) is characteristic of distillation apparatus. An increase in the number of purification stages leads to an exponential increase in the cost of the water, so that multistage distillation is used for the preparation of specially pure water only under laboratory conditions.[6]

The distillation method creates the illusion that it is ecologically clean, since at the site where the apparatus operates no discharge of harmful substances is observed, while in the liquid waste the mass of substances is not greater than the mass of substances extracted from natural waters. Nevertheless distillation must be classified as a harmful technology because of its exceptionally high energy consumption. Therefore in order to analyse the ecological effects of distillation, it is essential to estimate the ecological effects of the production of electrical energy.

Since the fraction of electrical energy generated by thermal power stations is 80%, we shall confine ourselves to the analysis of the gaseous waste in the combustion of a non-renewable organic fuel. It has been established that the generation of 1 kWh of electrical energy by the combustion of coal entails the discharge into the atmosphere of 14 g of slag, 80 g of ash, 1000 g of carbon dioxide, and 14 g of sulphur dioxide (21 g of sulphuric acid).[7] We may draw attention to the production of sulphur dioxide, the discharge of which exceeds the permissible amount for the turnover of sulphur in nature.[8] When the limiting permissible concentration (LPC) of sulphur oxides is exceeded, asthma, bronchitis, and emphysema are contracted.[9] It is also known that sulphur dioxide disturbs the photosynthetic process by decomposing chlorophyll.[9] Acid rain, containing sulphuric acid, destroys forests and fish, increases the corrosion of metals, and destroys ancient monuments.

The discharge of nitrogen oxides into the atmosphere has both positive and negative effects on the eco-system. The positive influence consists in supplementing the store of bound nitrogen, which is formed in limited amounts as a result of the functioning of nitrogen-fixing bacteria (on leguminous plants), fungi, and seaweed and is also derived from the molecular nitrogen in the atmosphere under the influence of electric discharges. However, the negative effect of the discharge of nitrogen oxides into the amtosphere is much more significant. On interaction with hydrocarbons in the presence of sunlight, such oxides give rise to peroxyacetyl nitrate and ozone. The reaction is an example of synergism, where certain contaminants react with one another in the environment and form secondary even more toxic compounds. Both peroxyacetyl nitrate

and ozone induce lachrymation and also exert an irritant effect on the respiratory pathways in man. Furthermore, both products are toxic to plants, since ozone intensifies the respiration of leaves and plants are destroyed through exhaustion, while peroxyacetyl nitrate blocks the Hill reaction in photosynthesis, which also leads to the destruction of plants caused by the low intensity of the synthesis of nutrient substances.[8]

Apart from sulphur and nitrogen oxides, the waste from thermal electric power stations contains also solid waste, slags, and dust and soot particles which nowadays occupy many millions of hectares of land which used to be arable. As the structure of the fuel–energy balance changes, in particular, with increasing contribution by nuclear power, the situation may alter fundamentally.

Since it is virtually impossible to take into account all the factors leading to the contamination of the environment on distillation of water because of their different influences, Mazo[10] suggested that analysis be restricted to the discharge of sulphur and nitrogen oxides, which are converted respectively into sulphuric and nitric acids. Account was also taken of the fact that the generation of 1 kWh of electrical energy leads to the discharge of 0.5 of an equivalent of sulphuric and nitric acids. The coefficient of the contamination of the environment, as a result the purification of water, can be expressed by the ratio of the mass of the acids formed to the volume of water V treated annually:

$$Cd = \sum_i m_i/V + \sum_k m_k/nV \,, \qquad (6)$$

where Cd is the coefficient of the contamination of the environment, m_i the mass of the contaminants entering the environment during the operation of the technological set up, m_k the mass of the contaminants entering the environment during the establishment of the technological set up, and n the duration of operation of the technological cycle. Eqn. (6) expresses the coefficient of the contamination of the environment as a quantity proportional to the rates of the reactions generating the products contaminating the environment. As a result, the contamination coefficient is given by the sum

$$Cd = \sum_i \frac{\partial C_i}{\partial \tau} \,, \qquad (7)$$

in which C_i is the concentration of the harmful substances produced and τ is the reaction time.

In order to be able to compare the different contaminants in the environment, it has been suggested[11] that norms be laid down for the limiting permissible concentrations (LPC). By introducing the dimensionless concentration

$$C_i^* = \frac{C_i}{C_{lim}} \,, \qquad (8)$$

representing the ratio of the concentration of the harmful component to its limiting permissible concentration C_{lim}, we obtain the following expression for the rate of production of the component contaminating the environment:

$$\frac{\partial C_i}{\partial \tau} = C_{lim} \frac{\partial C_i^*}{\partial \tau} \,. \qquad (9)$$

Here one should bear in mind that the product obtained may also react chemically. In one case it is assimilated by the eco-system, being converted into a harmless component or mixture of components, while in another it is converted, like nitrogen oxides, into a component even more dangerous to life (synergism). In both cases, account must be taken of the rate of reaction of the component:

$$\frac{\partial C^*}{\partial \tau} = K_1 - K_2, \qquad (10)$$

where k_i is the rate constant for the reaction leading to the formation of the component contaminating the environment and K_2 is the rate constant for the reaction leading to the consumption of this component. Eqn. (10) was formulated solely for zero-order reactions. For $K_1 \leqslant K_2$, i.e. when the reaction product does not contaminate the environment, it is possible to assess the ecological situation as favourable, because in this case nature fully processes the harmful waste.

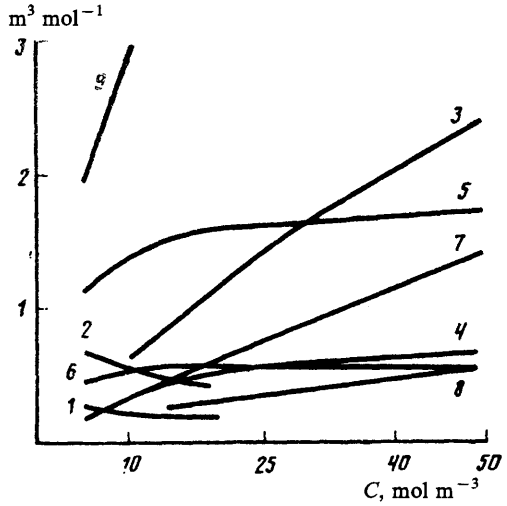

Figure 1. Dependence of the coefficient of the pollution of the environment on the salt content in the initial water subjected to extreme desalination by various methods: *1*, ion exchange (cation exchange–decarbonation–anion exchange–deionisation by a mixed bed); *2*, ion exchange with processing of waste water by electrodialysis; *3*, electrodialysis and ion exchange; *4*, ion exchange softening–electrodialysis–ion exchange; *5*, reverse osmosis–decarbonation–ion exchange; *6*, ion exchange softening–reverse osmosis–decarbonation–ion exchange; *7*, multichamber evaporation–ion exchange; *8*, ion exchange softening–multichamber evaporation–ion exchange; *9*, reverse osmosis–electrodialysis with ion exchange membranes and grains–ion exchange in a mixed bed.[10]

Fig. 1 presents the result of the calculation by Eqn. (7) of the coefficients of the pollution of the environment in the purification of water.[10] Analysis of the data presented in the figure shows that ion-exchange technology is ecologically less desirable than distillation technology, but the quality of water obtained by ion exchange is significantly higher than that produced by distillation.

III. The ion-exchange method for the preparation of ultrapure water

Ion exchangers are solid or liquid substances containing ions capable of exchanging with other ions of the same charge sign present in the solution where the given ion exchanger is insoluble.[12] Ion exchange was first used for the treatment of water with the aid of modified activated charcoals,[13] but, owing to their low stability in alkalies, the technology did not come to be widely employed. Furthermore, the natural and synthetic inorganic ion exchangers had a comparatively low exchange capacity. After Adams and Holmes[14] established in 1935 that the phenol-formaldehyde resin obtained by polycondensation has a much higher capacity compared with the known ion exchangers, commercial production of cation exchangers for the purification of water was organised in Germany. Less than a decade was needed to synthesise phenol-formaldehyde cation exchangers with sulpho-groups. D'Alelio[12] synthesised a sulphonated copolymer of styrene and diviylbenzene—the first monofunctional highly acid cation exchanger. Anion exchangers of the weakly basic and strongly types were soon synthesised. The present stage of the use of ion exchange for the purification of water began from that moment. The preparation of ultrapure water begins with cation exchange. The initial highly acid cation exchanger must be in the acid form and the cation exchange reaction then leads to the formation of the corresponding acids:

$$RH+NaCl=RNa+HCl\ ,$$
$$2RH+Ca(HCO_3)_2=R_2Ca+2CO_2+2H_2O\ ,$$
$$2RH+MgSO_4=R_2Mg+H_2SO_4\ .$$

The reactions are carried out so long as the cation exchanger in the acid form remains in the column. After the conversion of the cation exchangers into salt-forms, they must be regenerated. Chemical regeneration of cation exchangers with acids is usually employed in technology. The reason for the ecological undesirability of ion exchange for the intensive desalination of water arises from the necessity for the ion exchanger chemical regeneration reactions:

$$RNa+HCl=RH+NaCl\ ,$$
$$R_2Ca+2HCl=2RH+CaCl_2\ ,$$
$$R_2Mg+2HCl=2RH+MgCl_2\ .$$

Cation exchangers with the ionogenic sulpho-group have the maximum affinity for multicharged ions. The reason for this is both the direct and stronger electrostatic interaction of the multicharged counterions with the fixed ions and the strengthening of the hydrogen bond formed by the molecules of the water of hydration, the counterions, and the fixed ions. The sorbability series is as follows:

$$Fe^{3+}>Ca^{2+}>Mg^{2+}>Na^{+}>H^{+}\ .$$

The desorption of calcium and magnesium ions, the absorption of which is described by a convex isotherm, requires an appreciable excess of acids for regeneration. The complete regeneration of the cation exchanger in the sodium-form requires a 2.5-fold excess of acids. The desorption of doubly charged ions from an ion exchanger requires an even greater excess of acid and the regeneration is therefore carried out without restoring fully the capacity of the acid-form,[15] although this does not eliminate the need for the use of an excess of acid. As a result, the waste water from cation-exchange columns contains after regeneration an appreciable excess of acids together with sodium, calcium, and magnesium salts.

After cation exchange, the water is decarbonated to remove carbon dioxide, which is followed by anion exchange. The anion exchange process is carried out successively, initially on weakly basic and then on highly basic anion exchangers. The weakly basic anion exchangers contain primary, secondary, or tertiary amines as ionogenic groups which function effectively only in an acid medium. Therefore anion exchangers of this type sorb strong acid anions:

$$R'OH+HCl=R'Cl+H_2O\ ,$$
$$2R'OH+H_2SO_4=R_2'SO_4+2H_2O\ .$$

The necessity to use weakly basic anion exchangers is associated with the ease of their regeneration (the consumption of alkalies on the regeneration process is greater than the stoichiometric amount by a factor of 1.2–1.5). However, weakly basic anion exchangers hardly sorb weak acids, in particular silicic acid. An important feature is that highly basic anion exchangers function virtually in any pH range and sorb silicates from natural waters. On the other hand, highly basic anion exchangers are much more difficult to regenerate (the consumption of reagents is 5–10 times greater than the stoichiometric amount).

An exceptionally important step in the development of the ion-exchange method in the technology for the preparation of highly desalinated water was the application by Reents and Kahler[1] and almost simultaneously by Kunin and McGarvey[16] of a mixed bed of granulated cation and anion exchangers. The following reaction takes place in this case:

$$RH+ROH+NaCl=RNa+RCl+H_2O\ .$$

The proximity of heteropolar ion exchangers and the presence of a product with a low dissociation constant lead to a virtually irreversible reaction, which permits the complete demineralisation of water. Both a strongly acid cation exchanger and a strongly basic anion exchanger must be used for the complete demineralisation.

Since the electrochemical regeneration of a mixed bed of ion exchangers[17] has not come to be widely used, an obligatory stage is the separation of the components of the mixed bed. This operation is usually carried out by supplying water in the direction from below upwards. The cation exchanger, which is more dense, then settles downwards, while the anion exchanger forms the upper layer. After this, the cation exchanger and the anion exchanger are regenerated with acid and alkali respectively, the amounts consumed exceeding the stoichiometric amount by a factor of 2–3.

It is also important to draw attention not only to the necessity for an excess of the regeneration reagents but also for the necessity to double the mass of the reagents relative to the mass of the impurities extracted from natural water, because the cation and anion exchangers are regenerated separately. The cations of each electrolyte are sorbed on the cation exchanger and the anions are sorbed on the anion exchanger. They are regenerated in the same way. Altogether this leads to an increase in the mass of inorganic substances in waste waters by a factor of 3–15 depending on the quality of the initial water and the required degree of desalination.

Ultrapure water cannot be obtained by ion exchange without the preliminary sorption of organic susbtances.[15] Activated charcoals or anion exchangers of the macroporous and isoporous type are used for this purpose. Best results in the sorption of humates and fulvates from natural waters are obtained by the successive employment of weakly basic and highly basic anion exchangers. In particular, their successive adsorption on the USSR-produced anion exchangers IA-1 and AB-17P in the preliminary purification stage makes it possible to avoid the poisoning of the ion exchangers by humates and fulvates.[18] As a result of this, the principal units in the technology for the production of ultrapure water involve preliminary purification specific to a particular type of natural water, the adsorption of organic substances, cation exchange, decarbonation, anion exchange, and ion exchange in a mixed bed of cation and anion exchangers. Some of these operations can be repeated several times.[15]

After all these purification stages, the water is characterised by the lowest concentrations of impurities, approaching ideality in this respect. In the Soviet literature, a single term has not been established for the limiting quality of water and the concepts of ultrapure, specially pure, and highly pure water are used together with the term "deeply" desalinated water. The very term ultrapure water arose in the French language literature (l'eau ultrapure), while in the English language literature two terms exist—ultrapure water and high purity water. We have given preference to the term ultrapure water because it is most widely used in the world's scientific literature.

The question arises what characteristics shoudl utlrapure water possess? In view of the absence of a Government Standard (GOST) for ultrapure water, use is made of OST 11 029.003-80, where brands A, B, and C are distinguished in terms of their quality. The highest quality water of brand A must have a specific resistance not less than 18 MΩ cm at 20 °C, a permanganate oxidisability less than 0.5 mg O_2 litre^{-1}, a silicic acid content less than 0.01 mg litre^{-1}, iron and copper contents less than 0.002 mg litre^{-1}, not more than 2 microparticles per ml, and not more than 1 colony of microorganism. In the USA, the type 1 ASTM standard corresponds to water with a maximum specific conductance of 0.06 μS cm at 298 K (specific resistance 16.67 MΩ cm), a content of organic substances not more than 1 mg kg^{-1}, a content of dissolved gases not more than 200 mg kg^{-1}, a residue after evaporation not greater than 0.1 mg litre^{-1}, the absence of a positive response to the test for silicates, a maximum content of heavy metals of 0.01 mg kg^{-1}, and not more than 150 particles in 1 kg.

The development of the ion-exchange technology ensuring the preparation of water of the very highest quality by the most economical method, involving simple apparatus and permitting the attainment of virtually any required productivity of the latter, for a long time created the illusion that the problem of the preparation of ultrapure water has been solved. Difficulties arose when an attempt was made to organise a waste-free circulating water supply, which in our time has become absolutely essential, since the general ecological situation has become very much more acute. From the standpoint of the protection of nature the question arose whether or not the ion exchange technology transfers impurities to pure rivers and water-containing areas and whether or not the soil, air, and subterranean waters suffer as a result. It is known that water (rain and snow) precipitated on the surface of the soil in the active water exchange zone, where waste is in fact mainly stored, enters river water after approximately 17 years. Calculations show that in the immediate future the amount of chlorides of anthropogenic origin will exceed by a factor of 4 the natural background. By the end of the century, the antropogenic concentration of sulphates will exceed by a factor of almost 7 the concentration in 1980 and the LPC for commercial water-containing areas. The conversion of organic contaminants into mineral ones in the course of the biological purification of water does not in essence alter the fundamental situation. As a consequence of this, the discharge of mineralised waters, including regenerators of ion-exchange filters, is forbidden in the comparatively water-deficient Ukraine and individual sections of the Northern Donets and the Dneper.

We draw attention to the fact that, since the mass of mineral substances in the liquid waste from ion-exchange apparatus after chemical regeneration is more than three times greater than the amount of such substances extracted from natural waters, the degree of mineralisation of subterranean and river waters will increase after a certain time. Since the initial water will become more mineralised, this will entail the consumption of a greater mass of chemical reagents for regeneration. This will lead in its turn to an even greater pollution of the environment and ultimately to an additional increase in mineralisation. The reaction producing mineral substances will change from a zero-order process to a first-order process; since the production of mineral substances under such conditions is proportional to the concentration, we have

$$\frac{\partial C_i}{\partial \tau} = K_i C_i \,, \tag{11}$$

and this leads to an exponential increase in the concentration of mineral substances in subterranean waters and rivers:

$$C_i = C_{0,i} \cdot \exp(K_i \tau) \,. \tag{12}$$

Such a system may be characterised as an ecological boomerang, since not only an increase in the productivity of the devices using the ion-exchange method but also their functioning with a constant productivity entails a continuous impairment of the quality of the initial water and an exponential growth of the waste discharged as a function of time. The creation of the ion-exchange technology can be regarded nowadays as an ecological mistake with unforseeable harmful consequences involving a change in the environment, which vitiates the planned benefit and generates more problems than it solves. This entails a double tragedy, since it will be necessary to seek means not only for the liquidation of the waste discharged into natural waters but also for the solution of all the new problems arising in this connection (human diseases, destruction of fish farming, etc.). The "unpredictability" of the pernicious consequences is due to the inadequacy of the preliminary research and the underestimation of the impact on the environment and human beings.[8] Fig. 1 shows why ion exchange is an ecologically undesirable technology for the extreme purification of water.

IV. The membrane method for the extreme purification of water

The ecological undesirability of distillation and ion exchange necessitated the search for alternative methods leading to the solution of the problem of the preparation of ultrapure water. We shall consider the possibility of using membrane methods for the solution of the problem. Membrane is the term which has come to

be applied to a body whose extent in terms of two coordinates significantly exceeds its extent in terms of the third (a one-dimensional disperse system). The word membrane comes from the latin word meaning pellicle, shell, or partition. When generalised thermodynamic forces are applied to a membrane, mass fluxes arise.[19] Transport processes following the application of a chemical potential gradient (dialysis), a pressure gradient (microfiltration ultrafiltration, reverse osmosis), and an electric potential gradient (electrodialysis) are distinguished.

Baromembrane methods can be most usefully applied in the first stage of the purification of water. Natural water is initially filtered to remove coarsely dispersed impurities, after which it is subjected to microfiltration to remove finely dispersed impurities and bacteria.[20] In the next stage, colloid impurities, high molecular-weight and oligomeric compounds, and viruses are eliminated by means of ultrafiltration.[21,22] Using UAM-100 and UAM-150 ultrafiltration membranes, it was possible to remove about 80% of organic substances from water.[23] Next, reverse osmosis is used to purify water.[21,24]

In particular, when filter elements of the rolled up type with the MGA-95 cellulose acetate membranes are used, reverse osmosis makes it possible to obtain water with a specific resistance of 0.02–0.07 MΩ cm containing 0.25 mM silicate, exhibiting a permanganate oxidising capacity not more than 3.1 mg O_2 litre^{-1}, and showing the complete absence of microflora. On the other hand, one should immediately abandon the illusion that reverse osmosis makes it possible to obtain ultrapure water directly. Studies have shown that by this procedure it has not yet been possible to attain the state of distilled water formed after a single distillation and having a specific resistance of 0.1–0.3 MΩ cm. On the other hand, the role of reverse osmosis in increasing the ecological compatibility of the purification of water is so great that even its combination with ion-exchange deionisation by means of filters containing a mixed bed of granulated ion exchangers has come to be widely used.[25,26]

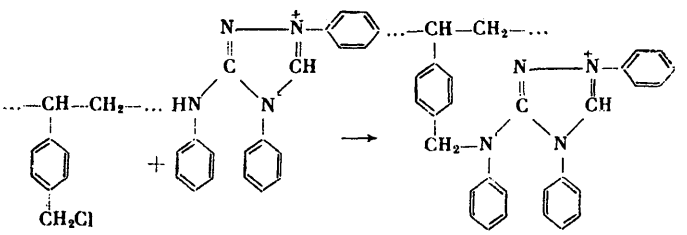
Extreme desalination of water treated by reverse osmosis can be achieved by electrodialysis using ion-exchange membranes. This can be best carried out in two steps. In the first step of the electrodialysis, the aim is to obtain water with a specific resistance of about 1 MΩ cm, while in the second the aim is to achieve a specific resistance of the order of 18 MΩ cm. Several versions of the procedure can be selected for the preparation of water with such a specific resistance. The first version represents electrodialysis employing ion-exchange membranes and a small distance between the membranes.[27] The intermembrane distance of 0.5 mm used by Tezikov and Saldadze makes it possible to obtain water in the required condition but at a relatively high coefficient of hydraulic resistance, requiring additional expenditure of electrical energy. The reason for the increase in the efficiency of desalination with decrease in the inter-membrane distance was investigated by laser interferrometry[28] and it was shown that the overlap of the boundary diffusion layers of the solution at the interfaces with the membranes plays a decisive role. For large intermembrane distances, there remains a zone in the middle of the desalination section in which no concentration changes occur. The second version, electrodialysis with the desalination section between the membranes filled with a mixed bed of granulated ion exchangers, was proposed by Walters, et al.[29] Glueckauf[30] investigated the function of the grains in electrodialysis with an ion-exchanger filled intermembrane section and found that heteropolar contacts between the anion-exchange grains and the cation-exchange membrane, on which water undergoes irreversible dissociation with formation of hydroxide ions migrating along the circuit and regenerating continuously the ion exchanger, play the main role. Subsequently anion exchange takes place between the hydroxide-form of the anion exchanger and the impurities in the water. Correspondingly water also decomposes the contacts between the cation-exchange grains and the anion-exchange membrane, hydrogen ions migrating along the chain of cation exchanger grains, regenerating them continuously. This is followed by ion exchange between the cationic impurities in the water and the hydrogen ions. Complete deionisation takes place because the desorption products (hydrogen and hydroxide ions) recombine to water—an electrolyte with a low dissociation constant. The impurity cations and anions migrate respectively along the chains of grains to equipolar membranes and are removed through them by the electric current to adjoining sections where the concentration takes place. In their study of the mechanism of transport through pairs of equipolar $\overrightarrow{C-C}$ and $\overrightarrow{A-A}$ grains (C and A denote cation-exchanger and anion-exchanger grains respectively and → indicates the direction of the direct current from the anode to the cathode) and also through heteropolar $\overrightarrow{C-A}$ and $\overrightarrow{A-C}$ grains, Gnusin and Grenenyuk established a series of fundamental features of the mass transfer.[31] They believe that equipolar contacts do not introduce significant changes into the distribution of local concentrations in the solution, whereas the C–A contacts concentrate the electrolyte in capillary gaps. The electrolyte concentrated in the capillary gaps is distributed by convection throughout the bulk of the solution in the desalination section, reducing fundamentally the efficiency of the process. This is the reason for the attempts to find a way of eliminating the C–A contacts. A solution was found using monolayers of alternating cation- and anion-exchanger grains placed in an inert grid.[32] The replacement of the inert grid by an ion-conducting grid makes it possible to reduce the energy expenditure to 0.2 kW h m^{-3}.[33]

Only electrodialysis with ion-exchange membranes and with the desalination sections between the membranes filled with a mixed bed of granulated ion exchangers can be used for the membrane preparation of ultrapure water in the final stage: in the regime with periodic circulation[34] and in the direct-flow continuous regime.[35] Many years after these investigations similar studies were performed in the USA by the Millipore Corporation[36] and in France.[37] As in the earlier studies,[34,35] the attainment of a specific resistance close to the limiting value was noted.[36,37] However, in addition to what was already known, it was stated[36] that the secondary contamination of water by solid particles is not observed. Thus the sequence of steps in the preparation of ultrapure water by membrane methods consists of filtration, microfiltration, and ultrafiltration stages, reverse osmosis, electrodialysis with ion-exchange membranes and a layer of granulated ion exchangers, and electrodialysis with ion-exchange membranes and the intermembrane space filled with a mixed layer of granulated ion exchangers.

In the membrane purification of water, there is no increase in the mass of substances in waste water compared with the mass of the extracted impurities. In the concentration sections, the mass is doubled and the concentration of inorganic substances is equal to the mass extracted, which imparts to membrane methods appreciable advantages over ion exchange and distillation. To some extent the future of membrane methods, which have been officially declared to be technologies for the XXIst century,[38] depends on the fraction of electrical energy which they consume. Estimation of the ecological compatibility of combined membrane methods yields the lowest coefficients of the pollution of the environment (Fig. 1), which

enables one to predict their successful development. On the other hand, we may draw attention to the large amount of scientific labour required by membrane methods[19] and also the necessity for qualified staff to use them. Theoretical studies in the field of mass transfer through membranes, which make it possible to create mathematical models optimising the membrane technology, have become particularly urgently required.

V. Removal of nitrates from natural waters



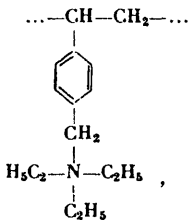
Apart from the tasks involving the general extreme purification of water, there are those concerned with local elimination of components which constitute a risk to human health. Among the problems which have given rise to particularly great alarm in society is that of the removal of nitrates from drinking water. Nitrates enter water as a consequence of the large-scale use of mineral fertilisers containing them. Mineral fertilisers began to be employed after Leibig developed in 1840 the theory of the mineral nutrition of plants, according to which man irreversibly extracts nitrogen compounds from the soil but their deficiency can be made good by nitrogen-containing inorganic salts (nitrates). The nitrates not assimilated by plants enter natural waters, which leads to two types of illness. The first is methaemoglobinemia induced by the oxidation of haemoglobin to methaemoglobin, which is incapable of chemisorbing oxygen. It has been established that an increase in the content of nitrates, nitrites, aniline, and nitrobenzene leads to methaemoglobinemia. Methaemoglobinemia is particularly dangerous for embryos and suckling infants, whose blood contains up to 85% of foetal haemoglobin, which is more susceptible to the action of nitrates than the haemoglobin of an adult human being. The second type of illness is caused by the reduction of nitrates to nitrites in the intestine followed by the reaction with amines, which converts them into carcinogenic nitrosamines. The content of nitrates in natural waters used for drinking has therefore been limited to 50 mg litre^{-1} in the countries of European Economic Community and in 1994 it is planned to reduce the limiting permissible concentration to 30 mg litre^{-1}.

Unfortunately the use of nitrates can no longer be avoided, since this would require a threefold increase in the arable land. It is therefore essential to determine nitrogen-containing substances in the soil in order to introduce fertilisers in controlled amounts. The use of a large mass of fertilisers, which cannot be immediately assimilated by soils and plants, is particularly dangerous. The membrane method for the controlled release of substances is therefore especially promising.[39] The Rose-Nelson pump, consisting of three sections separated by one semipermeable membrane and one impermeable elastic membrane, may serve as the simplest example of the use of this method. One of the three sections contains water, whilst the other, adjoining section contains the salt. The osmotic flux through the semipermeable membrane into the salt-filled section increases the osmotic pressure in the latter and, in the presence of the elastic membrane, leads to an increase in the volume of the section. The elastic membrane slowly forces out of the section the fertiliser solution or any preparation, including therapeutic preparations. One may foresee the wide scale future employment of this membrane method for the introduction of fertilisers into the soil. In the introduction of nitrate fertilisers, it is very important to select an appropriate time for this purpose. The best time for the feeding of plants is the vegetative period. Unfortunately at the present time the necessary agrochemical expertise involving the use of fertilisers is lacking and this leads to the limiting permissible concentration being appreciably exceeded in the drinking water in many regions, which require special methods for the elimination of nitrates from natural waters.

We shall consider the possibility of the elimination of nitrates from natural waters by biological and biotechnological methods. For the microbiological removal of nitrates, it is essential to create anaerobic conditions, which is in principle possible directly in the soil but requires not only the participation of bacteria but also of organic substances. For example, under laboratory conditions the anaerobic elimination of nitrates is carried out in the presence of ethanol and sodium phosphate. Such requirements cannot be satisfied in practice. The biotechnological method, in which bacteria convert nitrates into molecular nitrogen, has already found an application and has been proposed by the name Biodenit by the "Energy Equipment for Heidelberg Joint Stock Company". However, the application of this method leads to the production of a large amount of biomass and side products, which is also unacceptable for the conditioning of water in order to obtain drinking water yet alone for its intense purification. The ion-exchange method for the removal of nitrates from drinking water has come to be widely used. Its effective application required anion exchangers selective with respect to nitrates. There are two versions of the synthesis of selective ion exchangers. The first involves the introduction into the polymer of an ionogenic group with a specific strong interaction with a particular ion. The classical example is provided by the synthesis of the potassium-selective cation exchanger by Scogside,[12] who obtained it by introducing into the polymer hexanitrodiphenylamine (dipicrylamine), which is used as a reagent for the precipitation of potassium.

The second procedure involves the regulation of the properties of the polymers, promoting an increase in selectivity. For example, the introduction of the cross-linking agent diphenylbenzene in the polymerisation of styrene increases the selectivity of the ion exchangers as a result of the decrease in the water content. The reduction of the water content is accompanied by a decrease in the number of water molecules between the fixed ion and the counterion in the ion exchanger and an intensification of the electrostatic interaction. Electrostatic interactions involving ions of different radius and bearing different charges differ fairly markedly, whereas the energies of the hydrogen bonds formed by water molecules between the fixed ion and the counterion are similar.

A nitrate-selective anion-exchanger was obtained by the reaction of the chloromethylated styrene-divinylbenzene copolymer with 1,4-diphenyl-2-phenylaminodihydrotriazole (nitrone):[40]



The isotherms of the exchange of chloride and sulphate ions for nitrate ions obtained by Frölich and Weber[40] show the high selectivity of the above anion exchanger in relation to nitrate ions. The nitrone anion exchanger is regenerated chemically with a 5% solution of sodium chloride. After many repetitions of these cycles,

no losses in exchange capacity were observed. The traditional type of highly basic anion exchanger made of the styrene-divinylbenzene copolymer and comprising the benzyltrimethylammonium elementary unit (AV-17) exhibits a higher selectivity in relation to sulphate ions. The selectivity sequence is as follows:

sulphate > nitrate > chloride > bicarbonate

The replacement of methyl groups in the fixed ion by ethyl groups alters the selectivity sequence in the anion exchanger

and the latter becomes more selective in relation to nitrates.

The membrane methods for the removal of nitrates from natural waters are ecologically more promising. However, the membranes synthesised at the present time exhibit a selectivity of 86% with respect to nitrate ions, while the selectivities with respect to chloride and sulphate ions are 94 and 90% respectively. Furthermore, in reverse osmosis the membranes retain also cations. In particular, the selectivity with respect to calcium ions reaches 96%.[42] Therefore reverse osmosis makes it possible to demineralise water at the present time but does not allow the selective extraction of nitrates from it.

Electrodialysis with ion-exchange membranes is especially promising for the removal of nitrate from drinking water.[42] The use of a mixed layer of ion exchangers for the filling of the desalination sections permits the intense elimination of nitrates from water, but, as in reverse osmosis, it is not possible to achieve the selective removal of nitrates from water. Therefore the membrane method has still not solved the problem of the selective transport of nitrates through membranes and the ion-exchange extraction of nitrates with the aid of the nitrate-selective ion exchangers is most useful.

Nitrogen- and sulphur-containing macroheterocycles and their complexes. New low molecular models of enzymes†

M G Voronkov, V I Knutov
Irkutsk Institute of Organic Chemistry, Siberian Division of the Academy of Sciences of the USSR

ABSTRACT. Methods of synthesising *N,S*-containing macroheterocycles and their complexes with cations, anions and organic molecules are discussed. Complexes of copper(II) ions with thiazamacrocyclic ligands as low molecular structural models of the active centres of "blue" proteins are considered. The possibility of transporting metal ions through membranes by thiaza-crown compounds and the application of complexes of them in catalysis has been shown. Promising directions for using nitrogen- and sulphur-containing macroheterocycles in modelling enzymes are discussed.

The bibliography contains 98 references.

I. Introduction

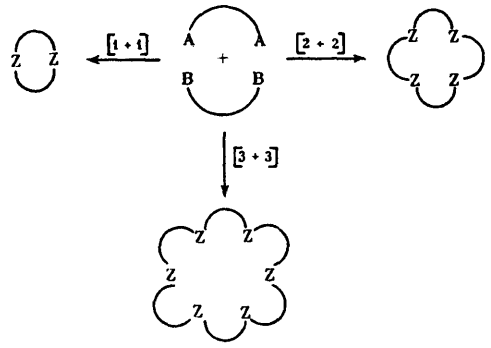
The vigorous development of the chemistry of macroheterocyclic compounds which has been observed in recent years is explained by the discovery of crown ethers and their ability to form stable complexes selectively with ions of the alkali and alkaline earth metals.[1–3] Further investigations in this area have shown that the macroheterocycles bind not only metal cations but also anions and even neutral organic molecules, forming complexes of the "host–guest" type.[2,3]

The study of nitrogen-sulphur-containing macroheterocycles and complexes of them as models of biological systems and processes occurring *in vivo* involving compounds of nitrogen and sulphur has become urgent. In particular, complexes of thiaza-crown compounds with copper(II) ions attract attention as models of copper proteins ("blue" proteins). The active centre of "blue" proteins is a complex of a copper(II) ion in an environment of nitrogen and sulphur atoms. It is characterised by spectral and oxidation–reduction properties unusual for copper(II) compounds. Investigation of the analogous physicochemical characteristics for complexes of macroheterocycles containing nitrogen and sulphur with copper(II) ions has shown that they are identical in this respect to a copper-containing "blue" protein. Copper proteins are important metal-containing enzymes for living organisms. They participate in electron-transfer, the metabolism of compounds and they catalyse oxidation–reduction functions of cell respiration. The study of copper(II) complexes with polythiazacrown compounds is urgent due to their use as low molecular models of metalloenzymes.

The metalloenzymes are highly organised systems possessing high substrate selectivity and catalytic activity. The further development of synthetic enzymes ("synzymes")[5,98] is only possible on continuing from simple monomolecular systems to oligomolecular systems, particularly to associates, bound by non-covalent interactions, i.e. by transferring from molecular chemistry to supramolecular chemistry.[4,5]

The development of supramolecular chemistry to date already enables the recognition and selective interaction of a macrocyclic receptor with various substrates to be effected.[5] This interaction is effected in two ways. Complex-formation may occur within the cavity of a macrocycle, when the receptor is able to "envelop" a substrate and retain it through the formation of many non-covalent bonds. Biological analogues of these endoreceptors may be found in the active centres of enzymes where a substrate insignificant in size is bound within the cavity of a large protein molecule. Another type of substrate binding uses the outer surface of the receptor. In this case complex-formation of the exoreceptor with the substrate occurs by surface–surface interaction. The biological analogy for this may be the protein–protein interactions occurring on the antigen–antibody interface, leading to immunological recognition processes.

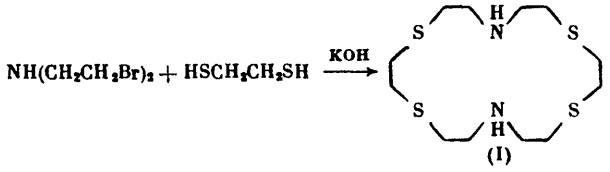
N,S-Containing macroheterocycles display the properties of both endo- and exoreceptors in that they selectively bind cations, anions and organic substrates. The further development of the chemistry of nitrogen- and sulphur-containing macroheterocycles and their investigation as enzyme models may become the chief instrument for studying the structure and biological properties of many biopolymers.



II. Synthesis of *N,S*-containing macroheterocycles

1. Aliphatic polythiaza crown compounds

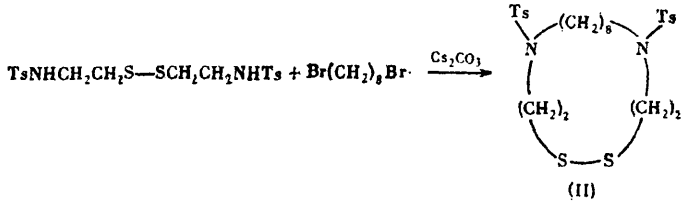
The formation of macrocyclic compounds is complicated by the presence of secondary linear polycondensation products since the oligomers formed as intermediates may later take part in both intra- and intermolecular reactions at the same time. One further difficulty is the occurrence of cyclisation at several stoichiometric levels



†Awarded first prize at the competition for reviews organised by section No. 4 "Organic and Hetero-organic Synthesis" of the Inter-departmental Scientific-Technical Bureau on the priority directions of chemical science and technology.

simultaneously. If one molecule of each starting material partakes in the formation of the macromolecule, that is designated a [1 + 1] condensation. There are also [2 + 2] and [3 + 3] condensations.

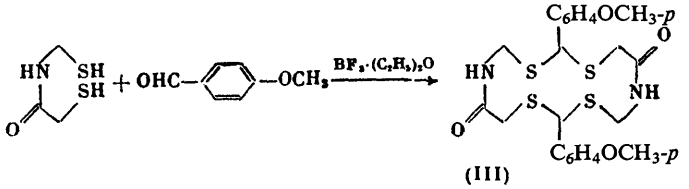
High dilution methods and template reactions are mainly used to prevent side reactions.



For example, the reaction of bis(2-bromoethyl)amine with ethane-1,2-dithiol takes place under conditions of high dilution by a [2 + 2] condensation.

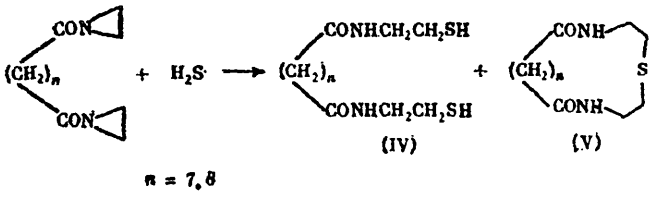
(I)

The yield of 1,4,10,13-tetrathia-7,16-diazacyclo-octadecane (I) was 45%.[6,7]



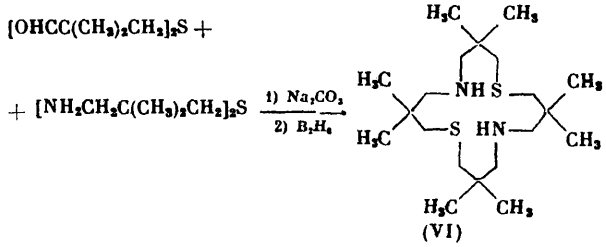
The macrocyclic disulphide (II) is obtained by the reaction of ditosylated cystamine with 1,8-dibromooctane in DMF in the presence of Cs_2CO_3.[8]

(II)



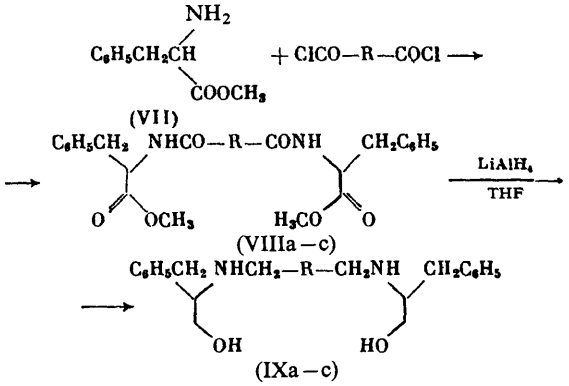
Reaction was carried out at room temperature for 24 h, the yield of macroheterocycle (II) was 20%.

The *N*-(mercaptomethyl)amide of thioglycolic acid reacts with anisaldehyde by a [2 + 2] condensation with the formation of the tetrathiadiaza crown compound (III) (61% yield).[9]



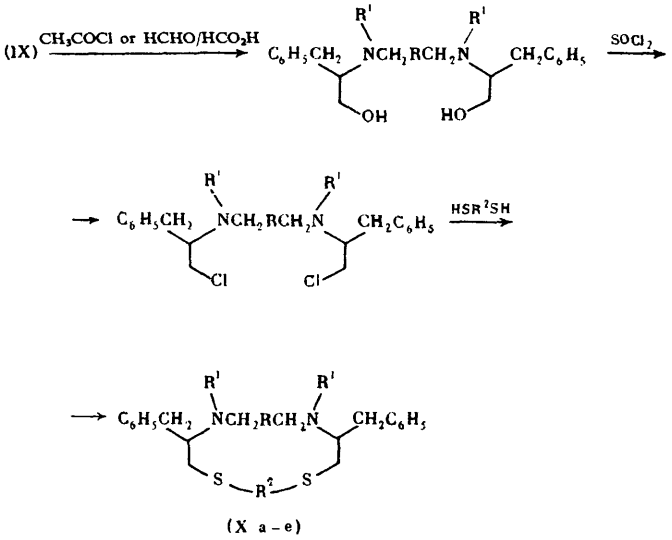
(III)

Fission of the aziridine rings of the bis-*N*-ethylenimides of azelaic and sebacic acids with hydrogen sulphide leads to a mixture of the linear bis(2-mercaptoethyl)diamides of the corresponding acids (IV) and the macrocyclic sulphide (V).[10]



The dithiadiaza crown compound (VI), containing quaternary carbon atoms, is obtained by the reaction of 2,2,6,6-tetramethyl-4-thiaheptane-1,7-dial with 2,2,6,6-tetramethyl-4-thia-1,7-heptanediamine with subsequent treatment with diborane in THF.[11]

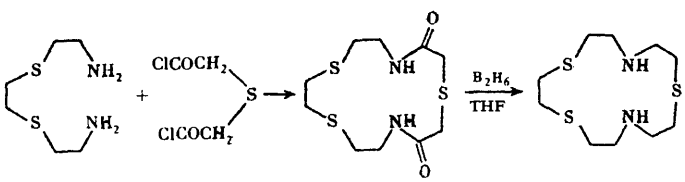
(VI)



The synthesis of chiral *N,S*-containing macrocycles is effected by the reaction of L-phenylalanine methyl ester (VII) with the diacid chlorides of dicarboxylic acids with several subsequent conversions.[12] On using the diacid chlorides of oxalic, succinic and diglycolic acids, the diamides (VIIIa–c) were obtained in 68–90% yield. Reduction of them with $LiAlH_4$ in THF leads to the diaminoalcohols (IXa–c).

R = a bond (a), $-(CH_2)_2-$ (b), $-CH_2OCH_2-$ (c)

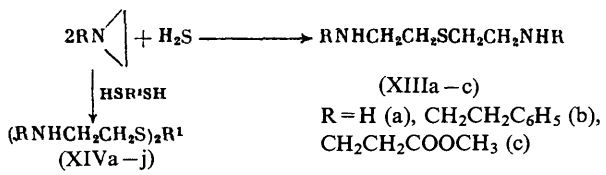
Treatment with CH_3COCl or $HCHO/HCO_2H$ and subsequent reduction gives the alkyl substituted diaminoalcohols. Reaction of the latter with $SOCl_2$ and subsequent cyclisation with α,ω-alkane-



dithiols leads to the chiral *C*- and *N*-substituted *N,S*-containing macrocycles (Xa–f) in 16–26% yield.

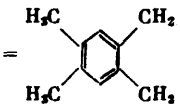
(X a–e)

(Xa): R = a bond, $R^1 = C_2H_5$, $R^2 = -(CH_2)_2-$;
(Xb): R = a bond, $R^1 = C_2H_5$, $R^2 = -(CH_2)_3-$;
(Xc): R = a bond, $R^1 = C_2H_5$, $R^2 = -(CH_2)_4-$;
(Xd): $R = -(CH_2)_2-$, $R^1 = C_2H_5$, $R^2 = -(CH_2)_3-$;
(Xe): $R = -(CH_2)_2-$, $R^1 = CH_3$, $R^2 = -(CH_2)_3-$;
(Xf): $R = -CH_2OCH_2-$, $R^1 = CH_3$,
$R^2 = -(CH_2)_2S(CH_2)_2S(CH_2)_2-$



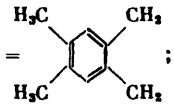
The most accessible method of synthesis of *N,S*-containing macroheterocycles is the acylation of open chain sulphur-containing diamines with diacid chlorides of dicarboxylic acids. On reacting 1,8-diamino-3,6-dithiaoctane with the diacid chloride of thiodiglycolic acid, a cyclocondensation of the [1 + 1] type takes place with the formation of the macroheterocycle (XI).[13]

(XI) (XII)

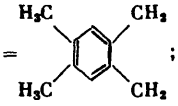


Reduction of the amide groups of the macrocycle (XI) with diborane leads to the crown compound (XII) in 57% yield.

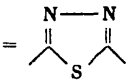
Methods have been developed for obtaining polycarbo-functional *N,S*-containing open chain compounds (XIIIa–c) and (XIVa–j) on the basis of which macroheterocycles with the same various exocyclic functional groups have been synthesised.[14–27]



(XIIIa–c)
R = H (a), $CH_2CH_2C_6H_5$ (b), $CH_2CH_2COOCH_3$ (c)



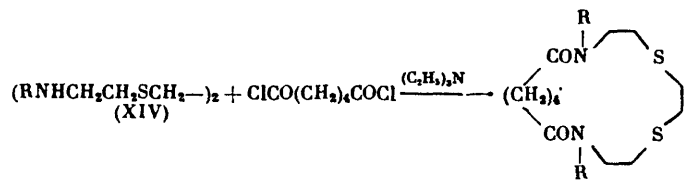
(XIVa): R=H, $R^1=CH_2CH_2$;



(XIVb): R = H, R^1 =  ,

(XIVc): $R = CH_2CH_2C_6H_5$, $R^1 = CH_2CH_2$;

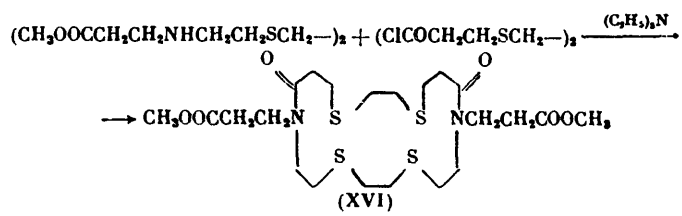
(XIVd): $R = CH_2CH_2C_6H_5$, R^1 =  ;



(XIVe): $R = CH_2CH_2COOCH_3$, $R^1 = CH_2CH_2$;

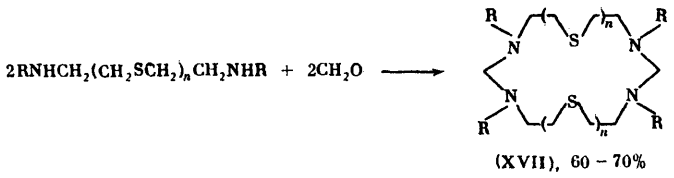
(XIVf): $R = CH_2CH_2COOCH_3$, R^1 =  ;

(XIVg): $R = CH(COOCH_3)CH_2COOCH_3$, $R^1 = CH_2CH_2$;
(XIVh): $R = CH(COOC_2H_5)CH_2COOC_2H_5$, $R^1 = CH_2CH_2$;
(XIVi): $R = CH_2CH_2CN$, $R^1 = CH_2CH_2$;
(XIVj): $R = CH_2CH_2COOCH_3$, R^1 = 



The sulphur-containing diamides are obtained by the reaction of ethylenimine or its *N*-substituted derivatives with hydrogen sulphide or α,ω-aliphatic, aromatic and heterocyclic dithiols.[14–27] The reaction with H_2S proceeds in methanol at room temperature and with α,ω-dithiols at 60 °C. The yields of diamines (XIIIa–c) and (XIVa–j) were 80–90%.

The cyclocondensation of diamines (XIVa), (XIVc), (XIVe) and (XIVi) with the diacid chloride of adipic acid leads to the 16-membered macroheterocycles (XV) in 70% yield.[16]

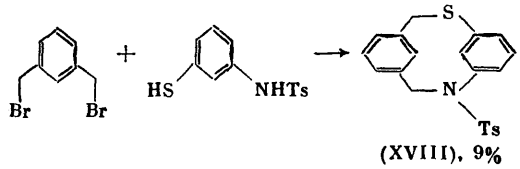


R = H, $CH_2CH_2C_6H_5$, $CH_2CH_2COOCH_3$, CH_2CH_2CN

The 20-membered macrocycle (XVI) containing exocyclic methoxycarbonylethyl groups is obtained by the reaction of diamine (XIVe) with the diacid chloride of dithiaoctane-dicarboxylic acid.[17]

(XVI)

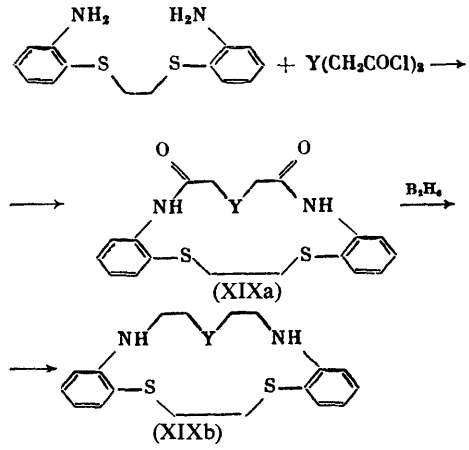
The macroheterocycles (XV) and (XVI) were synthesised in dry benzene under high dilution conditions. The secondary diamines (XIIIb, c) and (XIVc, e, g, i) form a 22-membered polythiaza-crown compound (XVII) with formaldehyde.[25-27]



(XVII), 60 – 70%

n=1: R=$CH_2CH_2C_6H_5$, $CH_2CH_2COOCH_3$; n=2: R=$CH_2CH_2C_6H_5$, $CH_2CH_2COOCH_3$, $CH(COOCH_3)CH_2COOCH_3$, CH_2CH_2CN.

The cyclocondensation proceeds in methanol under high dilution conditions according to a [2 + 2] type.



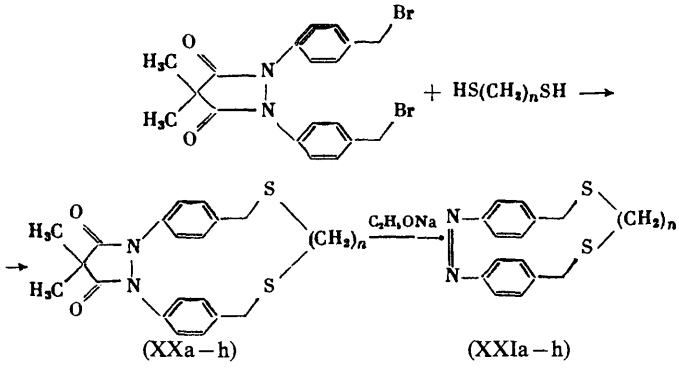
2. *N,S*-containing cyclophanes

Thiazamacrocycles containing a benzene ring in the molecule possess a stable cyclic skeleton which is important on complex-formation with metal ions and organic molecules. For example, the 10-membered cyclophane (XVIII) is obtained by the reaction of 1,3-bis(bromomethyl)benzene with 1-[(*p*-toluenesulphonyl)amino]-3-mercaptobenzene in the presence of caesium hydroxide under high dilution conditions.[28]

(XVIII), 9%

The acylation of 1,4-bis(2-aminophenyl)-1,4-dithiabutane with the diacid chlorides of glutaric and thiodiglycolic acids proceeds more successfully.[29] Reaction is effected under high dilution conditions in benzene, the yield of sulphur-containing diamides (XIXa) was 64–90%.

(XIXa)



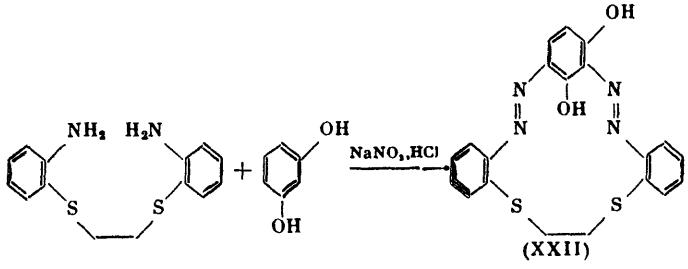
(XIXb)

Y = CH_2, S

Reduction of the amide groups with boron hydride leads to the macroheterocycle (XIXb) in 78–95% yield.

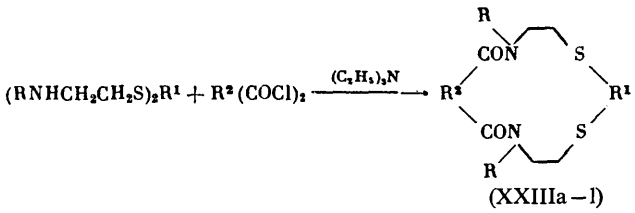
Crown compounds containing chromophoric groups are of interest as new types of macroheterocycle dyestuffs, organic reagents and extracting agents. One of the methods of synthesis of such chromophoric crown compounds is the introduction of an azo group into the molecule. An endocyclic azo group not only does not impair the complex-forming properties of crown compounds but also confers on them new interesting properties such as rigidity of the cyclic skeleton and the possibility of changing their ability towards complex formation under the action of irradiation due to *cis-trans*-isomerisation.

Dithiadiaza[2.n]paracyclophanes (XXa–h) are obtained by the reaction of the appropriate dibromides with α,ω-alkanedithiols. Treatment of them with sodium ethoxide leads to the *N,S*-containing macroheterocycles (XXIa–h) containing an endocyclic azo group.[30]



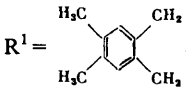
(XXa–h) (XXIa–h)

n=2 (a), 3 (b), 4 (c), 6 (d), 7 (e), 8 (f), 9 (g), 12 (h).



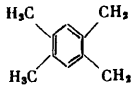
It was found that the macroheterocycles (XXIa–c) have the *cis* geometry while the cyclophanes of larger dimensions (XXIg, h) are more inclined to form *trans* isomers. The macrocycles (XXId–f) have both *cis* and *trans* configurations.

The azo coupling reaction of 1,4-bis(2-aminophenyl)-1,4-dithiabutane with resorcinol has been studied. It leads to a sulphur-containing cyclophane with two azo groups in the macrocycle (XXII).[31]



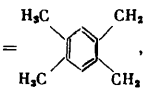
(XXII)

The synthesis of the *N,S*-containing macrocycles (XXIIIa–l) containing aromatic rings and exocyclic functional groups has been effected by the reaction of α,ω-diamines (XIVa–j) with the diacid chlorides of phthalic and terephthalic acids.[14–27,33–37]



(XXIIIa–l)

(XXIIIa): R = H, $R^1 = CH_2CH_2$, $R^2 = 1,2\text{-}C_6H_4$;
(XXIIIb): $R = CH_2CH_2C_6H_5$, $R^1 = CH_2CH_2$, $R^2 = 1,2\text{-}C_6H_4$;
(XXIIIc): $R = CH_2CH_2COOCH_3$, $R^1 = CH_2CH_2$, $R^2 = 1,2\text{-}C_6H_4$;
(XXIIId): $R = CH(COOCH_3)CH_2COOCH_3$, $R^1 = CH_2CH_2$, $R^2 = 1,2\text{-}C_6H_4$; (XXIIIe): $R = CH(COOC_2H_5)CH_2COOC_2H_5$, $R^1 = CH_2CH_2$; $R^2 = 1,2\text{-}C_6H_4$; (XXIIIf): R = H,



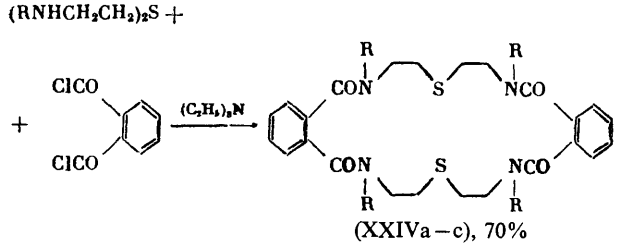
$R^2 = 1,2\text{-}C_6H_4$;

(XXIIIg): $R = CH_2CH_2COOCH_3$, $R^1 =$

$R^2 = 1,2\text{-}C_6H_4$; (XXIIIh): $R = CH_2CH_2COOCH_3$, $R^1 = CH_2CH_2$, $R^2 = 1,4\text{-}C_6H_4$; (XXIIIi): $R = CH_2CH_2C_6H_5$, $R^1 = CH_2CH_2$, $R^2 = 1,4\text{-}C_6H_4$; (XXIIIj): $R = CH(COOCH_3)CH_2COOCH_3$, $R^1 = CH_2CH_2$, $R^2 = 1,4\text{-}C_6H_4$;

(XXIIIk): $R = CH_2CH_2COOCH_3$, $R^1 =$

$R^2 = 1,4\text{-}C_6H_4$;

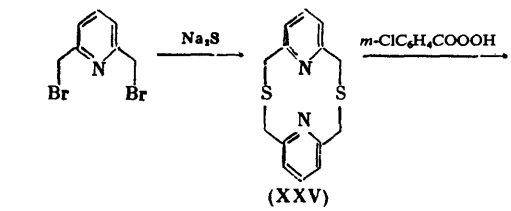


(XXIIIl): $R = CH_2CH_2COOCH_3$ $R^1 =$

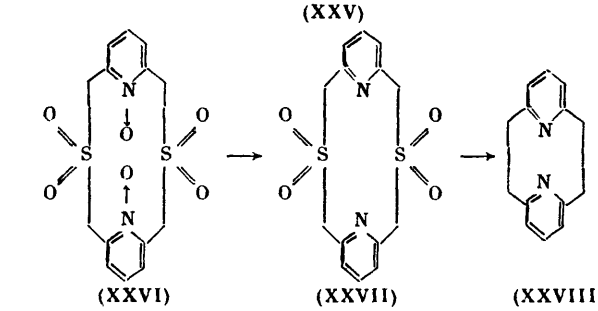
$R^2 = 1,2\text{-}C_6H_4$.

Cyclocondensation occurs according to the [1 + 1] type in dry benzene under high dilution conditions. The yields of the *N,S*-containing macroheterocycles (XXIIIa–l) were 70–80%.

Under analogous conditions the reaction of diamines (XIIIa–c) with the phthaloyl chloride was effected according to a [2 + 2] type with the formation of the 22-membered macroheterocycles (XXIVa–c).[32]



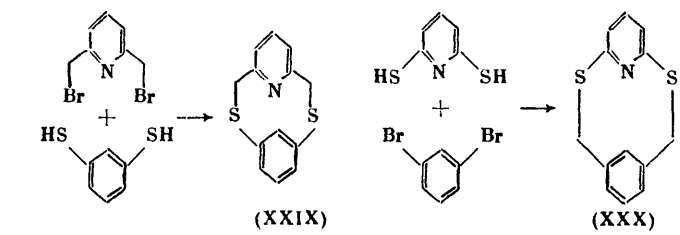
(XXIVa–c), 70%



R = H (a), $CH_2CH_2C_6H_5$ (b), $CH_2CH_2COOCH_3$ (c)

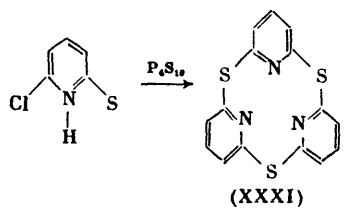
3. Sulphur-containing pyridinophans

The synthesis of pyridinophan (XXV) is effected by the reaction of 2,6-bis(bromomethyl)pyridine with sodium sulphide by a [2 + 2] condensation.[38]



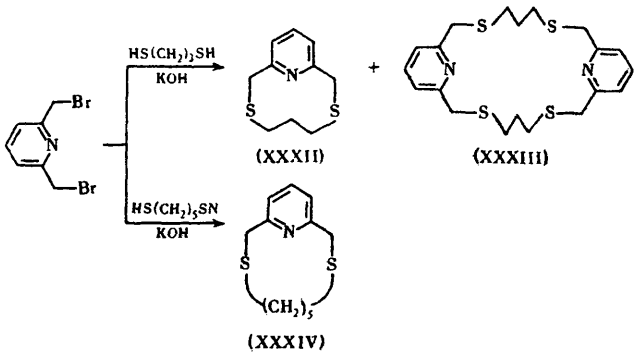
(XXV)

(XXVI) (XXVII) (XXVIII)



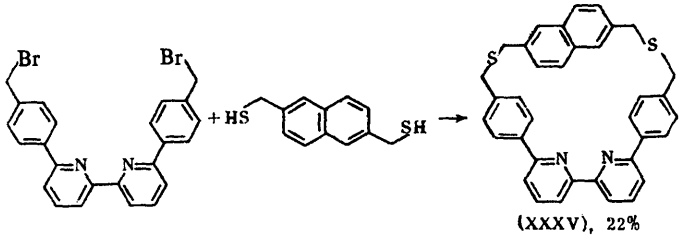
Oxidation of pyridinophan (XXV) leads to its bis-sulphone bis-*N*-oxide (XXVI). The selective reduction of the *N*-oxide groups with iron in trifluoroacetic acid gives the bis-sulphone (XXVII), pyrolysis of which leads to pyridinophan (XXVIII) in 46% yield.[39]

A series of pyridinophans such as (XXIX) or (XXX) containing bridge carbon–sulphur bonds is obtained by the reaction of 2,6-bis(bromomethyl)pyridine with dithioresorcinol[40] and other dithiols,[41–44] and also by the reaction of 2,6-bis(mercaptomethyl)pyridine or 2,6-pyridinedithiol with 1,3-dihaloalkylbenzenes.[45–50] Other methods of synthesis of such pyridinophans have also been described.[51,58]



(XXIX) (XXX)

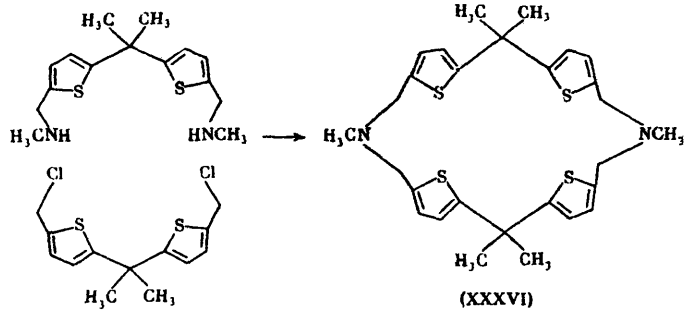
The pyridinophan (XXXI) with bridging sulphur atoms is obtained by intramolecular condensation of 6-chloropyridine-2-thione in the presence of P_4S_{10}.[52]



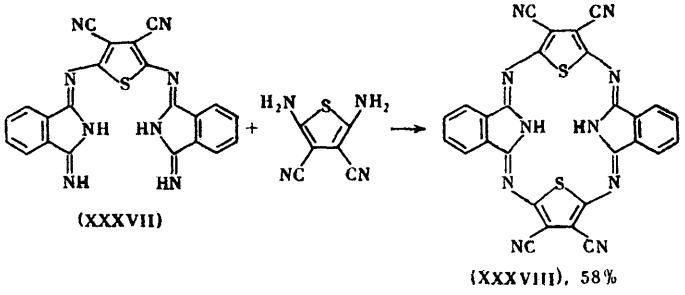
(XXXI)

The reaction of 2,6-bis(bromomethyl)pyridine with 1,3-propanedithiol occurs by a [1 + 1] and a [2 + 2] condensation simultaneously and leads to a mixture of the ten (XXXII) and twenty-membered pyridinophans (XXXIII) respectively.[53]

The analogous reaction with 1,5-pentanedithiol leads exclusively to the twelve-membered macroheterocycle (XXXIV), the formation of the dimeric macrocycle was not observed.

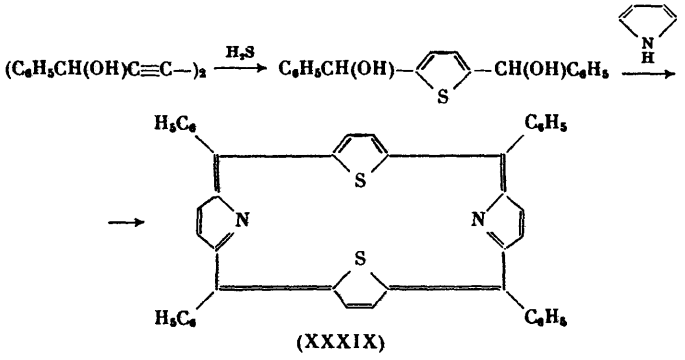


The thiaza crown compound (XXXV) containing a bipyridyl fragment is obtained by the reaction of 6,6′-di-(4-bromomethylphenyl)-2,2′-bipyridyl with 2,6-bis(mercaptomethyl)naphthalene under conditions of high dilution.[54,55]



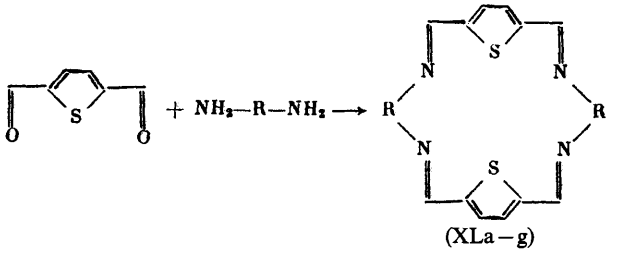
The reaction occurs in the presence of Cs_2CO_3 at 50 °C in DMF.

4. Nitrogen-containing thiophenophans



Methods have been developed for the synthesis of macroheterocycles in which thiophene rings are included as structural subunits and chains of C–N–C fragments form bridges. For example, the reaction of 2,2-bis(5′-methylaminomethyl-2′-thienyl)propane with 2,2-bis(5′-chloromethyl-2′-thienyl)propane in benzene at 40 °C leads to the *N,S*-containing macrocycle (XXXVI).[56]

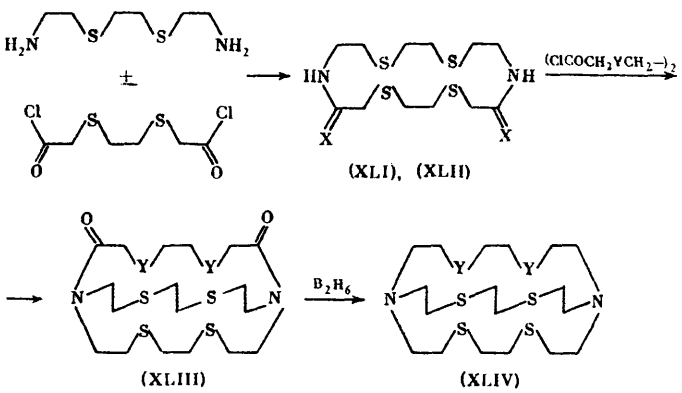
The macroheterocyclic compound (XXXVIII) is formed on treatment of the derivative (XXXVII) with 2,5-diamino-3,4-dicyanothiophene.[57,58]



The dithiaporphyrin (XXXIX) is synthesised from 2,5-bis(phenylhydroxymethyl)thiophene and pyrrole.[59]

2,5-Bis(phenylhydroxymethyl)thiophene was obtained by the reaction of the corresponding diacetylene with hydrogen sulphide. Cyclisation was effected in a mixture of chloroacetic acid–benzene, chloroacetic acid–toluene or in propionic acid. The yield of compound (XXXXIX) was 4–10%.

The reaction of thiophene-2,5-dicarbaldehyde with α,ω-alkylenediamines has been studied.[60]



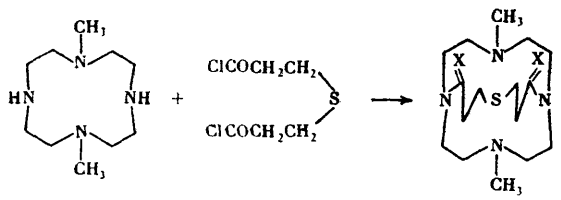
R = $(CH_2)_3$ (a), $(CH_2)_4$ (b), $(CH_2)_5$ (c), $(CH_2)_6$ (d), $(CH_2)_2S(CH_2)_2$ (e), $(CH_2)_2NH(CH_2)_2$ (f), $(CH_2)_3NH(CH_2)_3$ (g).

The reaction occurs in methanol at room temperature in 2.5 h or on heating in 0.5 h with the formation of the dimeric product ([2 + 2] condensation). The yield of *N,S*-containing macrocycles (XLa–g) varied from 50 to 90%.

5. *N,S*-Containing trimeric macroheterocyles

Trimeric macroheterocycles, cryptands, clathrochelants, form exceptionally stable complexes with a wide range of cations. They are capable of completely encapsulating a metal ion. Consequently there is undoubted interest in *N,S*-containing macrobicycles (cryptands) which form stable complexes with transition metals.[61]

The reaction of 1,8-diamino-3,6-dithioctane with the diacid chloride of 3,6-dithioctanedicarboxylic acid leads to the diamide (XLI). The subsequent reduction of diamide (XLI) with diborane gives the *N,S*-containing macrocycle (XLII). The macrobicyclic diamides (XLIII) are obtained by the condensation of the latter with diacid chlorides of dicarboxylic acids. The cryptands (XLIV) are obtained in 30% yield by reduction of the diamides with diborane.

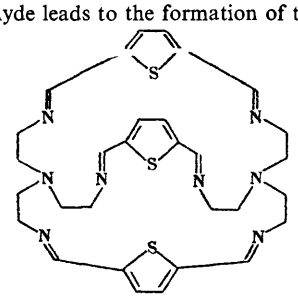


(XLI), (XLII)

(XLIII) (XLIV)

(XLI): X = O; (XLII): X = H_2; (XLIII), (XLIV): Y = S, N—Ts, NH.

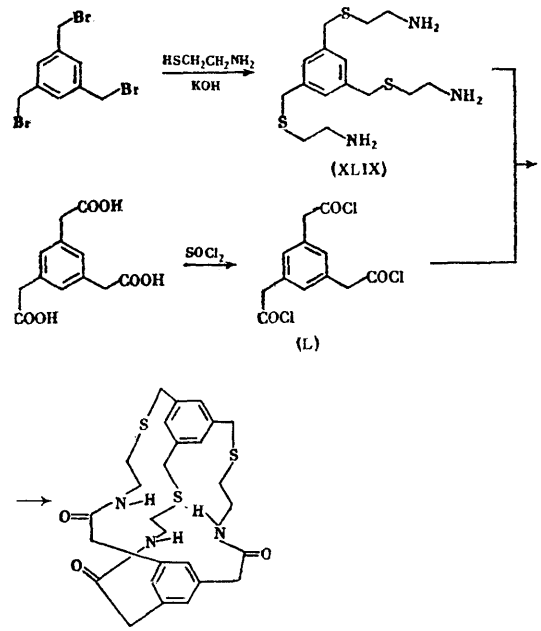
The synthesis of cryptand (XLVII), containing four nitrogen atoms and one sulphur atom in the molecule has been carried out.[62]



(XLVI), (XLVII)

(XLVI): X = O; (XLVII): X = H_2.

The basis of the preparation of (XLVII) is the reaction of the monomacrocyclic compound 1,7-dimethyl-1,4,7,10-tetraazacyclododecane with the diacid chloride of 3,3'-thiodipropionic acid. The macrobicyclic diamide (XLVI), formed in 75% yield, is reduced in diborane in THF. The cryptand (XLVII) is isolated in 68% yield.

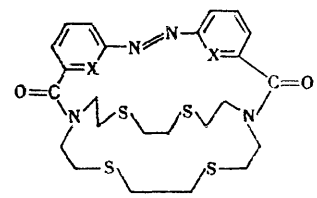


Treatment of tris(2-aminoethyl)amine with thiophene-2,5-dicarbaldehyde leads to the formation of the cage molecule (XLVIII).[63]

(XLVIII)

The reaction occurs at a molar ratio of trisamine and dialdehyde of 2:3 [yield of the macrobicycle (XLVIII) was 56%].

The synthesis of trithiacyclophan (LI) containing three amide groups is effected by the condensation of the triamine (XLIX) with the triacid chloride (L) by the following scheme.[64]



(XLIX)

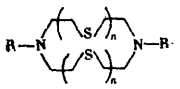
(L)

(LI)

The triamine (XLIX) is obtained by the reaction of 1,3,5-tris-(bromomethyl)benzene with cysteamine in the presence of KOH in methanol and the triacid chloride of benzene-1,3,5-triacetic acid (L) is synthesised by reaction with thionyl chloride in toluene. Reaction of the triamine (XLIX) with the triacid chloride (L) occurs in dry THF [yield of macrobicycle (LI) is 11%].

The photosensitive *N,S*-containing cryptands (LII) and (LIII) are synthesised by the cyclocondensation of the triaza-crown compound (XLII), with 6,6'-bis(chloroformyl)-2,2'-azopyridine and with 3,3'-bis(chloroformyl)azobenzene respectively under high dilution conditions.[65]

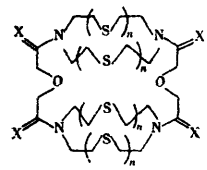
(LII): X = N;
(LIII): X = CH.



(LII), (LIII)

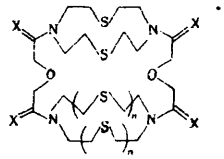
The yields of *trans*-cryptands (LII) and (LIII) were 33 and 24% respectively.

Polymacrocyclic systems may enclose two or more metal cations in the internal cavity of the molecule. Such cryptates are of interest as models of polynuclear biological complexes or as polynuclear catalysts.



A general method of constructing cylindrical polymacrocyclic systems has been proposed.[66,67] Synthesis of the sulphur-containing trimacrocyclic tetraamide (LVa) is based on the condensation of the

macrocycle (LIVd), containing reactive substituents at the nitrogen atoms, with the macroheterocycle (LIVa). Subsequent reduction of the tetraamide (LVa) with diborane leads to the cylindrical trimacrocyclic tetrathiatetraamine (LVb).



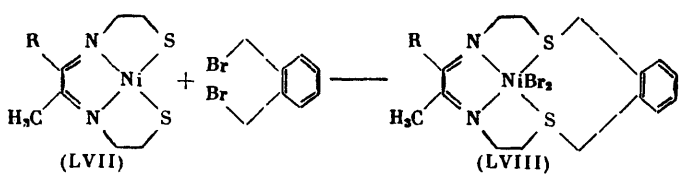
(LIVa–g)

(LIVa): $n=1$, R = H;
(LIVb): $n=1$, R = CH_3;
(LIVc) $n=1$, R = $COCH_2OCH_2COOH$;
(LIVd): $n=1$, R = $COCH_2OCH_2COOC_6H_4NO_2$-*p*;
(LIVe): $n=2$, R = CH_3;
(LIVf): $n=2$, R = $COCH_2OCH_2COOH$;
(LIVg): $n=2$, R = $COCH_2OCH_2COOC_6H_4NO_2$-*p*;

(LVa–d)

(LVIa, b)

(LVa): $n=1$, X = O;
(LVb): $n=1$, X = H_2;
(LVc): $n=2$, X = O;
(LVd): $n=2$, X = H_2;

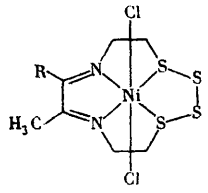


(LVIa): $n=2$, X = O;
(LVIb): $n=2$, X = H_2

The trimacrocycles (LVc) and (LVIb) are obtained in a similar manner.

