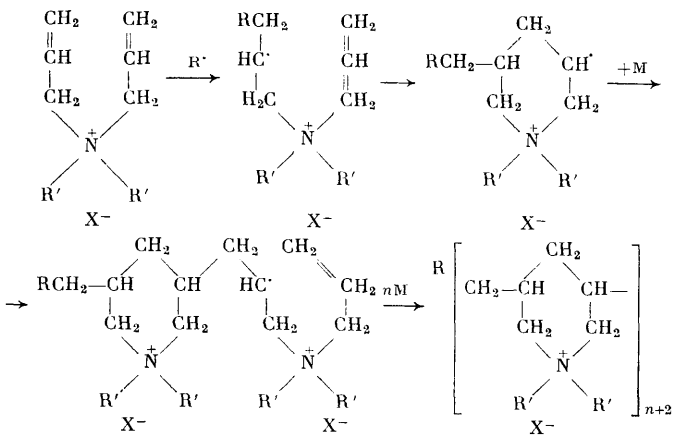
The development of optimum procedures for the preparation of various polymers or polymer systems by radical polymerisation has been achieved over several decades on the basis of the theory of radical reactivity and the advances in technology. As a result, the view has been established in practice that the optimum components for the preparation of polymers ensuring the necessary molecular structure and properties of the product and a satisfactory reproducibility of the process are monofunctional components—monomers, initiators, regulators, emulsifying agents, etc. Indeed, in recipes for polymerisation systems using monofunctional components, the highest selectivity of the polymerisation process is achieved and possible side reactions, associated with polyfunctionality and introducing disturbances and defects into the structure of the macromolecules formed, are eliminated. These factors account for the fact that in the course of a long period efforts in the research into radical polymerisation processes and in the development of procedures for polymerisation systems were directed to the study of the reactivity of functional groups and the possibility of regulating it for monofunctional compounds—monomers, initiators, emulsifying agents, etc. By the beginning of the 1960's, the construction of an elegant theory of radical polymerisation, which has since become classical, ensuring the development of a technology for many large-scale processes involving the synthesis of polymers and polymer systems, was completed. This was the reason for the temporary loss of interest by investigators in radical polymerisation processes.



However, for some time there has been a renewed growth of interest in radical polymerisation processes. On the one hand, this has been reflected in the new scientific field of complex-radical polymerisation,[1–3] which suggested ways of controlling the elementary reactions in radical polymerisation via the formation of complexes by monomer molecules and the radicals. On the other hand, investigators have become interested in polymerisation systems involving the use of components (monomers, initiators, and emulsifying agents) of the polyfunctional type, capable of reacting via different functional groups.[4–7] Such polymerisation systems make it possible to reduce the number of components in procedures for polymerisation systems, for example, by combining the functions of the monomer and initiator in one molecule, to simplify the technology of the process, and to obtain reactive polymer systems with new chemical structures, capable, without special additives, of further chemical or structural changes. Such polymers can be used to obtain block-copolymers or graft polymers[4,5,7] in processes involving the liquid-phase formation of polymer articles,[8,9] for the creation of rubbers capable of self-induced structure formation,[10] etc.

Yet another important consideration has been developed very recently. Using polyfunctional components in polymerisation systems, it is possible to achieve under appropriate conditions a consecutive series of reactions via the appropriate functional groups and the formation of a pre-specified structure of the polymer matrix produced. This approach makes it possible to devise specific rules for the preparation of linear, comb or three-dimensional macromolecules with a particular branching density, reactive oligomers or polymers, and hence block-copolymers based on them. Thus, it is possible to devise procedures for regulating the structure of the macromolecular systems formed in the polymerisation process and to some extent also procedures for macromolecular design.

Numerous results of studies of the kinetics and mechanism of the polymerisation of systems with polyfunctional components have accumulated during the last 15 years. A survey of such data has become not only realistic but also desirable. In the present review, we attempt to consider the main advances in the use of polyfunctional components in polymerisation systems. Naturally, whilst endeavouring to achieve an objective analysis, the author is not always able to avoid a subjective view on the problem, which is reflected also in the treatment and selection of data. Nevertheless, the author hopes that the review will be of interest to a wide range of specialists in the field of the synthesis of polymers.

II. Polyfunctional monomers

Polyfunctional monomers include those whose molecules contain, apart form the polymerisable double bond, also another functional group (or other functional groups). Monomers with conjugated double bonds (butadiene, isoprene, etc.) can also be classified as polyfunctional monomers (PFM). Bearing in mind that information about such monomers is widely available in the literature on rubbers,[11] we shall not discuss the characteristic features of their reactions. As regards polyfunctional monomers with non-conjugated double bonds, the results of systematic studies on the intramolecular and intermolecular mechanisms of chain propagation in the polymerisation of non-conjugated dienes have been included in numerous other reviews and monographs[12,13] and were subsequently revised in a more recent publication.[14]

The cyclisation process in the polymerisation of various conjugated dienes can also proceed vigorously with formation of six-membered[13] and five-membered[14] rings or may not occur at all. The characteristic features of the polymerisation of alkene-alkyne polyfunctional monomers are determined by their structure. The polymerisation process usually involves a double bond with formation of reactive macromolecules with multiple bonds in the side chain which subsequently readily form a structured system.

In the last two decades, there has been a wide-scale growth of interest in monomers with peroxy-groups, which arose as a result of the studies by Yurzhenko and his school.[10,15–25] Monomers involving a combination of peroxy-groups of different structure in their molecules have been synthesised. This made it possible to regulate within certain limits the reactivity of the multiple bond and of the initiating peroxy-group.

In the first studies, the polymerisation of peroxides of the polyfunctional monomer type was achieved by simply heating them or by initiating the process by their own peroxy-groups. The polymerisation proceeded up to a conversion of 20–50%, after which the reaction mixture decomposed with formation of gaseous products without the formation of the polymer.

In copolymerisation with other monomers, a decrease in the rate of polymerisation and in the molecular weight of the copolymer formed with increase in the concentration of the peroxide monomer was observed, which made it possible to put forward the hypothesis of weak inhibiting effects of the peroxide monomer in the polymerisation process as a result of the degradative chain transfer to the peroxide monomer with formation of a less reactive radical.[17,18]

In self-initiation without the addition of another initiator, the polymerisation process is complicated by structure formation in the polymer, which precludes a reliable determination of the molecular weight and of the structure of the polymer formed. Because of this, the subsequent study of the polymerisation of peroxide monomers was carried out using another lower-temperature initiator and temperatures permitting the maximum retention of the peroxy-groups of the polyfunctional monomer in the unreacted state. The conditions for the preparation of virtually unbranched soluble copolymers of styrene with unsaturated esters of α-hydroxydialkyl peroxide containing peroxy-groups in the side chain were thus established.[19] Comb graft polymers can be readily obtained from such polymers.[20]

New procedures for the preparation of impact-resistant polystyrene plastics, (including ABS-plastics),[5,22,23] synthetic rubbers capable of sulphur-free vulcanisation, benzene- and oil-resistant cured rubbers, reactive oligomers, reactive latexes, and other polymer systems of practical importance have been proposed on the basis of polyfunctional monomer peroxides.[5,10,15,24,25]

The data presented above demonstrate the possibility of using polyfunctional monomers for the synthesis of branched and cross-linked polymers and copolymers and for the preparation of microheterogeneous polymer systems with a controllable microheterogeneity.

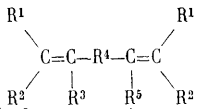
III. Polyfunctional initiators of radical polymerisation

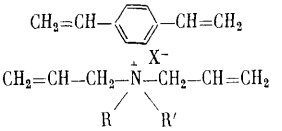
Polymer systems based on polyfunctional components have been developed most vigorously in the last two decades using polyfunctional initiators.[4–7] Compounds (Table 1) whose molecules contain two or more groups capable of generating free radicals initiating the polymerisation process, or containing, apart from the initiating group, other functional groups capable of subsequent chemical reaction can be classified as polyfunctional initiators (PFI). Peroxides and azo-compounds of different structure have come to be most widely used as polymerisation initiators. Peroxides and azo-compounds with functional group substituents, for example, di-, oligo- and polyperoxides,[4,5,7,9] di- and poly-azo-compounds,[4,5,7,9] azoperoxides,[5,7,9] as well as peroxides or azo-compounds containing other reactive functional groups (hydroxy-, carboxy-, etc.,[4,7,9]) have been most widely used as polyfunctional initiators. Polyfunctional initiators of the last type do not differ, as regards the mechanism of their initiating action in polymerisation, from monofunctional initiating systems and are normally used in the preparation of reactive oligomers and polymers with functional end groups. They have been examined in detail in other reviews.[7,9]

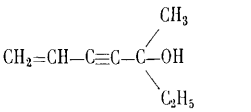
Polyfunctional initiators of the type of di- and poly-peroxides have been studied systematically by Ivanchev and co-workers[4–6,9,26–30,36–39] and Tsvetkov and co-workers.[31–34]

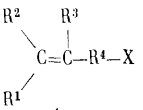
In the study of the initiating capacity of diperoxides with structurally identical peroxy-groups separated by aliphatic bridges, it has been shown that the kinetics of the thermal decomposition of peroxy-groups can be characterised by a single set of parameters.[4,26] As shown in Fig. 1, the rate constants for the decomposition of diperoxides based on aliphatic dibasic acids depend on the length of the methylene bridge n between the peroxy-groups, the rate constant increasing with increase in n from 1 to 6 and subsequently remaining unchanged for $n \geqslant 6$.

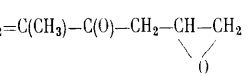
Table 1. Polyfunctional components of polymerisation of systems.

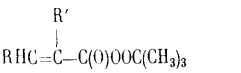


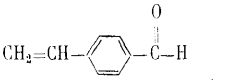


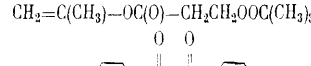


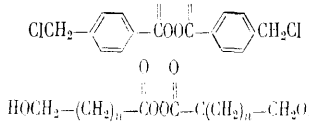


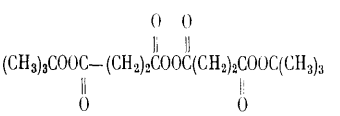


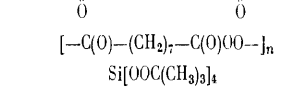


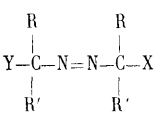


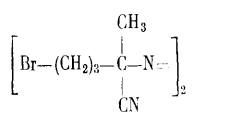


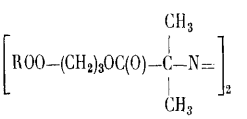


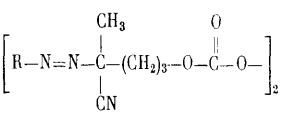


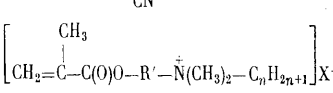


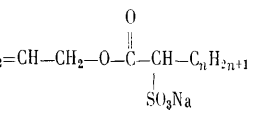


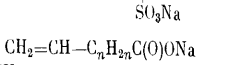


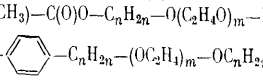












Class of compound	Chemical formula	Examples of compounds
Non-conjugated dienes	 R^1, R^2, R^3, R^5 = Alk or H; R^4 = Alk; X = halogen	
Alkene – alkyne systems	$CH_2=CR-C\equiv C-CRR^1R^2$	
Monomers containing other reactive groups	 $R^1R^2R^3$ = Alk or H; R^4 = Alk or Ar; X = functional group	   
Peroxides	$X'ROO-RX$ X, X' = functional groups	   
Azo-compounds	 R = Alk; R' = Alk or CN	 
EM-monomers		      

Table 1 (contd.).

Class of compound	Chemical formula	Examples of compounds
EM-initiators		$R(OCH_2CH_2)_nOC(O)-CH_2CH_2-C(O)OC(CH_3)_3$ $R(OCH_2CH_2)_nOC(O)-CH=CH-CH_2$ CH_2 C $C-R^2$ $R^1-C=O$ O O OOH $ROO-(CH_2CH_2O)_n-H$ $RC(O)OOC(O)CH_2CH_2C(O)(OCH_2CH_2)_nOC(O)-CH_2CH_2C(O)OOC(O)R$ $CH_3(CH_2)_6-C(OOH)-CH=CH-(CH_2)_7C(O)ONa$
Filler-monomers	E—R=R'	Si—$OCH_2CH=CH_2$ Si—O, Si—O, $CH-CH=CH_2$ Si—$CH_2OC(O)C(CH_3)=CH_2$, CH_3
Filler-initiators	E—ROOR'	OR, Si—CH—OOH, CH_3 CH_3CN, —Ca—$OC(O)-(CH_2)_2-C$, N, N, —Ca—$OC(O)-(CH_2)_2-C$, CH_3, CN Si—O, Si—O, $Si(CH_3)_2-CH=CH-COOCH_3$, CH_3, CH_3

The rate of polymerisation initiated by diperoxides varies in parallel with their k_{decomp}. A model has been proposed recently[35] which describes the rates of formation of various growing radicals and molecules in the polymerisation of styrene initiated by diperoxide initiators. The unimodal nature of the molecular weight distribution of the polymers formed, the slight increase in the molecular weight of the polymer with increase in the degree of conversion, and the inadequate fraction of polymers formed with terminal peroxide fragments lead to the conclusion that diperoxides with identical structures of peroxy-groups differ little as regards the mechanism of the initiating action from monoperoxides and are relatively ineffective in processes involving the formation of reactive polymers with peroxy-groups.[4,26]

It has been shown[31–34] that in the case of diacyl oligo- or polyperoxides the decomposition of peroxy-groups takes place statistically at rates which depend on the length of the bridge between the peroxy-groups and involve the insertion of polyperoxide fragments, and not individual peroxy-groups, into the macromolecule produced.

The degree of retention of the undecomposed peroxy-groups depends on the decomposition time and the process temperature. Systems of this type used as initiators make it possible to obtain reactive polymers and block-copolymers, but work with them entails a series of experimental difficulties because of the dangerous properties of polyperoxides.