6. Template synthesis of *N,S*-containing macroheterocycles

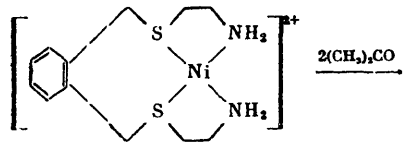
The basis of the template method of synthesis is the stereochemical organisation and orientation of reactants by a metal ion or by a metal-containing molecule. This leads to reaction of functional groups which under normal conditions is either difficult or generally impossible.[68]



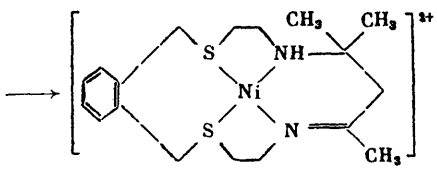
One example of template synthesis is the condensation of α-diketones with mercaptoamines in the presence of nickel salts leading to the complex (LVII) which may in its turn serve as a matrix for the formation of the macrocyclic compounds (LVIII) under the action of α,α′-dibromo-*o*-xylene.[69]

(LVII) (LVIII)

R = CH_3, C_2H_5, C_5H_{11}



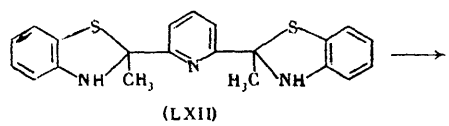
The reaction of the complex compounds (LVII) with sulphur monochloride proceeds in a similar manner and leads to the nickel-containing tetrathiadiazamacrocycle (LIX).[70]



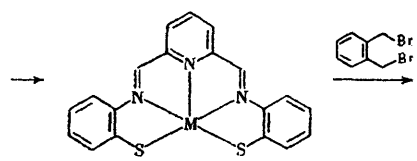
(LIX)

R = CH_3, C_2H_5, C_5H_{11}

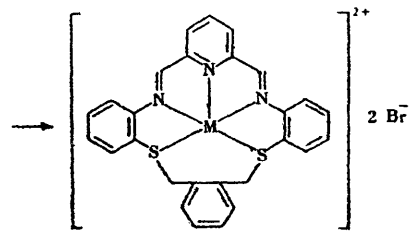
The nickel chelate (LX) reacts with two molecules of acetone with the formation of the complex (LXI).[71]



(LX)

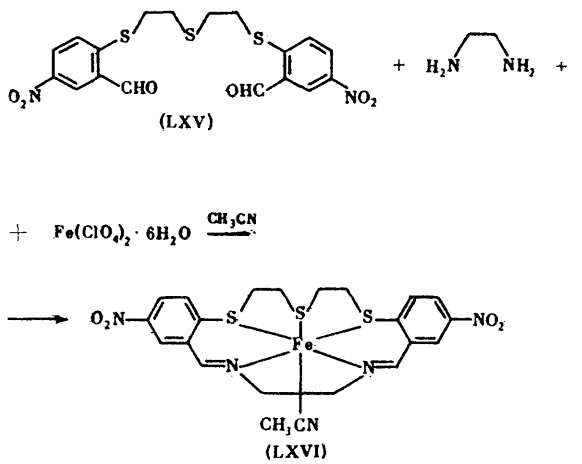


(LXI)

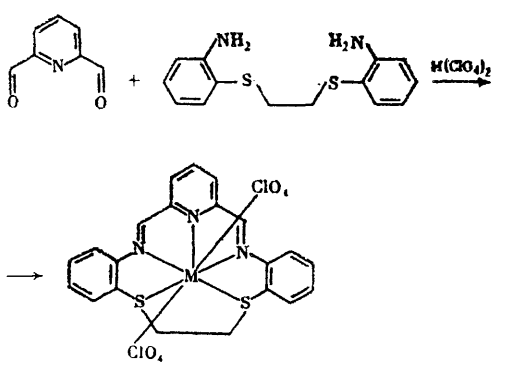


The product (LXII) of the condensation of 2,6-diacetylpyridine with 2-aminothiophenol undergoes an intramolecular rearrangement on reaction with zinc and cadmium acetates being converted into the complex (LXIII). Subsequent template reaction of it with α,α′-dibromo-*o*-xylene in acetone leads to the metal-containing macrocycle (LXIV).[72,73]

(LXII)

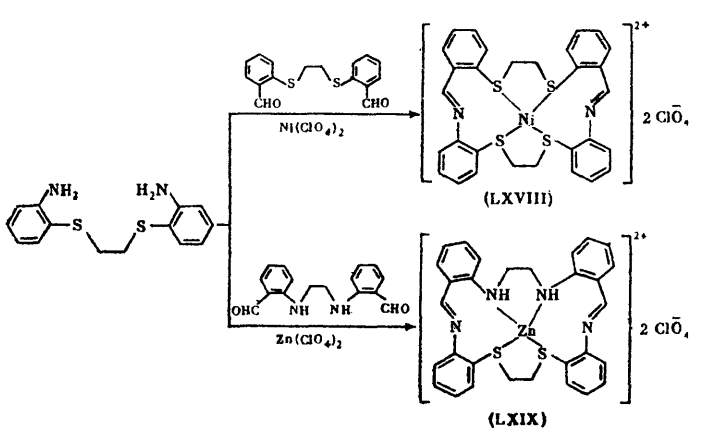


(LXIII)

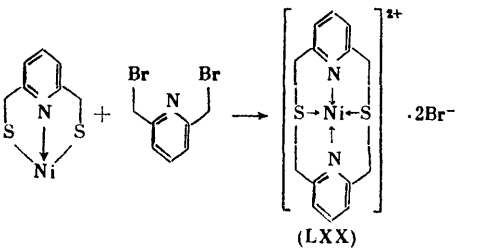


(LXIV)

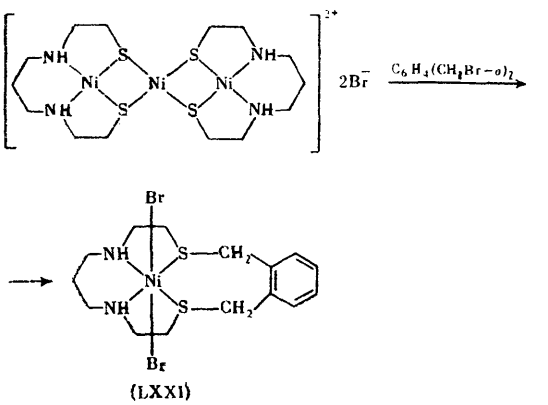
M = Zn, Cd



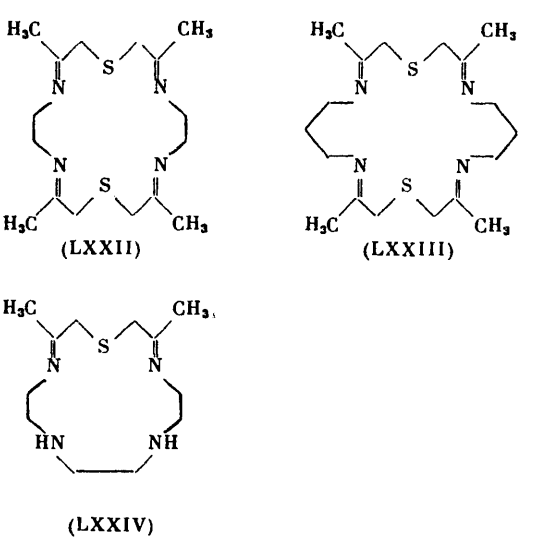
A complex of iron ion with the *N,S*-containing macrocycle (LXVI) is obtained by the condensation of the dialdehyde (LXV) with ethylenediamine in acetonitrile in the presence of $Fe(ClO_4)_2.6H_2O$.[74]



The coordination compound (LXVII) with a pentadentate *N,S*-containing macrocyclic ligand was obtained according to the following scheme.[75]

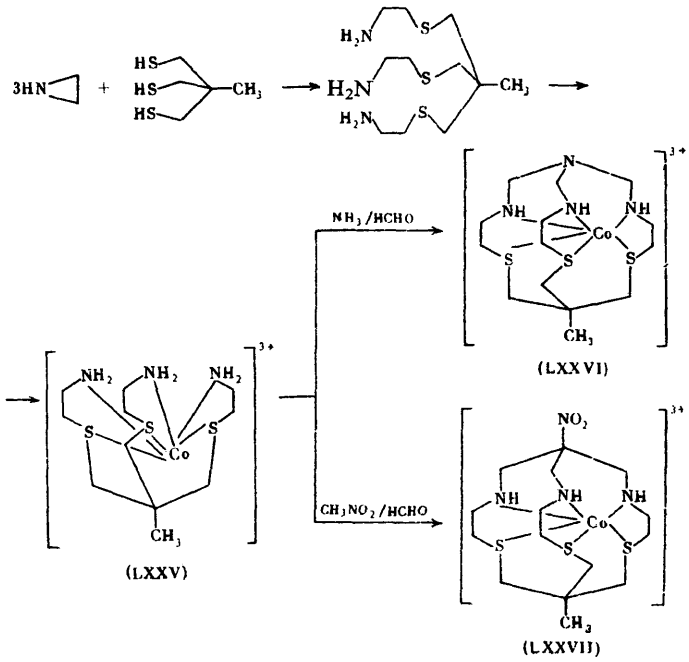


Condensation of 1,2-bis(2-aminophenylthio)ethane with 1,4-bis-(2-formylphenyl)-1,4-dithiabutane or 1,4-bis(2-formylphenyl)-1,4-diazabutane in the presence of nickel or zinc perchlorates leads to the complexes (LXVIII) and (LXIX) respectively.[76–78]

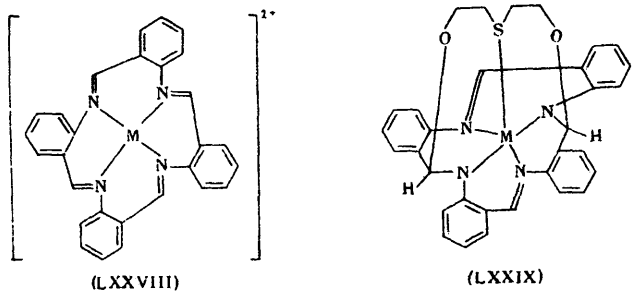


The complex (LXX) of a sulphur-containing pyridinophan with nickel ion is obtained in 86% yield by the reaction of the nickel(II) complex of 2,6-bis(mercaptomethyl)pyridine with 2,6-bis(bromomethyl)pyridine in DMF.[79]

The reaction of α,α′-dibromo-*o*-xylene with bis(3,7-diazanonane-1,4-dithiolate)trinickel(II) bromide leads to the formation of the nickel complex of 3,13-dithia-6,10-diazabicyclo[13.4.0]nonadeca-(15),16,18-triene (LXXI).[80]



A series of nickel complexes containing macrocyclic Schiff's bases as ligands (LXXII)–(LXXIV) are obtained by the condensation of 1,2-diaminoethane, 1,3-diaminopropane or triethylenetetramine with 4-thiaheptane-2,6-dione in the presence of a nickel(II) salt.[81]



The macrocycles (LXXII)–(LXXIV) are not formed in the absence of nickel(II) ions. The reaction occurs on heating a mixture of diamine, 4-thiaheptane-2,6-dione and the nickel salt in dry ethanol for 0.5–4.0 h. The yield of complexes was 70%.

The template method of synthesising cage-like molecules (sepulchrates, sarcophagins) has been successfully effected in the presence of ions of cobalt(III), rhodium(III), iridium(III) and platinum(IV).[82] The sepulchrate (LXXVI) with an encapsulated cobalt(III) ion is formed on reaction of the hexadentate complex (LXXV) with formaldehyde and ammonia. Reaction of the same complex with nitromethane and formaldehyde leads to the sarcophagin (LXXVII).

(LXXV) (LXXVI) (LXXVII)

The synthesis of "basket-like" complexes with bicyclic ligands (LXXIX) has been effected by the reaction of compounds (LXXVIII) with bis(2-hydroxyethyl) sulphide.[83]

(LXXVIII) (LXXIX)

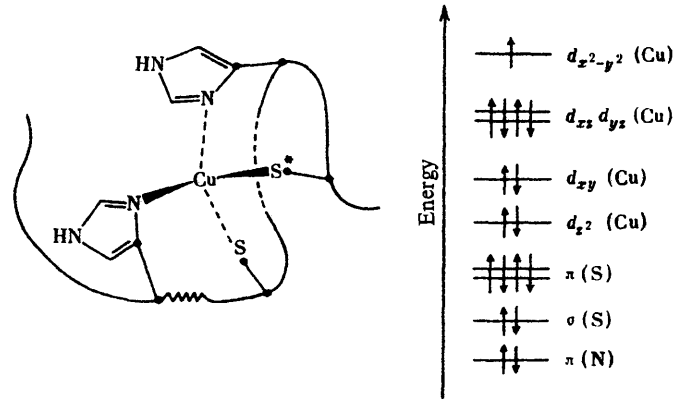
M = Ni, Cu

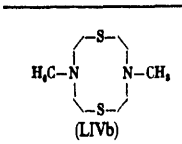
In such complexes the central sulphur atom is sterically located so as to occupy an axial position in the coordination sphere of the metal atom, as a result of which the square pyramidal pentacoordination complex (LXXIX) is formed.

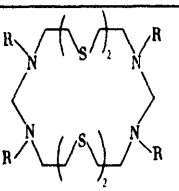
III. *N,S*-containing receptors binding cations, anions and neutral organic molecules

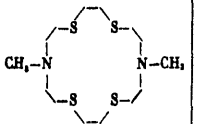
1. Cation-binding receptors

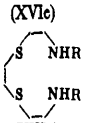
N,S-Containing macrocycles form complexes with copper(II) ions which may be considered as low molecular structural models of the active centres of copper-containing "blue" proteins. The copper(II) ion in these proteins is in an environment of donor atoms of nitrogen and sulphur.[84,85] Investigation of the physicochemical characteristics of low molecular complexes showed that they possess the unusual spectral and oxidation–reduction properties characteristic of many copper-containing proteins. The electronic spectra of blue proteins have a strong absorption band in the 600 nm region and a high Cu(II)/Cu(I) oxidation–reduction potential (0.2–0.8 V). The copper-containing proteins, such as plastocyanin, azurin, etc., contain blue copper which is coordination bound with two histidine groups and the sulphur atoms of cysteine and methionine [the coordination polyhedron of copper is a distorted tetrahedron (Fig. 1)].[85,86]

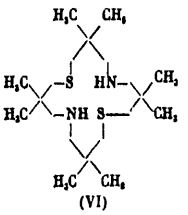


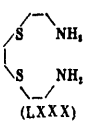


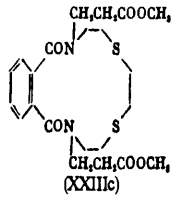


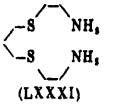


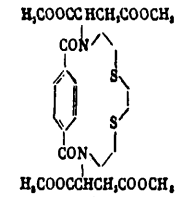












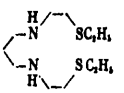


Figure 1. Structural representation of the distorted tetrahedral CuN_2SS^* centre (S is S of Cys; S* is S of Met) in plastocyanin and azurin.[85]

The parameters of the electronic spectra and the oxidation–reduction potentials of the complexes of *N,S*-containing macrocycles and of their open chain analogues and also of plastocyanin and azurin are given in Table 1.

The high intensity absorption bands in the spectra of plastocyanin and azurin with maxima at 752 and 778 nm belong to the charge transfer band (CTB) $\pi(S) \rightarrow d_{x^2-y^2}(Cu)$. The absorption bands at 606 and 552 nm in the spetrum of plastocyanine and at 631 and 567 nm in the spectrum of azurin also belong to CTB $\sigma(S) \rightarrow d_{x^2-y^2}(Cu)$. The absorption bands in the 428–481 nm region are linked with transitions occurring in the highest occupied π-orbitals of the imidazole ring [$\pi(N) \rightarrow d_{x^2-y^2}(Cu)$].[85]

The complexes of the copper(II) ion with *N,S*-containing macrocycles and open chain ligands have absorption bands with a maximum at $\lambda < 300$ nm caused by intraligand transitions, the absorption at 300–400 nm belongs to the CTB $\sigma(S) \rightarrow d(Cu)$ and that in the 650–850 nm region to a $d-d$ transition.[84]

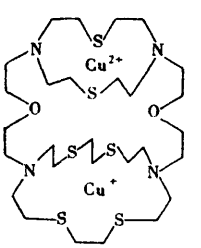

Table 1. Parameters of the electronic absorption spectra and oxidation–reduction potentials of CuL^{2+} at 25 °C.

Ligand L	Solvent	λ_{max}, nm(ε)	$E_{1/2}$, mV	Refs.	Ligand L	Solvent	λ_{max}, nm (ε)	$E_{1/2}$, mV	Refs.
 (LIVb)	80% CH_3OH+ +20% H_2O	370 (5000) 605 (1200)	495	[66]	 (XVIc)	CH_3CN	282 (3840) 333 (2150) 666 (52)	–	[84]

 (XXVIj)	CH_3CN	232 (2100) 275 (1200) 787 (45)	940	[84]	 (LXXXII)	80% CH_3OH+ +20% H_2O	–	342	[87]
					Plastocyanin	Thin film	428 (100) 450 (300) 552 (1163) 606 (4364) 752 (1289)	347	[85]
					Azurin	ditto	481 (198) 567 (504) 631 (3798) 779 (686)	330	[85]

The oxidation–reduction potentials of "blue" proteins, *N,S*-containing macrocycles and open chain analogues with the copper(II) ion are 312–940 mV, but for Cu^{2+}(aq) this value is 150 mV (see Table 1).

The copper complexes of the macrotricyclic ligands (LVb, d) and (LVIb) may be considered as binuclear models of copper proteins.[66,67] They have intense absorption near 400 and near 600 nm (375, 565, 430, 590, 375, 563 nm respectively). The oxidation–reduction potential of the copper complex (LVb) is 445 mV.

A mixed complex (LVIc) is formed by the reaction of copper(I) and copper(II) perchlorates (1 : 1) with the unsymmetrical macrotricycle (LVIb).[66] The electronic spectra of the complex indicate that the copper(I) and copper(II) cations are located in the 18- and 12-membered rings of the macrocycle respectively.

(LVIc)

According to the data of X-ray structural analysis the distance between the copper ions in the binuclear complex compounds (LVb, d) and (LVIb) is 5.7–6.0 Å. The macrotricyclic cryptates therefore possess a free space into which a molecule of oxygen or nitrogen may be introduced. Introduction of a molecule of oxygen or nitrogen between the two cations leads to a cascade complex

which may be used in binuclear catalysis or for the fixation of molecules of oxygen or nitrogen. On adding KO_2 or O_2 to the complex of macrotricycles, absorption bands appear at 330 and 370 nm respectively in addition to a wide absorption band at 550–850 nm. These changes in spectra are possible when superoxides or oxygen are included in the binuclear complex. Copper complexes with macrotricyclic ligands are therefore a new type of transition metal polynuclear complex and are potential bioinorganic models of biological processes occurring, for example, with the participation of copper proteins, superoxide dismutase, etc.[66]

N,S-Containing macrocycles also form complexes with cations of silver(I),[88–90] mercury(II),[89–90] nickel(II),[81,88] cobalt(II),[88] palladium(II)[53,88–90] and rhodium(III).[53,88]

2. Anion-binding receptors

Receptor molecules containing positively charged groups, neutral electron-deficient atoms (boron, silicon, tin, etc.), amide or carboxyl groups are capable of binding halide, azide and other anions.[3]

The trithiacyclophan (LI) containing three amide groups is able to form complexes with small-sized anions.[64] According to the data of X-ray structural analysis the size of the cavity of the macrobicycle corresponds to the size of a fluoride or hydroxide anion. In addition the hydrogen atoms of the N–H groups are directed into the ring which aids complex-formation due to the generation of three hydrogen bonds. This type of binding, which was confirmed by ^1H and ^{19}F NMR data, was established in the reaction of tetrabutylammonium fluoride with the macrobicycle (LI).

A cascade type of complex-formation is recorded in the reaction of the macrocyclic receptor (LXXXIII) with copper nitrate and sodium azide.[91] The structure of the complex $Cu_2^{2+}(N_3^-)_4L$ [L is the macrocyclic ligand (LXXXIII)] is shown in Fig. 2.

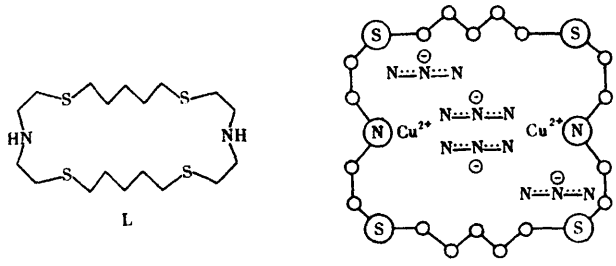

Figure 2. Schematic representation of the $Cu_2^{2+}(N_3^-)_4L$ complex (L is a macrocyclic ligand).[91]

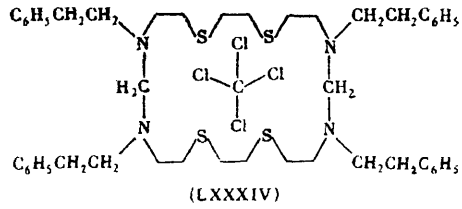


The principle of the cascade complex formation consists of a stepwise reaction. Initially the receptor binds the metal cations which then themselves become centres of association for anions.

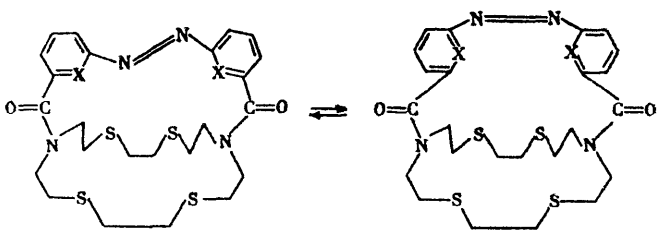
3. Receptors forming complexes with neutral molecules

Crown ethers and cryptands form molecular complexes with various neutral molecules. Complex formation has been established with water, molecular bromine, methanol, ethanol, chloroform, urea, acetonitrile, acetylene-dicarboxylic acid dimethyl ester, malonodinitrile, phenylhydrazine, 2,4-dinitrophenylhydrazine, 2,4-dinitroaniline, 3-nitrophenol, etc.[3] Complex formation is effected by all three forms of intermolecular reaction, viz. hydrogen bonds, dipole–dipole interactions, van der Waals forces and hydrophobic binding. Selective binding of the receptor with the substrate leads to a supermolecule, which may consist of an associate of two or more molecular particles. This type of complex formation plays a basic role in such biochemical processes as enzyme–substrate reactions or drug–receptor interactions, etc.

The *N,S*-containing macrocycle (XXXV) forms a molecular complex with CH_3SnCl_3 of composition 1:1 in a mixture of $CDCl_3–CD_3CN$ as solvent. The formation of the complex was established by ^1H NMR spectral data.[54]

The 22-membered macroheterocyclic receptor (XVIIc), containing four exocyclic phenylethyl groups, binds a molecule of chloroform to form the crystalline complex (LXXXIV) which is stable on storage and on heating.[27]

Complex formation with chloroform did not take place on replacing the phenylethyl groups in the macrocycle (XVIIc) by methoxycarbonylethyl or cyanoethyl groups. The main factor in the reaction of this macromolecule with chloroform is therefore of a stereochemical nature created by the bulky phenyl groups.



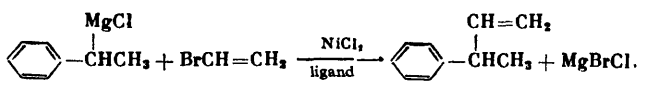
The macrocycle (XVIId), containing exocyclic ester groups, is capable of binding six molecules of urea by a type of complex-formation occurring on the receptor surface.[32] Reaction is effected by the formation of hydrogen bonds of the urea amino groups with the carbonyl oxygen atoms of the ester fragments of the macrocycle.

IV. Transport of metal ions by *N,S*-containing receptors through membranes, catalysis

Crown ethers and cryptands are capable of transferring metal cations through synthetic or natural membranes. It is possible to consider them as simplified models of natural ionophores such as valinomycin, nonactin, etc.[92]

The transport of metal cations through membranes is caused by the extraction of ions from the first aqueous phase due to complex-formation with the carrier and rapid release of them from the complex, which is in the membrane, into the second aqueous phase. The best carriers are therefore ligands forming complexes of average stability. Photoreversible macroheterocycles are attractive for this purpose, as they are capable, under the action of UV irradiation, of reversibly changing the ionophore structure and therefore its stability in complex-formation.[3]

The cryptands (LII) and (LIII), containing azopyridine and azobenzene groups respectively, are such photoreversible carriers.[65]



trans-(LII), (LIII) *cis*-(LII), (LIII)

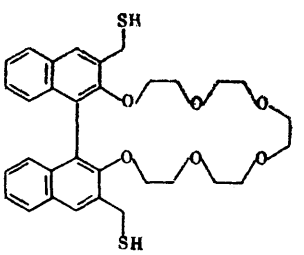
(LII): X = N; (LIII): X = CH

The *cis*—*trans*-isomerisation of these compounds occurs reversibly under photoirradiation. The extraction of the Hg^{2+} ion is effected most efficiently in the presence of the *cis*-isomer of the macrobicycle (LII) compared to the *trans*-isomer, and also by the *cis*- and *trans*-isomers of the cryptand (LIII). The *trans*-isomer of (LIII) does show an appreciable affinity for ions of Cu^{2+}, Co^{2+}, Ni^{2+} and Pb^{2+}. The *trans*-isomer of cryptand (LII) does not react significantly with Cu^{2+} ions while the *cis*-isomer extracts copper(II) ion almost quantitatively. This circumstance enables the transfer of Cu^{2+} ion by the macrobicycle (LII) through a liquid membrane (*o*-dichlorobenzene—n-butanol, 4:1) to be studied. The investigations showed that the rate of transfer of the ion through the membrane was increased significantly by UV irradiation.

The cross-coupling reaction of the Grignard reagent (LXXXV) with vinyl bromide (LXXXVI) proceeds with the formation of (but-1-en-3-yl)benzene (LXXXVII).[12]

(LXXXV) (LXXXVI) (LXXXVII)

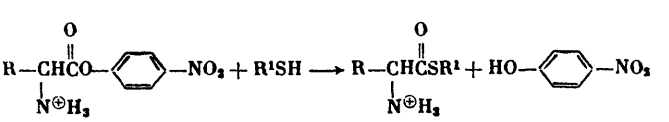
The yield of (but-1-en-3-yl)benzene was 10% in the presence of $NiCl_2$. The yield of compound (LXXXVII) was increased to 74—100% on using the complex of $NiCl_2$ with the chiral *N,S*-containing macrocycles (Xa—e) as catalyst.



The complexes of copper(II) with the *N,S*-containing macrocycles (XXIII) proved to be efficient catalysts for the oxidation of thiols by oxygen in the air.[93]

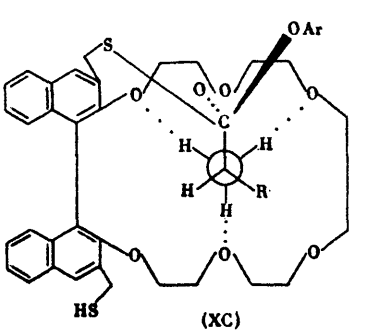
V. Conclusion

The design and synthesis of compounds imitating the action of enzymes is one of the most complex and important problems of organic chemistry. Certain successes have been achieved in this direction during the years of development of the chemistry of macroheterocyclic compounds.



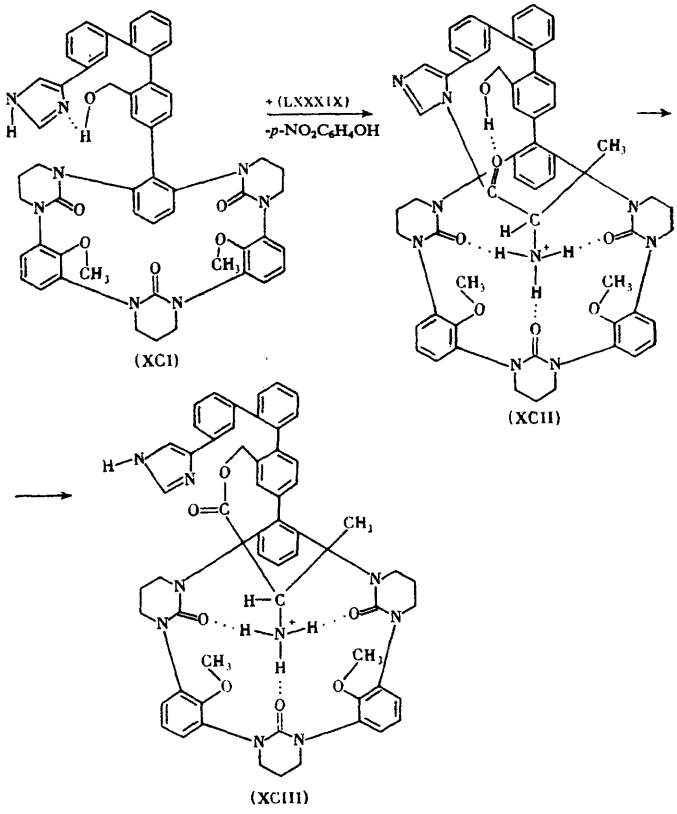
The proteolytic enzymes catalysing the hydrolysis of peptide and ester bonds are the most widely studied among the large number of enzyme systems. The basic conditions for enzymic catalysis are desolvation of the reaction centres of the enzyme—substrate complex[94] and stabilisation of the transition state or reactive form of the substrate.[95] Quantum chemical investigations carried out on the reaction of formamide with the CH_3O^- anion in the active centre of α-chymotrypsin ("the catalytic triad" Ser-195—His-57—Asp-102) confirmed these conclusions. Stabilisation of the transition state of the active centre of α-chymotrypsin may be effected by the formation of hydrogen bonds between the oxygen atom of the substrate carbonyl group and the NH groups of the polypeptide chain amides. Another important factor is the stabilisation of the reactive form of the substrate which leads to significant acceleration of the reaction.

Macroheterocyclic compounds containing donor oxygen atoms in the ring may serve as the cavity in which substrate binding occurs. At present the most studied is the three-point model of binding ammonium ion acting as guest, by a crown ether.[3] The next stage of developing "synzymes" is the synthesis of macrocycles containing a cysteine sulphur atom as active nucleophile. This is used as a model of SH-enzymes of the papain type (LXXXVIII).[3]



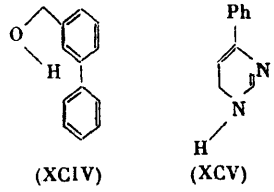
(LXXXVIII)

The crown ether ring serves as the "cavity" and the substrate is the ammonium salt (LXXXIX) which forms a three-point bond with the oxygen atoms of the polyether (XC).



(LXXXIX)

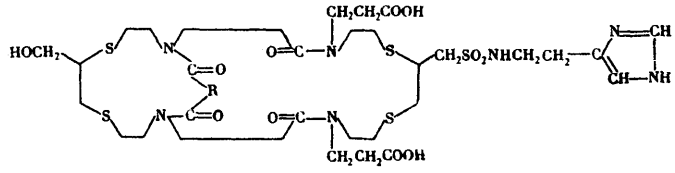
(XC)



A comparison of the rate constants for the transacylation of the amino acid salts (LXXXIX) showed that the reaction occurs more rapidly with the macrocyclic compound (LXXXVIII) than with its open chain analogue.

A multistage synthesis has been developed for the macrocycle (XCI), which has a complex-forming centre, a nucleophilic hydroxyl and an imidazole proton-transfer agent.[96]

(XCI) (XCII) (XCIII)



The salt of the amino ester (LXXXIX), which forms a complex with the crown compound (XCI), instantaneously acylates the imidazole group giving the complex (XCII), which is then converted into the more stable complex (XCIII). Acylation has also been studied in the presence of the non-complexing compounds (XCIV) and (XCV).

(XCIV) (XCV)

The rate constant for acylation of the macrocyclic complex is 10^{10} times higher than the rate of acylation with compounds (XCIV) and (XCV). This investigation shows that complex-formation of the receptor with the substrate stabilises the transition state and the reactive form of the substrate, thereby increasing the reaction rate appreciably.[96]

In order to construct new synthetic biomimetic systems as catalysts for the hydrolysis of polypeptides and polyesters, high molecular compounds are required which contain functional groups capable of binding substrates and of catalysing their reactions. We have developed methods of synthesis of the thiazacrown compounds (XCVI). These contain exocyclic hydroxyl, carboxyl and imidazole groups, prearranged for hydrogen bonds, imitating the active centre of the enzyme α-chymotrypsin.[97]

(XCVI)

R = $-(CH_2)_4-$, 1,2-C_6H_4

Further investigations in this region of chemistry will enable, even in the near future, the preparation of the most varied types of "synzymes" based on macroheterocycles and the development of vaccine-like and other biologically important materials.

Thiophenethiols†

M V Ul'ev, E D Shtefan, V Yu Vvedenskii
The Institute of Organic Chemistry of the Siberian Section of the Academy of Sciences of the USSR, Irkuts

ABSTRACT. **New data on the chemistry of thiophenethiols have been reviewed systematically. Synthetic routes to these compounds, their reactions with nucleophiles and radicals, and a number of other properties have been examined.**

The bibliography contains 78 references.

I. Introduction 1309
II. Synthesis of thiophenethiols 1309
III. Physical properties 1310
IV. Reactions of thiophenethiols 1311

I. Introduction

Thiophenethiols are highly reactive compounds which are used widely in organic synthesis. Since the publication of an earlier review in this field,[1] the chemistry of this class of compound has developed and a number of new aspects have been brought to light. These include, in particular, new methods of their synthesis, their reactions with radicals, and their recently discovered autothiylation. The reactivity of certain thiophenethiols has also been noted with much interest as new routes to key compounds have been developed. These include drugs and biologically active compounds, scents, polymers and 'organic metals'.

II. Synthesis of thiophenethiols

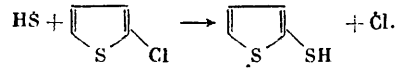
The primary route to thiophenethiols, notably for industrial syntheses, involves the reaction of halogenothiophenes with H_2S or lower alkyl mercaptans in the gas phase.[2] The reaction proceeds by a radical mechanism. It has been found that the yield of 2- and 3-thiophenethiols is higher with alkyl mercaptans than with H_2S. This would be expected from energetic considerations, since the C–S bond energy is 25–30 kcal/mol less than that of the S–H bond energy in H_2S. Thus, 2-chlorothiophene reacts with isopropyl mercaptan at 540 °C in a quartz tube to give 2-thiophenethiol in 23.6% yield.[3]

+ HCl + CH_2=$CHCH_3$ + $\dot{S}H$.

† This article received the third prize in a competition of reviews on 'Organic and Elementoorganic Synthesis' (Section No. 4), organised by the Inter-departmental Scientific and Technical Council set up to monitor the direction of chemical research and technology.

Dialkyl disulphides, which also produce thiyl radicals on thermolysis, may be used instead of alkyl mercaptans:

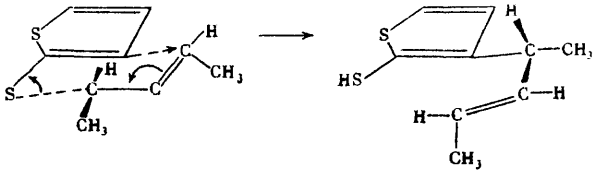
$$C_2H_5SSC_2H_5 \longrightarrow 2C_2H_5\dot{S} \xrightarrow{2(C_2H_5)_2S} 2C_2H_5SH + CH_3\dot{C}HSSCH_2CH_3,$$
$$2C_2H_5SH \longrightarrow 2CH_3\dot{C}H_2 + 2SH^{\cdot}.$$



The yield of 2-thiophenethiol by this route is 36.4%.[4]

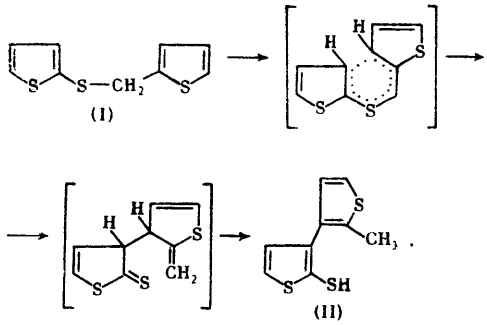
The low yield of thiophenethiols obtained by the high temperature reaction of halogenothiophenes with H_2S is explained, in part, by their thermal instability and, in part, by the formation of a number of side-products, of which bis(2-thienyl) sulphides predominate. It has been shown that thermolysis of bis(2-thienyl) sulphide, e. g. on hydrothiolysis in the liquid phase at 180 °C in the presence of an excess of sulphur, affords 2- and 3-thiophenethiol in 29.9% and 12.6% yield, respectively.[5,6] A similar yield of thiols is obtained under the same conditions by hydrothiolysis of bis(2-thienyl) disulphides.[7] The added elemental sulphur provides an additional source of thiyl radicals, both by interaction with H_2S and by fission of the S_8 ring.

$$S_8 + H_2S \rightarrow H\dot{S} + H\dot{S}_8 \rightarrow H\dot{S} + S_7.$$



It has been found[8] that the addition of dimethyl selenide, which is readily cleaved into radicals above 300 °C, increases the yield of 2-thiophenethiol on reaction of 2-chlorothiophene with H_2S:

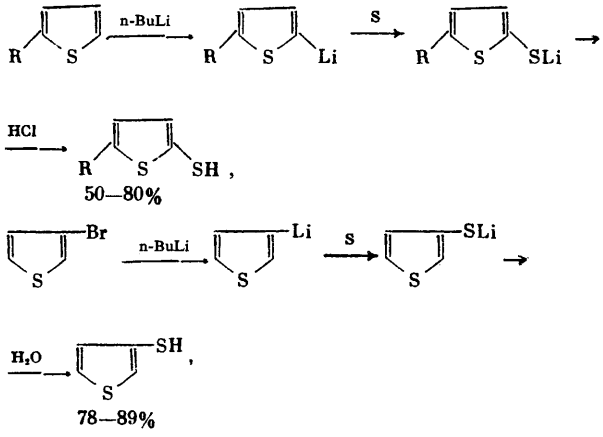
$$(CH_3)_2Se \longrightarrow \dot{C}H_3 + CH_3\dot{S}e \longrightarrow Se + \dot{C}H_3,$$
$$\dot{C}H_3 + H_2S \longrightarrow CH_4 + \dot{S}H,$$



The maximum yield of 2-thiophenethiol is 31.1%.

A V Anisimov et al. have studied the thio-Claisen rearrangement of various thienyl sulphides to give the corresponding substituted thiophenethiols on heating in different solvents.[9,10] (±)-*S*-2-(*trans*-Pent-3-en-2-ylthio)thiophene has been shown to rearrange with retention of optical activity, confirming that reaction proceeds by a concerted [3.3]-sigmatropic shift.[11]

Quantum chemical calculations on the rearrangement of allyl 2-thienyl sulphide have shown that the sulphide and thiol exist in the stable 'open' conformation with a clear separation of the reactive centres.[12] It is thus considered that the rate of the reaction will be determined predominantly by the energetics of the conformational interconversion and by entropy factors.

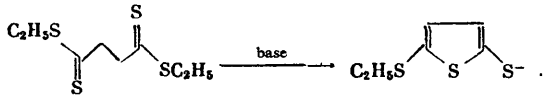


Thio-Claisen rearrangement also provides a convenient route to binuclear heterocyclic thiols.[13] Thus, 2-thienyl 2-thienylmethyl sulphide (I) and 2-benzofurylmethyl 2-thienyl sulphide afford 3-(2-methyl-3-thienyl)-2-thiophenethiol (II) and 3-(2-methyl-3-benzofuryl)-2-thiophenethiol, respectively, in 31% and 30% yield.

(I)

(II)

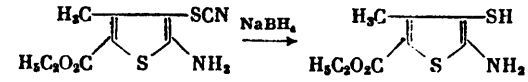
The commonest laboratory preparations of thiophenethiols are based on the intermediate formation of lithiothiophenes:[10]



50—80%

78—89%

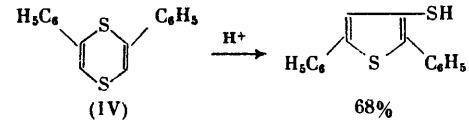
where R = H, Me, Et, Bu^t, Pr^i, etc. 3,4,5-Trichloro-2-thiophenethiol has also been prepared by this route in 86% yield.[14]



3,4-Thiophenedithiol has recently been obtained in one step by treatment of 3,4-dibromothiophene with two equivalents of butyllithium, followed by addition of flowers of sulphur and water.[15] This contrasts with the former two-step route.[16,17]

Among alternative methods of preparing thiophenethiols, it is worth noting the cyclisation of diethyl tetrathiosuccinate.[18] Cooling is necessary during the reaction, for which a number of tertiary amines or dimethylformamide acetals may serve as catalyst.

60%



The 2-amino-3-thiophenethiol (III) may be obtained by reduction of the corresponding 3-thienyl thiocyanate with $NaBH_4$ or sodium dithionite:[19]

85%

(III)

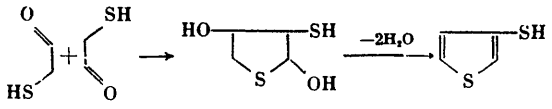
A substituted 3-thiophenethiol was also isolated by an unusual acid-catalysed rearrangement of the 1,4-dithiin (IV).[20] The reaction proceeds on heating at 180 °C in σ-dichlorobenzene in a sealed tube.

(IV)

68%

2-Thiophenethiol may also be obtained by reduction of 2-thiophenesulphonic acid with PPh_3.[21]

III. Physical properties



The physical properties of a number of thiophenethiols are given in Table 1. These data were reported after the publication of the previous review.

Table 1. Physical properties of thiophenethiols.

R^2	R^3	R^4	R^5	m.p. °C	b.p. °C/mmHg	^{1}H NMR (ppm)*	Reference
SH	Cl	Cl	Cl	39.0–41.0	56/0.1	3.55 (s) [$CDCl_3$]	[14]
SH	2-Methyl-3-benzofuryl	H	H	–	–	7.5–6.8 (m, 6H, arom.,thiophene); 3.35 (s, 1H, SH); 2.3 (s, 3H, CH_3) [CCl_4]	[13]
SH	2-Methyl-3-thienyl	H	H	–	–	6.5–7.3 (m, 4H, thiophene); 3.15 (s, 1H, SH); 2.27 (s, 3H, CH_3) [CCl_4]	[13]
SH	H	H	SC_2H_5	–	125/0.3	1.26 (t, 3H, CH_3); 2.78 (t, 2H, CH_2); 3.57 (s, 1H, SH); 6.90 (s, 2H, 3-, 4-H) [$CDCl_3$]	[18]

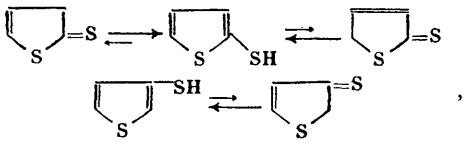
NH_2	SH	CH_3	CO_2Et	125–128	–	–	[19]

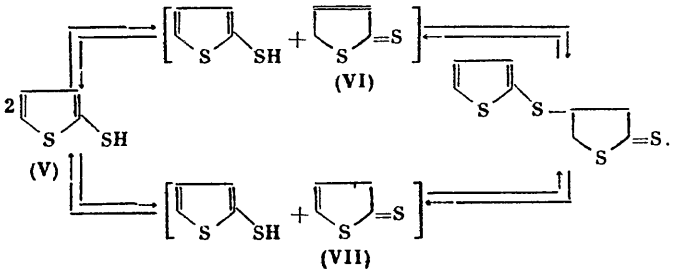
*In parenthesis are given the multiplicity of the signal, its integral intensity (the number of protons) and the position of the protons in the molecule.

Recently much attention has been paid to thermolytically prepared thiophenethiols for their aromatic properties and as starting materials for the synthesis of novel aromatic compounds.[22–34] Chromato-mass spectrometric and gas chromatographic analyses have indicated that 2-thiophenethiol, 3-thiophenethiol and 2-methyl-3-thiophenethiol are responsible for the fleshy odours which have been detected in certain pyrolytic experiments, supporting the view that thiophenethiols play a key role in the formation of sulphur-containing compounds in meat. It is thought that thiophenethiols are formed by condensation of the products derived by thermolysis of cysteine or by reaction with hydrocarbons and hydrogen sulphide. Thus, 3-thiophenethiol may be formed from two molecules of mercaptoacetaldehyde:



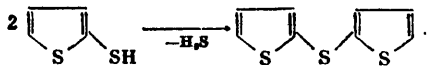
To assist identification and separation of aromatic thiophenethiols in mixtures, mass and IR spectroscopic studies of simple thiophenethiols and the corresponding alkyl thienyl sulphides have been undertaken and retention times on capillary gas chromatography columns determined.[35]

The dipole moments of a number of 3-thiophenethiols and 3-(alkylthio)thiophenes in benzene have also been determined in order to provide conformational information on the structures of the compounds.[36]

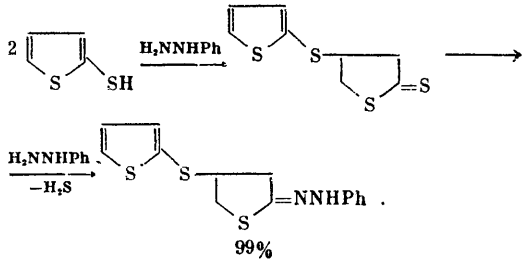


IV. Reactions of thiophenethiols

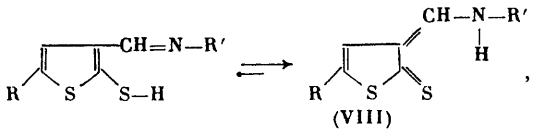
1. Nucleophilic addition



In the tautomeric system:

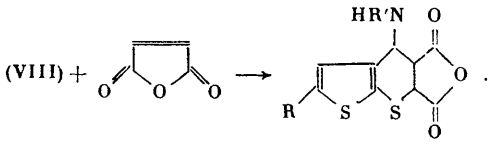


the equilibrium is clearly shifted in favour of the thiol form. This has been established both by quantum chemical calculations[38] and by the fact that proton signals from the thione form are absent in the ^{1}H NMR spectra of thiophenethiols. However, there is evidence that certain reactions of thiophenethiols involve the thione form, such as the recently discovered autothiylation of 2-thiophenethiol to give 4-(2-thienylthio)tetrahydrothiophene-2-thione.[39–42] Reaction takes place on exposing the thiol to air or in the presence of an amine as catalyst. It is most likely that the conversion takes place by a radical mechanism or by the ionic addition of 2-thiophenethiol (V) to the tautomeric thione form (VI) or (VII):

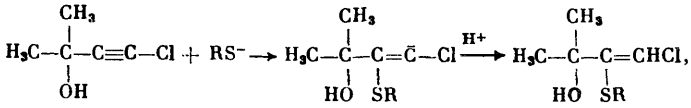


The reaction is reversible, although the equilibrium lies very much to the right. The dimer reverts to the monomer on distillation *in vacuo*. A side-reaction accompanies the autothiylation: the formation of bis(2-thienyl) sulphide with evolution of H_2S, as follows:

If autothiylation takes place in the presence of phenylhydrazine, the hydrazone derivative of the dimer is isolated:[43]

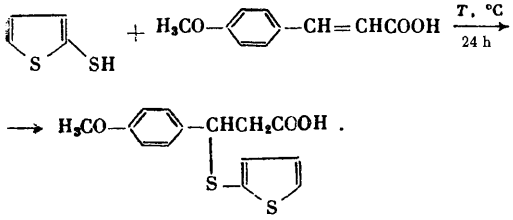


In-depth studies by Ya L Gold'farb et al. of the chemistry of mercaptoaldimines (e.g. Refs. 44 and 45), confirmed the existence of thiol-thione tautomerism in thiophenethiols. In solution, it has been found that mercaptoaldimines (VIII) exist as an equilibriated mixture of tautomers, shifted almost exclusively to the side of the thione form:



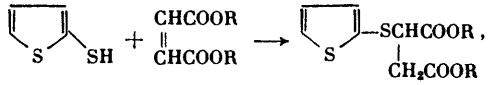
R = Et, OMe; R′ = *cyclo*-C_6H_{11}.

These compounds participate in the Diels–Alder reaction as heterodienes:[46]



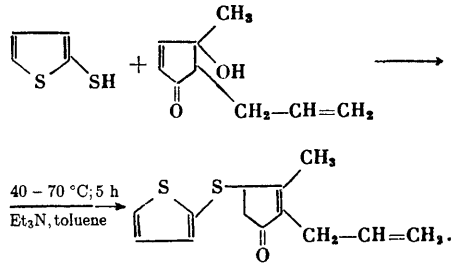
However, from the data available at present, it is clear that thione-type reactions of thiophenethiols are the exception rather than the rule. In fact, all of the reactions outlined below proceed from the thiol form.

The most characteristic and studied reaction of thiophenethiols is their addition to multiple bonds. Thus, treatment of dimethyl(chloroethynyl)carbinol with thienylmercaptide anion leads to the formation of the corresponding chlorovinylcarbinol which may be used subsequently for the preparation of ethynyl sulphides:[47]

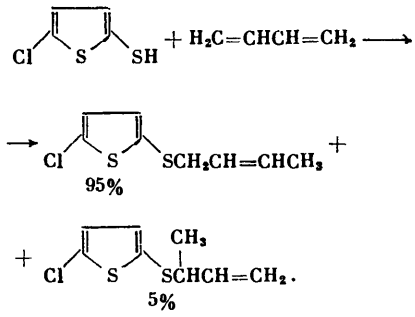


R = thienyl.

There are references to the addition of thiophenethiols to various unsaturated carbonyl compounds.[37,48] Thus, the reaction of 2-thiophenethiol with 4-methoxycinnamic acid yields an adduct which has been used for the preparation of antiglaucoma agents:[49]

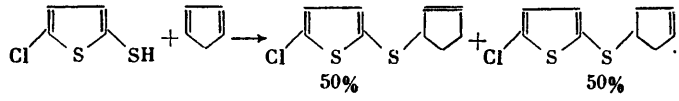


It is interesting that the addition of 2-thiophenethiol to diallyl maleate proceeds exclusively across the double bond of the maleic residue:[50]



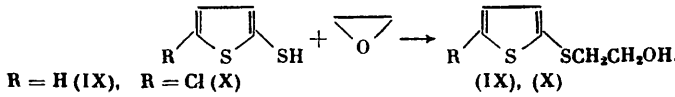
R = $CH_2CH=CH_2$.

A series of cyclopentenones, including 2-allyl-3-methyl-4-(2-thienylthio)-2-cyclopentenone, has been prepared in high yield as follows:[51]

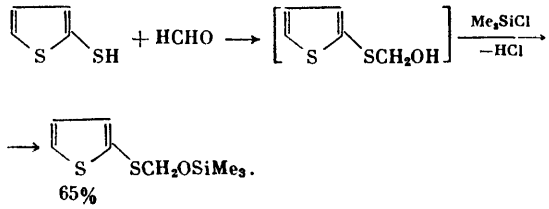


As in the previously described reaction, the allyl group is unaffected.

The addition of 5-chloro-2-thiophenethiol to 1,3-butadiene affords predominantly the 1,4-adduct:[52]

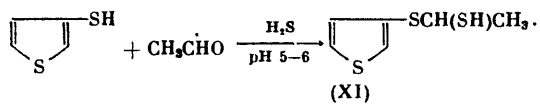


The reaction takes place in the presence of ethanesulphonic acid. In contrast, cyclopentadiene reacts with 5-chloro-2-thiophenethiol to give a 1 : 1 mixture of 1,2- and 1,4-adducts in 79% yield:



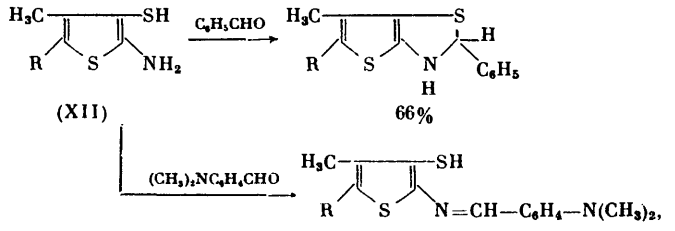
The fact that rate of the addition and the yield of adducts increases in the presence of a protic acid, e. g. ethyl sulphate, confirms the nucleophilic character of the addition of 5-chloro-2-thiophenethiol to such 1,3-dienes.

A study has been made of the interaction of ethylene oxide with heteroaromatic thiols in the liquid phase at 20 °C in the presence of an acid catalyst.[53] It was shown that the yield of the resulting heterocyclic β-hydroxyethyl sulphides increases with increase in the acidity of the thiols. The addition of an acid catalyst, e. g. aluminium oxide or an aluminosilicate, also increases the yield of product. Under optimum conditions, the yield of sulphides (IX) and (X) was 75% and 91%, respectively:

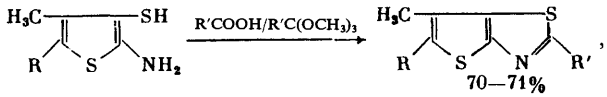


The observed effect of thiol acidity and addition of catalyst confirms that the mechanism of the epoxide ring opening involves protonation of the oxygen atom. The products obtained by addition of thiols to expoxides possess fungicidal and acaricidal activity.[54]

Simple aldehydes react with thiophenethiols to give monothiohemiacetals. Thus, the interaction of 2-thiophenethiol with paraformaldehyde in the presence of an excess of trimethylsilyl chloride affords 2-thienyl trimethylsiloxymethyl sulphide, as follows:[55]

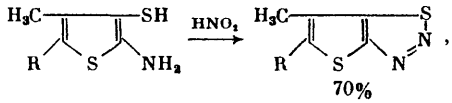


Bis(2-thienylthio)methane is formed as a by-product in 20% yield. The condensation of 3-thiophenethiol with acetaldehyde in the presence of H_2S affords the hemimercaptal (XI):[34]



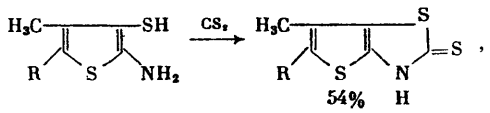
The interaction of 2-amino-3-thiophenethiols (XII) with benzaldehyde leads to substituted thieno[2,3-*d*]thiazolines.[19] It is likely that the reaction involves intramolecular addition of the thiol group across the C=N bond arising by initial condensation of the aldehyde with the amino group. It is interesting that the cyclisation

does not take place with *p*-dimethylaminobenzaldehyde. This has been supported by IR- and ^{1}H NMR spectroscopic data.



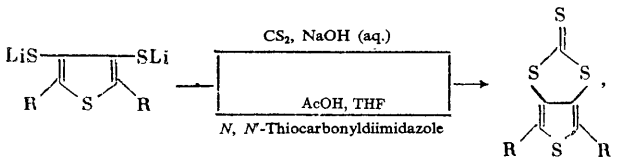
R = $CO_2C_2H_5$.

Substituted thieno[2,3-*d*]thiazoles are obtained by interaction of (XII) with formic or acetic acid and their orthoester derivatives:



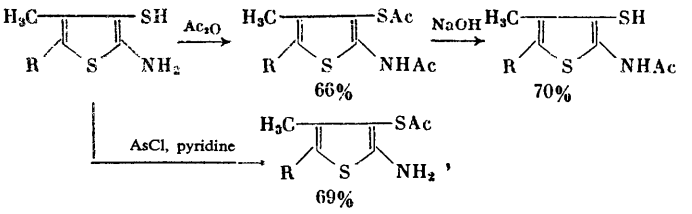
R = CO_2CH_3, $CO_2C_2H_5$; R′ = H, CH_3.

Diazotisation of the amino group in compound (XII) also leads to ring closure:



R = $CO_2C_2H_5$.

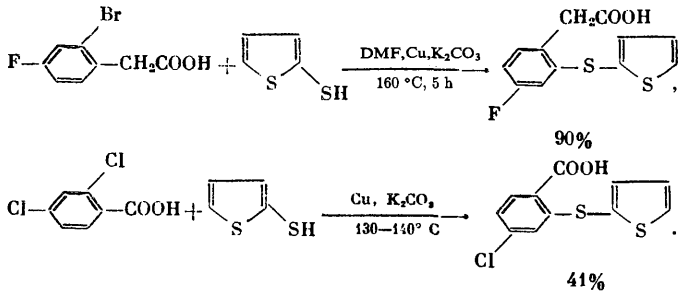
The reaction of (XII) with carbon disulphide exemplifies nucleophilic addition of a mercaptan across a C=S bond:



R = $CO_2C_2H_5$.

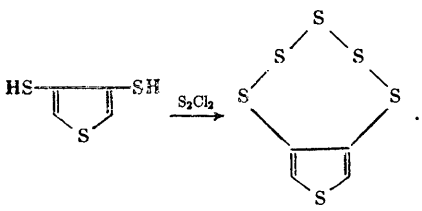
A similar reaction with thiophenedithiolates leads to $\Delta^{2,2'}$-bithieno-[3,4-*d*][1,3]dithioles, which have been used to prepare "organic metals" in the tetrathiafulvalene series:[56,57]

R = H, Me.



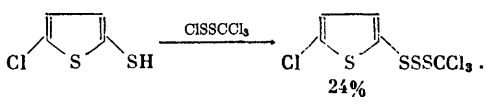
Acylation is also characteristic of thiophenethiols, as exemplified below with acetic anhydride or acetyl chloride as acylating agent:

R = $CO_2C_2H_5$.

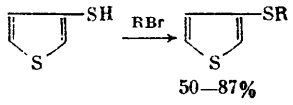


2. Nucleophilic substitution

2-Thiophenethiol participates in nucleophilic substitution of halogen in activated aromatics by heating in the presence of copper as catalyst:



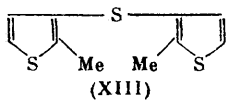
The resulting products have been used as intermediates in the synthesis of neuroleptic compounds.[58–60] The dye, 1-amino-5,8-bis-(2-thienylthio)anthraquinone, has been prepared in a similar way from the corresponding dichloroanthraquinone and 2-thiophenethiol.[61]



The formation of thieno[3,4-*f*]-1,2,3,4,5-pentathiepin from 3,4-thiophenedithiol and sulphur monochloride in dichloroethane also involves a nucleophilic substitution:[15]

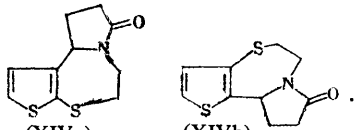
Trichloromethylthiosulfenyl chloride reacts similarly with 5-chloro-2-thiophenethiol to give the corresponding trisulphide:[62]

Thiophenethiols are readily *S*-alkylated to give a wide variety of thienyl sulphides. Thus, *n*-alkyl 3-thienyl sulphides may be obtained by reaction of 3-thiophenethiol with alkyl bromides, RBr, in the presence of potassium tert-butoxide.[63]



50—87%

R = C_nH_{2n+1}, where $n = 1$—6, 8, 10, 12.

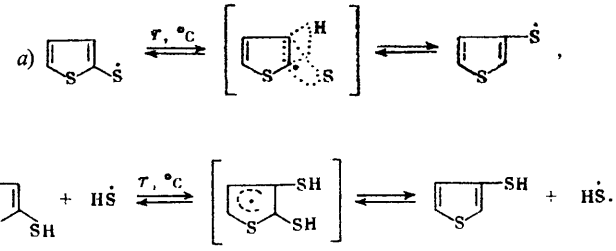


Dimethylformamide acetals may also be used as alkylating agent.[18]

3-Bromo- or 3-tosyloxy-2-methyltetrahydrothiophene has been converted to the bis(thienyl) sulphide (XIII). The latter is a component of certain natural aromas, having a smell of roasted nuts:[33]

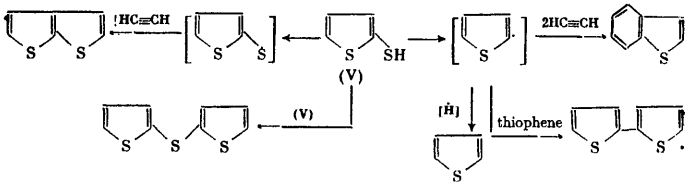
(XIII)

The isomeric tricyclic compounds, (XIVa) and (XIVb), are obtained by condensation of 2- and 3-thiophenethiol, respectively, with *N*-(2-chloroethyl)succinimide, followed by partial reduction with sodium borohydride and ring closure of the resulting lactamol in the presence of formic acid.[64]



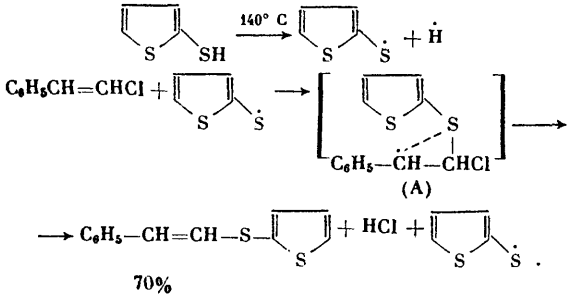
(XIVa) 38% (XIVb) 44%

These products are analogues of biologically active compounds.



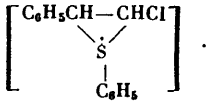
3. Radical reactions

Radical reactions take place on thermolysis or hydrothiolysis of thiophenethiols (at 400—600 °C) to give a mixture of products containing thiophene, dithienyls, and condensed systems.[5] The conversion of 2-thiophenethiol to 3-thiophenethiol also takes place under these conditions and is worthy of note.[5,6,8] Two mechanisms, *a*) and *b*), have been considered:



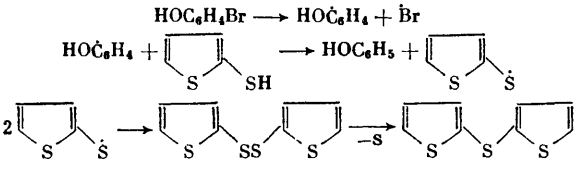
Reaction is favoured by the increased thermal stability of the 3-substituted thiophene, relative to the 2-substituted derivative.

It has been established that 2-thiophenethiol reacts with acetylene at 550—650 °C to give a mixture of thieno[*b*]thiophene, bis(2-thienyl) sulphide, thiophene, and benzo[*b*]thiophene.[65] Dithienyls are also obtained above 530 °C. The yield of each product varies according to the temperature and the proportion of the two reactants. The complexity of the reaction is a result of competing S—H and C—S cleavage in the initial phase of the heterolysis. The acetylene molecule then traps the resulting thiyl and 2-thienyl radicals:



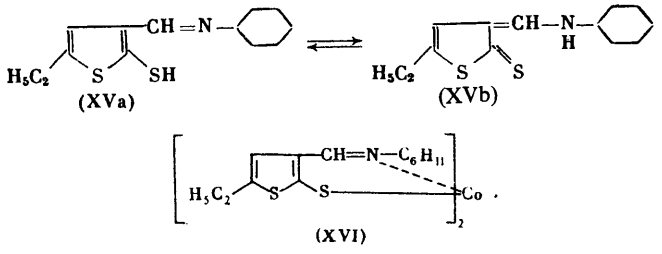
Thiophenol reacts under the same conditions to give benzo[*b*]thiophene as the only product.

The formation of β-styryl 2-thienyl sulphide from 2-thiophenethiol and β-chlorostyrene exemplifies radical substitution of halogen bonded to an unsaturated carbon atom.[66]



70%

By comparison with substitution by thiphenol, the reaction is much slower and stereo-random as a consequence of steric hindrance in the transition state (A). In the case of thiophenol, there is a clearly defined intermediate (below) which determines the stereospecificity of the reaction.



At 180 °C 2-thiophenethiol reduces bromophenols to the corresponding phenols while being oxidised to the disulphide.[67]

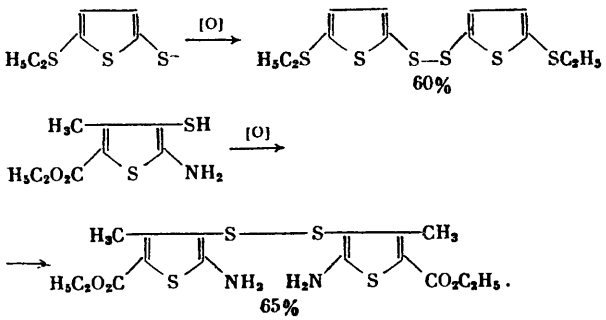
The reaction takes palce below the temperature at which the C—Br bond of bromophenols normally dissociates.

2-Mercapto-5-ethyl-3-thienylmethyleneaminocyclohexane and its cobalt(II) chelate complex are used as inhibitors in the oxidation of hydrocarbons.[68,69]

Mechanistically, these inhibitors would appear to function as radical traps interrupting the chain process. In complex (XVI) it is the cobalt(II) atom which is responsible for the deactivation, while in compound (XV) it is either the SH group (of XVa) or the C=S group (of XVb).

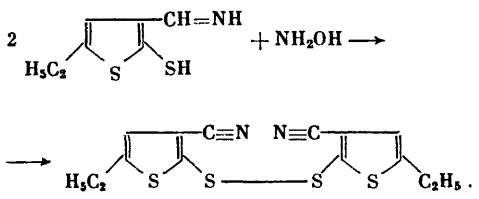
$$RO_2^{\cdot} + RSH \rightarrow RO_2H + RS^{\cdot},$$
$$2RS^{\cdot} \rightarrow RSSR.$$

However, the effectiveness of these compounds as inhibitors is less than what might be expected. This is a result of the competing reaction of (XVa) with peroxides, producing both radicals and unreactive products:



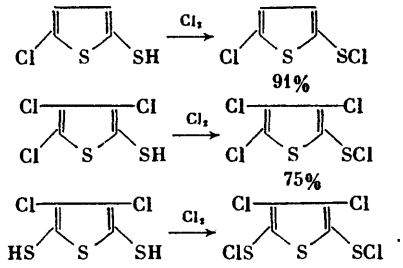
$$RSH + RO_2H \rightarrow RS^{\cdot} + H_2O + RO^{\cdot},$$
$$RSH + RO_2H \rightarrow \text{stable products}.$$

The activity of the inhibitors is thus gradually eroded.



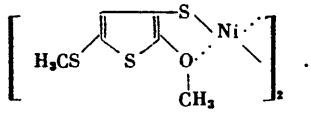
Polymers have been obtained by copolymerisation of 2,5-thiophenedithiol with divinylthiophene or divinylbenzene under UV irradiation or in the presence of radical initiators. These products may be used principally in the manufacture of light-sensitive materials and polaroid films.[70–72]

4. Other properties



Thiophenethiols are readily converted to the corresponding disulphides in the presence of mild oxidants (air, iodine, iron(III) salts).[73–75] The following conversions are notable:[18,19]

These reactions take place simply on exposing solutions of the mercaptan to air. 2-Mercapto-5-ethyl-3-thienylaldimine is oxidised to bis(3-cyano-5-ethyl-2-thienyl)disulphide in hydroxylic or aqueous alcohol media:[76]



The formation of thienylsulphenyl chlorides from thiophenethiols and chlorine is synthetically very interesting:[14,62]

The reaction takes place in carbon tetrachloride. It is important that the 5-position is blocked. If not, the resulting sulfenyl chlorides react with the starting mercaptans at the unsubstituted 5-position with liberation of HCl. A variety of thienylthio derivatives may be obtained from thienylsulphenyl chlorides, the chlorine atom of which is very labile.

A number of transition metal complexes, e.g. (XVI), may be formed from thiophenethiols and their derivatives. The nickel chelate (below) is formed by heating nickel acetate with a methanolic solution of 2-methoxy-5-methylthio-3-thiophenethiol.[37]

Recently, the synthesis of titanocenethienyl and niobocenethienyl thienylmercaptides was reported,[77,78] and a study made of the stability of the latter towards I_2.

***

Thiophenethiols are an interesting class of heterocyclic compound from both the theoretical and practical viewpoint. From the volume of data published on these compounds in recent years, one can anticipate further developments in this field.

The synthesis, structure and reactivity of (α-trihalomethyl)carbinols

A O Gukasyan, L Kh Galstyan, A A Avetisyan
Erevan State University

ABSTRACT. Data on the methods of synthesis and chemical properties of (α-trihalomethyl)carbinols are correlated and systematised in the review. Features of the structure are considered and certain effects of the nature of the halogen on their reactivity and physicochemical properties are discussed. An important role has been shown for the (α-trihalomethyl)carbinols as intermediates and synthons.

The bibliography contains 153 references.

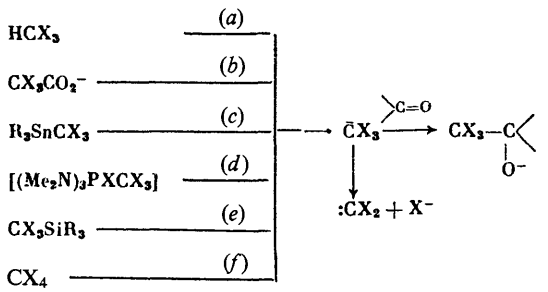
III.	Conversions of (α-trihalomethyl)carbinols	1321

I. Introduction

Interest in the synthesis of (α-trihalomethyl)carbinols has been increasing since the first studies appeared on the preparation of this class of compounds.[1–3] Significant success has been achieved in the synthesis and practical application of these compounds. New degradable organochlorine pesticides have been synthesised, based on (α-trichloromethyl)carbinols, which do not accumulate in vertebrates and are decomposed by enzymic systems.[4–7] It has been established recently that systematic rapid changes in the toxic chemicals used enable the self-purification of the environment from their metabolites and residues to be maintained at a low level. The large number of compounds used for plant protection is increased by a range of (α-trichloromethyl)carbinols.[4]

(α-Trichloromethyl)carbinols are used in medicine as narcotics and analgesics and in recent years effective tranquillisers have been found among the (α-trichloromethyl)carbinols of the acetylenic series,[8,9]

(α-Trichloromethyl)arylcarbinols (ATMC) are converted by a one-stage method, dehydration–rearrangement reaction, into α,β,β-trichlorostyrenes which are co-monomers for heat- and light-stable polymers.[10,11]



The current review is the first attempt in the Soviet and foreign literature to embrace completely all aspects of the chemistry of the (α-trihalomethyl)carbinols.

II. Methods of synthesising (α-trihalomethyl)-carbinols

1. Condensation of trihalomethyl anions with carbonyl compounds

The most widespread and general method of synthesising (α-trihalomethyl)carbinols is the condensation of trihalomethyl anions with carbonyl compounds. The generation of trihalomethyl anions (THA) is effected by various routes using a wide range of reagents, e. g. from haloforms in basic medium,[12–24] decarboxylation of trihaloacetic acids[25–27] or their salts,[28] from trihalomethyl-organotin compounds[29] and trihalomethylphosphonium salts,[30] from trihalomethylorganosilicon compounds[31] or the electrochemical reduction of carbon tetrachloride.[32–36] The resulting THA tend to dissociate into dihalocarbenes which is an undesirable process in the synthesis of (α-trihalomethyl)carbinols.[37] Experimentally this is readily prevented at relatively low (0 °C and below) temperatures in the presence of carbonyl compounds (Scheme 1).

Scheme 1

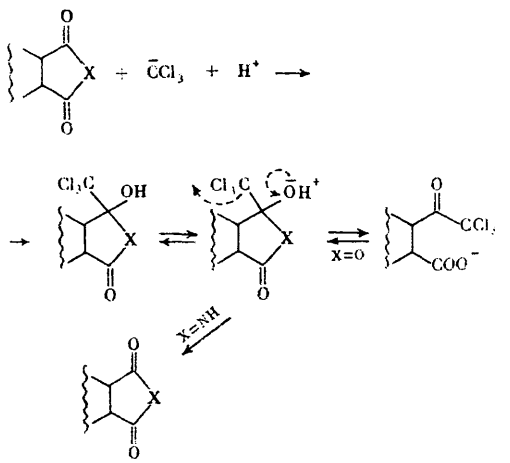
X = Cl, Br, combination Cl and Br

It has been shown that THA are formed from the majority of haloforms by a rapid reversible reaction. Many investigators,[12–24] using haloforms as a source of THA, have paid much attention to the choice of basic catalyst and to their proportion in the system of carbonyl compound–haloform–solvent. The generation of THA with almost the same success was effected with potassium and sodium hydroxides,[12,15,16,20,21] alkali metal alkoxides[13,14] and calcium oxide in dimethyl sulphoxide.[17,18] A serious difficulty in the process of simultaneously generating THA from haloforms and condensing them with carbonyl compounds is the inclination of the latter to undergo aldol condensation and Cannizzaro oxidation–reduction processes under the same base catalysis conditions. This hinders appreciably the synthesis of (α-trihalomethyl)carbinols. With the aim of suppressing the competing side reactions mentioned above, many authors have used various solvents, such as aliphatic acetals, ketals, vicinal glycols[38] or, which is particularly important, have tried to reduce the quantity of the basic catalyst to the minimum. In contrast to the early studies[12–19] where the catalyst was used in equimolar ratio to the aldehyde (or ketone), it was shown that the use of liquid ammonia as solvent was extremely convenient and it was possible to reduce the quantity of base (aldehyde : chloroform : potassium hydroxide = 1 : 1 : 0.3–0.5) and simultaneously provide low temperature conditions when the process of dissociative

fission of the THA into dihalocarbene is suppressed. The yield of the desired carbinol was 41–95%.[20] The yield of the desired carbinol was 41–95%.[20] A procedure, competitive at the technological level, has been described[21] in which it was shown that the optimum conditions for synthesising the narcotic chloretone, viz. (α-trichloromethyl)dimethylcarbinol, were a ratio of acetone : chloroform : potassium hydroxide = 10 : 1 : 0.1 without solvent at −5 °C. During the synthesis the excess of acetone was returned into the cycle and yield was 76%.

It was shown, using as example the condensation of benzaldehyde with mixed haloforms (dichlorobromo- and dibromochloromethanes) that under conditions of base catalysis the latter also generate the corresponding THA.[39,40] Condensation has been described with heterogeneous base catalysis (powdered calcium hydroxide) without solvent[39] and with homogeneous catalysis using potassium t-butoxide and t-butanol.[40]

The generation of THA from haloforms is also effected under conditions of phase transfer catalysis.[41,42] This method does not lead to a high yield of product, exceptions being only the higher representatives of aliphatic aldehydes and ketones and also certain aldehydes of the heterocyclic series (2-, 3-, 4-pyridyl-).[43] It must be noted that aromatic ketones do not react at all under phase transfer catalysis conditions.



In 1959 Wagner[44] reported the generation of dichlorocarbene by the thermal decomposition of sodium trichloroacetate (TCAA) in 1,2-dimethoxyethane. However Winston and co-workers[28] under the same conditions succeeded in decomposing sodium trichloroacetate in the presence of aldehydes and isolating (α-chloromethyl)carbinols as products of the trichloromethylation of the carbonyl group, albeit in extremely modest yield (29–47%). Decarboxylation of trihaloacetate anions with the formation of trichloro(bromo)methyl anions (Scheme 1, *b*) takes place with comparatively low yields. The reason, in our opinion, is graphically illustrated in recently patented work where it was shown that, when using DMSO, DMF or other related compounds as solvent, spontaneous addition of $\bar{C}X_3$ and CO_2 takes place at the carbonyl group with the formation of the corresponding carbonates. Under specific experimental conditions the reaction may be directed completely to carbonate formation.[45]

$$>C=O + \bar{C}X_3 + CO_2 + Na^+ \longrightarrow >C(CX_3)OCO_2^-Na^+$$

It was shown recently by English scientists[25,27] that THA are readily generated at room temperature by dissolving trichloro- and tribromoacetic acids in DMSO. The use of halogenated acids as sources of THA completely excludes carbonate formation and the desired (α-trihalomethyl)carbinols are isolated in 50–80% yield.[25,27] It is interesting to note that 4-nitrobenzaldehyde does not react with haloforms[46] but 4-nitrophenyl(trichloromethyl)carbinol is formed in 80% yield with trichloro(bromo)acetic acid.[25] This experimentally observed fact is seemingly linked with the use of the highly polar DMSO solvent which in fact reduces the deactivating effect of the 4-nitro group on the α-carbon atom to zero.

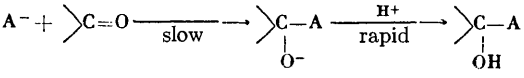
This synthetic method enables several pyridinaldehydes to take part in the reaction but not furfural and its homologues, which are rapidly resinified in a TCAA medium. The problem of trichloromethylating these compounds was successfully resolved by the decarboxylation of trichloroacetates (K, Na) in a medium of DMSO or DMF.[47]

The trichloromethylation of cyclic anhydrides and imides in a TCAA–DMSO system is of interest. This reaction leads to a lactone or lactam containing a trichloromethylcarbinol structural unit in the γ-position of the heterocycle. It was shown[48] that either ring–chain isomeric conversions or partial haloform fission occur in this case.

By using various solvents the equilibrium system is successfully displaced in the direction of ring or chain isomers.

It must be noted in regard to the decarboxylation of TCAA into the trichloromethyl anion (TCA) that it is possible to use hexamethylphosphoramide (HMPA) successfully in place of DMSO, which while maintaining the pH of the medium close to neutral has certain advantages over DMSO from the preparative point of view.[49]

Trihalomethylphosphonium salts are also sources of THA. Tris(dimethylamino)trichloromethylphosphonium chloride, on reaction with aliphatic aldehydes and cycloalkanones, forms (α-trichloromethyl)carbinols in preparative yield.[30] Tributyl(trichloromethylstannanes, which are convenient synthons for generating THA, form (α-trihalomethyl)carbinols in 20–69% yield with aliphatic and aromatic aldehydes.[29] The authors excluded any effect of initiators and inhibitors of radical processes from the reaction and demonstrated strictly the heterolytic fission of the $-Sn-CCl_3$ bond with the formation of TCA.



From the preparative point of view it is best to heterolyse the carbon–silicon bond in α-trichloromethylsilanes in a medium of tris(dimethylamino)sulphonium difluorotrimethylsilicate (TASX). This route provides a 75% yield of trichloromethylated carbinols.[31]

The method of generating TCA by the cathodic reduction of carbon tetrachloride in chloroform or DMF is interesting. In the presence of alkyl-, heteryl- or arylaldehydes the corresponding (α-trichloromethyl)carbinols are fomred in 11–92% yield.[32–36]

$$RCHO + CCl_4 \xrightarrow[CHCl_3 \text{ or } DMF]{2\bar{e}} RCH(OH)CCl_3.$$

The synthesis of several previously undescribed (α-trichloromethyl)carbinols has been achieved by this means although the complexity of the experimental conditions places the value of this method in use under some doubt.

The condensation reaction of TCA with aldehydes and ketones proceeds according to the widely known mechanism where the carbanion ($\overline{C}X_3$ in this case) attacks the carbonyl group.

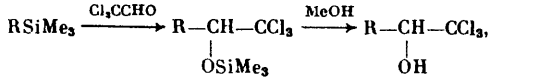
The first stage determines the rate of the reaction which makes it possible to make certain comparisons with the kinetically related Darzens (glycidyl condensation) and Perkin reactions.[50] Because of the absence of sufficient literature data on the kinetic parameters of the Darzens reaction, Reeve and co-workers[51] studied the reactivity of seven aryl aldehydes taking the kinetic data of the Perkin reaction as standard. The results obtained are in good agreement, and in several cases are even identical.

It must be noted that a neighbouring group effect or a secondary steric effect of an *ortho* substituent is observed in the condensation reaction of haloforms with aryl aldehydes. The displacement of the aldehyde group from the plane of the aromatic ring, accompanied by a disturbance of the conjugation, and consequently by the exclusion of the mesomeric effect of the substituent on the reaction centre, is the reason for the acceleration.

2. Syntheses based on chloral

The method of synthesis of (α-trichloromethyl)carbinols next in significance is based on chloral.

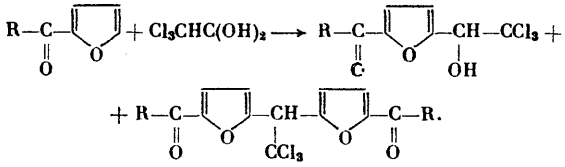
Chloral reacts under conditions of acid–base catalysis with aromatic hydrocarbons with the formation of aryl(trichloromethyl)-carbinols (ATMC) in good yield (70–91%). Both acidic (H_2SO_4, HCl, $AlCl_3$, $AlBr_3$, BF_3, $ZnCl_2$) [52–57] and basic catalysts (potassium hydroxide, pyridine, potassium carbonate) [58–60] are used for the condensation. Until recently it was considered that the method was effective only for benzene and its 1,4-disubstituted derivatives and in the remaining cases (monosubstituted benzenes) a mixture of 2- and 4-isomers is formed. It was shown, however, that this synthetic barrier was readily overcome on using a 10-fold excess of aromatic hydrocarbon relative to chloral.[61]



The hydroxybenzaldehydes do not take part in the condensation of haloforms with aryl aldehydes since the hydroxy group is converted into a phenoxide ion under base catalysis conditions, the electronic effect of which reduces significantly the positive charge on the carbon carbon and makes it inactive in relation to TCA. This synthetic gap in obtained 2-, 3-, and 4-hydroxyphenyl(trichloro-methyl)carbinols is eliminated by the reaction of phenoxides of the alkali metals with chloral.[62,63]

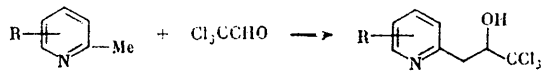
Many organometallic compounds also react with chloral with the formation of (α-trichloromethyl)carbinols, however, this method is not used widely due to low yields of the desired carbinols (< 50%) and the poor accessibility of the starting materials.[3,64–66] Furthermore the majority of alkylmagnesium halides react with chloral by an oxidation–reduction reaction forming trichloroethanol and the corresponding olefin (the Grignard reagent is a reducing agent). Exceptions are only the methyl- and benzyl magnesium halides which are not able to undergo such conversions and give adducts in good yield.[67] Vinyl- and substituted vinylmagnesium halides also react satisfactorily with chloral (30% yield) and the vinylcarbinols obtained are readily hydrogenated on palladium–carbon catalyst.[68]

In order to prepare new tranquillisers French scientists[8,9] have effected the synthesis of several(α-trichloromethyl)carbinols by the reaction of silylated hydrocarbons, in which the Si–C bond is activated by vinyl, acetylene and other electron-accepting substituents, with chloral in the presence of Lewis acids.



R=BuC≡C, $Me_3SiC{\equiv}C$, $Me_3SiCH_2C{\equiv}C$, PhC≡C, $EtOCOCH_2$, Et_2NCOCH_2,

pyrid-3-ylethynyl, 2-pyridyl, propargyl, allyl, vinyl.



A series of interesting (α-trichloromethyl)carbinols containing α-ester groups has been synthesised by the reaction of chloral with orthoesters in the presence of mineral and Lewis acids.[69]

Studies[70,71] by Spanish scientists merit attention. These are devoted to the synthesis of substituted 2-furyl(trichloromethyl)-carbinols by the reaction of esters and amides of furane-2-carboxylic acid with chloral hydrate. In these studies, carried out for the purpose of obtaining effective pesticides, it was shown that, depending on the temperature and solvent, the reaction may stop at the required ratios of carbinol and the product with the bis structure.

R = NH_2, COOR′.

Chloral readily condenses with CH-acids. The condensation of picolines and lutidines with chloral is important from the applied point of view since the pyridomethyl(trichloromethyl)carbinols display local anaesthetic activity.[72,73]

Seemingly the ease of condensation is explained by the fact that the methyl and methylene substituents at the C(2) and C(4) atoms of the pyridine ring are potential centres for forming carbinols in view of their high CH-activity, which is readily stabilised by delocalisation, particularly if the heteroatom is quaternised. Such an approach is also substantiated by the fact that many authors have effected the condensation of chloral with picolines in the presence of Lewis acids.[74]

III. Conversions of (α-trihalomethyl)carbinols

(α-Trihalomethyl)carbinols are polyfunctional compounds. They react at the hydroxyl and trihalomethyl groups and it is interesting that anything affects one functional group leads to a modification of the other, i.e. there are very few reactions which are selective for one of these groups (exceptions are the partial and complete reduction of the trihalomethyl group and exchange of hydroxyl of halogen and acetoxy groups). Briefly, the numerous studies relate to the two types of conversions of (α-trihalomethyl)carbinols by reaction with basic and acidic reagents or by dehydrohalogenation and dehydration.

1. Reactions with acids

Acid hydrolysis of the isolated trichloromethyl group proceeds with the formation of an intermediate $R\overset{+}{C}Cl_2$ cation which is readily hydrolysed.[75] In sulphuric acid compounds of the type of $RCCl_3$ (R = Alk) at 90–100 °C form the $R\overset{+}{C}Cl_2$ cation,[76] which dissociates according to the scheme.[77]

$$RCCl_3+3H_2SO_4 \rightarrow R-\overset{+}{C}Cl_2+HOSO_2Cl+H_2O^+ +2HSO_4^-.$$

The formation of $R\overset{+}{C}Cl_2$ also occurs as a result of the thermal dissociation of the trichloromethyl group at high temperatures.[78,79]

$$RCCl_3 \rightleftarrows R\overset{+}{C}Cl_2+\overline{Cl}.$$

The hydroxyl group in the α position to the trichloromethyl group in (α-trichloromethyl)carbinols facilitates acidic hydrolysis, however, the reaction goes with complications. Alkyl trichloromethycarbinols form one product and aryl trichloromethylcarbinols form another.

On sulphuric acid hydrolysis of (α-trichloromethyl)carbinols the hydroxyl group is first involved in the reaction,[79,80] and it is possible to form the same $R\overset{+}{C}Cl_2$ cation by fission of hydroxyl and migration of a chlorine atom. Such a route of forming the $R\overset{+}{C}Cl_2$ cation occurs far more easily than through the difficult thermal dissociation of a C–Cl bond of the trichloromethyl group.

The first stage of the reaction of chloretone with 98% sulphuric acid is the protonation of the hydroxyl group with the formation of an oxonium cation, then follows elimination of water, the formation of the carbenium ion $Me_2\overset{+}{C}-CCl_3$, a 1,2-migration of chlorine atom and hydrolysis.[79]

$$Me_2C(OH)CCl_3 + H^+ \longrightarrow Me_2C(\overset{+}{O}H_2)CCl_3 \longrightarrow Me_2\overset{+}{C}CCl_3 \longrightarrow$$

$$\longrightarrow Me_2C\overset{Cl}{\underset{\odot}{\diagup\diagdown}}CCl_2 \longrightarrow Me_2C(Cl)\overset{+}{C}Cl_2 \xrightarrow{HOH}$$

$$\longrightarrow Me_2C(Cl)CCl_2\overset{+}{O}H_2 \longrightarrow Me_2C(Cl)COCl + HCl + H^+$$

With insufficient water the reaction stops at the stage of forming the acid chloride.

It is interesting that aryl[di(tri)chloromethyl]carbinols (ADMC, ATMC) do not give similar products on solvolysis with sulphuric acid.[81] In this case compounds of two types are formed, viz. a product of replacement of the hydroxyl group and a product of elimination of the HOCl fragment.[81]

$$ArCHCCl_2X \xrightarrow{H_2SO_4} ArCH(Cl)CCl_2 + ArCH=CCl_2,$$

$$\begin{matrix} | \\ OH \end{matrix} \qquad\qquad \begin{matrix} | \\ X \end{matrix}$$

X = H, Cl; Ar = *o*-, *p*-ClPh.

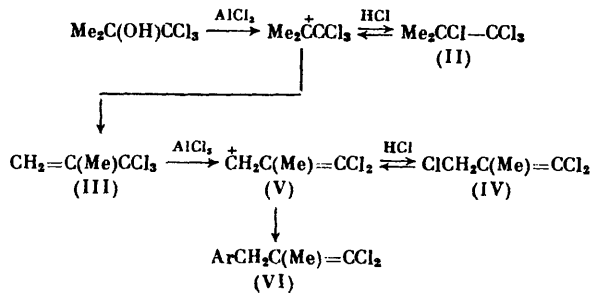
The reasons for the toxicity of diphenyldichloromethylmethane (DDD) have appeared in recent investigations and are a drawback for these medicinal preparations which have been approved for the treatment of adrenal neoplasia. It is proposed[81] that the increase toxicity of DDD and its analogues is linked with the formation of side products in their preparation by the condensation of the corresponding ADMC with chlorobenzene catalysed by acids.[82,83]

$$ArCH(OH)CCl_2X + PhCl \xrightarrow{H^+} Ar_2CHCCl_2X,$$

X = H, Cl; Ar = *o*-, *m*-, *p*-Cl, Alk-, AlkOPh.

Non-persistent analogues of DDD and DDT are obtained on an industrial scale by this reaction from readily available carbinols. Nevertheless yields are mainly low at 30–50% [82,83] and this already indicates the presence of side reactions. The products have been identified[81] and are formed by the action of concentrated H_2SO_4 on ADMC, ATMC and phenyltrichloropropanols. In contrast to ADMC and ATMC, 2,2-dichloro-1-(2-chlorophenyl)propanol forms only 1-(2-chlorophenyl)-1-chloropropanone with concentrated H_2SO_4. It is proposed that the reaction proceeds through an intermediate chloronium ion.

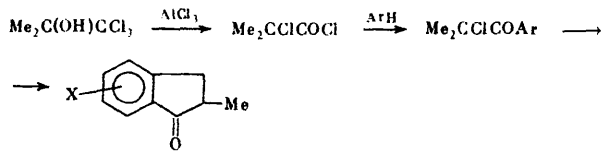
$$ArCH(OH)CCl_2Me \xrightarrow[-H_2O]{H^+} Ar-CH\overset{Cl}{\underset{\odot}{\diagup\diagdown}}CClCH_3 \xrightarrow[H^+]{H_2O}$$



$$\longrightarrow ArCHClC(OH)ClCH_3 \xrightarrow[-HCl]{} \underset{(I)}{ArCHClCOMe}$$

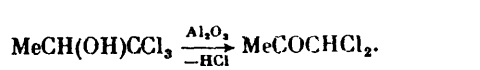
It was shown by ^1H NMR using an acidified sample of carbinol that the quantity of water formed in the first stage of the reaction was sufficient for the transition into ketone (I). In fact the rearrangement occurs far more rapidly, condensations with chlorobenzene do not occur and ketone (I) is formed completely. On the other hand esterification in a sulphuric acid–acetic acid mixture occurs without anomaly with the formation of the acetoxy derivative of the starting carbinol.[81]

The use of Lewis acids for the dehydration of (α-trichloromethyl)-carbinols leads to a complex mixture of trichloroalkanes and tetrachloroalkanes.[84]



Even in the last century Willgerodt and Genieser[1] reported that on condensing chloretone with benzene, toluene and *o*-xylene in the presence of anhydrous $AlCl_3$ products of the replacement of a chlorine atom and the hydroxyl group were isolated in low yield. Kundiger and collaborators[84] repeated this reaction with toluene, chlorobenzene and anisole. The conclusions of the original authors[1] were not confirmed, alkylation of aromatic compounds by (α-tri-carbinols)carbinols by the direct replacement of chlorine atoms did not occur and neither did replacement of the hydroxyl. It was shown,[84] using chloretone as example, that dehydration occurs initially and the resulting 3,3,3-trichloro-2-methylpropene (III) is isomerised into 1,1,3-trichloro-2-methylpropene (IV). Compound

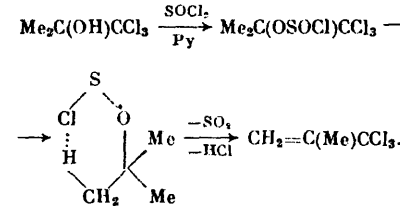
(IV) alkylates the aromatic nucleus via the allylic chlorine with the formation of 1,1-dichloro-2-methyl-3-arylpropenes (VI).



This scheme was confirmed by direct alkylation with individual (II)–(IV). Each of the intermediate products may give a carbonium ion of the type of (V) which forms the above-mentioned products in the course of the reaction.

On using chloretone under the conditions of the Friedel-Craft reaction the acid chloride of α-chloroisobutyric acid is formed together with the 1,1-dichloro-2-methyl-3-arylpropene.[84] If the experiment is carried out with small quantities of $AlCl_3$ it is possible to isolate the acid chloride mentioned above which condenses with aromatic hydrocarbons with an excess of $AlCl_3$ and gives 2-methyl-indanones.[84]

X = H, Cl



Primary and secondary trichloromethylated alcohols readily form alkoxy chlorides of the $ROAlCl_2$ type with $AlCl_3$,[85] which are comparatively stable. In this case alkylation by these carbinols proceeds not at the carbon linked with the hydroxyl but at the trichloromethyl group.[86] Seemingly the above-mentioned carbinols form mainly dehydrochlorination and not dehydration products under the action of zinc chloride and for the same reason. For example, it was shown[87] that 1,1,1-trichloropropan-2-ol forms 1,1-dichloroacetone on reaction with zinc chloride in hydrochloric acid solution. The same result was obtained on passing the same carbinol over a heated layer of aluminium oxide at 200–250 °C.[87]

Analysis of the available experimental data shows that under the influence of a trichloromethyl group all types of aliphatic α-carbinols should lose the ability to alkylate at a carbon atom linked with a hydroxyl group. Under the condensation conditions trichlorinated alcohols are either dehydrated with the formation of reactive compounds which lead to alkylation,[84] or the reaction proceeds at the expense of chlorine atoms of the trichloromethyl group.[85]

From the preparative point of view the dehydration reactions of (α-trihalomethyl)carbinols are attractive since interesting halogenated alkenes of various structures are generally obtained.

A mixture of thionyl chloride with various amines is used successfully for the dehydration of t-(α-trichloromethyl)carbinols.[88] The success of the dehydration depends critically on the molar ratio of thionyl chloride to amine. It was shown[89] that an increase in the quantity of amine leads to the formation of sulphates and chlorosulphonate esters. When using a catalytic quantity of amine (pyridine, aniline hydrochloride, t-butylamine, di-n-butylamine, *N,N*-dimethylaniline, triethylamine) 3,3,3-trichloro-2-methylpropene was obtained from chloretone in good yield.

On the other hand the use of a catalytic quantity of tetramethylammonium iodide leads to the allyl isomer due to the catalytic action of the resulting molecular iodine causing isomerisation.[88]

The introduction of a phenyl group into the α-position reduces the possibilities of dehydration. The absence of α-hydrogen atoms in phenyl(trichloromethyl)carbinol leads to the formation of α,β,β,β-tetrachloroethylbenzene (88%).[90] The latter was also obtained in 87% yield on using phosphorus pentachloride as dehydrating agent.[91] Replacement of the benzene ring by an aliphatic group leads to complications. In the case of ethyl-(trichloromethyl)carbinol Reeve[92] isolated the product of replacing the hydroxyl by chlorine in only 18% yield, the product of further dehydrohalogenation, viz. 1,1,2-trichlorobut-1-ene, in 13% yield and a high boiling mixture of phosphate and α-chloro-carboxylic acid ester.

$$EtCH(OH)CCl_3 + PCl_5 \longrightarrow \underset{18\%}{EtCH(Cl)CCl_3} + \underset{13\%}{EtC(Cl)=CCl_2} +$$
$$+ MeCH=CH-CCl_3 + \underset{4\%}{MeCH(Cl)-CH=CCl_2} + EtCH(Cl)COOEt$$

In the case of vinyl(trichloromethyl) carbinol the reaction is accompanied by a double allylic isomerisation.

$$CH_2=CH-CH(OH)CCl_3 + PCl_5 \longrightarrow CH_2=CH(Cl)CCl_3 \longrightarrow$$
$$\longrightarrow ClCH_2-CH=CH-CCl_3 \xrightarrow{Cu,\ 220^\circ C} ClCH_2-CHCl-CH=CCl_2$$

The products obtained by the reaction of alkynyl(trichloromethyl)carbinols with phosphorus pentachloride indicate the trivial course of the reaction. In this case the authors also identified the crystalline phosphate ester of the initial carbinols.[92]

$$RC\equiv C-CH(OH)CCl_3 + PCl_5 \longrightarrow RC\equiv C-CH(Cl)CCl_3 +$$
$$+ RCCl=C=CH-CCl_3 + (RC\equiv C-\underset{\displaystyle Me}{\underset{|}{CH}})_3PO_4$$

R = H, n-C_5H_{11}

It is interesting that replacement of the hydroxyl group in phenyl(trichloromethyl)carbinol by chlorine by the action of hydrochloric acid in the presence of 20% (by weight) zinc chloride was unsuccessful, while in phenyl(methyl)carbinol exchange occurs by the action of gaseous hydrogen chloride.[91] Bis(trichloromethyl)carbinol also does not react with hydrochloric acid.[93] This phenomenon may be explained by the presence of the electron-accepting trichloromethyl group, the effect of which on the reaction of the hydroxyl group is extremely significant.

Acid dehydrating agents such as phosphorus pentachloride are used for the dehydration of alkyl(trichloromethyl)carbinols. It was shown[94] that chloretone is dehydrated with difficulty. Mainly, resinification occurs and the dehydration product, 3,3,3-trichloro-2-methylprop-1-ene is obtained in very low yield (8%), the isomeric 1,1,3-trichloro-2-methylprop-2-ene is formed in somewhat larger amounts (15%).

The dehydration of 1,1,1-trichloropropan-2-ol has been studied by many authors. Here the literature data are fairly contradictory. Only in one case do the data agree. Pierce and collaborators[87] and Kirrmann and collaborators[95] assigned the structure of 1,1,2-trichloroprop-1-ene to the dehydration product of 1,1,1-trichloroisopropanol, both studies giving the yield as very small (8–10%). The dehydration products, which distilled over a wide temperature range (11°), were divided into four fractions of which only one was identified as 1,1,2-trichloroprop-1-ene.[87]

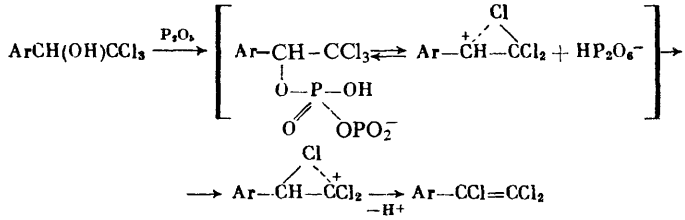
$$MeCH(OH)CCl_3 \xrightarrow{P_2O_5} MeCCl{=}CCl_2.$$

While carrying out the dehydration under the same conditions Henne and co-workers[96] reported that mainly 3,3,3-trichloroprop-1-ene was obtained with very little of the isomerised 1,1,3-trichloroprop-1-ene.

$$MeCH(OH)CCl_3 \xrightarrow{P_2O_5} \underset{85\%}{CH_2{=}CH{-}CCl_3} + ClCH_2{-}CH{=}CCl_2.$$

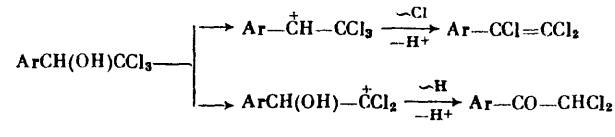
Using the same reaction as an example Kharasch and collaborators[97] considered that they had a 1,1,1-trichloro-containing compound. Fractions were separated during the dehydration which were distillable over a wide temperature range. On a second distillation two products were separated. The first was assigned the structure 3,3,3-trichloroprop-1-ene and the second 1,3-dichloroallene (based on IR spectroscopy).

$$MeCH(OH)CCl_3 \xrightarrow{P_2O_5} CH_2{=}CH{-}CCl_3 + ClCH{=}C{=}CHCl.$$



The constants for the first product agree with the data for the product obtained by Henry[98] but do not agree with the constants of Vitoria.[99] The authors[97] explain this by the fact that Vitoria most probably had a mixture of a propene and an allene and not the individual 3,3,3-trichloroprop-1-ene.

When generalising the results of all the studies in which phosphoric anhydride is used as the dehydrating agent in the reaction with alkyl(trichloro)carbinols (chloroetone, isopral), it may be concluded that dehydration occurs in this case by a mechanism leading to a complex mixture of isomeric chloroalkanes and allenes. It is quite probable that some products of the same dehydration process were successfully identified by one author and others by another. The low selectivity of this dehydration process is linked with the stabilisation of the intermediate carbenium ion simultaneously by several sources independently leading to one or other product, fission of the α-proton, shift of a double bond or skeletal rearrangement.



From the point of view of selectivity the considered reactions are only of theoretical interest, including the dehydration of aryltrihalo(chloro, bromo) methylcarbinols which leads to α,β,β-trihalo(chloro, bromo)styene in high yield (61–93%) by dehydration rearrangement with phosphorus pentoxide or oxychloride[10] and also on industrial aluminosilicates.[11]

$$ArCH(OH)CHal_3 \xrightarrow[Hal = Cl,\ Br.]{\text{dehydration}} Ar - CHal = CHal_2,$$

The dehydration of aryl(trihalomethyl)carbinols proceeds highly selectively compared with their aliphatic analogues because in this case the other means of stabilisation of the intermediate carbenium ion, which predominate in the aliphatic analogues, are suppressed. The relative reactivity of ATMC towards phosphorus pentoxide in cyclohexane was determined by the method of competing reactions.[100] The combination of the values for the ratio of the rate constants of substituted and unsubstituted carbinols (k/k_0) and the reaction constant ρ enabled the reaction mechanism to be established.

Industrial aluminosilicate (NBNZ) was also used as a dehydrating agent. Depending on its previous heat treatment this leads the process either towards dehydrochlorination with the formation of dichloromethyl aryl ketones[11] or towards a dehydration isomerisation reaction.

Evidently the previous heat treatment has a strong effect on the acid–base properties of the catalyst surface which also leads to a product of dehydration and dehydrochlorination.

The dehydration isomerisation reaction was used for a comparison of the migration properties of certain functional groups (halogens, alkyls) which form the series Br > Cl ≫ Alk in migrating ability under structurally identical conditions. Various α,β,β-trisubstituted styrenes, which are difficultly accessible by other methods of synthesis, were synthesised by the dehydration isomerisation one-stage method while of solving the theoretical problems.[101]

2. Reduction of the trichloromethyl group

The selectivity of the reduction of the trichloromethyl group in compounds of the $RCCl_3$ type depends on the nature of the initiator of the reduction reaction.

Carbon tetrachloride is selectively reduced by isopropanol to $CHCl_3$ on initiation by various peroxides,[102,103] by complexes of transition metal hydrides[104,105] or iron carbonyl $[Fe(CO)_5]$,[106] and further reduction of the resulting $CHCl_3$ to CH_2Cl_2 does not occur in practice. In the presence of $Mn_2(CO)_{10}$ and $Mo(CO)_6$ reduction occurs selectively with the formation of a mixture of $CHCl_3$ and CH_2Cl_2.

The reduction of the trichloromethyl group in compounds of the DDT type was the subject of several investigations with the aim of discovering new biologically active preparations.

The trichloromethyl group in DDT is exceptionaly inert towards the action of weak reducing agents. It is reduced by zinc in concentrated hydrochloric acid.[107] However it must be noted that the reduction proceeds non-selectively, the trichloromethyl group is reduced both to a dichloromethyl and to a methyl group with the formation of a mixture of 1,1-dichloro-2,2-di-(4-chlorophenyl)ethane, 1,1-di-(4-chlorophenyl)ethane and 4,4′-dichlorostilbene as the side product of the main reaction.

The selectivity of the reduction is significantly greater for the precursors of DDT, the (α-trichloromethyl)carbinols, however it also depends strongly on the character of the reduction initiator used and the substituent in the aromatic ring. Under the action of aluminium amalgam in alcohols, ATMC form the corresponding (dichloromethyl)carbinols in preparative yield.[108,109] Metallic aluminium (modified Meerwein-Pondorf method),[110,111] complexes of polystyrene with Ru, Rh and Ir containing organophosphorus ligands[112] and $Fe(CO)_5$ [106] in isopropyl alcohol have also been successfully applied for the same purpose.

$$ArCH(OH)CCl_3 \xrightarrow[iso-PrOH]{\text{reduction}} ArCH(OH)CHCl_2.$$

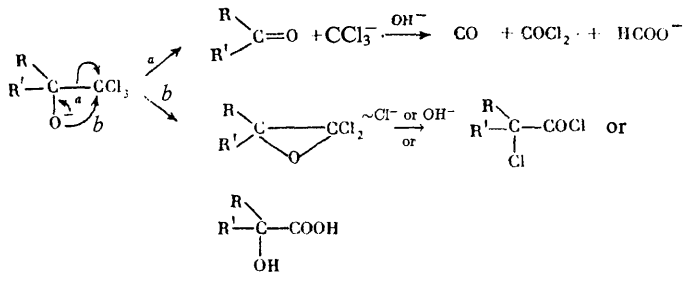
When reducing ATMC with zinc dust in acids or with lithium in liquid ammonia the selectivity of the process falls sharply.[113] The reduction of phenyl(trichloromethyl)carbinol with zinc dust in neutral or acid medium leads to a mixture of β,β-dichlorostyrene and β-chlorostyrene and in acetic acid to the methyl ether of phenyl(dichloromethyl)carbinol. Lithium in liquid ammonia gives α-phenylethanol in low yield and acetophenone and 2-phenylethan-1-ol as byproducts.

$$PhCH(OH)CCl_3 \begin{cases} \xrightarrow{Zn/H^+} PhCH{=}CCl_2 + PhCH{=}CHCl \\ \xrightarrow{Zn/AcOH} PhCH(OH)Me + CHCl_2 \\ \xrightarrow{Li/NH_3} PhCH(OH)Me + PhCOMe + PhCH_2CH_2OH \end{cases}$$

The introduction of a methoxy group into the 4-position of the aromatic nucleus in phenyl(trichloromethyl)carbinol increases the lability of the hydroxyl hydrogen. Reduction of the carbinol in isopropyl alcohol in the presence of $Fe(CO)_5$, $Mo(CO)_6$ or $Mn_2(CO)_{10}$ leads to a mixture of 4-methoxyphenyl(dichloromethyl)carbinol and 4-methoxyphenylisopropoxycarbinol in a ratio dependent on the nature of the carbinol and metal.[106] β,β-Dichlorostyrene is obtained as the main reaction on electrochemical reduction of the same carbinol.[114]

$$4\text{-}MeOC_6H_4CH(OH)CCl_3 \rightarrow 4\text{-}MeOC_6H_4CH{=}CCl_2.$$

There is even less selectivity on reducing the trichloromethyl group in alkyl(trichloromethyl)carbinols and in trichloromethylethanol. According to the data of Favorskii[115] a mixture of 1,1-dichloro-2-methylprop-1-ene and 1-chloro-2-methylprop-1-ene and isobutene, which are products of further reduction, is obtained from chloretone by reduction with zinc dust in ethanol.



A dichlorocarbinol is obtained in 32% overall yield by the reduction of trichloroethanol in isopropyl alcohol in the presence of $RuCl_2(PPh_3)_3$.[116] The same dichloromethylcarbinol was obtained as a byproduct by electrochemical reduction when the main product was dichloroethylene.[117]

$$HOCH_2CCl_3 \longrightarrow CH_2{=}CCl_2 + \underset{\text{(byproduct)}}{HOCH_2CHCl_2}.$$

3. Reactions with bases

The isolated trichloromethyl group is inert to the action of nucleophilic reagents in general and of OH^- ions in particular.[118] The first studies devoted to the reaction of (α-trichloromethyl)carbinols with bases were carried out using as example dimethyl(trichloromethyl)carbinol (chloretone), however it turned out that in the course of the reaction chloretone is subject to alkaline decomposition with the formation of acetone, chloroform, carbon monoxide, phosgene and formic acid,[119] i.e. a reaction is observed which is the reverse of the chloretone synthesis with subsequent alkaline hydrolysis of chloroform. A similar decomposition was even observed by Iotsich in the reaction of phenyl(trichloromethyl)-carbinol with aqueous KOH.[2] In parallel, Willgerodt and collaborators[120] successfully isolated a small quantity of α-hydroxy-, and Ostropyatov[121] α-chloroisobutyric and methacrylic acids from the products of the reaction of chloretone with aqueous KOH. Seemingly both the decomposition and the formation of the acids mentioned proceeds through the same alkoxide ion of the (α-trichloromethyl)carbinol (Scheme 2).

Scheme 2

In numerous studies devoted to this reaction the molar ratios of carbinols and bases were selected which provide the maximum yields of α-chloro- and α-hydroxyacids, i.e. experimental conditions directed to the suppression of route *a*. This is successfully carried out at the expense of hydrolysis of the carbinols in aqueous dioxan in the presence of ion exchange resin[122] or by replacement of the aqueous by alcohol alkali, the use of which leads to α-alkoxyacids in preparative yields. The observed phenomenon is seemingly linked with the basicity of the RO^- formed from the initial carbinol, which further attacks selectively the electrophilic centre in the trichloromethyl group to a greater extent than is regulated by haloform decomposition.

It was shown that chloretone forms α-ethoxyisobutyric acid in 72% yield on reaction with three equivalents of sodium ethoxide in ethanol.[123] The mechanism by which this conversion occurs passes, "indisputably" according to Jacob,[124] through the intermediate dichloroepoxide which then undergoes alcoholysis. The author arrived at this conclusion from the reaction of chloretone with dimethylaniline and comparison of these results with data on the alcoholysis of the epoxide ring.[125]

$$Me_2C(OH)CCl_3 \xrightarrow[EtOH]{EtONa} Me_2C(O)CCl_2 \xrightarrow[EtOH]{EtONa} Me_2C(OEt)COOEt$$

The formation of α-alkoxyacids may be considered probable from the intermediate acid chloride of the α-chloroacid, the rearrangement product of the dichloroepoxide. However the high yields of the final products make this alternative variant less probable. The absence of the formation of unsaturated acid and of chlorine-containing products excludes the rearrangement of the dichloroepoxide before its alcoholysis.

α-Butoxyisobutyric acid is isolated on reaction with 4 M KOH in alcoholic medium or with potassium butoxide in butanol at 0 °C.[126]

$$Me_2C(OH)CCl_3 + KOH \longrightarrow Me_2C(O)CCl_2 + KCl + H_2O,$$

$$Me_2C(O)CCl_2 + 2KOH \longrightarrow Me_2C(O)C{=}O + 2KCl + H_2O,$$

$$Me_2C(O)C{=}O + ROH \longrightarrow Me_2C(OR)COOH.$$

At the same time the preparation of an alkoxyacid ester may take place without the participation of an α-lactone.

$$Me_2C(O)CCl_2 + ROH + 2KOH \longrightarrow Me_2C(OH)(OR)C + KCl + H_2O,$$

$$Me_2C(OH)(OR)C + ROH \longrightarrow Me_2C(OR)COOR + H_2O.$$

Reeve and collaborators,[127] while studying the reaction of ATMC with bases as though resuming their investigations on the study of the mechanism of the conversion in question, published stereochemical data on the reaction of (*S*)-(+)- and (*R*)-(−)-phenyl(trichloromethyl)carbinols with MeONa/MeOH at 40 °C leading to (*S*)-(+)- and (*R*)-(−)-α-methoxyphenylacetic acids respectively. It was shown that the conversion proceeds with 9% inversion of configuration and 91% racemisation of the initial carbinol. The mechanism considered does not differ appreciably from the mechanisms discussed by Bergman and Jacob. According to Reeve's mechanism HCl is eliminated from the initial carbinol by the action of methoxide ion with the formation of the dichloroepoxide, which then is subjected to methanolysis and hydrolysis with the formation of α-methoxyphenylacetic acids. The inversion of configuration occurs during methanolysis of the dichloroepoxide.

$$PhCH(OH)CCl_3 \xrightarrow[-HCl]{} PhCH(O)CCl_2 \xrightarrow{MeO^-} PhCH(OMe)COCl \xrightarrow{hydrolysis} PhCH(OMe)COOH$$

According to an alternative mechanism the dichloroepoxide is rearranged with migration of a chlorine atom to the acid chloride of α-chlorophenylacetic acid with inversion of configuration due to attack by the migrating chlorine atom at the α-carbon atom from the side opposite the epoxide oxygen. After hydrolysis of the acid chloride, replacement of chlorine by a methoxy group occurs.

$$PhCH(O)CCl_2 \xrightarrow{-Cl} PhCH(Cl)COCl \xrightarrow{hydrolysis} PhCH(Cl)COO^- \xrightarrow{MeO^-}$$

(inversion of configuration)

$$\longrightarrow PhCH(OMe)COO^- \xrightarrow{H^+} PhCH(OMe)COOH$$

It was shown experimentally[127] that under the reaction conditions the (*R*)-(−)-acid chloride of α-chlorophenylacetic acid is 96% racemised by the action of methoxide ion and the racemisation of the (*R*)-(−) configuration occurs more rapidly than that of the (*S*)-(+).

It is proposed that methanolysis leading to the α-methoxy ester also occurs through the intermediate gem-dichloroepoxide.[128]

The deacetoxychlorination of chloretone acetate leading to α-ethoxyisobutyric acid ethyl ester in 55% yield has been carried out[129] by boiling with an ethanolic solution of sodium ethoxide. The authors postulate the formation of this ester through the same intemediate dichloroepoxide.

α-Alkoxyarylacetic acids, obtained by the reaction of ATMC with alcoholic bases, have a high practical value (in analytical chemistry, agriculture).[130–134] Proceeding from this, a broad investigation was undertaken to optimise the synthesis of these acids.[130,135] The synthesis of aryl[trichloro(bromo)methyl]carbinols, their subsequent dehydrohalogenation and alcoholysis of the intermediate dihaloepoxide have been successfully combined in one stage.

$$ArCHO + CHHal_3 \xrightarrow[MeOH]{KOH} [ArCH(OH)CHal_3] \xrightarrow{KOH} ArCH(O)CHal_2 \xrightarrow{MeO^-}$$

(without isolation)

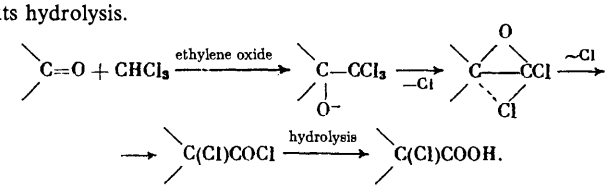
$$\longrightarrow ArCH(OMe)COHal \longrightarrow ArCH(OMe)COOMe,$$

Hal = Cl, Br.

It is interesting that the synthesis of phenyl(tribromomethyl)carbinol from an aldehyde and bromoform occurs with difficulty and in low yield (10–40%) but under the conditions of the reaction being considered (without isolation of the carbinol) the yield of the final α-methoxyarylacetic acids was 75% of theoretical. The condensation of 3-chlorobenzaldehyde with chloroform also proceeds with difficulty and the yield of the desired 3-chlorophenyl(trichloromethyl)carbinol was 12% overall.[15] Under the conditions of the given reaction α-methoxy-(3-chlorophenyl)acetic acid was isolated in 70% yield.

Replacement of methanol by liquid ammonia in the system aldehyde–haloform–potassium hydroxide–methanol leads to the formation of α-amino acids in low yield (29–48%) as a result of fission of the epoxide ring by amide ion.[14]

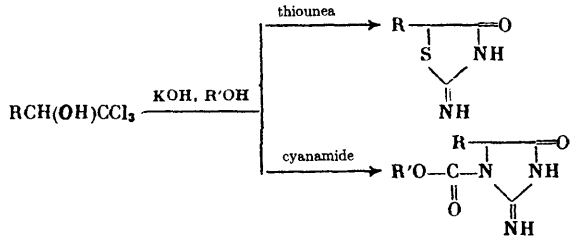
$$RCHO + CHCl_3 \xrightarrow[-33^\circ C]{KOH,\ NH_3} RCH(OH)CCl_2 \xrightarrow[-HCl]{} RCH(O)CCl_2 \xrightarrow{NH_3}$$



(isolation not obligatory)

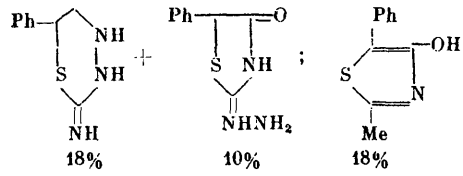
$$\longrightarrow RCH(NH_2)COOH.$$

Although this method contradicts somewhat the synthesis of (α-trichloromethyl)carbinols under the same conditions,[20] it has been confirmed by recent work by Chinese authors,[136] in which a similar synthesis of amino acids was effected by the condensation of aliphatic aldehydes, ketones and cyclic ketones with chloroform and ammonia by phase transfer catalysis (dichloromethane–water, the catalyst was diethylbenzylamine ethochloride).



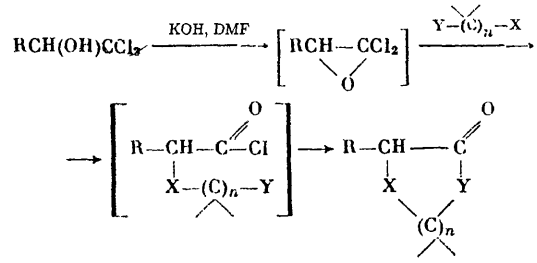
It should be mentioned that an analogous single-reactor method was used for the first time by Link.[137]

By a method similar to that of Link and Reeve, Buddrus and collaborators[138,139] carried out the condensation of isobutyraldehyde, acetone and cyclohexanone with chloroform taking ethylene oxide as base. The corresponding α-chlorocarboxylic acids were isolated in this case and are products of the rearrangement of the intermediate dichloroepoxide into the acid chloride of the α-chlorocarboxylic acid and its hydrolysis.



The high preparative value of α-haloacids and their acid chlorides in synthetic organic chemistry, particularly as synthons of α-amino acids and other functionalised α-carboxylic acids, was the reason for the in-depth study of the dehydrochlorination of (α-trihalomethyl)-carbinols. As was mentioned above the haloform fission of (α-trihalomethyl)carbinols (Scheme 2, route *a*) is the main obstacle to the dehydrochlorination process. It was established that the process depends strongly on temperature, reaction time and also on the alkali used.[140] Optimum conditions for obtaining α-chloroaryl-acetic acids were 0 °C, 10% aqueous KOH (10% aqueous NaOH forms a gel and the yield of product is reduced), the carbinol : KOH = 1 : 4 (yield 60–70%) and the reaction time was several days. The use of (tribromomethyl)- or mixed (chloro, bromo)carbinols leads to a significant reduction in the quantity of alkali, in the reaction time and to an increase in the yield of the desired α-haloacetic acids (17–100%).[141] Since the limiting stage of the process is the formation of the gem-dihaloepoxide, it is evident that the replacement of chlorine by bromine facilitates the intramolecular S_N2' substitution of halogen in the trihalomethyl grouping (Scheme 2, route *b*) with the formation of the epoxide ring and also rearrangement into α-haloacetic acids.

The single reactor method of Link and Reeve has limited application since the majority of the nucleophiles enter into direct condensation with carbonyl compounds with an incommensurably higher rate than does THA. For this reason the reaction of certain nucleophiles was studied directly on (α-trichloromethyl)carbinols. Cyanamide and thiourea[142–144] were tested with ATMC in various alcohols (methanol, ethanol, ethyleneglycol) and cycloadducts were isolated, viz. functionally substituted 1-imidazolinecarboxy imidates and thiazolidinones in low yields.



R was varied in (α-trichloromethyl)carbinols (alkyl, aryl, vinyl, ethinyl), but the yield of cycloadduct was not increased successfully. Replacement of nucleophiles (thiosemicarbazide, thioacetamide) also did not lead to the expected result. A mixture of dihydro-2-imino-6-phenyl-2H-1,3,4-thiadiazin-5-(6H)-one and 5-phenyl-2,4-thiazoldinedione-2-hydrazone in yields of 18 and 10% respectively was isolated from phenyl(trichloromethyl)carbinol by reaction with thiosemicarbazide. With thioacetamide by 4-hydroxy-2-methyl-5-phenylthiazole was isolated in 18% yield.[145]

The yield of cycloadduct was sharply increased on replacing a protic solvent by the dipolar aprotic solvent DMF. 2,5-Disubstituted thiazolidin-4-ones (a) were isolated from ATMC by reaction with thioacet(benz)amides in 40–85% yield,[146] tetrahydro-2-hydroxy-3-aryl-1,4H-quinoxalines (b) in 70–80% yield with *o*-phenylenediamine, 2-hydroxy-3-arylpiperazines (c) in 57–60% yield with ethylenediamine, 2-hydroxy-3-aryl-1,4-benzodioxans (d) in 63–84% yield from pyrocatechol and 2-aryl-3-hydroxy3,4-dihydro-2H-1,4-benzoxazines (e) from 2-aminophenol in 70–85% yield (Scheme 3).[147]

Scheme 3

R = Ar, Het;
X = S, Y = N, n = 1(a), X = Y = N, n = 2(b); X = Y = N, n = 2(c); X = Y = O, n = 2(d); X = P, Y = N, n = 2(e).

Since all the addition reactions considered above proceed through the intermediate gem-dihaloepoxide, the favourable influence of the dipolar solvent DMF on the dehydrochlorination of (α-trichloro-methyl)carbinols[146,147] is explained by the fact that the oxygen atom in DMF, being a centre of increased electron density, strongly coordinates potassium ions but the less effective positive portion weakly solvates the alkoxide ion. The weakly solvated anion possesses greater energy consequently the energy of activation of the intramolecular epoxidation is appreciably reduced in comparison with the use of protonated solvents.

The available literature data obtained by spectral methods in combination with quantum chemical calculations of the distribution of electron density in epoxides show that the epoxide carbon atoms, independent of the nature of the substituent, are extremely electron deficient. The value of the electron density on these atoms differs little.[148] This explains why the nucleophilic fission reaction of

epoxides occurs at both the α- and at the β-carbon atoms. However analysis of the total literature data on the fission of gem-dichloroepoxides by mono- and dinucleophiles shows that only the α-carbon atom is subject to nucleophilic attack. The reason for the observed regioselective fission of the ring may be attributed to shielding of the β-carbon atom by the bulky chlorine atoms. However the data on the X-ray structural analysis of the only stable gem-dichloroepoxide, 1,1,3,3,3-pentachloropropylenepoxide† gave a complete answer. According to X-ray structural analytical data the unfavourable conditions for the approach of a nucleophile to the β-carbon atom created both by the steric screening of the chlorine atoms, and by the strengthening of the C–O bond with the participation of the β-carbon atom which creates additional blocking from the side of the "adjacent" oxygen atom. On the other hand the O(1)–C(3) bond involving the α-carbon atom is longer than the O(1)–C(2) bond and is therefore weaker to a considerable extent (Fig. 1).[150]

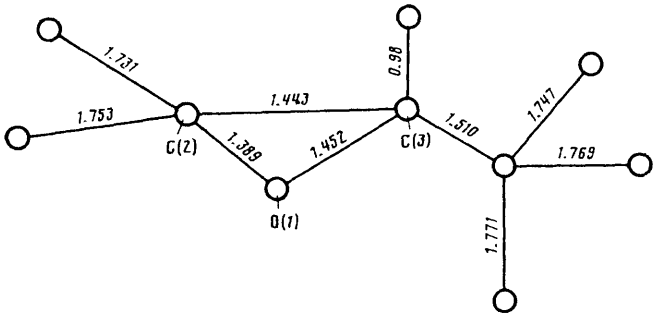


Figure 1. The structure of the 1,1,3,3,3-pentachloropropylene oxide molecule; σ = 0.003–0.004 Å.[150]

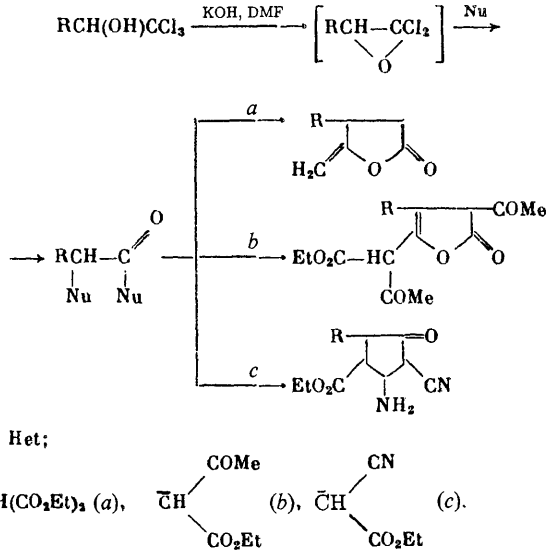
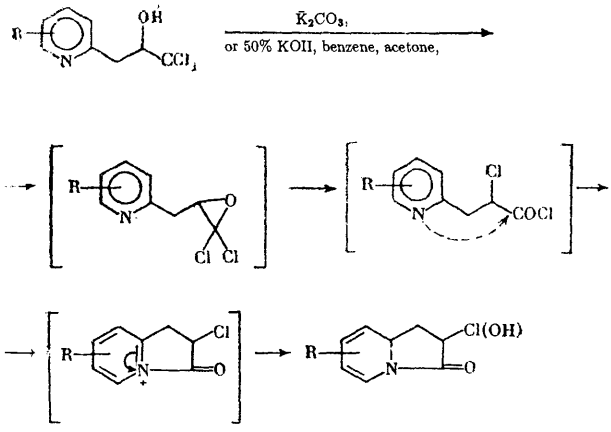
The reaction of aromatic and heterocyclic (α-trichloromethyl)-carbinols with mono-*C*-nucleophiles, viz. malonic, acetoacetic[151] and cyanoacetic[152] esters, has been studied with a view to clarifying the synthetic possibilities of gem-dichloroepoxides. It was established that adducts of vicinal structure are formed by the reaction and are the diethyl esters of substituted adipic acids which thermally, catalytically or spontaneously cyclise into substituted hetero- and carbocyclic ketones (Scheme 4).



† 1,1,3,3-Pentachloropropylene oxide is the sole stable representative of the gem-dichloroepoxides. It is obtained by the reaction of bis-trichloromethylcarbinol with 2 N NaOH at 20 °C.[93]

$$Cl_3C{-}CH(OH){-}CCl_3 \xrightarrow{NaOH} Cl_3CCH{-}CCl_2$$



It is appropriate to mention that this dichloroepoxide was also obtained by Seyferth and collaborators[149] by the reaction of the carbenoid $PhHgCCl_3$ with chloral in boiling benzene and the physicochemical constants given agree exactly[93] although the author describes this compound as being synthesised for the first time.

In the studies considered the direction of the reaction of (α-trichloromethyl)carbinols of the aromatic and heterocyclic series with mono-*C*- and 1,3,1,4-dinucleophiles is the same and the difference consists only in the yield of the cycloadduct.

Scheme 4

It is interesting that the 2-pyridomethyl(trichloromethyl)carbinols are converted by base phase transfer catalysis (PTC) in the absence of external nucleophiles into [2,3H]-indolizines as a result of a rearrangement–heterocyclisation of the gem-dichloroepoxides generated as intermediates.

Depending on the type of PTC (liquid–solid, liquid–liquid) the product of heterocyclisation, the [2,3H]-indolizine, has either an α-chloro- or an α-hydroxyketone grouping. Since the indolizine structure forms part of the composition of the veratrum alkaloids, which are obtained by the multistage syntheses of Barret, Chichibabin and Shol'ts, the observed conversion acquires value in applied chemistry.[153]

In general the chemistry of [α-trihalo(chloro, bromo)-methyl]-carbinols is at the stage of promising development. The universal nature of these compounds for the solution of a whole series of problems of theoretical and practical chemistry has been demonstrated. The facile generation from them of highly reactive, little-studied gem-dihaloepoxides, which are synthons for a whole range of compounds with various properties, is just one factor indicating that the development of this field extends knowledge and creates new areas for using (α-trihalomethyl)carbinols.

I. Introduction

Nucleophilic replacement of halogen in the aromatic nucleus has always been a focus of attention in view of the enormous synthetic implications. The large volume of experimental and theoretical data published in this field has been reviewed several times.[1–6] The replacement of aromatic halogen by RS-groups has been covered in part, but interest in this particular substitution has noticeably increased during the last ten years. This is partly because the theoretical aspects of this conversion have been under scrutiny, and partly because of the development of new practical routes to sulphur-containing compounds of potential use as antioxidants, polymer stabilisers, pesticides and drugs, and in the oil and petroleum industry.[7]

The replacement of aromatic halogen by organothio groups is by no means straightforward, and several key routes have been developed: 1) purely ionic processes, notably involving activation by strong bases and/or specific solvents; 2) catalytic processes, involving both metal complexes and phase transfer catalysts; 3) high-temperature, free-radical processes; and 4) photo- and electro-chemical processes, principally of an ion-radical nature.

A number of publications on the thiylation of aromatic halides prior to 1972 has been examined in a monograph.[8] However, there have been no recent surveys covering this theme in its entirety. This is a systematic review of data published in this field during the last 10–15 years.

II. Nucleophilic thiylation of aryl halides without the use of specific catalysts

In the initial attempts to replace aromatic halogen by mercaptide (RS^-) or thiyl (HS^-) anions, sodium sulphide and polysulphide were used as reagent. Unactivated aromatic halides were inert under these conditions. Thus, chlorobenzene reacts with Na_2S only at 350–360 °C under a pressure of 180–190 atm.[9] In an aqueous ethanolic solution of Na_2S, activated aromatic halides, e.g. *o*- and *p*-nitrochlorobenzene, afford a mixture of products. Here, intermediate thiophenoxide anions react with the starting halide to give the corresponding symmetrical diaryl sulphide, while, at the same time, being oxidised to the corresponding disulphide.[9] Heating *p*-nitrochlorobenzene with an excess of Na_2S_2 in an alcoholic medium for a short period of time leads to the formation of *p*-nitrothiophenol in 65% yield:[1]

$$6\,p\text{-}ClC_6H_4NO_2 + 4Na_2S_2 + 6NaOH \rightarrow 6\,p\text{-}NO_2C_6H_4SNa + 6NaCl + 3H_2O + Na_2S_2O_3.$$

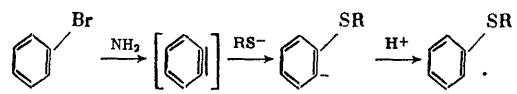
2,4-Dinitrochlorobenzene has a reactivity similar to alkyl chlorides: on heating in an aqueous alcoholic medium with Na_2S it is converted to the tetranitrodiphenyl sulphide in 79% yield.[9] Treatment of activated nitroaryl halides with Na_2S results in both substitution and reduction of the nitro group to give azoxy compounds and aniline derivatives.[1]

The majority of the early syntheses of unsymmetrical thioesters were based on the reactions of halogenonitrobenzenes with methanethiol and *o*- or *p*-nitrothiophenol in the presence of alcoholic base.[1] Data published before 1970 on the reactions of halogenonitrobenzenes with MeS^- and PhS^- in alcoholic media have been surveyed in a monograph.[10]

By measuring the rate of the reaction of PhS^- with 1-halogeno-2,4-dinitrobenzenes in methanol between 0–15 °C, Bunnett and Merritt verified that the kinetic data were in accord with an S_N2 mechanism.[11] The reactivity of aryl halogen followed the order $F \gg Br > I > Cl$. The rate of replacement of Br, I and Cl was approximately the same, but that of F was approximately twice as great.

Unactivated aromatic halides interact more smoothly with mercaptide anion in the presence of a strong base. Thus, bromobenzene reacts with PhS^- in liquid ammonia in the presence of alkali metal amide.[12,13] However, as ammonia itself is weakly nucleophilic, the formation of diphenyl sulphide is accompanied by amination products:

$$PhBr + PhS^- \xrightarrow{NH_3} \underset{10\%}{PhNH_2} + \underset{12\%}{Ph_2NH} + \underset{52\%}{Ph_2S}.$$



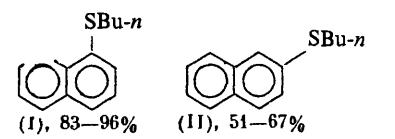
As the reaction of 1-bromonaphthalene with PhSNa yields a mixture of 1- and 2-naphthyl phenyl sulphide, it is assumed that under these conditions an elimination-addition (benzyne-type) mechanism prevails.[12]

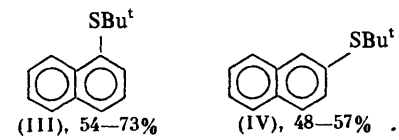
The substitution of bromobenzene can be extended to other mercaptans if an aprotic solvent (a mixture of hexamethylphosphoramide and THF) is used in the presence of sodium amide at 35–40 °C.[14,15]

$$\mathrm{PhBr + RSH \xrightarrow[12-66\%]{HMPA+THF} PhSr,}$$

R = Et, *n*-Bu, $PhCH_2$, Ph.

Here too, it is considered that reaction involves intermediate formation of benzyne, which undergoes subsequent nucleophilic attack by RS^-:



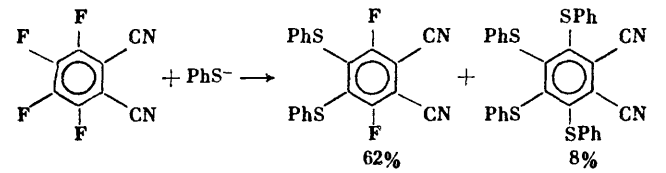


Judging by the products formed by interaction of *o*-toluyl iodide with thiophenol in DMSO containing tert-BuOK, it would appear that benzynes are also involved in the reaction of aryl iodides with aryl mercaptans:

$$\mathrm{PhSH + PhI \rightarrow \underset{100\%}{PhSPh}}$$

$$\mathrm{PhSH + \textit{o}\text{-}MeC_6H_4I \rightarrow \underset{50\%}{\textit{o}\text{-}MeC_6H_4SPh} + \underset{50\%}{\textit{m}\text{-}MeC_6H_4SPh}.}$$

1-Fluoro- and 2-fluoro-naphthalene, as well as the bromine analogues, react with n-butyl and tert-butyl mercaptan on heating in DMSO (110 °C) in the presence of MeONa to give the corresponding naphthyl thioethers (I)–(IV):[17,18]



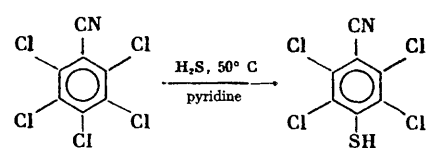
Under these conditions, butyl 2-naphthyl sulphide is not formed from 1-bromo- or 1-fluoro-naphthalene, so that the intermediate formation of the corresponding benzyne (1,2-dehydronaphthalene) can be excluded.

From a synthetic point of view, it is interesting that hexahalogenobenzenes—C_6F_6, C_6Cl_6 and C_6Br_6—react smoothly and rapidly with mercaptides on heating in a mixture of ethylene glycol and an organic base, e. g. pyridine. In the reaction of C_6Br_6 with RS^-, there is the possibility of both substitution and protodebromination, according to the following proposed scheme:[19]

$$\mathrm{C_6Br_6 + MeS^- \rightarrow C_6Br_5SMe,\ C_6Br_4(SMe)_2,\ C_6Br_2(SMe)_4,}$$
$$\mathrm{C_6Br_5H,\ C_6Br_2H(SMe)_3,\ C_6H_2Br_3(SMe),}$$
$$\mathrm{C_6Br_6 + EtS^- \rightarrow C_6Br_4H(SEt),\ C_6Br_5H,\ C_6Br_4H_2.}$$

Products such as C_6Br_4HSEt and $C_6Br_2(SMe)_4$ have never previously been prepared. However, the reaction of C_6F_6 and C_6Cl_6 with RS^- (R = Me, Et, Ph, C_6F_5, CH_2CH_2SH) proceeds only by substitution (up to 4 atoms of halogen being replaced by an organothio group); there is no protodehalogenation.[20–22]

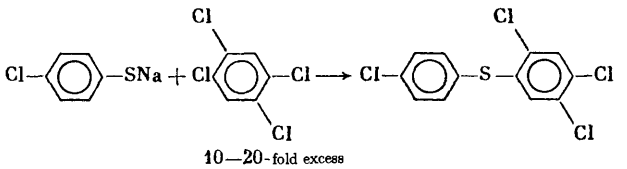
The interaction of tetrafluorophthalonitrile with PhS^- in methanol proceeds primarily by replacement of two atoms of fluorine:[23]



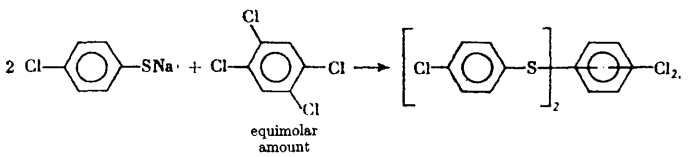
Hexafluoro- and hexachloro-benzene react with NaSH on heating in a mixture of ethylene glycol and pyridine to give the corresponding pentahalogenothiophenol:[24,26]

$$\mathrm{C_6Cl_6 + NaSH \rightarrow \underset{95\%}{C_6Cl_5SH} + NaCl,}$$

$$\mathrm{C_6F_6 + NaSH \rightarrow \underset{59\%}{C_6F_5SH} + NaF.}$$

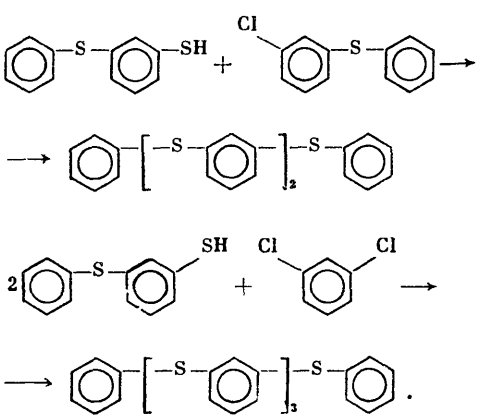


However, no such reaction takes place with hexabromobenzene.[19]

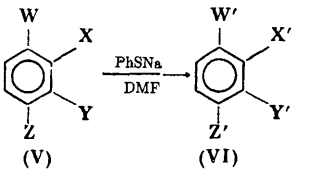


Pentachlorothiophenol can also be obtained by treatment of C_6Cl_6 with alkali metal hydrogen sulphide under 1 atm in DMF [2] or methanol.[27] Polychlorocyanobenzenes react with H_2S in pyridine in the presence of triethylamine to give the corresponding *p*-cyanothiophenol,[28] e. g.

In the 1960s it was discovered that aprotic solvents significantly enhance nucleophilic processes involving alkali metal salts by solvating the cation. Aromatic thiylation is no exception. Thus, both symmetrical and unsymmetrical diaryl sulphides have been prepared by prolonged heating of aryl mercaptides with aromatic halides in DMF—a solvent with weak dipolarophility.[29] The following thiylating agents were used: PhSNa, *p*-MeC_6H_4SNa,



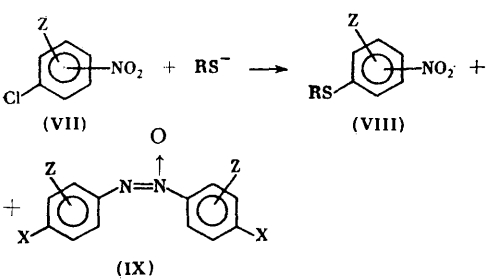
p-ClC_6H_4SNa. The reactivity of aromatic halides towards these thiophenoxides was in the following order: PhBr < bromonaphthalene < $C_6H_4Cl_2$ < $C_6H_3Cl_3$ < $C_6H_2Cl_4$. With polychlorobenzenes, the degree of substitution depends on the molar proportion of the starting materials:



In order to extend the reaction as a preparative route to diaryl sulphides from unactivated aromatic halides, while at the same time improving the overall yield without complicating the procedure, Campbell et al. proposed the use of various amide or amine solvents: dimethylacetamide (DMA) at 170–175 °C; diethylaniline at 210–216 °C; and *N*-methyl-2-pyrrolidone at 185–190 °C.[30–32]

A thermal route is recommended for the preparation of aryl mono-, bis-, tris-, and poly-thioethers, alkyl aryl thioethers, and phenylthiobiphenyls. Thus, the conversion of bromobenzene at high temperature affords diphenyl diphenyl sulphide in ~65% yield, contrasting with 13% by the conventional route.[29] Polyphenyl thioethers with four or five aromatic nuclei were obtained for the first time as follows:[32]

It is suggested that the mechanism of the reaction is of a bimolecular, S_NAr, type,

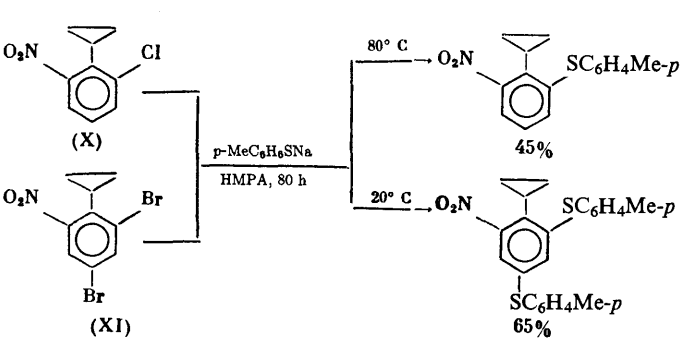


The thiylation of activated aromatic halides can be conducted at a much lower temperature by using an aprotic solvent, e.g. DMF. Thus, bis(phenylthio)benzenes (VI) were obtained from dihalogenonitrobenzenes (V) at 0 °C.[33]

(V) (VI)

(Va) W = NO_2, X = Cl, Y = H, Z = Cl; (VIa) W′ = NO_2, X′ = SPh, Y′ = H, Z′ = SPh (72%)
(Vb) W = Cl, X = NO_2, Y = H, Z = Cl; (VIb) W′ = SPh, X′ = NO_2 Y′ = H, Z′ = SPh (27%)
(Vc) W = NO_2, X = H, Y = Cl, Z = Cl; (VIc) W′ = NO_2, X′ = H, Y′ = SPh, Z′ = SPh (31%).

Another advantage of using DMF for thiylation of halogenonitrobenzenes is that side-reactions are reduced. The reaction of halogenonitrobenzenes with RS^- in alcoholic base[1] is complicated by competitive reduction of the nitro group. However, the preparation of thioethers (VIII) is significantly improved by using DMF as solvent, in which the formation of azoxybenzenes as by-product is suppressed.[34] Adjusting the order of addition of the reactants also has a beneficial effect:

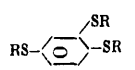


(VII) (VIII) (IX)

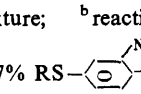
Z = H (a); CF_3 (b); R = Me, Pr^i, CH_2Ph, Ph; X = Cl, SPh.

As an example, the yield of (VIIIb, R = Me) and azoxybenzene (IXb) is 18% and 81%, respectively, by the conventional route.[1] However, in DMF [34] the yield of (VIIIb, R = Me) is 95%.

Replacement of halogen in (nitrohalogenophenyl)cyclopropanes (X, XI) by *p*-tolylthio groups with sodium *p*-thiocresolate can be carried out in *N*-methyl-2-pyrrolidone or hexamethylphosphoramide.[35]



(X) (XI)



On the other hand, heating the chloride (X) with sodium *p*-thiocresolate in ethanol results in reduction of the nitro group to give 3,3′-dichloro-2,2′-dicyclopropylazobenzene.

The method described above is essentially limited to the reaction of aromatic halides with arylmercaptides (ArS^-). The same reaction with alkylmercaptides (RS^-) can be achieved in hexamethylphosphoramide, as reported by Italian chemists in a series of publications.[36–40]

Activated aryl halides, such as *o*- and *p*-nitrochlorobenzene (XIII), 1-chloro-2,4-dinitrobenzene (XIII) and picryl chloride (XIV) react at room temperature with excess of RSNa (where R = Me, Et, iso-Pr, tert-Bu) in hexamethylphosphoramide by replacement of both halogen and nitro groups (Table 1).[36] The highest yield of poly(alkylthio)benzene is obtained with sodium isopropylmercaptide in hexamethylphosphoramide. It should be noted than an alkylthio group in the *ortho*- or *para*-position activates replacement of the nitro group by RS^-.

Table 1. Reaction of *p*-nitrochlorobenzene (XII) 2,4-dinitrochlorobenzene (XIII) and picryl chloride (XIV) with RSNa in HMPA at room temperature.[36]

Substrate, *R*	Yield of product %		
	 from (XII)	 from (XIII)	 from (XIV)
Me	7 [a]	–	6 [a]
Et	14 [a]	15 [a]	68
Me_2CH	65	50	69
Me_3C	44 [b]	44 [c]	33

[a] RSSR is present in the reaction mixture; [b] reaction mixture contains unreacted (XII); [c] also isolated 17% 

Competitive reduction of the nitro group depends on the structure of the nitroaryl halide and the nature of the mercaptide. If the nitro group is not activated by an isopropylthio group in the *ortho*- or *para*-position, it is possible that a mechanism other than the S_NAr type is involved. In such instances, reaction may be initiated by a single electron transfer from RS^- to the substrate to give a nitroaryl radical anion:

$$ArNO_2 + RS^- \xrightarrow{\bar{e}} ArNO_2^{\cdot -} + RS^{\cdot},$$

$$2RS^{\cdot} \rightarrow RSSR,$$

$$ArNO_2^{\cdot -} \rightarrow \text{products of reduction}.$$

Unactivated aryl halides (PhF, PhCl, PhBr, PhI) react with sodium isopropylmercaptide in hexamethylphosphoramide at a higher temperature (80 °C) to give isopropyl phenyl sulphide in 57–81% yield.[37] By measuring the relative rates of replacement of each halogen by the isopropylthio group, the relative lability of halogen was found to decrease in the order: I > F > Br > Cl. This sequence is not that which would be anticipated for substitution of an activated aryl halide according to a S_NAr mechanism.[11] Nonetheless, the authors of this work still propose such a mechanism by taking into account the differing rates of the addition and elimination steps and their dependence on the nature of the halogen atoms.[37]

The same authors also studied the reaction of iso-PrSNa with dihalogenobenzenes in hexamethylphosphoramide.[37] Thus, *o*-, *m*- and *p*-dichlorobenzene afford mono- or bis(isopropylthio)benzenes, depending on the relative proportion of the mercaptide. Other *m*- and *p*-dihalogenobenzenes (except *p*-difluorobenzene) under these conditions are converted exclusively into the corresponding isopropyl *p*-halogenophenyl sulphides. The reaction of tri-, tetra-, penta- and hexa-chlorobenzenes with excess of iso-PrSNa (or EtSNa) proceeds readily in hexamethylphosphoramide with substitution of all the chlorine atoms in 80–95% yield.[38] Both hexachlorobenzene and hexafluorobenzene afford the corresponding hexakis(alkylthio)-benzene in hexamethylphosphoramide, while partial replacement of halogen takes place in other solvents, as indicated above.[20–22]

1,3-Dimethyl-2-imidazolidone may be used as solvent in place of hexamethylphosphoramide for the preparation of hexakis(alkylthio)-naphthalenes[41] and hexakis(arylthio)benzenes[42] in high yield. The relatively inaccessible hexakis(*p*-tert-butylphenylthio)benzene (76%) and hexakis(β-naphthylthio)benzene (72%) were also obtained under these conditions.

The reactions of polychlorobenzenes with MeSNa are complicated in certain instances by partial cleavage of the resulting methylthio groups by nucleophilic attack of mercaptide anion.[38] This leads to the formation of poly(methylthio)thiophenols,† as exemplified below:

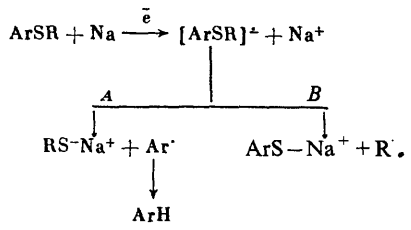
$$C_6Cl_6 \xrightarrow{MeSNa} C_6(SMe)_6 \longrightarrow C_6(SMe)_5SH.$$

Aromatic mercaptans may also be prepared from unactivated aryl halides under the same conditions.[39] Reaction proceeeds in two steps: nucleophilic replacement of the halide according to an S_NAr mechanism, followed by dealkylation according to the more familiar S_N2 displacement at a saturated carbon:

$$ArX + MeSNa \rightarrow ArSMe + NaX,$$

$$ArSMe + MeSNa \rightarrow ArSNa + Me_2S.$$

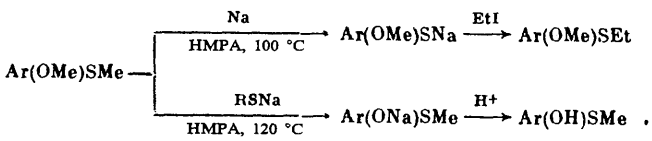
Table 2. Reaction of aryl halides with MeSNa in HMPA at 100 °C.[39]



Thiol	Time, h	Yield, %	X in ArX
Thiophenol	5	90	Cl
α-Mercaptonaphthalene	3.5	90	Br
β-Mercaptonaphthalene	5	97	Br
p-Mercaptobiphenyl	2	96	Br

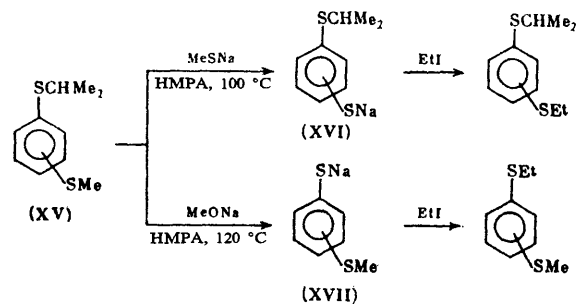
Some examples of this conversion are given in Table 2.

† Data on the cleavage of alkylthiobenzenes to give the corresponding thiophenols by alkali metals in liquid ammonia, ether or methylamine have been given previously.[40,43,44]



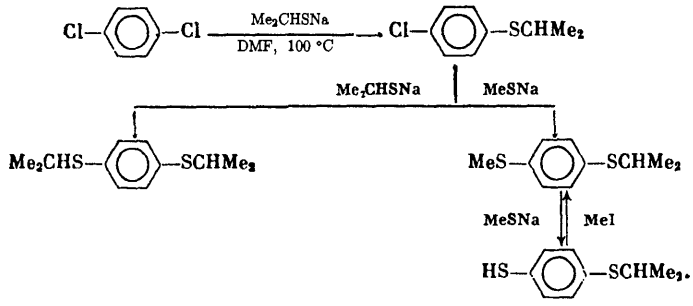
Dealkylation of alkyl aryl sulphides to give the corresponding monomercaptoarenes can be achieved with both MeSNa and EtSNa.[39] Polymercaptobenzenes may be obtained from the corresponding polychlorobenzenes via treatment of the intermediate isopropylthiobenzenes with sodium in hexamethylphosphoramide at 100 °C.[45] Alternatively, the polychlorobenzenes may be treated with NaSMe in 1,3-dimethyl-2-imidazolidone, followed by demethylation with sodium in liquid ammonia.[46] By comparison with the reaction with MeSNa, cleavage with sodium in hexamethylphosphoramide is not selective and proceeds with total dealkylation of all RS groups.