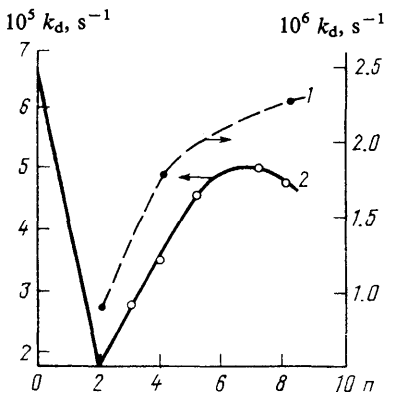


Figure 1. Dependence of the decomposition rate constant k_d on the length of the methylene bridge n between the peroxy-groups of peresters (1) and diacyl peroxides (2) based on unsubstituted aliphatic acids.

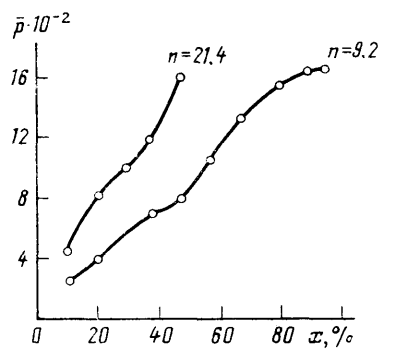

Figure 2. Dependence of the average degree of polymerisation $\bar{p}$ of polystyrene on the degree of conversion x for different "functionalities" of the initiator $[OOC(CH_2)_5COOCHBr(CH_2)_4C(=O)-]_n$ (initiator concentration 0.025 M, temperature 80 °C).

In order to eliminate these difficulties, bifunctional[4,27,36] and oligomeric[4,28,30,38] peroxides with peroxy-groups having different thermal stabilities, trifunctional peroxides having the bis-structure,[4,29,37] and azoperoxides[7,9,39–41] have been synthesised and investigated in polymerisation processes. It was shown that, depending on the polymerisation process temperature, new polyfunctional initiators make it possible to obtain polymers containing peroxy-groups in the polymer macrochain, or as end groups (bifunctional and trifunctional systems), or within the macrochain (polyfunctional systems). The rate of polymerisation is determined by the kinetic parameters of the decomposition of the peroxy-groups, whereas the molecular weight of the polymer formed depends on the degree of conversion and increases with polymerisation time. As shown in Fig. 2, the average degree of polymerisation of the polystyrene formed also depends on the "functionality" of the initiator and increases appreciably with the degree of conversion. Differential molecular weight distribution curves likewise vary sharply with the degree of conversion (Fig. 3) and the molecular weight distribution remains fairly narrow at advanced stages of the reaction.

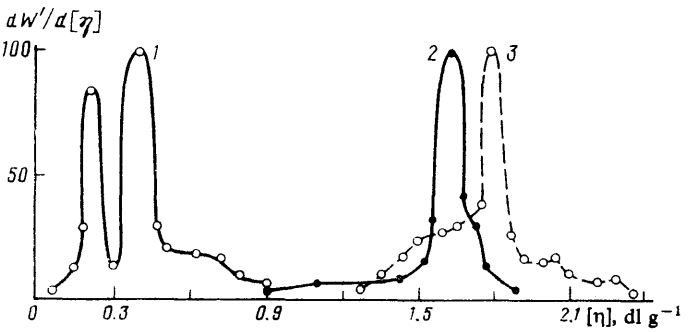

Figure 3. Differential molecular weight distribution curves for polystyrene obtained in polymerisation initiated by the oligoperoxide $[C(O)(CH_2)_7C(O)OOC(O)CHBr(CH_2)_8C(O)OO]_{18}$. Initiator concentration 0.0125 M; degree of conversion 6% (curve *1*) and 100% (curves *2* and *3*); polymerisation temperature 60 °C (curves *1* and *3*) and 60 and 80 °C under two-stage polymerisation conditions (curve *2*).

All these data enabled us to put forward a new polymerisation-polyrecombination mechanism of the formation of macromolecules[4] for radical polymerisation initiated by monofunctional initiators. This mechanism reduces to the following elementary reactions:

(1) initiation:

$$PFI \xrightarrow{k_{decomp}} 2R^{\cdot}; \quad R^{\cdot} + M \xrightarrow{k} RM^{\cdot};$$

(2) chain propagation:

$$RM^{\cdot} \xrightarrow[k_p]{nM} RM^{\cdot}_{n+1};$$

(3) chain termination:

$$RM^{\cdot}_{n+1} + RM^{\cdot}_{m} \begin{cases} \xrightarrow{\text{recombination}} \Pi_a \\ \xrightarrow{\text{disproportionation}} \Pi_{1a} + \Pi_{2a} \end{cases};$$

(4) repeated initiation by the initiating groups which have entered the macromolecule (reinitiation):

$$\Pi_a \xrightarrow{k_{decomp}} 2R_p^{\cdot} \xrightarrow{M} R_pM^{\cdot};$$

chain propagation:

$$R_pM^{\cdot} \xrightarrow[k_p]{nM} R_pM_{n+1}^{\cdot} \quad ;$$

chain termination:

$$R_pM_{n+1}^{\cdot} + R_pM_m^{\cdot} \xrightarrow{k_t} \Pi'_a(\Pi'_{1a} + \Pi'_{2a}),$$

$$\Pi'_a \xrightarrow{k_{decomp}} 2R_{p_2}^{\cdot}, \text{ etc.}$$

In the general case, all the elementary reactions should naturally be taken into account in the above scheme including reactions involving chain transfer to the monomer, the polymer, etc., but the reinitiation reactions or reactions involving the repeated formation of initiating radicals of the macromolecules formed, which depend on the functionality of the polyfunctional intiator employed, are decisive and fundamental.

The proposed mechanism of the formation of macromolecules makes it possible to explain the observed kinetics of the initiated polymerisation and the nature of the variation of the molecular weight and the molecular weight distribution of the polymer formed. It is of interest to note that, in the initiation of polymerisation by polyfunctional initiators, the inverse relationship, which follows from the main equation of radical polymerisation, between the rate of polymerisation and the molecular weight of the polymer formed as a function of the increasing initiator concentration may not hold because of the specific features of the mechanism of the formation of macromolecules.

Thus in industrial practice, the optimum process conditions and rate of initiation, ensuring the necessary molecular weight and the appropriate operating properties of the polymer, are selected in the preparation of the principal assortment of polymers. These requirements significantly restrict the possibilities of increasing the productivity of the reactor by increasing the rate of polymerisation as a result of increasing the concentration of the initiator. For polyfunctional initiators, this limitation is manifested to a much lesser extent because if the polyrecombination-polymerisation mechanism of the formation of macromolecules and the significant increase of the molecular weight with increasing degree of conversion. For polyfunctional initiators, it is possible to carry out a polymerisation with formation of a conditioned polymer having a narrow molecular weight distribution even at variable process temperatures.[4,5]

We are now able to predict the average molecular weight and the molecular weight distribution of the polymers formed when polymerisation is initiated by a polyfunctional initiator. Thus equations for the variation of the molecular weight and hence of the molecular weight distribution as a function of the degree of conversion of styrene were derived[42] in a study of the polymerisation of styrene initiated by various polyfunctional initiators. The calculation was performed on the assumption that the peroxy-groups decompose independently of one another, that the decomposition rate constant does not vary, that the radicals are formed effectively in the decomposition reaction, and that the rate of initiation is proportional to the overall concentration of peroxy-groups regardless of the nature of their distribution. The structure of the macromolecules formed during polymerisation constitutes a number of interconnected monomer units separated by peroxide clusters (Fig. 4).

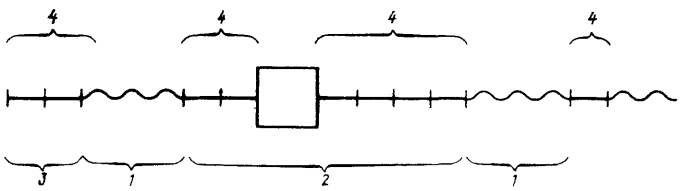

Figure 4. Schematic illustration of the structure of the macromolecules of the polymers formed in polymerisation initiated by a polyfunctional peroxide: *1*, elementary polymer chain; *2*, and *3*, closed and semi-open clusters; *4*, peroxide blocks.

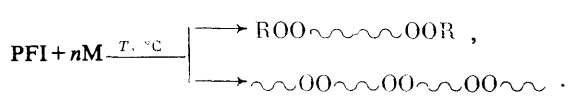
Assuming that the contribution of the peroxide clusters to the molecular weight may be neglected because of their small size compared with the sequences of monomer units, the molecular weight distribution can be regarded as a superposition of the distributions of random quantities. As a result, we obtain the following equation for the dependence of the number-average molecular weights on the process time:

$$\frac{\overline{M}_n}{\overline{M}_n'} = \frac{\lambda + 1}{\lambda + 1 - \rho}; \quad \rho = \frac{1 - \sum_{j=1}^{\infty} \alpha_j (1 + \theta)^j}{\theta \sum_{j=1}^{\infty} j\alpha_j}, \qquad (1)$$

where $\overline{M}_n'$ is the number-average molecular weight of the polymer obtained using a simple monofunctional initiator under the same conditions and at the same concentration of $-O-O-$ groups, λ the probability of termination as a result of disproportionation, α_j the fraction of initiator molecules containing j peroxy-groups, and θ the fraction of the effectively decomposed $-O-O-$ groups: $\theta = f(1-e)^{-k_{decomp}t}$ (f is the initiation efficiency).

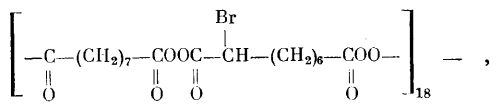


Putting Eqns. (1) in the form

$$\overline{M}_{n\infty} = \overline{M}_n \frac{\lambda + 1}{\lambda + 1 - \rho_\infty}; \quad \rho_\infty = \frac{\left[1 - \sum \alpha_j (1 - f)^j\right]}{\theta f \sum j\alpha_j}, \qquad (2)$$

we find that the molecular weight increases continuously from $\overline{M}_n'$ to a limiting value $\overline{M}_{n\infty}$, which depends on the functionality of the peroxide and the initiation efficiency. The experimental confirmation of the validity of the proposed equations is demonstrated in Fig. 5. Somewhat later we carried out a similar calculation by solving differential material balance equations.[43]

The incorporation of the initiating groups into the composition of macromolecules in polymerisation initiated by polyfunctional initiators gives rise to effective possibilities for the preparation of block-copolymers. The essential feature of the mechanism of the formation of block-copolymers reduces to a two-stage process.



The first stage is the polymerisation of the first monomer using a monofunctional initiator under conditions ensuring the formation of polymer molecules with initiating groups incorporated into the macrochains, for example:

The second stage reduces to the polymerisation of the second monomer M_2 initiated by the "active" polymer (macroinitiator) obtained in the first stage.

styrene (polymerisation in block at 60 °C) using a polyfunctional initiator—oligoazelaoyldiperoxy-α-bromoazelaoyl peroxide having the general structure

a study was made of the kinetics of the decomposition of peroxy-groups by the method of inhibitors regulating simultaneously the variation of the average degree of polymerisation in the course of the decomposition of peroxy-groups. As shown in Figs. 6 and 7, the decomposition of the peroxy-groups in the macroinitiator produced is a first-order reaction; there is a simultaneous decrease in the degree of polymerisation of the macroinitiator, which confirms the intermolecular statistical distribution of the initiating groups in the macroinitiator.

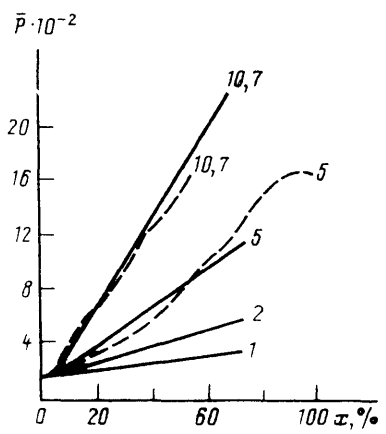


Figure 5. Dependence of the average degree of polymerisation of styrene $\bar{p}$ initiated by the oligoperoxide $[C(O)(CH_2)_7.C(O)OOC(O)CHBr(CH_2)_6C(O)OO-]_n$ for different values of n on the degree of conversion x at 80 °C and an initiator concentration of 0.025 M; continuous lines—calculated theoretically; dashed lines—determined experimentally. The numerals opposite the curves correspond to the numbers of peroxy-groups (n) in the peroxide.

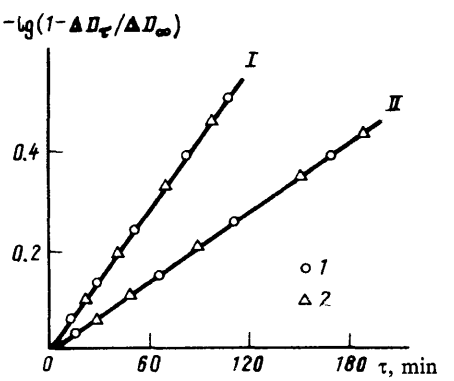

Figure 6. Semilogarithmic plots of the decomposition curves for the peroxy-groups in "active" polystyrene obtained in the presence of the oligoperoxide $[C(O)(CH_2)_7C(O)OOC(O)CHBr(CH_2)_6.C(O)OO-]_{18}$ at 80 °C (I) and 75 °C (II); $\Delta D\tau$—the change in the optical density of the inhibitor (iodine) solution during the decomposition of the initiator during a period τ; ΔD_∞—ditto for the complete decomposition of the initiator.

The dependence of the functionality of the polyfunctional initiator on the number of peroxy-groups in the macroinitiator is fairly simple.[4,5] For bifunctional initiators, there is a possibility of obtaining macromolecules which have on average one peroxy-group, while trifunctional initiators can give rise to macromolecules with two and more initiating groups. Accordingly, the second stage of the block-copolymerisation can give rise to block-copolymers of different structure—from diblock polymers of the type A–B (bifunctional initiators) to multiblock polymers of the type A–B–A–B.