It is considered that the interaction of isopropylthiobenzenes with sodium in hexamethylphosphoramide involves an electron transfer,[45] as a result of which a thioether anion radical is formed:

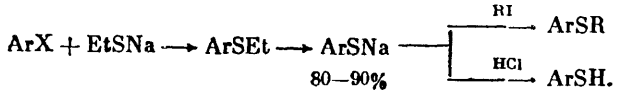


Pathway *B*, i.e. cleavage of the R–S bond, is preferred under these conditions and can only be suppressed sterically if the RS group is in an *ortho* position.

By choosing a suitable dealkylating agent (Na, MeSNa, MeONa) in hexamethylphosphoramide, selective dealkylation may be achieved. Alkoxyaryl alkyl sulphides, for example, may be selectively cleaved to give alkoxythiophenols, mercaptophenols or (alkylthio)-phenols:[47–49]

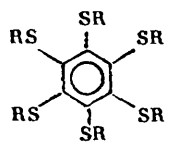


Preferential dealkylation of bis(alkylthio)benzenes having different RS-groups may also be carried out, as exemplified below.[50]

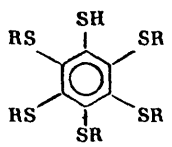


As seen above, the reaction of compound (XV) with sodium methylmercaptide involves nucleophilic aliphatic substitution by an S_N2 mechanism, which explains the selectivity towards the methyl group to give product (XVI). In contrast, sodium alkoxides in aprotic media function as strong bases, inducing elimination of the isopropyl group as propene with the formation of mercaptide (XVII).[50]

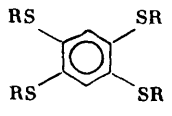
In view of the carcinogenic properties of hexamethylphosphoramide, the above-described substitution of aryl halides and the dealkylation of the resulting thioethers have been studied in DMF and dimethylacetamide.[51] Thus, nucleophilic aromatic substitution of unactivated aromatic halides by mercaptide anion proceeds smoothly in DMF at 100 °C:



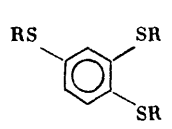
Selective monodealkylation with excess of MeSNa can be achieved at 160 °C in DMF by nucleophilic aromatic substitution. In this respect, tert-BuOK is better than MeONa for selective dealkylation in DMF. Dealkylation by electron transfer with sodium is more effective in dimethylacetamide than in DMF.



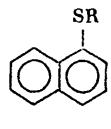
Reference has also been made[51] to the one-step synthesis of thiophenols by heating unactivated aryl halides with excess of EtSNa in DMF:



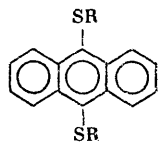
Recently, polyglymes have been used as solvents for the substitution of activated[52,53] and unactivated[54,55] aryl halides by mercaptide anion. The effectiveness of polyglymes is in the order: tetraglyme > triglyme > diglyme > monoglyme. The following products have been obtained by heating aromatic halides with RSNa at 130–200 °C in tetraglyme:



R = Ph (23%)
R = *n*-$C_{12}H_{25}$ **(95%)**
R = Et (30%)

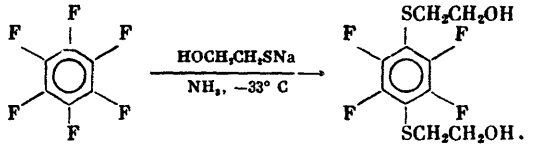


R = Et (25%)

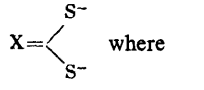


R = Et (63%)
R = *n*-C_8H_{17} (87%)
R = *n*-$C_{12}H_{25}$ (86%)
R = Ph (56%)

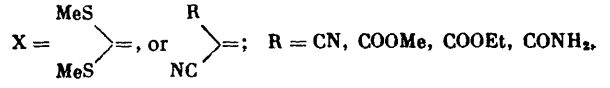
R = Ph (16%)
R = *n*-$C_{12}H_{25}$ (96%)



R = *n*-C_8H_{17} (67%)
R = *n*-$C_{12}H_{25}$ (81%)
R = Ph (62%)

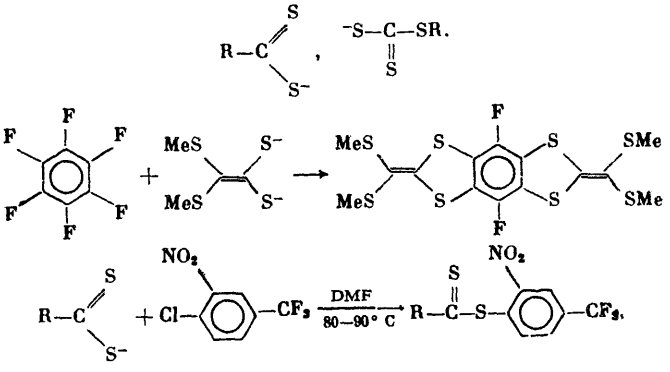


R = *n*-$C_{12}H_{25}$ (95%).



Tetraglyme is recommended as an alternative to hexamethylphosphoramide, DMF and dimethylacetamide as a solvent for the thiylation of aromatic halides.

Liquid ammonia also serves as a useful solvent, selectively solvating the cation of alkali metal mercaptides. Under these conditions it is possible to achieve thiylation of polyfluoro- and nitrohalogeno-aromatic compounds without side reactions.[56,57] This is exemplified below:



It should also be noted that activated aromatic halides react with ambident *S*-nucleophiles, such as dithiolates[58,59] of the type:

The sodium salts of dithiocarboxylic and trithiocarbonic acids, i.e. RC(S)SNa and RSC(S)SNa, are also effective nucleophiles.[60,61] The following two reactions exemplify the displacement of aromatic halogen by such *S*-nucleophiles:

where R = dimethylamino, diethylamino, and morpholino.

From the information set out in this part of the review, it is clear that the inertness of unactivated aromatic halides can only be effectively overcome by using a strong base in an aprotic, bipolar solvent. Such conditions are often used for the reactions of activated aromatic halides, and have been recommended for preparative purposes.

III. Thiylation of aryl halides in the presence of catalysts

Aromatic nucleophilic substitution is promoted by transition metals and their salts, those of copper being the most prominent.[62–64] Such catalysed thiylation of aromatic halides can be regarded as the sulphur equivalent of the classical Ullman reaction.

Copper may be used for thiylation in two ways: a) on the one hand by an exchange mechanism of the type

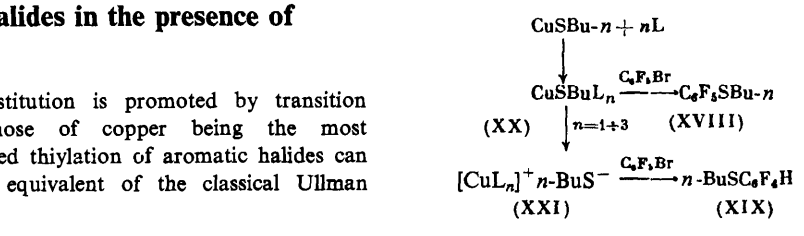
$$ArX + CuY \rightarrow ArY + CuX,$$

where X = halogen, and Y may be SAlk or SAr; and b) on the other hand by a nucleophilic displacement of aromatic halogen with Cu, Cu_2O, or a copper salt as catalyst:

$$ArX + Y^- (\text{or } HY) \xrightarrow{Cu} ArY + X^- (\text{or } HX).$$

As an example of method a), 1-bromonaphthalene reacts with cuprous phenylmercaptide in a polar organic solvent.[65] Thus, on heating the reactants in pyridine for 24 h, 1-naphthyl phenyl sulphide is obtained in 26% yield, while the same product is formed in 21% yield by heating in DMSO for 4 h at 144 °C, and in 31% yield in DMF.

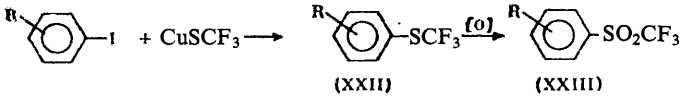
As an example of method b) thioethers are obtained in preparatively useful yield by thiylation of aromatic halides in an aprotic solvent in the presence of a catalytic amount of suspended Cu_2O.[66] Thus, heating 1-bromonaphthalene with PhSNa or EtSNa for 24 h in the presence of Cu_2O affords 1-naphthyl phenyl sulphide and ethyl 1-naphthyl sulphide in 99% and 95% yield, respectively.



Where mercaptans (RSH) are used as substrate, reaction involves initial formation of CuSR, which then reacts with the aromatic halide. The mercaptide anion, RS^- (PhS^- or EtS^-), is more effective than the corresponding neutral mercaptan (RSH). Thus, diaryl sulphides are obtained in low yield (21%) in the system $ArBr/Cu_2O/PhSH$, but in high yield (99%) in the system $ArBr/Cu_2O/PhSNa$.

A variety of aromatic halides (ArX) may be used in the reaction with cuprous mercaptides: Ar = $C_6H_4NH_2$, C_6H_4OMe, C_6H_4Me, C_6H_4OH, C_6H_4Br, C_6H_4Cl with CuSR (R = Ph, Et, n-Bu).[67–69] The reactants are heated at 200 °C for 1–5 h in a mixture of quinoline and pyridine until the medium becomes homogeneous. It should be noted that unactivated aromatic chlorides react under these conditions with PhSCu but not AlkSCu, while both of these mercaptides react with aryl bromides and activated aryl chlorides (e.g. *o*-$ClC_6H_4NO_2$) to give the corresponding thioethers in 50–90% yield.

The replacement of bromine in bromoperfluoroaryl derivatives may be achieved with mercaptides RSCu (R = C_6F_5, Me, n-Bu):[70–72]



$$C_6F_5Br + CuSBu\text{-}n \rightarrow \underset{\text{(XVIII)}}{C_6F_5SBu\text{-}n} + \underset{\text{(XIX)}}{n\text{-}BuSC_6F_4H}.$$

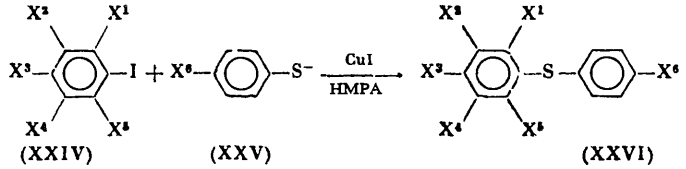
The proportion of (XVIII) and (XIX) in the product depends on the nature of the solvent. The former predominates in DMF while the partially reduced product, (XIX), predominates in pyridine. It is thought that the reaction involves the intermediate formation of complex (XX) derived from the cuprous mercaptide and solvent:

n-Butylmercaptide anion coordinates with copper in the weakly ligating DMF to give (XVIII). However, in the strongly ligating pyridine, an ionic complex (XXI) is formed prior to reaction with C_6F_5Br to give (XIX).

Aryl trifluoromethyl sulphides (XXII) are obtained in high yield of reaction of CF_3SCu with aromatic iodides in DMF at 150 °C.[73] The products are oxidised to the corresponding sulfones (XXIII) possessing the strongly electron-withdrawing SO_2CF_3 group:

(XXII) (XXIII)

R = H, 4-Me, 2-NO_2, 4-NO_2.



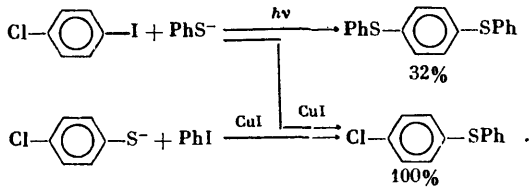
Aryl trifluoromethyl sulphides are also obtained by interaction of aromatic bromides with $HgSCF_3$ and Cu.[64]

The preliminary isolation of cuprous mercaptide, CuSr, and its insolubility are the main limitations of the above-described method. However, these may be avoided in the direct conversion of aromatic halides to alkyl aryl sulphides or diaryl sulphides with dialkyl or diaryl disulphides in dimethylacetamide containing copper at 160–170 °C:[74]

$$RSSR + PhBr \xrightarrow{Cu} PhSR,$$
$$RSSR + BrC_6H_4Br \rightarrow RSC_6H_4SR,$$
$$R = n\text{-Bu, Ph, } m\text{-}MeC_6H_4 .$$

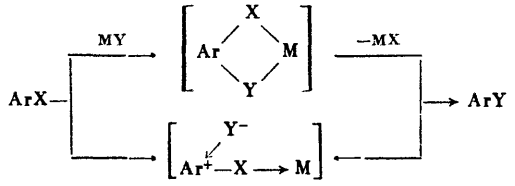
The reaction involves copper-induced cleavage of the disulphide bond to give the corresponding cuprous mercaptide, which then reacts with the aromatic halide. Disulphides may also be reduced by other metals (Zn, Na, Al), normally in the presence of an acid, to give the corresponding mercaptan. Certain cuprous mercaptides prepared by method[67] are unstable. Thus, cuprous benzylmercaptide is converted to the corresponding benzyl sulphide and stilbene on reaction with aromatic halides. *m*-Bis(benzylthio)benzene is obtained from *m*-dibromobenzene in 46% yield via *in situ* formation of Cu(I)-benzylmercaptide from dibenzyl disulphide.[74]

The *in situ* formation of cuprous arylmercaptides from CuI and ArS^- (XXV) is considered likely during the formation of diaryl sulphides from unactivated aromatic iodides (XXIV):[75]



(XXIV) (XXV) (XXVI)

X^1 = Me, NO_2; X^{2-5} = H, Me; X^6 = H, Cl.

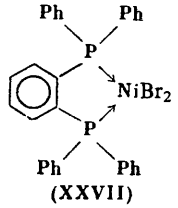


Thus, diaryl sulphides (XXVI) are obtained in 60–75% yield by heating a mixture of the appropriate aryl iodide (XXIV), alkali metal mercaptide (XXV) and CuI in hexamethylphosphoramide at 70–80 °C for 1–2 h.

Catalysis by copper(I) is recommended where processes involving an $S_{RN}1$ mechanism do not give the desired result.[76] Thus, whereas photo-initiated $S_{RN}1$ thiylation of certain dihalogenobenzenes leads exclusively to disubstitution (see also Section V), only monosubstitution takes place under Cu(I) catalysis:

Copper complexes containing P-, As- or Sb-ligands may also be used as catalyst for the thiylation of aromatic halides.[77]

The mechanism of copper-catalysed substitution of aromatic halides is thought to involve initial coordination of copper to the displaced halogen with the intermediate formation of a σ-complex:[64]



X = halogen; Y = nucleophile .

For nucleophilic substitution in the presence of copper salts, the facility of the initial addition of catalyst across the carbon-halogen bond increases with decrease in the electronegativity of the halogen and with increase in its polarisability (F < Cl < Br < I), reflecting the lability of halogen. This order is the reverse of that found for non-catalytic substitution.[1]

Copper-catalysed nucleophilic substitution may also involve coordination of the copper salt as a π-complex, in which Cu^+ serves as an acceptor.[62,63] A radical mechanism, involving a single electron transfer, has also been proposed for copper-catalysed substitution of halides.[62]

Other transition metals are reported to catalyse thiylation of aryl halides. For example, diaryl sulphides may be prepared in the presence of *o*-bis(diphenylphosphino)benzenenickel(II) bromide (XXVII).[78]

(XXVII)

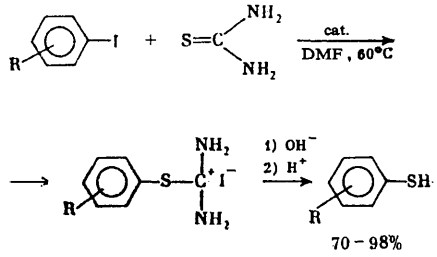


Table 3. Reaction of aryl bromides, ArBr, with NaSPh by method (200 °C, 24 h, ethylene glycol).[78]

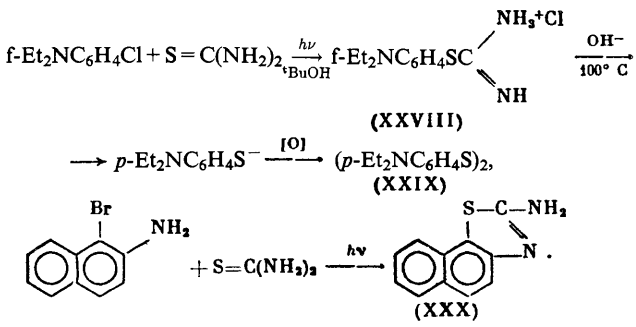
Ar	Ph	*p*-MeC_6H_4	*o*-MeC_6H_4	*m*-MeC_6H_4	anthracene	*p*-CNC_6H_4
Yield of sulphide, %	100[a]	94	90	98	90	80

[a] In the absence of catalyst the yield of Ph_2S was 3%.

The reaction conditions and yields for this latter conversion are given in Table 3. The method is regioselective, and reaction is not suppressed by electron-donating groups in the benzene ring of the aryl bromide.

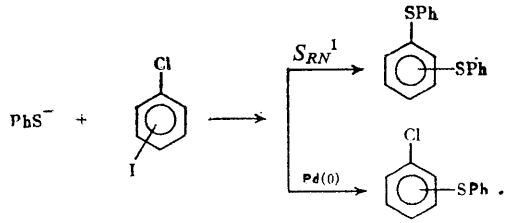


Catalysis by Ni(II) complexes has also been applied successfully to the synthesis of aromatic mercaptans from unactivated aromatic iodides and thiourea. The method is mild and involves the intermediate formation of *S*-arylisothiouronium salts.[79] It is known that unactivated aromatic halides do not form isothiouronium salts with thiourea under normal conditions.[80]

R = H, *p*-Me, *o*-Me, *p*-MeO, *p*-NH_2, *p*-Cl, *p*-Br.

In this reaction, the Ni(II) complex is formed *in situ* from bis(triethylphosphine)nickel(II) chloride and sodium trihydridocyanoborate.

S-Arylisothiouronium salts are also formed on irradiation of thiourea (or thiosemicarbazide) with *o*- or *p*-substituted aryl halides having electron-donating substituents in the benzene ring.[81] However, the mechanism of the reaction is quite different from the $S_{RN}1$ process proposed for photo-substitution of aromatic halogen by mercaptide anion, RS^- (see also Section V). Reaction ceases on formation of the arylisothiouronium salt (XXVIII). *p*-Substituted derivatives may be converted to the corresponding diaryl disulphides by basic hydrolysis at 100 °C, followed by oxidation of the resulting arylmercaptides. *o*-Substituted derivatives, however, are partially cyclised to give thiazoles, e. g. (XXX):



Palladium(0) complexes e.g. tetrakis(triphenylphosphine)-palladium(0), may also be used as catalyst for the reaction of unactivated aromatic halides with mercaptide anion.[82,83] Thus, phenyl and tolyl iodides or bromides react with mercaptans, RSH (R = Ph, Et, tert-Bu, *n*-Bu), in the presence of tert-BuONa as base and $Pd(PPh_3)_4$ as catalyst on heating in DMSO [82] or in alcoholic media.[83] It has been found that PhBr interacts with mercaptans more slowly than PhI. Thus Pd-catalysed reaction of PhSH with PhBr and PhI in refluxing ethanol affords diphenyl sulphide in 19% and 100% yield, respectively. There was no formation of sulphide in the absence of catalyst. Chlorobenzene is noticeably less reactive under these conditions, affording only a trace of diphenyl sulphide on heating in DMSO. Iodobenzene reacts nine times more rapidly with tert-BuS^- than with PhS^-.

It is thought that the mechanism of the substitution involves the formation of an anion radical, $ArX^{\cdot-}$. However, an $S_{RN}1$ process may be excluded for the following reasons:

1) palladium(0)-catalysed substitution is not inhibited by *p*-dinitrobenzene — a good electron acceptor, conventionally used to suppress $S_{RN}1$ reactions. Thus, there is no electron transfer initiation;

2) mono-substitution of iodochlorobenzene by PhS^- predominates under Pd(0) catalysis:

The authors propose that Pd-catalysed thiylation takes place by the following mechanism:

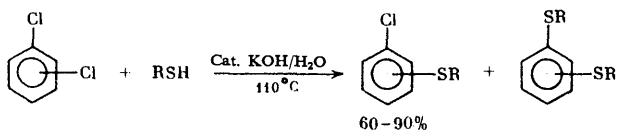
a) oxidative addition of the aryl halide, ArX, to Pd(0) with formation of an adduct:

$$ArX + Pd(0) \rightarrow Ar-Pd(II)-X;$$

b) nucleophilic substitution of the adduct:

$$Ar-Pd(II)-X + RS^- \rightarrow Ar-Pd-SR + X^-;$$

c) reductive elimination:

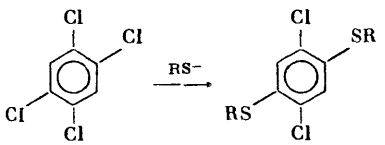


$$Ar-Pd-SR \rightarrow ArSR + Pd(0).$$

As indicated previously, the thiylation of weakly activated aryl halides requires forcing conditions: high temperatures, strong base, and a transition metal complex as catalyst. In the last five years, phase transfer catalysis, which often enhances anionic substitution, has been applied to the thiylation of aromatic halides under mild conditions.[84]

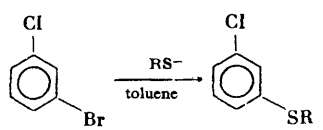
The phase-transfer catalysed thiylation of strongly activated aryl halides (by the nitro group) is worth noting.[85,86] Here, both thiophenols[85] and thiophenoxides (obtained *in situ* by reduction of the corresponding diaryl disulphide with aminoiminomethanesulphinic acid[86]) have been used as the nucleophile. Thus, diaryl sulphides have been prepared in 80–97% yield at room temperature by using a quaternary ammonium salt as phase transfer catalyst in a two-phase medium comprising aqueous base and an organic solvent (THF or toluene).

It has been reported that the rate of reaction depends on the leaving group (deceasing in the order: F > Cl > Br > I), and on the degree of activation of the aromatic ring (decreasing in the order: di-2,4-$(NO_2)_2$ > *o*-NO_2 > *p*-NO_2 > *m*-NO_2).[85] Thioethers are not formed, however, from mononitroaryl halides in the absence of catalyst; with dinitro compounds, the rate of reaction is increased 4 times in the presence of catalyst. Less activated aryl halides, e.g. *m*-BrC_6H_4Cl, are unreactive.[86]



It has been found that the S_NAr reaction of dichlorobenzenes with alkylmercaptide anion is noticeably more facile under liquid-liquid phase transfer catalysis.[87] The synthesis of alkyl aryl sulphides can be carried out at 110 °C by stirring a heterogeneous mixture of the halide, catalyst and mercaptan in 60% aqueous alkali under an inert atmosphere mixture. Dicyclohexano-18-crown-6 is a suitable catalyst for this conversion:

R = Pr^i, Bu^t, *n*-Bu.



There was no reaction in the absence of catalyst. It has been shown that the rate of displacement of the first chlorine atom in dichlorobenzenes decreases in the order 1,2- > 1,3- > 1,4-dichlorobenzene. This would indicate that the inductive effect is primarily responsible for activation of the leaving group. The order of reactivity of the mercaptide anion is: n-alkyl > sec-alkyl > tert-alkyl ≫ aryl.

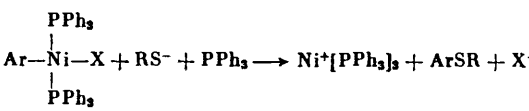
A wide range of chlorobenzenes has been submitted to displacement by alkylmercaptide anion.[88] Reaction proceeds in toluene at 25 °C in the presence of a phase transfer catalyst (n-Bu_4NBr, n-Bu_4PBr, 18-crown-6):

R = *n*-C_7H_{15}, *n*-C_8H_{17}, *n*-$C_{12}H_{25}$.

Substitution of halogen in 1,2,4-trichlorobenzene proceeds more slowly than the reaction with tetrachlorobenzene, and takes place exclusively at the 2 position. All three isomeric dichlorobenzenes are less reactive still, and require heating in toluene. Aromatic bromides are substituted more rapidly than chlorides,[88] as confirmed by the following reaction:

R = *n*-C_7H_{15} (86%).

Quaternised 4-dialkylaminopyridinium salts are also effective phase transfer catalysts.[89] They are stable up to 300 °C and increase the rate of thiylation in non-polar solvents (or without solvent) at temperatures below 200 °C.

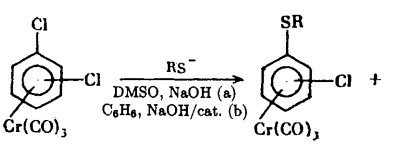


It is also reported that transition metal complexes are effective under phase transfer catalysis.[90] Thus, unactivated aryl halides interact with mercaptides in a mixture of aqueous alkali and toluene in the presence of σ-arylbis(triphenylphosphine)-nickel or -palladium complexes and triphenylphosphine (see Table 4).

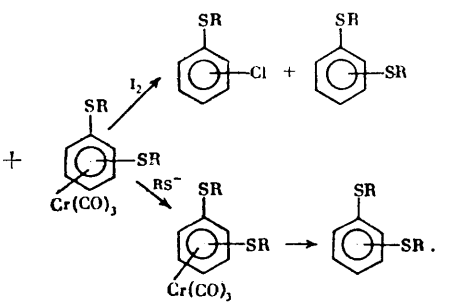
Table 4. Reaction of bromobenzenes and chlorobenzene with thiophenol under conditions.[90]

PhX	Catalyst	Time, h	Temperature °C	Yield, %
Br	A	7.5	100	97
Br	A (without PPh_3)	5	100	94
Br	B	23	55	95
Cl	B (without PPh_3)	20	55	70

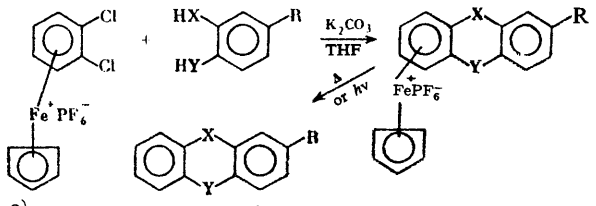
Key: σ-arylbis(triphenylphosphine)nickel complex (a) or palladium analogue (B).



Even chlorobenzene reacts with mercaptide anion in high yield under these conditions. It is thought that the displacement involves a catalytic cycle,[90] the overall process being represented as follows:



Nucleophilic substitution of halogen in aryl halides may also be activated by π-coordination with transition metal carbonyl or cyclopentadienyl complexes.[91] Reactivity increases in the order:



$$Cr(CO)_3 < Mo(CO)_3 \ll (\eta^5\text{–}C_5H_5)Fe^+ < Mn^+(CO)_3.$$

Particular reference has been made to S_NAr substitution of tricarbonyl(halogenobenzene)chromium complexes with alkylmercaptides ($AlkS^-$, where Alk = Me, iso-Pr, tert-Bu, n-Bu) in aprotic media either under a) phase transfer catalysis or b) solid-liquid conditions.[92,93] The following halogenobenzenes participate in this conversion: PhF, PhCl, *m*-MeC_6H_4Cl, *p*-MeC_6H_4Cl, and dichlorobenzenes, e.g.

The reaction of π-coordinated *o*-dihalogenobenzenes with binucleophiles is of potential for the synthesis of heterocyclics,[94,95] as exemplified below.

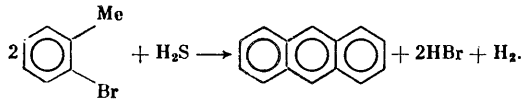
a) X = S, Y = O, R = H (76%)
b) X = Y = S, R = Me (82%)
c) X = NH, Y = S, R = H (23%).

These results confirm that activation of aryl halides by π-coordination with metals is equivalent to activation by strongly electron-accepting substituents in the aromatic ring, which facilitate thiylation under mild conditions either in aprotic solvents or under phase transfer catalysis.

Thus, specific catalysts may be used for thiylation, notably in combination with phase transfer catalysts. The only limitation of this method is the relative inaccessibility of the catalysts themselves.

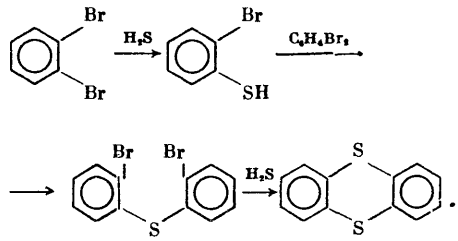
IV. High-temperature thiylation

High temperature thiylation of aryl halides has been conducted at 500–700 °C with H_2S, thiophenol, alkyl mercaptans, dialkyl sulphides and disulphides. Studies in this area have been carried out systematically by M G Voronkov et al. at the Institute of Organic Chemistry of the Siberian Section of the Academy of Sciences of the USSR.



Thiophenol, diphenyl sulphide and benzene are the main products obtained by reaction of chloro-, bromo-, and iodo-benzene with H_2S.[96,98] In the high temperature conversion of halogenobenzenes with H_2S, thiophenol is formed initially and diphenyl sulphide is an intermediate, arising in the second stage:

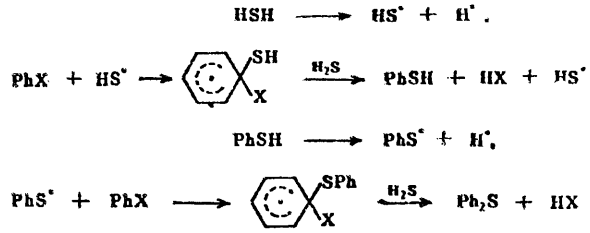
$$PhX+H_2S\rightarrow PhSH+HX,$$
$$PhX+PhSH\rightarrow PhSPh+HX,$$
$$PhX+H_2S\rightarrow C_6H_6+HX+S.$$



Fluorobenzene does not react with H_2S in the gas phase up to 700 °C. At this temperature and above, thermolysis takes place with cleavage of a C–H bond.

The proportion of thiol : sulphide in the reaction of PhX with H_2S increases in the following order of X; I < Br < Cl. The principal products from the reaction of iodobenzene with H_2S are benzene and diphenyl sulphide, formed also by oxidation of thiophenol with liberated iodine.[98] In comparative experiments, the reaction of bromobenzene with H_2S is more selective for the formation of diphenyl sulphide, while the reaction with chlorobenzene is more selective for the formation of thiophenol. At a fairly low ratio of H_2S : PhBr (1.25), the yield of diphenyl sulphide increases to 72% at 60% conversion.

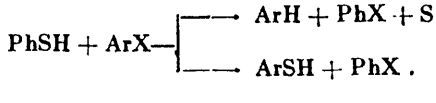
Both electron-accepting and -donating substituents in the *para*-position (relative to halogen) accelerate the reaction with H_2S and increase the overall conversion. The distribution of electron density in the intermediate thiophenol has a pronounced effect on the ultimate thiol : sulphide ratio and is largely responsible for the rate of the reaction.[99] Thus, electron-donating groups (Me, OMe) favour formation of thiol. However, *o*-methyl groups induce side reactions by virtue of their steric effect, e.g.



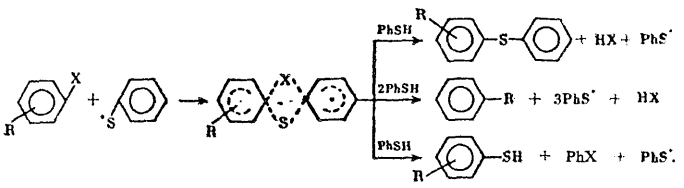
The reaction of *o*-dihalides with H_2S leads to the formation of heterocycles, e. g.

The reactions of fused halogenobenzenoid systems with H_2S have also been studied.[100] Thus, 1-chloronaphthalene reacts in the gas phase at 600 °C to give 1-thionaphthol, bis(1-naphthyl) sulphide, and naphthalene. 1-Bromonaphthalene and brominated derivatives of anthracene and phenanthrene react with H_2S in the liquid phase at 180–250 °C with the formation of symmetrical diaryl sulphides.

The authors have classified the high temperature reaction of aromatic chlorides and bromides with H_2S as a homolytic bimolecular substitution of halogen by thiyl radicals.[101] The following radical chain mechanism has been proposed:



Thiophenol interacts with aryl halides at 400–600 °C primarily with the formation of unsymmetrical sulphides:[102]



$$PhSH + ArX \rightarrow PhSAr + HX,$$

X = Cl, Br; Ar = *o*-, *p*-, *m*-MeC_6H_4, 3,4-$Me_2C_5H_3$, *o*-, *p*-OHC_6H_4, *o*-, *p*-$MeOC_6H_4$, *o*-, *p*-XC_6H_4.

The reaction is more selective at low temperature and with an excess of halide. An increase in the temperature favours reduced and exchange reactions:

The mechanism of the reaction of thiophenol with aryl halides is evidently a bimolecular homolytic process involving substitution by thiyl radicals. This takes place synchronously via a transition state which reacts with the mercaptan by one of three routes depending on the temperature:

For such high temperature conversions of aryl halides, the requisite thiyl radicals may also be generated from aryl mercaptans, dialkyl sulphides or disulphides.[103,104] Alkyl mercaptans react with chlorobenzene at 600–660 °C with the formation of thiophenol, diphenyl sulphide, and benzene as side-product. Lower (C_1–C_3) mercaptans are more reactive than higher ones. By comparing reactions with H_2S and alkyl mercaptans, treatment with the latter is less facile but the thiol : sulphide proportion is greater. Co-pyrolysis of chlorobenzene with dialkyl sulphides $[Me(CH_2)_n]_2S$ (n = 0, 1, 3, 6) and disulphides affords, primarily, benzene, thiophenol, and diphenyl sulphide, together with thiophene, benzothiophene and toluene.

The high temperature thiylation of aryl halides is synthetically attractive as a one-step route to important aromatic organosulphur compounds, namely aromatic and heteroaromatic thiols and sulphides. However, such methods require much energy and are complicated by side-reactions which reduce selectivity and the yield of desired product. This clearly limits the usefulness of these routes for practical purposes.

V. Photo- and electro-chemical thiylation

As indicated above, the thiylation of unactivated aromatic halides requires relatively harsh conditions (high temperatures, aprotic solvents) to secure high yields of the desired thioether, or may be conducted in strongly basic media or under transition metal catalysis. These reactions usually take place by an anionic mechanism, involving the formation of a σ-complex (S_NAr) or aryne-type intermediates, or by a free-radical pathway.

Substitution of unactivated aromatic halides can be effected under mild conditions by photo- or electro-chemical activation. Reaction proceeds by a 'radical, nucleophilic, monomolecular' ($S_{RN}1$) mechanism, as originally proposed and reviewed by Bunnett[105,106] (recent review, see Ref. 6). The key steps of such $S_{RN}1$ substitutions are as follows:

initiation $ArX + \bar{e} \rightarrow (ArX)^{\cdot-}$,

chain propagation $(ArX)^{\cdot-} \rightarrow Ar^{\cdot} + X^-$,

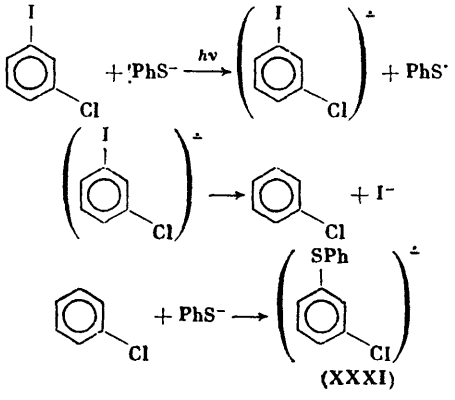
$Ar^{\cdot} + Nu^- \rightarrow (ArNu)^{\cdot-}$,

$(ArNu)^{\cdot-} + ArX \rightarrow ArNu + (ArX)^{\cdot-}$.

The length of the chain depends on the reaction conditions.

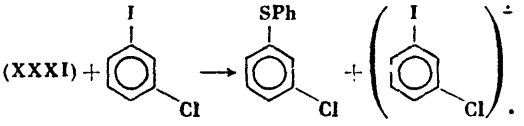
The photo-induced (λ_{max} = 350 nm) reaction of aryl iodides with thiophenoxide anion in liquid ammonia is quite facile (1–3 h), affording aryl phenyl sulphides in 70–95% yield:[107]

$$ArI + PhS^- \xrightarrow{h\nu} ArSPh + I^-,$$



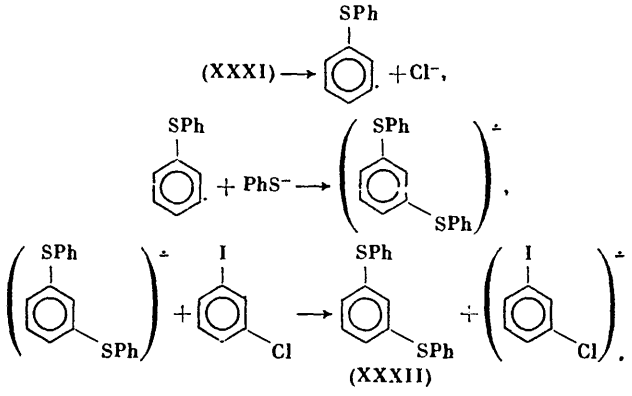
Ar = Ph, 1-naphthyl, *o*-, *p*-, *m*-MeC_4H_4,

o-, *p*-, *m*-$MeOC_6H_4$.



Aryl bromides also participate in this reaction, but more slowly than aryl iodides. Thus, irradiation of a mixture of PhI and PhS^- affords diphenyl sulphide in 94% yield after 70 min, but the yield from PhBr is 23% after 120 min.

The substitution is more effective in the presence of an organic base as catalyst.[108,109] Thus, the conversion of unactivated aryl bromides to diaryl sulphides can be achieved in higher yield (e.g. PhBr affording Ph_2S in 65–70% yield) by photo-initiation in the presence of tetra-n-butylammonium hydroxide or triethylamine; even chlorobenzene reacts under these conditions, Ph_2S being formed in 30% yield.[108] It is likely that such catalysts accelerate the single electron transfer in the initial formation of anion radical by the $S_{RN}1$ mechanism outlined above. The effect of tetra-n-butylammonium hydroxide on the photo-initiated reaction of aryl halides with pyridylthio anion (PyS^-) is less pronounced than its effect on the same reaction by PhS^-.[109] 2-(Phenylthio)pyridine is obtained from PhI in 68% yield, from PhBr in 19% yield, and from PhCl in 3% yield. The relatively inaccessible 3-(nitrophenylthio)pyridines may be prepared by this route under fairly mild conditions.



Irradiation of dihalogenobenzenes in liquid ammonia results in disubstitution.[110] Usually, the yield of mono-substitution product is poor or negligible. An $S_{RN}1$ mechanism has been proposed, the initial steps being the following:

The resulting anion radical (XXXI) may react further by two independent pathways. One involves an electron transfer:

The other is a fragmentation, leading ultimately to the disubstituted product (XXXII):

With the majority of dihalogenobenzenes (except fluorides), the formation of monosubstituted product by electron transfer from (XXXI) to the substrate is not significant, and fragmentation is the predominant process. With aromatic halogenofluorides, however, only monosubstitution takes place, i.e. electron transfer is more facile than loss of fluoride ion. This is a result of the greater strength of the C–F bond, relative to the C–Cl and C–Br bonds.

The photo-initiated reaction of alkylmercaptide anion with aryl halides affords the corresponding alkyl aryl sulphide by direct electron transfer (rate constant, k_t); fragmentation of the intermediate anion radical (rate constant k_f) results in formation of an alkyl radical which is unable to perpetuate the chain process:[111–113]

$$Ar^{\cdot} + AlkS^{-} \longrightarrow (Ar{-}S{-}Alk)^{\cdot -} \begin{cases} \xrightarrow{k_t} ArSAlk \\ \xrightarrow{k_f} ArS^{-} + Alk^{\cdot} \end{cases}$$

The relative contributions of these two processes depends on the nature of the alkyl residue and the aryl radical (Tables 5 and 6).

Table 5. The relative amount of the products of substitution and fragmentation in the reaction

$$Ph^{\cdot} + RS^{-} \xrightarrow{h\nu} PhSR + PhS^{-},$$

depending on the nucleophile.[113]

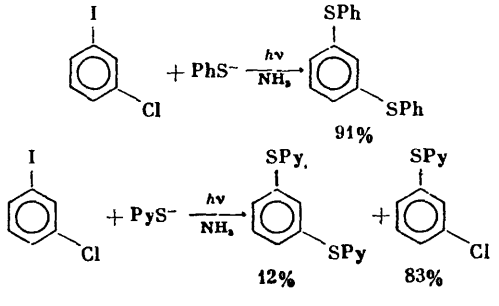
R	Ratio of the rate constants k_t, k_f	Relative yield, %		Overall yield, %
		PhSR	PhS⁻	
Ph	$k_t \gg k_f$	100	0	94
Me, Et, *n*-Bu, Bu^t	$k_t \approx k_f$	50	50	30–70
$PhCH_2$	$k_t \ll k_f$	0	100	4

Phenyl radicals react with phenylmercaptide anion to give the substitution product only (PhSPh),[107] while the interaction with alkylmercaptide anion (R = Me, Et, n-Bu, tert-Bu) affords approximately equal amounts of substitution and fragmentation product.[111,113] The reaction with benzylmercaptide anion, however, takes place only by fragmentation.[113]

Table 6. Relative amount of the products of substitution and fragmentation

$$Ar + n\text{-}BuS^{-} \xrightarrow{h\nu} ArSBu\text{-}n + ArS^{-1},$$

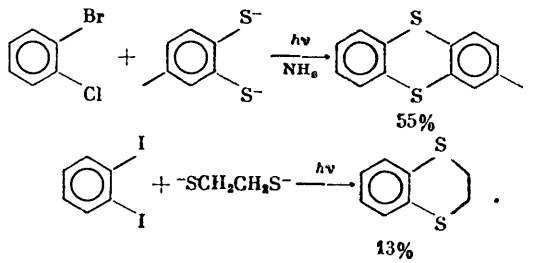
depending on the nature of the substrate.[113]



Ar	Ratio of the rate constants k_t, k_f	Relative yield, %	
		ArSBu	ArS⁻
Ph	$k_t < k_f$	50	50
1-Naphthyl	$k_t > k_f$	100	0

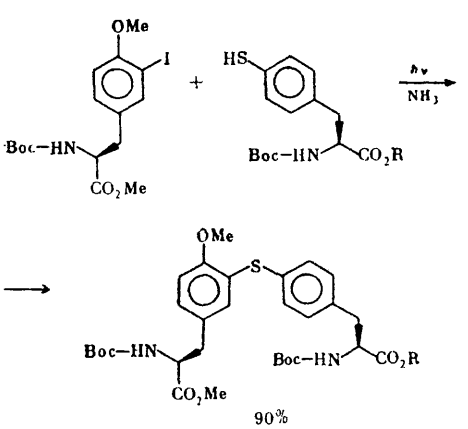
Since substitution proceeds as a chain reaction via electron transfer, while fragmentation is involved in the chain termination, the overall yield of substitution product will be decreased as fragmentation becomes more prominent. The relative contribution of electron transfer and fragmentation also depends on the nature of the aryl group.[112,113]

The difference between the reactivity of 1-naphthyl and phenyl radicals towards alkylmercaptide anion can be explained by the increased stability of the alkyl 1-naphthyl sulphide anion radical (relative to alkyl phenyl sulphide anion radical) and its ability to participate in the required electron transfer.



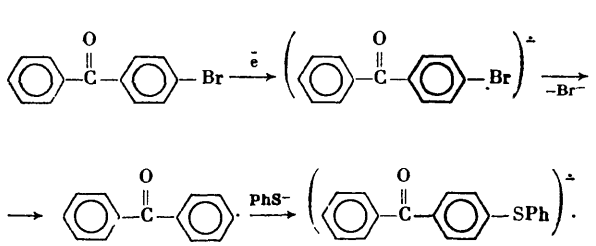
The rationale for mono- or di-substitution in the photo-initiated $S_{RN}1$ reaction of dihalogenobenzenes with RS^{-} anion has been studied.[114–117] The following factors affecting electron transfer or fragmentation have been identified:

a) the nature of the nucleophile[114,115]:



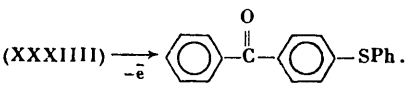
b) the structure of the substrate (in particular, the effect of electron-accepting substituents in the aromatic ring[116,117]).

Recently, heterocyclic compounds have been prepared by the $S_{RN}1$ reaction of *o*-dihalogenoarenes with dithiolate anions:[118]



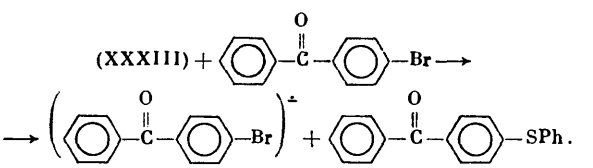
The low yield of product obtained by reaction with ethanedithiolate anion is explained by fragmentation of the intermediate anion radical.

Photo-stimulated thiylation has been applied in recent years as a mild route to complex, biologically significant, molecules. Thus, *p*-mercaptophenylalanine derivatives react effectively with iodotyrosine or iodohydroxyphenylglycine derivatives in liquid ammonia to give the corresponding diaryl sulphides by $S_{RN}1$ displacement:[119]



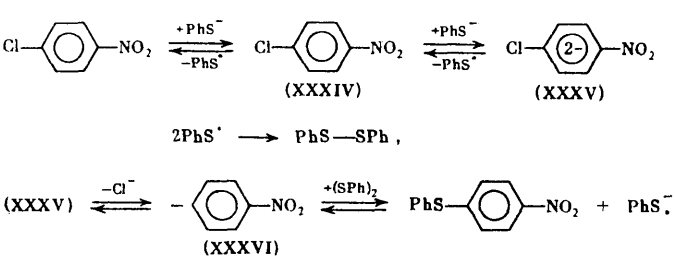
R = Me, H; Boc = ^{t}BuOCO.

It has also been shown that a number of halogenoaromatic compounds participate in electrochemically initiated $S_{RN}1$ substitution.[120–122] Thus, electrochemical reduction of 4-bromobenzophenone in DMF or acetonitrile in the presence of phenylmercaptide anion leads to 4-phenylthiobenzophenone[120] in high yield:



(XXXIII)

In the course of the reaction, the anion radical (XXXIII) may be oxidised at the surface of the electrode to give the desired diaryl sulphide:



Alternatively, it may transfer its unpaired electron to another substrate molecule:

The reaction of PhS^- with 4-bromoacetophenone, *p*-bromobenzonitrile, *p*-iodobenzonitrile and 1-bromonaphthalene may, in certain instances, be complicated by competitive reduction of the aryl radical by a molecule of solvent:[122]

$$Ar^{\cdot} \xrightarrow{HA} ArH + A^{\cdot}.$$

From studies of electrochemical modelling,[123,124] it has been proposed that activated nucleophilic replacement of halogen in *p*-halogenonitrobenzenes can proceed via the intermediate formation of an anionic σ-complex. Thus, the formation of 4-nitrophenyl phenyl sulphide from *p*-chloronitrobenzene and phenylmercaptide anion is thought to involve intermediate formation of *p*-chloronitrobenzene anion radical (XXXIV) and dianion (XXXV), obtained as a result of sequential electron transfer from phenylmercaptide anion. However, the anion radicals themselves are not directly implicated in the displacement. Rather, the end product is formed by thiylation of *p*-nitrophenyl anion (XXXVI) with diphenyl disulphide, the latter anion arising by elimination of chloride ion from the dianion (XXXV);

Photochemically and electrochemically initiated thiylation of aryl halides under mild conditions is of potential interest from the synthetical and theoretical viewpoint.

* *
*

This literature survey has revealed that there is a broad spectrum of routes for the thiylation of aryl halides. Thus, the development of new methods of introducing the RS group into the aromatic ring

under mild conditions has been traced. The displacement in question is subject to a variety of activating influences, most notable from the synthesis viewpoint being transition metal catalysis, phase transfer catalysis and photochemical and electrochemical initiation. One might anticipate that further work in this area will provide more detailed information on the mechanism of these reactions as well as the nature and role of the intermediates.

Investigations on the Arbuzov and retro-Arbuzov reactions among the organic derivatives of arsenic

B E Abalonin
Kazan State Pedagogical Institute

ABSTRACT. Results of attempts to effect the Arbuzov and retro-Arbuzov reactions with esters of arsinous acid and with oxides and sulphides of tertiary arsines have been correlated. The general rules and special features of these conversions are considered as well as the reactions accompanying them as a function of the environment of the arsenic atom, the nature of the electrophilic reagent and the reaction conditions. Recent and previously known results are considered from a common position.

The bibliography contains 88 references.

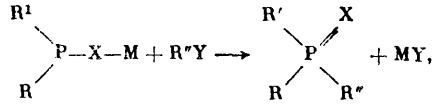
IV.	Conclusion	1357



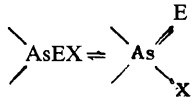
I. Introduction

The problem of nucleophilic reactivity and its link with the nature of the nucleophilic centre, with the character of its surroundings and the degree of coordination is one of the most important and pressing problems of modern chemistry. Investigation of the basic rules and, more specifically, the reactions of organoarsenic nucleophiles with electrophilic reagents is also of particular interest in connection with attempts to effect conversions analogous to the Arbuzov reaction, known in phosphorus chemistry, with the organic derivatives of arsenic. The process occurring in the reverse direction and known as the retro-Arbuzov reaction is also of interest, and has proved to be more characteristic of compounds of tetracoordinated arsenic.[1]

Numerous data have been accumulated to date by domestic investigators.[1–12] However, until now separate, sometimes contradictory, aspects of this problem have been considered which hinder an understanding of the results obtained. These problems are analysed in the present review from a common position in the light of the work of recent years.

II. Attempts to effect the Arbuzov reaction with esters of As(III) acids

After the discovery by A E Arbuzov of the reaction, which has become one of the most important synthetic methods in the chemistry of organophosphorus compounds,[13] numerous attempts were undertaken to effect a similar conversion among the organic compounds of arsenic, the closest analogue of phosphorus. On the one hand these attempts were justified by the importance acquired by the Arbuzov reaction in phosphorus chemistry. On the other hand, there is some basis to suppose that a similar reaction with the esters of trivalent arsenic is, in principle, possible. There is, in fact, the well known Michaelis–Becker reaction in the chemistry of arsenic.[14]



R, R′=Alk, Ar, AlkO; R″=Alk, Ac;
X=O, Y=Hal; M=metal

This reaction may correspond to one of the most important reactions in the arsenal of synthetic methods for this element, viz. the Meyer reaction and its modification proposed by Ozhe,† Scheller, Bart and others.[14]

$$Na_3AsO_3+RHal\rightarrow RAs(O)(ONa)_2+NaHal,$$
$$RAs(ONa)_2+R'Hal\rightarrow RR'As(O)ONa+NaHal,$$
$$R_2AsOAsR_2+2RI\rightarrow 2R_3AsO+2NaI,$$
$$RAs(ONa)_2+ArN_2Hal\rightarrow RArAs(O)ONa+N_2+NaHal,$$
R, R′=Alk; Hal=Cl, Br, I.

The point of this process, as for phosphorus derivatives, is an increase in the degree of coordination of the central atom, which is accompanied by the appearance of a new C–E bond and the generation of an E(O) grouping, where E = P, As. The conditions for carrying out these reactions are also closely similar.

Judging by the analogous phosphorus derivatives, the problem of tautomerism will arise in the arsenic compounds.

, where X=H, M.

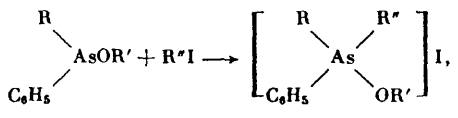
However this problem has not been studied in practice. For phosphorus compounds, as is known,[15] the tautomeric equilibrium lies markedly to the right.

† This name is a transliteration and may be in error (Ed. of Translation).

Unlike phosphorus acid, arsenous acid is tribasic. Its triply substituted salts are well known. This suggests that the equilibrium of the tautomeric conversion, if it occurs among trivalent arsenic derivatives, is shifted in the direction of compounds with a lower degree of coordination of the central atom.

The need to use an alkaline medium, in spite of a whole range of side reactions, is a general feature of the conversions under examination. This is evidently linked with the high stability of tetracoordinated derivatives of arsenic in alkaline medium.

At the same time, as is well known,[16] the stability of the highest valence state of the IVth period *p* elements, as in other subgroups of the Mendeleev periodic system, is significantly less than in the IIIrd period. Consequently it might be expected that conversions accompanied by an increase in the degree of coordination must be less characteristic for arsenic derivatives than for the phosphorus analogues.



In reality, attempts to isomerise esters of As(III) acids, carried out under the conditions of the Arbuzov reaction, gave negative results. No isomerisation was observed on heating equimolar quantities of alkyl esters of phenyl- and diphenylarsinous acids with methyl and ethyl iodide for a fairly extended time (up to 18 h) at temperatures of 100–102 °C.[2]

Similar attempts were made with practically all possible classes of esters of trivalent arsenic acids, including fully esterified arsenous acid $(RO)_3As$ where R = Alk or Ar, alkyl and aryl esters of alkylarsonous acids $RAs(OR)_2$ and esters of dialkyl- and alkylphenylarsinous acids RR′AsOr″.[2]

In no case was isomerisation successfully recorded in spite of varying the reaction conditions and the reactant ratios.

Several authors have recorded cases when crystalline products were formed on reacting esters of trivalent arsenic acids with alkyl halides. Kamai and collaborators[2] first paid attention to this phenomenon but the structure of the products remained unclarified. The reaction of the triethoxypropyleneglycol ester of ethylarsinous acid with methyl iodide was also recorded and leads to the formation of a crystalline product close in composition to a trimethylethylarsonium salt.[2]

Later[17] crystalline products were isolated on reacting alkyl esters of alkylphenylarsinous acids with alkyl halides, which were assigned the structure of dialkylphenylalkoxyarsonium salts on the basis of data of arsenic and halogen analysis. The authors assumed that the reaction proceeds in a manner similar to the first stage of the Arbuzov rearrangement.

R, R′, R″=CH_3, C_2H_5, C_3H_7, C_4H_9.

Following this, communications appeared on the isolation of trialkylalkoxyaronsium salts from the reaction of esters of dialkylarsinous acids with alkyl halides.[2] The authors also used only data of elemental analysis for arsenic and halogen to infer the structure of the products formed.

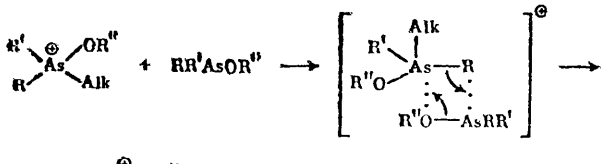
Thus for esters of trivalent arsenic containing only one alkoxy group, the reaction is similar to the Arbuzov rearrangement as though stopped at the first stage.

Attention is also drawn to the fact that some properties of the products of the reaction of esters of dialkyl- and alkylphenylarsinous acids with alkyl halides do not correspond completely with the properties of alkoxy-arsonium salts. Thus dialkylphenylalkoxyarsonium iodides exchange iodide ion for nitrate ion on heating with dilute nitric acid with no change in the composition of the cation containing the alkoxy group.[2] However it is well known that an alkoxy group on an arsenic atom is fairly sensitive to hydrolysis.

The inconsistencies indicated call for a wider investigation of the products which were assigned the structure of alkoxyarsonium salts. Such investigations were subsequently undertaken.[6] The result was the unexpected conclusion that alkoxy groups were not present in the crystalline products examined. Data of IR and PMR spectra, results of conductiometry, comparison of physicochemical characteristics and data of more complete elemental analysis of the reaction products indicated that alkoxyarsonium salts were not formed by the reaction but the products were the well known quaternary arsonium salts containing no alkoxy groups.

$$RR'AsOR''+RX\rightarrow[R_3R'As]X.$$

Evidently the lack of using spectroscopic methods, the small difference in elemental composition for the compounds $[R'R_2AsOAlk]X$ and $[R'R_2AsAlk]X$, which are close in structure, and also the suggestive analogy with the first stage of the Arbuzov rearrangement biased the authors, working in this area for the first time, towards that structure for the products which seemed to be expected naturally in the reactions examined.



Subsequent investigations of this reaction carried out on several series of esters of dialkyl- and alkylphenylarsinous acids,[18] showed that the composition of the quaternary arsonium salts formed did not depend on the nature of the hydrocarbon residue in the ester group. This enabled exclusion of the scheme proposing exchange of hydrocarbon residues between the alkoxy group of the ester and the alkyl halide from the number of possible reaction schemes.

$$RR'AsOR''+RX\not\rightarrow RR'AsOR+R''X$$

Of the possible schemes proposed to explain the formation of quaternary arsonium salts in this reaction, two are most probable. According to one of them (Scheme 1) the increase in the coordination number of the arsenic atom occurs at the first stage.[6,9]

Scheme 1

$$RR'AsOR''+AlkHal\rightarrow[RR'AlkAsOR'']^{\oplus}Hal^{\ominus}, \quad (1)$$

$$\rightarrow R'AlkAs^{\oplus}(OR'')_2 + R_2R'As, \quad (2)$$

$$R_2R'As+AlkHal\rightarrow[R_2R'AlkAs]Hal. \quad (3)$$

The alkoxyarsonium cation formed, being unstable to nucleophilic attack, is converted into the corresponding tertiary arsine by the action of a second molecule of the initial ester [Scheme 1, stage (2)]. The appearance of a tertiary arsine in the presence of the alkyl halide leads to the formation of the quaternary arsonium salts [Scheme 1, stage (3)].

Another possible reaction route (Scheme 2) consists of a disproportionation of the initial ester, which also leads to the appearance of tertiary arsines, and as a result to the isolation of quaternary arsonium salts as final products [Scheme 1, stage (3)].[6]

Scheme 2

$$2RR'AsOR'' \rightleftharpoons R_2R'As + R'As(OR'')_2.$$

As the reaction mechanism was unexplained, an invetigation of its kinetics was later undertaken.[19] Partial reaction orders, determined by a differential method, for the case of the ethyl ester of diethylarsinous acid and ethyl iodide in acetone at 50 °C proved to be close to unity, which indicates an overall second order. The comparatively simple kinetics for a reaction which is evidently not so simple are explained by the authors by the presence of a limiting step, most probably at the beginning of the process.

It became clear later that the method of obtaining the initial ethyl ester of diethylarsinous acid has an effect on the kinetic data.

$$(C_2H_5)_2AsCl + NaOC_2H_5 \rightarrow (C_2H_5)_2AsOC_2H_5 + NaCl.$$

Haloarsine and tertiary arsine contaminants contained in the reaction product distort the kinetics of the process in the case of the simpler and therefore more frequently used method.

On making the initial ester from bis(diethylarsine)oxide the data of the kinetic investigation proved to be more stable and led to a reproducible result.[9,19]

$$[(C_2H_5)_2As]_2O + 2C_2H_5OH \xrightarrow[-H_2O]{} 2(C_2H_5)_2AsOC_2H_5.$$

It should be noted that both routes considered as most probable for forming quaternary arsonium salts propose the appearance in the reaction mixture of the same products, viz. esters of arsonous acids $R'As(OR'')_2$. These esters were successfully isolated somewhat later.[20]

$$2RR'AsOR'' + AlkX \rightarrow [R_2R'AsAlk]X + R'As(OR'')_2,$$
$$Alk=R=R'=C_2H_5,\ R''=C_6H_5,\ X=I;$$
$$Alk=R=C_2H_5,\ R'=C_6H_5,\ R''=C_4H_9,\ X=I;$$
$$R=R'=C_2H_5;\ R''=Alk=C_4H_9,\ X=Br.$$

It is interesting that the possibility of forming quaternary arsonium salts by a similar reaction was also discovered for esters of arsonous acids.[9]

$$3C_2H_5As(OC_2H_5)_2 + C_2H_5I \rightarrow [(C_2H_5)_4As]I + 2(C_2H_5O)_3As.$$

Further investigations showed that in the case of the lower esters of dialkylarsinous acids the formation of alkoxyarsonium salts may nevertheless be observed under fairly mild conditions.[21]

$$(CH_3)_2AsOCH_3 + CH_3I \rightarrow [(CH_3)_3AsOCH_3]I.$$

The structure of the product was confirmed by IR and PMR spectroscopy. However in addition to bands (655, 1013 cm^{-1}) indicating the presence of the $\rangle AsOC\langle$ grouping, signs of hydroxyl were detected which the authors link with admixture of a compound arising as a result of hydrolysis.

$$[(CH_3)_3AsOCH_3]I + H_2O \rightarrow [(CH_3)_3AsOH]I + CH_3OH.$$

The formation of hydroxyarsonium salts in the reaction of the ethyl ester of dicyclohexylarsinous acid with ethyl iodide is also linked with the increased sensitivity of alkoxyarsonium salts towards hydrolysis.[9]

Cases of the formation of difficultly separable mixtures containing, in the authors' opinion, alkoxyarsonium salts were also noted in the case of the ethyl ester of diethylarsinous acid. However, another product is proposed as contaminant here, viz. a quaternary arsonium salt containing no alkoxy group.[20]

$$(C_2H_5)_2AsOC_2H_5 + C_2H_5I \rightarrow [(C_2H_5)_3AsOC_2H_5]I + [(C_2H_5)_4As]I.$$

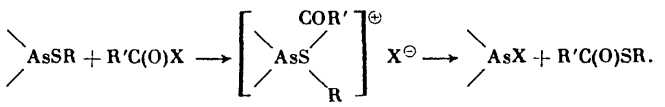
On the basis of this the hypothesis was made that tetraethylarsonium iodide is formed from the corresponding alkoxyarsonium salt, i.e. Scheme 1 (see above). However such an interpretation is seemingly not indisputable since the combined isolation of two products does not always indicate that one is not formed from the other. The most persuasive confirmation of the scheme in question might be to attempt to convert the alkoxyarsonium salt directly into a quaternary arsonium salt. So far this has not been successful.

Scheme 2, proposing the disproportionation of the intial ester, is less vulnerable. This property of the esters of As(III) acids was confirmed by GLC.[22] The results obtained by chromatography indicate that the disproportionation is essentially an important property of esters of arsinous acids, which it is impossible not to consider when analysing conversions involving them. The presence in the reaction mixture of haloalkanes capable of binding the generated tertiary arsine in the quaternary arsonium salt isolated in the solid may be considered as a factor assisting disproportionation.

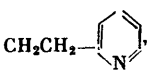
At the same time it would be premature to make a final conclusion regarding the route of formation of the quaternary arsonium salts in the reaction.

Attempts have also been undertaken to effect conversions like the Arbuzov reaction in several thioesters of trivalent arsenic acids. However they were also unsuccessful here. The appearance of another nucleophilic centre, the sulphur atom, together with the arsenic atom evidently leads to a change in the direction of attack of the nucleophile and the reaction leads to the formation of dialkyl disulphides or sulphonium salts.[8,23]

$$R_nAs(SR')_{3-n} + (3-n)R''X \longrightarrow$$
$$\longrightarrow [R_nAs(SR')^{\oplus}_{2-n}SR'R'']X^{\ominus} \longrightarrow R_nAsX_{3-n} + (3-n)R'SR'',$$



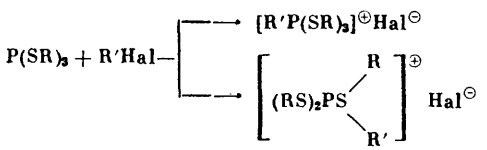
$R=C_2H_5$, C_6H_5, $NH(C_6H_4)_2$; $R'=C_2H_5$, C_4H_9,



$-CH_2CH_2$, $C(O)CH_3$, CH_2CH_2OH, $C_6H_4NH_2$-*o*;

$R''=CH_3$, C_2H_5; X=Br, I; $n=0$, 1, 2.

Similarly carboxylic acid chlorides react with thioesters with fission of the As–S bond.[5] Reaction occurs at the sulphur atom as in the case of the alkyl halides.



$$R=C_4H_9,\ CH_2CH_2OH,\ CH_2CH_2N(C_2H_5)_2,$$

$$R'=CH_3,\ C_6H_5;\ X=Cl,\ Br.$$

Such a reaction course is not unexpected since even thiophosphites, in which the phosphorus atom is more nucleophilic than arsenic in the thioesters of the corresponding As(III) acids, may be alkylated under analogous conditions both at phosphorus and at sulphur.[24–33]

It is interesting to compare these data with the conversions of antimonous acid under the action of halogen derivatives.[34]

$$Sb(OR)_3+nR'X\rightarrow X_nSb(OR)_{3-n}+nROR'$$

$$R=Alk,\ R'=Alk,\ Ac,\ CH_2OAlk;\ X=Cl,\ Br,\quad n=1\text{ to }3.$$

The formation of an oxonium compound was proposed at an intermediate stage and the process itself is considered as a variation of the Williamson reaction, i.e. the reaction of alkyl halides with alkoxides. In the opinion of the author, the polarity of the E–O bond changed in derivatives of the type $(RO)_3E$ (E = P, As, Sb). The phosphorus atoms acts as the nucleophilic centre in phosphites (E = P) and the oxygen atom in esters of antimonous acid (E = Sb). A similar approach was also confirmed by the results of other conversions.[34]

$$(RS)_3Sb+nR'X\rightarrow (RS)_nSbX_{3-n}+(3-n)RSR',$$
$$R=Alk;\ R'=Alk,\ Ac;\ X=Cl,\ Br,\ I,$$
$$(C_2H_5O)_3P+3HBr\rightarrow H_3PO_3+C_2H_5Br,$$
$$(C_2H_5O)_3As+3HBr\rightarrow AsBr_3+3C_2H_5OH.$$

Returning to the esters of arsinous acids it is interesting to note the attempt to alkylate their anhydrides $(RR'As)_2E$ (E = O, S),[35] which may be considered as derivatives of esters RR'AsER'' when R'' = AsRR'. It is assumed that the presence of a system of three interconnected nucleophilic centres may change the ratio of their nucleophilicities and make the first stage of the Arbuzov reaction more probable.

As it turned out, in this case also the reaction occurs in a more complex manner and led to the formation of a quaternary arsonium salt and haloarsines. When using thioanhydrides the reaction requires more forcing conditions and is accompanied by side reactions.

$$RR'AsEAsRR'+RX\rightarrow RR'AsER+RR'AsX,$$

when E = O [Ref. 35]:

$$RR'AsOR+RX\rightarrow [R_3R'As]X,$$
$$RR'AsX+RX\rightarrow R_2R'AsX_2,$$

when E = S [Ref. 36]:

$$RR'AsSR+RX\rightarrow RR'AsX+[R_3R'As]X,$$
$$R=R'=C_2H_5,\ n\text{-}C_3H_7,\ iso\text{-}C_3H_7,\ n\text{-}C_4H_9,$$
$$R=Alk,\ R'=C_6H_5;\ X=Br,\ I.$$

In similar reactions the corresponding esters and haloarsines were isolated from acid chlorides of carboxylic acids.[35]

$$(RR'As)_2E+R''X\rightarrow RR'AsER''+RR'AsX,$$
$$R=R'=Alk,\ C_6H_5;\ R''=CH_3C(O),\ C_6H_5C(O);\ X=Cl.$$

The data presented permit the conclusion that even in the most nucleophilic esters of As(III) acids and their derivatives, a reaction like the Arbuzov does not occur under similar conditions but a more complex process takes place accompanied by fission of the $\rangle As-E$ (E = O, S) bond.

The inability of esters of As(III) acids to react with halogen derivatives in a manner like their phosphorus analogues is evidently explained by the reduction of nucleophilicity on going from phosphorus to arsenic.[6] The significantly higher sensitivity of the arsenic atom to the inductive effect of substituents is an important circumstance.[37] Of the possible types of esters of As(III) acids, viz. $R_2As(OR')$, $RAs(OR')_2$ or $As(OR')_3$, only the esters of arsinous acid $R_2As(OR')$ display a clearly marked ability to react with alkyl halides. For the corresponding phosphorus derivatives with the Arbuzov reaction proceeds both with esters of phosphinic acids and with full phosphites, although at different rates. It may be proposed that with phosphorus the reduction in electron density is compensated to a greater extent than with arsenic by the attraction of the unshared electron pair of the oxygen of the alkoxy groups to the *d* orbitals of the central atom. At the same time, in spite of the abundant literature proposing conjugation with the *d* orbitals of the phosphorus atom, a fairly sound view exists on the insignificant role of similar effects in bond formation.[38] In this connection, as an alternative, it would have been useful to clarify the possibility of displaying an α-effect ("supernucleophilicity") as a feature inherent to certain phosphorus derivatives in contrast to the arsenic-containing analogues. The presence of an unshared electron pair on the atom connected directly to the nucleophilic centre is, as is known,[39,40] one of the most important factors determining the order of the nucleophilicity. However there are no literature data capable of successfully confirming a deviation from the Brønsted rule for esters of P(III) acids.

Among the other reasons explaining the difference in behaviour of esters of P(III) and As(III) acids it is impossible not to mention the unique nature of the phosphorus–oxygen bond in the phosphoryl group arising in reactions of this type. The high thermodynamic stability of this bond (estimated at 552 kJ/mol) is one of the driving forces of the Arbuzov reaction (the strength of the As–O bond is estimated at 443 kJ/mol [41]). Finally new E–C bonds arising in the course of side reactions, when E = P, prove to be more stable (for example by 40.2 kJ/mol), while the fissile E–OC bonds in esters of

As(III) acids are more labile. The latter circumstance superimposes a special imprint on the properties of these esters, imparting to them, in contrast to the phosphorus analogues, an increased hydrolytic instability, but the intermediate product containing an alkoxy group on the arsenic atom is susceptible to a different sort of side reaction, complicating significantly the course of the reaction.

Evidently these same special features may explain the more marked inclination of tetracoordinated arsenic derivatives to conversions occurring with a reduction in valency.

III. The retro-Arbuzov reaction in organic derivatives of As(V)

1. Reactions of compounds containing an arsenyl group

The first information on the possibility of conversions of esters of tetracoordinated arsenic acids occurring with a reduction of its valency were known even before the discovery by A E Arbuzov of the reaction bearing his name.

Even in 1867 Kraft[2] showed that reduction of arsenic to the trivalent state occurred on heating a mixture of arsenic acid with tetraethoxysilane to 230 °C.

However only in 1947 did Komissarov and collaborators[42] realise that the conversion of esters of alkylarsonic acids on heating to a temperature of the order of 200 °C was similar to the process occurring in the reverse direction to the Arbuzov reaction

$$CH_3As(O)(OCH_3)_2 \rightarrow (CH_3O)_3As.$$

The isomerisation was accompanied by the formation of alcohols and a fraction in which the arsenic content was higher than in the corresponding trialkyl arsenites.

These studies appear to be the starting point for the investigations of more recent times on the possibility of achieving conversions with the oxygen derivatives of tetracoordinated arsenic proceeding in a direction opposite to the Arbuzov reaction.

In reality a wider study of the behaviour of trialkylarsine oxides[4] and esters of dialkylarsinic and alkylarsonic acids[2,4] at temperatures close to 200 °C confirmed the conclusions on the thermal instability of oxygen derivatives of As(V). Certain features linked primarily with the fairly complex character of the conversions were clarified.

On pyrolysis of esters of alkylarsonic acids, in addition to the isomerisation product (I) [2,4] the yield of which proved to be generally insignificant and rarely exceeded 10%. The formation was observed of reduction products, viz. the corresponding esters of alkylarsonous acids (II).

$$RAs(O)(OR)_2 \xrightarrow{\Delta} \begin{cases} \rightarrow (RO)_2As \text{ (I), 2—11\%} \\ \rightarrow RAs(OR)_2 \text{ (II), 6—40\%} \end{cases}$$

The authors also indicated the formation in the reaction of an alcohol with the residue of the alkoxy group of the initial ester. On pyrolysis of the dibutyl ester of methylarsonic acid the presence was detected of a carbonyl compound which reacted with 2,4-dinitrophenylhydrazine.[4]

The esters of diethylarsinic acids proved to be even less stable to heat and decomposed with resinification even on attempted distillation.[2,4] It is necessary to record that the formation of isomerisation products was hardly observed by the authors in this case. In addition to the reduction products, viz. the corresponding esters of dialkylarsinous acids, alcohols containing the hydrocarbon residue of the alkoxy group and also dialkylarsinic acids were successfully identified. The dibutyl ester of ethylarsonic acid was isolated in 8% yield from the products of oxidation of the butyl ester of diethylarsinous acid as a result of thermal decomposition.

The main products of the pyrolysis of tertiary arsine oxides, as has been clarified,[4] are also reduction products, viz. the corresponding tertiary arsines and alcohols. The formation in small quantities of isomerisation products, esters of dialkylarsinous acids, was observed.

$$R_3AsO \xrightarrow{\Delta} \begin{cases} \rightarrow R_3As, ROH \\ \rightarrow R_2AsOR \end{cases}$$

The authors considered a disproportionation reaction probable, since tributylarsine was isolated from the pyrolysate of methyldibutylarsine oxide.

A more detailed investigation of the thermal conversions of derivatives containing the arsenyl group indicated the complexity of the processes taking place. The yield of isomerisation products was, as a rule, below 10%, a significant proportion of the starting material resinified.

A higher yield of isomerisation products (32—46%) was observed in the pyrolysis of the diethyl ester of ethylarsonic acid and the dibutyle ester of butylarsonic acid obtained by the method of esterification.[3,4] The authors came to the conclusion that admixture of selenium compounds, used previously to obtain the initial As(V) esters, catalyses oxidation—reduction side reactions accompanying the isomerisation. It was shown by thermography that the reaction proceeds in one stage and, depending on the character of the environment of the arsenic atom, the temperature for the initiation of conversion (TIC) varied within the limits 115—282 °C. The TIC increased with an increase in the length and branching of the hydrocarbon substituents. From the thermographic data a stability series at increased temperature was drawn up for the esters as a function of the structure of the hydrocarbon residue bound to the arsenic atoms.

$$(CH_3)_2CHCH_2 > C_4H_9 > C_2H_5 > CH_3 > C_6H_5CH_2 > CH_2{=}CHCH_2 > (CH_3)_2CH.$$

Subsequent investigations of the retro-Arbuzov reaction in esters of arsinic acids showed that on adding small quantities of electrophilic reagents (alkyl halides, salts and acids) conversion began at lower temperatures and the yield of products grew to 50—63%.[3,4] Thermographic data indicated a two-stage process and the absence of an effect on adding nucleophilic reagent (sodium ethoxide, pyridine) on the temperature for the initiation of conversion. An increase of two orders of magnitude in the specific conductivity on mixing the reactants indicated the formation of an ionic intermediate.