The incorporation of initiating groups into the molecular chain of the macroinitiator formed when a polyfunctional initiator is used has been demonstrated experimentally.[44] For the synthesised and reprecipitated macroinitiator, obtained in the polymerisation of

Naturally, both the distribution of macromolecules with respect to molecular weight and the distribution with respect to the number of initiating functional groups are statistical. The block-copolymer is therefore non-uniform as regards the alternation of blocks.

The structure of the polyfunctional initiator, i.e. the presence in the structure of identical initiating functional groups or such groups differing in reactivity or thermal stability, is important in the synthesis of "active" polymers in the first stage. When polyfunctional initiators with initiating groups having identical structures are used, additional complications arise in the formation of macroinitiators, namely the necessity to restrict the process in time (and hence as regards the degree of conversion) in order to retain at least some of the initiating groups in the macroinitiator.

Polyfunctional initiators with initiating groups having different thermal stabilities, especially when these groups alternate in the molecule, are more convenient for the synthesis of the macroinitiator. The choice of temperature conditions in conformity with the thermal decomposition constant for the more reactive initiating group makes it possible to achieve the first stage of the polymerisation up to high degrees of conversion and to obtain a macroinitiator which is comparatively uniform as regard composition and molecular weight.

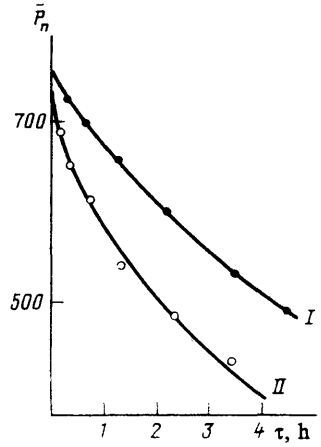

Figure 7. Variation of the degree of polymerisation of "active" (containing peroxy-groups in the macrochain) polystyrene in the thermal decomposition of peroxy-groups in solution in chlorobenzene in the presence of iodine at 70 °C (I) and 80 °C (II).

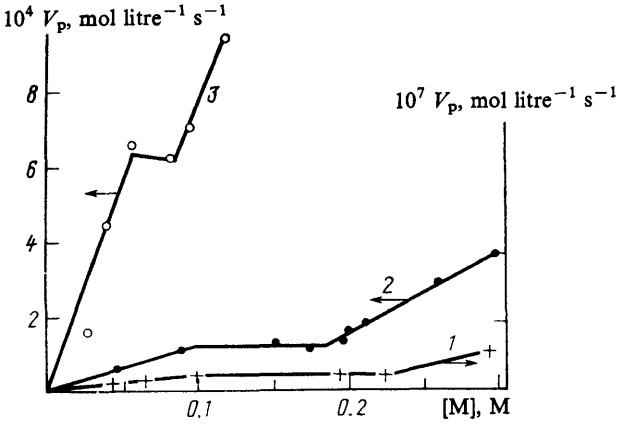

Figure 8. Dependence of the initial rate of polymerisation of polyfunctional emulsifier salts of methacryloylethylammonium (curves *2* and *3*) and allyl ammonium (curve *2*) at 70 °C on the monomer concentration in water:

(*1*) $[CH_2{=}CH{-}CH_2\overset{+}{N}(CH_3)_2CH_2COOC_{12}H_{25}]Br^-$;
(*2*) $[CH_2{=}C(CH_3){-}COOC_2H_4\overset{+}{N}(CH_3)_2CH_2COOC_{12}H_{25}]Br^-$;
(*3*) $[CH_2{=}C(CH_3){-}COOC_2H_4\overset{+}{N}(CH_3)_2CH_2COOC_{16}H_{25}]Br^-$.

The block-copolymers formed using a polyfunctional initiator are non-uniform both in molecular weight (molecular inhomogeneity) and in composition (composition inhomogeneity).

The synthesis of block-copolymers using polyfunctional initiators has been described in greater detail in a number of communications,[44–52] while other reports[49–52] give a more detailed account of polyfunctional azo-initiators or azoperoxides.

A calculation of the composition and microstructure of the block-copolymers formed using a polyfunctional initiator with two types of initiating groups differing in thermal stability, taking into account the molecular weight distribution of the macroinitiator formed in the first polymerisation stage, has been proposed.[46] The adequacy of the relations obtained has been tested experimentally.

The above brief analysis shows that the use of polyfunctional initiators of polymerisation makes it possible to improve significantly the possibilities available to us in the synthesis of polymers as a result of the increase in the amount of polymers recovered from a unit volume of the reactor and the preparation of reactive oligomers, polymers, and block-copolymers of different composition based on them.

IV. Polyfunctional surfactants

Investigators have recently clearly manifested their interest in two types of polyfunctional surfactants—surface-active monomers (SAM), which are compounds exhibiting the properties of surfactants and simultaneously retaining their capacity for polymerisation or copolymerisation, and surface-active initiators (emulsifier-initiators) (SAI), which combine the properties of a surfactant with ability to generate free radicals in a certain temperature range (Table 1).

Surface-active monomers have been known for a comparatively long time.[53] In the first studies devoted to such monomers, attention was concentrated on the study of their copolymerising capacity without a profound analysis of the kinetic behaviour of these compounds in polymerisation systems. During the last two decades, there has been a growth of interest in their investigation and they have become the subject of a review.[54]

The characteristics of the molecular structure of surface-active monomers and their ability to form associated species (micelles, lamellae, etc.) make it possible to predict their influence on the polymerisation (or copolymerisation) process. For a well founded explanation of the behaviour of such monomers in polymerisation systems, the polymerisation kinetics were therefore compared with the colloidal-chemical characteristics of solutions of surface-active monomers and the polymers formed from them.

Different dependences of the initial rate of polymerisation on the concentration of the surface-active monomer in water were observed for vinylpyridinium salts differing in the length of the aliphatic chain. For short-chain surface-active monomers, a linear growth of the rate of polymerisation with increase in the monomer concentration is observed, whereas in the case of long-chain surface-active monomers a break is observed at a certain concentration with a change in the slope of the straight line in the direction of an increase in the rate.[54] The increase in the rate of polymerisation is accompanied by the increase in the ratio of the propagation rate constant to the square root of the chain termination rate constant and by an increase in the rate of initiation.[55]

In the study of aqueous dispersions of surface-active monomer salts of methacryloylethylammonium and allylammonium, an even more complex dependence of the initial rate of polymerisation on the surface-active monomer concentration was observed. As shown in Fig. 8, in the region corresponding to the existence of micellar formations there are three sections on the curve relating the rate of polymerisation to the monomer concentration.[56] The first, initial section is characterised by a linear growth of the rate, the second by a constant rate, and the third by a renewed growth of the rate of polymerisation. The three linear sections in the variation of the rate of polymerisation were attributed by the authors to structural changes in the monomer formations within certain concentration ranges (spherical micelles, anisotropic micelles, multilayer lamellae).

In drawing a general conclusion concerning the outcome of the studies in this field,[53–58] one may note the following principal features. The polymerisation of surface-active monomers in aqueous micellar dispersions exhibits a series of differences from homogeneous polymerisation in solution, associated primarily with structure formation processes involving the molecules of the surface-active monomer and influencing the polymerisation kinetics and the microstructure of the polymer formed.

The nature of the kinetics of the polymerisation of surface-active monomers may vary as a function of the variation of the constants for the elementary reactions or of the reaction order with respect to the monomer and the initiator. The copolymerisation of surface-active monomers with other monomers takes place in those cases where the reactivity of the surface-active monomer is close to or greater than the reactivity of the comonomer.

Surface-active monomers can be used to prepare latexes not containing the free emulsifier in the aqueous phase, especially stable monodisperse latexes, ion-exchange resins, polymeric carriers for medicinal and biological preparations, etc. Surface-active monomers used to obtain thin molecular polymer layers are of special interest.

The effects observed in polymerisation systems of another type, comprising surface-active initiators—compounds in which surface-active properties and initiating capacity are combined—are extremely interesting. The location of the initiating centres in the region of adsorption layers or of the interface in heterogeneous polymerisation systems leads to extremely interesting kinetic effects associated with the change in the rates of elementary polymerisation reactions, in the first place initiation and chain termination reactions. We demonstrated experimentally the change in the rate of decomposition of a peroxide initiator located in the surface region of latex particles.[60]

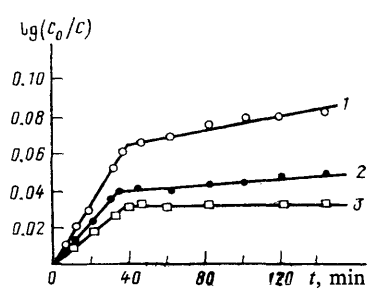

Figure 9. Semilogarithmic forms of the kinetic curves for the decomposition of the peroxy-groups of the polymeric initiator in the n-butyl acrylate—permonomer copolymer latex at 333 K. Diameter of the latex particles (nm): *1*, 50; *2*, 96; *3*, 160.

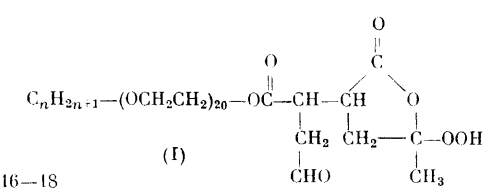
Fig. 9 presents the logarithmic forms of the curves for the decomposition of peroxy-groups located in the surface region of polymer-monomer species as a result of a special procedure for the metered introduction of the peroxide monomer in seeded emulsion copolymerisation in the system butyl acrylate–methacrylic ester of t-butyl α-hydroxyethyl peroxide.[59–61] Fig. 9 shows that the rate of decomposition of the peroxy-groups in the surface region is appreciably higher than in the bulk of the particle. A decrease in the rate constant leads to an alteration of the ratio of the peroxy-groups in the surface region of the particles. If kinetic relations are plotted taking into account the initial concentration of the peroxide, corresponding to its amount in the surface region of latex particles, then all the curves have the same slope regardless of the dispersity of the particles.



In the case of surface-active initiators, the region corresponding to the formation of free radicals is located either in the micelles or in the surface layers of latex particles depending on the characteristics of the structure of the surface-active initiator. This factor makes it possible to follow the influence of adsorption layers on the reactivity of the peroxy-groups and to investigate the characteristic features of the initiation reaction. The data presented in Table 2 make it possible to demonstrate the influence of the characteristics of the absorption layer on the rate constant for the decomposition of the surface-active initiator k_{decomp}.

Table 2. Parameters of the thermal decomposition of surface-active peroxides (SAI) in aqueous solutions.

SAI*	T, K	pH	$10^5 k_{decomp}$, s^{-1}	E, kJ mol^{-1}

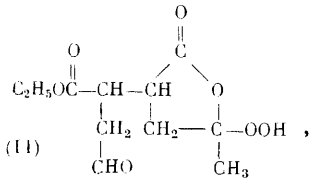
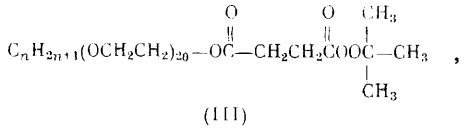
(III) with added Alkamon OS-2	363	5	0.9	–

*Alkamon OS-2 = $[C_{16-18}H_{32-37}(OCH_2CH_2)_2CH_2\underset{\displaystyle CH_3}{\underset{|}{N}}(C_2H_5)_2]^+ . C_6H_5SO_3^-$; E-30 = $C_{15}H_{31}SO_3Na$; SDS = sodium dodecyl sulphate.



Evidently k_{decomp} for micelle-forming surface-active initiators (I), having the same structure of the peroxy-group, i. e.

(I)



n = 16–18

is initially higher than for the non-micelle-forming surface-active initiators (II):

(II)

It is of interest to note that, for the perester analogue (III), i.e.

(III)

$n = 16-18$

k_{decomp} does not differ from the values for the usual peresters in hydrocarbon media. This is due to the fact that a special structure of the micelles, in which the hydrophobic fragment with the peroxy-group is drawn into the hydrocarbon nucleus of the micelle, is characteristic of compound (III).

The data presented emphasise the significant role not only of the structure but also of the location of the peroxy-group in the hydrophilic region of the micelle on the decomposition rate constants k_{decomp}.

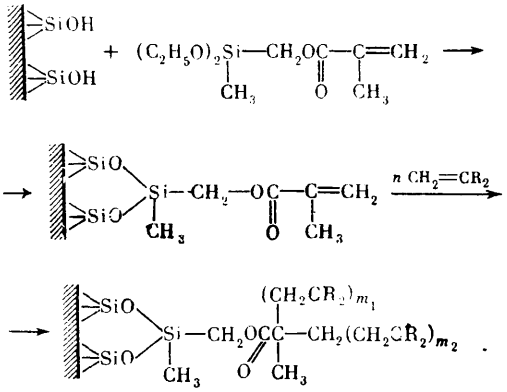
The efficiencies of the initiation of emulsion polmerisation using surface-active initiators proved to be low (0.10–0.03).[60,61] This is probably due to the difficulties arising in the interaction of the primary radicals, fixed in the adsorption layer, with the monomer in the hydrocarbon nucleus of the micelle. The high rate of destruction of the primary radicals owing to their local concentration can be abolished with decrease in the concentration of the surface-active initiator. The observed increase in the initiation efficiency on reduction of the concentration of the surface-active initiator is associated with this factor.

The change in the initiation efficiency with decrease in the concentration of the surface-active initiator in the adsorption layer makes it possible to explain the change in the emulsion polymerisation reaction order with respeect to the initiator and the emulsifier. These phenomena are caused by the change in the average number of radicals in the polymer-monomer particles.

Experiments carried out[61] in order to investigate the influence of the surface-active initiator on the chain propagation reaction lead to the conclusion that the chain propagation reaction parameters in emulsion polymerisation are independent of the characteristics of the adsorption layer and the type of initiating group. Calculation showed that in this case the chain termination rate constants decrease sharply (by 2–4 orders of magnitude) compared with those for homogeneous systems and depend on the type of polymerisation system, the volume of the polymer-monomer particles, and the fixation of the growing radicals in the surface region. This is associated with the increase to some extent of the translational and possibly the conformational entropy of the macroradicals (depending on the structure of the surface-active initiator). These data permit the conclusion that in such systems the initiation reaction influences the chain termination steps and hence the chain termination constant. Hence the possibility arises of regulating with the aid of the surface-active initiators the chain termination reaction in emulsion polymerisation and of obtaining thereby ultra-high-molecular-weight polymers (with molecular weights up to 10^7 and above).