A study of the kinetics of the isomerisation of esters of alkylarsonic acids by alkyl halides[3] indicated the overall second order of the reaction which, together with the results of

thermographic investigations,[3,4] afforded the conclusion that the conversion occurred in the opposite direction to the Arbuzov reaction.

$$R(OR')_2AsO+R''X \rightleftharpoons [RAs(OR')_2(OR'')]^{\oplus}+X^{\ominus} \rightarrow$$

$$\rightarrow (R'O)_2AsOR''+RX.$$

Later, similar conversions were investigated for esters of dialkylarsinic acids.[1,43] Here the addition of alkyl halides also reduced the TIC significantly. The use of GLC enabled a more complete analysis of the products formed. When relatively less stable $As-C_{Alk}$ bonds were absent from the initial esters the main route of the process was an exchange of hydrocarbon residues between the alkoxy group and the alkyl halide if the reaction was carried out under conditions when the volatile products formed were continuously distilled out (yield 75–95%).

$$(C_6H_5)_2As(O)OR+R'Hal \rightarrow (C_6H_5)_2As(O)OR'+RHal,$$
$$(C_6H_5)As(O)(OR)_2+R'Hal \rightarrow (C_6H_5)As(O)(OR)(OR')+RHal,$$
$$R'=CH_2C_6H_5;\ Hal=Br;\ R=C_3H_7.$$

The following processes, which the authors regard as oxidation–reduction, occur in parallel

$$(C_6H_5)_2As(O)OR + C_6H_5CH_2Br \xrightarrow[-HBr]{} (C_6H_5)_2AsOR + C_6H_5C(O)H,$$
$$C_6H_5As(O)(OR)_2 + C_6H_3CH_2Br \xrightarrow[-HBr]{} C_6H_5As(OR)_2 + C_6H_5(O)H.$$

This reaction course predominates when R = $C_6H_5CH_2$ although it requires more forcing conditions. Triphenylarsine also appears in the reaction products, which the authors link with the disproportionation.

$$3(C_6H_5)_2AsOCH_2C_6H_5 \rightleftharpoons 2(C_6H_5)_3As+(C_6H_5CH_2O)_3As.$$

In the case of esters containing the less stable $As-C_{Alk}$ bonds the predominant reaction route is retro-Arbuzov accompanied by symmeterisation and exchange processes.

$$Alk_2As(O)OR + R'Br \xrightarrow{-RBr} Alk_2As(O)(OR') \xrightarrow[-AlkBr]{\sim 10\%} AlkAs(OR)(OR') \rightleftharpoons AlkAs(OR)_2 + AlkAs(OR')_2$$
$$\sim 65\%$$

The authors came to the conclusion that irrespective of the nature of the isolated products the first stage of the reaction is the formation of the corresponding alkoxyarsonium salt (V).

$$R_2As(O)OR' + R''CH_2Hal \rightarrow [R_2As(OCH_2R'')OR']^{\oplus}Hal^{\ominus}$$
(III) (IV) (V)

The formation of this salt is confirmed by the increase in conductivity on mixing the reactants (III) and (IV).

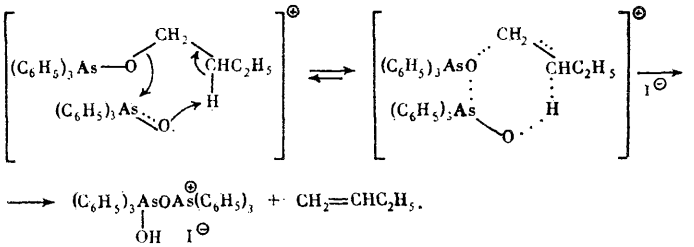
The further conversions of the intermediate (V) are determined by the nature of the reaction participants and conditions.

$$(V) \xrightarrow[-RHal]{a} RAs(OR')(OCH_2R'') \rightleftharpoons RAs(OR')_2 + RAs(OCH_2R'')_2$$
$$(V) \xrightarrow[-R'Hal]{b} R_2As(O)OCH_2R'' \xrightarrow{-R''CHO} R_2AsOR'$$
$$(V) \xrightarrow[-R''CHO]{c} R_2AsOR'$$

R=Alk, Ar; R′=Alk; R″=Alk, Ar.

Route *a* (retro-Arbuzov reaction) is most characteristic for esters containing an alkyl group on the arsenic atom. When alkyl groups are absent (R = Ar) route *b* predominates if conditions are created for displacing the equilibrium by removing the more volatile alkyl halide formed. In the opinion of the authors[1,43] an increase in temperature favours the oxidation–reduction reaction (route *c*). In esters having only one $As-C_{Alk}$ bond the retro-Arbuzov reaction may therefore be the main route for conversion under appropriate conditions.

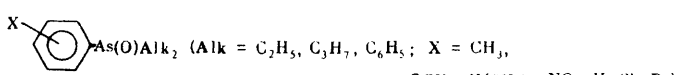
A different situation is generated in attempts to effect the retro-Arbuzov reaction with tertiary arsine oxides. As was explained, on reacting triethylarsine oxide with isopropyl and isobutyl iodide a crystalline compound is formed, the analysis of which indicated a composition $C_{12}H_{31}As_2O_2I$, in place of the expected esters of arsinous acids.[44] Initially the obtained product was assigned the structure of triethyl(triethylhydroxyarsoxy)arsonium iodide.



$$(C_2H_5)_3As-O-As^{\oplus}(C_2H_5)_3.\ I^{\ominus}$$
$$\quad\quad\quad

assuming the intermediate formation of an alkoxyarsonium salt capable of being later converted by an irreversible reaction (Scheme 4) to the final products.[44,45]

Scheme 3



$$(C_6H_5)_3AsO + ICH_2CH_2C_2H_5 \rightleftharpoons \left[(C_6H_5)_3AsO\ldots\underset{\displaystyle CH_2C_2H_5}{\overset{\displaystyle |}{CH_2}}\ldots I\right] \rightleftharpoons$$
$$\rightleftharpoons [(C_6H_5)_3AsOCH_2CH_2C_2H_5]^{\oplus} + I^{\ominus}$$

Scheme 4

$$\longrightarrow (C_6H_5)_3AsO\overset{\oplus}{As}(C_6H_5)_3 + CH_2{=}CHC_2H_5.$$
$$\quad\ |$$
$$\quad OH\ \ I^{\ominus}$$

As was shown by further investigations,[44,46] the adducts of type $(R_2R'AsO)_2HHal$ are formed when using a fairly wide range of reactants. Alkyl halides RHal of normal and branches structure (R = CH_3, C_2H_5, n = C_3H_7, n-C_4H_9, iso-C_4H_9, $CH_2C_6H_5$; Hal = I, Br, Cl) have been used in reactions with trialkylarsine oxides Alk_3AsO (Alk = CH_3, C_2H_5, n-C_3H_7, cyclo-C_6H_{11}) and also with a series of dialkylarylarsine oxides.

The formation of hydroxyarsonium salts in place of 2 : 1 adducts occurred only in certain cases. Attempts have been made to show that hydroxyarsonium sals result from the decomposition of these adducts.[7,44]

$$(R_3AsO)_2HI \rightarrow [R_3AsOH]I + R_3AsO.$$

However the similar conversion was unsuccessful. This compelled the authors to acknowledge that it is impossible to explain the isolation of hydroxyarsonium salts in the reactions of tertiary arsine oxides with alkyl halides by more profound conversions and that the reason for the appearance of these salts remains unclear.

When analysing the first results obtained on investigating the conversions of tertiary arsine oxides by alkyl halides it is important to note that in the overwhelming majority of cases only alkyl iodides are used in these reactions[44–46] but the yield of crystalline products, as a rule, is far from quantitative. Only for trimethyl- and triethylarsine oxides reacting with methyl iodide was the yield 61.7 and 65.6% respectively while in all the remaining cases it varied between 25 and 50%.

Analysis of the gaseous reaction products indicated the formation of olefins, which is in agreement with the proposed Scheme 4. However on using methyl iodide, the presence of methane and ethane was recorded in addition to ethylene.[7] This indicates the presence of side reactions.

The problem of the composition of the liquid portion of the reaction mixture, in which the products of a retro-Arbuzov reaction would be sought, remained on one side for some time. This may be explained by the unexpected formation of crystalline products of unusual structure such as $(R_2R'AsO)_2HHal$. Only later was it discovered that on reacting diethylphenylarsine oxide with alkyl bromides were esters of ethylphenylarsinous acid isolated in up to 70% yield.[47] It was therefore shown possible to effect a conversion opposite to the Arbuzov reaction for certain tertiary arsine oxides.

$$(C_2H_5)_2(C_6H_5)AsO + AlkBr \rightarrow$$
$$\rightarrow [(C_2H_5)_2C_6H_5AsOAlk]Br \rightarrow (C_2H_5)(C_6H_5)AsOAlk + C_2H_5Br$$
$$Alk = C_2H_5,\ n\text{-}C_3H_7,\ n\text{-}C_4A_9.$$

Somewhat later an analogous route for the reaction was also reported for trialkylarsine oxides (the yield of esters was only ~10%).[48] However the closeness of the boiling points of the reaction products did not enable results to be obtained which could be acknowledged to be sufficiently clear.

Subsequent investigations were performed using diphenylalkylarsine oxides.[49] First of all evidence was obtained that this reaction may be carried out as the main process accompanied by the formation of esters of diphenylarsinous acid in 65% yield.

$$(C_6H_5)_2RAsO + AlkX \rightarrow (C_6H_5)_2AsOAlk + RX,$$

$$R = C_2H_5,\ n\text{-}C_3H_7,\ n\text{-}C_4H_9;\ Alk = CH_3,\ C_2H_5,$$

$$n\text{-}C_3H_7,\ n\text{-}C_4H_9;\ X = Br,\ I$$

The most important feature of these conversions is the formation of the corresponding haloarsines, which was noted for the first time, together with the esters of diphenylarsinous acid.[11,49]

Triphenylarsine oxide, containing no akyl groups capable of being split off by activated halogen derivatives of the type $HalCH_2Z$ (where Z = $C(O)OCH_3$, $C(O)OC_2H_5$, CN, $C(O)CH_3$; Hal = Cl, Br) forms hydroxyarsonium salts $[Ph_3AsOH]Hal$ ($Ph_3AsO.HHal$) (1 : 1) in place of adducts of composition $(Ph_3AsO)_2HHal$ (2 : 1).[50]

Similar hydroxyarsonium salts were isolated on using the usual alkyl bromides under more forcing conditions.[50] This suggested that the formation of 2 : 1 adducts such as $(Ph_3AsO)_2HHal$ or 1 : 1 adducts like $Ph_3AsO.HHal$ is determined by the nature of the halogen in the initial halogen derivative.

These facts together with the possibility mentioned above of forming haloarsines as side products enabled the following hypotheses to be put forward:

—the first stage of the process is the formation of an alkoxyarsonium salt $[R_2R'AsOAlk]Hal$ irrespective of the nature of the products isolated:

—the appearance of adducts $(R_2R'AsO)_2HHal$ is the result of the reaction of the hydroxyarsonium salt $[R_2R'AsOH]Hal$ with the initial oxide $R_2R'AsO$;

$$R_2R'AsO + [R_2R'AsOH]Hal \rightarrow (R_2R'AsO)_2HHal$$

—the hydroxyarsonium salts themselves appear as a result of the decomposition or hydrolysis of the intermediate alkoxyarsonium salts;

$$R_2R'AsO + AlkHal \rightarrow [R_2R'AsOAlk]Hal \xrightarrow{H_2O} [R_2R'AsOH]Hal + AlkOH$$
$$[R_2R'AsOAlk]Hal \xrightarrow{\Delta} [R_2R'AsOH]Hal + \text{olefin}$$

—the isolation of haloarsines together with esters of trivalent arsenic acids in those cases when a reverse Arbuzov reaction occurs is linked with the decomposition of thermally unstable hydroxyarsonium salts formed as side products:

$$[R_2R'AsOH]Hal \xrightarrow{\Delta} RR'AsHal.$$

The central point of these conversions is the formation in the first stage of an alkoxyarsonium salt $[R_2R'AsOAlk]Hal$ as an intermediate. Attempts to isolate these salts in the reactions of tertiary arsine oxides with alkyl halides were unsuccessful. The difficulty of isolating byproducts is explained by their instability linked with the increased reactivity of the alkoxyarsonium cation.[1,3,4,7]

Nevertheless the reduction of the positive charge on the arsenic atom in the cation by replacing phenyl by alkyl, the introduction of a less nucleophilic bromide anion and the use of carefully dried solvents and apparatus enabled the formation of an alkoxyarsonium salt to be recorded in one of the examples.[51]

$$(n\text{-}C_3H_7)_3AsO + C_2H_5Br \rightarrow [(n\text{-}C_3H_7)_3AsOC_2H_5]Br$$

Confirmation was also obtained for the other hypotheses in a similar manner. The synthesis and study of the thermal conversions of hydroxyarsonium salts was the subject of a special investigation.[52]

These results enabled an overall Scheme to be drawn up for the conversion of tertiary arsines by alkyl halides as a single process, the route of which is determined by the environment of the arsenic atom.[53–55]

Scheme 5

$$R_2R'AsO + R''X \rightarrow [R_2R'AsOR'']X$$
$$[R_2R'AsOR'']X \xrightarrow[-RX]{a,\ X^{\ominus}} R_2AsOR'' \rightleftharpoons R_3As + RAs(OR'')_2$$
$$[R_2R'AsOR'']X \xrightarrow[-\text{olefin}]{b,\ R_2R'AsO} [R_2R'AsOH]X \xrightarrow{R_2R'AsO} (R_2R'AsO)_2HX$$
$$[R_2R'AsOH]X \xrightarrow{-ROH} (RR'As)_2O \xrightarrow{R''X} RR'AsOR'' + RR'AsX$$

The more basic trialkylarsine oxides (R = R′ = Alk) react predominantly as bases undergoing dehydrohalogenation of the alkyl halide (Scheme 5, route *b*). If the retro-Arbuzov reaction (Scheme 5, route *a*) also takes place under these conditions then it is only a side reaction. In the case of the less basic dialkylphenyl- and alkyldiphenylarsine oxides (R = Alk, R′ = C_6H_5, R′ = Alk) the contribution of route *a*, leading to a retro-Arbuzov reaction product, is significantly increased and route *b* plays the role of a side reaction. Route *b* remains the sole possible route in the case of triphenylarsine oxide, which contains no $As-C_{Alk}$ bond capable of fission.

The Scheme represented above for the conversion of tertiary arsine oxides by halogen derivatives enables the available data to be combined, considering them as different aspects of a single fairly complex and interconnected process, certain steps of which are worthy of further study. Processes of elimination, which frequently accompany nucleophilic substitution are of particular interest in this connection. The possibility of α- and β-elimination of alkoxyarsonium salts arising in the intermediate stage was investigated in special experiments using triphenylarsine oxide.[56] The detection of tertiary arsines, olefins and aldehydes in the reaction products indicates the need to take the side reactions into account although their contribution may prove to be small (~6–10%).

2. The retro-Arbuzov reaction with tertiary arsine sulphides

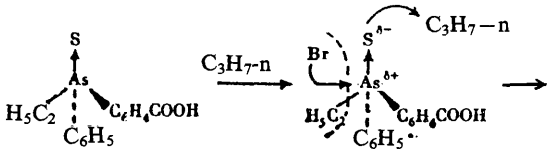
Tertiary arsine sulphides are the sole representatives of the thioarsenyl compounds for which the conversions occurring with a reduction in the valency of the arsenic atom have been investigated at the present time. This may explain the unsuccessful attempts to synthesise esters of tetracoordinated arsenic containing a $\rangle As(S)$ group, although here definite progress has been planned for some time past.[57–59]

The first information on the pyrolysis of tertiary arsine sulphides was published in 1966.[60] As was explained, the pyrolysis of diethylphenylarsine sulphide in a sealed tube and in vacuum leads to the formation of an isomerisation product in 6–9% yield.

$$(C_2H_5)_2C_6H_5AsS \xrightarrow{200-240^{\circ}\,C} (C_6H_5)(C_2H_5)AsSC_2H_5.$$

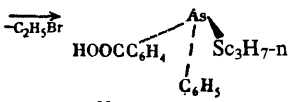
The thermal decomposition of trialkylarsine sulphides proceeds in a similar manner. On heating triethyl-, tripropyl- and methyldipropylarsine sulphides in vacuum at 200 °C for 1 h the corresponding esters of dialkylthioarsinous acids were obtained in 20–26.8% yield.[60,61] The isolation of other pyrolysis products was not reported although the formation of a complex reaction mixture was obvious, as on the pyrolysis of the oxides.

An investigation of the decomposition of triethylarsine sulphide by DTA with simultaneous recording of the conductivity change showed the presence of two exo effects.[61] The position of the first of them coincided in time with an increase in conductivity. It was concluded that heterolytic fission of an As–C bond occurred with the subsequent formation of a thioether.



$$(C_2H_5)_3AsS \xrightarrow{\Delta} [(C_2H_5)_2As^{\ominus}S + {}^{\oplus}C_2H_5] \rightarrow (C_2H_5)_2AsSC_2H_5.$$

Similar results were obtained on investigating the thermal isomerisation of tripropyl-, and methyldipropyl- and diethylphenylarsine sulphides by DTA.[5,8,61]



As was clarified by subsequent investigations the addition of small quantities (up to 0.1 mol) of alkyl halides and salts to tertiary arsine sulphides leads to an appreciable reduction in the temperature for the initiation of conversion.[5,8,62] The yield of product of the retro-Arbuzov reaction thereby grows significantly. The ester of

propylphenylthioarsinous acid was isolated in 60% yield by the reaction of a 1:1 ratio of ethyl bromide and dipropylphenylarsine sulphide at 100 °C for 2.5 h. Trialkylarsine sulphides are converted by alkyl halides into the corresponding thioesters in 25–67% yield.[8,62]

The retro-Arbuzov reaction was used for a series of tertiary arsine sulphides with the aim of obtaining asymmetric esters of the RR'AsSR'' type.[63] A change in the rotation of the initial (enantiomeric) sulphides to the opposite sign was recorded.

$[\alpha]_D^{20} + 19{,}12$

$[\alpha]_D^{20} - 3{,}18$

It should be noted that the esters of thioarsinous acids were not the only products isolated in the course of the retro-Arbuzov reaction with tertiary arsine sulphides. In several cases the formation was noted of the corresponding monohaloarsines as byproducts, the content of which grew with an increase in temperature, in contact time and on going from alkyl bromides to iodides.[5,8,62,64]

On reacting ethylphenyl-α-naphthylarsine sulphide with methyl iodide, diethyl-α-naphthylarsine, α-naphthyldiphenylarsine sulphide and free sulphur were isolated in addition to the corresponding ester of thioarsinous acid.[65]

The synthesis of the alkylthioarsonium salts formed as intermediates was carried out to confirm the two-stage nature of the retro-Arbuzov reaction.[66]

$$R_2R'AsS + AlkX \rightarrow [R_2R'AsSAlk]X,$$

R, R', Alk=C_2H_5, C_3H_7, C_4H_9, C_6H_5; X=Br.

The corresponding esters of thioarsinous acids were successfully obtained in up to 50% yield by the decomposition of these salts.

The retro-Arbuzov reaction was also observed for several tertiary arsine sulphides on using organic acids, their anhydrides and halogen derivatives as electrophilic reagents.[67,68]

$$Alk_2C_6H_5AsS + RC(O)X \longrightarrow [Alk_2C_6H_5AsSC(O)R]X \xrightarrow{-AlkX} \longrightarrow AlkC_6H_5AsSC(O)R,$$

Alk=C_2H_5, C_3H_7, C_4H_9; R=CH_3, C_2H_5, C_3H_7, CH_2Cl, $CHCl_2$, CCl_3; X=OH, RC(O).

When using carbon tetrachloride and alkyl chloroformates as electrophiles the authors also proceeded from an analogous reaction scheme.

$$R_2R'AsS + R''Cl \rightarrow [R_2R'AsSR'']Cl \rightarrow \rightarrow RR'AsSR'' + RCl,$$

R, R'=Alk, Ar; R''=CCl_3, $CH_2C(O)OCH_3$

A more complex character was noted for the conversions indicated requiring their further study.

The reaction of tertiary arsine sulphides with acid chlorides has been investigated in a fairly detailed manner.[69–71] On carrying out the reaction with acetyl chloride in a solvent, either the thioacetylarsine (VIII) (in benzene)[8] or the acetylthioarsonium chloride (VII) (in acetone) were formed.[8,70]

$$\underset{(VI)}{R_2R'AsS} + CH_3C(O)Cl \longrightarrow \underset{(VII)}{[R_2R'AsSC(O)CH_3]Cl} \xrightarrow{-RCl} \underset{(VIII)}{R_2R'AsSC(O)CH_3},$$

R=R'=C_2H_5, n-C_3H_7, n-C_4H_9; R'=C_6H_5, R=C_3H_7.

On carrying out the same reaction without a solvent, the corresponding chloroarsines and *S*-alkyl esters of thioacetic acid were isolated.[69]

$$\underset{(VI)}{(C_6H_5)Alk_2AsS} + CH_3C(O)Cl \rightarrow \underset{(IX)}{(C_6H_5)AsAlkCl} + \underset{(X)}{CH_3C(O)SAlk},$$

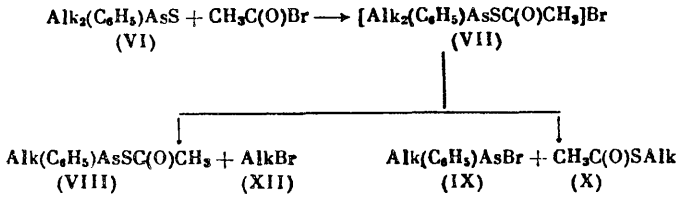
Alk=C_3H_7, C_6H_{13}.

No thioacetylarsines (VIII) were observed in the reaction products on repeatedly reproducing these experiments.[71] In this case a tertiary arsine dichloride (XI) was isolated in place of the intermediate (VII) and the corresponding chloroarsines (IX) in place of the thioacetylarsines (VIII).

$$\underset{(I)}{R_2R'AsS} + 2CH_3C(O)Cl \longrightarrow \underset{(XI)}{R_2R'AsCl_2} \xrightarrow[-RCl]{\Delta} \underset{(IX)}{RR'AsCl},$$

R=R'=C_2H_5, n-C_3H_7, iso-C_3H_7;

R=CH_3, C_2H_5, n-C_3H_7, R'=C_6H_5.



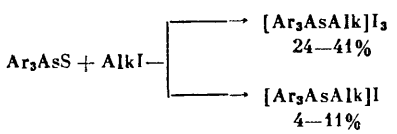
The formation of tertiary arsine dichlorides (XI) has been reported in a whole series of other cases.[72]

$$R_2R'AsS + R''Cl \rightarrow R_2R'AsCl_2,$$

R''=H, COCl, PCl_2, CH_2CN, $CH_2C(O)CH_3$, $C_6H_5C(O)$, $CH_2C(O)OCH_3$.

Considering that similar conversions are also known for teriary arsine oxides,[73] it may be proposed that here also a process alternative to the retro-Arbuzov reaction is taking place, occurring without changing the valency of the arsenic.

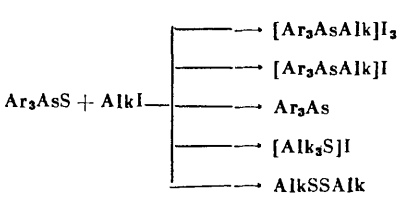
Reaction with acetyl bromide leads to the formation of a more complex mixture of products.[69,74]]



At a 1:1 ratio of starting materials the reaction occurs fairly energetically at room temperature and is completed by the formation of (VIII) and (X) contaminated with alkyl halide (XII). With a 2:1 excess of acetyl bromide and an increase in the contact time the reaction, in the authors' opinion, goes further so that it is not possible to isolate the thioacetylarsine (VIII) in the pure state or its yield is reduced. From this it was concluded that the haloarsine (IX) is formed by secondary conversions.

$$(VIII)+(XII)\rightarrow(IX)+(X)$$

In parallel to the investigations mentioned and independently of them the reaction of tertiary arsine oxides with alkyl halides has been studied by one further group of authors.[75–77]



Using as starting materials triarylarsines containing the more stable As–C_{Ar} bonds these authors showed that at an excess of alkyl iodide (1:8, acetone, boiling for 15–50 h) the reaction took place without a change in arsenic valency.

Ar=C_6H_5, $CH_3C_6H_4$;

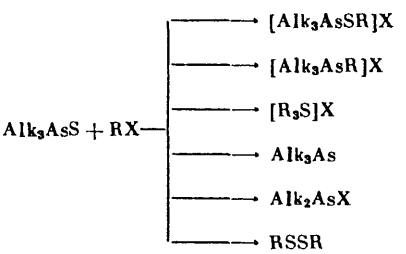
Alk=CH_3, C_2H_5, C_3H_7, $CH_2C_6H_5$, $CH_2C(O)OC_2H_5$.

One of the sulphur-containing products, trimethylsulphonium iodide, was successfully isolated in 6% yield in the case of triphenylarsine sulphide and methyl iodide. In addition it was suggested that dialkyl disulphides and tertiary arsines were present in the reaction mixture. The results of the reaction of triarylarsine sulphides with alkyl halides may be expressed by the following scheme.

It is important to note that in the experiments mentioned only the most reactive alkyl halides were used since the application of alkyl bromides led to the isolation of unreacted starting sulphide.

The trialkylarsine sulphides proved to be more reactive in alkylation reactions. Alkylthioarsonium salts are formed fairly rapidly on reaction under mild conditions.

$$Alk_3AsS+RX\rightarrow[Alk_3AsSR]X,\quad {}_{23-88\%}$$



Alk=C_2H_5, n-C_3H_7 cyclo-C_6H_{11};

R=CH_3, C_2H_5, n-C_4H_9; X=Br, I

Under more forcing conditions the quaternary arsonium salt, containing no sulphur, was isolated once again.

$$(C_2H_5)_3AsS+RI\rightarrow[(C_2H_5)_3AsR]I,$$
$$R=CH_3,\ C_2H_5.$$

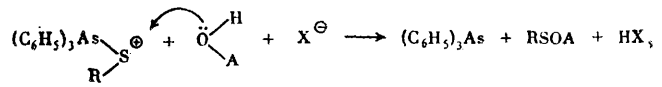
The impossibility of isolating the corresponding triiodides is explained by their solubility in the reaction mixture. Attempts to identify the sulphur-containing products gave no clear results. Only in the case of methyl iodide was trimethylsulphonium iodide successfully isolated from the reaction mixture. On reacting triethylarsine sulphide with n-propyl bromide a broad fraction was obtained containing, in the authors' opinion, bromodiethylarsine, triethylarsine and di-n-propyl sulphide. The data obtained indicate the formation of an even more complex mixture in the reaction of trialkylarsine sulphides with alkyl halides.

The crystalline reaction products were isolated and identified, the liquid products were not successfully separated. The formation of the latter was confirmed only indirectly. Quaternary arsonium salts may arise from trialkylarsines and sulphonium salts from dialkyl disulphides.

Comparison of the composition of the products isolated on alkylation of triaryl- and trialkylarsine sulphides indicates that these reactions have a general character. The main differences are the possibility of breaking the As–C bond in the case of trialkylarsine sulphides (haloarsine formation) and also the appearance in this case of the intermediately formed trialkyl(alkylthio)arsonium salts. Difficulties linked with the isolation of the analogous triaryl-(alkylthio)arsonium salts are explained by the authors by the stability of these salts due to the electron-accepting action of the phenyl groups and the high nucleophilicity of the anion. In fact triphenyl(ethylthio)arsonium tetrafluoroborate proved to be a completely stable compound. Addition of a carrier of more nucleophilic anions, such as sodium iodide, to a solution of this compound in acetone led to decomposition of the salt due to the reduction of its stability.

$$[(C_6H_5)_3AsSC_2H_5]BF_4+NaI\rightarrow[(C_6H_5)_3AsOH]I+$$
$$+[(C_6H_5)_3AsOH]I_3+(C_6H_5)_3As.$$

Similar observations enabled the important conclusion to be drawn that an alkylthioarsonium salt is stable if one of two factors are present. Either the anion has a low nucleophilicity or the substituents bound to the arsenic atom have a small electronegativity. This conclusion was confirmed by the synthesis of a whole series of fairly stable trialkyl- and triarylthioarsonium salts containing an anion of reduced nucleophilicity (BF_4^-, $CH_3SO_4^-$).



$$R_3AsS+[Alk_3O]^{\oplus}BF_4^{\ominus}\rightarrow[R_3AsSAlk]^{\oplus}BF_4^{\ominus}+Alk_2O,$$
$$R_3AsS+(CH_3)_2SO_4\rightarrow[R_3AsSCH_3]^{\oplus}CH_3SO_4^{\ominus},$$
$$R=CH_3,\ C_2H_5,\ C_3H_7,\ \text{cyclo-}C_6H_{11},\ C_6H_5;$$
$$Alk=C_2H_5,\ C_4H_9.$$

The preparation of a whole series of alkylthioarsonium halides and more stable representatives of these salts containing anions of reduced nucleophilicity was a turning point in the investigation of the features of carrying out the retro-Arbuzov reaction with tertiary arsine sulphides. The study of the structure and properties of the alkylthioarsonium salts was an important step in this investigation.[77,78] As was clarified, alkylthioarsonium salts in acetone behave as weakly associated electrolytes with fairly high specific conductivity values. This indicates their ionic structure. The action of nucleophiles depends on their nature and on the character of the environment of the arsenic atom. Thus trialkyl(alkylthio)arsonium salts are isolated unchanged after extended contact with water and alcohols at 50–60 °C. Triphenyl(alkylthio)arsonium tetrafluoroborates give triphenylarsine (70–97%) and the complexes 2 $(C_6H_5)_3AsO.HBF_4$ (40–82%) on hydrolysis and the complex $(C_6H_5)_3AsO.BF_3$ on alcoholysis.

Amines, being stronger nucleophiles, react fairly rapidly at ordinary temperatures irrespective of the environment of the arsenic atom.

$$[(C_6H_5)_3AsSC_2H_5]BF_4+(C_2H_5)_2NH\rightarrow(C_6H_5)_3As+\underset{85-89\%}{[(C_2H_5)_2NH_2]BF_4}$$
$$[(C_2H_5)_3AsSC_2H_5)Br+(C_2H_5)_3N\rightarrow\underset{90\%}{[(C_2H_5)_3NH]Br}$$

The authors considered the possibility of attack by the nucleophile at the sulphur atom

$$2RSOA\rightarrow RSSR+AOOA,$$
$$(C_6H_5)_3As+AOOA\rightarrow(C_6H_5)_3AsO+AOA,$$
if A = H, then $(C_6H_5)_3AsO+HX\rightarrow[(C_6H_5)_3AsO]_2HX.$

The notion of attack by the nucleophile at the sulphur atom is also attractive for explaining the results obtained on reacting tertiary arsine sulphides with alkyl halides.

Scheme 6

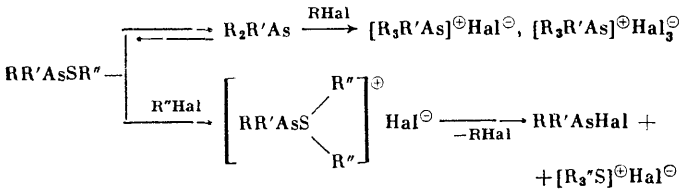
$$R_3AsS+R'I\rightarrow[R_3AsSR']^{\oplus}I^{\ominus}, \quad (1)$$

$$R'SI\rightleftharpoons[2R'S^{\cdot}+2I^{\cdot}]\rightleftharpoons R'SSR'+I_2,$$
$$R'SSR'+4RI\rightarrow2[R_3'S]^{\oplus}I^{\ominus}+I_2,$$
$$R_3As+I_2\rightarrow R_3AsI_2,$$
$$2R_3AsI_2\rightleftharpoons R_3As+[R_3AsI]^{\oplus}I_3^{\ominus},$$
$$R_3As+R'I\rightarrow[R_3R'As]^{\oplus}I^{\ominus}.$$

The proposed chain of reactions (Scheme 6) differs appreciably from the Scheme considered previously (see Section III, 2) except for stage (1) which is common..

Thus inconsistencies have been detected in relation to the interpretation of the routes of conversion of the alkylthioarsonium halides generated at the intermediate stage. In reality the results obtained indicate the conversion of the alkylthioarsonium salts to the corresponding thioesters in fairly high yield.[62–66] On the other hand the sequence of interactions proposed (Scheme 6), in which there is no place for thioesters, i.e. the route connected with the existence of the retro-Arbuzov reaction for tertiary arsine sulphides, is considered impossible.[75,76] From the point of view of one group of authors,[75,76] the main reaction products are quaternary arsonium salts $[R_3R'As]Hal$ or $[R_3R'As]Hal_3$ while the formation of such salts is not even mentioned in the communications of another group of authors.[62–66]

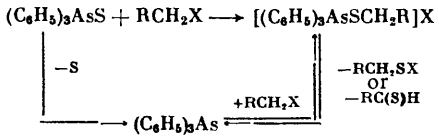
Nevertheless, as was clarified, the inconsistencies indicated were not differences in principle since the authors were investigating two sides of the same process. In each case attention was paid to the identification of either the liquid or the crystalline reaction proucts. In any event special investigations were necessary in order to resolve these inconsistencies.[10] It was shown by PMR spectroscopy using alkylthioarsonium tetrafluoroborates that the most probable place for nucleophilic attack in the alkylthioarsonium cation was not the sulphur atom but was the positively polarised carbon atom of the alkyl group on the arsenic.[79] In other words, the decomposition of the alkylthioarsonium salts must be effected as the second stage of the retro-Arbuzov reaction and leads to the formation of thioesters of thioarsinous acids. This posed the problem of finding a method capable of identifying the components of the complex reaction mixture containing derivatives of trivalent arsenic which are close in properties. Gas-liquid chromatography (GLC) was such a method. With the aid of GLC, the presence of esters of thioarsinous acids in the products of the reaction of tertiary arsine sulphides with alkyl halides was unequivocally confirmed and in addition one of the important properties of these esters, viz. their ability to disproportionate, was also confirmed.[80–83]



$$2RR'AsSR''\rightleftharpoons R_2R'As+R'As(SR'')_2,$$
$$3RAs(SR'')_2\rightleftharpoons R_3As+2As(SR'')_3,$$
$$R,\ R''=Alk,\ R'=C_6H_5$$

The formation of a tertiary arsine by the disproportionation of thioesters enabled the experimental data concerning the reaction of tertiary arsine sulphides with alkyl halides to be assessed in a new

way. The inconsistencies are successfully eliminated if it is assumed that the formation of the thioesters of arsinuous acids are the main course of the reaction.



$$R_2R'AsS+R''Hal \rightarrow [R_2R'AsSR'']^{\oplus}Hal^{\ominus},$$
$$[R_2R'AsSR'']^{\oplus}Hal^{\ominus} \rightarrow RR'AsSR''+RHal.$$

Secondary processes linked with the possibility of disproportionation of the thioesters formed or with their alkylation then follow. A similar disproportionation may be the reverse process with an unfavourable position of the equilibrium. However the presence of the alkyl halide binding the tertiary arsine into an insoluble arsonium salt shifts this equilibrium to the right.

The proposed Scheme for the conversions of tertiary arsine sulphides by alkyl halides[81,82] in contrast to that put forward previously[62,76] enables a large number of features of this reaction to be understood, including the reasons for the formation of arsonium and sulphonium salts in addition to the thioesters, and also of haloarsines and tertiary arsines. At the same time this Scheme must not be considered final. In any event it is impossible to extend it to triarylarsine sulphides which do not contain a relatively readily fissile $As-C_{Alk}$ bond and consequently may not be converted into the corresponding thioesters.

It is evident that as a minimum three alternative routes of conversion must be considered in this case.

The relatively high stability of the intermediates in the retro-Arbuzov reaction involving tertiary arsine sulphides enabled a more stepwise investigation of the kinetics of this conversion.[84–86] Conductiometry was used as the method for monitoring the running concentrations of the alkylthioarsonium salts. The high sensitivity of this method enabled investigation of areas of concentration uncomplicated by the reverse reaction and by secondary conversions.

As expected the partial order of the first step proved to be close to one and its overall order close to two. A change from acetone to the more polar dimethyl sulphoxide and propan-1-ol and also replacement of ethyl bromide by the iodide leads to an increase in the reaction rate. The data obtained were interpreted from the position of an S_N2 mechanism. Comparison of these data with the results of investigations of the kinetics of the conversions of tertiary arsine oxides by alkyl halides led to the recognition of the close similarity of the nucleophilic reactivity of the oxides and sulphides.[84] This fact is particularly interesting since the basicities of these two classes of compounds differ quite appreciably.

Later an investigation was carried out of the kinetics of the second stage of the reaction using the decomposition of triethylethylthioarsonium iodide and bromide in acetone.[85,86] Processing the experimental data when calculating the overall salt concentration in the solution did not enable a conclusion to be drawn between a first or second kinetic order for the reaction. In view of the conductimetric data indicating association of the alkylthioarsonium salts in solution,[77,78] the authors proposed that not all the salt, but only the fraction present as an ion pair, is subject to decomposition under the conditions investigated. Processing the results obtained according to a kinetic equation, in which the concentration of ion pairs is expressed through the dissociation constant,[87] confirms the proposals made. It is interesting that other investigators studying the kinetics of the decomposition of alkoxyphosphonium salts are also inclined to the conclusion of the possibility of association through hydrogen bond formation.[88]

IV. Conclusion

In conclusion it may be recorded that the numerous attempts to bring about the Arbuzov reaction in esters of trivalent arsenic acids proved to be unsuccessful. Ideas on the possibility of a simple and unequivocal carrying out of the first stage of this reaction with esters of dialkyl- and alkylphenylarinous acids have not been confirmed. In spite of the difference in interpretation of the routes of forming quaternary arsonium salts as one of the products of the conversions being considered, the conclusion on the appreciable reduction of the nucleophilic reactivity of the esters of trivalent arsenic acids in comparison with their phosphorus-containing analogues undoubtedly seems more important. The reason for this lies in the characteristics of the reaction centres and the differences in character of the effect of substituents in the derivatives of phosphorus and arsenic. This, together with the reduction in strength of the E(O) and E–C (E = P, As) bonds on going from phosphorus to arsenic and the enhanced lability of the As–OR bond, strictly limits the possibility of using the Arbuzov reaction in the chemistry of organoarsenic compounds. The unusually high nucleophilic reactivity of esters of trivalent phosphorus acids singles them out among similar derivatives along the period and group and also determines the amazingly unique nature of the Arbuzov reaction.

Conversions accompanied by a reduction in the degree of coordination of the central atom proved to be more characteristic of the organic derivatives of arsenic. The possibility of effecting a retro-Arbuzov reaction among the oxides and sulphides of tertiary arsines is determined by the special features of the arsenic–heteroatom bond, by its strength, by the basicity of the initial nucleophile and by the presence in them of an $As-C_{Alk}$ bond capable of fission. The investigation of the general rules and distinctive features of these conversions and the reactions accompanying them as a function of the environment of the arsenic atom, of the nature of the electrophilic reagent and the reaction conditions, indicates the complexity of the processes taking place and the need for their further study. Inconsistencies emerging in the first stages of the investigations in this field may be connected with the fact that in a large number of studies either the liquid or the crystalline products of the reaction were examined preferentially, which could not possibly give a complete picture. Investigations in recent years have shown the possiblity of effecting a retro-Arbuzov reaction among tertiary arsine oxides containing just one alkyl group

in the environment of the arsenic atom. The isolation of byproducts from this reaction, such as haloarsines and hydroxyarsonium salts, enabled the character of the processes occurring to be linked with the environment of the arsenic atom. The more basic trialkylarsine oxides react predominantly in the direction of dehydrohalogenation of the electrophilic reactant. The retro-Arbuzov reaction occurs as a competing reaction on going to the less basic oxides of dialkylphenyl- and alkyldiphenylarsines. Due to the absence of alkyl groups capable of fission triphenylarsine oxide reacts as a base under these conditions.

The retro-Arbuzov reaction may be considered as the main process for tertiary arsine sulphides, complicated by secondary conversions of the thioesters formed. The necessary conditions for the retro-Arbuzov reaction are here the participation of a soft electrophile, alkyl halide, and the presence in the initial sulphide of at least one $As-C_{Alk}$ bond. In the case of harder chlorine-containing electophiles (hydrogen chloride, acetyl and benzoyl chlorides), chloroacetonitrile, chloromethyl methyl ether, etc.) the reaction may proceed without a change in the degree of coordination of the arsenic atom and is completed by the formation of tertiary arsine dichlorides or the products of their thermal decomposition, viz. the corresponding chloroarsines.

Elemental phosphorus-strong base as a system for the synthesis of organophosphorus compounds

B A Trofimov, T N Rakhmatulina, N K Gusarova, S F Malysheva
The Institute of Organic Chemistry of the Siberian Section of the Academy of Sciences of the USSR, Irkutsk

ABSTRACT. A systematic review is presented on the reactions of elemental phosphorus with organic compounds in the presence of base, proceeding via polyphosphide and polyphosphinite anions. Particular attention has been paid to new effective methods of activating red phosphorus by superbase complexes, formed from alkali metal hydroxides and polar, non-hydroxylic solvents (HMPA, DMSO, DMF, triethylphosphine oxide), by the sodium/liquid ammonia system, or under phase transfer catalysis. The direct phosphorylation of organic halides, activated alkenes, acetylenes and oxiranes is also discussed.

The bibliography contains 92 references.

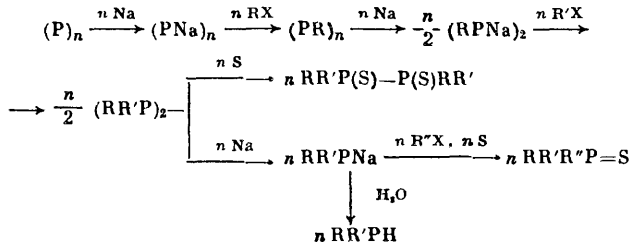
I. Introduction

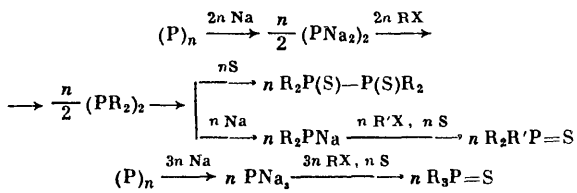
Organophosphorus compounds occupy an important place in the chemistry of elementoorganic compounds. Their influence on living organisms is well known,[1] and a wide spectrum of organophosphorus compounds has been prepared for use as extractants,[2,3] antipyretics[4,5] and emulsifiers,[6,7] as fuel additives and in lubricating materials,[8,9] as plasticizers,[10,11] and as biologically active agents for medicinal and agricultural application.[12,13] Triorganophosphines and -phosphine oxides have also been used, and are currently being developed, as effective ligands for complex metal catalysts.[10,14–16]

Organophosphorus compounds with a P–C bond are usually prepared from phosphorus halides or phosphines, which are toxic and ecologically unsuitable for industrial-scale syntheses. Furthermore, it is reported that many important organophosphorus compounds prepared from phosphorus chlorides have been threatened with liquidation because "hydrogen chloride, a by-product, corrodes steel apparatus and leads to the formation of a number of poisonous compounds in the aqueous effluent. For each ton of useful product, around six tons of effluent are produced, the refinement of which is sometimes more costly than that of the product itself".[17]

In view of this, the synthesis of organophosphorus compounds from elemental phosphorus (primarily from non-toxic and non-flammable red phosphorus) has attracted far more interest both from the point of view of the simplicity of the procedures and the fact that organophosphorus compounds can be prepared by this means in one step. The ecological advantages of this methodology also enhances the marketability of organophosphorus compounds in the difficult times which the economy faces.[17]



Information published prior to 1979 on the reactions of elemental phosphorus with organic compounds has been covered systematically in five short reviews.[18–22] It is pointed out in these that classical phosphorylation is normally carried out with white phosphorus at high temperatures (200–400 °C), i.e. under conditions for radical initiation.

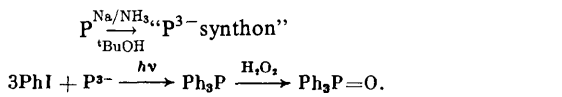


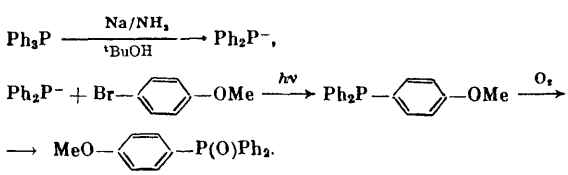
In the present review we have surveyed data on the reactions of elemental phosphorus with electrophilic agents in the presence of strong base. This relates to information published in the last 10–15 years, during which time a number of novel and effective routes to organophosphorus compounds (notably organic phosphines and phosphine oxides) have been developed. Among these new procedures for phosphorylation, much attention has been paid to syntheses with red phosphorus, which may be activated by superbases, such as Na/liquid ammonia,[23–25] alkali metal hydroxide in polar, non-hydroxylic solvent (e.g. HMPA, DMSO),[26–28] or under phase transfer catalysis.[28–30] It should be emphasised that the superbase system, KOH–DMSO (or KOH–HMPA), has already been successfully utilised for direct chalcogenation with elemental sulphur and metallic selenium or tellurium. Here, the superbasic hydroxide ion reacts with the chalcogen to generate the milder, more nucleophilic chalcogen anions, which react subsequently with suitable electrophiles (notably acetylenes).[31–33]

II. Reactions of elemental phosphorus with organic halides in superbasic systems

In 1966, Bogolyubov and Petrov published for the first time a general procedure for carrying out reactions of red phosphorus with organic halides in the presence of the classical superbasic system, Na/liquid ammonia.[23,24] This resulted in the development of new routes to organic phosphines and their derivatives. Depending on the proportion of the reactants, the process takes place with the

participation of polyphosphide anions, according to the following generalised scheme:[23]





R=Me, Et, $PhCH_2$; X=Cl, Br, I.

The products are obtained in 17–34% yield.

Continuing this theme, the direct phosphorylation of aryl halides with red phosphorus was subsequently carried out with the system, Na/liquid ammonia, under UV-activation.[25] As a result, an effective route to symmetrical and unsymmetrical triarylphosphine oxides has been developed. Thus, triphenylphosphine oxide was obtained in 75% yield from iodobenzene and red phosphorus, followed by oxidation of the intermediate triphenylphosphine with hydrogen peroxide.[25]

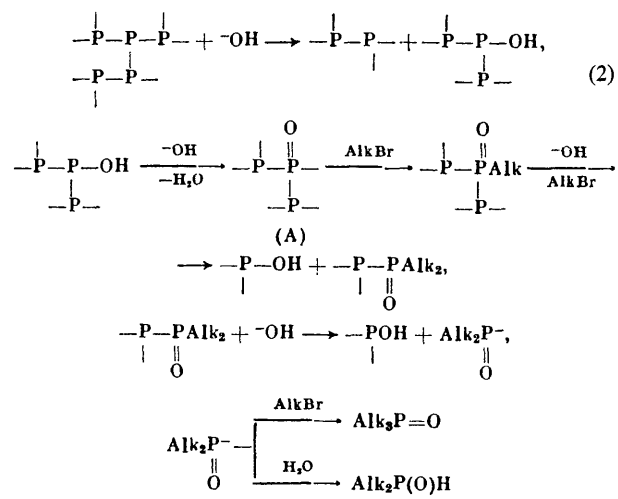
p-Anisyldiphenylphosphine oxide was prepared in 55% yield by treatment of triphenylphosphine with *p*-bromoanisole in the system, Na/liquid ammonia, under irradiation on exposure to air.[25]

The authors of this research[25] did not provide additional supporting evidence in favour of the ion-radical mechanism which they proposed. There was no reference to an earlier finding that there is a noticeable increase in the rate of the reaction of diphenylphosphide[34] and diphenylphosphinite ion[35] with aryl halides on UV-irradiation in the systems, potassium *tert*-butoxide/liquid ammonia and potassium *tert*-butoxide/DMSO.

The same authors[25] also consider that an ion-radical mechanism prevails for the reaction of aryl halides with elemental arsenic and antimony on UV-irradiation in the system, Na/liquid ammonia. The yield of triphenylarsine and triphenylstibine by this procedure was 75% and 40%, respectively. No indication was given by the authors[23–25] of the manner in which they calculated the product yield.

Superbases generated under phase transfer catalysis (50–60% aqueous solution with an organic solvent in the presence of a phase transfer catalyst)[36,37] have been used for the synthesis of trialkylphosphine oxides from alkyl halides and red phosphorus.[28,29,38,39] The reaction also produces a small amount of the corresponding dialkylphosphinous acid.[29]

R = Et, *n*-Pr, *n*-Bu, *n*-Am, n-C_8H_{17}; X = Cl, Br, I. (1)



Under optimum conditions (on heating at 93–95 °C for 6–7 h with dioxane as the organic solvent), the yield of trialkylphosphine oxides was 60–65% (based on the alkyl halide).[28]

In studying the above reaction with butyl halides, it was found that butyl bromide was the most suitable substrate. The yield of tributylphosphine oxide was noticeably less with butyl chloride under the same conditions, while butyl iodide reacted with red phosphorus to give a low yield of tetrabutylphosphonium iodide.[29]

It should be stressed that tiralkylphosphines were not detected among the products of reaction (1), even on carrying out the conversion under argon.

Evidently, the interaction of alkyl bromides with the system, P–KOH–H_2O, proceeds with the participation of the polyphosphinite anion (A), formed by cleavage, with hydroxide ion, of a P–P bond of the irregular trimeric phosphorus clusters which unite the red phosphorus macromolecule.[40]

On heating benzyl chloride with red phosphorus in the system, KOH–DMSO (or KOH–HMPA), at 70–80 °C, tribenzylphosphine oxide (I) was isolated as the main product in 30% yield

(based on benzyl chloride), together with small amounts of tribenzylphosphine (II) and tetrabenzylphosphonium chloride (III).[41]

$$PhCH_2Cl + P \xrightarrow{KOH/DMSO} \underset{(I)}{(PhCH_2)_3P{=}O} + \underset{(II)}{(PhCH_2)_3P} + \underset{(III)}{[(PhCH_2)_4P^+]Cl^-}. \quad (3)$$

The process is thought to involve generation of polyphosphide ions by action of the superbase on red phosphorus, followed by reaction with benzyl chloride. This leads to tribenzylphosphine (II), which is then quaternized with a further molecule of benzyl chloride to give the phosphonium chloride (III) prior to its reaction with base to give the phosphine oxide (I). Toluene, eliminated in the final step of the reaction was identified by g.l.c.[29]

$$P_n + {}^-OH \rightarrow P_m^- + P_k{-}OH,$$

$$P_m^- + 3PhCH_2Cl \longrightarrow (PhCH_2)_3P_m \xrightarrow[-P_{m-1}]{} \underset{(II)}{(PhCH_2)_3P} \xrightarrow{PhCH_2Cl} \underset{(III)}{[(PhCH_2)_4P^+]Cl^-} \xrightarrow{KOH} [(PhCH_2)_4P^+]OH^- \xrightarrow[-PhMe]{} \underset{(I)}{(PhCH_2)_3P{=}O}.$$

Since only traces of dimethyl sulphide were detected during the course of the reaction, it can be assumed that the phosphine oxide (I) is not formed from the corresponding phosphine (II) by oxidation with DMSO.[29]

The selectivity and efficiency of conversion (3) can be increased by carrying out the reaction in the 3-phase system comprising red phosphorus, aqueous KOH, dioxane, and benzyltriethylammonium chloride at 94–96 °C. The yield of the phosphine oxide (I) under these conditions increases to 50% on complete conversion of phosphorus.[28,42]

Heating allyl halides with red phosphorus at 60–65 °C in the system, KOH–H_2O–THF containing benzyltriethylammonium chloride, affords *tris*-(*E*-propen-1-yl)phosphine oxide as well as the expected *tris*(propen-2-yl)phosphine oxide.[28,29,43,44]

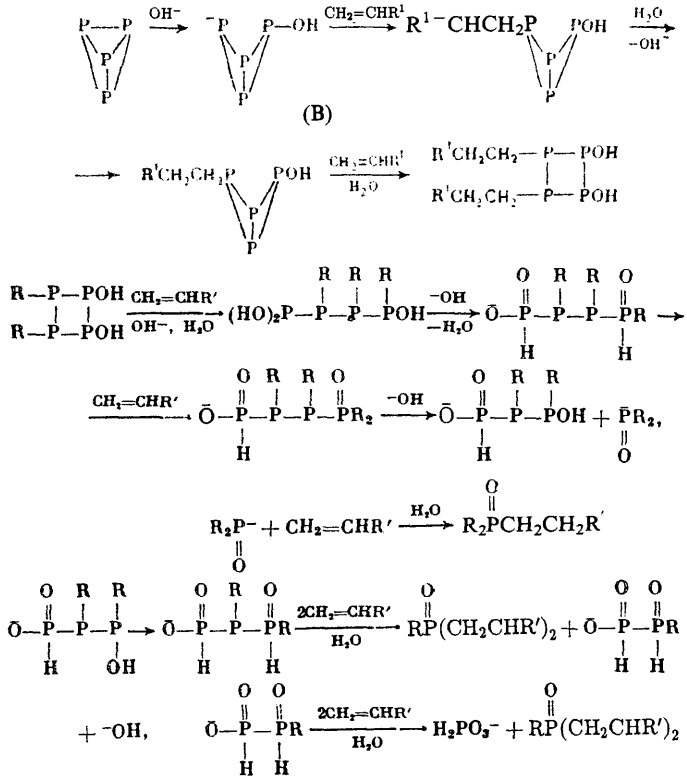
$$CH_2{=}CHCH_2X + P \xrightarrow{KOH/H_2O} \underset{35\%}{(E\text{-}MeCH{=}CH)_3P{=}O} + \underset{30\%}{(CH_2{=}CHCH_2)_3P{=}O}$$

X=Cl, Br.

1,1-Dialkoxy-2-bromoethanes also serve as electrophile. Thus, heating these compounds in the system, P–KOH–DMSO, at 70–100 °C in the presence of a small amount of water provides the corresponding *tris*(2,2-dialkoxyethyl)phosphine oxide in up to 15% yield. The products are potentially useful synthons, having three protected aldehyde functions.[45]

$$(RO)_2CHCH_2Br + P \xrightarrow{KOH/H_2O} [(RO)_2CHCH_2]_3P{=}O$$

R = Et, *n*-Bu



A brief reference has been made to the alkylation of red phosphorus with butyl bromine in the superbasic system, KOH–hydrazine hydrate.[46] When the molar proportion of P : KOH : BuBr is 1 : 12 : 3, reaction proceeds on heating at 80–85 °C, and is reported to lead, not only to tributylphosphine oxide, but also to a small proportion of tributylphosphine. The latter evidently forms by reduction of the phosphine oxide with hydrazine hydrate. Further products were also isolated in 8 and 1.4% yield (based on butyl bromide), but, unfortunately, these were unidentified.

III. Phosphorylation of alkenes with elemental phosphorus in the presence of base

Some interesting results have been obtained by studying the reaction of white phosphorus with acrylonitrile and acrylamide in the presence of KOH.[47] The reaction was conducted at –5 to 35 °C in a system containing an organic solvent (acetonitrile) and 10 N aqueous KOH under an inert atmosphere. The principal products of the reaction were *tris*(2-cyanoethyl)phosphine oxide and *tris*(2-carbamoylethyl)phosphine oxide, the optimum yields of which were 53 and 74%, respectively (based on phosphorus).

$$P_4 + 2KOH + 4H_2O + 9CH_2{=}CHR \rightarrow 3(RCH_2CH_2)_3P{=}O + K_2HPO_3,$$
R=CN, $CONH_2$.

In the opinion of the authors,[47] reaction is initiated by attack of hydroxide ion on the tetrahedral white phosphorus clusters to give the phosphide anion (B), which then undergoes Michael addition to the activated double bond of the starting alkene:

R=CH_2CH_2R', R'=CN or $CONH_2$.

Subsequently, the same reaction was performed with *N*-alkyl- and *N,N*-dialkyl-acrylamides to give the corresponding *N*-substituted *tris*(2-carbamoylethyl)phosphine oxides in 45–87% yield (based on phosphorus).[48]

$$P_4+2KOH+4H_2O+9CH_2=CHCONR^1R^2\rightarrow$$
$$\rightarrow 3(R^1R^2NCOCH_2CH_2)_3P=O+K_2HPO_3,$$
$$R^1=Me,\ R^2=H\ (45\%);\ R^1=R^2=Et\ (87\%);$$
$$R^1=R^2=CH_2CH=CH_2\ (72\%);\ R^1-R^2=(CH_2)_4\ (75\%);$$
$$R^1-R^2=(CH_2)_5\ (84\%).$$

Vinyldiorganophosphine oxides and sulphides,[48] and dialkyl vinylphosphonates,[49] also undergo Michael addition with phosphide ions (generated from yellow phosphorus and KOH) under mild conditions (25–30 °C) to give the corresponding functionalised phosphine oxide (in 50–100% yield).

$$P_4+KOH+H_2O\xrightarrow{R_2P(X)CH=CH_2}[R_2P(X)CH_2CH_2]_3P=O$$
$$\xrightarrow{(AlkO)_2P(O)CH=CH_2}[(AlkO)_2P(O)CH_2CH_2]_3P=O$$
$$R=Alk,\ Ar;\ X=O,\ S.$$

Recently, it was found that styrene and 4-vinylpyridine may also be phosphorylated with red phosphorus in the system, KOH–DMSO or KOH–HMPA.[50,51] Thus, the phosphorylation of styrene at 75–125 °C affords *tris*(2-phenylethyl)phosphine oxide (IV) in 65% yield (based on styrene) together with a small amount of *bis*(2-phenylethyl)phosohinous acid (V).[28,50]

$$P+PhCH=CH_2\xrightarrow[KOH/DMSO/H_2O]{KOH/HMPA/H_2O}\underset{(IV)}{(PhCH_2CH_2)_3P=O}+$$
$$+\ \underset{(V)}{(PhCH_2CH_2)_2P(O)H}. \qquad (4)$$

For the above reaction, the system, KOH–HMPA–H_2O, is somewhat more effective than the system, KOH–DMSO–H_2O. However, the base generated in the system, 70% aqueous KOH–dioxane– benzyltriethylammonium chloride, is not strong enough to activate the process, only traces of (IV) being detected. Neither the standard radical initiator, azodiisobutyronitrile, nor the radical quencher, hydroquinone, have any effect on the reaction. Evidently, a polyphosphinite anion is involved in the formation of (IV) and (V), i.e. the reaction takes place in the same manner as the previously described phosphorylation of alkyl halides, as outlined in scheme (2).[29]

4-Vinylpyridine reactions in the same way with red (or white) phosphorus in the system, KOH–DMSO–H_2O, leading to *tris*-[2-(4-pyridyl)ethyl]phopshine oxide in 20% yield.[51]

In spite of the lowish yields, the method described above is of preparative value since, at present, there are no other available routes to functionalised phosphine oxides, which are key synthetic intermediates and synthons.

IV. The interaction of elemental phosphorus with alkynes in the presence of superbase

By studying the reactions of phenylacetylene, it was shown for the first time that red phosphorus interacts with acetylenes on heating (at 60–90 °C) in the system, alkali metal hydroxide-polar (non-hydroxylic) solvent (HMPA, DMSO, DMF, Et_3PO), as well as under phase transfer catalysis (aqueous alkali metal hydroxide-organic solvent-phase transfer catalyst). Thus, phenylacetylene affords *tris*(*Z*-styryl)phosphine (VI) in up to 44% yield (based on the alkyne) together with a small amount of *tris*(*Z*-styryl)phosphine oxide (VIII).[26–28,39,44,52–58]

$$PhC\equiv CH+P\xrightarrow{KOH/H_2O}\underset{(VI)}{(Z\text{-}PhCH=CH)_3P}+$$
$$+\ \underset{(VII)}{(Z\text{-}PhCH=CH)_3P=O}.$$

Evidently, reaction involves attack of the triple bond by polyphosphide anion, P_m^- generated from red phosphorus and the superbase.[28]

$$P_n+{}^-OH\rightarrow P_nOH+P_m^-,$$
$$P_m^-+HC\equiv CPh\longrightarrow P_mCH=\bar{C}Ph\xrightarrow[-OH^-]{H_2O}P_mCH=CHPh\xrightarrow[-P_kOH]{-OH}$$
$$\longrightarrow PhCH=CHP_g^-\xrightarrow[H_2O]{PhC\equiv CH}(PhCH=CH)_2P_g\xrightarrow[-P_hOH]{OH^-}$$
$$\longrightarrow (PhCH=CH)_2P_e^-\ \text{etc.}$$

According to ^1H and ^{31}P NMR spectroscopic data, all the styryl groups in (VI) and (VII) are in the *Z*-configuration, i.e. of the four possible stereoisomers, only the *Z,Z,Z*-isomer is formed. This would be anticipated as *trans*-nucleophilic addition to triple bonds in the norm.[28]

For the phosphorylation of phenylacetylene, the 2-phase systems, KOH–DMSO, KOH–Et_3PO and KOH–DMF, and the 3-phase system comprising red phosphorus, 50–70% aqueous KOH and an organic solvent (THF, toluene, dioxane), with or without benzyltriethylammonium chloride,[28] are less effective than the system, KOH–HMPA. Replacement of KOH by NaOH under the same conditions leads to a clear (3-fold) decrease in the yield of (VI).

At the same time, the activity of red phosphorus towards phenylacetylene is enhanced on ultrasonic irradiation in the presence of a strong base. Under these conditions, reaction takes place without external heating, and the yield of (VI) is increased by 50% while the reaction time is reduced to 1 h.[52]

The reaction of phenylacetylene with red phosphorus proceeds equally well under inert atmosphere and on exposure to air. The yield of the phosphine oxide (VII) is always around 2–4%.[28]

Naturally, the question arises: why is it that phenylacetylene affords the corresponding phosphine (VI) almost exclusively, while, under the same conditions, styrene and 4-vinylpyridine afford predominantly the corresponding phosphine oxide? In the original publications,[26,28,50,51] there was no comment on this anomaly. One possible explanation is the competing behaviour of the two different types of P-nucleophile (i.e. the polyphosphide and polyphosphinite anions). With alkynes, the polyphosphide anion is more complementary (according to the principle of hard and soft acid and

base), while the polyphosphinite anion (A) is more complementary with alkenes.

More recently, phosphorylation of acetylene with red phosphorus was carried out under pressure at 105–115 °C in the system, KOH–hydrazine hydrate–aqueous HMPA.[46] Trivinylphosphine was identified in the reaction product by chromato-mass spectrometry. A 10% yield was quoted, but the method by which the yield was calculated was not given. It was not possible to isolate the product nor characterise it further.[46]

V. Reactions of elemental phosphorus with oxygen- and sulphur-containing compounds in the presence of base

By studying the reactions of α-aminoalcohols, Maier was first to demonstrate that white phosphorus reacts with such compounds by an ionic mechanism via intermediate formation of polyphosphide and polyphosphinite ions.[59,60] Almost equal amounts of the corresponding *tris*(dialkylaminomethyl)phosphine oxide (VIII), *bis*(dialkylaminomethyl)phosphinic acid (IX), and dialkylaminomethylphosphonic acid (X) were obtained in a total yield of 90% (based on phosphorus).

$$2P_4+20R_2NCH_2OH \rightarrow 5(R_2NCH_2)_3P{=}O+$$
(VIII)
$$+2(R_2NCH_2)_2P(O)OH+R_2NCH_2P(O)(OH)_2+8H_2O.$$
(IX) (X)

$R_2N = Me_2N$, Et_2N, C_4H_8N, $C_5H_{10}N$, $CH_2CH_2OCH_2CH_2N$, $(n\text{-Bu})_2N$, $(cyclo\text{-}C_5H_{11})_2N$.

It was not possible to carry out this reaction with red phosphorus.[60]

Later, a series of publications appeared on the interaction of white phosphorus with alcohols and alkali metal alkoxides in carbon tetrachloride at 50–60 °C under N_2, leading to the formation of trialkyl phosphites as the main product (in 70–80% yield), together with small amounts of trialkyl phosphates and dialkyl alkanephosphonates (in up to 10% yield).[61–66]

$$P_4+ROH+ROM+CCl_4 \rightarrow (RO)_3P+(RO)_3P{=}O+(RO)_2P(O)R,$$
M – alkali metal, R = Alk.

This reaction involves initial nucleophilic attack of the P–P bond of the phosphorus cluster with alkoxide, as proposed by Brown, et al.[66]

$$P_4+6RO^-+6ROH+6CCl_4 \rightarrow 4(RO)_3P+6CHCl_3+6Cl^-.$$

The reaction of white phosphorus with sodium alkylmercaptides in the presence of the corresponding mercaptan and an excess of CCl_4 proceeds in a similar way at room temperature. Trialkyl trithiophosphites were thus obtained in high yield.[67,68]

$$P_4+6RSH+6RSNa+6CCl_4 \rightarrow 4(RS)_3P+6CHCl_3+6NaCl,$$
R = Et, *n*-Bu.

The corresponding dialkyl disulphides and *tris*(alkylthio)methanes were formed as by-products.

The reaction of white phosphorus with alkali metal phenoxide and CCl_4 in an aprotic dipolar solvent (DMF at 0–100 °C under a dry, inert atmosphere) leads to a mixture of organophosphorus compounds, of which the main component is triphenyl phosphite (70% yield).[69]

$$P_4+PhOM+PhOH+CCl_4 \rightarrow (PhO)_3P+ClCH_2P(OPh)_2+$$
$$+Cl_2CHP(OPh)_2+[(PhO)_2P]_2CH_2,$$
M – alkali metal.

Recently, Ivanov, et al. extended this reaction to other phenols (in the presence of the corresponding phenoxide), and found that the composition and yield of product depends on the acidity of the phenol and the nature of the ring substituent.[70] Phenols with a pK_a in the range 9–11 participate in this reaction.

A number of patents has appeared on the reaction of phosphorus (white or yellow) with alcohols and epoxy compounds in the presence of a catalyst (alkali or alkaline earth hydroxide or alkoxide) at 25–200 °C.[71–76] The products of the reaction have P–H, P–C and P–O linkages in varying proportion, the molecular formula approximating to $(RO)_{3-n}PR'_n$ (where R is an alkyl radical from the alcohol, and R′ = H or a ZOH residue, where Z represents an alkylidene (–C–C–) residue formed by cleavage of the epoxide). These products are potentially useful for the preparation of surface-active compounds and as epoxy resin hardeners.

White phosphorus reacts with alkene oxides in the presence of compounds with an acidic hydrogen and metal alkoxides (or amides) to give phosphorus-containing polyols.[77–79] This reaction was studied in more detail by Ivanov, et al.,[80] who found that a mixture of P_4, propylene oxide, Me_3N and HX (HX = $MeCO_2H$, PhOH, MeC_6H_4OH, H_2O, ^{t}BuOH) in 1 : 5 : 0.8 : 1 proportion leads to the formation of oligomers containing the fragment C–C–P(O)–O as repeating unit.

By studying the reactions of propylene oxide and [2-(vinyloxy)-ethoxy]methyloxirane, it was shown for the first time that epoxides may react with the less toxic, and more convenient, red phosphorus. Phosphorylation proceeds effectively in the 3-phase system comprising red phosphorus, 50% aqueous KOH and an organic solvent (dioxane, toluene or THF) in the presence of benzyltriethylammonium chloride at 60–93 °C. The resulting phosphorus-containing polyols were shown to have structures (XI–XIV) from ^{31}P NMR and IR spectroscopic data, and by elemental analysis.[81,82]

$$P + R^1\text{–}\underset{O}{\text{CH}}\text{–}\text{CH}_2 \rightarrow R^2_{3-n}P(O)[(CH_2CHO)_mH]_n \quad (5)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad R^1$$
(XI)–(XIV)

(XI): R^1 = Me, R^2 = H, n = 2, m = 3;

(XII): R^1 = Me, R^2 = OK, n = 2, m = 4;

(XIII): $R^1 = CH_2{=}CHO(CH_2)_2OCH_2$, R^2 = OK, n = 2, m = 1;

(XIV): $R^1 = CH_2{=}CHO(CH_2)_2OCH_2$, R^2 = OK, n = 1, m = 4.

As seen with the formation of (XIII) and (XIV), the vinyloxy group remains intact, which further supports the anionic (nucleophilic) character of the reaction.[81] Our finding that butyl vinyl ether remains inert to the above phosphorylation is consistent with this view.

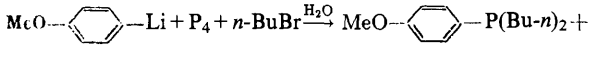
VI. Reactions of elemental phosphorus with organometallic compounds

Carbanions of certain organometallic compounds may also be used to generate polyphosphide anions from elemental phosphorus.[83–91] This was first demonstrated by Rauhut, et al., who studied the interaction of white phosphorus with phenylmagnesium bromide or phenyllithium at 25–40 °C in diethyl ether or THF, followed by treatment with water.[83] Among the products of the reaction, the following were identified: phenylphosphine (in 40% yield based on the conversion of phosphorus); small amounts of diphenyl- and triphenyl-phosphine; and organopolyphosphines, being insoluble, amorphous compounds with a yellow colouration.[83]

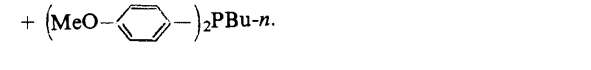
$$P_4 \xrightarrow{\text{PhMgBr, PhLi}} \xrightarrow{H_2O} PhPH_2 + Ph_2PH + Ph_3P + Ph_mH_{3-m}P_n,$$

$m=1-3$.

Later, Kaabak, et al. discovered suitable conditions (240–250 °C) for increasing the selectivity and efficiency of this reaction.[84] Thus, triarylphosphines were obtained in 70–83% yield (based on phosphorus) from white phosphorus and arylmagnesium iodides.[84]



$$P_4 + RMgI \xrightarrow{H_2O} R_3P,$$
$$R=Ph,\ 4\text{-}MeC_6H_4.$$

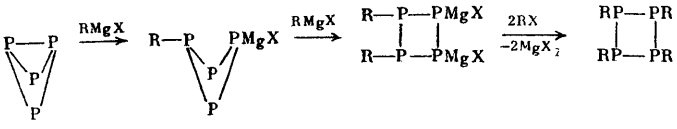


The same authors developed a method of preparing *tris*(*sec*-alkyl)phosphine oxides (in 57–82% yield) by heating white phosphorus with *sec*-alkyl halides and Mg (or Zn) at 120–210 °C, followed by treatment of the mixture with base at 270 °C.[85]

Unsymmetrical tertiary phosphines may be obtained under mild conditions (20–50 °C in an inert organic solvent) by the simultaneous treatment of white phosphorus with an organometallic compound and an alkyl halides.[86,87] The main products from the reaction of white phosphorus with butyl halide and phenyl-lithium or -sodium are dibutylphenyl- and butyldiphenyl-phosphine, obtained in 20–44% yield (based on phosphorus).[86] In certain instances, small amounts (8–11%) of butyldiphenylphosphine oxide were also detected.[86]

$$PhM + P4 + n\text{-}BuHal \xrightarrow{H_2O} PhP(Bu\text{-}n)_2 + Ph_2PBu\text{-}n +$$
$$+\ Ph_2P(O)Bu\text{-}n,$$
$$M=Li, Na;\quad Hal=Cl, Br.$$

The reaction of white phosphorus with 4-methoxyphenyllithium and butyl bromide proceeds in a similar way, though less efficiently, to give dibutyl(4-methoxyphenyl)phosphine and butyl-*bis*(4-methoxyphenyl)phosphine (in 15 and 20% yield, respectively).[87]



At the same time, it was found that only trace amounts of the expected di- and tri-butylphosphine were formed by using butylmagnesium bromide as the organometallic compound. The main product of this reaction was tetrabutylcyclotetraphosphine (42% yield).[86]

$$P_4 + 2n\text{-}BuMgBr + 2n\text{-}BuBr \rightarrow \begin{matrix} n\text{-}BuP-PBu\text{-}n \\ | \quad | \\ n\text{-}BuP-PBu\text{-}n \end{matrix}$$

The authors consider that the reaction proceeds as follows:[86]

R = Alk.

Later, it was shown that other tetraalkylcyclotetraphosphines, e.g. $(EtP)_4$ and $(n\text{-}PrP)_4$, were obtainable by this route.[87]

However, the reaction of white phosphorus with isopropylmagnesium bromide or cyclohexylmagnesium bromide and the corresponding alkyl bromide proceeds by a quite different pathway, leading to products of composition R_2P_8 (R = isopropyl, cyclohexyl).[88]

Comparatively recently, unambiguous evidence was provided for the formation of polyphosphide ions from white phosphorus and methyllithium. Thus, organopolyphosphines (XV–XVII) were obtained by quenching intermediate polyphosphide ions with trimethylsilyl chloride or methyl bromide.[89]

$$P_4 + LiMe \rightarrow Li_3P_7 + Li_2P_7Me + LiP_7Me_2 \rightarrow$$

$$\xrightarrow{Me_3SiCl} P_7(SiMe_3)_3 + P_7(SiMe_3)_2Me$$
(XV) (XVI)

$$\xrightarrow{MeBr} P_7Me_3$$
(XVII)

Alkali metal pentaphosphides were also obtained by interaction of white phosphorus with Na (or Li) in diglyme or THF in the presence of a phase transfer catalyst (18-crown-6).[90]

References have been given in the patent literature to the formation of lithium aminophosphides, (XVIII) and (XIX), by heating white phosphorus with butyllithium and dialkylamines in benzene.[91,92] The two products were

$$P_4 + n\text{-}BuLi + R_2NH \rightarrow R_2NPLi_2 + (R_2N)_2PLi,$$
(XVIII) (XIX)
$$R=Me,\ Et.$$

obtained in quantitative yield.

Attempts to carry out the reaction of organometallic compounds (methylmagnesium iodide and diethylzinc) with red phosphorus met with failure.[40]

---o0o---

Simple, convenient, and efficient routes to triorganophosphines and -phosphine oxides (including unsaturated derivatives) have been developed, based on the novel activation of red phosphorus by multi-phase superbasic systems (e.g. KOH–HMPA, KOH–DMSO, 50–70% aqueous KOH–organic solvent–phase transfer catalyst).[9,26–30,41–45,50–58,81] This method is currently being developed broadly. In particular, technological aspects of these processes are being improved, and the search continues for suitable electrophiles for redox phosphorylation with red phosphorus.

Synthesis of spiro[piperidine-4,C'_n-hetero(carbo)cycles]

R A Kuroyan
The A L Mndzhoyan Institute of Pure Organic Chemistry of the Academy of Sciences of the Armenian SSR, Erevan, Armenia

ABSTRACT. **A systemic survey is presented on methods of preparing *N*-containing spiroheterocycles in which a piperidine ring is spiro-condensed at the four position with various carbocycles and heterocycles. The biological properties of these compounds is also discussed.**

The bibliography contains 250 references.

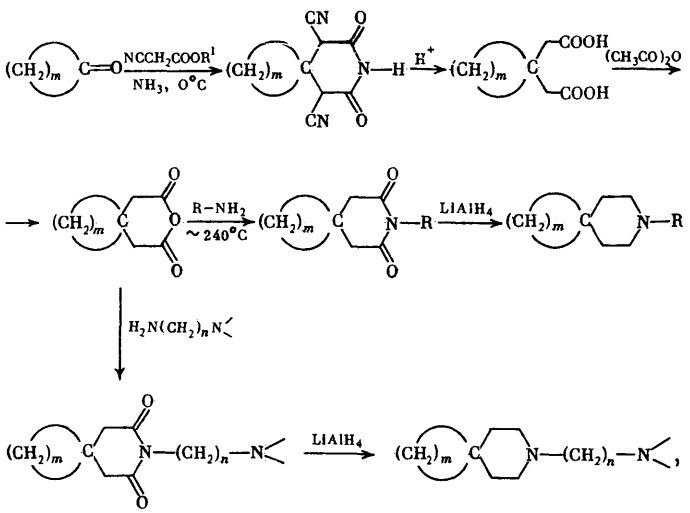
III. Spiro-*N*-heterocycles in which the piperidine ring is spiro-condensed at the four position with condensed heterocycles 1375

I. Introduction

In recent years much attention has been focussed on methods of preparing spiroheterocycles, in particular spiro-N-heterocycles, and studying their biological activity. This was intensified after the isolation of the biogenic amine, histrionicotoxin, from the skin of the tree frog, *Dendrobates histrionicus*.[1] This amine is a derivative of 1-azaspiro[5.5]undecan-8-ol, having highly unsaturated groups at the 2- and 7-positions, the structure and absolute configuration of which has been established by X-ray analysis. Subsequently, more than ten other 1-azaspiro[5.5]undecanes having a variety of unsaturated functions at the same ring positions were isolated from the genus *Dendrobates*.[2–5] In view of the biological significance of histrionicotoxin (which blocks the transmission of nervous impulses following activation by acetylcholine[1,6,7]), and because it is difficult to isolate in large amounts from the tree frog, much research has been devoted to the chemical synthesis of histrionicotoxin and variously hydrogenated derivatives.

Racemic octahydrohistrionicotoxin has been prepared by several routes, but, at the present time, no total synthesis of histrionicotoxin itself has been reported, primarily because of the lability of the unsaturated residues. A review published in 1982[8] covers this aspect, but since this time new data has been published, largely in connection with stereoselective and non-stereoselective routes to variously hydrogenated histrionicotoxin derivatives.[9,10] A further impetus to research in this field came with the discovery that the biological activity of histrionicotoxin is not entirely associated with the unsaturated functions in the side chain. For example, perhydrohistrionicotoxin—2-amyl-7-butyl-1-azaspiro[5.5]undecan-8-ol—has a biological activity very similar to that of histrionicotoxin. The development of non-stereoselective and stereoselective routes to 1-azaspiro[5.5]undecanes has already born fruit.[11–25]

At the beginning of the 1980's, Yunusov, et al. isolated the alkaloids, nitramine, isonitramine and sibirine, from *Nitraria schoberi, Nitraria sibirica* and *Nitraria sibirica Pall*, respectively.[26,27] These compounds were shown to have the 2-azaspiro[5.5]undecane skeleton, the first two having an asymmetric centre at C_7. Although the biological properties of these alkaloids are unknown, much work has been published on their non-stereoselective and stereoselective synthesis.[28–34]

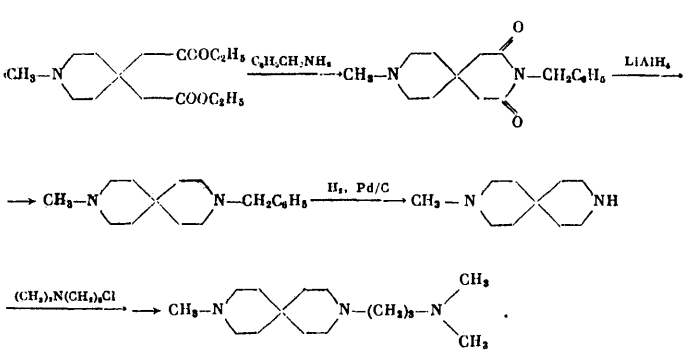


Spirocycles without a nitrogen atom have also been isolated from plants and living organisms. Thus, the components of the pheromone complex from the olive fly, *Dacus olfae*, have the 1,7-dioxaspiro[5.5]undecane skeleton.[35] Although few spiro compounds have been isolated from nature, there is sufficient evidence that spiroheterocycles perform key biological functions. It is for this reason that much research has been devoted both to the synthesis of analogues of spiro-fused alkaloids and biogenic amines, and to methods of preparing new spiroheterocyclic bases. Such compounds possess a wide spectrum of biological activity, and certain derivatives have been used medicinally, notably as pyschotropic drugs.[36–38]

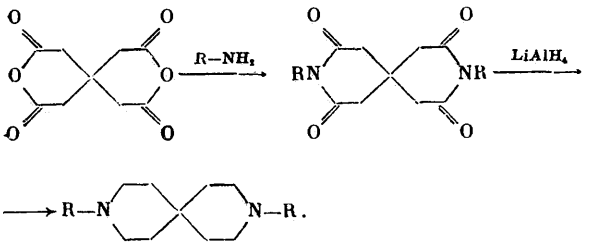
The volume of literature on the synthesis of spiroheterocycles and the study of their chemistry and biological activity is so large that it would be impossible to digest in one review. The present review covers the methods of preparing, and the biological activity, of nitrogen-containing spiroheterocycles in which a piperidine ring is spiro-fused at the 4-position with a variety of carbo- and heterocycles. However, there has been no attempt to present an all-embracing review of the literature. Rather, the objective has been to highlight the problems which chemists have experienced in the synthesis of such compounds as potential drugs.

II. Spiro-*N*-heterocycles in which a piperidine ring is spiro-condensed at the four position with carbo- and heterocycles

It was in the 1960's that research into the synthesis and biological activity of spirocycles, such as azaspiranes, commenced. 1,1-Bis-(carboxymethyl)-carbocycles and -heterocycles were the key intermediates used for the preparation of azaspiranes in which a piperidine ring is spiro-fused at the 4-position by various carbo- and heterocycles. The well-established route to such intermediates involves interaction of a ketone with ethyl cyanoacetate under mild conditions in ammonia-saturated ethanol to give the corresponding Guareschi's imide, subsequent hydrolysis of which affords the desired *gem*-disubstituted diacetic acid.[39] The latter are then



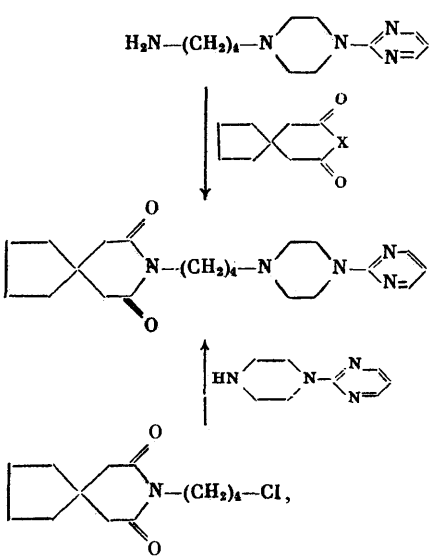
converted to the corresponding cyclic anhydride spiro-fused with a variety of carbo- and heterocycles, and subsequent treatment with a whole range of amines or diamines yields the corresponding imide in reasonably high yield. These undergo hydride reduction, as shown below.[40–57]



R = H, alky, isoalkyl, aryl; n = 2, 3; m = 2–7.

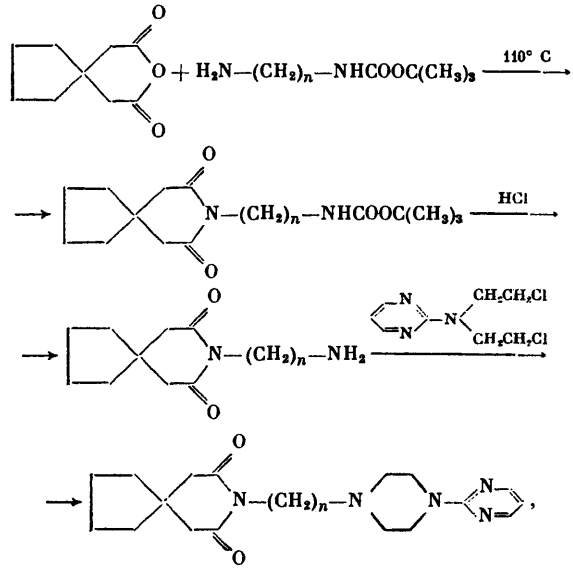
Depending on the nature of the substituent on the piperidine nitrogen and the nature of the ring fused at C_4, the resulting 3-azaspiranes and their salts display a variety of biological activities. The compounds act on the central nervous system,[40–43,46–49,55,57] possess analgesic,[41] antihypertensive,[41–43,45–47] antihistamine,[48] antimicrobial and antibacterial activity,[40,41] and suppress the growth of tumour cells.[52–54] In certain instances, the intermediate 3-azaspirane-2,4-diones were submitted to biological tests and shown to have both antimicrobial[58,59] and, notably, psychotropic activity.[60–63]

The above-described 3-azaspirane synthesis is also applicable to 1-methyl-4-piperidone as the cyclic ketone, so that it is possible to prepare diazaspiranes having two piperidine rings spiro-fused at the 4-position. The intermediate 1-methylpiperidine-4,4-diacetic acid was converted to the diethyl ester (rather than the cyclic anhydride), which reacted with benzylamine to give the corresponding imine; hydride reduction of the latter then gave the desired 3-benzyl-9-methyl-3,9-diazaspiro[5.5]undecane, as shown below. Cleavage of the *N*-benzyl group was effected by hydrogenation over palladium-on-carbon, and the resulting secondary amino function was further alkylated to give, for example, the γ-(dimethylamine)propyl derivative as a useful intermediate for the preparation of pharmacologically active agents.[64,65]



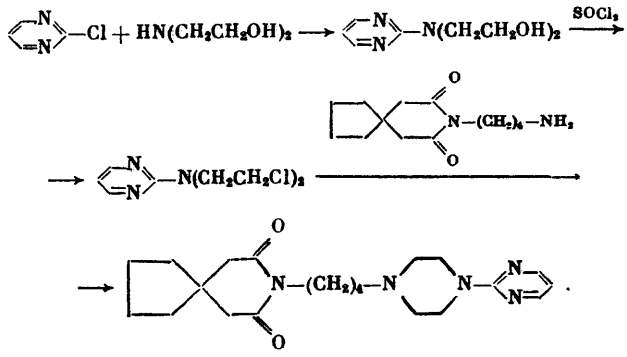
In an alternative synthesis of 3,9-diazaspiranes, methanetetraacetic acid was converted to its spirocyclic bisanhydride, which afforded the desired product on treatment with primary amine followed by hydride reduction.[64]

The main advantage of the previous route over this alternative procedure is that the resulting diazaspiranes may have different substituents on the two nitrogen atoms.



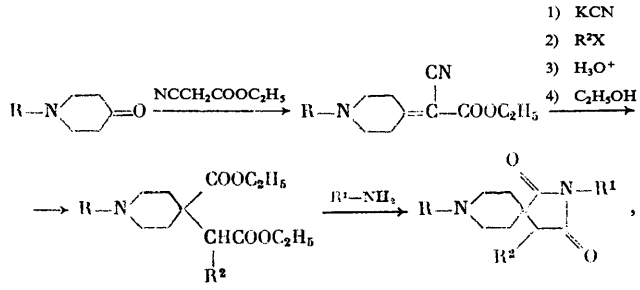
One of the 3-azaspiranes obtained by the first method is 8-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-8-azaspiro[4.5]decane-7,9-dione, which displays neuroleptic properties and is used medicinally under the name buspirone.[66] In one synthesis of this drug, 3,3-tetramethyleneglutaric anhydride is converted to the corresponding imide with 1-(4-aminobutyl)-4-(2-pyrimidinyl)piperazine in pyridine; alternatively, it can be prepared by interaction of *N*-(4-chlorobutyl)-3,3-tetramethyleneglutarimide with *N*-(2-pyrimidinyl)piperazine in butanol.[67,68]

X=O, NH.



In recent years, a variety of methods has been used for the synthesis of buspirone and its analogues. Thus, treatment of 3,3-tetramethyleneglutaric anhydride with *tert*-butyl *N*-(ω-aminoalkyl)carbamates affords the corresponding imides, which undergo

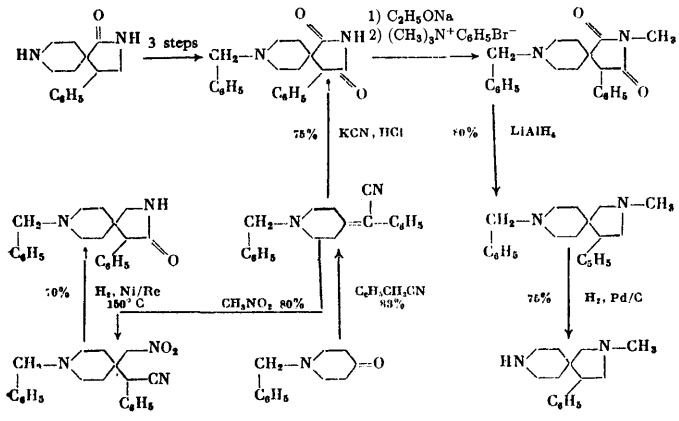
selective hydrolysis to the corresponding *N*-ω(aminoalkyl)-3,3-tetramethyleneglutarimides. Interaction of the latter with 2-[*bis*(2-chloroethyl)amino]pyrimidine gives buspirone and its analogues in high yield, according to the following scheme.[69]



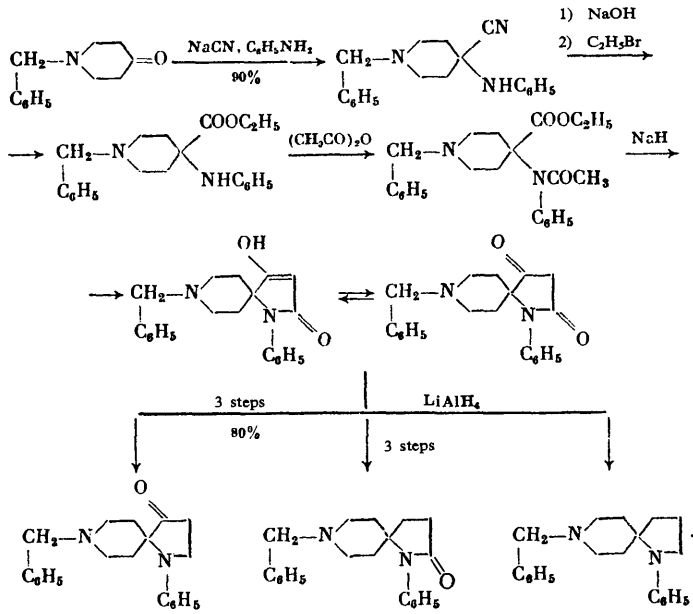
$n = 2-5$.

Buspirone was also obtained by the route shown below. Thus, 2-chloropyrimidine interacts with diethanolamine to give *N*-(2-pyrimidinyl)diethanolamine, which is converted to the corresponding bis(2-chloroethyl)amine with thionyl chloride. Subsequent condensation with *N*-(ω-aminobutyl)-3,3-tetramethyleneglutarimide affords the desired compound in high yield.[70]

Other routes to buspirone,[71–73] its precursors,[74] and novel analogues[75–78] have been reported. For diagnostic purposes, a buspirone derivative having a dideuteriated piperazine ring has also been prepared.[79]

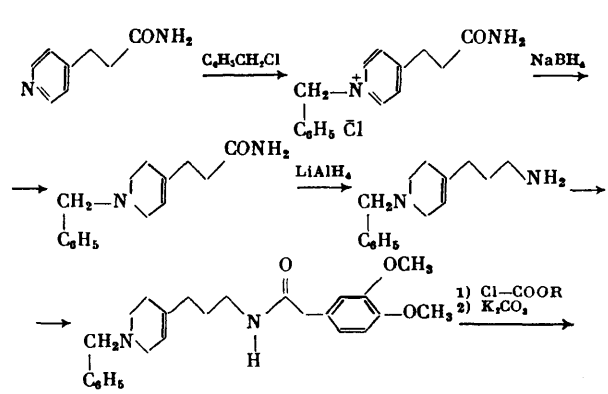


The Knoevenagel reaction has been applied in a useful synthesis of azaspiranes in which a piperidine ring is spiro-fused at the 4-position with a succinimide ring. The latter may have a variety of substituents in the 2- and 4-positions. Thus, 4-piperidones condense with ethyl cyanoacetate to give the Knoevenagel product, which undergoes Michael addition with HCN to give the corresponding dicyanoester; hydrolysis of the latter, followed by decarboxylation and esterification affords the corresponding *gem*-disubstituted diethyl succinate, which reacts with primary amines to give the desired 2-substituted 2,8-diazaspiro[4.5]decanes.[80–87] The same authors have also prepared spirosuccinimides with substituents in both the 2- and 4-position. This was achieved by hydrolysing the dicyanoesters, and then α-alkylating (or α-arylating) with various alkyl (or aryl) halides prior to succinimide ring closure.[81]

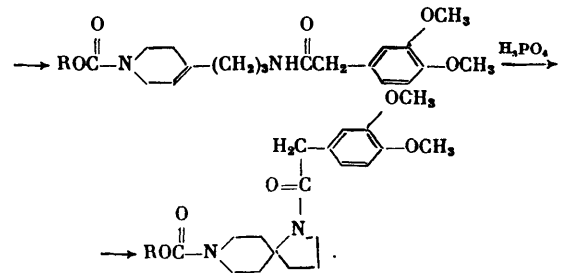


R = H, alkyl, isoalkyl, phenyl, benzyl, phenylethyl, allyl, benzoylethyl; R^1 = H, alkyl, isoalkyl, allyl, phenyl, benzyl, phenylethyl; R^2 = H, alkyl, isoalkyl, aryl, allyl.

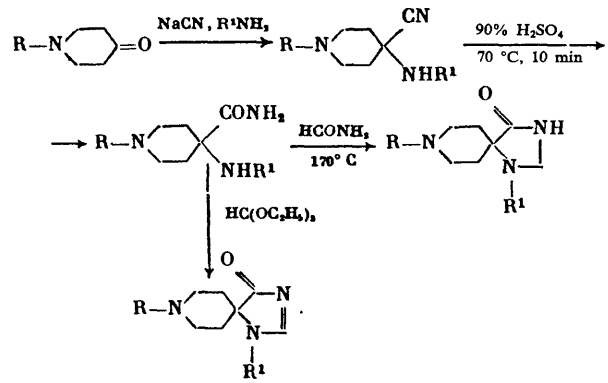
Having prepared *N*-benzylpiperidine derivatives by this route, the benzyl group may then be readily cleaved by standard methods to give the corresponding *N*-unsubstituted derivatives; the latter may then be *N*-alkylated to give compounds with potential pharmacological activity. Thus, alkylation with 3-chloropropyl *p*-fluorobenzoate affords an azaspirosuccinimide with neuroleptic activity.[82,83]



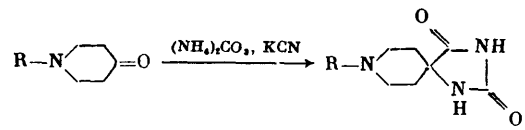
In a modification of the above 2,8-diazaspiro[4.5]decane synthesis, it is also possible to prepare azaspiranes with a phenyl group. Thus, Knoevenagel condensation of *N*-benzyl-4-piperidone with phenylacetonitrile, followed by addition of HCN leads to the corresponding dinitrile by Michael addition; without isolation, this is cylised with HCl to give 4-phenyl-8-benzyl-2,8-diazaspiro[4.5]decane-2,4-dione, which is partially or completely reduced to give 4-phenyl-8-benzyl-2,8-diazaspiro[4.5]decane or the corresponding 1-oxo- and 3-oxo-derivatives.[88] The latter may also be prepared by addition of nitromethane to α-[*N*-benzylpiperidin-4-ylidene]benzyl cyanide, followed by hydrogenation over Raney nickel under pressure.[88] These conversions are shown below.



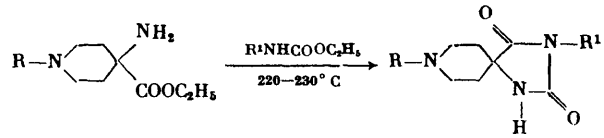
1,8-Diazaspiro[4.5]decanes have also been synthesised from *N*-benzyl-4-piperidone. Thus, treatment of the latter under Strecker conditions affords 1-benzyl-4-cyano-4-anilinopiperidine, from which the corresponding α-anilinocarboxylic acid ethyl ester is obtained and then *N*-acetylated with acetic anhydride. Subsequent intramolecular Dieckmann cyclisation provides *N*-benzyl-1-phenyl-1,8-diazaspiro[4.5]decane-2,4-dione (in 45% yield), which is completely or partially reduced to 8-benzyl-1-phenyl-1,8-diazaspiro-[4.5]decane or the 2-oxo- and 4-oxo-derivatives, as shown below.[89]



Alternatively, the 1,8-diazaspiro[4.5]decane ring can be prepared from 4-(2-carbamylethyl)pyridine. Thus, treatment of the latter with benzyl chloride affords the corresponding *N*-benzylpyridinium salt, which undergoes sequential reduction, first with $NaBH_4$ to give 1-benzyl-1,2,3,6-tetrahydro-β-(4-pyridyl)propionamide, reduction of which with $LiAlH_4$ affords the corresponding 3-substituted propylamine. Condensation of the latter with 3,4-dimethoxyphenylacetic acid gives the corresponding amide (in 70% yield), which, in the key step, is converted to the *N*-carbalkoxy derivative by treatment with chloroformic acid ester. Cyclisation with 80% phosphoric acid then provides the desired 1,8-diazaspiro-[4.5]decane.[90]

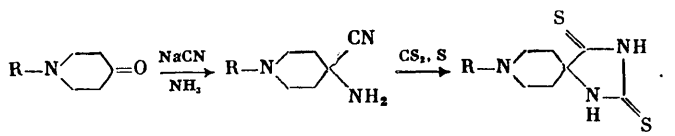


In an extension of these routes, biologically active 1,3,8-triazaspiro[4.5]decanes have also been prepared from 4-piperidones. The synthesis involves Strecker conversion to the corresponding α-aminonitriles, followed by hydrolysis to the corresponding amides and cyclisation of the latter with formamide or ethyl orthoformate.[91,92]

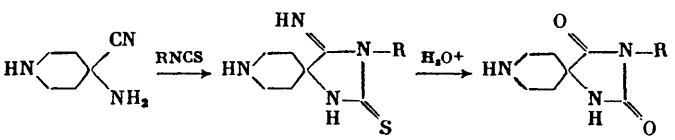


A large number of 1-phenyl-1,3,8-triazaspiro[4.5]decan-4-ones have been prepared by this route by varying the substituent on the piperidine nitrogen atom. These have been shown to possess neuroleptic,[93–95] tranquilizing,[96–98] analgesic,[97–101] sedative,[100,105] hypotensive, and antiinflammatory[97] activities, and, furthermore, are apomorphine antagonists and CNS depressants.[102–104] One of these compounds—8-[3-(4-fluorobenzoyl)propyl]-1-phenyl-1,3,8-triazaspiro[4.5]decan-4-one—is a neuroleptic drug used medicinally under the name 'spiperone'.[106] Labelled spiperone derivatives having an isotopic carbon, fluorine, iodine or bromine atom have also been prepared for diagnostic purposes.[107–114]

The 1,3,8-triazaspirane skeleton also incorporates spiro[piperidine-4,5′-hydantoins], obtained in high yield by interaction of 4-piperidones with a mixture of KCN and ammonium carbonate.[115–120]



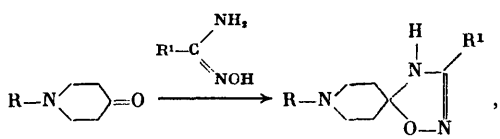
Such spirohydantoins are also obtainable by condensing 4-amino-4-ethoxycarbonylpiperidines with *N*-substituted carbamates.[121,122]



R = phenyl, benzyl; R^1 = alkyl, cyclohexyl, phenyl.

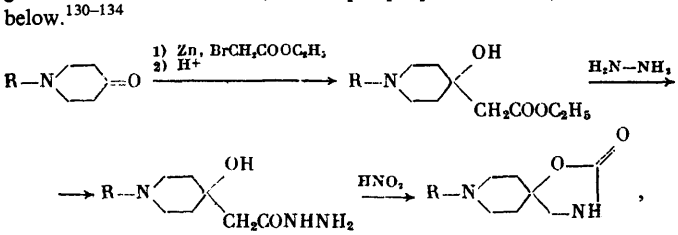
Spirohydantoins possess analgesic, antispasmolytic and antiinflammatory activities.

Antiinflammatory 1,3,8-triazaspiro[4.5]decane-2,4-dithiones are obtained from 4-piperidones via Strecker synthesis, followed by treatment of the resulting α-aminonitriles with carbon disulphide.[123]



These same α-aminonitriles interact with isothiocyanates to provide a new route to 4-imino-1,3,8-triazaspiro[4.5]decane-2-thiones,[124] hydrolysis of which leads to the corresponding hydantoins.[125]

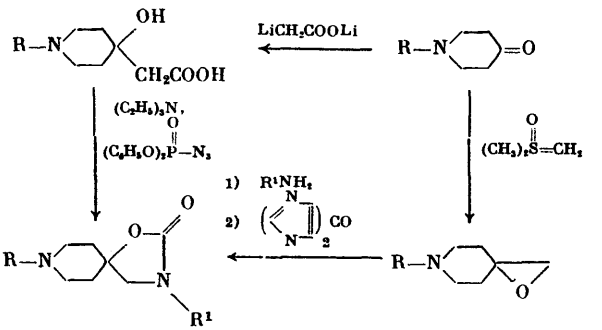
R = alkyl, cyclohexyl, phenyl, α-naphthyl.



Piperidines spiro-fused with the 1,2,4-oxadiazoline ring have been prepared by interaction of 4-piperidones with amidoximes in the presence of various acids.[126–129]

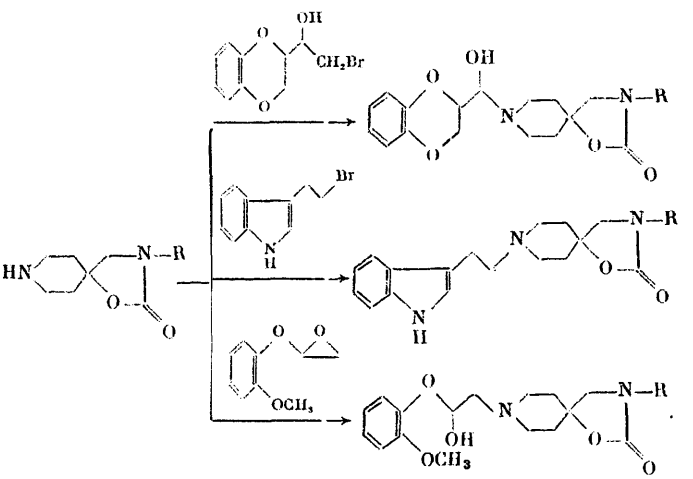
R = H, alkyl, acyl, aryl; R^1 = alkyl, phenyl, benzyl, *p*-tolyl.

Such 1-oxa-2,4,8-triazaspiro[4.5]dec-2-enes possess sedative, analgesic, and antiinflammatory activity, and reduce blood levels of sugar and cholesterol.



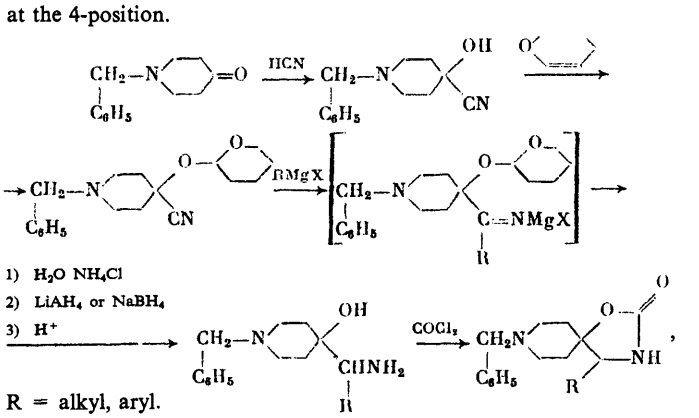
Piperidines spiro-fused at the 4-position with the 2-oxazolidone ring have been obtained via Reformatskii reaction with 4-piperidones. The resulting β-hydroxycarboxylic acid esters are converted to the corresponding hydrazides which undergo Curtius rearrangement to give the desired 1-oxa-3,8-diazaspiro[4.5]decan-2-ones, as shown below.[130–134]

R = alkyl, aryl.



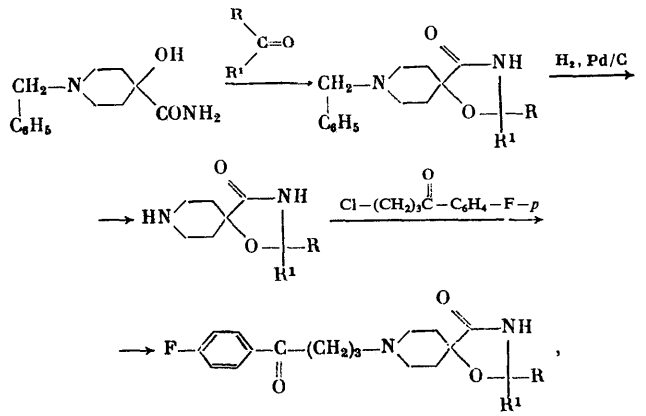
These compounds possess antiinflammatory, antiasthmatic, analgesic, and tranquillizing activity.

A wide range of 1-oxa-3,8-diazaspiro[4.5]decan-2-ones has been prepared by other researchers, both by the route shown above and by two other methods.[135] One of these is based on the conversion of 4-piperidones to the corresponding spirooxirane which is cylised to the desired 1-oxa-3,8-diazaspiro[4.5]decan-2-ones in two steps. Alternatively, in a one-step route, the same products are obtained by interaction of 4-carboxymethyl-4-hydroxypiperidines with diphenyl phosphorazidate.[135]



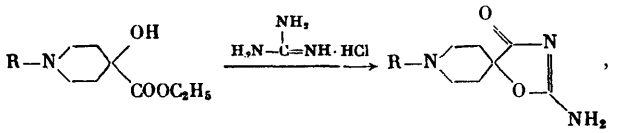
R^1 = H, alkyl.

Treatment of 1-oxa-3,8-diazaspiro[4.5]decan-2-ones with a variety of halides or epoxides affords *N*-substituted derivatives with antihypertensive properties.[135]



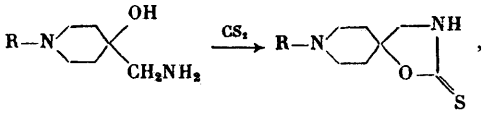
In an alternative 1-oxa-3,8-diazaspiro[4.5]decan-2-one synthesis, 4-piperidone cyanohydrins are protected as their tetrahydropyran-2-yl ethers, which afford the corresponding 2-aminoalcohol derivatives by reaction with Grignard reagents followed by reduction and deprotection. Cyclisation with phosgene then secures the desired spirocyclics.[136] This method has been applied to the preparation of 1-oxa-3,8-diazaspiro[4.5]decan-2-ones with a variety of substituents at the 4-position.

R = alkyl, aryl.



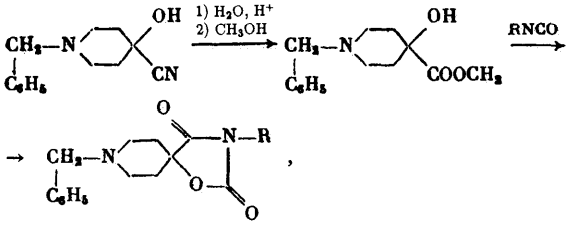
Debenzylation of these compounds, followed by *N*-alkylation (notably with 2-chloromethyl-1,4-benzodioxane) leads to *N*-substituted derivatives which possess pharmacological activity and are suitable for the treatment of diseases of the cardiovascular system.[137]

1-Oxa-3,8-diazaspiro[4.5]decan-4-ones have been prepared by interaction of 1-benzyl-4-hydroxypiperidine-4-carboxamide with carbonyl compounds in acidic media. Subsequent debenzylation and *N*-alkylation with 3-(4-fluorobenzoyl)propyl chloride affords the desired spirocyclics which possess neuroleptic, cataleptic, adrenolytic, and sedative properties.[138]



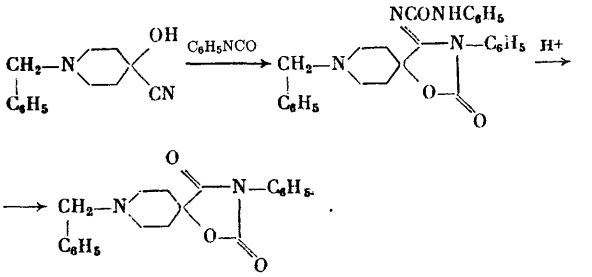
R = H, methyl; R^1 = methyl, phenyl, benzyl.

Condensation of 4-carbethoxy-4-hydroxypiperidines with guanidine hydrochloride affords 2-amino-1-oxa-3,8-diazaspiro-[4.5]dec-2-en-4-ones which display CNS depressant activity.[139]



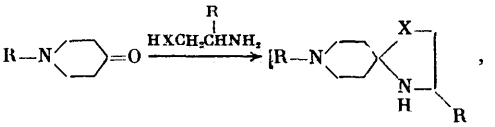
R = H, alkyl, aralkyl.

1-Oxa-3,8-diazaspiro[4.5]decane-2-thiones have been prepared by interaction of 4-aminomethyl-4-hydroxypiperidines with carbon disulphide.[140,141] Compounds of this type possess neuroleptic, broncodilator, analgesic, antibacterial, and hypotensive properties.



R = benzyl, 4-fluorobenzoylpropyl.

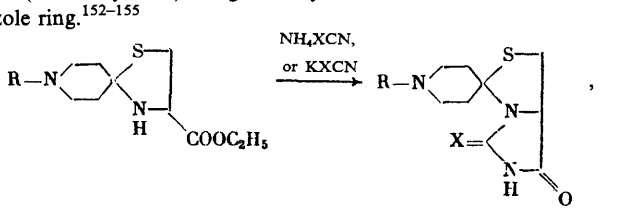
1-Oxa-3,8-diazaspiro[4.5]decane-2,4-diones have been synthesised from *N*-benzyl-4-piperidone cyanohydrin by hydrolysis, esterification, and subsequent interaction with isocyanates.[142–144]



R = alkyl, benzyl, aryl.

The same authors have prepared 8-benzyl-3-phenyl-4-phenylcarbamylimino-1-oxa-3,8-diazaspiro[4.5]decan-2-one from the same cyanohydrin and phenyl isocyanate; hydrolysis of the product in acidic media leads to 8-benzyl-3-phenyl-1-oxa-3,8-diazaspiro-[4.5]decane-2,4-dione.[145]

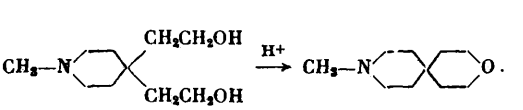
Derivatives of this ring system possess CNS depressant activity.



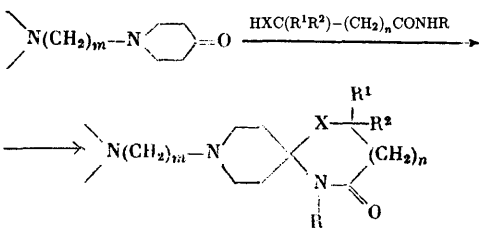
A general method of preparing 1-oxa-4,8-diazaspiro[4.5]decanes and 1-thia-4,8-diazaspiro[4.5]decanes has also been devised. This is based on the interaction of 4-piperidones with 2-aminoalcohols and 2-aminomercaptans, respectively, under acidic catalysis.[146–149]

X = O, S; R = H, alkyl, phenyl, acetyl, ethoxycarbonyl; R^1 = H, carboxyl, ethoxycarbonyl.

For the preparation of 1-thia-analogues, a mixture of the corresponding aziridine and hydrogen sulphide may be used in place of 2-aminomercaptans.[149]



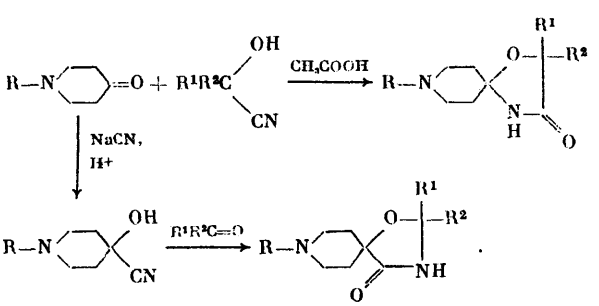
Similar results have been obtained by using *N*-substituted 2-aminoalcohols.[150,151] Compounds in this class possess analgesic,[146,147] psychotropic, CNS stimulatory,[146–148] and antibacterial activity.[149] 1-Thia-4,8-diazaspiro[4.5]decanes with an ethoxycarbonyl group at the 3-position react further with potassium or ammonium cyanate (or thiocyanate) to give tricyclic derivatives with a fused imidazole ring.[152–155]



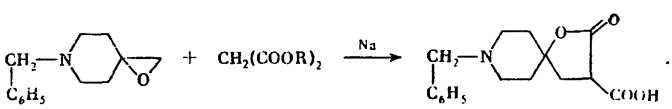
X = O, S; R = H, alkyl, acyl, aryl, ethoxycarbonyl.

Of the numerous derivatives with this ring system, some have shown neuroleptic properties,[155] while others display anti-hallucinogenic, sedative,[152] psychotropic,[153] and antithromotoxic properties.[154]

9-Methyl-3-oxa-9-azaspiro[5.5]undecane has been prepared from 1-methyl-4,4-*bis*(2-hydroxyethyl)piperidine by heating in an acidic medium.[156] The substrate is obtainable by reduction of the 4,4-*bis*-(carboxymethyl) derivative with $LiAlH_4$.

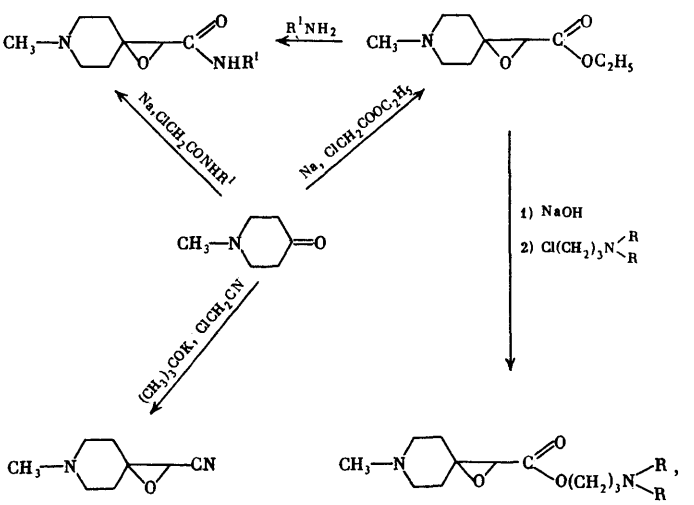


Much research has been devoted to the synthesis of derivatives of 1-oxa- or 1-thia-4,8-diazaspiro[4.5]decan-3-one and 1-oxa- or 1-thia-5,9-diazaspiro[5.5]undecan-4-one.[157–187] All routes to these compounds are based on *N*-substituted 4-piperidones, which cyclise to the desired spirocyclics on reaction with various hydroxy- or mercapto-carboxylic acids under acidic catalysis.



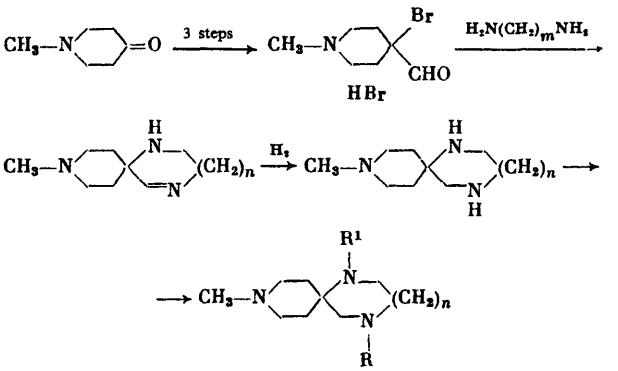
R = H, alkyl, aryl, benzyl, 2-furfuryl, 2-pyridyl; R^1 and R^2 = H, alkyl, phenyl; n = 0, 1; m = 2, 3; X = O, S, SO, SO_2.

Similar results are obtained if the hydroxy- or mercapto-carboxamides are replaced by a mixture of the corresponding hydroxy- or mercapto-carboxylic acid and a primary amine or ammonium carbonate.[188–193] Interest in these spiroheterocyclic systems has increased since certain of the compounds possess CNS stimulating activity,[161] reserpine antagonist,[158,163] tranquillizing,[167,173] analgesic,[167,179] psychotropic,[168,169,180,192] depressant,[191] neuroleptic,[174] and antiinflammatory[160,172,184] activities; certain compounds also reduce cholesterol levels,[159,184] the toxicity of carbon tetrachloride in the liver,[157,166] and sugar levels in the blood;[158] certain also suppress the activity of acetylcholine, and are used in the treatment of intestinal spasms and ulcers;[186] sedative and anticonvulsant activities have also been reported.[187] It should be noted that a number of these compounds are used medicinally as drugs.



1-Oxa-4,8-diazaspiro[4.5]decan-3-ones have also been obtained by condensation of 4-piperidones with cyanohydrins.[194] Treatment of 4-cyano-4-hydroxypiperidines with ketones, however, leads to 1-oxa-3,8-diazaspiro[4.5]decan-4-ones.[194]

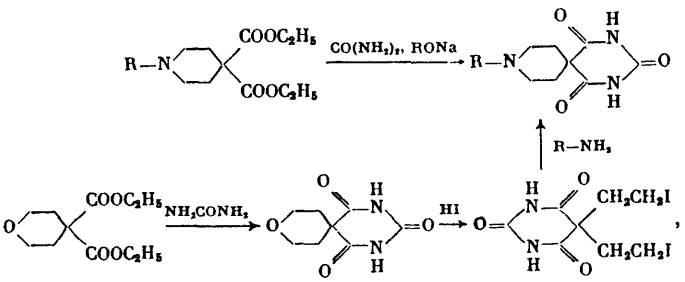
1-Oxa-6-azaspiro[2.5]octanes interact with malonic acid esters to give 3-carboxyazaspirocyclic lactones.[195]



Derivatives of 1-oxa-6-azaspiro[2.5]octane having a carbalkoxy, amino-substituted carbalkoxy, carbamyl, or cyano groups at the 2-position have been prepared from 4-piperidones by the Darzens condensation.[196–199] For the cyano derivatives, potassium *tert*-butoxide was used as base, while metallic sodium was preferred for the preparation of the other derivatives.

R = methyl, ethyl, piperidyl, morphoyl; R^1 = H, methyl, ethyl, phenyl.

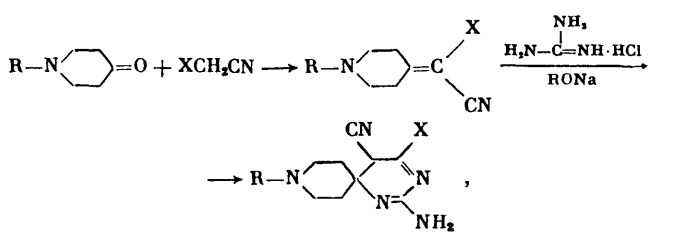
The mass spectrometric fragmentation of aminoalkyl 1-oxa-6-azaspiro[2.5]octane-2-carboxylates has been studied.[200]



Spirocyclics with a piperidine ring spiro-fused at the 4-position with the piperazine or perhydrodiazepine ring (or partially dehydrogenated derivatives) have also been prepared.[201,202] It has been shown that the nitrogen atom situated alpha to the spirocarbon atom in both 9-methyl-1,4,9-triazaspiro[5.5]undecane and 3-methyl-3,7,11-triazaspiro[5.6]dodecane is relatively unreactive, so that it is possible to prepare both mono- and di-*N*-substituted derivatives.

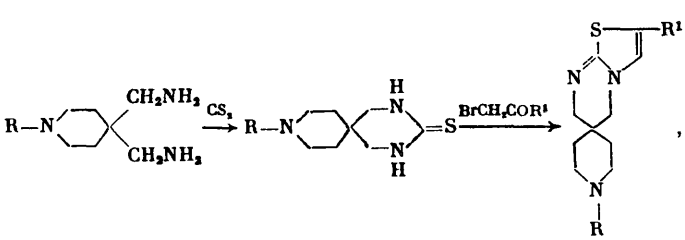
R=CH_2CH_2CN, CH_2CN, CH_2CONH_2, $CH_2CH_2CONH_2$, $CH_2COOC_2H_5$, $CH_2CH_2COOC_2H_5$, $CH_2CH_2NH_2$, $(CH_2)_3-NH_2$, $CH_2CONHNH_2$; R'=H, $CH_2COOC_2H_5$, $CH_2CONHNH_2$; m=2, 3; n=1, 2.

2,4,9-Triazaspiro[5.5]undecane-1,3,5-triones have been prepared by two different routes. One is based on the cyclocondensation of 4,4-bis(carbethoxy)piperidines with urea in the presence of sodium



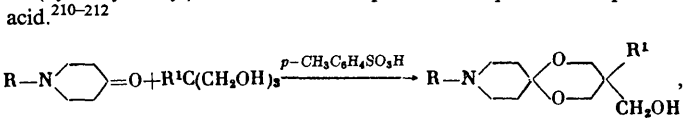
ethoxide, while the other involves cyclisation of 5,5-bis-(2-iodoethyl)barbituric acids with primary amines.[203] These barbituric acids are obtainable from 9-oxa-2,4-diazaspiro[5.5]-undecane-1,3,5-trione, as shown below.[204]

R = alkyl, allyl, aryl, benzyl, cyclohexyl.



Recently it was shown that 2,4,9-triazaspiro[5.5]undecane-1,3,5-trione derivatives with various substituents on the piperidine nitrogen possess neuroleptic properties.[205,206]

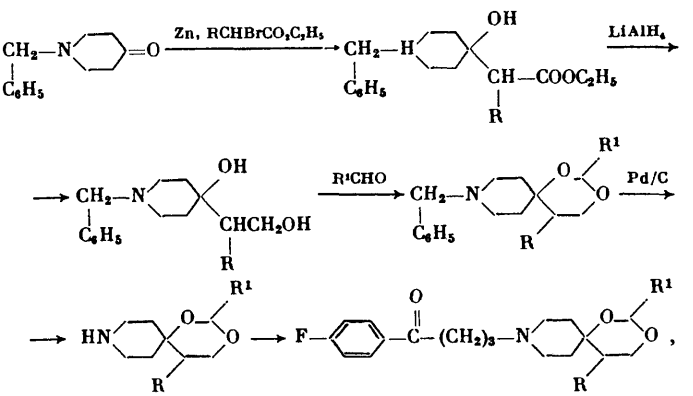
1,3,9-Triazaspiro[5.5]undecane-1,3-dienes have been prepared by interaction of unsaturated nitriles with guanidine.[207] These products are effective for the treatment of Parkinson's disease.



R = methyl, phenylethyl, dimethylaminoethyl; X = OH, NH_2.

The interaction of 1-substituted 4,4-bis(aminomethyl)piperidines with carbon disulphide leads to 9-substituted 2,4,9-triazaspiro-[5.5]undecane-4-thiones, which condense with α-halogenoketones to give spiro[piperidine-4,6-thiazolo[3,2-a]pyrimidines. The latter display antidepressant and thymoanaleptic properties.[208,209]

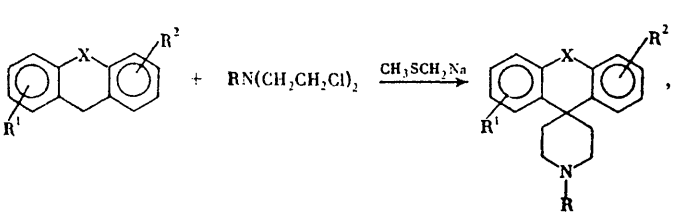
R = alkyl, aryl, benzyl, furyl, thienyl.



Substituted 1,5-dioxa-9-azaspiro[5.5]undecanes have been synthesised by condensation of 4-piperidones with alkyl-substituted tris(hydroxymethyl)methanes in the presence of *p*-toluenesulphonic acid.[210–212]

R = H, alkyl, aryl, aralkyl, acyl, ethoxycarbonyl, thienylalkyl; R^1 = alkyl.

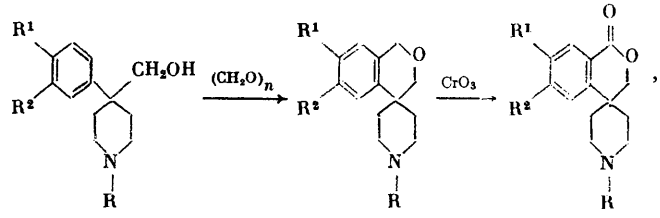
In the above scheme, 4-piperidone ketals have been used in place of 4-piperidones,[213] and substituted 1,3-dioxanes in place of the triols.[214] Certain of the resulting azaspirodioxanes have been shown to possess tranquillizing activity.[215]



1,3-Dioxa-9-azaspiro[5.5]undecanes have been prepared from 1-benzyl-4-piperidone.[215] Thus, Reformatskii reaction with the latter, followed by reduction of the resulting β-hydroxyesters with $LiAlH_4$, yields the corresponding 1,3-diols, which are cyclised to the desired spiro[piperidine-1,3-dioxanes] with aldehydes:

R = H, alkyl; R^1 = H, alkyl, aryl.

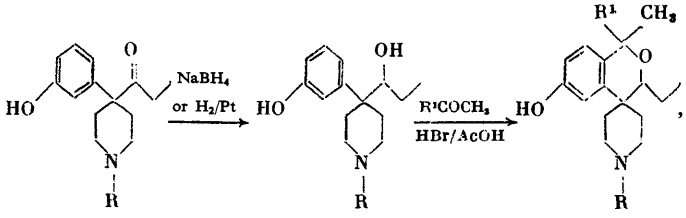
III. Spiro-*N*-heterocycles in which the piperidine ring is spiro-condensed at the four position with condensed heterocycles



Xanthenes, thioxanthenes and dihydroanthracenes with various substituents in the benzene ring undergo cycloalkylation with bis(2-chloroethyl)amines to give the corresponding 4-spiropiperidines. Certain of these compounds have been used medicinally as analgesics.[216–218]

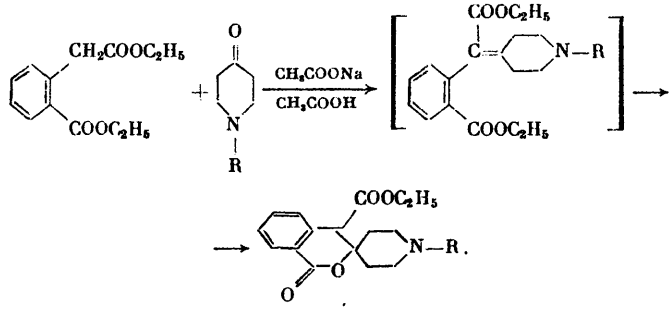
R = alkyl, aryl, benzyl, alkenyl; R^1 = R^2 = H, OMe, Cl, OH, etc.

References have also been made to the preparation of spiro-[isochroman-4,4'-piperidines] and spiro[isochroman-3,4'-piperidines]. One route to the former involves hydroxymethylation, followed by ring closure of the resulting 4-aryl-4-hydroxymethylpiperidines.[219–223] The starting 4-hydroxymethylpiperidines were obtained by reduction



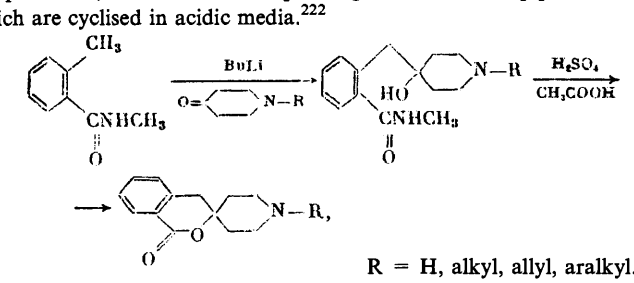
of the corresponding 4-carbalkoxy-derivatives. The spiroisochromans prepared by this method were oxidised to the corresponding spiroisocoumarins with CrO_3.[219,222]

R = alkyl, aryl, benzyl, aralkyl; $R^1 = R^2 = H$, MeO, etc.



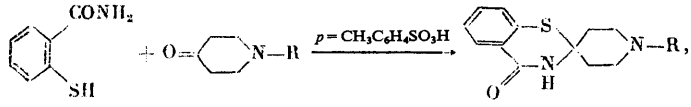
N-Substituted spiro[isochroman-4,4′-piperidines] may also be prepared by reductive *N*-debenzylation, followed by *N*-alkylation.[219]

In an alternative route to these spirocycles, 4-aryl-4-acylpiperidines may be reduced to the corresponding alcohol, and subsequently condensed with alkyl methyl ketones. In this way, derivatives with substituents at the 1 and 4 positions may be prepared.[224]



R = alkyl, allyl; R^1 = methyl, ethyl.

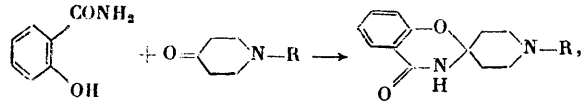
Spiro[isochroman-3,4′-piperidines] have been prepared by interaction of diethyl homophthalate with 4-piperidones, followed by cyclisation of the resulting 4-piperidinylidene-derivatives in acidic media.[219]



Alternatively, benzylic metallation of *o*-(*N*-methylcarbamyl)-toluene with *n*-butyllithium, followed by treatment with 4-piperidones, affords the corresponding 4-substituted 4-piperidinols, which are cyclised in acidic media.[222]

R = H, alkyl, allyl, aralkyl.

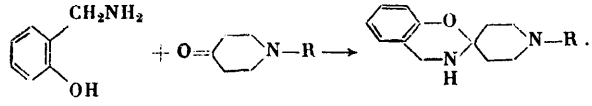
Such spiroisochromans possess analgesic activity.



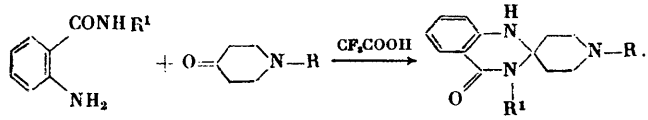
4-Oxospiro[1,3-benzothiazine-2,4′-piperidines] may be obtained by condensation of thiosalicylamide with 4-piperidones.[225]

R = H, butyl, acetyl, benzyl, benzoyl.

These compounds possess sedative, analgesic and hypoglycaemic properties.



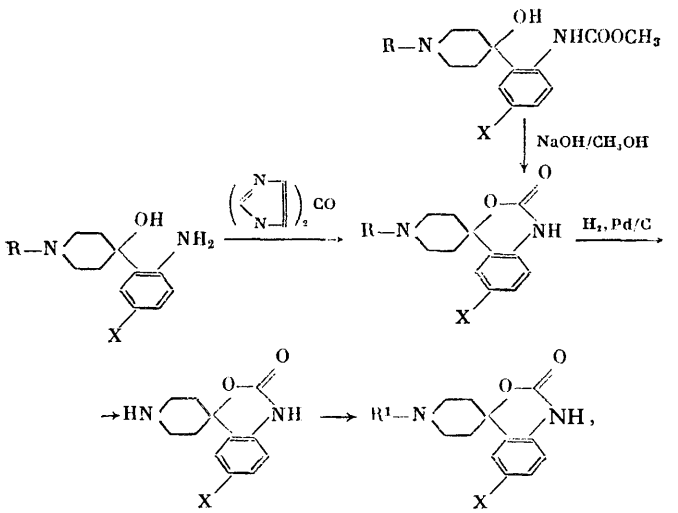
In a similar way, 4-oxospiro[1,3-benzoxazine-2,4′-piperidines] may be prepared by condensation of 4-piperidones with salicylamide.[226]



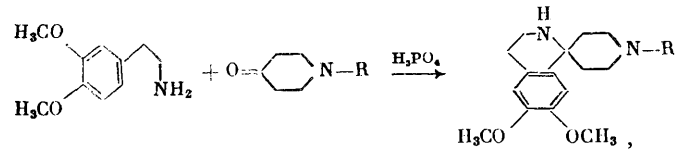
R = H, acetyl, benzyl, ethoxycarbonyl.

It is interesting that these compounds also possess sedative, analgesic, and hypoglycaemic properties.

Spiro[1,3-benzoxazine-2,4′-piperidines] are obtained if *o*-aminomethylphenols are used in place of salicylamides.[227]

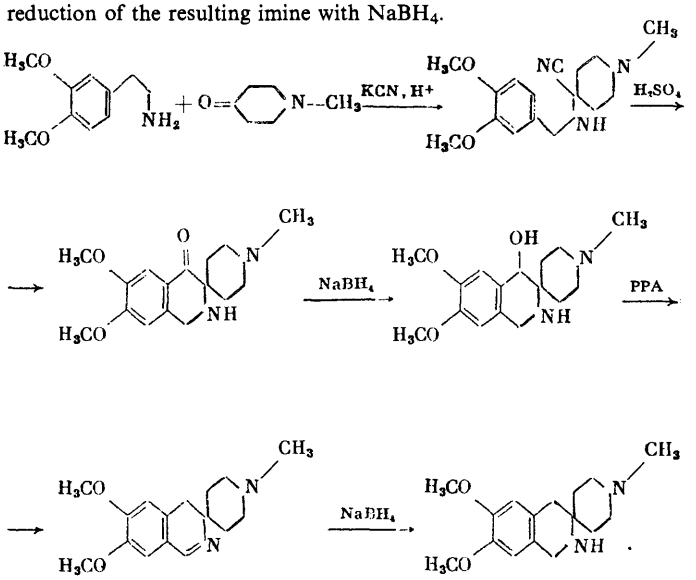


The condensation of anthranilamides with 4-piperidones in the presence of trifluoroacetic acid affords 4-oxospiro[tetrahydroquinazoline-2,4′-piperidines], which display bronchodilator and CNS depressant activity.[228]



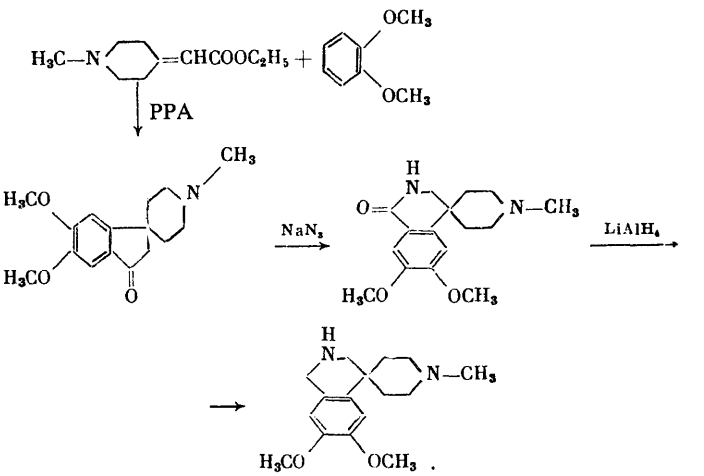
There are two routes to 2-oxospiro[4*H*-3,1-benzoxazine-4,4′-piperidines] based on *N*-substituted 4-hydroxy-4-(2-aminophenyl)piperidines.[229,230] In one of these methods, the latter compounds are converted to *N*-carbomethoxy derivatives with methyl chloroformate, and then cyclised in aqueous ethanolic NaOH. In the other method, the starting 4-piperidinols are cyclised directly with *N*,*N*′-carbonyldiimidazole. A variety of *N*-substituted derivatives may be obtained by reductive cleavage of *N*′-benzyl-2-oxospiro[4*H*-3,1-benzoxazine-4,4′-piperidines], followed by appropriate *N*-alkylation of the *N*-unsubstituted derivatives. These

products possess hypotensive properties and are used medicinally in combination with other drugs.

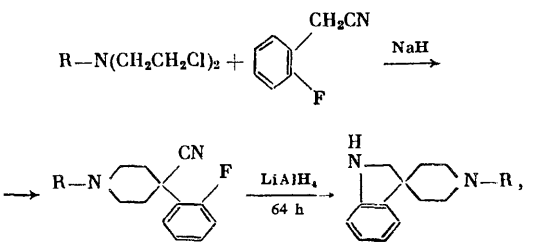


R = H, alkyl, benzyl; R^1 = benzoylbutyl; X = H, Cl.

There are convenient one-step routes to spiro[tetrahydroisoquinoline-1,4′-piperidines] by Pictet-Spengler ring closure of 3,4-dimethoxyphenylethylamine with 4-piperidones in polyphosphoric acid.[231]

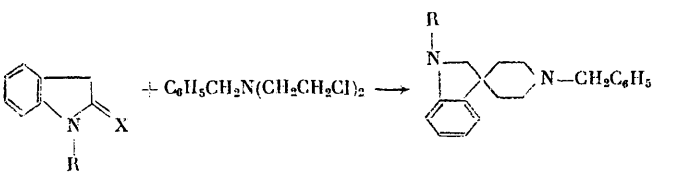


R = methyl, benzyl.



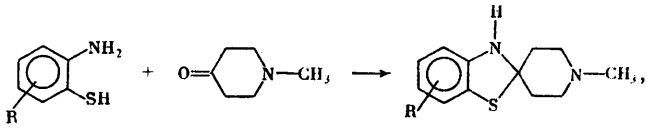
The synthesis of spiro[tetrahydroisoquinoline-3,4′-piperidines] has also been reported.[231] Thus, 3,4-dimethoxyphenylethylamine condenses with 1-methyl-4-piperidone in the presence of KCN to give the corresponding 4-amino-4-cyanopiperidine, which cyclises to 4′-methyl-4-oxo-6,7-dimethoxyspiro[1,2,3,4-tetraisoquinoline-3,4′-piperidine]. The 4-deoxy derivative is obtained by reduction to the corresponding alcohols, followed by dehydration and a second reduction of the resulting imine with $NaBH_4$.

Spiro[isoquinoline-4,4′-piperidines] have been prepared by Schmidt rearrangement of the corresponding spiroindanones, followed by hydride reduction of the resulting lactams.[231] The starting spiroindanones are obtained under Friedel-Crafts conditions by interaction of the corresponding phenolethers with the appropriate 4-carboxymethylenepiperidines or their esters.[232]



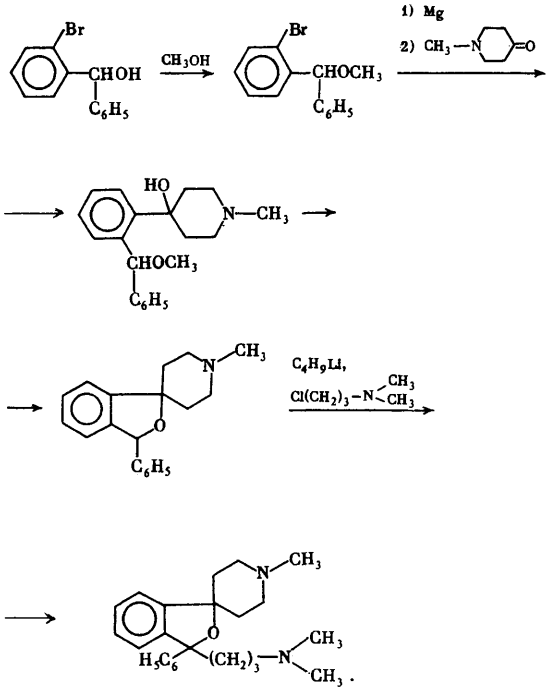
Methods of preparing spiro[indoline-3,4′-piperidines] have been reported in the patent literature.[233,234] These involve condensation of bis(2-chloroethyl)amines with *o*-fluorobenzyl cyanide in the presence of NaH. The resulting 4-cyano-4-(*o*-fluorophenyl)-piperidines are reduced with $LiAlH_4$ over > 60 h, during which time indoline ring closure takes place with liberation of fluoride ion.

R = H, alkyl, CN, acyl, phenyl.



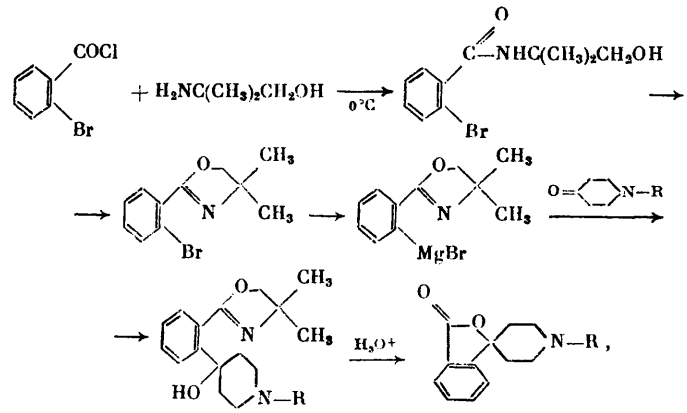
The obtained *N*-substituted indolines are used medicinally as anticonvulsant, antidepressant, and transquillizing drugs.

The preparation of spiro[indoline-3,4′-piperidines] and their 2-oxo-derivatives has been achieved by cycloalkylation of the corresponding indolines with *N*-benzylbis(2-chloroethyl)amine, followed by debenzylation and subsequent *N*-alkylation with various alkyl halides.[235,236] According to the authors, these compounds possess antiarrhythmic, analgesic and antihypertensive activity.



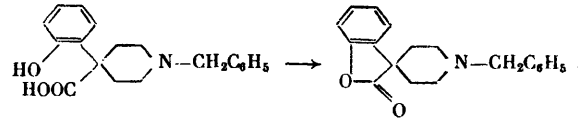
R = H, alkyl, phenyl; X = H_2, O.

o-Aminothiophenols condense with 1-methyl-4-piperidones to give spiro[benzthiazoline-2,4′-piperidines] which possess antiasthmatic properties.[237]

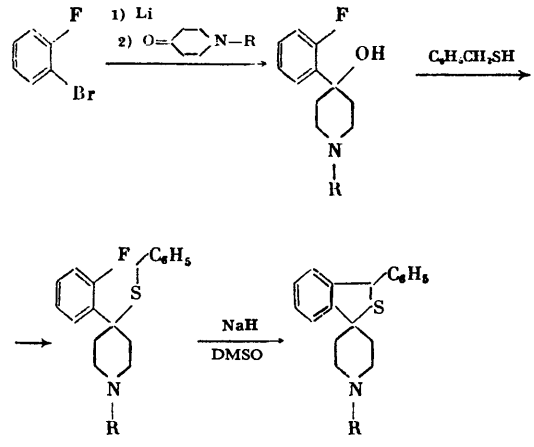


R = H, Cl, Me, MeO.

Spiro[isobenzofuran-1,4-piperidines] are obtained by conversion of *o*-bromobenzhydryl alcohol to the corresponding methyl ether, which, following conversion to the corresponding Grignard reagent, adds to 4-piperidones to give the corresponding 4-aryl-4-piperidinols; the latter are then cyclised to the desired spirocycles, as exemplified below. The resulting 3-phenyl-1,3-dihydrospiro[isobenzofuran-1,4′-piperidine] is converted to the 3-(3-dimethylaminopropyl) derivative by metallation with butyllithium followed by alkylation with 3-dimethylaminopropyl chloride.[238] A number of such spiroisobenzofurans have been discussed in the patent literature.[239]

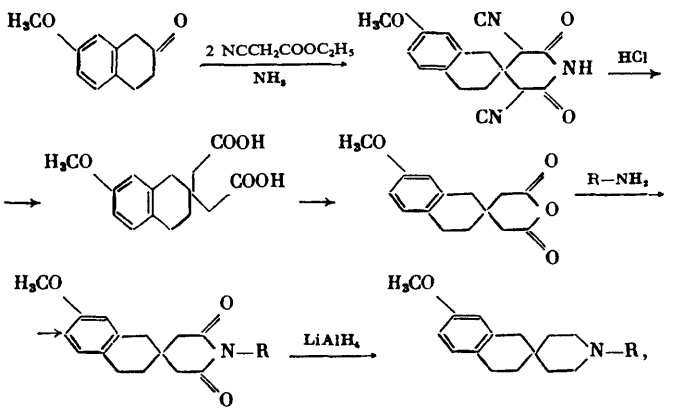


3-Thienyl-1-spiroisobenzofuran analogues have been prepared by the same method and shown to possess tranquillizing and antidepressant activity.[240] The following route is available for preparing 3-oxospiro[isobenzofuran-1,4′-piperidines]. Thus, *o*-bromobenzoyl chloride condenses with 2-amino-2-methylpropanol to give the corresponding benzamide, which undergoes cyclodehydration with $SOCl_2$ to give 2-(2-bromophenyl)-4,4-dimethyl-2-oxazoline. The corresponding Grignard reagent reacts with 4-piperidones to give the corresponding 4-aryl-4-piperidinols which cyclise to the desired spirocycles in acidic media. A number of these compounds possess analgesic, tranquillizing, antidepressant and anticonvulsant activities.[241,242]



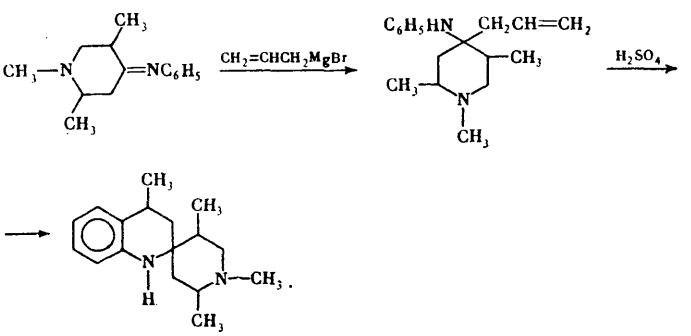
R = methyl, benzyl.

2-Oxospiro[benzofuran-3,4′-piperidines] are formed by cyclisation of *N*-benzyl-4-carboxy-4-(*o*-hydrophenyl)piperidines.[243]



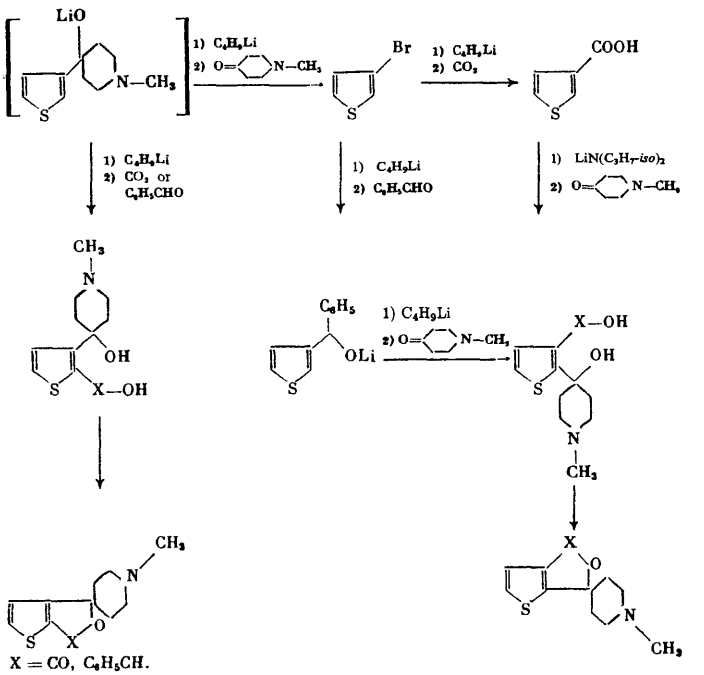
A 3-methylenespiro[benzofuran-2,4′-piperidine] has also been prepared and shown to possess hypotensive properties.[244]

Spiro[benzo[c]thiophene-1,4′-piperidines] have been synthesised as follows. *o*-Fluorophenyllithium, obtained from *o*-fluorobromobenzene by bromine-lithium exchange, condenses with 4-piperidones to give the corresponding 4-aryl-4-piperidinols, which are converted to the desired spirocycles by condensation with benzyl mercaptan followed by ring closure.[245,246]

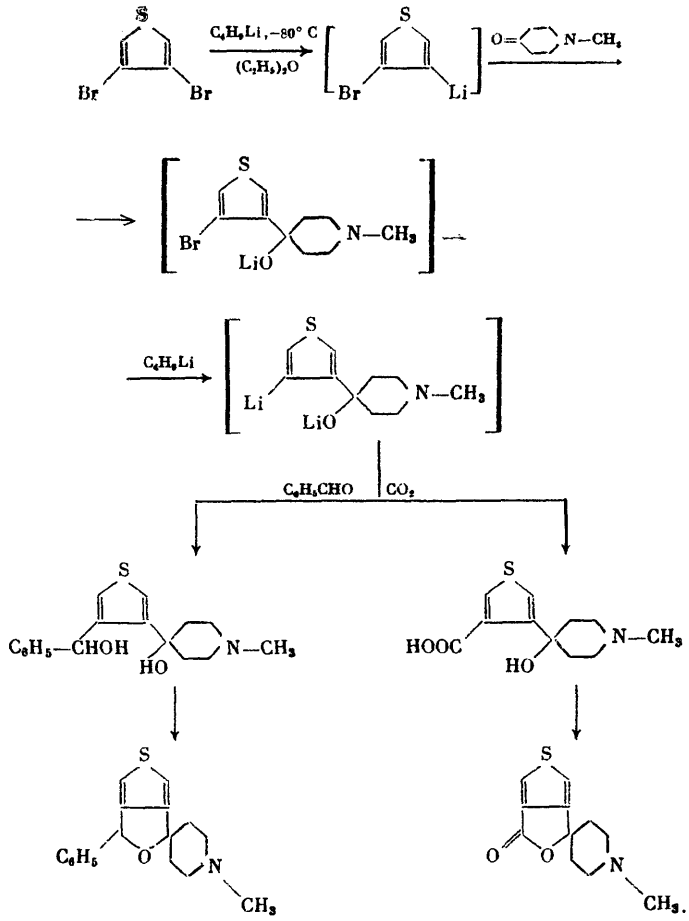


Such spirobenzothiophenes possess anticholinergic properties and are effective antidepressants and sedatives.

Spiro[tetrahydronaphthalene-2,4'-piperidines] have been obtained by conversion of 7-methoxy-2-tetralone to the corresponding Guaveschi's imide, followed by the sequence of steps shown below.[247]



R = dimethylaminopropyl.



Tetrahydro-1,3,5,7-tetramethylspiro[quinoline-2,4'-piperidine] has been prepared by the high-yielding reaction of 1,2,5-trimethyl-4-phenyliminopiperidine with allylmagnesium bromide, followed by heating the resulting 4-allyl-4-anilinopiperidine in acidic media.[248]

Spiropiperidines having a spiro-condensed thieno[2,3-c]furan ring at the 4-position have been prepared from 3-bromothiophene, which offers scope for incorporating further substituents in the thiophene ring via metallation.[249] Thus, sequential treatment of 3-bromothiophene with butyllithium and 1-methyl-4-piperidone affords the corresponding 4-(3-thienyl)-4-piperidolate, which reacts, sequentially, with a second equivalent of butyllithium and carbon dioxide or benzaldehyde to give the corresponding 2-carboxy- or 2-hydroxyalkylthiophenes. The latter then undergo cyclodehydration as shown below. Alternatively, 3-lithiothiophene reacts with carbon dioxide or benzaldehyde to give the corresponding 3-substituted thiophenes which undergo lithiation at the 2-position. These derivatives then condense with 1-methyl-4-piperidone to give the desired spirocycles.

Piperidines having a spiro-fused thieno[3,4-c]furan ring at the 4-position have been prepared by the above method from 3,4-dibromothiophene. Thus, treatment of the latter with butyllithium at low temperature affords 3-bromo-4-lithiothiophene, which, without isolation, adds to 1-methyl-4-piperidone; the intermediate 4-piperidolate (again without isolation) is further lithiated and the resulting *O,C*-dianion is converted to the desired spirocycle by quenching with benzaldehyde or carbon dioxide, followed by cyclodehydration of the intermediate diol or hydroxyacid in acidic media, as shown below:[250]

- - - o0o - - -

The discovery of spiropiperidine-type biogenic amines and alkaloids has stimulated intense research, notably in the chemistry of azaspiranes having a piperidine ring spiro-fused at the 4-position with various heterocycles containing both nitrogen and other heteroatoms.