Polyfunctional initiators can be used successfully in polymerisation systems in the preparation of ultra-high-molecular-weight polymers, highly stable polymer dispersions, polymer dispersions with a narrow size distribution of particles, etc.[59,60]

Although the history of the research into polyfunctional surfactants has so far been short, the possibilities in their use to obtain stable latexes with a specified particle size, for the creation of microheterogeneous polymer systems with a controllable size of the region of microheterogeneity, or for the creation of polymeric molecular layers are unique. It is difficult to overestimate their importance. They will undoubtedly develop in the near future.

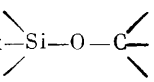


V. Polyfunctional active fillers

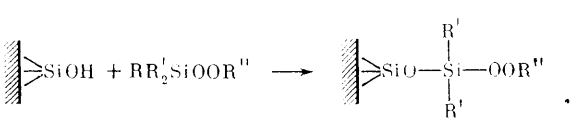
Filled polymer compositions have been finding in recent years increasingly wider applications in a wide variety of fields in engineering and the National Economy. The introduction of various solid disperse or fibrous fillers into the polymer matrix makes it possible not only to economise on the polymer (which is important in the case of scarce polymers) but also to improve greatly the physicomechanical and operating properties of the polymer compositions obtained.[62–67]

One of the main factors determining the strengthening effect of fillers in polymer compositions is the polymer–filler interfacial interaction, which depends on the nature of the polymer and of the filler surface.[64–67] The partial or complete binding of the polymer matrix to the surface of inorganic fillers makes it possible to vary widely the physicomechanical, rheological, thermal, electrical, and other properties of filled polymer compositions. As shown comparatively recently,[65–67] the occurrence of such interaction may be predicted beforehand in the preparation of filled polymer compositions by the method of polymerisation filling. The physical significance of polymerisation filling reduces to carrying out the polymerisation (or copolymerisation) in a heterogeneous system containing a filler subjected to the preliminary surface modification by the chemical binding of compounds capable of interacting with the polymerisable monomer or the growing macroradicals. Such fillers, which are capable of reacting via their surface functional groups with the polymerising monomer, can be classified as polyfunctional fillers. Table 1 presents examples of polyfunctional filler-initiators and polyfunctional filler-comonomers, which, in conformity with the structure of the compounds grafted to the surface, can either initiate polymerisation or can function as comonomers. The characteristics of the behaviour of polyfunctional fillers in polymerisation reactions are described in detail in a recently published review.[65,67] Here we shall deal only with the most important features.

The fixation of groups capable of polymerising on the surface of the filler makes it possible to obtain a polymer grafted to the surface as a result of the copolymerisation reaction. The fixation of such compounds on the surface can be achieved via the formation of strong chemical bonds, for example, by the interaction of the hydroxy-groups of aerosil or silica gel with functional carboxy- and halo-groups. Thus the possibility of achieving the copolymerisation of unsaturated ethers or acetals (obtained by the reaction of silanol groups on the silica gel surface with allyl alcohol or acrolein)



with butadiene has been described.[68] Alkoxy- or chloro-silanes, deposited on the surfaces, subjected to a preliminary treatment with an inorganic acid, of silica gel, aerosils, quartz, glass, etc. are widely used for the preparation of polyfunctional fillers.[69,71] The modification and grafting scheme is as follows [in relation to diethoxy(methacryloyloxymethyl)methylsilane]:



The density and hence the concentration of the monomeric groups bound to the surface can be regulated by varying the specific surface of the disperse filler and the conditions of the treatment of the surface.[67] The usual initiators are as a rule employed to initiate the polymerisation. During the polymerisation, a polymer not grafted to the surface is inevitably formed together with the grafted copolymer. The ratio of the grafted and non-grafted polymers depends on the degree of reaction, the content and surface area of the modified filler, and also the initiation procedure.[65,67]

It is possible to combine the stages involving the modification of the filler surface with the stage involving the copolymerisation and formation of the grafted copolymer.[73] The order in which the reactions between the modifier-copolymer and the filler surface and the copolymerisation reaction take place depends on the relative reactivities of the copolymerising groups and on the reactivity of the functional group which reacts with the surface silanol groups. However, when the modification and polymerisation stages are combined, it is not possible to avoid the excess consumption of the polyfunctional monomer, which is as a rule more scarce.

Another aspect of the chemical modification of the filler surface is the fixation on it of compouds with initating groups. For example, Dekking[74] achieved for the first time the synthesis of a monomer grafted to kaolin (or bentonite) via the emulsion polymerisation of vinyl monomers initiated by 2,2′-azobisisobutyramidine hydrochloride bound to the filler surface. Initiating systems for the surface-initiated polymerisation of vinyl monomers have been described. One of such systems consists of particles of calcium carbonate modified with 4-azobis-4-cyanopentanoic acid.[75–77]

Peroxidised fillers based on silicon-containing peroxides and not containing the hydrolytically weak  bonds are of great interest:[67,78]

where R = Cl, OR′, or NH_2 and R′ and R″ = alkyl. A convenient method for obtaining surface-peroxidised mineral fillers from modified vinyl-containing fillers by ozonisation has been proposed.[79,80] It must be emphasised that the use of peroxidised fillers with groups fixed to their surfaces makes it possible under certain conditions to synthesise monomers grafted to the filler surface without an admixture of non-grafted polymers. It has been shown[81] that, when an oxidation-reduction initiating system grafted to the surface of the hydroperoxide–iron stearate–benzoin system is used, it is possible to achieve the initiation of polymerisation exclusively on radicals grafted to the filler surface.

The kinetics of polymerisation with participation of polyfunctional fillers are associated, firstly, with the microheterogeneous nature of the polymerisation system and, secondly, with certain consequences of the fixed position of the monomeric or initiating group on the polyfunctional filler. The fixation of these groups on a solid surface leads to the restriction of the mobility of the comonomer groups or the primary initiating radicals and simultaneously to the concentration-dependent location of these groups on the surface. The set of these factors (taking into account the influence of the surface on the reactivity) leads to either the acceleration or retardation of the decomposition of the initiating group.[67] A common feature is the decrease of the initiating efficiency when polyfunctional filler-initiators are employed[67,75,78] and the dependence of the efficiency of the initiation of graft polymerisation on the concentration of the monomer in the surface region.

The fixation of the comonomers on the surface of silicon-containing fillers leads to a significant decrease in its reactivity relative to free radicals. The decrease depends on the structure of the monomer and on the nature of the surface.[82,83] An increase in the lifetime and a decrease in the probability of interaction with one another are characteristic of growing radicals fixed on the surface.[67] It has been noted that in this case the gel effect is manifested at earlier reaction stages than in the usual systems.[67,84] The increase in the molecular weight of the polymers formed as a result of the decrease in k_0 has been demonstrated.[76,81,82]

The prospects for the employment of polyfunctional fillers in the preparation of new polymeric composite materials are associated with the possibility of achieving high degrees of filling without disturbing the uniformity of the structure of the composition and with retention of high strength parameters.[85] An increased rigidity and thermal stability are characteristic of such systems. They are also distinguished from other systems in terms of their thermomechanical and rheological behaviour.[85,86]

The possibility of using polymers grafted to a disperse inorganic phase as sorbents for chromatography has been demonstrated recently.[87,88]

The polyfunctional components used to obtain polymer compositions were not touched upon to any extent in the preceding sections. The extensive possibilities for the use of polyfunctional fillers in the preparation of filled polymer compositions were examined in fair detail in previous publications. The prospects for the use of such fillers in polyolefin compositions capable of being cross-linked have also been examined in fair detail.[89,90]

In the general case, one should note that reactive oligomers and polymers readily obtained with the aid of polyfunctional components of polymerisation systems are exceptionally convenient for the formation of polymer compositions of a wide variety of types.

By varying the ratio of the components in the recipe, it is possible to vary within wide limits the structure and microheterogeneity of such compositions and hence their operating characteristics.

VI. Classification of polyfunctional components of polymerisation systems

The above analysis of studies concerning the possibility of using polyfunctional components in polymerisation systems makes it possible to undertake a new attempt at a classification of such components.

From the standpoint of polyfunctionality, the components of polymerisation systems can be most conveniently classified as a function of the nature and number of the reactive functional groups in the molecule taking into account the main purpose of the component. Accordingly, we can distinguish (1) polyfunctional monomers (PFM), (2) polyfunctional initiators (PFI), (3) polyfunctional surfactants or polyfunctional emulsifiers (PFE), (4) polyfunctional fillers (PFF), and (5) polyfunctional modifiers, etc.

The principal purpose of the components is determined by the nature of the reactive group which reacts under the given conditions (monomeric, initiating, etc.) and determines the course of the main reaction in the given process. Depending on the reaction conditions (temperature, medium, additives) the interaction in the polyfunctional component can proceed via different functional groups. Thus, depending on the polymerisation conditions, there is a possibility of the transformation of the functional groups of the polyfunctional component, for example, from a monomer to an initiator, and conversely. Naturally, the proposed classification may be expanded and transformed as new data are accumulated.

In conclusion of the consideration of polyfunctional components of polymerisation systems, we must emphasise the exceptionally dynamic nature of the development of this field of polymer chemistry. The approaches to the preparation of reactive polymers and the introduction of functional groups into the polymer matrix for a wide variety of purposes have been vigorously discussed at conferences in recent years. The data presented in this review will help to some extent to arrange systematically the available approaches in this field.

Polymerisation and characterisation of nitrile-terminated diacetylene materials

R P Grasso, J B Lando
Department of Macromolecular Science, Case Western Reserve University, Cleveland, Ohio 44106, USA

ABSTRACT. A family of nitrile-terminated diacetylene materials were synthesised. Samples were prepared in various forms and polymerisation was performed photochemically and thermally. The resulting materials exhibited low molecular weights and were obtained in low yields. Although the diacetylene group had oligomerised, no evidence was found in support of $-C\equiv N$-chain formation. Thermochromism was exhibited by the irradiated 8-nitrile sample and a molecular interpretation of this chromic transition was discussed. Diffraction data implied that strong intermolecular interactions were present between adjacent nitrile groups in the low temperature phase. It is suggested that stresses are built up during polymerisation which cause the low degree of polymerisation and yield.

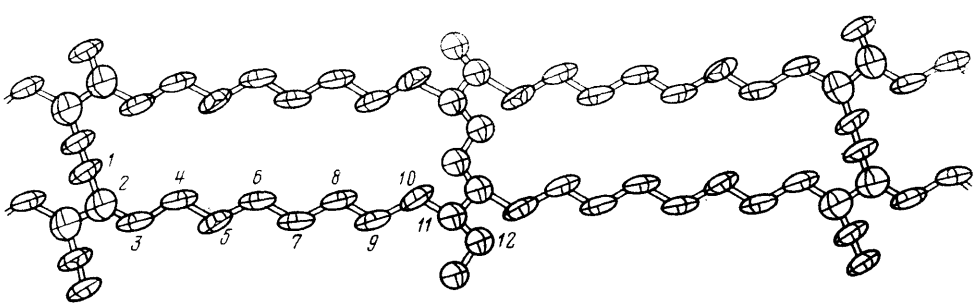
I. Introduction

The polymerisation of diacetylenes has attracted a great deal of interest which was initially due to the unique nature of this solid state polymerisation reaction.[1–5] Initiation can be carried out simply by exposing crystals of the diacetylene monomer to high energy radiation (UV, gamma, X-ray) or by annealing the crystals at temperatures below their melting points. The resulting polymers are highly crystalline since there is relatively little movement of the molecules during polymerisation. As a result, fully extended conjugated backbones are formed which give rise to their deeply coloured appearance.

In recent years, polydiacetylenes have been reported to exhibit unique properties in fields such as non-linear optics, ferromagnetism, thermochromism/solvatochromism and electrical conductivity.[6–11] The polymerisation of acetylenes has also been the focus of much interest recently. Most of this interest has been a result of the relatively high electrical conductivity of this organic material when oxidised or reduced.[12–14]

Our previous work has concentrated on the polymers of a family of diacetylene materials of the form: $HC\equiv C(CH_2)_nC\equiv C-C\equiv \equiv(CH_2)_nC\equiv CH$. The polymers obtained from this class of diacetylene monomers are interesting not only from the viewpoint of polymer physics and crystallography, but, in addition, they have been observed to exhibit several properties unique for the crystalline solid state such as electrical and optical conductivity.[15–17]



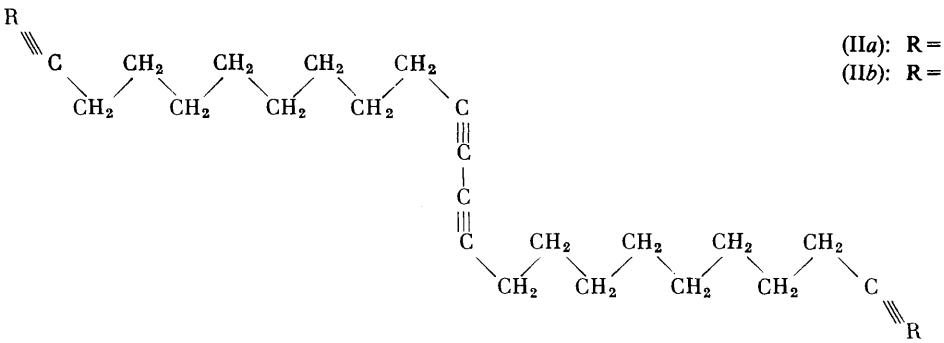


Figure 1. The *ac* section of the polymerised 1,11-dodecadiyne dimer. *1,2*, carbons in the PDA backbone; *11,12*, carbons in the PA backbone; *3–10*, methylene carbons.

(II*a*): R = CH,
(II*b*): R = N.

Figure 2. Nitrile terminated analogue of the 1,11-dodecadiyne dimer.

In addition to possessing a polydiacetylene backbone, the crystalline polymerised dimer of 1,11 dodecadiyne (II*a*) has been shown to have its adjacent acetylene groups polymerised in a head-to-head fashion. The resulting structure is composed of sheets of two dimensional networks of polyacetylene (PA) and polydiacetylene (PDA) backbones interconnected by eight methylene groups (Fig. 1).[18] Adjacent sheets are shifted one-half of a unit cell dimension along the "*a*" direction relative to one another. This results in a three-dimensional structure where polyacetylene chains are "sandwiched" between two polydiacetylene chains and *vice versa*. One possible explanation of its high room temperature conductivity of ca. 10^{-3} Ω^{-1} cm^{-1} utilised partial charge calculations in addition to π-electron overlap to propose a "self-doping" mechanism between sheets.[16]

One problem that persisted in working with this family of symmetric dimers (II*a*) is a result of the fact that they are aliphatic and contain no polar functional groups. Therefore, they are difficult to crystallise prior to solid state polymerisation. Due to this difficulty, a multistep synthetic route was developed with the intention that chemically pure species crystallise easier than the oligomeric mixtures which had been obtained previously using a controlled condensation reaction.[17] While the crystallisability of this diacetylene product was slightly increased, large macroscopic single crystals could not be obtained for other measurements.

We are presently considering a system analogous to the acetylene terminated dimers where the end groups have been replaced by nitrile groups (Fig. 2, II*b*). The added polarity of this functional group compared to substituted acetylene should aid the attempt to obtain large crystals of this polymerisable monomer. As an analogue to the acetylene terminated dimer, we can expect the diacetylene linkage to polymerise by the previously mentioned 1,4-addition reaction since the chemical distinction between the two materials is far removed from the diacetylene group.

The cyano group has been polymerised by cationic, anionic, radical and coordination catalysts.[19–23] Recent interest in these polymers has also focussed on their use as potential electrically conductive materials. However, the measured conductivities from various nitrile polymers were not as high as were anticipated ($10^{-8}-10^{-6}$ Ω^{-1} cm^{-1}). This is at least partially a result of the low crystallinity of the samples which is caused by the extra degrees of freedom allowed by the polymerisation conditions (solution or bulk liquid).

The radiation chemistry of the nitrile group has also been studied and is comparable to the acetylene group in that the main reaction is addition to the triple bond. The majority of work in this area has been performed on acetonitrile in both the solid and liquid phases. Although the degree of polymerisation is lower in nitrile compounds than in the acetylene compounds, the main product is a solid polymer. Ultraviolet and infrared spectroscopies are consistent with a conjugated $-C=N-$ chain.[24,25]

Perhaps the most interesting example of nitrile polymerisation is the one which occurs as polyacrylonitrile (PAN) is heated to 250–350 °C. The reaction of these nitrile groups in PAN and its copolymers was originally studied in order to understand the thermal discolouration of these polymers. The resulting material is sometimes referred to as "black Orlon" and typically exhibits 5–10 consecutively reacted nitrile groups.[26]

The colouration process has been studied using a variety of characterisation techniques. Thermal analysis has shown that an exothermic reaction occurs at about 250–350 °C.[27,28] Simultaneous gravimetric analysis indicates that a 10% loss in weight occurs at 270 °C, while spectral analysis of the products evolved showed that HCN and NH_3 are the major constituents. Hydrogen is suggested to be evolved at higher temperatures (450–700 °C). A series of papers by Coleman, et al.[29–31] utilises the advantages of FTIR spectroscopy to monitor the thermally induced reaction. It was found that the intensity of the nitrile absorbance steadily decreased as a function of degradation time. During the same period, numerous bands appeared which could be assigned to functional groups consistent with the proposed mechanism discussed in Ref. 21.

The conductivity of vacuum pyrolysed PAN has been studied by Lerner.[32] Using FTIR as a probe, it was reported that the pyrolysed PAN did not absorb iodine until the length of the cyclised segments exceeded a threshold value of 18 units. When the cyclicity exceeded this value, iodine could be absorbed by the polymer at room temperature to the extent of almost two iodine atoms per cyclised ring. The highest conductivity obtained was 10^{-2} Ω^{-1} cm^{-1}. Variable temperature studies yielded an activation energy of 0.59 eV and the room temperature mobility was calculated to be on the order of 10^{-5} cm^2/V sec. This is of the same order of magnitude as the mobilities of other polymeric conductors such as lightly doped polyacetylene.[33,34] Conduction in the iodine-doped pyrolysed PAN was suggested to be due to a hopping mechanism.

It was therefore decided to investigate the polymerisation and properties of the diacetylene-nitrile materials. This decision was made on the basis of the polarity and the polymerisability of the nitrile group, the electrical properties of the resulting nitrile polymers and the assumption of non-interaction between the nitrile and diacetylene groups. Since these materials are not commercially available, a synthetic route was devised to obtain the diacetylene nitrile analogues.

II. Experimental

In order to perform a more complete study, it was desired to obtain all members of the diacetylene-nitrile family with the number of methylene groups varying between 0 and 8. Materials with fewer than 2 methylene groups had to be prepared differently due to their reactivity. The synthetic pathways used here are illustrated in Fig. 3. Further synthetic details can be found elsewhere.[35] The convention used for nomenclature here and throughout takes the form of "*n*-nitrile dimer", where "*n*" represents the number of methylene groups present between the diacetylene and nitrile groups.

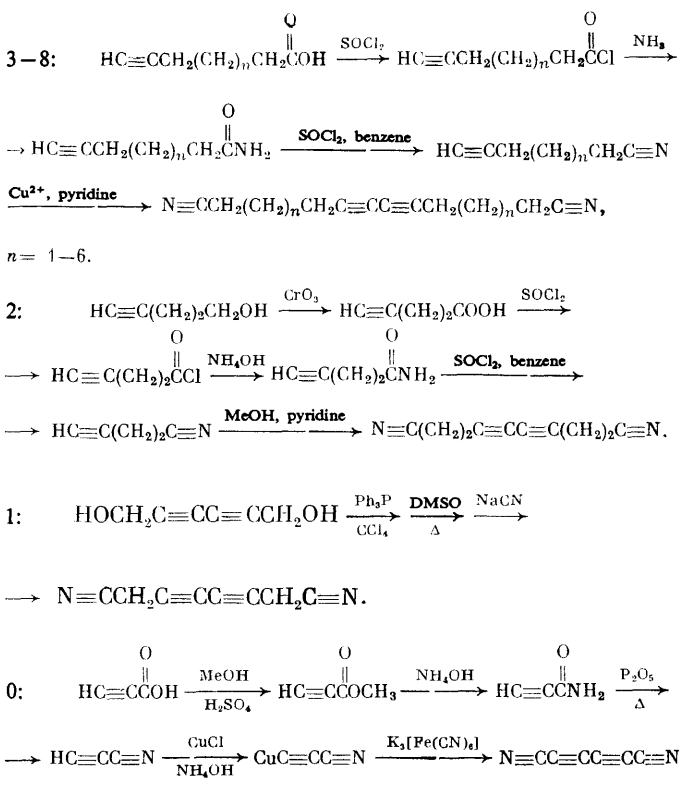

Figure 3. Synthetic pathways used in the preparation of the 0-through 8-nitrile diacetylene materials.

3-Through 8-nitrile synthesis:

A sample of acetylenic acid was reacted to form its amide using the method of Bishop.[36] The dehydrolysis of the amide to form the nitrile was accomplished using the method described by Krynitsky and Carhart.[37] Yields were typically on the order of 80%. The acetylenic nitrile was oxidatively coupled using a modified Glaser reaction[38] to give the desired product. All products were purified using column chromatography.

2-Nitrile synthesis:

The oxidation of 4-pentyn-1-ol to form 4-pentynoic acid was performed following the method of Heilbron, et al.[39] The acid could then be converted to the desired product as described above.

1-Nitrile synthesis:

The diacetylenic diol, 2,4-hexadiyn-1,6-diol, could be directly converted to the desired nitrile compound using the procedure described by Brett, et al.[40] to replace the hydroxyl groups with nitriles.

O-Nitrile synthesis:

Cyanoacetylene could not be obtained through commercial sources and was therefore prepared using the method of Moureu and Bongrand.[41] The coupling of the cyanoacetylene was accomplished using a cuprous derivative intermediate as described by Brockman.[42]

III. Polymerisation of nitrile diacetylenes

Sample preparation. Numerous experiments were performed on all of the synthesised nitrile materials in an attempt to polymerise both the diacetylene and nitrile functional groups. Three methods were employed to prepare samples for the solid state polymerisation experiments. The samples thus prepared were in the form of macroscopic crystals, thin microscopic polycrystalline films and thick microscopic polycrystalline films.

Chromic studies were performed on a Perkin-Elmer Lambda Nine UV/Visible/NIR spectrometer. The thermal characterisation was carried out using a Perkin-Elmer DSC-7 differential scanning calorimeter equipped with a workstation. X-Ray diffraction was measured using a Philips Diffractometer (Model APD 3520) with nickel filtered CuK_α radiation.

Ultraviolet polymerisation. Ultraviolet (UV) irradiation was performed at an intensity of 1600 μW/cm^2 at a wavelength of 254 nm. Ultra High Purity (UHP) argon was used as a purge gas in order to provide an inert atmosphere during irradiation. Samples were intentionally kept thin in order to minimise the surface absorption of UV light by the coloured reaction products. Exposure times of 5, 10, 20 and 45 minutes were used.

Gamma polymerisation. Gamma irradiation was carried out using a Gammacell 220 ^{60}Co source. The intensity of the source at the sample position has been calculated to be 48.2 krad/hour. The samples were flushed with UHP argon and sealed in glass containers before placing them into the source. The sample temperature could be controlled either internally or externally.

Thermal polymerisation. Polymerisation attempts at elevated temperatures were performed using a vacuum oven. Before heating, the oven was repeatedly purged with UHP argon and evacuated. Temperatures of 225, 250 and 300 °C and treatment times of 5, 15, and 30 hours were utilised.

IV. Results and discussion

The 0-nitrile dimer was found to be unstable during the course of these experiments and, therefore, no meaningful data could be obtained regarding its polymerisability.

It is known from numerous studies on other compounds that both polydiacetylenes and poly(nitriles) are highly coloured due to the conjugation present in the polymer backbone. It was, therefore, immediately noted that the absence of a coloured product from the various treatments in the case of the 1-, 2-, 3- and 4-nitrile materials probably inferred that no polymerisation had occurred. In addition, the physical appearance of the original diacetylene compounds and their experimental products were identical. This conclusion was substantiated by the infrared spectra of the monomer and irradiated samples which were identical throughout the scanned region ($3600-450$ cm^{-1}). A possible explanation for this observation will be discussed later.

A synopsis of the polymerisation attempts on the remaining crystalline diacetylene-nitrile materials (with $n > 4$) and the general results are listed in Table 1. Overall, the various methods employed were unsuccessful in producing a material with fully polymerised diacetylene and nitrile groups.

Table 1. Synopsis of polymerisation attempts and the general observations.

Treatment	Appearance	Physical characterisation	Spectroscopy
UV	blue → orange (R.T.)	melts, soluble	No C=N–
Gamma	blue → orange (R.T.)	melts, soluble	No C=N–
UV/gamma	blue → orange (R.T.)	melts, soluble	No C=N–
Heat	melts/evaporates	—	—
UV/gamma/heat	blue → orange → black	insoluble, not crystalline	No C≡N, –C=N–
n-Butyllithium	viscous yellow liquid	insoluble in benzene	No C≡N

The ultraviolet treatment of the crystalline nitrile dimers at subambient temperatures resulted in materials which are blue in reflected light. When these products were allowed to warm to room temperature, they underwent a transition from blue to reddish-orange in colour. In addition, the crystal habit was destroyed and the resulting material exhibited an appearance which could best be described as severely fragmented, pieces of orange film which precipitated from the crystallisation solution or the bulk melted dimer depending on which sample preparation was used. The coloured product was isolated in low yield (2–3%) and was found to be soluble in a variety of common solvents (e.g. acetone, methylene chloride, carbon tetrachloride and tetrahydrofuran). Infrared samples were prepared by solution casting a film onto a KBr plate. The resulting spectra gave no indication of polymerisation through the C≡N bond. This was determined by the intensity ratio of the C≡N stretching band (2240 cm^{-1}) relative to that of the aliphatic C–H stretching bands which remained constant throughout the radiation treatment. In addition, no absorbances which could be attributed to a poly(nitrile) chain were found (e.g. conjugated –C=N– bonds at 1570 cm^{-1}, C=N linkages at 1640–1610 cm^{-1} or C–N bonds at 1220 and 1145 cm^{-1}).[28,43]

Since the coloured product was soluble in tetrahydrofuran (THF), gel permeation chromatography could easily be used to follow the conversion of the diacetylene-nitrile dimers. The elution volume/molecular weight relationship was calibrated with monodisperse polystyrene standards using THF as a solvent. The maximum extent of polymerisation was not large. Using the 8-nitrile dimer as an example, the approximate maximum degree of polymerisation was calculated to be ca. 12 assuming that the calibration of the GPC data is valid in this low molecular weight range.

The results of experiments performed using gamma radiation for initiation were very similar in many respects. A blue sample at subambient temperatures transformed into the orange form after warming to room temperature. Infrared spectroscopy suggested that the C≡N groups did not appreciably react using this technique. Solubility and maximum molecular weight data were also in agreement with UV results. It was interesting to note that the yield of coloured product, although low in all cases, was approximately equal for the UV and gamma treatments in samples prepared in similar manners. That is Yield (crystals, UV) ≈ Yield (crystals, gamma) or Yield (thin film, UV) ≈ Yield (thin film, gamma). However, the yields using thin films were larger than those using thick films or crystals. Since the major difference between these samples lies in the surface area/volume ratio, which is largest for these thin samples, it would appear to be a surface related phenomenon. Certainly, it cannot be related to a surface absorption effect since the penetrating power of gamma radiation is much higher in this case than UV. But the observation does appear to be related to the relative surface area and this will be discussed later in more detail.