Studies of the biological properties of these compounds have shown that they possess a broad spectrum of activity, certain of which have been utilised medicinally. From this survey, one might predict that in the near future these azaspiranes will be used as effective drugs for treating irregularities of the central nervous system.

Pyrolysis of methane in the temperature range 100–1700 K

V S Arutyunov, V I Vedeneev
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The results of studies on the pyrolysis of methane in the temperature range 1000–1700 K, which is of greatest practical importance, are surveyed. The influence of heterogeneous factors, pressure, temperature, and the products formed on the process is examined. The composition of the products is analysed and the mechanism of the process is discussed.

The bibliography includes 61 references.

I. Introduction

The enhancement of the role of natural gas in the fuel–energy system as well as in many technological processes has aroused a new wave of interest in fundamental problems of the processing of the simplest hydrocarbons, including the main primary processes involved in the conversion of methane—its oxidation and pyrolysis. The complexity of the problem and the enormously wide variety of the real conditions encountered in technological processes have precluded to date a unique theoretical description of these processes. Depending on the specific purpose of the process, the pyrolysis of methane can be carried out over a wide temperature range. This range can be divided arbitrarily into three regions: low temperatures (up to 1000 K), moderate temperatures (1000–1800 K), and high temperatures (above 1800 K). Fairly reliable kinetic data have been obtained for the low temperature range and have already been surveyed.[1,2] Studies in the high-temperature range have developed by virtue of the wide scale adoption of the experimental shock wave method.[3,4] However, the specific features of the method resulted in mainly the initial stages of the pyrolysis being investigated.

The range of moderate temperatures, in which most of the technological processes are carried out, for example, the reduction of sulphur dioxide by methane at 1200–1500 K in the waste gases from non-ferrous metallurgy,[5] has in fact been least investigated at the present time. The pyrolysis of methane in this temperature range is the initial and rate-limiting stage of the entire SO_2 process.[6] During the last six years, many studies have been published on the pyrolysis of methane in the range of moderate temperatures, but these were mainly studies with a technological bias. Their fragmentary nature and association with specific conditions precluded a reliable answer to three principal questions: concerning the rate of pyrolysis in this temperature range and its dependence on external parameters, the concentration of the main gaseous pyrolysis products and the kinetic mechanism of the pyrolysis under these conditions. The aim of the present review is to survey the available data on these problems.

The study of the pyrolysis of methane was initiated in 1809 by Dalton, who demonstrated the possibility of decomposing methane into its elements by an electric discharge. On the other hand, the thermal decomposition of methane was first achieved by Davy with the aid of an electrically heated platinum wire. The first study devoted to the thermal decomposition of methane was carried out by Berthelot[7,8] in 1862. He passed methane through a heated porcelain tube and observed the formation, together with carbon, of a mixture of different hydrocarbons, primarily acetylene and olefins, as well as traces as more complex hydrocarbons—benzene and naphthalene. He assumed that the primary stage of the process is the bimolecular reaction

$$2CH_4 \rightarrow C_2H_2 + 3H_2. \quad (1)$$

In 1908 Bone and Coward,[9] who investigated the kinetics of the decomposition of CH_4 at temperatures in the range 773–1473 K, put forward the hypothesis of the intermediate formation of the fragment species CH_3, CH_2, and CH. The experimental demonstration of the formation of hydrocarbon radicals (methylene and methyl) in the pyrolysis of methane was first obtained by Belchetz[10] and Rice and Dooley[11] using Paneth's method (the metallic mirror method). Mayer and Altmayer,[12,13] who investigated the equilibrium

$$CH_3 \rightleftharpoons C + 2H_2, \quad (2)$$

at atmospheric pressure and different temperatures, demonstrated the reversibility of the decomposition of methane into the elements.

The most fundamental study of the kinetics of the pyrolysis of methane up to the 1950s remains that of Kassel,[14] who carried out the pyrolysis under static conditions in a quartz reactor in the temperature range 973–1123 K. He concluded that the reaction is homogeneous and of first order although under certain conditions an induction period of unknown nature is observed. The expression which he obtained for the methane pyrolysis rate constant $k = 7.3 \times 10^{11} \exp(-79\,385/RT)\ s^{-1}$ describes the process satisfactorily up to temperatures in the region of 1500 K. Having

surveyed the results of earlier studies[15,16] concerning the influence of hydrogen on the pyrolysis of methane, Kassel established that the rate of pyrolysis decreases markedly in the presence of hydrogen and he derived the empirical relation $W \propto [CH_4]^2/[H_2]^3$. The experiments carried out by Storch,[17] who carried out the pyrolysis of methane on an incandescent carbon filament in a flask whose surface was cooled to a definite low temperature which made it possible to stabilise and isolate the primary reaction product, were very important for the understanding of the mechanism of the decomposition of methane. On cooling with liquid nitrogen (77 K), 95% conversion of methane into ethane was observed, on cooling with liquid oxygen (91 K) cracking resulted in the formation of ethane, ethylene, and acetylene, while on cooling the surface of the flask to 203 and 273 K the cracking products were carbon and hydrogen. On the basis of these data, the following scheme for the consecutive dehydrogenation of methane was put forward:[14]

$$CH_4 \rightarrow CH_2 + H_2, \quad (3)$$

$$CH_4 + CH_2 \rightarrow C_2H_6, \quad (4)$$

$$C_2H_6 \rightarrow C_2H_4 \rightarrow C_2H_2 \rightarrow C + H_2. \quad (5)$$

Subsequently Storch[18] interpreted data for the rate of the thermal decomposition of methane obtained in earlier investigations,[16,19–21] etc. His conclusions will be partly considered below.

Two important factors in the study of the pyrolysis of ethane were established by Kobozev and co-workers.[22–24] Firstly, a change in the nature of the surface does not affect the rate of decomposition of methane itself but can influence greatly the rate of formation of solid carbon products[22,23] and, secondly, the pyrolysis is accelerated by the addition of ethane.[24] Subsequently the accelerating effect of all C_2 hydrocarbons (ethane, ethylene, acetylene) was demonstrated in many investigations. In a series of studies by Germain and Vaniscotte,[25–27] etc. at temperatures near 1273 K and atmospheric pressure, the induction periods in the pyrolysis process were thoroughly investigated and their dependence on the process conditions was established.

Since the end of the 1950s, the shock wave method came to be used widely for the study of the early stages of the pyrolysis of methane,[28,29] but most of the results obtained by this method refer to the high-temperature range. The studies of this period have been briefly surveyed by Khan and Crynes.[1] At the same time, a series of studies devoted to practical problems of the preparation of acetylene by the pyrolysis of methane have been carried out.[30–33]

II. Heterogeneous factors in the pyrolysis of methane

The results of early studies of the influence of heterogeneous factors on the pyrolysis of methane are fairly contradictory. Whereas Kassel[14] and Holliday and Exell[15] did not detect the influence of a change in the ratio S/V on the pyrolysis of methane in the range of moderate temperatures in quartz reactors and reactors coated with a layer of carbon formed on pyrolysis even when this parameter was varied widely (by a factor of 20 in Kassel's study[14]), Wheeler and Wood[20] claimed that the pyrolysis of methane in a quartz reactor is mainly a surface process (an appreciable catalytic effect in the presence of iron was also noted). The study of Kobozev et al.[22] was devoted to the influence of the nature of the surface (quartz or porcelain) and also of the known catalytic poisons on the pyrolysis of methane at 1433 K. It was established that the rate of formation of products such as ethylene and acetylene is independent of changes in the material of the surface or the presence of catalytic poisons, but these factors do affect greatly the rate of formation of soot on the surface of the reactor. The conclusion that the reaction is homogeneous was confirmed[24] by the identical yields of ethylene and acetylene in carbon and porcelain tubes at 1883 K.

It has been shown[25,34] that at temperatures of about 1273 K an increase in the ratio S/V diminishes the induction period and increases somewhat the maximum rate of reaction. The influence of the state of the surface on the process during the induction period was also noted. However, at higher temperatures (1373 and 1423 K) a change in S/V ceases to influence even the initial stage of the pyrolysis.[35] The claim that the pyrolysis of methane is heterogeneous, made in the study of Shantorovich and Pavlov[36] on the basis of experiments under flow conditions at low pressures, also refers to the initial stage involving the self-acceleration of the reaction. An increase in the rate of reaction as carbon was deposited on the surface of the porcelain reactor was also noted in the above investigation, the activation energy for the pyrolysis on the carbon-coated surface amounting to only 60 kcal mol^{-1} compared with 90 kcal mol^{-1} on the procelain surface.

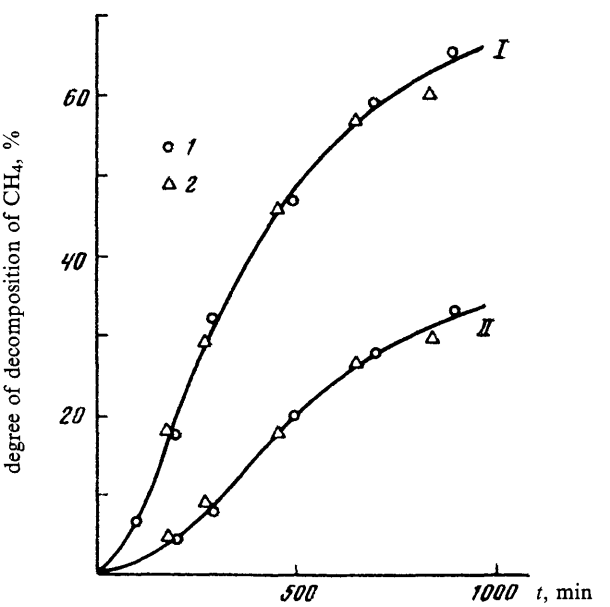

Figure 1. Kinetics of the decomposition of methane for S/V = 2 cm^{-1} (*1*) and 4 cm^{-1} (*2*): *I*, initial CH_4 concentration C_0 = 10% at T = 1423 K; *II*, C_0 = 16% at T = 1373 K. P = 740 torr.[35]

A dependence of the pyrolysis of methane on heterogeneous factors was not observed in many studies.[35,37–40] The independence of the degree of conversion of methane and of the quasi-stationary rate of pyrolysis of the surface area of the reactor for times exceeding the induction period has been demonstrated[35,37] for mixtures of methane (10–16%) with nitrogen and helium at temperatures of about 1400 K (Fig. 1). Chen et al.[38] demonstrated

this for lower temperatures (995–1103 K). Arutyunov et al.[39] observed in a static reactor a satisfactory agreement between the kinetics of the decomposition of methane at 1200 K and the kinetics of the production of hydrogen when S/V was altered by a factor of approximately 2.2. They noted that it is virtually impossible to observe differences in the process kinetics and in the composition of the products when the pyrolysis is carried out in a clean quartz reactor, in a reactor where a large number of experiments have already been carried out, or in a reactor flushed repeatedly with oxygen at 1200–1300 K after pyrolysis. The independence of the final composition of the pyrolysis products of the diameter of an alumina flow reactor has been demonstrated.[40]

The formation of soot in the volume of the reactor apparently influences greatly the pyrolysis of methane. Thus it has been shown[35] that the introduction of 1% of naphthalene vapour into the reactor leads to a thirtyfold increase in the rate of decomposition of methane. On the basis of these experiments, the authors concluded that the initial autoacceleration of the pyrolysis on the soot nuclei, formed in the volume of the reactor and on the surface, is heterogeneous.

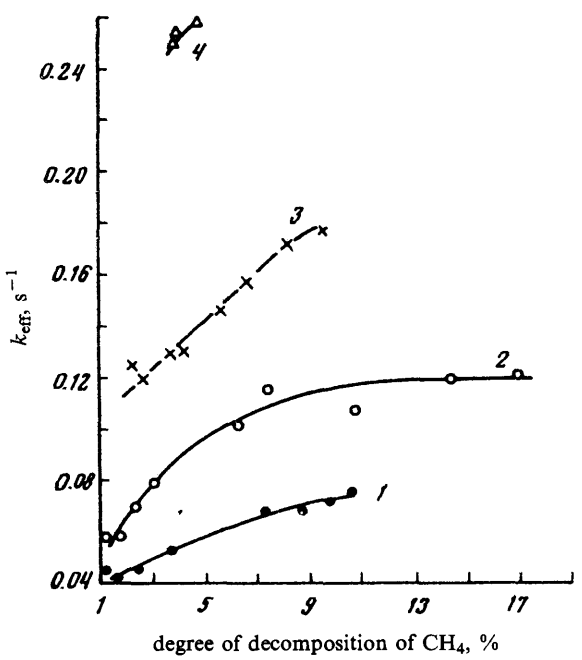

Figure 2. Dependence of the effective unimolecular rate constant for the decomposition of methane (k_{eff}) on the degree of conversion of the latter at different temperatures (K) (pressure 1 atm): *1*, 1280; *2*, 1306; *3*, 1326; *4*, 1346.

Many workers suggest the existence of a pathway leading to the direct decomposition of methane into carbon and hydrogen, bypassing the formation of intermediate C_2 hydrocarbons,[33,41,42] on the surface of the reactor,[42] which might explain the low activation energies for the carbon deposition process on the surfaces of graphite (36.0 kcal mol^{-1} [41]) and alumina (16.2 kcal mol^{-1} [33]) reactors. Similar activation energies (~25 kcal mol^{-1}) have been obtained for the methane decomposition and carbon deposit formation reactions in a tubular graphite reactor with a high ratio S/V = 10 cm^{-1} in the temperature range 1573–2473 K, while the temperature dependence of the yield and of the rate constants for the formation of ethylene and acetylene was more marked.[42] This led the authors[42] to the conclusion that a single dehydrogenation mechanism [reaction (5)] is insufficient for the description of the pyrolysis of methane under these conditions.

Only for the very high ratios $S/V > 10^4$ cm^{-1}, obtained[43] by introducing finely disperse materials (gas carbon black, Al_2O_3 powder) into the reaction zone in quartz and copper flow reactors, does the reaction become fully heterogeneous. According to the authors,[43] this is associated with the fact that the rate of formation of active centres per unit volume is greater by a factor of 10^4 than per unit surface. Therefore, even for $S/V < 20$ cm^{-1}, the induction period reappears.

On the whole, despite the existence of fairly notable contradictions between the results of individual studies, one may conclude that in the range of moderate temperatures and for the usual S/V ratios and reactor materials, heterogeneous factors have an appreciable influence on the pyrolysis of methane only in the initial period of the autoacceleration of the reaction and that with increase in temperture this influence gradually weakens and at $T > 1400$ K is virtually inappreciable. Heterogeneous factors affect much more strongly the deposition of solid carbon on the surface, but examination of these processes is outside the scope of the present review.[44]

III. Autocatalysis of the initial stage of the pyrolysis of methane

In the vast majority of cases, the pyrolysis of methane is regarded as a first-order reaction and is described by the corresponding kinetic equation. However, the presence of an induction period in this reaction was already established in the early studies. Kassel[14] noted that the presence of the induction period is most striking at low pressures and in reactors which have not yet been coated by a layer of carbon; in the case of large S/V ratios, there are no induction periods. An increase in the rate of pyrolysis of methane with increase in the degree of pyrolysis, i.e. the occurrence of autocatalysis, has been demonstrated[34] for low degrees of conversion (Fig. 2). The phenomenon of autocatalysis and its dependence on the process parameters have been investigated by Germain and Vaniscotte[25–27] at temperatures near 1273 K. According to their results, changes in the S/V ratio for the reactor have a fairly appreciable albeit not very strong influence on the induction period and the rate of reaction in the initial period (Figs. 3 an 4). Evidently an increase in S/V approximatley by a factor of 10 leads to only a twofold decrease in the induction period and increase in the maximum rate of reaction. Small amounts of added ethane (0.5–3%) have approximately the same effect.[27] The influence of added ethane on the initial period of the pyrolysis has been investigated[45] over a wider temperature range: from 1323 to 1823 K. At 1323 K, the presence of even 0.21% of ethane alters qualitatively the nature of the methane decomposition curve, leading to the disappearance of the reaction autoacceleration section (Fig. 5). Similar changes have been obtained also for the kinetics of the evolution of hydrogen in this process. With increase in temperature,

the autoacceleration becomes less marked and at $T > 1500$ K neither autoacceleration (Fig. 6) nor the influence of added ethane (0.69%) on the kinetics of the pyrolysis are observed.[45] Apart from an increase in temperature, an appreciable increase in the S/V ratio (S/V > 20 cm^{-1}) leads to the disappearance of the autoacceleration period.[43]

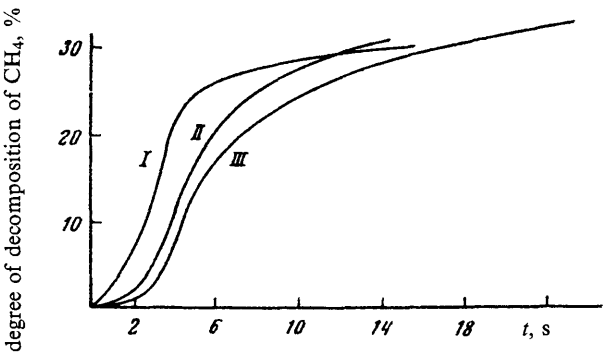

Figure 3. Kinetics of the decomposition of methane for different S/V ratios (cm^{-1}): *I*, 25.3; *II*, 5.0; *III*, 2.8. Temperature 1273 K; pressure 1 atm; methane concentration 95%.[25]

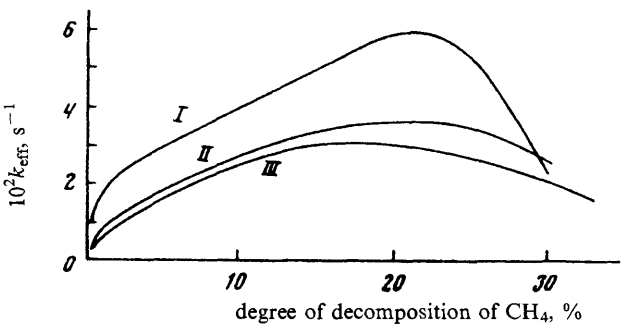

Figure 4. Dependence of the effective unimolecular rate constant k_{eff} for the decomposition of methane on the degree of conversion of the latter for different S/V ratios (cm^{-1}): *I*, 25.3; *II*, 5.0; *III*, 2.8.[25]

In a review[2] devoted to the pyrolysis of methane at temperatures of about 1000 K, it was shown on the basis of a series of experimental studies that the autocatalysis in this reaction cannot be accounted for by the formation of a layer of carbon on the surface of the reactor. Thus the formation of carbon on the surface of the reactor was followed from the absorption of light in a static system at about 1000 K.[46] The sensitivity of the method made it possible to detect less than a monolayer of the carbon formed. It was noted that carbon begins to be formed appreciably after the start of the autoacceleration of the reaction (Fig. 7). Furthermore, the use of a reactor in which the initial stage of the pyrolysis had already been carried out up to the onset of autocatalysis and then all the volatile products were removed did not affect appreciably the formation of products, i.e. the autoacceleration effect cannot be attributed to the presence of small amounts of undetected carbon on the surface. Probing of the volume of the reactor with the beam from a helium–neon laser also demonstrated the absence in this stage of even small carbon particles in the reactor volume which could be responsible for the autocatalysis, since their presence should have given rise to the corresponding scattering of the laser beam.[2] Thus it was necessary to seek an explanation of the phenomenon of autocatalysis in the gas-phase processes, which was in fact done for the above conditions (T = 1038 K, P = 433 torr) by Roscoe and Thompson[47] and Dean.[48] Mathematical modelling of the process showed[47] that the main causes of the autoacceleration are the secondary initiation of the pyrolysis by hydrocarbon products more complex than ethane and the subsequent chain processes involving methyl radicals. With increase in temperature, the role of higher hydrocarbons in the pyrolysis of methane diminishes, which reduces the autocatalytic effect up to its complete disappearance at $T > 1500$ K.

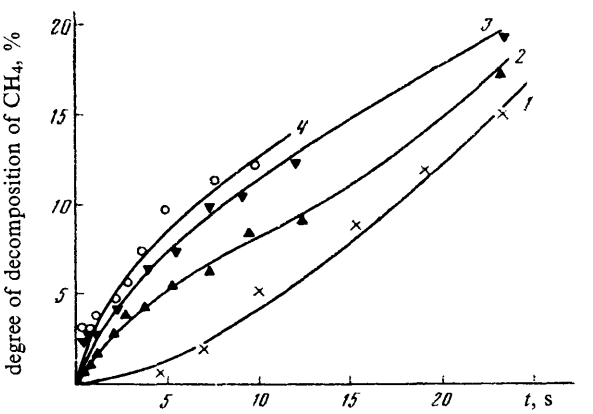

Figure 5. Dependence of the kinetics of the decomposition of methane on the initial C_2H_6 concentration C_0 (T = 1323 K, P = 760 torr); C_0 (%): *1*, 0; *2*, 0.21; *3*, 1.02; *4*, 1.45.[45]

IV. The influence of hydrocarbons on the pyrolysis of methane

The acceleration of the pyrolysis of methane in the presence of added ethane was already observed by Kobozev and Shneerson.[24] Gordon[34] showed for pyrolysis under flow conditions at temperatures near 1273 K that the addition of 0.72% of acetylene increases the rate of pyrolysis by a factor of 2–2.5 and that acetylene itself is initially vigorously consumed in the reaction. At the addition of 1% of ethylene to methane being pyrolysed has a similar effect but in this case the concentration of ethylene itself does not fall below 0.85% and the catalytic effect was attributed solely to the acetylene formed in the reaction and detected in the products in approximately the same amount as for the addition of acetylene itself.

A detailed study of the influence of small amounts of added ethane on the initial stage of the pyrolysis of methane was carried out by Germain and Vaniscotte[27] under flow conditions at T = 1273 to

1373 K. A decrease in the induction period and an increase in the maximum rate of pyrolysis after the addition of 0.5–3% of ethane were demonstrated, but with increase in the ethane concentration the relative efficiency of the additive fell. With increase in temperature in the above range, the influence of ethane also diminishes. The accelerating effect of ethane on the pyrolysis of methane under flow conditions was also observed in the temperature range T = 1100–1200 K.[37] The influence of ethane on the initial period of the process, manifested by the disappearance of the induction period and of the reaction acceleration region,[45] was examined in a previous section. It is of interest that, regardless of the initial concentration of the added ethane, a concentration characteristic of the pyrolysis of pure methane is established after a certain time (Fig. 8), i.e. the accelerating effect of hydrocarbon additives is manifested in the initial period of the reaction.

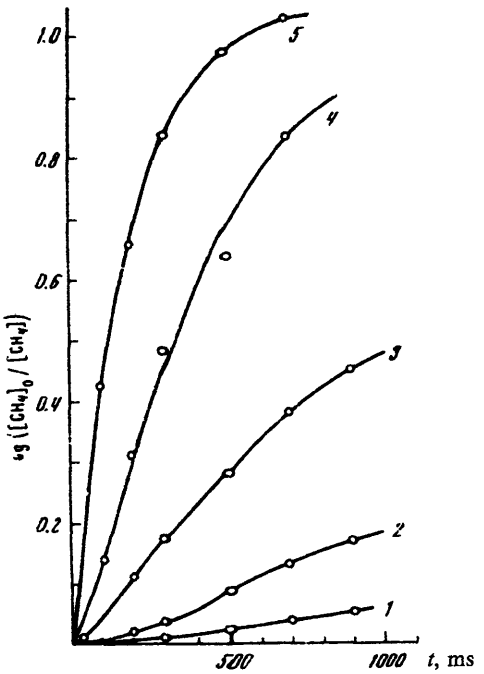

Figure 6. The influence of temperature on the kinetics of the decomposition of methane in the initial period; pressure 740 torr; methane concentration 10%;[35] T (K): *1*, 1323; *2*, 1373; *3*, 1423; *4*, 1473; *5*, 1523.

Using a radiochemical method,[49–51] the influence of the addition of 0.5–3% of acetylene, ethylene, and ethane on the pyrolysis of methane at T = 1293 and 1343 K was studied systematically. A clear accelerating effect of the C_2 hydrocarbons was observed in all cases, but, as in the study of Germain and Vaniscotte,[27] the effectiveness of the additives fell appreciably as their concentration approached 3%. Apparently further increase in the concentration of the additive has only a weak effect on the pyrolysis.

Added hydrocarbons exert the greatest influence on the yield of hydrogen for short reaction times. For example, in the pyrolysis of methane at 1293 K for 1.96 s, the presence of 1.5% of ethane increases the yield of hydrogen by a factor of approximately 10.[51] The yield of C_2 hydrocarbons can also increase severalfold under these conditions. With increase in the reaction time (8–8.5 s) and especially at a higher temperature (1343 K), the addition of hydrocarbons has almost no effect on the yield of hydrogen and C_2 hydrocarbons. In all three cases, the use of initiating additives with the ^{14}C radioactive isotope results in almost the entire radioactivity being concentrated in methane even after the shortest period of observation. This agrees well with the concept of the leading role of the CH_3 radicals in the pyrolysis, whose ready formation on decomposition of C_2 hydrocarbons is apparently responsible for the initiating effect in the initial period of the pyrolysis of methane.

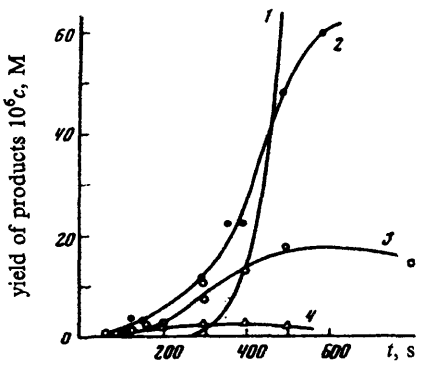

Figure 7. The yield of certain methane pyrolysis products at T = 1118 K and P = 307 torr;[2] products: *1*, carbon; *2*, C_2H_6; *3*, C_2H_4; *4*, C_4H_6.

V. The influence of hydrogen on the pyrolysis of methane

The inhibiting effect of hydrogen on the pyrolysis of methane was already established by Holliday and Exell[15] and Wheeler and Wood,[20] who explained it by the formation of a layer of adsorbed hydrogen on the reactor surface. According to the authors, this layer does not allow the heterogeneous pyrolysis of methane to go to completion, which results in the establishment of a false equilibrium in the system which is far from thermodynamic equilibrium.[20] On the basis of the scheme involving the consecutive dehydrogenation of methane [Eqns. (3)–(5)], Kassell explained the inhibiting effect of hydrogen by the occurrence of the corresponding reverse hydrogenation reaction, which enabled him to obtain, in terms of the approximation of quasi-stationary concentrations, a relation for the rate of pyrolysis, namely $W \propto [CH_4]^2/[H_2]^3$, describing satisfactorily the experimental results which he obtained in a static reactor at T = 1033 K. The only study where the accelerating effect of hydrogen was reported was that of Gordon,[34] who described the pyrolysis of methane at T = 1280 K and P = 1 atm in a porcelain

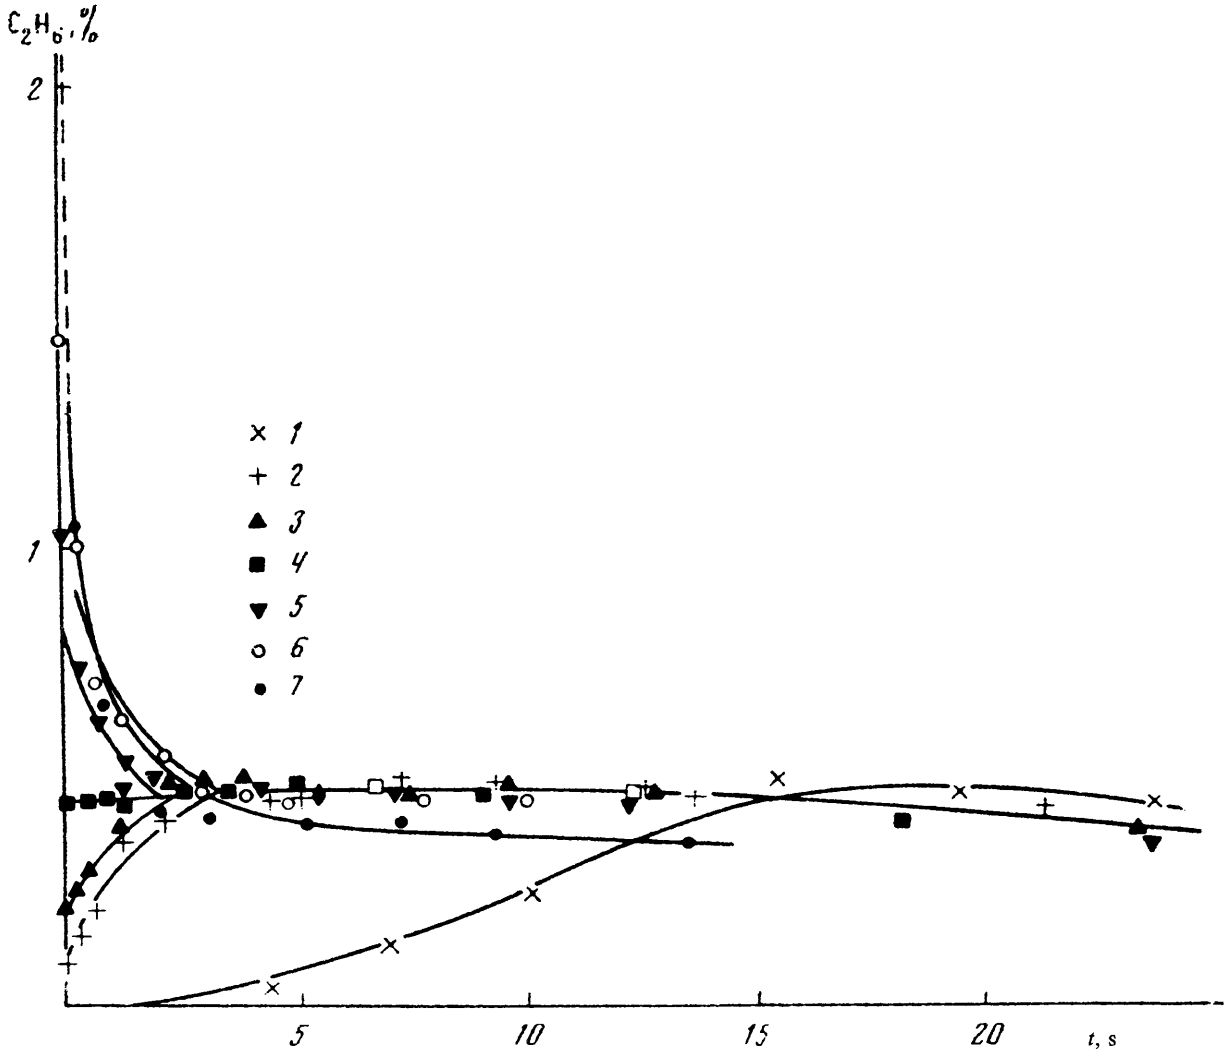

Figure 8. Kinetics of the formation and decomposition of C_2H_6 in the pyrolysis of methane at different initial C_2H_6 concentrations (T = 1323 K, P = 760 torr);[45] C_2H_6 concentration (%): *1*, 0; *2*, 0.09; *3*, 0.21; *4*, 0.45; *5*, 1.02; *6*, 1.45; *7*, 4.56.

flow reactor. It was noted that the addition of 2% of H_2 accelerates the rate of the initial stage of the decomposition of methane by 20–30% (degree of decomposition of methane 1.64–3.09%). There has been yet another study[52] in which an inhibiting effect of hydrogen was not observed when the decomposition of methane was investigated by the shock wave method in the higher temperature range 1656–1695 K. This may be explained by the fact that the effect of hydrogen is associated with later stages of the reaction, which do not manage to be manifested for the short times characteristic of the processes in shock waves.

The identity of the inhibiting effects of the hydrogen formed during the reaction and specially added to the initial mixture has been demonstrated[53] at T = 1123 K, P = 150 torr, and for degrees of decomposition of methane not exceeding 1% (Fig. 9).

The influence of the addition of 50% of hydrogen on the pyrolysis of methane at 1273–1373 K has been investigated.[26] In contrast to nitrogen, the addition of which has only a slight effect on the pyrolysis, dilution of the mixture with hydrogen in proportions of 1 : 1 led to an appreciable increase in the induction period and to an approximately fivefold decrease in the maximum rate of the process (Fig. 10). However, such appreciable dilution with hydrogen and nitrogen had no effect on the process activation energy (87 kcal mol^{-1}).[26] These results have been confirmed[37] in a flow reactor at 1458 K for mixtures containing 15% of CH_4 in nitrogen and H_2/CH_4 ratios ranging from 0.1 to 2. It has been shown[39] in a static reactor at 1200 K and a pressure of 400–450 torr that dilution of methane with hydrogen in proportions of 1 : 3 diminishes the maximum concentration of ethylene in the course of the reaction by a factor of 10–15 and entails a decrease in the overall rate of pyrolysis by a factor of 2–3. The formation of ethane and acetylene under these conditions could not be detected at all (volume concentration < 0.01%).

In a number of studies devoted to practical aspects of the pyrolysis of methane, the influence of dilution of the reaction

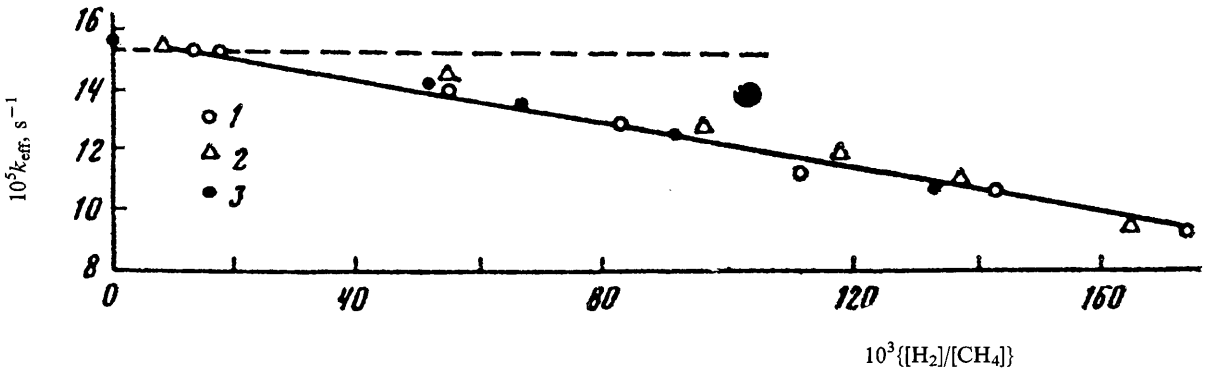

Figure 9. Dependence of the effective unimolecular rate constant k_{eff} for the decomposition of methane at 1123 K on the degree of accumulation of H_2 in the reacting gas:[53] *1*, P = 150–162 torr, H_2 added to the initial mixture; *2*, P = 101.0 torr; *3*, P = 158.3 torr, H_2 accumulating in the reacting gas.

mixture with hydrogen on the yield of acetylene in this reaction was investigated. Kunugi et al.[30] carried out the process in a quartz flow reactor, filled with lumps of quartz, in the temperature range 1373–1673 K. The dependence of the yield of acetylene on the dilution of methane with hydrogen is illustrated in Fig. 11. Evidently, the yield of acetylene increases with increase in the hydrogen/methane ratio and reaches a maximum when the ratio is approximately 2.5 at 1473 K and approximately 3.5 at 1573 and 1673 K. With increase in the hydrogen/methane ratio, the time required for the attainment of the maximum yield of acetylene also rises. The increase in the yield of acetylene on dilution with hydrogen, which clearly diminishes the rate of pyrolysis, is associated with the fact that it suppresses to an even greater extent the rate of formation of hydrocarbon products from acetylene. It may be that the latter process is heterogeneous and takes place when hydrogen interacts with the soot deposits in the system.[33]

Yampol'skii et al.,[42] who investigated the pyrolysis of methane in a graphite flow reactor for high dilutions with hydrogen (H_2/CH_4 up to 21) and at high temperatures (2003–2173 K) also concluded that hydrogen inhibits certain heterogeneous processes associated with the pyrolysis of methane. Under these conditions, dilution with hydrogen reduced the formation of carbon deposits in the reactor and diminished the concentration of unsaturated C_3–C_4 hydrocarbons in the reaction products, increasing simultaneously the yield of acetylene. However, the decrease in the yield of carbon deposits on dilution of methane with hydrogen was attributed[42] primarily to the selective inhibition of the direct heterogeneous decomposition of methane into carbon and hydrogen.

A marked influence of hydrogen on the heterogeneous decomposition of methane at 1088–1373 K has been observed[43] in a reactor with a high S/V ratio (up to 10^5 cm^{-1}). However, the effect diminishes with increase in temperature. Thus at 1073 K the addition of 10% H_2 reduces the rate of formation of pyrocarbon by a factor of 140, while at 1573 K the decrease is only by a factor of 5. According to the hypothesis put forward by Makarov and Pechik,[43] the much stronger inhibiting effect of hydrogen under the conditions of pure heterogeneous pyrolysis is associated with the fact that under these conditions the inhibition is by atomic hydrogen, while in homogeneous pyrolysis the inhibitor is molecular hydrogen.

VI. Dependence of the process on the concentration of methane and on pressure

Data concerning the influence of the concentration of methane on its pyrolysis have been obtained in a number of studies. An appreciable influence of 50% dilution of methane by nitrogen or water vapour on the rate of pyrolysis was not observed in a study[34] at P = 1 atm and 1280 K. A similar dilution of methane with nitrogen in proportions of 1:1 and 1:2 at 1273–1373 K led to a slight increase in the degree of decomposition of methane (Fig. 10).[26] The reverse effect was observed in a study[27] where an increase in the methane concentration in nitrogen in a flow reactor from 15 to 25% (T = 1373 K, P = 1 atm) resulted in a slight (~10%) increase in the degree of its decomposition for a fixed observation time. On the other hand, in another study,[35] when the concentration of methane in helium was increased from 1 to 10%, the degree of its decomposition in a porcelain flow reactor at T = 1473 K and P = 740 torr remained virtually constant. Only for short reaction times was an increase in the degree of decomposition with increase in the methane concentration observed, but it was so slight that the authors themselves expressed doubts about the reliability of the effect. The contradictory nature of the data presented above combined with the smallness of the effect in those cases where it was observed apparently mean the dilution with inert gases in the above temperature range at atmospheric pressure hardly affects the pyrolysis of methane.

The dependence of the rate of pyrolysis of methane on pressure is related primarily to the pressure dependence of the reaction rate constant:[38,54]

$$CH_4 \rightarrow CH_3 + H. \qquad (6)$$

It has been established[55] that this transitional range of pressures in the above temperature range extends almost up to 500 atm. Fig. 12 illustrates the increase in the unimolecular rate constant for the pyrolysis of methane with pressure, observed[39] in the range 115 to 700 torr at T = 1100 and 1200 K. Although in certain early studies, for example, those of Kassel[14] (pressure range 13.0–296.4 torr, temperature 1008 K) and Shantorovich and Pavlov[53] (low degrees of conversion not exceeding 2–2.5%, methane pressure range 28.7 to

232.0 torr, temperature 1123 K), no pressure dependence of the rate of pyrolysis of methane was observed, nevertheless, such a dependence undoubtedly exists.

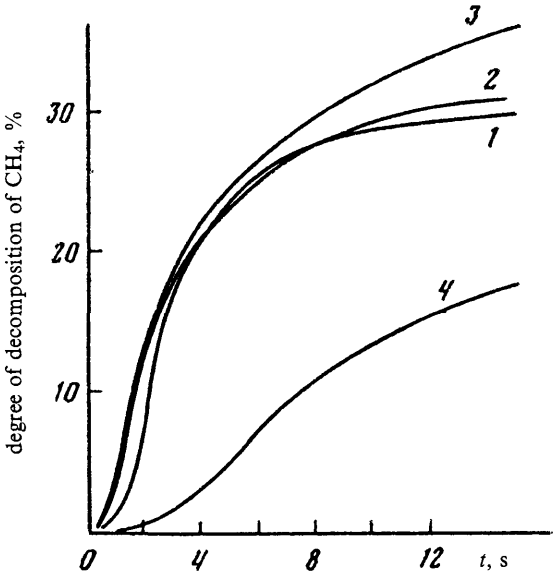

Figure 10. Kinetics of the decomposition of methane on dilution of the mixture with N_2 and H_2 (T = 1273 K, P = 1 atm):[26] *1*, 100% CH_4; *2*, CH_4/N_2 = 50/50; *3*, CH_4/N_2 = 33/66; *4*, CH_4/H_2 = 50/50.

VII. Composition of the methane pyrolysis products

Thermodynamic calculations of the equilibrium composition of the gaseous pyrolysis products (of the gaseous C/H system), taking into account the existence of more than 70 seperate components, have been carried out[56] for C/H ratios from 1/10 to 3, at temperatures of 500–5000 K, and at pressures of 0.1, 1.0, and 10 atm. Calculations taking into account the formation of solid carbon were performed separately. In all cases the main gaseous product in the relevant temperature range is H_2 (up to 70%) (Fig. 13). In this temperature range the stable hydrocarbons with a small number of atoms reached their maximum concentrations, after which their concentrations decreased monotonically with increase in temperature. At T > 1400 K the dominant hydrocarbon is acetylene (Fig. 13), whose concentration reaches 25% of the total volume of the gas phase. The concentrations of the remaining stable hydrocarbons are appreciably lower and even for ethylene the maximum concentration does not reach 1%. In this temperature range, there is an appreciable amount of methane at thermodynamic equilibrium in the gas phase. The equilibrium concentrations of atoms and radicals are extremely low at such temperatures. When the ratios C/H and the pressure do not vary appreciably in this system, the situation does not change significantly.

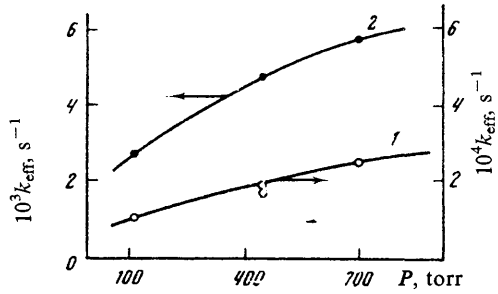

Figure 12. Dependence of the effective unimolecular rate constant k_{eff} for the decomposition of methane on pressure at different temperatures (T, K): *1*, 1100; *2*, 1200.[39]

The picture changes sharply when account is taken of the formation of the solid carbon phase. In this case, in the temperature range from 1000 to 3000 K the gas phase consists almost exclusively of hydrogen (~100%). The equilibrium concentration of methane falls sharply (<1% at T > 1200 K) and the concentrations of all the remaining hydrocarbons decrease. Since it is difficult to claim that the solid phase was taken adequately into account in the above calculations (one of two ratios, C/H = 10^3/1 or 10/1, was adopted for the composition of the solid phase), the practical value of the results of these calculations is primarily an indication of the qualitative trends associated with the presence of the solid phase. However, the real formation of the solid phase precludes a direct comparison with experiment of the results of thermodynamic calculations on a single-phase system, although it may be that such single-phase description reflects to some extent the ratio of the gaseous products of the initial stage of pyrolysis. Thus the uncertainty of the results of the thermodynamic calculations, associated with the inadequate allowance for the formation of the solid phase during pyrolysis, necessitates the analysis of the available experimental yields of the final methane pyrolysis products.

The kinetics of the formation and the final composition of the gaseous methane pyrolysis products in the range of moderate temperatures have been investigated in many studies. Germain and

Vaniscotte[25] studied the formation of C_2 hydrocarbons at 1273 K at atmospheric pressure in quartz reactors with S/V ranging from 2.8 to 25.3. Under these conditions, the concentration of methane at the end of the experiment was about 50% of the volume of the gas phase, the concentration of ethylene was less than 1%, and the concentrations of ethane and acetylene were approximately an order of magnitude smaller (slow conversion of methane and of the remaining products continued also for the maximum observation time, which was 20 s in the given study). The concentrations of all the C_2 hydrocarbons passed through a maximum, the time of attainment of which diminished with increase in S/V, but neither the size of the maxima ($\sim$1.5% of the volume of the gas phase for ethylene) nor the degree of decomposition of methane depended significantly on this ratio. Similar results were obtained by Schneider[45] (temperature range 1323–1823 K). An increase in the maximum concentrations of ethylene and acetylene is observed with increase in temperature—$[C_2H_2]_{max}$ is approximately 10% at 1833 K and approximately 1% at 1323 K. Small amounts of added ethane (up to 4.5%) have a similar effect as an increase in S/V, diminishing the time of attainment of the maximum concentration of C_2 hydrocarbons but not affecting its value.[45]

The kinetics of the reaction of methane and the formation of the principal gaseous products in the temperature range 1100–1400 K in a static reactor at a pressure of 440 torr have been investigated.[39] The kinetic curves for T = 1200 K are presented in Fig. 14*a*. At this temperature the pyrolysis virtually terminates after 5 min and the final degree of conversion of methane is about 50%. Direct measurement of the final pressure and the decrease in the relative concentration of the nitrogen added to the mixture as a permanent reference standard ($\sim$10%) indicate a pressure rise by about 22% (Fig. 14*b*). Such a change in pressure combined with the insignificant content of C_2 hydrocarbons in the pyrolysis products lead to the formula CH for the solid product remaining on the walls of the reactor and partly deposited on the cold connecting tubes during its evacuation. The principal gaseous hydrocarbon pyrolysis product in this temperature range is ethylene, but, whereas at 1100 K its concentration exceeds by a factor of approximately 10 the concentrations of the hydrocarbons next in importance (acetylene and ethane), at 1300 K the concentrations of ethylene and acetylene are almost comparable. Nevertheless, even at 1300 K the maximum concentrations of these products remain at the level of 1% of the total volume of the mixture. Although the maximum concentration of ethane increases somewhat with increase in temperature to 1300 K compared with the value at T = 1100 K, it is still amost an order of magnitude lower than the maximum concentration of ethylene.

At 1300 K the maximum concentrations of ethylene and acetylene are attained almost simultaneously but later than the attainment of the maximum concentration of ethane, which is consistent with Gordon's data.[34] At 1200 K, the maximum concentrations of all three C_2 hydrocarbons are attained almost simultaneously (Fig. 14*a*). Apparently the dehydrogenation scheme involving the successive transformation of methane during pyrolysis,[14] which describes satisfactorily the kinetics in the region of low temperatures (T < 1000 K), [2] becomes less suitable with increase in tempereature. An increase in temperature entails a sharp shortening of the time of attainment of the maximum concentrations of ethylene and acetylene—from 60 s at 1200 K to 5 s at 1300 K. At 1100 K the ethane and ethylene concentration profiles have very broad maxima, which are virtually converted into quasi-stationary concentrations, attained after 7–15 min and maintained for periods exceeding 30 min. Only the concentration of acetylene passes through a maximum at t = min and then falls sharply, so that at t > 15 min acetylene cannot be detected at all.[39] The time of attainment of the maximum in the ethane concentration coincides with the time of attainment of the maximum rate of decomposition of methane (induction period) (Fig. 14). This is clearly seen also on comparing the corresponding kinetic curves obtained under flow conditions at a higher temperature (1373 K).[35]

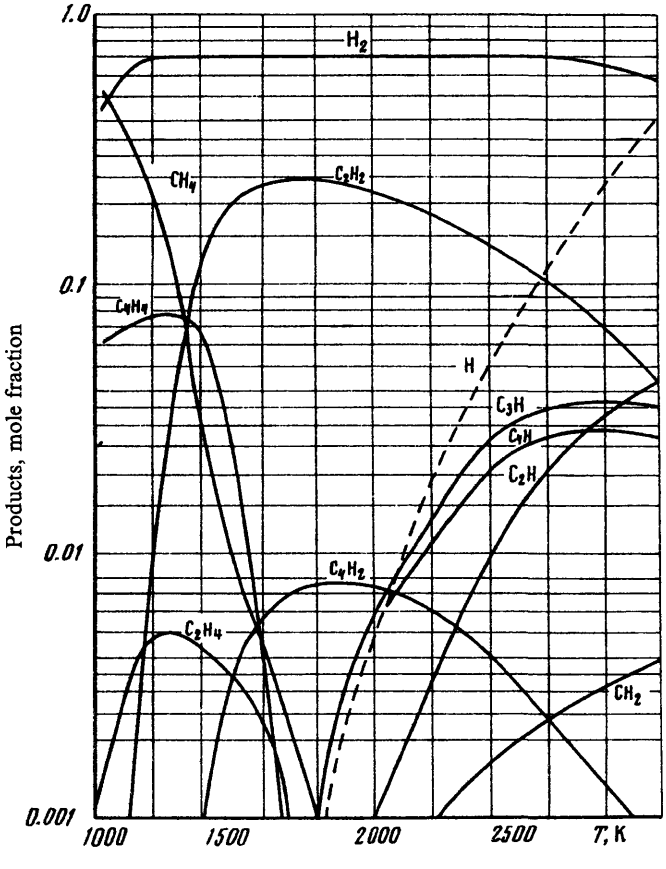

Figure 13. Results of the thermodynamic calculation for the C/H equilibrium system at temperatures in the range 1000–3000 K without taking into account the formation of a solid phase; P = 0.1 atm; C/H = 1/4 (methane).[33,56]

The temperature variation of the yield of the main final gaseous methane pyrolysis products is illustrated in Fig. 15. The results obtained can be compared with those of thermodynamic calculations[56] (Fig. 13) although the system is apparently still fairly far from thermodynamic equilibrium. Whereas the final concentrations of methane and hydrogen are virtually identical with the values calculated without taking into account the solid phase, the final amounts of C_2 hydrocarbons are several times lower than the calculated values. The results of the calculations of the equilibrium composition taking into account the solid phase[56] show that, in the experimental temperature range used by Arutyunov et al.[39]

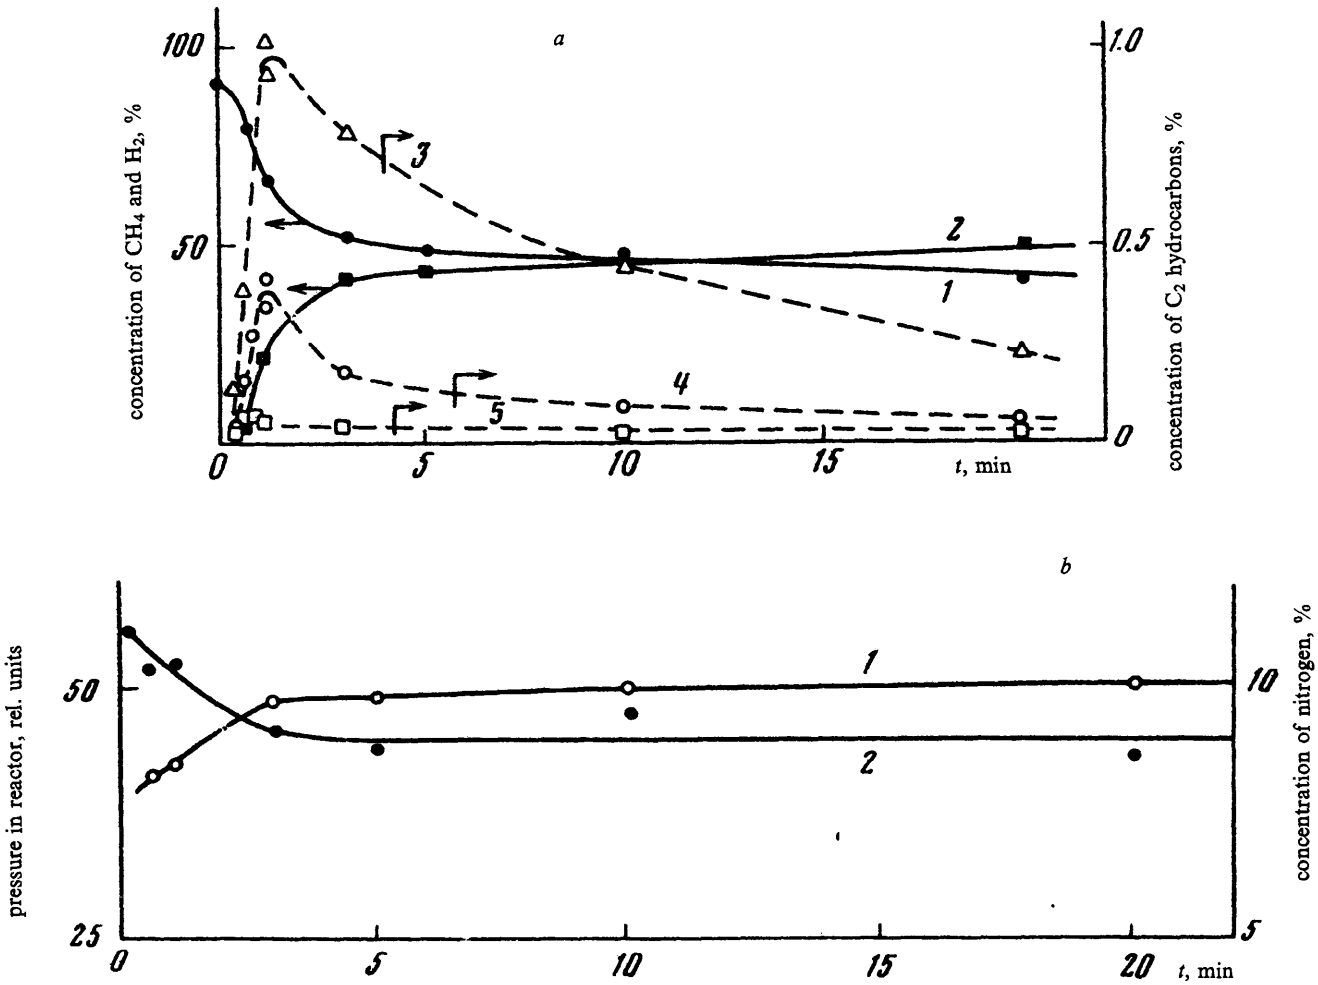

Figure 14. Kinetics of the variation of the concentrations of the principal gaseous products (*a*) and variation of the pressure and concentration of nitrogen in the pyrolysis of methane (*b*); initial mixture: CH_4 (90%) + N_2 (10%); T = 1200 K, P = 438 torr;[39] *a*: *1*, CH_4; *2*, H_2; *3*, C_2H_4; *4*, C_2H_2; *5*, C_2H_6; *b*: *1*, variation of pressure; *2*, variation of N_2 concentration.

(1100–1400 K), almost the only gaseous product should be hydrogen, since even the calculated residual concentration of methane is less than 1%, and those of the remaining hydrocarbons are lower by several orders of magnitude. The cause of such appreciable discrepancy may be either inadequate allowance for the composition of the solid phase in the calculation or appreciably longer times of attainment of equilibrium in the heterophase system.

The temperature variation of the yields of methane, ethylene, and acetylene obtained in a flow reactor at a pressure of 5–10 atm and over a very wide temperature range (1573–2473 K) has been published.[42] The detection of small amounts of C_3–C_4 products (propene, allene, methylacetylene, buta-1,4-diene, and vinylacetylene) is indicated in the above communication. These substances are the products of the thermal transformation of ethylene and acetylene at high temperatures. At lower temperatures, a wide range of high-molecular-weight products can also be detected.

Chen and Back[46] followed the kinetics of the formation of pyrolysis products ranging from ethylene to fluoranthene at 1118 K and 307 torr. The maximum concentration of fluoranthene reached $\sim 1.5 \times 10^{-6}$ M, which is only an order of magnitude lower than the maximum concentration of actylene under these conditions. The formation of the solid product followed directly the formation of the most complex of the aromatic compounds detected—fluoranthene. Since in the overall amount of aromatic compounds formed on pyrolysis of methane on silica gel those with an even number of carbon atoms constitute 97%,[57] it was concluded that they are formed from C_2 hdyrocarbons. Apparently the mechanism of the formation of polyatomic hydrocarbons involves both radical and molecular processes, their relative roles in the formation of any product depending on the process temperature and pressure. Products with a low molecular weight are formed mainly in radical reactions. The rate of formation of large polyatomic molecules can be determined by addition reactions of the Diels–Alder type.[2] We shall not dwell on a detailed consideration of the mechanisms and

kinetics of the formation of macromolecular pyrolysis products and solid carbon, because these questions are outside the scope of the present review.

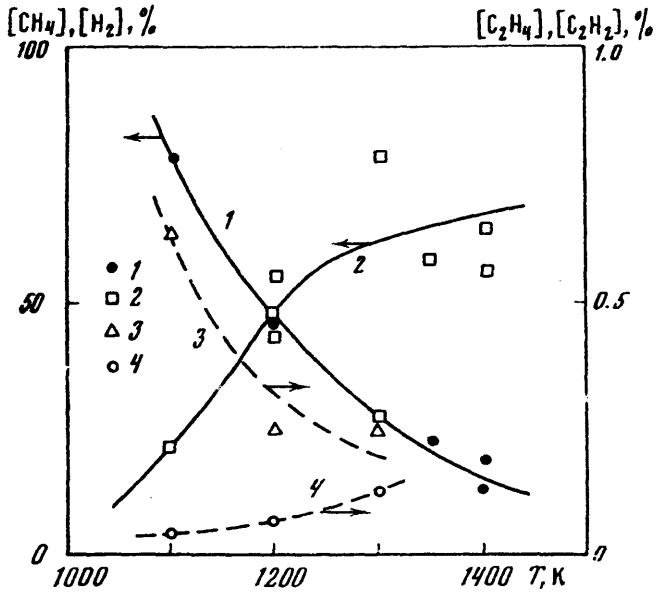

Figure 15. Temperature variation of the yields of the principal gaseous methane pyrolysis products:[39] *1*, CH_4; *2*, H_2; *3*, C_2H_4; *4*, C_2H_2.

Since the concentrations of C_2 hydrocarbons pass through a maximum in the course of the pyrolysis of methane (Fig. 14*a*), there is in principle a possibility of obtaining them in amounts greatly exceeding the values corresponding to thermodynamic equilibrium. Fig. 16 presents the maximum degrees of conversion of methane into ethylene and acetylene $C_{max}/\Delta[CH_4]_{t_{max}}$ obtained by Arutyunov et al.[39] The results of experiments at higher temperatures are also presented.[30] At 2100 K the maximum concentrations of ethylene and acetylene reach respectively ~35 and ~65%,[58] i.e. in the region of 2000 K the maximum concentrations C_{max} reach their highest values.

VIII. Temperature dependence of the pyrolysis of methane

The temperature dependence of the effective unimolecular rate constant for the pyrolysis of methane has been determined in numerous studies, the activation energies obtained varying from 63 to 104 kcal mol^{-1}. Many studies undertaken to determine the rate constants and activation energies for the initial stage of the pyrolysis [reaction (6)] in the range of temperatures from 1700 to almost 3000 K were carried out by the shock wave method.[59] The rate constant for reaction (6) was determined by Chen et al.[38] for the region of 1000 K. All these results refer to a transitional range of pressures, which makes it possible to determine also the pressure dependence of the rate constant for reaction (6). The recommended values of this constant for the temperature range from 300 to 2500 K have been published,[59] the recommended activation energy amounting to 104.4 kcal mol^{-1}. In the region of moderate temperatures 1100–1700 K, the experimental activation energies for the pyrolysis of methane differ from the activation energy for reaction (6) and are close to 80–85 kcal mol^{-1}. Certain activation energies obtained for this process in the range of moderate temperatures are given blow (in kcal mol^{-1}): 79.4,[14] 85,[53] 87,[26] 87.3 [45] and 83.2.[42] Fig. 17 illustrates the temperature variation of the effective unimolecular rate constant for the decomposition of methane obtained by Arutyunov et al.[39] Evidently, although the rate of pyrolysis depends on the pressure, the activation energy remains constant at 82 ± 3 kcal mol^{-1}. The expression obtained[39] for the effective unimolecular rate constant for the pyrolysis of methane, i.e.

$$k_{eff} = (3.0 \pm 1.0) \cdot 10^{12} \exp[-(82\,000 \pm 3000)/RT],\ s^{-1}$$

described satisfactorily the majority of the experimental results for the temprature range 1100–1700 K.

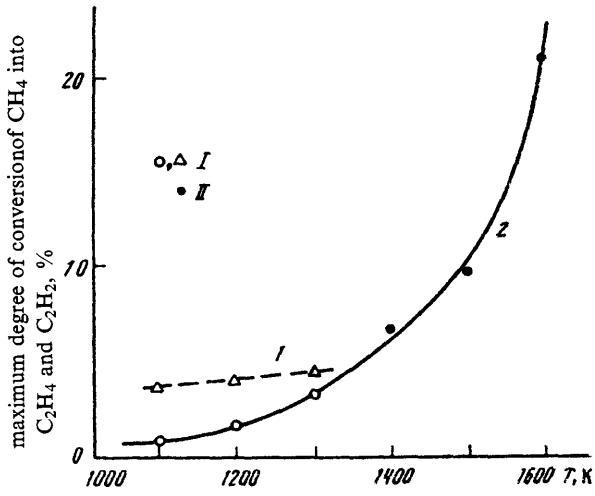

Figure 16. Maximum degrees of conversion of methane $C_{max}/\Delta[CH_4]_{t_{max}}$ into C_2H_4 (curve *1*) and C_2H_2 (curve *2*) at P = 440 torr: *I*, according to the data of Arutyunov et al;[39] *II*, according to the data of Kunugi et al.[30]

Fig. 18 presents the literature data for the rate of pyrolysis of methane under various conditions in the temperature range 1100 to 1700 K. Mathematical treatment of these results by the method of least squares yields a pyrolysis activation energy of 82 kcal mol^{-1}, which agrees with the value obtained by Arutyunov et al.[39] It is readily seen that, with the exception of several clearly deviating results, the entire set of experimental data is described satisfactorily by the expression quoted above, which may be recommended for these conditions.

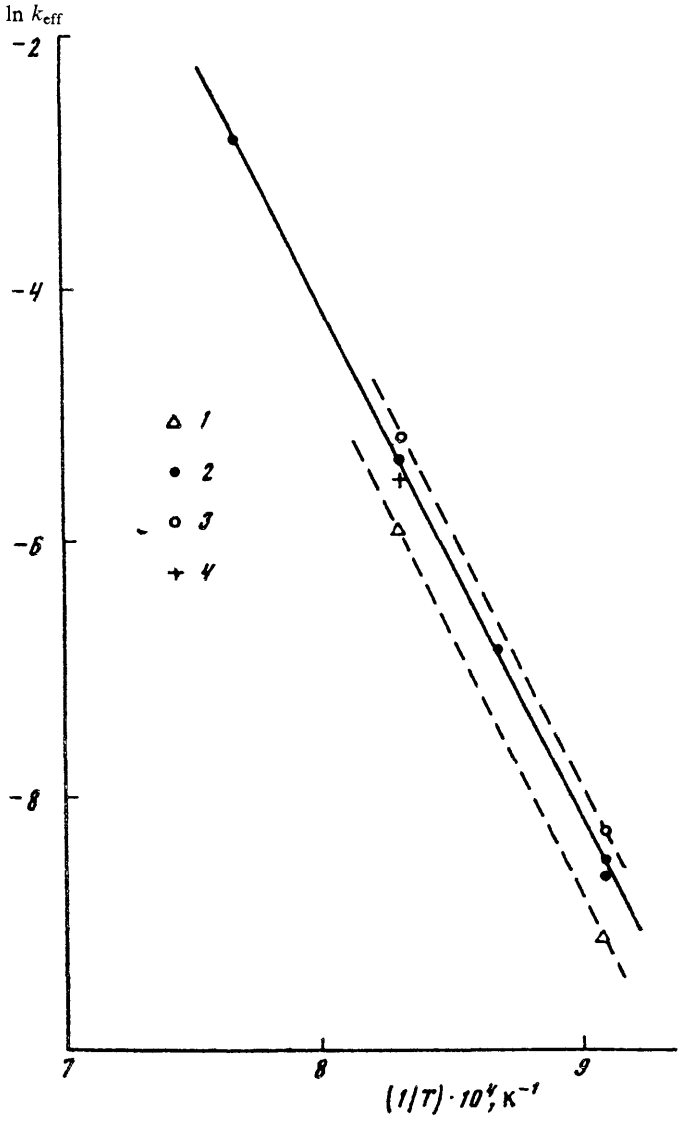

Figure 17. Temperature variation of the effective unimolecular rate constant for the decomposition of methane in reactors 46 mm (*1*–*3*) and 21 mm (*4*) in diameter at different pressures (*P*, torr):[39] *1*, 115; *2*, 440; *3*, 700; *4*, 435.

IX. The mechanism of the pyrolysis of methane

There is at present no generally accepted mechanism of the pyrolysis of methane up to the carbon formation stage. The problem of devising such a mechanism is extremely complex, since it is necessary to take into account a large number of parallel processes occurring simultaneously in this complex system, their relative roles varying markedly as the external conditions are altered. At moderate temperatures, the initial stages of the pyrolysis of methane are apparently fairly well described by a simple scheme taking into account the parallel occurrence of chain dehydrogenation and methylation reactions, which explains and describes the formation of both simple hydrocarbons (C_2) and the highest unsaturated hydrocarbons with increasing molecular weight and descreasing hydrogen content up to the formation of carbon.[2] The key hypotheses on which the above scheme is based are (1) the dominant role of methyl radicals, chain reactions with the latter constituting the main pathway leading to the removal of all the hydrocarbon products, (2) the insignificant role of the thermal dissociation of secondary hydrocarbon products and the mainly thermal decomposition of higher hydrocarbon radicals, and (3) the involvement in the reaction with methane molecules of almost all the hydrogen atoms formed. These hypotheses are entirely realistic for temperatures in the region of 1000 K and a little above.

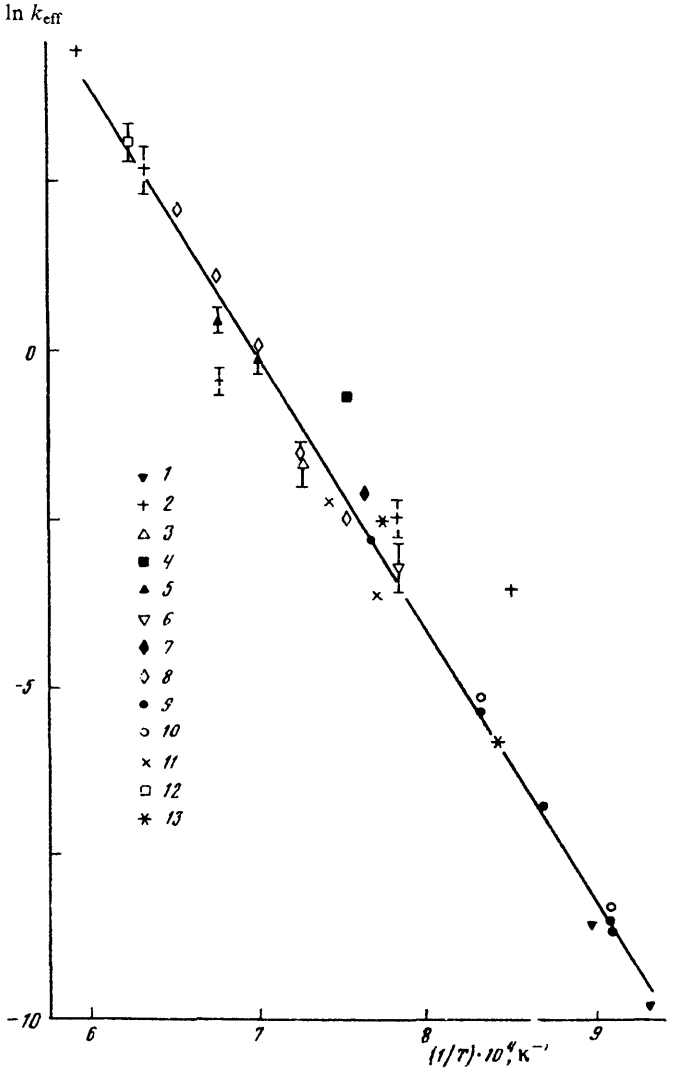

Figure 18. Temperature variation of the effective unimolecular rate constant for the decomposition of methane in the temperature range 1100–1700 K plotted on the basis of the set of literature data: *1*, Ref. 14; *2*, Ref.16; *3*, Ref. 19; *4*, Ref. 20; *5*, Ref. 21; *6*, Ref.25; *7*, Ref.34; *8*, Ref. 35; *9*, Ref. 39 (P = 440 torr); *10*, Ref. 39 (P = 700 torr); *11*, Ref. 43; *12*, Ref. 60; *13*, Ref. 61.

The mathematical modelling of the pyrolytic process carried out[47] on the basis of this scheme for $T = 1038$ K and $P = 433$ torr made it possible to explain the phenomenon of autocatalysis in the formation of ethane, which was observed experimentally by Chen et al.[38] Calculations confirmed the hypothesis[2] that the most important causes of autocatalysis are secondary initiation and subsequent methylation propagated by the addition of methyl radicals to olefins. The same model makes it possible to describe satisfactorily the experimental profiles for the formation of ethane, ethylene, acetylene, and propene in the pressure range $5 < P < 50$ atm and the temperature range $1073 < T < 1148$ K in the initial stage of the reaction (up to the onset of autocatalysis).[55] According to the results of Barnes and Pratt,[55] the main cause of autocatalysis under the given conditions is secondary initiation, mainly via the reaction

$$C_3H_6 \rightarrow C_2H_3 + CH_3.$$

However, the model proposed[47] has been criticised[48] because of the lack of consistency in many instances between the constants adopted for the forward and reverse reactions. After the adjustment for such consistency in the case of reverse reactions, the results changed significantly and the phenomenon of autocatalysis vanished from the model. A new mechanism has been proposed[48] for the pyrolysis, according to which the acceleration of the reaction is achieved as a result of the dissociation of cyclopentadiene formed in large amounts even for the very lowest degrees of conversion of methane (~0.1%). However, even if this mechanism is the real cause of the autocatalysis at 1000 K, it is difficult to say to what extent it is valid at higher temperatures, especially those exceeding 1500 K.

There exist several models† for the description of the high-temperature pyrolysis under shock wave conditions. However, the question of the modelling of the pyrolysis in the range of moderate temperatures remains essentially open.

* * *

The data considered in the present review refer to the study of the pyrolysis of methane in the range of moderate temperatures which is of greatest practical importance. Attention was concentrated on the process kinetics, the composition of the products, their influence on the course of the process, and the role of external factors (pressure and temperature) on the reactor surface. The limited size of this review precluded the consideration of many aspects of the pyrolysis of methane which are of practical importance, in particular, the questions of promotion, for example, by halogen compounds. All the technological aspects of the process remain outside the scope of the review. Apparently it would be desirable to devote a separate review to these questions. As regards further investigations, in our view attention should be concentrated on the construction of a quantitative kinetic model of the pyrolysis of methane in the region of moderate temperatures taking into account all the reliably established facts, including the occurrence of autocatalysis, the acceleration by hydrocarbon additives, and the influence of hydrogen on the yield of hydrocarbons, the rate of the process, and the composition of at least the principal pyrolysis products. The existence of such a model would make it possible to predict reliably the course of high-temperature processes involving methane, which is extremely important bearing in mind the rapid expansion of the range and scale of the industrial applications of natural gas.

Inorganic anion exchangers

A E Kapustin
Mariupol Metallurgical Institute

ABSTRACT. Data on inorganic substances showing basic and anion-exchange properties have been reviewed. The structural dependence of the number and strength of the basic centres has been discussed.

The bibliography contains 162 references.

I. Introduction

Ion exchange materials are widely used in the most varied spheres of human activity. Ion exchange processes are acquiring particular importance in attempts to create waste-free technologies and closed technological schemes.

The need to prepare and purify water, to purifiy effluents and air from harmful impurities, and to obtain pure substances has for the last 50 years stimulated the development of research in the field of ion exchange and the production of new ion exchangers. The development of the industrial production of various ion exchangers has been no less intensive. There has been an extremely rapid increase in the number of publications on the synthesis and production of ion exchangers and the theory and practice of ion exchange, and a number of reviews have appeared.[1–3]

A basis for this rapid development has been provided by progress in the field of macromolecular compounds. The great majority of ion exchangers that have been studied, to say nothing of those used in industry, have been based on organic polymers.

It is appropriate to remember that the ion exchange process was first detected and studied in inorganic compounds—soils, earth, clays, and zeolites. A new stimulus to the development of ion exchange in inorganic materials was provided by progress in nuclear energy and radiochemistry. It became necessary to produce ion exchange materials with high stability to heat and radiation. It also became clear that the development of polymeric materials containing functional groups with a higher stability to heat and radiation is not promising,[4] since the stability of an ion exchanger is determined by the stability of the polymer matrix.[5]

Data on the properties of compounds such as aluminosilicates, oxides, hydroxides, sulphides, phosphates, salts of heteropolyacids, ferrocyanides, graphite oxides, and complex hydrated oxides have now been accumulated and systematised.[6,7] Zeolite aluminosilicate ion exchangers have been particularly well studied.[8,9]

Zeolites and the other compounds listed above, however, are almost all acidic substances, that is they are cation exchangers. Inorganic anion exchangers are much less familiar, and there are no published data on their use in industry.

The aim of the present review was to systematise published data on inorganic anion exchangers.

II. Terminology

Traditionally,[10–12] an "anion exchanger" is an ion exchanger containing fixed ions (or ionogenic groups) and exchanging anions. An ion exchanger is a two-phase heterogenous system, capable of dissociation and containing fixed ions, etc.

This definition is not comprehensive, however. In general, all anion exchangers are solid bases (ion exchangers in the salt form can be regarded as potential solid bases). The term solid base can be applied to a substance which is a proton acceptor or an electron donor.[13]

We shall use the term anion exchanger to describe a solid insoluble substance which contains Brönsted or Lewis basic centres and which shows basic properties over a wide pH range. It is assumed that the basic form of an anion exchanger can be obtained from the salt form by ion exchange.

The complete characterisation of an anion exchanger should include the following parameters:

1, the total concentration (mmol g^{-1}) of basic centres relative to the highest theoretically possible value;

2, the concentration of basic centres on the surface of the anion exchanger and in its bulk;

3, the strength distribution of the basic centres;

4, the physicochemical properties (specific surface, pore volume and radius, chemical, thermal, and radiation stability, accessibility of the centres in relation to steric factors);

5, the ion exchange properties (the form of the isotherms, and selectivity coefficients and series).

III. Determination of the basic properties of anion exchangers

To obtain a picture of the basic properties of solids, it is necessary to know the total quantity, nature, and strength distribution of the basic centres.

A solid base can convert an adsorbed acidic molecule into the conjugate base form. The basic centre may be a proton acceptor, taking them from the adsorbed molecule (Brönsted basic centre) or an electron donor, transferring them to the adsorbed molecule (Lewis basic centre).

The most complete information on the state of a surface is given by the indicator method. When an electrically neutral acidic indicator in a non-polar solvent is adsorbed on a solid base, the colour of the indicator changes to that characteristic of the conjugate base form. This indicates the presence of centres whose basic strength is sufficient to transfer electrons to the acid molecule.

By successively adsorbing indicators with different pK_a values on fresh specimens it is possible to obtain a qualitative picture of the basic strength distribution.