Several other solid state polymerisation techniques were utilised in an attempt to polymerise the nitrile group and increase the molecular weight and yields. A combination of UV treatment followed by gamma irradiation at low temperature was not found to be statistically different from either of the two separate treatments. Although expected, heat treatment of the nitrile dimers under vacuum similar to that used in the cyclisation of polyacrylonitrile resulted in the material melting and finally evaporating. A combination of UV irradiation followed by gamma irradiation, which was then followed by heat treatment, gave rise to a black-coloured product. X-Ray diffraction suggested that the material was not crystalline. Since the product was not soluble, infrared samples were prepared using a KBr pellet. Analysis of the spectra gave no indication that –C=N– bonds formed even though the C≡N band at 2240 cm^{-1} was absent. The presence of broad bands centred around 1636 cm^{-1} suggested that a dehydrocyanation reaction[26] may have occurred to form C=C linkages. Crosslinking may then randomly occur through these groups by the radical species which can form at elevated temperatures.

1. Thermochromism

The ability of a material to exhibit a shift in the UV/visible absorbance maximum with a change in temperature is referred to as thermochromism. A large number of polydiacetylenes have been shown to exhibit these effects. Initially, these chromic changes in polydiacetylenes were thought to be a manifestation of an electronic transition along the polymer backbone.[44] This can be visualised as a change in the bonding arrangement from the acetylenic to the butatrienic mesomer. More recently, experimental evidence suggests that the chromic transition in crystallisable samples is brought about conformationally by a transition which causes a decrease in the effective conjugation length of the polydiacetylene backbone.[45–47] This reduction in conjugation can be induced in the polydiacetylene backbone by either a crystal–crystal transformation[48] or by disordering the flexible side groups, if present.[49] It should be noted that the order–disorder transition can be caused not only by thermally randomising the side groups, but also by other methods which increase the entropy or disorder of these groups. An example of this can be found in situations where the polydiacetylene chains are soluble. When the solvating power of the solvent is reduced in these cases by the addition of a miscible non-solvent, intramolecular forces predominate over the intermolecular (solvating) ones and the conformation of the extended polydiacetylene backbone is regained. With the increase in effective conjugation length, a bathochromic (red) shift is observed in the visible absorbance maximum. This reversible, solvent-induced change of conformation in polydiacetylenes is commonly referred to as the coil-to-rod transition,[50] which emphasises the nature of the polydiacetylene chain in solution. The ease of reversibility of this transition has been attributed to the presence of functional groups which are capable of intrachain interactions (e.g. urethanes, esters, etc.). Although a sizable amount of work was performed in this area, a controversy still exists as to whether the chromic transition is a result of an isolated chain event[51–54] or an aggregation event.[55,56]

Polydiacetylenes have also been observed to undergo irreversible chromic transitions.[57] A number of these irreversible changes can occur during polymerisation. It is well established that the solid state polymerisation of diacetylenes requires a simultaneous rotation and translation of the diacetylene rod.[58] The movement of this set of atoms in each of the reacted monomeric units leads to the production of large stresses within the crystalline material for some diacetylene compounds. At some point, these stresses are relieved in the form of a crystallographic phase change and/or an order–disorder transition.[47] Disorder in the side groups can induce a conformational change in the polydiacetylene backbone as discussed above. This has the effect of reducing the coordinated conjugation length and a chromic shift is observed.

In the present study, the family of diacetylene-nitrile materials which could be polymerised all exhibited similar thermochromic characteristics. Since most of the data could easily be obtained using the 8-nitrile dimer, those data will be discussed throughout this section. Generalisation to the other materials may be implied except where noted.

As was mentioned previously, the nitrile materials which polymerised at subambient temperatures in the solid state all exhibited a blue colour in reflected light. When allowed to warm to room temperature, the result was a breakup of the crystal habit and the material became reddish-orange in colour. This product was isolated and a film was solution-cast onto a clean quartz plate. A UV/Visible spectrum of the resulting reddish-orange 8-nitrile material exhibited its lowest energy optical transition at 528 nm (18 900 cm^{-1}).

Since the blue phase is stable only at subambient temperatures, an isothermal spectrum could not be obtained for it, due to the lack of a sample cooling device. However, several qualitative spectra were obtained on the blue phase using quick scans over a short range. A piece-by-piece comparison of the spectra, which were cumulatively taken over the range of 300 nm to 700 nm, indicated that the lowest energy optical transition for the blue phase occurs at about 628 nm (15 900 cm^{-1}). These values are in good agreement with those reported for most polydiacetylene crystals or films which exhibit the chromic transition.[59–62]

Numerous recent studies have shown that the optical transition is accompanied by a loss of planarity in the polymer backbone.[45,59,63] A variety of experimental techniques have been used in these studies. For example, infrared spectroscopy has been used to monitor the disruption of hydrogen bonding in the side groups and the formation of "free" N–H in the polydiacetylene, poly-3BCMU (R = $(CH_2)_3OCONHCH_2COOC_4H_9$). Furthermore, ^{13}C NMR chemical shift and relaxation time data has been used to explain the post-transition changes as resulting from a decrease in the delocalisation of π-electrons and thus a decrease in the conjugation length.[63]

Studies performed on an optical microscope equipped with a hot stage in conjunction with DSC measurements have shown that the blue-red transition temperature correlates with the melting temperature of the original dimer. It appears that the melted dimer may act as a solvent for the polymer side groups. As will be discussed later, a large amount of stress is incurred on polymerisation. Once this stress is relieved by disordering the side chains, which in turn decreases the conjugation length of the polydiacetylene backbone, the order present in the original unpolymerised material cannot be recovered. As a result of the unrecoverable conjugation length, the transition from red back to blue does not occur.

It should be noted that another chromic transition, from reddish-orange to yellow, can be observed in these materials. This has been accomplished both in the solid state (thermochromism) and in solution (solvatochromism). Furthermore, it appears to be reversible unlike the previously discussed transition. A similar transition has been observed in other polydiacetylenes such as poly-3BCMU, poly-4BCMU and the polymerised dimers of α,ω-alkadiynes.[59,62,64,65] It had been suggested that the low temperature transition (blue–red) was due to the melting of the side groups whereas the high temperature transition (red–yellow) was a result of the polydiacetylene backbone becoming disordered.[61]

2. Structure work

In an attempt to understand at the molecular level why the yields and molecular weights of the products were so low, X-ray structure analyses of the unpolymerised dimer, the blue phase of the polymer in solid solution with the monomer and the reddish-orange phase of the polymer were sought for the 8-nitrile material.

Both the unpolymerised dimer and the partially polymerised blue phase undergo a transition if allowed to warm to room temperature. Various attempts at subambient-temperature single crystal work were unsuccessful, therefore, polycrystalline diffractometer data at subambient temperatures was taken instead. The reddish-orange phase was obtained from the blue phase by allowing the sample to warm to room temperature. This polymeric phase transition was accompanied by the melting of the dimer which constituted the

larger fraction of the sample. Note that all the samples include a rather large percentage of unpolymerised dimer. The results are shown in Fig. 4. All three spectra were taken on approximately equal amounts of material and the scales for each run are identical.

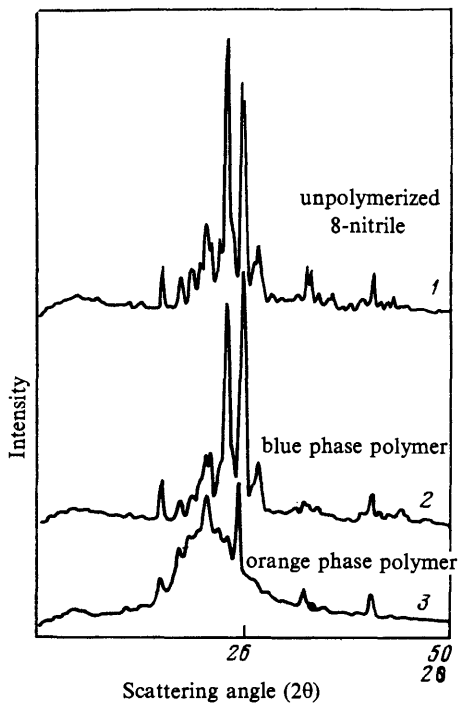

Figure 4. X-Ray diffractograms illustrating the crystallographic changes which accompany the polymerisation and the blue to reddish-orange transition in the 8-nitrile material.

A number of crystalline peaks can be observed in the top two diffractograms. Upon closer examination, it can be noted that peak positions and intensities are nearly identical for the unpolymerised dimer and the blue phase. There is a slight shifting of some of the peaks in the polymerised sample to larger scattering angles suggesting some contraction in the unit cell upon exposure to radiation. This would be expected in the solid state polymerisation of unsaturated compounds. In comparison to the other two diffractograms, the orange sample displayed a broad amorphous peak with some fine structure still present. The amorphous contribution is largely due to the melted dimer which is present in the sample. The observed crystalline peaks are located approximately at the same scattering angle as those seen in the blue phase. Some shifting to larger *d*-spacings is noted and can be attributed to a release of structural constraints which will be discussed later.

d-Spacings of the unreacted 8-nitrile dimer were measured and a unit cell which fits the data was determined by the method of least squares (see Table 2).

X-Ray density calculations performed on the unit cell indicated that there were two molecules per unit cell. A ball and stick model of the molecule was constructed using standard bond lengths, bond angles and dihedral angles. One molecule was placed at each corner of the unit cell and was centred at the midpoint of the diacetylene rod. The other molecule could be placed at (0, ½, ½), (½, ½, 0) or (½,½,½) in fractional coordinates. There are not enough data at the present time to determine which position is correct. The dimensions of the unit cell imply that there is some interdigitation of the nitrile groups on adjacent molecules. This interdigitation could be in either the *c* direction or the *b* direction (see Fig. 5).

Table 2. Unit cell data for the 8-nitrile material.

a=26.03 Å,	α=90.0°	
b=8.10 Å,	β=92.8°	Volume = 1122.4 Å^3
c=5.33 Å,	γ=90.0°.	Density = 0.960 g/cm^3

Considering the former case, the strong polar interactions of the adjacent nitrile groups obviously stabilise this structure. In addition, the intermolecular distance and orientation of the diacetylene rods in the polymerisation direction meet the requirements for diacetylene polymerisation as described by Baughman.[58] The other possibility for interdigitation would also have the polar interactions to stabilise the structure, but in order for these groups to be positioned as shown, the angle that the diacetylene rod makes with the *c*-axis must be larger than in the previous case. A qualitative calculation of this angle (ca. 57°) suggests that the diacetylene molecule will not polymerise according to Baughman's criteria.[58] From the experimental observations on the 8-nitrile material, it can be concluded that the diacetylene group does react and therefore the former model is more probable.

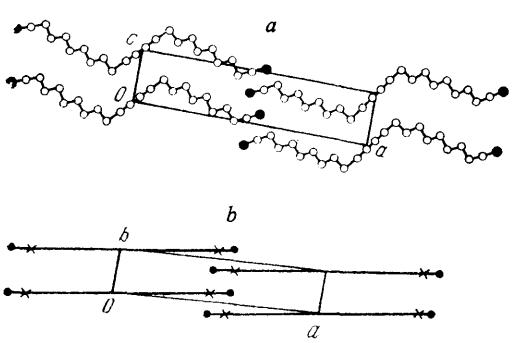

Figure 5. Projections of the 8-nitrile material illustrating nitrile interdigitation in the (*a*) *c*-direction and (*b*) *b*-direction. Hydrogens have been omitted for clarity, ● = nitrogen.

The reason as to why the diacetylene compound does not polymerise to a large degree can now be addressed. From a comparison of the crystal size and the rate of crystallisation for the

nitrile dimers and their acetylene terminated analogues, it is apparent that the polar nitrile groups interact strongly with each other. The interaction is strong enough such that one may consider the interdigitated nitriles to act as non-covalent "tie-points". Once the polymerisation of the diacetylene group is initiated, the rotation and translation which accompanies the diacetylene polymerisation is restricted at a certain point. This is a result of stresses which are built up with the addition of each molecule to the growing chain (lattice mismatch between dimer and polymer). Energetically, one may consider that the decrease in free energy associated with the polymerisation of the diacetylene group (with its required movement) is not great enough to overcome the intermolecular attraction of adjacent nitrile groups. This explains why the yield and the molecular weights of the reaction products are so low. Since the diacetylene polymerisation is considered to be topochemical, initiation occurs homogeneously throughout the crystalline lattice.[66] Thus, one would expect relatively similar yields for samples of the same mass even though the surface area may be different. The observation that this does not occur suggests that the polymerisation stress may be relieved at the crystal edges or faces by relaxation of the polymer.

The blue-to-red colour change exhibited by the polymer can be explained as a crystal–crystal transition or as an order/disorder transition. From the polymer yield calculations, the blue polymer phase can be considered to be dissolved in a crystalline matrix of dimer. As the temperature is increased, the dimer melts and can solvate the polymer side groups in the conventional sense. The disorder induced in these side groups can be covalently transmitted to the polydiacetylene backbone which is then manifested by a change in colour. However, the presence of crystalline peaks in the diffractograms of the orange phase implies that order is still present in this phase. This observation would favour the suggestion that the polymer itself undergoes a crystalline phase change once the structural constraints of the monomer are released as the monomer melts. Crystallographic phase changes which cause a chromic transformation have been observed in other polydiacetylene materials.[48,67] Finally, one must consider the possibility that a combination of these effects may account for the observed results. There are not enough data at the present time to determine which of these explanations governs the chromic transition.

At this point, some explanation must be given as to why the 8-nitrile material was chosen for most of the experimental work and discussion. Quite simply, this material exhibited the highest yields and molecular weight of all the nitrile dimers which were prepared. In consideration of the cyclisation reaction in polyacrylonitrile, it was initially believed that the nitrile groups in the irradiated 8-nitrile material would not polymerise because the long methylene chains were too flexible. As a result, adjacent nitrile groups could not be brought together into position to react. It was believed that after polymerising the diacetylene groups in nitrile dimers with fewer methylenes ($n < 8$), the nitrile group could be subsequently polymerised thermally if not photochemically. However, the number of nitrile groups per unit volume increases as the number of methylene groups decreases and the strong electrostatic interactions of the C≡N groups prevent the diacetylene polymerisation from occurring at all at a certain point.

3. Further work

Other attempts at obtaining a material which possessed both conjugated polydiacetylene and polynitrile chains were investigated. One of these involved varying the crystallisation procedure since there is a possibility that the diacetylene materials may exhibit polymorphism with one of the phases being more reactive than the others.[68,69] Crystallisations in various solvents and at different rates were performed. However, the results indicate that no different phases were achieved.

A number of procedures which may result in the simultaneous crystallisation and polymerisation of the materials were also attempted. Diacetylene materials which are analogous to those used in the present study have been reported to simultaneously crystallise and polymerise from solution upon exposure to gamma radiation.[70,71] This procedure was attempted using the nitrile materials but no polymer was observed before radiation damage took place.

Nitrile groups have been polymerised electrochemically from solution as was demonstrated by Tourillon, et al.[72] using acetonitrile. They have also been polymerised from pendant groups on polyacrylonitrile which had been deposited on the electrode.[43] It is known that polar species such as the C≡N group are oriented by an electric field and this may aid in the polymerisation process. However, the various electrochemical and chemical methods which were performed gave no evidence of the desired effect.

The authors would like to acknowledge the support of the Office of Naval Research (grant number N00014-83K-0246).

Progress and problems in activated polycondensation

R D Katsarava
Institute of Molecular Biology and Biological Physics, Georgian Academy of Sciences, Tbilisi

ABSTRACT. New polycondensation methods for the synthesis of polymers based on non-traditional ways of activating monomers are classified. For the sake of convenience and as a contrast to traditional low-temperature polycondensation, it has been proposed to combine the new methods under the general title of "activated polycondensation". It is shown that the most versatile method in terms of synthesis is that based on the activation of the "leaving" part of the biselectrophile—the "activated amide and ester method". The considerable future potential of the latter is demonstrated. Questions relating to the synthesis, structure, and reactivity of different classes of activated diesters are examined. The possibility of synthesising various heterochain polymers by reaction of activated diesters with di- and poly-functional nucleophiles is demonstrated. The advantages of this method for the synthesis of polymers are established.

The bibliography includes 145 references.

I. Introduction

It is widely known that two methods are principally used to synthesise large chains of macromolecules—polymerisation and polycondensation.

Each of these methods has its distinct features. Without analysing them in detail, we shall merely note that in terms of synthesis the polycondensation method has advantages which are reflected in particular by the fact that it can be used to obtain a higher proportion of novel polymers.[1]

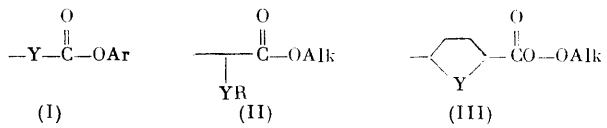
In turn, it is usual to subdivide polycondensation processes into two types—high-temperature and low-temperature.

With high-temperature polycondensation[2] (carried out at 200–300 °C in a molten state or in a high-boiling organic solvent) it is possible to use monomers (mainly biselectrophiles) with low reactivity either in an "inactive" state or as their low-activity derivatives (for example, dicarboxylic acids and their alkyl esters for the synthesis of polyamides, polyesters, etc.). High-temperature polycondensation, however, occurs in many cases at a low rate and is accompanied by numerous side reactions which lead to decomposition of the functional groups (and hence to disruption of their equimolarity) as well as to the formation of anomalous chain units ("unit heterogeneity").[3] In a number of cases such as when aromatic diamines are used, high-molecular-weight polyamides are not formed at all.[4]

In such cases low-temperature polycondensation methods (most frequently carried out over a temperature range from –30 to +50 °C in an organic solvent or by phase transfer) are more effective. These are based on the use of activated monomers—acid dichlorides, cyclic dianhydrides, bischloroformates, diisocyanates, and others.[5–8]

These methods have contributed to the further development of macromolecular chemistry and to the solution of many practical problems, but they are characterised by a number of disadvantages, the main ones being:

1) numerous side reactions (namely, the "multi-channelling" of the process),[3,5–8] leading to a restriction in chain growth and also to "unit heterogeneity";[3]

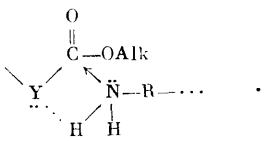


2) the need to synthesise individual activated monomers (acid dichloride, dichloroformate, or diisocyanate) that are not possible to obtain in a number of specific cases;

3) limited synthetic opportunities, for example, in the development of novel macromolecular systems, particularly of functional polymers.

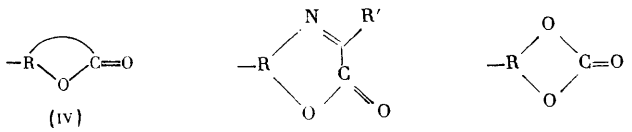
These factors have in many respects determined during the last 10–15 years the development of new polycondensation methods of polymer synthesis based on nontraditional ways of activating monomers, the so-called "activated polycondensation".

Five main variants of activated polycondensation can be distinguished in relation to the method of activating the monomers.



1) "Activated alkyl esters" method. This may also be called the "skeletal activation" method, and it is based on the introduction of heteroatoms (O, S, N) into the skeleton of a dicarboxylic acid at the α- or β-position relative to the carbonyl group of the ester;[9–21] the heteroatom can form part of the main molecular chain [compound (I)], of side groups (II), or a heterocycle (III).

(I) (II) (III)

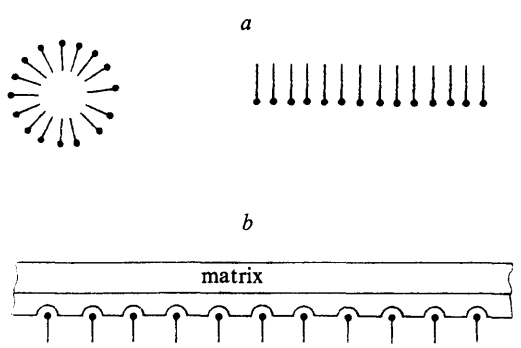


Y = O, S, NR_2, where R = H or a univalent radical.

The reactivity of alkyl diesters of the type (I)–(III) increases approximately by a factor of 10^1-10^4 compared to the unsubstituted analogues,[22] and they react with aliphatic diamines under quite mild conditions. The acceleration in these cases is mainly achieved through the so-called "anchor effect":

The inductive effect of heteroatom Y may also play a decisive role, particularly if it is situated at the α-position.

2) "Active rings" method. Many bifunctional monomers which contain different heterocycles—lactones (IV),[23–27] azalactones (V),[28–40] cyclic carbonates (VI),[41–44] and others—as functional groups exhibit a higher activity than their linear analogues as a result of intramolecular electronic effects or ring strain, and they react with nucleophiles (mainly with highly basic aliphatic diamines) under mild conditions to give high-molecular-weight polyamides, including those with different functional groups.



(IV) (V) (VI)

3) "Direct polycondensation" method (or "activation *in situ*"). The reaction between dicarboxylic acids or carbon dioxide and bisnucleophiles (mainly aromatic amines and bisphenols) occurs under mild conditions in the presence of various condensation agents (B).

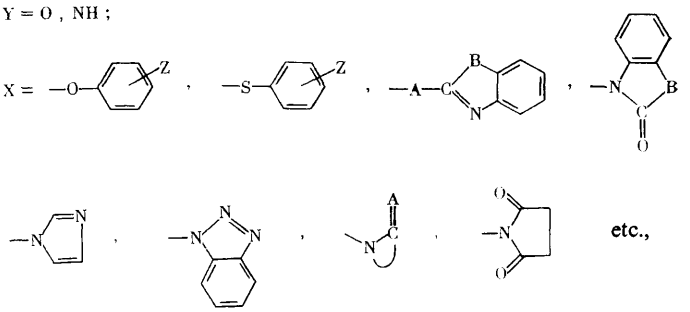
$$n\text{HOOCRCOOH} + n\text{HY} - \text{Ar} - \text{YH} \xrightarrow{B} -(-\text{CORCOYArY}-)_n-,$$

Y = NH, O.

This modification of polycondensation as well as the condensation agents used have been reviewed by Katsarava.[45]

where | – is a molecule of monomer

Figure 1. Polycondensation of "organised molecular masses". Possible molecular orientation: *a*, in micellar and liquid-crystalline forms; *b*, in matrix forms.



4) "Organised molecular masses" method. It has been shown that a considerable acceleration of the reaction that forms the basis of many polycondensation processes can be achieved by the formation of organised molecular masses (according to Oakenfull[46] this acceleration in a number of cases reaches a factor of 10^6, which corresponds to the level of enzyme processes) of a micellar or liquid-crystalline phase[45–47] (Fig. 1*a*) or by the introduction of various matrices, more often those that are polymeric in nature, into the reaction medium[58–67] (Fig. 1*b*).

In these systems the acceleration is achieved either through the favourable relative configuration of the monomers in space or through the increase in their local concentration. We should note that the formation of organised molecular masses not only accelerates the reaction but also alters its course. For example, when α-amino acid derivatives are used, high-molecular-weight polypeptides are formed instead of cyclic diketopiperazines.[47–49] A change in the course of the reaction was also detected in the polycondensation of urea with formaldehyde in the presence of a polyacidic matrix.[68,69]

5) "Activated esters and amides" method. In contrast to the "activated alkyl esters" method, this method is based on activation of the leaving groups, i.e. that part of the monomer which is eliminated as a low-molecular-weight by-product of polycondensation.

$$n\text{XOC—R—COX} + n\text{HY—R'—YH} \xrightarrow[-2n\text{HX}]{} \longrightarrow -[-\text{CO—R—CO—Y—R'—Y}-]_n-,$$

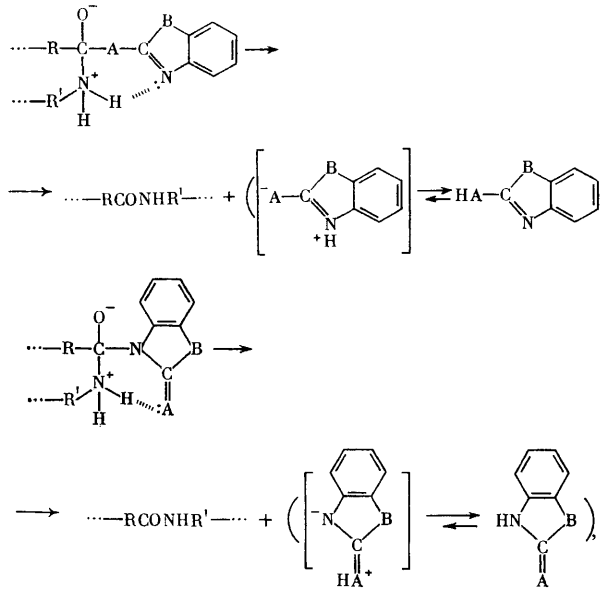
Y = O, NH;

(A, B = O, S); Z = electron-withdrawing substituent.

Attempts to use activated dicarboxylic acid derivatives other than acid chlorides in polycondensation (polyamidation) were made as early as the 1950s. Thus, for example, mixed anhydrides of dicarboxylic acids and diesters of orthophosphoric acid[70] or monoesters of carbonic acid[71] as well as dinitrodiamides[72] and diimidazole derivatives of dicarboxylic acids ("activated amides")[73] have been used. However, the majority of these compounds, frequently obtained in a fairly complex manner, on reaction with diamines only gave low-molecular-weight polyamides that were of little use for practical application. This circumstance would appear to have played not an inconsiderable role in causing this promising method to have remained without propert attention being given to it until the beginning of the 1970s.

At the end of the 1960s it was shown that activated esters[74] and "cyclic activated amides" such as benzoylenebenzimidazoles[75] could be used for the synthesis of heterochain polymers. Systematic studies of this modification of activated polycondensation, however, were only started in the 1970s.[76]

Formally the "leaving group" method is similar to traditional low-temperature polycondensation based on the use of acid dichlorides, but it has wider synthetic possibilities because of the use of "leaving groups" of varied nature and structure as well as "single-channelling", namely, the absence (or minimal contribution) of side reactions.



The activation of the monomers (biselectrophiles) in the "leaving group" method is achieved as follows:

1) by introduction of electron-withdrawing substituents into the leaving group or by the use of sulphur-containing leaving groups (thioesters), which are more active than those containing oxygen because of the lower basicity (better stabilisation of the negative

charge in the leaving anion X^-)† resulting from the larger radius of the sulphur atom;

2) by using nitrogen-containing leaving groups (activated amides), which when having the same pK_a values are approximately 10^4 times more reactive than oxygen-containing leaving groups;[77]

3) by making use of anchimerically assisting leaving groups

A, B = 0.5.

Anchimeric assistance

Thus, activated diamides of dicarboxylic acids, in particular those with anchimerically assisting leaving groups, have high acylating potential and are used for the synthesis of high-molecular-weight polyamides under mild conditions (see the study of Katsarava[76] and the references in it). However, they are characterised by a number of disadvantages, which can be mainly classified as: 1) the relatively high cost and complexity of obtaining the activating agents—various benzazoles and other nitrogen-containing heterocycles; 2) the synthesis of activated diamides, mainly via the corresponding acid dichlorides, which imposes certain synthetic restrictions on the method (the synthesis of only activated diamides of dicarboxylic acids and hence a single class of heterochain polymers—polyamides—is described in the literature).

In relation to the above, activated diesters have greater potential as monomers, displaying the following advantages: 1) availability and economical price of the activating agents XH (substituted phenols, etc.);[76] 2) simple "direct" syntheses of activated diesters that achieve complete independence of the method of activated polycondensation; 3) the possibility of controlling the reactivity of activated diesters and hence the polycondensation processes over a wide range by varying the leaving groups together with the low tendency of diesters to undergo side reactions; and, what is particularly important, 4) the ready availability of activated esters of different classes and hence the possibility of synthesising various heterochain polymers (Scheme 1) using activated polycondensation.