The concentration of basic centres (usually expressed in millimoles per unit weight or unit surface area) is determined quantitatively by titrating a suspension of the powdered solid base in a non-polar solvent with an acid solution. The quantity of acid required to convert the indicator into the acidic form corresponds to the number of basic centres whose basic strength is lower than pK_a for the indicator used in the titration. By using a range of indicators it is possible to obtain the distribution of the number of centres with respect to basic strength (Table 1).

Table 1. Indicators used to obtain information on the basic properties of solids.[7]

Indicator	Colour		pK_a
	acidic form	basic form	
Bromothymol Blue	yellow	green	7.2
2,4,6-Trinitroaniline	"	orange	12.2
2,4-Dinitroaniline	"	violet	15.0
4-Chloro-2-nitroaniline	"	orange	17.2
4-Nitroaniline	"	"	18.4
4-Chloroaniline	colourless	pink	26.5

The main disadvantage of the indicator method is that the basic strength is measured in a given specific medium, and with change in the conditions, both the concentration and the distribution of the basic centres may be quite different. Moreover, the large indicator molecules cannot penetrate to the centres inside fine pores.[9] This last restriction does not appear to be significant, however, since it is more important that the basic centres be accessible to the acid titrant, and to observe the indicator change the quantity adsorbed on the outer surface is sufficient. Thus the results obtained by titrating mercarbides with benzoic acid in the presence of Bromothymol Blue are close to those obtained by other methods, although this indicator cannot penetrate into the mercarbide pores.

A more significant limitation of the indicator method is that it cannot be used to determine the basic properties of solid anion exchangers in forms other than the hydroxide form. If the Brönsted centres are in the hydroxide form, the indicator method gives the total Brönsted and Lewis basic strength; otherwise, it gives only the Lewis basic strength.

Titration using aqueous solutions of acids makes it possible to determine the total quantity of basic centres, and Brönsted centres present in salt forms can also be titrated. Here it is necessary to be sure that the affinity of the titrant acid for the anion is appreciably greater than its affinity for the counter-ion, otherwise an equilibrium is established, and the number of centres found in this way is too low. In this case, naturally, the concentration of anions in the solution, and not the change in the pH of the medium, is followed.

In the titration with acid it is necessary to be certain that the solid framework does not break down.

The concentration of Brönsted basic centres on the surface of a solid can be estimated from data on exchange between the hydroxide groups of the surface and the anions from salt solutions.

If the number of centres is being determined for a new substance, it is necessary to carry out at least several measurements with different solutions containing different ions, since the selectivity of anion exchangers may be different.

This method can sometimes be used to determine the number of centres in a solid in different anion forms; here, the limitations are the same as those for aqueous titration with acids.

Calorimetric titration can be used to determine the basic strength by observing the increase in temperature due to the liberation of heat in the reaction of the anion exchanger with an acid in the liquid phase.

When gravimetric methods are used, gaseous acidic compounds such as phenol and carbon dioxide are used as adsorbates. After adsorption at a given pressure and temperature, the acid is desorbed from the anion exchanger, and the quantity of desorbed acid determined by DTA [12] or chromatography.[11]

Calorimetric and gravimetric methods can be used to find the quantity of Lewis basic centres and Brönsted centres in the OH form. Gravimetric methods also give a qualitative picture of the strength distribution of the centres, which can be made the basis of quantitative calculations.[11,12]

Important information on the basic strength of anion exchangers could be obtained by spectral methods. The spectra (infrared, ultrviolet, EPR) of acidic substances adsorbed on anion exchangers can be used to determine the nature of their interaction with the basic centres. The reactions of adsorbed molecules with Lewis basic centres and with hydroxide groups should give different spectra. There are no published data, however, on the spectroscopic study of the basic properties of solids.

Thus there is at present no general method for determining the nature, strength, and number of basic centres in all cases. The situation is particularly complicated if the anion exchanger is in the salt form. For a complete estimation of the basic strength of anion exchangers it is necessary to use several methods in succession. The study of the basic properties of solids should include the following stages:

1, conversion of the anion exchanger to the OH form (the degree of conversion can be followed, for example, by elemental analysis);

2, determination of the total basic strength by one of the methods;

3, determination of the Brönsted basic strength by one of the methods;

4, determination of the strength distribution of the basic centres by the indicator method;

5, conversion of the Brönsted centres to the salt form (with determination of the degree of conversion);

6, determination of the distribution of Lewis basic centres by the indicator method;

7, determination of the strength distribution of the Brönsted basic centres from the data balance.

The number of basic centres is expressed in mol g^{-1} or equiv g^{-1}; we shall use the dimensions given in the original works.

The great majority of inorganic anion exchangers are products of isomorphous replacement in the crystal lattice. The replacement of one element by another in a higher oxidation state leads to the production of an excess positive charge, whose compensation requires an anion. This structure is shown by many compounds which at present are assigned to different classes: mixed hydroxides, cyanides, insoluble salts, and inverse zeolites. We shall retain the traditional classification, although the above compounds have many similar properties; in particular, they show similar structure–property relationships.

IV. Double hydroxides

Double hydroxides form the most widespread class of inorganic anion exchangers. A very large number of representatives of this class are known, and they have been studied in considerable detail and are beginning to be used in industry. Related to the hydroxides is the class of mixed oxides, since most double oxides are obtained from double hydroxides and, most importantly, the oxides formed by heating double hydroxides with basic properties may also have a considerable number of basic centres. Moreover, it is impossible to draw a distinct boundary between oxides and hydroxides, or for that matter between mixed oxides and salts.

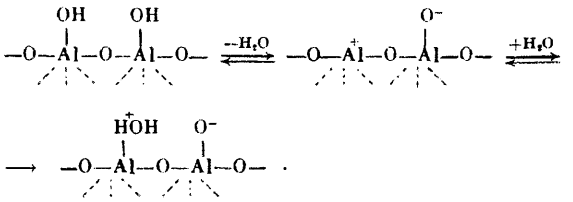
The discovery that preciptitating metal hydroxides form a mixture of solutions of the salts gives a new double hydroxide phase with anion exchange properties[13,14] was followed by further studies in this direction.[15–19]

For convenience, double hydroxides can be divided into three groups:

1, hydroxides formed by metal ions whose oxidation states differ by 1, for example $Ca_2Al(OH)_7$;

2, hydroxides in which the oxidation states of the metals differ by more than 1, for example $LiAl_2(OH)_7$;

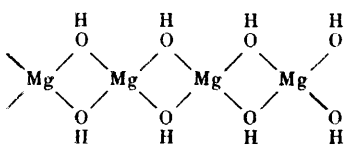
3, hydroxides in which the metals have the same oxidation state, for example $MgNi(OH)_4$.



There also exist more complex hydroxides containing three or more metal cations with different oxidation states,[20] but these can be regarded as combinations of the above double hydroxides.

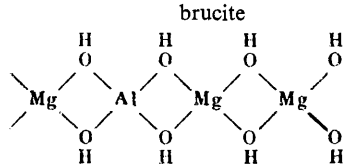
The structure and basic properties of complex hydroxides are best studied by regarding them as synthetic analogues of anionic clays. All clays are layer compounds made up of metal oxides. For example, clays of the simples type (kaolins) contain two layers: a tetrahedral silicate layer and an octahedral aluminate layer. At the edges and corners of each layer there are hydroxide groups, which on immersion in a salt solution can exchange with anions, but exchange between protons and various cations is also possible. Since cation exchange and anion exchange take place on the same groups, the exchange capacity of kaolins is approximately the same for cations and anions.[6]

Since clay minerals and double and other hydroxides have terminal hydroxide groups, they all are both cation exchangers and anion exchangers, and their ion exchange properties are determined primarily by the pH of the medium:



$$\underset{\text{pH}<7}{M^+ + OH^-} \rightleftharpoons \underset{\text{pH}>7}{MOH \rightleftharpoons MO^- + H^+}$$

The exchange capacity of ion exchangers in which exchange takes place on terminal groups is extremely low, and proportional to the surface area. The basic strength of these neutral hydroxides can be increased by covering the acidic centres, for example with water:[7]



The ion exchange capacity of hydroxides increases considerably on isomorphous replacement of the metal cations. For example, the cation exchange capacity of layers of the type present in kaolins can be increased considerably by replacing Al^{3+} cations in the octahedral layer by Mg^{2+} or Fe^{2+}, and by replacing the Si^{4+} cations in the tetrahedral layer by Al^{3+}. The layers acquire a negative charge, which is compensated by alkali and alkaline earth metal cations situated between the layers, and also by solvating water molecules. These cations can be replaced by others, and this is responsible for the cation exchange properties of clay minerals. The ion exchange capacity depends on the extent of the isomorphous replacement, and in most cases it is much greater than that due only to exchange at edges and corners. Anionic clay minerals are mostly synthetic, but they are also found in nature.

Hydroxides with anion exchange properties can also be obtained by the isomorphous replacement of the cations of the basic layers. Naturally, in this case the oxidation state of the replacing cations must be greater than that of the replaced cations. For example, hydrotalcite can be obtained by the isomorphous replacement of Mg^{2+} ions by Al^{3+} ions in brucite.[15]

brucite

hydrotalcite

From the same elements it is possible to obtain both a cation exchanger and an anion exchanger. The isomorphous replacement of Mg ions by Al ions produces an excess positive charge, and therefore gives a substance anion exchange properties, and the replacement of Al ions in $Al(OH)_3$ by Mg gives cation exchangers. Thus it is always possible to calculate the degree of replacement of ions giving the greatest anion exchange capacity. This degree of replacement usually also corresponds to the most stable structure $M^I_xM^{II}_y(OH)_x$. The weakest basic centres are those in complex hydroxides containing metals with the same oxidation state. Their strength is determined only by the weak inductive influence due to the displacement of the electron density.

Mixed hydroxides can be prepared by different methods. The most frequently employed and well developed method is by precipitating the hydroxides from salt solutions.[21–31] Liquid-phase methods for synthesising anionic hydroxides have been reviewed.[15] From the advantages and disadvantages examined,[15] the following method, close to the optimal, was proposed for synthesising anionic hydroxides. A solution of the metal salts with concentrations of about 100 g litre^{-1}, taken in stoichiometric proportions, is added with stirring to a solution containing an approximately two-fold excess of alkali and carbonates (final pH 8–10). The precipitate is crystallised with heating for not less than 18 h. The higher the temperature and the longer the crystallisation time, the higher the quality of the product. At low temperatures, undesirable secondary phases may be formed.[32]

The properties of the hydroxides obtained, in particular their ion exchange properties, may be influenced by the nature of the precipitant and solution, the rate of precipitation, the nature of the salts used, the intensity of stirring, and various other factors. By varying these parameters it is possible to increase the yield of the desired product, to improve its properties, and, which is most important, to avoid the formation of secondary phases. Solutions of KOH, NaOH, Na_2CO_3, or ammonia are used as precipitants. Their selection requires justification. For example, the presence of super-stoichiometric quantities of sodium hydroxide increases considerably the range of crystallisation of double calcium aluminium hydroxide sulphate as a result of a decrease in the range of crystallisation of aluminium hydroxide.[33] Further increase in the concentrations of lithium, sodium, or potassium, however, may lead to breakdown of the compound obtained and conversion of the components into different phases.[34]

Not all double hydroxides can be obtained using strongly basic precipitants. Double copper aluminium hydroxides are formed only in hydroxide carbonate solutions, since at high pH values copper is precipitated as hydroxide carbonates.[35] Precipitation by ammonia is of limited application, because of possible complex formation.

The pH of the solution has a marked influence on the precipitation of hydroxides; the rate of precipitation and the stability of the compounds formed generally increase with increase in pH,[36] but on the other hand the selectivity of the process decreases. The formation of double hydroxides and their salts may take place over a period of several months or even years.[37] The highest selectivity is achieved by precipitating with dilute solutions of alkali or ammonia, taken in stoichiometic quantities.[38]

The formation of double hydroxides by precipitating with ammonia shows interesting features.[39] In the preparation of double hydroxides of zinc and chromium it was found that increase in temperature from 20 °C to 60 °C leads to the appearance of various secondary phases, both as a result of their parallel formation and as a result of decomposition of the principal phase. The ratio of the reagents being precipitated has less influence on precipitate formation than the basic strength of the solution; at different pH values, precipitates with different atomic ratios Zn : Cr are obtained from solutions with the same composition. The ratio also depends on the rate of the process. In general, increase in temperature and decrease in the rate of the process lead to the formation of secondary phases as a result of more extensive hydrolysis.

Danilov and co-workers[39] observed an extremely interesting fact, namely that the selectivity of formation of double zinc chromium hydroxide nitrate increases sharply when a very small quantity of acetic acid is added to the reaction mixture. The authors cited give no explanation for this phenomenon; it is quite possible that acetate ions (or acetic acid itself) are applicator anions. This is also indicated by the fact that the precipitate does not contain amorphous zinc- and chromium-containing hydroxide phases.

Decrease in the concentrations of the salts being precipitated and of the precipitant is accompanied by an increase in the degree of solvation of the hydroxides obtained,[2] and this also influences their properties, including the ion exchange properties. If however the precipitate is subsequently subjected to ageing[40] or thermal treatment, then this factor has no significant influence.

The nature of the metal being precipitated determines the conditions for its precipitation. Thus under the same conditions, selective precipitation of double magnesium aluminium hydroxides takes place but the formation of mixed nickel and cobalt hydroxides is accompanied by the formation of $Ni(OH)_2$ and $Co(OH)_2$.[15]

It is considered that the ability of zinc to form double hydroxides is weak.[13] Nevertheless, mixed hydroxides based on zinc have been studied in detail.[41–46] Only synthetic hydrotalcite $[Mg_xAl_y(OH)_x].X_n$ has been more intensively studied than anionic hydroxides based on zinc. The great majority of double hydroxides that have been synthesised, studied, and described are compounds based on divalent and trivalent metals. Double hydroxides containing alkali metals (except lithium) have not been studied in such detail.

Table 2 lists double hydroxides containing M^I and M^{II} whose properties were studied in the works cited.

Table 2. Literature sources containing information on the methods and characteristics of the preparation of synthetic anionic double hydroxides.

Note. The symbol "+" indicates that the information can be found in many sources.

The double hydroxides listed in Table 2 show anion exchange properties only at certain M^I/M^{II} ratios and with the condition that certain requirements are met in their synthesis. When these requirements are not met and at other ratios, the products may show not anion exchange but cation exchange properties, or may not be formed at all.

Table 3 lists double hydroxides with anion exchange properties, but these data were taken from the patent literature, and should be approached with care.

Double hyroxides with anion exchange properties are not formed for all M^I-M^{II} combinations. In particular, they are not formed if one of the ions M^{n+} oxidises the other M^{m+} (for example Fe^{3+}/Mn^{2+}). Moreover, although transition metals (Cr, Co, Ni, etc.) form double hydroxides, this is accompanied by the secondary formation of the oxides, hydroxides, and carbonates of the metals, and their mixtures. Solutions containing ions which can be readily oxidised in air must be treated in an inert atmosphere.

The starting materials for preparing double hydroxides may be not only the salts but also the alkoxides of the corresponding metals, and the precipitation can be carried out by alkaline hydrolysis.[72] All the regularities described above should be observed in this case also, but by using the alkoxides of the appropriate alcohols an attempt can be made to produce the required structure in the process of synthesis.[73]

The mechanochemical method for obtaining double hydroxides appears more promising. Thus hydroxides based on zinc and chromium are obtained[42,46] either by grinding for 24 h at pH 4 a paste of zinc oxide and chromium salt (with an excess of the chromium salt) or by mechanically mixing dry zinc oxide and chromium(VI) oxide.[42] In the last case the mixture was moistened slowly with grinding, after which an equivalent quantity of water (16% of the total mass of the oxides) was added. The double hydroxides obtained by these methods had different properties; in particular, the specific surfaces of different specimens prepared by the "dry" method were 5, 13, and 22 $m^2 g^{-1}$, whereas those of specimens obtained by precipitating were 77 $m^2 g^{-1}$ and 99 $m^2 g^{-1}$. Coprecipitated hydroxides synthesised at different temperatures also have different specific surfaces (for hydrotalcite, 120 $m^2 g^{-1}$ at 65 °C and 12 $m^2 g^{-1}$ at 200 °C[35]).

The most promising method for obtaining complex hydroxides is by the sol–gel method, used to obtain hydrated salts.[28] Electrolytes are removed by decomposing the acid formed by passing an electric current. The decomposition gives sols of the corresponding hydrated oxides.

The most suitable initial salts are of course the chlorides, iodides, etc. The redox potentials of the metals may also influence the selectivity of the process, but by using different membranes—semi-permeable ion exchange membranes and porous crystalline membranes—it is possible to obtain various metal hydroxides. The sol–gel method has been used to obtain various sorbents based on metal hydroxides,[74–76] but there are no published data on the synthesis of complex basic hydroxides.

The alkali metals, except lithium form hydroxometallates or double basic salts with corresponding trivalent metals. Lithium also forms compounds with basic and anion exchange properties, but with a different structure. The lithium aluminium compound $[LiAl_2(OH)_6]OH$ has been studied in most detail.[24,30] Most workers tend to regard it not as product of the isomorphous replacement of some cations by others but as a product of the intercalation of lithium ions into the aluminium hydroxide lattice.[51] Lithium aluminium hydroxide can be obtained both by the traditional method of precipitation[77] and by solid-phase synthesis from crystalline $Al(OH)_3$ and lithium hydroxide[51] or the corresponding salts.[78] The yield is quantitative only when $Al(OH)_3$ particles are impregnated with LiOH. The optimum ratio of the liquid and solid phases is 5 : 1.[79] $Li_2Al_2(OH)_8$,[80] which also shows anion exchange properties, is less stable.

Theoretically, the exchange capacity of double hydroxides can reach high values—up to 5 mequiv g^{-1} for the hydroxides of light metals. A value of the anion exchange capacity of 3 mequiv g^{-1} (Mg, Al) has been given.[81] The real values differ considerably from the theoretical, however.

The factors responsible for the anion exchange or cation exchange properties of double hydroxides can be considered.

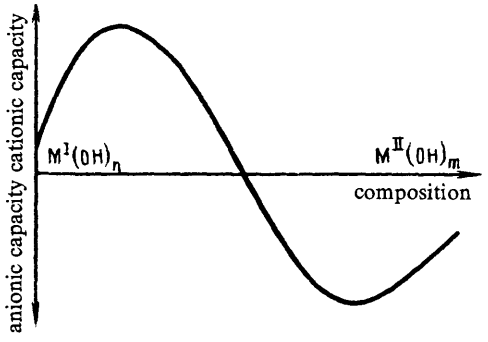

Figure 1. Composition dependence of the ion exchange capacity of a complex hydroxide.

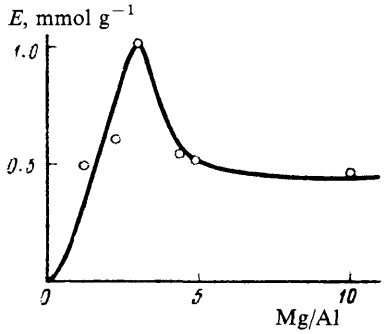
If metal cations with charges lower than that on the original cations are introduced by isomorphous replacement into a polymeric hydroxide layer [for example if some Al^{3+} in $Al(OH)_3$ are replaced by Mg^{2+}], then the layer acquires an overall negative charge and begins to show cation exchange properties. If on the other hand cations with higher charges are introduced into the hydroxide layer [for example if some Mg^{2+} in $Mg(OH)_2$ are replaced by Al^{3+}], then the positively charged layer acquires anion exchange properties.

The ion exchange capacity should obviously depend on the degree of isomorphous replacement; a double hydroxide of metals in different oxidation states can be both a cation exchanger and an anion exchanger. The presence of ion exchange centres is determined by the displacement of electron density and the redistribution of charges.[82] There exists an optimum degree of isomorphous replacement, at which the maximum ion exchange capacity is reached.

Although lithium aluminium hydroxide is formed not by isomorphous replacement but by the introduction of Li^+ ions oetween two $Al(OH)_3$ layers, leading to the production of a positive charge,[77] all that has been said about the relationship between the isomorphous statistical replacement and the strength and number of basic and acidic centres remains applicable in this case also. The other alkali metal hydroxides show genuine isomorphous replacement.[83–86]

The approximate form of the composition dependence of the acid–base properties of a double hydroxide is shown in Fig. 1. The overall or observed exchange capacity is characterised, for example, by the pH of a salt solution when the ion exchanger is immersed in it; this pH is determined by the cation exchange and anion exchange reactions.

The dependence of the number of basic centres E on the surface of MgAl hydroxide in the carbonate form on the degree of replacement[87] is given as an example in Fig. 2.



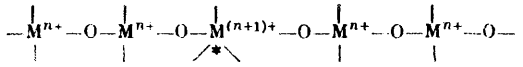


Figure 2. Composition dependence of the capacity of magnesium aluminium hydroxide.[87]

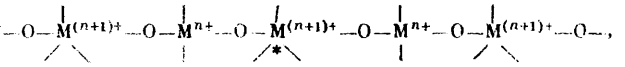


Similar observations were reported in another paper.[88] The curve shown in Fig. 1 was not obtained completely in any case, although the extremal character of the composition dependence of the capacity is mentioned in many papers. This curve naturally cannot be continuous, since the double hydroxide phases do not exist at all M^I/M^{II} ratios.[39] A study[29] of the formation of $Fe^{II}-Fe^{III}$ hydroxides gave the following results (the plus sign indicates that a double hydroxide is formed, the minus sign indicates that it is not formed, and i indicates impurity)

Fe^{II}/Fe^{III}	5.1	4.1	3.2	2.9	3.1	6.9	3.0	6.6	4.7	7.6
Hydroxide	+	+	+, i	–	+	+, i	+, i	–	–	–

The chief factors determining the number of basic centres (the exchange capacity) and their strength are the number of isomorphous replacements and their frequency. A centre of the type indicated by the asterisk

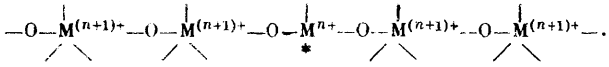
should obviously have a much higher basic strength than a centre of the type

because of the greater displacement of electron density. Account must of course be taken of the fact that the inductive influence decreases rapidly with increase in the distance, and becomes practically insignificant after two chain units.

What has been said about the relationship between the degree of isomorphous replacement and the strength and number of basic centres remains applicable when the oxidation states of the metals are equal, as for example in $Mg_xNi_{1-x}(OH)_2$.[89] In the examination of these systems it is necessary to compare the effective charges on the atoms; strictly speaking, this should also be done in all other cases.

The strength of the basic centres and the exchange capacity are inversely proportional to one another. The greatest strength should be shown by the basic centre in a specimen in which isomorphous replacement of one single atom has taken place; this specimen will have the lowest capacity. Correspondingly, the strength of the basic centres will be lowest in the specimen with the highest capacity.

The strength distribution of the basic centres can be predicted qualitatively by examining the structure of the specimen. Restricting the treatment to an idealised one-dimensional model, the following cases can be distinguished:



1) –A–A–A–A–B–A–A–A–A–
2) –A–A–A–B–A–A–B–A–A–B–A–A–A–
3) –A–A–A–B–A–B–A–B–A–A–A– .

Combinations of these are also possible. The inductive influence extending over more than three atoms can be neglected. The spectrum of the basic strength of real octahedral and tetrahedral systems in layer hydroxides is more complex, but the general approach remains the same.

For any ratio M^I/M^{II}, the real structure of layer hydroxides is far from ideal, that is from a regular alternation of isomorphous replacement centres ...AABAABAAB...

When the structures of double hydroxides is discussed, we refer to the isomorphous replacement of some cations by others. This treatment is extremely convenient, but it does not necessarily take place in practice. It is most likely, at any rate in hydrothermal synthesis, that the process taking place is not replacement but growth of the oxide chain, the sequence in which the cations are arranged in this chain being determined statistically, with allowance for their reactivity. Since the statistical factors are decisive, in real

complex hydroxides at all stoichiometric ratios, acidic centres of the following type exist

The number and strength of acidic centres undoubtedly also depend on the degree of isomorphous replacement.[90,91] A study[90] of the dependence of the number of basic and acidic centres on the degree of isomorphous replacement, that is on the ratio M^{I}/M^{II}, gave the following results:

Molar ratio MgO/Al_2O_3	2.49	3.8	5.23	9.33	17.6
Acidity, mmol g^{-1}	0.41	0.32	0.21	0.06	0
Basic strength, mmol g^{-1}	0.63	0.54	0.73	0.85	0.94 .

The basic centres were determined by titrating with a 0.1 M solution of benzoic acid in benzene in the presence of 2,4-dinitroaniline.

The strength of the basic centres lies mainly in the range $18.0 > H_0 > 17.2$. Thus the curve given in Fig. 1 is in fact the result of the summation of two curves giving the change in the number of basic and acidic centres (Fig. 3).

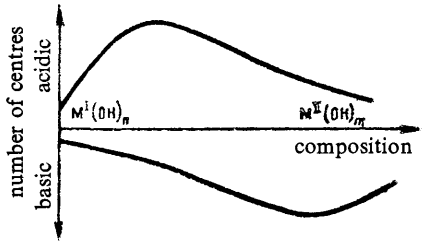


Figure 3. Dependence of the number of basic and acidic centres on the composition of double hydroxides.

Table 4. Observed and calculated exchange capacities of double magnesium aluminium hydroxide.

theoretical	observed		
1.7	0.1	SO_4	[18]
1.6	1.0	SO_4	[74]
4.5	1.5	CO_3	[36]

The actual magnitude of the exchange capacity of double hydroxides differs considerably from the theoretical value calculated from elemental analysis data. There are two main reasons for this—inaccessibility of the centres and the presence of structural defects. The term structural defects is applied to the above-mentioned isomorphous replacements and breakdown of the sequence in the arrangement of the cations in the three-dimensional structures, shown in Fig. 4.

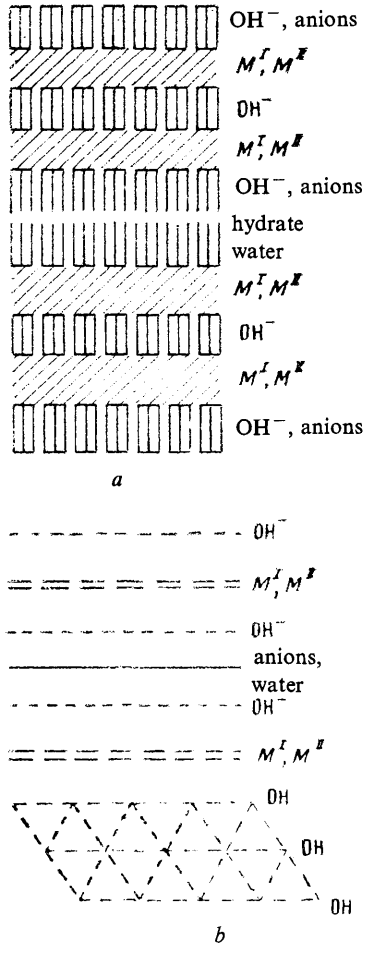

Figure 4. Diagram of the structure of a double hydroxide (*a*)[16] and the structure of hydrotalcite (*b*).[56]

The exchange capacity of a complex hydroxide cannot be regarded as the sum of the capacities of the individual hydroxides, as has been done.[52]

The exchange capacities of hydroxides of the $M^{I}_{x}M^{II}_{y}$ type also are not additive quantities, as indicated by the composition dependence of the anion exchange capacity of the double nickel magnesium hydroxide (Fig. 5).[92]

The observed exchange capacities are practically never equal to the theoretical values (Table 4).

Although the observed exchange capacity is much lower than the value calculated from the elemental analysis data, there is no reason to suppose that exchange involves only those centres on the outer

surface. This can be illustrated by the following example. Theoretically, the exchange capacity of ZnCr hydroxide in the carbonate form is about 1.6 mmol g^{-1}, but in practice the value is about 1.0 mmol g^{-1}; on the other hand, the specific surface of the specimen is about 150 $m^2 g^{-1}$, and the outer surface is about 3 $m^2 g^{-1}$.[45] If only the centres on the outer surface functioned, then the exchange capacity values should also differ by a factor of 50.

The internal centres in double hydroxides are accessible even to extremely complex organic molecules. The view is held that ion exchange taking place does not prove that the centres are accessible, and that the actual exchange may take place on the external surface after migration of ions from the internal space.[45] These suggestions, however, are not consistent with a large amount of data on the relationship between the size of the internal cavities and the size of the exchanging anions. The interplanar spacings in various double hydroxides are given in Table 5.

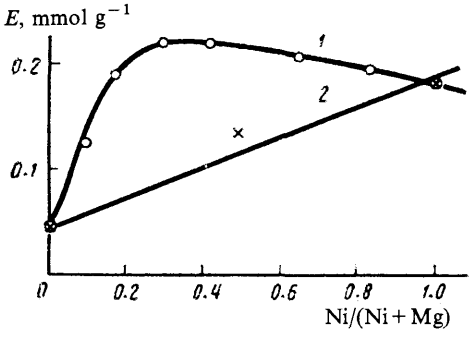

Figure 5. Dependence of the capacity of a hydroxide on its degree of isomorphous replacement:[92] *1*, complex NiMg hydroxide; *2*, mechanical mixture of Ni and Mg hydroxides.

The interplanar spacing is determined not only by the type of anion.[101] On ion exchange in which anions of one type are replaced by anions of another type, the change in the distance between the layers takes place abruptly,[44,56] and the appearance of phases with mixed anions in the space between the layers is unlikely, since this is energetically unfavourable because of the high activation energy of anion transfer. If nevertheless the hydroxide contains either alternating layers or separate regions with different anions within a given inter-layer space, which leads to deformation of the layers, then the determination of the interplanar spacings is complicated by the marked broadening of the X-ray diffraction lines.

The interplanar spacings also depend on the crystal structure of the complex hydroxide. This dependence is not so great, however; for example, the difference between the interplanar spacings for the hexagonal and trigonal forms of pyroaurite is 0.16 Å.[102]

The interplanar spacing is influenced much more strongly by the type of solvent in which anion exchange takes place and which acts as solvating agent. If water is used as solvent, there are usually 1–3 molecules of solvating water for every basic centre.

Table 5. Dependence of the interplanar spacings in double hydroxides on the nature of the anion.

*Notation used: NY = Naphthol Yellow; anions of dicarboxylic acids: C_2 = oxalic, C_3 = malonic, C_4 = succinic, C_6 = adipic, C_{10} = sebacic; normal alkyl sulphates: AC_8 = octyl sulphate, AC_{10} = decyl sulphate, AC_{12} = dodecyl sulphate, AC_{14} = tetradecyl sulphate, AC_{16} = hexadecyl sulphate, AC_{18} = octadecyl sulphate; DPS = 4,7-diphenyl-1,10-phenanthroline disulphate.

Change in the degree of solvation leads to a change in the interplanar spacings,[103,104] and this may take place gradually or abruptly. Miyata and Okada[23] obtained two values for the interplanar spacing, depending on the moisture content of the specimen; no intermediate values were observed. Replacing water by another solvent with bulkier molecules leads to an increase in the interplanar spacing.

Table 6 shows the change in the interplanar spacings when a double zinc chromium hydroxide in the alkyl sulphate form is kept in different alcohols.

Table 6. Change in the interplanar spacing when a layer double hydroxide of zinc and chromium is kept in various normal alcohols.[46]

Alcohol	d, Å	Alcohol	d, Å
C_3H_7OH	28.3	$C_{10}H_{21}OH$	38.2
C_4H_9OH	29.2	$C_{12}H_{25}OH$	41.1
$C_6H_{13}OH$	30.8	$C_{14}H_{29}OH$	42.4
$C_8H_{17}OH$	33.7	$C_{16}H_{33}OH$	44.9

The influence of both the length of the hydrocarbon group in the anion and the length of the group in the solvent molecule on the interplanar spacing is given by the equation

$$d=a+bn,$$

where a and b are the contributions to the increase in the interplanar spacing made by the terminal (methyl and functional) groups and the CH_2 group respectively.[29] This relationship is possible for mutually perpendicular or almost mutually perpendicular arrangements of the hydrocarbon groups in the basal plane. In fact, it is known that the ions of dibasic acids can bind neighbouring hydroxide layers.[98,105] It is also known that after the ion-exchange replacement of the NO_3^- ion in zinc chromium hydroxide by alkyl sulphate anions and the alkylglycol sulphate anion $C_{12}H_{25}(OCH_2CH_2)SO_4^-$, the chains of the surface-active substances are arranged in a monomolecular layer strictly perpendicular to the layers of the hydroxide, and after drying the angle of slope is only 56°.[106] After drying, these heterolayer compounds retain the solvate molecules of the C_6-C_{18} alcohol solvents. A double layer consisting of alcohol molecules and the ions of the surface-active substance is formed.

Some workers assume that the interplanar spacing is determined not so much by the size of the counter-ions as by the structure and size of the anions present during the synthesis in the liquid phase. Thus when bulky alkyl sulphate anions are used in the synthesis, the interplanar spacing is increased by 2–3 Å, but when anion exchange involves lauryl sulfate, toluenesulphonate, dihydroxybenzene-sulphonate, terephthalate, or $Mo_7O_{24}^{6-}$, $W_7O_{24}^{6-}$, and $V_{10}O_{28}^{6-}$ anions, the interplanar spacing remains unchanged.[107]

The change in the interplanar spacing and exchange capacity of MgAl hydroxide during the sorption of various C_1-C_{20} primary and secondary alcohols has been studied.[108] A correlation was observed between the length of the group of the alkyl alcohol and the exchange capacity of the anion exchanger, and it was shown that the active centres are blocked by the hydrocarbon groups. At the same time, the absence of any significant change in the interplanar spacing indicated parallel arrangement of the planes.

The interplanar spacing depends significantly on the degree of isomorphous replacement. This can be seen for the double hydroxide of magnesium and aluminium:[24]

Mole fraction Mg	0.09	0.69	0.71	0.73	0.95
d, Å	7.55	7.60	7.64	7.7	7.8

Thus the interplanar spacing is influenced by different factors. In certain cases, one or two of these factors are decisive (for example, the interplanar spacings in various double hydroxides of the types Zn_2Al, Zn_2Cr, and Ni_3Al containing the $V_{10}O_{28}^{6-}$ ion have the same value, 11.9 Å [109]), and in other cases the different factors have comparable effects.

Thermal treatment of the hydroxides leads to appreciable changes in their structure and composition and hence in their physico-chemical properties. These changes are naturally greatest when the thermal treatment is carried out in air or in another gaseous medium. In the liquid phase the changes are slight. Thus MgAl and ZnCr hydroxides undergo no changes when heated to 150–170 °C in an aqueous or alcohol medium.[143]

In the thermal treatment of hydroxides in a gaseous medium, two main processes take place—the loss of solvating water and dehydration with breakdown of the brucite-like layer. Typical thermal analysis curves are shown in Fig. 6. The first endothermic effect, corresponding to the loss of the solvating water and breakdown of the carbonium ion [sic. carbonate ion? Ed. of Translation)], is observed in the range 200–250 °C, and the second, corresponding to dehydration is observed at 400–450 °C. The position of the peaks depends on the molar ratio of the cations and on the nature of the anion.

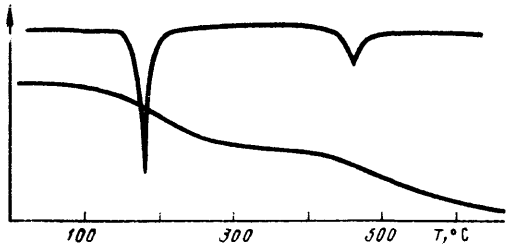

Figure 6. Typical thermal analysis curves for a double hydroxide.[55]

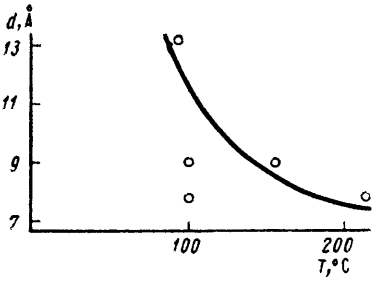

Figure 7. Dependence of the interplanar spacing in lithium aluminium hydroxide on the temperature at which dehydration starts.[100]

The temperature at which the first endothermic effect appears for lithium aluminium hydroxide (°C) has the following values for different anions:[110] CO_3^{2-} 120, SO_4^{2-} 130, OH^- 139, NO_3^- 201, Cl^- 250.

At the same time, the dependence of the interplanar spacing in this hydroxide on the temperature at which dehydration starts has the form shown in Fig. 7.

For the thermal treatment of MgAl hydroxide,[111] completely different values were obtained for the temperature at which dehydration starts, °C: OH^- 165, CO_3^{2-} 200, SO_4^{2-} 200, Cl^- 240, NO_3^- 140.

The strength of the retention of water in the space between the layers is most probably determiend by the strength of the hydrogen bond, with allowance for the mutual repulsion of the anions.

In general, the greater the bond strength, the higher the temperature at which water is removed. The first endothermic process involving the loss of water of crystallisation is completely reversible; when the product obtained by heating is placed in water, all its physicochemical properties are restored. Breakdown of the brucite-like layer on dehydration leads to the production of spinel-like structures. Contrary views that this process is completely irreversible[90] and that it is completely reversible[99] have been expressed.

A study of the behaviour of MgAl hydroxide when treated with water after heating at 600 °C showed[108] that the original hydroxide, with the same anion exchange properties is restored.

The structure and properties of MgAl oxide obtained by heating the corresponding hydroxide have been studied.[99] Specimens heated at 900 °C sorbed water from the gas phase, with complete restoration of the original hydroxide structure. An interesting feature is that the properties and structure of the restored hydroxide depended on the type of anion in the solution, although its concentration did not exceed 0.05%.

The reversibility of the processes taking place on thermal treatment is confirmed indirectly by the fact that the double hydroxides can be obtained by hydrolysing the corresponding oxides.[112]

Thermal treatment generally decreases the interplanar spacings, as a result of a rearrangement and a decrease in the width of the internal layers.

The temperature dependence of the interplanar spacing in Mg-Al hydroxide is shown below.[98]

T, °C	20	100	150	200	250
d, Å	11.18	10.91	10.39	10.80	8.04

In the gas phase the distance between the layers is determined not only by the type of anion but also by the degree of hydration, which in turn depends on the partial pressure of water vapour.[59,100]

The thermal treatment of double hydroxides influences their sieve properties, and also the number and strength of the basic centres. The dependence of the number of basic centres on the treatment temperature is generally extremal in character.

The highest number of basic centres is produced in MgAl oxide obtained by heating the hydroxide at 450 °C; the basic strength of specimens heated below 400 °C is too low.[113]

The indicator method has been used to determine separately the change in the numbers of Brönsted and Lewis basic centres when ZnCr hydroxide is heated in air (Fig. 8).[108]

There are insufficient published data on the change in the strength of the basic centres on thermal treatment, and the solution of this problem lies in the future. Published data[87] show that the dependence of the strength of the basic centres on the treatment temperature is complex. At higher temperatures, thermal treatment of double hydroxides gives spinel structures,[43] and the temperatures of their formation are lower than those when a mixture of the hydroxides is heated.[114]

Thermal treatment at high temperatures leads to the appearance of acidic centres. The formation of acidic centres when Zn-Cr hydroxide was heated was observed only above 500 °C (the number of centres was less tha 0.1 mmol g^{-1-1}).[108] The change in the number of acidic centres when double Mg-Al hydroxide is heated is shown in Fig. 9.

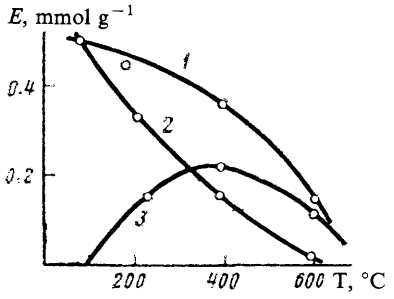

Figure 8. Change in the number of basic centres when zinc chromium hydroxide is heated in air:[108] *1*, total; *2*, Brönsted; *3*, Lewis.

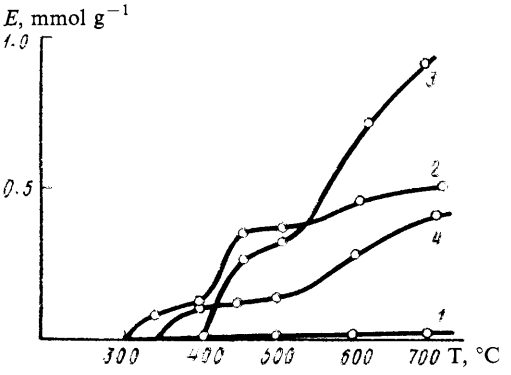

Figure 9. Change in the number of acidic centres when double magnesium aluminium hydroxide is heated in air; Mg/Al molar ratio: *1*, 0.05; *2*, 4; *3*, 6; *4*, 10.[87]

The specific surface of complex hydroxides can vary over a wide range, but there are no definite data on which parameters determine this quantity. The dependence of the internal surface of the pores on the average pore radius has been given.[115] The specific surface is influenced by the crystallisation temperature (in the hydrothermal synthesis[35]). Thus crystallisation at 65 °C for 18 h gives platelets with dimensions of 0.5 μm and a surface are of 120 $m^2 g^{-1}$, whereas crystallisation at 200 °C for 18 h gives crystals with dimensions of 1–2 μm and a surface area of about 12 $m^2 g^{-1}$.

The external specific surface of double hydroxides obtained under industrial conditions has been measured by the diffraction of laser beams in suspensions of the hydroxide in water and in glycol solution. All the hydroxides were obtained by precipitating from concentrated solutions at low temperatures. Different double hydroxides had the following surface areas, $cm^2 g^{-1}$: Mg-Al 674, Zn-Cr 298. When Zn-Cr hydroxide was kept for a long time in aqueous methanol, its specific surface increased to 592 $cm^2 g^{-1}$.[116] This is of course much smaller than hundreds of square metres per gram,[15,35] so that when the specific surface is mentioned, it must always be made clear whether the total surface or only the external surface is meant.

The surface area of hydroxides changes on thermal treatment, the changes being very different for different compounds, and also for the same compound obtained in different ways.[34,42] In most cases, thermal treatment leads to an increase in the specific surface. This is most probably due to the formation of a large number of fine pores (there is a two-fold increase in the surface area and the volume),[115] possibly as a result of the conversion of an appreciable proportion of the specimen from the octahedral to the tetrahedral state. Contrary data indicating a marked decrease in the specific surface on thermal treatment have also been published.[117]

In the liquid phase, double hydroxides have an extremely high thermal stability. They are very stable in basic media, but even in neutral media their stability is extremely high.[118] All double hydroxides undergo changes, however, in acidic solutions. The reaction with acids, as far as complete solution of the mineral framework, limits the possible applications of double hydroxides in acidic media.

Table 7. Anion exchange properties of various double hydroxides.

Anion exhanger	Selectivity series	References
Mg-Al	$I^- < Br^- < Cl^- < F^- < SO_4^{2-} \leqslant OH^- < CO_3^{2-}$	[81]
Li-Al	$AcO^- < CO_3^{2-} \approx NO_3^- < Cl^- < SO_4^{2-}$	[75]
Ca-Al	$AcO^- < NO_3^- < Cl^- < CO_3^{2-} \approx SO_4^{2-}$	[59]
Fe-Zr	$I^- < Br^- < Cl^- < MoO_4^{2-} \approx PO_4^{3-} < SO_4^{2-}$	[52]
Ni-Fe Ni-Co	$AcO^- < NO_3^- < ClO_4^- < Cl^- < SO_4^{2-} \ll CO_3^{2-}$	[56]
Zn-Cr	$AcO^- < ClO_4^- < MnO_4^- < NO_3^- < Cl^- < CO_3^{2-}$	[44]

The stability of hydroxides in basic and neutral media depends on many factors, however.[119] In solution, for example, calcium aluminium hydroxide sulphate reacts with carbon dioxide in the pH range 9–12 and is converted completely into the corresponding carbonates and hydrogen carbonates.[114] The same reaction takes place between CO_2 and the dry hydroxide sulphate, Zinc chromium basic nitrate is also fairly unstable in neutral solutions; it is hydrolysed to give the individual basic salts, or zinc oxide if the process is prolonged sufficiently.[24] This question was examined in more detail in a study[40] of double hydroxides of chromium and nickel to determine how and why their sorptive capacity changed. No definite correlation was found between the concentration of hydroxide groups and the exchange capacity (the capacity gradually decreases, and the concentration of hydroxide groups and structural water increases slightly).

Published data[39] would seem to indicate that the structure of double chromium zinc hydroxide is completely unstable. For example, at 20–60 °C and pH 6.5–7.0 the hydroxide is hydrolysed rapidly to zinc oxide and the basic nitrate. In fact, however, double zinc chromium hydroxide can exist for an extremely long time, and the exchange capacity of the corresponding nickel chromium hydroxide decreases by only about 15% after 6 months.[40] Double hydroxides can be kept for an unlimited time at high pH values.[33,120]

The effective exchange capacity also depends on the pH of the solution, the effect being greatest for amorphous compounds.[121] The stronger the basic properties of a compound, the weaker the influence of the pH of the medium on the exchange capacity.

Ion exchange in double hydroxides has been studied in considerable detail. The selectivity series for ion exchange by various hydroxides are given in Table 7.

The selectivity series given in various other sources are less complete than those in Table 7. Deviations from these sequences are observed.

The selectivity series given correspond almost completely to the magnitude of the interplanar spacings (see Table 5) and hence to the sizes of the ions, although in general the selectivity of inorganic anion exchangers depends on the characteristics of the synthesis.[122,123] The interplanar spacings in double hydroxides, unlike those in ion exchange resins, correlate with the sizes of the non-hydrated ions. The CO_3^{2-} ion shows the highest stability to exchange, probably because of the planar arrangement of the oxygen atoms and the high effective ionic charge.

Since practically all double hydroxides show a high selectivity with respect to carbonate ions, the preparation of double hydroxides as the pure sulphates, chlorides, etc. by ordinary ion exchange is not always possible, although theoretically there are no problems.[81] A much more effective method has been proposed.[124] MgAl and NiAl hydroxides in dilute acid solutions lose carbon dioxide rapidly and completely as a result of the exchange

$$DH.CO_3 + 2HCl \rightarrow DH.Cl_2 + CO_2 + H_2O.$$

This reaction can take place with any acid stronger than carbonic acid.[125]

Anion exchange in double hydroxides takes place not only with ordinary inorganic anions but also with the anions of dicarboxylic acids,[22] anionic complexes,[21,52,99] complex alkyl sulphates and alkanesulphonates,[46,126] optically active compounds,[127] alkyl halides,[45,128] and hydroxyalkylated alcohols.[162]

Double hydroxides are anion exchangers not only in liquid media but also in gaseous media.[45]

The rate of ion exchange in a liquid phase depends markedly on the pH of the medium. Anion exchange by NiFe hydroxide at pH 0–3 takes not more than a few minutes, whereas at pH > 6 no exchange has taken place after several hours. The $Cl^- \rightleftharpoons OH^-$ exchange rate constants in NiAl hydroxide in neutral and basic media are 1.4×10^3 s^{-1} and 9×10^3 s^{-1} respectively.[129] The types of cation present in the solution have a marked influence on the rate of exchange.[21]

V. Natural double hydroxides

Inorganic anion exchangers belonging to the class of complex hydroxides can be synthesised, and also occur naturally as various minerals. Almost all these minerals belong to the pyroaurite–sjögrenite group, since their elementary structure corresponds fairly closely to the general formula of pyroaurite (trigonal form) or sjögrenite (hexagonal form).

Table 8 lists minerals of this group and corresponding minerals having anion exchange properties. This Table can be reduced considerably if account is taken of the fact that all the minerals listed in it are capable of ion exchange. The name can be based on the hydroxide form of the mineral, correpsonding to the traditional nomenclature of ion exchange resins: "meixnerite carbonate" or "meixnerite in the carbonate form" instead of "hydrotalcite". Alternative names can be formed in accordance with accepted mineralogical nomenclature, taking as a basis the most stable natural form, that is the carbonate form. It is then necessary to use the name "hydroxohydrotalcite" instead of "meixnerite", and "sulphotakovite" instead of "carrboydite".

Table 8. Natural anion exchange minerals.

Name	Formula	Symmetry	Impurities	References
Hydrotalcite (Faulknerite)	$Mg_6Al_2(OH)_{16}CO_3\cdot 4H_2O$	trigonal	Ni, Cl	[102, 130]
Manasseite	$Mg_6Al_2(OH)_{16}CO_3\cdot 4H_2O$	hexagonal		[102]
Stichtite	$Mg_6Cr_2(OH)_{16}CO_3\cdot 4H_2O$	trigonal	Fe	[102, 130]
Barbertonite	$Mg_6Cr_2(OH)_{16}CO_3\cdot 4H_2O$	hexagonal		[102]
Pyroaurite (Igel'stremit)*	$Mg_6Fe_2(OH)_{16}CO_3\cdot 4H_2O$	trigonal	Fe, Al, Ni	[102]
Sjögrenite	$Mg_6Fe_2(OH)_{16}CO_3\cdot 4H_2O$	hexagonal		[102]
Brugnatellite	$Mg_6Fe(OH)_{13}CO_3\cdot 4H_2O$	trigonal		[102, 130]
Kolingit*	$Mg_{10}Fe_2(OH)_{24}CO_3\cdot 2H_2O$	hexagonal		[102, 130]
Cyanotrichite	$Cu_4Al_2(OH)_{12}SO_4\cdot 2H_2O$	–		[130]
Woodwardite	$Cu_4Al_2(OH)_{12}SO_4\cdot(2\div 4)H_2O$			[124, 130]
Meixnerite	$Mg_3Al(OH)_9\cdot 2H_2O$	trigonal		[131]
Motukoreaite	$Mg_{10}Al_6(OH)_{28}(CO_3)_3\cdot(SO_4)_2\cdot 14H_2O$	hexagonal		[130]
Takovite	$Ni_6Al_2(OH)_{16}CO_3\cdot 4H_2O$	trigonal		[124, 132]
Reevesite	$Ni_6Fe_2(OH)_{16}CO_3\cdot 4H_2O$	"		[133]
Carrboydite	$Ni_3Al_2(OH)_{10}SO_4\cdot H_2O$	hexagonal		[134, 135]
Aiovatit*	$Mg_4Fe(OH)_{16}Cl\cdot H_2O$	"		[124]
Hydrocalumite	$CaAl_2(OH)_6OH\cdot 6H_2O$	–	$\frac{1}{2}SO_4$	[124]
Khonessit*	$Ni_6Fe_2(OH)_{16}SO_4\cdot 4H_2O$	–		[124]
Comblainite	$Ni_6Co_3(OH)_{18}(CO_2)_2\cdot 9H_2O$	orthorhombic		[136]
Erdlegit*	$Zn_6Al_2(OH)_{16}CO_3\cdot 4H_2O$	–		[137]
Ettringite	$Co_6Al_2(OH)_{16}(SO_4)_3\cdot 26H_2O$	–		[33]
Aurichalcite	$Cu_2Zn_3(OH)_6(CO_3)_2$	–		[138]

[*Transliterations. Equivalents in Western nomenclature are not clear. (Ed. of Translation)].

It would be quite incorrect to use names such as, for example, "chromobrugnatellite"[102] instead of "stichtite", since when M^I or M^{II} is replaced the structure and properties of the mineral may be changed considerably.

Of the minerals having anion exchange properties, only hydrotalcite is widely encountered, and all the others are relatively rare or very rare minerals.

Like the other minerals, the compounds showing anion exchange properties have been studied mainly from the mineralogical viewpoint, that is most attention has been paid to their structure and chemical composition.

For an understanding of the characteristics of ion exchange and an evaluation of the minerals as possible anion exchangers, most information is given by the following mineralogical data: chemical composition, interplanar spacing, stability in aqueous solutions, thermal analysis data, and data on the isomorphous replacement of cations and anions.

The chemical compositions of the minerals have been determined fairly accurately, and the data obtained by different authors show no discrepancies. Sometimes, minerals with complex compositions are encountered, for example $Mg_3Zn_3Al_2(OH)_{16}CO_3$, or isomorphously substituted minerals in a background of the basic mineral, for example ferristichtite in mixtures or intergrowths with stichtite.[130] The isomorphism is often determined by the rock in which the given mineral occurs.

The interplanar spacings depend mainly on the anion. Replacement of the anion has a much greater effect on the interplanar spacing than the isomorphous replacement of a cation. The interplanar spacing changes little in the series hydrotalcite (Mg, Al)–stichtite (Mg, Cr)–pyroaurite (Mg, Fe), the values being 7.83, 7.8, and 7.6 Å respectively.[102,130] Anion exchange leads to a greater change in the interplanar spacing: 7.64 Å for meixnerite (Mg, Al, OH), 7.83 Å for hydrotalcite (Mg,Al,CO_3), and 11.32 Å for motukoreaite (Mg,Al,SO_4).[102,130]

The polymorphic form has comparatively little influence on the interplanar spacing. The interplanar spacings for different minerals are (Å): pyroaurite (trigonal form) 7.6, sjögrenite (hexagonal) 7.78; and hydrotalcite (trigonal) 7.83, manasseite (hexagonal) 7.67.[130]

The interplanar spacings in minerals are influenced not only by the nature of the anion but also by the solvated state of the ion being exchanged. Anionic minerals can sorb both solvated and non-solvated anions. The transfer of solvating water from the solid to the gas phase and back takes place readily even at room temperature, the direction of the process depending on the humidity of the surrounding medium. For example, carrboydite loses water reversibly, as a result of which the interplanar spacing decreases from 10.5 Å to 8.6 Å.[134] When the humidity of the medium changes from 0 to 100%, only two values of the interplanar spacing are observed in takovite — 10.8 Å at a high humidity and 8.9 Å at a low humidity.[124] The same phenomenon is observed for motukoreaite (11.1 Å at a high humidity and 8.7 Å at a low humidity).[132]

If however the solvating agent is not water, the increase in the interplanar spacing may be even greater. Thus after hydrotalcite is treated with ethylene glycol,[124] the interplanar spacing is at first 12.9 Å, after which it gradually changes to 10.0 Å; when water is removed by drying, the spacing decreases to 7.87 Å. An additional ethylene glycol layer is apparently first produced in hydrotalcite, after which ethylene glycol solvates the exchange centres with the anions present there together with hydrate water, and finally ethylene glycol remains only as the solvating agent.

Diagnostic tests on minerals invariably include the action of various acids. In the study of practically all the minerals, breakdown of their structure and complete solution under the influence of strong mineral acids was observed; solution is generally accompanied by slight "effervescence".[98] Published data on the effect of aqueous solutions of mineral and organic acids are somewhat contradictory. Thus it has been reported[98] that brugnatellite dissolves readily in dilute acid solutions in the cold, and also[132,139] that treating pyroaurite minerals with dilute solutions of various acids does not lead to breakdown of the basic structure. The action of 0.1 M solutions of nitric, sulphuric, and hydrochloric acids on takovite and hydrotalcite has been studied.[124] X-Ray diffraction and infrared spectroscopy established that specimens treated with HCl and HNO_3 are identical to the untreated materials, except that they are in a different salt form. The diffraction patterns of the sulphate materials differ from those of the starting materials; the interplanar spacings increase as a result of the geometric differences between the leaving carbonate ion and the sulphate ion.

The stability of the anionic minerals in solutions of salts and bases has not been reported, but if the minerals are analogous to the synthetic layer double hydroxides, they should be extremely stable in these solutions.[33]

Thermal studies have been carried out only for the anionic minerals containing the carbonate ion.[130] Practically all of them give differential thermal analysis curves of identical form. Two endothermic effects are observed, the first in the temperature range 180–250 °C (300 °C for manasseite) due to the liberation of water of crystallisation, and the second in the range 420–500 °C (320 °C for kolingit) due to the loss of hydroxide water and carbon dioxide. Spinel formation takes place at higher temperatures.

The first process is completely reversible; keeping the heated specimen in a moist atmosphere restores the original structure. The second process, however, involving the loss of water and carbon dioxide, is irreversible, although restoration of the structure in a solution saturated with CO_2 has been reported.[131]

The non-carbonate forms of the anionic minerals have not been studied by thermal analysis, but the form of the DTA curves should be the same in this case also, apart from the appearance of additional peaks corresponding to the decomposition and removal of the anions.

Of much greater interest is the fact that although different anions are encountered in the minerals being considered, the structure of a mineral, usually determined by X-ray diffraction, remains unchanged. This indicates again the possibility of replacing the anions in the minerals, that is their anion exchange properties.

The anion exchange properties of the layer minerals have been studied only for takovite and hydrotalcites.[124] Their selectivity with respect to anions changes in the same order:

$$CO_3^{2-} > NO_3^- > OH^- > Cl^- > SO_4^{2-}.$$

The position of the sulphate ion in this series is unexpected. The existence of such minerals as cyanotrichite, woodwardite, and others encountered in nature in the sulphate form indicates stability of the sulphate forms. Carrboydite is found in weathered rocks, and if its selectivity with respect to the carbonate ion were a maximum, it should have been converted completely into takovite after a geologically momentary time interval. The work cited[124] in fact points out that the carbonate groups of the original mineral are readily exchanged for sulphate ions at room temperature. For the synthetic analogues, the following order of selectivity has been given:[81]

$$CO_3^{2-} > SO_4^{2-} > OH^- > F^- > Cl^- > Br^- > NO_3^- > I^-.$$

VI. Inverse zeolites

The most promising anion exchangers are undoubtedly the inverse zeolites, which represent a completely new class of solids having basic properties; they were first described in 1987.[140]

Inverse zeolites, like other inorganic anion exchangers, are products of isomorphous replacement. In contrast to mixed hydroxides, salts, etc., however, in inverse zeolites it is not the metal ions that are replaced, but silicon ions, which are replaced by phosphorus ions. The introduction of an ion with a higher oxidation state produces an excess of positive charge, whose compensation requires anions.

The replacement of silicon by phosphorus in zeolites presents no problems. Inverse zeolites of the types NaX, NaA, KY, and 4A have been prepared and studied. Inverse zeoliites can apparently be obtained from zeolites of any type, and in general from any aluminosilicates. An important feature is that inverse zeolites retain practically completely the structure of the cavities of the original materials, although they do not contain the same quantity of water.

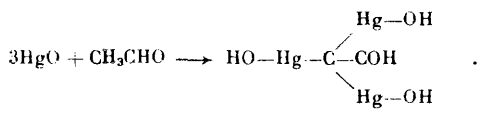
Inverse zeolites, like other anion exchangers obtained by isomorphous replacement, show the dependence of the strength and number of the basic centres on the degree of isomorphous replacement described above.

The exchange capacity of various inverse zeolites that have been studied[140] is 2–3 mequiv g^{-1}. Unfortunately, the composition dependence of the exchange capacity was not examined; it was merely reported that in the range of molar ratios P/Si from 0.002 to 0.05 there is no correlation between the exchange capacity and the phosphorus concentration. This result is somewhat unexpected, since if static isomorphous replacement is assumed, the number of centres should be practically linearly dependent on the concentration of the element introduced.

The concentration of phosphorus in inverse zeolites based on NaA,for treatment times of 17, 22, and 23 h, had the values 2, 4, and 50 mg g^{-1} respectively.[140] In a study by the present author, the anion exchange capacity of the same zeolite for treatment times of 9, 15, and 21 h had the values 0.56, 0.8, and 0.52 mequiv g^{-1} respectively; the concentration of acidic centres remained at practically the same level. The number of Brönsted basic centres was greater than the number of Brönsted acidic centres (more accurately, not the number but the sum of the products of the number of centres and their dissociation constant, $\Sigma k_i C_i$). The rate of ion exchange was not very high, since the contact time for its study was not less than one week. The selectivity of inverse zeolites with respect to the anions F^-, Cl^-, and NO_3^- is different; the isotherms of the $F-NO_3$ and $Cl-NO_3$ exchange processes have a sigmoid form. The selectivity of inverse zeolites with respect to carbonate ions is particularly high.

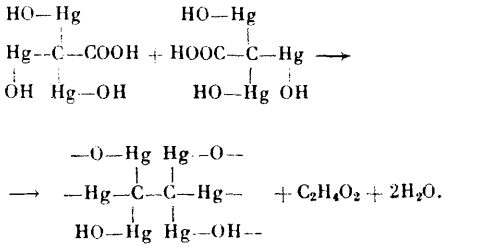
The thermal stability of inverse zeolites is determined practically by the properties of the starting material, so that they have a high thermal stability. The temperature at which the main dehydration begins for all the compounds studied is not lower than 400 °C. Their chemical stability is also similar to that of the original zeolites.

VII. Mercarbide



Salts of mercarbide, or simply mercarbides, are unique basic compounds. They have a high concentration of basic centres, a unique stability, and a well developed three-dimensional structure.

Salts of mercarbide are readily obtained by heating the yellow form of mercuric oxide for a long time in a highly concentrated solution of alkali in alcohol.[142] Red mercuric oxide can also be used, but the reaction rate is then lower. The rate is even lower if potassium or sodium alkoxides are used instead of the corresponding hydroxides.



The initial stage of the process is possibly the oxidation of ethanol to acetaldehyde:

$$HgO+C_2H_5OH\rightarrow CH_3CHO+Hg+H_2O.$$

This is confirmed by the fact that an appreciable quantity of the original mercuric oxide is reduced to metallic mercury; the reaction is much more difficult in the absence of alcohol. The acetaldehyde formed is mercurated by three molecules of the oxide:

This compound is then oxidised by another molecule of mercuric oxide to give the sodium salt of the corresponding acid. Up to 40% of the original oxide is reduced to metallic mercury. Intermolecular removal of water gives mercarbide (water is also removed from the hydroxide groups of mercury):

In addition to ethanol as starting material it is possible to use saturated alcohols, aldehydes, cellulose, starch, and acids. Ethanehexamercarbide (the correctness of this name will be discussed below) can be obtained from ethanol and primary and secondary propanol. If the starting materials used are compounds which are not alcohols, or are alcohols whose molecular weight differs greatly from that of ethanol, the properties of the mercarbides obtained are quite different. Neither methanol nor formaldehyde give mercarbides or analogous products.

From the formula $C_2Hg_6O_2X_2$, where X is the exchangeable anion,

$$C_2Hg_6O_2X_2+2Y^-\rightleftharpoons C_2Hg_6O_2Y_2+2X^-,$$

the theoretical exchange capacity is about 1.5 mequiv g^{-1}. The actual values of the exchange capacity are extremely close to the theoretical value: 1.4 for the bromide ion, 1.5 for the hydroxide ion, and 1.5 for the chloride ion;[6] or 1.34 for the iodide ion, 1.37 for the ethoxide ion, and 0.052 for the chloride ion[143] (values in mequiv g^{-1}). The low value of the exchange capacity with respect to chloride ion in the last case is evidently due to the higher strength of the bond formed with the hydroxide ion compared with that with the chloride ion. Since the theoretical and actual values of the exchange capacity of mercarbides are approximately equal, the centres on the mercarbide surface and the centre in its bulk are evidently both accessible.

In some cases the exchange capacity of mercarbide can be increased considerably by carrying out the reaction

$$[C_2Hg_6O_2](OH)_2 \xrightarrow{HCl} [C_2Hg_6O_2]Cl_2 \xrightarrow{HCl} C_2Hg_6Cl_6.$$

This reaction is reversible, and treating the chloride with sodium hydroxide gives the original mercarbide. In this case, however, the structure undergoes significant changes.

The structure of ethanehexamercarbide, also called Hofmann's base in honour of the man who first studied it, indicates that it has active centres of only one type, namely Brönsted centres. The exchange capacity of mercarbide, established in a study of the basic centres by the indicator method in the presence of 2,4-dinitroaniline with $pK_a = 15.0$, was 1.5 mmol g^{-1}.[144] The same value was obtained when the exchange capacity was determined in KI and HI solutions. In the presence of 4-chloroaniline, however, the concentration of basic centres was 0.8 mmol g^{-1}. This may indicate that the mercarbide molecule contains centres of two types.

There is lack of agreement on whether mercarbides are derivatives of ethane[144,145] or methane.[146–149] The detection of centres of two types with different strengths in approximately equal quantities apparently indicates that the name "ethanehexamercarbide" is correct.[144] Further evidence that this compound is a derivative of ethane is provided by the fact that an exchange capacity higher than 1.5 mmol g^{-1}, that is higher than the theoretical value for ethanehexamercarbide, has never been observed, whereas the theoretical exchange capacity of methanetetramercarbide is 2.3 mmol g^{-1}.

A striking feature is that in all cases the elemental analysis data confirm the structure proposed by the authors concerned, although the same method was used to obtain the mercarbide.

Mercarbides have a rigid structure, and contain fairly large cavities, accessible to ions such as Br^-, I^-, SCN^-, ClO_4^-, SO_4^{2-}, and CrO_4^{2-}. C_7-C_{10} normal alcohols and benzoic acid can penetrate into the pores of mercarbide.[143]

The unique chemical stabilty of mercarbides is due to the strength of the C—Hg bond. The stability of mercarbide in acid solutions is particularly striking. Hydroxomercarbide reacts with acids to give the corresponding salts, which are stable in concentrated mineral acids, even aqua regia. It is also stable to oxidising agents such as potassium permanganate, chromic acid, hypochlorites, and hypobromites, but reacts slowly with reducing agents when heated (when heated with hydrazine hydrate it gives a mixture of gases, one of which is ethane[142]).

Treating mercarbide with acids gives salts of two types—the product of the replacement of two hydroxide groups and the product of the replacement of all the oxygen groups. There arises the question of how to characterise this property of mercarbides in terms of the basic properties and the ion exchange properties. On the one hand, the solid may sorb anions from the liquid (and gas) phase by a reversible process, that is apparently ion exchange. On the other hand, this basic or exchange centre cannot be determined *a priori*, either by the indicator method or by anion exchange. Hexaequivalent exchange can be detected only by titrating with highly

concentrated mineral acid, which leads to an unacceptable change in the structure.

The thermal stability of mercarbide is not as high as its chemical stability. When heated in air, hydroxomercarbide explodes with the effect of a high explosive; the published temperatures of the explosion vary from 120 °C [145] to 250 °C.[142] Our DTA studies showed that in air, mercarbide explodes at 140 °C, but in a liquid phase it is stable for an indefinite period at 200 °C.[143]

The order of selectivity of mercarbide with respect to various anions is as follows:[6]

$$NO_3^- < Cl^- < Br^- < OH^- \leqslant CN^- < I^-.$$

VIII. Heteropolar salts

Insoluble salts can often act as ion exchangers.[75] Their properties have been studied in detail.[6] All the compounds that have been described, however, are either cation exchangers or amphoteric substances. Only a few compounds based on salts and showing clearly defined basic properties over a wide range are known. One group of compounds of this kind is formed by transition metal tellurides.[150,151]

As noted above, it is difficult to draw a boundary between hydroxides and complex oxides obtained by heating hydroxides. A criterion is apparently provided by the conversion of the oxides into the hydroxides in an aqueous phase, observed, for example, for spinels obtained from mixed hydroxides, but not for the above-mentioned tellurides.

The tellurides of zirconium[150] and tin,[151] and also various molybdates,[152] are good anion exchangers with an extremely small number of acidic centres. The tellurides are obtained by hydrothermal synthesis in a strongly acidic medium. The precipitate is usually aged for a long time at increased temperature.

The anion exchange capacity of tellurides has been determined with respect to chloride ions, but it was subsequently established that these compounds show a low selectivity with respect to these anions. Tin telluride has a capacity of 1.12 mequiv g^{-1}, and zirconium telluride a capacity of 0.98 mequiv g^{-1}.[150,151]

The ideas about the statistical formation of exchange centres are also applicable to complex oxides and salts, but the deviations from the ideal distribution are much smaller in this case.

Tellurides are true ion exchangers, and anion exchange in these materials is completely reversible. For zirconium telluride, the selectivity decreases in the following anion order:[150]

$$CrO_4^{2-} \gg MoO_4^{2-} > SO_4^{2-} > PO_4^{3-} > AsO_4^{3-} > Fe(CN)_6^{4-} > Br^- > Cl^-.$$

For tin telluride the order is:[151]

$$SO_4^{2-} > PO_4^{3-} > Fe(CN)_6^{4-} > MoO_4^{2-} > CrO_4^{2-} > AsO_4^{3-} > SCN^- > NO_3^- > Cl^- > Br^-.$$

The tellurides are white solid amorphous substances, and their structure should be fairly rigid. They have a high chemical stability, and are stable for an indefinite period in acid (1–5 M), alkali (1–2 M), and salt (5 M) solutions.

The maximum replacement of anions in tellurides requires 36 h at a concentration of 0.8–0.9 M.[150,151]

IX. Carbon anion-exchange materials

Activated carbons show both cation exchange and anion exchange properties. Carbon obtained by heating saccharose acquires its maximum basic strength after heating to 400 °C.[7] The values of the capacity obtained by titrating with benzoic, acetic, and hydrochloric acids are 48.2, 26.5, and 0.43 mmol g^{-1} respectively.

To increase the basic strength of carbons, various methods of activating their surface have been studied. A remarkable feature is that the greatest number of basic centres was observed for specimens heated at 800 °C.[7]

Both the acidic and the basic properties of activated carbons are determined by the presence of oxygen groups on their surface. In a study of the acid–base properties of carbons obtained by oxidising swollen graphite in a liquid phase with hydrogen peroxide, a correlation was observed between the composition of the liquid phase and the ratio of the acidic and basic centres. This ratio can vary over a wide range; the anion exchange capacity for the lowest concentration of acidic centres is ~2 mequiv g^{-1}. Significant suppression of the acidic groups could not be achieved.

The number and ratio of the acidic and basic centres may change by a factor of several tens with change in the oxidising agent.[153]

With increase in the oxidation time, the concentration of both basic and acidic groups on the surface of carbon oxidised by nitric acid or potassium dichromate increased; the number of basic groups on unit surface area remained approximately unchanged[154] (Table 9).

Table 9. Dependence of the concentration of basic centres on the surface of oxidised carbon, heated at 800 °C, on the oxidation time.[154]

Concentration of basic centres	Oxidation time, h					
	0	0.5	1	2	4	6
Quantity, mmol g^{-1}	94	149	164	173	208	210
Surface concentration, centre nm^{-2}	0.54	0.58	0.53	0.54	0.58	0.45

The basic groups on the surface are carboxyl, lactone, phenol, carbonyl, and pyrone groups. On thermal treatment the carboxyl, carbonyl, and phenol groups decompose readily, whereas the number of lactone groups changes to a much smaller extent. The number of basic groups increases approximately ten-fold on heating, but increase in the treatment temperature above 800 °C leads to a decrease in their number.

X. Other anion exchangers

There are a number of compounds which do not belong to the above groups or which are amphoteric but show clearly defined basic character, at least under certain conditions.

Thus a new anion exchanger which shows its properties in neutral and in basic media and which is formed by the reaction of aluminium ions with 2,2′,2″-nitrilotri(ethanol) has been described.[155]

In it, two molecules of 2,2′,2″-nitrilotri(ethanol) are combined with one aluminium atom, but the molar ratio nitrogen : aluminium is always equal to 3. The formula and structure of the substance have not been established. Strictly speaking, this compound cannot be described as "inorganic". Anion exchange properties are also shown, however, by the substances obtained by heating it at temperatures up to 300 °C. This anion exchanger has an exchange capacity of about 1 mequiv g^{-1}, which correlates with the concentration of $-\overset{|}{\underset{|}{N^+}}-$ groups. It is stable in neutral and alkaline (2 M) solutions, but decomposes readily in acidic solutions. The anion exchanger has a particular affinity for the hydroxide ion. Other anions can be arranged in the following order:

$$CrO_4^{2-} > PO_4^{3-} > SO_4^{2-} \gg Cr_2O_7^{2-} > S_2O_3^{2-} > S_2O_8^{2-} > IO_3^- > MoO_4^{2-} \approx Fe(CN)_6^{3-} \approx SO_3^{2-} \geqslant HSO_4^- > AsO_2^- > Cl^- > BrO_3^- > Fe(CN)_6^{4-} > AsO_3^{3-} \approx SCN > Br^- > I^-.$$

The selectivity can be altered slightly by changing the pH and composition of the liquid phase. Equilibration is fairly rapid, and takes several minutes.

The following compounds with anion exchange properties have been used: polyantimonic acid, hydrated tin oxide, and hydrated titanium oxide.[156] These compouunds are produced industrially as anion exchangers. Their capacity is fairly low, 0.2–0.5 mequiv g^{-1}. None of the ion exchange processes studied is truly reversible, and in some cases, in particular in the case of iodide ions, the process is most probably not exchange but simply addition. The selectivity series for the compounds studied are approximately the same:

$$SO_4^{2-} \gg Cl^- > I^- > Br^- > NO_3^-.$$

These compounds are stable both in basic and in acidic (0.1 M) media, but they are dehydrated at about 130 °C when heated in air. All the substances studied have a large number of cation exchange centres.

The exchange capacity of hydrated cerium oxide[137] decreases with increase in the temperature of drying, possibly due to a decrease in the specific surface. The following selectivity series has been obtained for this compound:

$$ClO_4^- < Br^- < BF_4^- < NO_3^- < Cl^- < F^-.$$

Anion exchange on the hydrated oxides studied by different authors[122,123] was carried out in neutral and weakly acidic media, since hydrated oxides are mainly amophoteric, and are generally unstable in acidic media. The properties of hydrated oxides depend markedly on the method of synthesis.

Hydrated tin oxide[157] is stable to nitric and sulphuric acid solutions. Its anion exchange capacity reaches 2 mg-equiv g^{-1} (cation exchange capacity 1.5 mg-equiv g^{-1}), and the selectivity series is

$$I^- < Br^- < MoO_4^- < Cl^- < Fe(CN)_6^{3-} < Fe(CN)_6^{4-} < Cr_2O_7^{2-} < SO_4^{2-} < CrO_4^{2-} < PO_4^{3-}.$$

The use of amophoteric ion exchangers for absorbing and separating anions does not require their additional treatment. In some cases, however, the presence of acidic centres is quite inadmissible. It is then necessary, before using the anion exchanger, to "poison" the acidic centres using a strong base, for example KOH solution. This process, however, like any ion exchange process, is reversible, and when an ion exchanger of this kind is used it is necessary to control the reverse transfer of base to the liquid phase.

Transition metal phosphates, in particular zirconium phosphates, are widely known as cation exchange materials.[6] The properties of zirconium phosphate as an anion exchanger have been much less extensively studied.[158] Anion exchange properties are also shown by salts of antimonic acid, arsenic acid, and heteropolyacids.[159]

The ion exchange properties of ferrocyanides and cyanides in general are fairly widely known.[2,6] Mainly their cation exchange properties have been studied, however, although there are reports that certain cyanides act only as anion exchangers.[6]

It has been suggested that basic properties should be shown by cyanides containing metal cations in different oxidation states.[160] Methods for obtaining the anion exchangers $[Zn_2Co(CN)_6]OH$ and $[Zn_2Fe(CN)_6]OH$ have been described in detail,[161] and some of their properties studied. The structure of these compounds is very similar to that of double hydroxides. Cyanides, however, have a rigid hexgonal structure, so that they are excellent molecular sieves, capable of separating various organic molecules. The anion exchange capacity of $[Zn_2Co(CN)_6]OH$ is 2.5–2.7 mmol g^{-1}, and the number of acidic centres is low. These anion exchangers are extremely promising, but they have not yet been studied in detail.