It is appropriate to mention here that, starting in the middle of the 1950s, the "activated ester" method has been successfully used in peptide chemistry for obtaining both pure peptides[78–81] and poly(amino acids)[82,83] and regularly alternating polypeptides.[84–87]

In drawing a parallel between peptide chemistry and activated polycondensation, the considerable differences between them should be pointed out. In peptide synthesis the problem of the retention of optical purity is central. Of course, single-channelling of the reaction is of considerable importance in multistage peptide synthesis, but the small contribution from side reactions (1–5%) is not so significant. In polycondensation single-channelling of the reaction acquires particular significance—activated monomers (or low-molecular-weight reaction products) should not undergo side reactions with monomers of an opposite kind, solvents, or products being formed. At the concluding stages of polycondensation the rate of reaction (fundamental act) is of crucial significance—it must be high so as to achieve chain propagation with the vanishingly small concentrations of terminal functional groups.

Scheme 1

Activated diesters of dicarboxylic acids XCORCOX	→	Polyamides Polyesters Polybenzazoles
Activated biscarbonates of diols XCOOROCOX	→	Polyurethanes
Activated carbonates XCOX Activated biscarbamates XCONHRNHCOX	→	Polyureas

Therefore the questions relating to the synthesis, structure, and reactivity of activated diesters, as well as their tendency to undergo side reactions, are key ones in activated polycondensation and in the present review considerable attention is given to them.

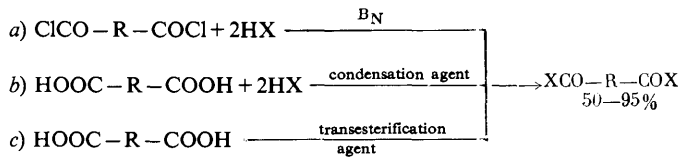
II. Synthesis, structure, and reactivity of monomers. Model reactions

1. Synthesis of activated diesters

The reactions which form the basis of the synthesis of different classes of activated diesters are shown in Scheme 2. These monomers can, of course, be readily obtained via the corresponding traditional forms of activated monomers—acid dichlorides, bischloroformates, and diisocyanates—a genetic link being retained between activated polycondensation and traditional low-temperature polycondensation. This approach is justified in a number of cases. It can be used to change to monomers of a "milder" nature, leading to better results in the synthesis of polymers (see below). However, for a number of reasons, as mentioned above, direct methods of synthesising activated diesters have greater future potential.

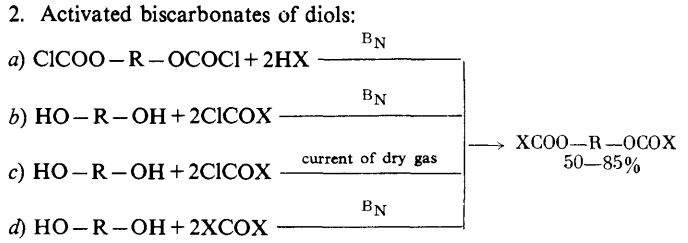
Activated diesters of dicarboxylic acids are synthesised using free dicarboxylic acids and condensing agents according to reaction (1*b*) or transesterification agents according to reaction (1*c*)[76,88–91] (see Scheme 2).

Activated biscarbonates of diols can be obtained by the reaction of diols with suitable chloroformates [reactions (2*b*) and (2*c*)] or carbonates [reaction (2*d*), and the former, depending on the synthetic requirement, can be carried out even in the absence of an acceptor of HCl (B_N).[76,92]



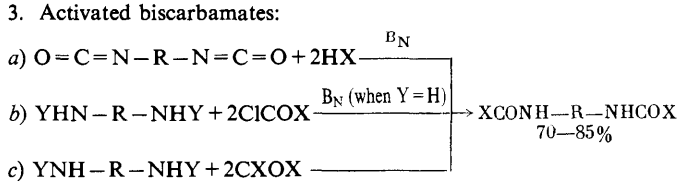
† For the reaction mechanisms, see below.

The "direct" method of synthesising activated biscarbamates involves the treatment of free diamines with a chloroformate or carbonate [reactions (3*b*) and (3*c*), Y = H]. Bis(trimethylsilyl) derivatives of the diamines (Y = $SiMe_3$) can be used successfully in these reactions. In this case there is no need for an acceptor of HCl (B_N), which would cause the dissociation of the resulting carbamate to a diisocyanate (see below).

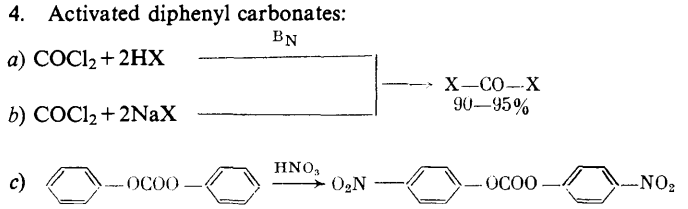


Scheme 2

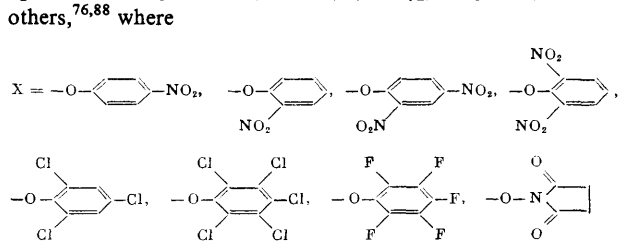
Syntheses of different classes of activated diesters



1. Activated diesters of dicarboxylic acids:



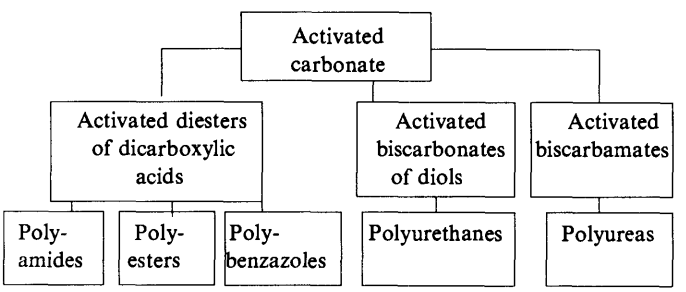
2. Activated biscarbonates of diols:



3. Activated biscarbamates:

4. Activated diphenyl carbonates:

Note. Condensation agents are: dicyclohexylcarbodiimide, PCl_3, $SOCl_2$, TsCl, $COCl_2$ $(CF_3CO)_2O$, and others.[45,76] Transesterification agents are: X_3P, X_2SO, X_2CO, $(XCO)_2$, CF_3COX, ClCOX, and others,[76,88] where

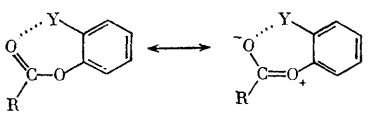


and others (Ref.76). Y = H, $SiMe_3$, B_N = tertiary amine.

Activated diphenyl carbonates (which are also of interest as transesterification agents) are obtained by reaction of phosgene (diphosgene and triphosgene, which are more convenient to handle, can also be used) with a suitable phenol in the presence of B_N [reaction (4*a*)] or a phenoxide [reaction (4*b*)] (Scheme 2). Activated diphenyl carbonates can also be synthesised by nitration of diphenyl carbonate.[93] The latter, in turn, is obtained by a phosgene-free method using CO_2 and phenol as the starting materials.[94] This opens up a route to a new phosgene-free scheme for the synthesis of polyurethanes and polyureas.

Many of the methods that have been developed lead to activated diesters in high yield and it is possible to standardise their syntheses. For example, by using a single transesterification agent it is possible to synthesise an almost unlimited number of diesters of dicarboxylic acids. Similarly, a variety of activated biscarbonates of diols and biscarbamates can be obtained from a single activated phenyl chloroformate. When starting from an activated carbonate X_2CO, it is possible to standardise the syntheses of virtually all classes of monomers and their corresponding polymers (Scheme 3).

Scheme 3

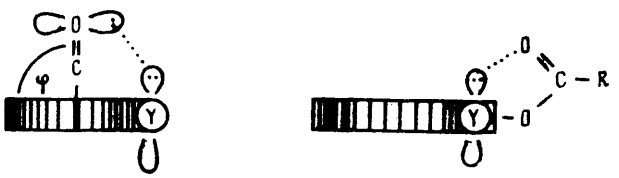


At the same time because of the wide choice of esterification and condensation agents it is possible to vary flexibly the strategy and tactics of designing macromolecular systems, in particular the so-called functional polymers, taking into account both economic and ecological requirements.

2. Structure and reactivity of activated phenyl esters

From IR and ^{13}C NMR spectroscopic studies of *ortho*-, *para*-, and poly-substituted phenyl esters in solution[95–98] it was possible to assign a *trans*-conformation to them, with the torsion angle (φ) of the plane of the ester group relative to the plane of the benzene ring of the phenol residue close to 90° (Fig. 2*a*). The literature data on the conformation of esters also attest to this.[99–102]

With such a conformation of the ester there is no through conjugation between the substituents of the phenyl residue and the carbonyl group, although an interaction occurs through space (in the case of *ortho* substituents), which gives rise to a reduction in contribution from the canonical structure (*K*2).



(*K*1) (*K*2)

This, in turn, leads to an increase in the double-bond character of

and a reduction in polarity of the π-bond, which manifests itself (especially strong when halogen atoms are present in *ortho*-positions) in an increase in frequency of the carbonyl stretching vibration and in an upfield displacement of the chemical shift of the $^{13}C=O$ group.[98] The "ortho effect" which occurs on reaction of activated esters with nucleophiles, as will be demonstrated below, leads to a reduction in the apparent rate constant of reaction.

The dependence of the reactivity of esters on the nature of the leaving groups has been studied in the case of the anilinolysis of activated adipates in hexamethylphosphoramide (HMPA).[103] The leaving groups can be arranged in the series given in Table 1 in accordance with the values of the second-order rate constants of reaction (k_2^{app}) (with decreasing activity of the respective esters).

a *b*

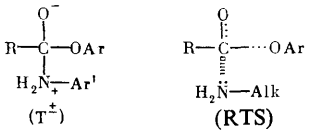


Figure 2. Conformation of *ortho*-substituted phenyl esters of carboxylic acids in solution: *a*, front view; *b*, side view.

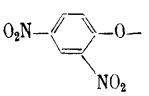
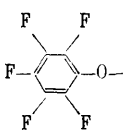
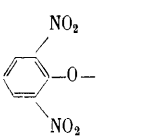
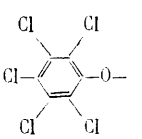
On the basis of these results the following conclusions can be made:

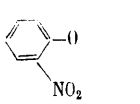
1. By changing the nature of the leaving groups it is possible to vary the activity of the diesters over a wide range (in this case by a factor of 10^6). This factor—one of the most important advantages of the activated ester method—clearly suggests the possibilities for controlling the reactivity of electrophilic monomers and hence polycondensation processes without external influences (changes in properties of the medium, temperature, use of a catalyst, etc.).

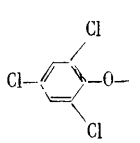












2. The most active esters are 2,4-dinitrophenyl esters, and they are superior to their pentafluorophenyl analogues in every case regardless of the nature of the acyl residue, reacting amine, and reaction medium,[98] which is inconsistent with the results of Covacs et al.,[111] obtained for α-amino acid derivatives.

3. There is no correlation between the apparent rate constants (k_2^{app}) and the pK_a values of the leaving groups (phenols—conjugate acids to the base); the magnitude of the pK_a characterises the stability of the leaving phenoxide anion and correlates with the Hammett σ-constants.[109] Consequently, there is a lack of that kind of correlation between the activity of the esters and the Hammett σ-constants which usually occurs for esters substituted only at the *para* position[112] and which suggests that the leaving groups become detached at the rate-determining stage. It is known that if pre-barrier processes—the formation of intermediate complexes—are rate-determining (see below), the rate constant must correlate with the Taft σ^0-constants because of the virtually orthogonal structure of the esters and the absence of "through resonance". The frequencies of the carbonyl stretching vibrations of esters correlate well with the σ^0-constants.[98-100] If decomposition of the intermediate complexes is rate-determining, the rate constant correlates with the Hammett σ-constants.[99,112] It is appropriate to note that according to Oleinik et al.,[113] a zwitterionic tetrahedral intermediate $T^{\pm}$ is formed in the reaction between esters and arylamines: with alkylamines the reaction occurs via a reactant-like transition state (RTS), which is shifted to the left on the reaction coordinate as the electrophilicity of the ester increases (i.e. with an increase in electrophilicity of the ester the barrier decreases).

$(T^{\pm})$ (RTS)

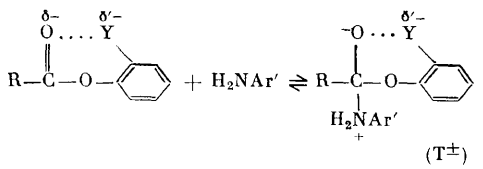


Table 1. Kinetics of the reaction of $ArOOC(CH_2)_4COOAr + H_2NPh$ (molar ratio of 1 : 2) in HMPA at 30 °C.[103]

ArO–	k_2^{app}, litre mol^{-1} s^{-1}	pK_a in water	σ (or Σσ)	σ^0 (or $\Sigma\sigma^0$)
	>1.05	4.0 [104] 4.1 [105–107] 4.39 *	2.48	2.00
	$1.3 \cdot 10^{-2}$	5.3 [106] 5.5 [104] 5.86 *	1.82	2.09
	$6.9 \cdot 10^{-3}$	3.7 [105] 4.39 *	2.48	2.54
	$5.4 \cdot 10^{-4}$	4.5 [108] 5.3 [104. 106] 4.72 *	2.33	2.33
	$2.6 \cdot 10^{-4}$	7.16 [104] 7.15 [109]	1.24	0.73
	$3.9 \cdot 10^{-5}$	7.21 [104]	1.24	1.27
	$3.6 \cdot 10^{-6}$	6.42 [108] 7.59 [104] 6.37 *	1.59	1.57

* The pK_a values calculated according to the study of Barlin and Perrin[109] are given because of discrepancies in the experimental pK_a values (H_2O). According to Bykova and Petrov,[110] the acidity series in water for acids of a single group (phenols in this case) is also retained in organic solvents.

An analysis of the results of Table 1 using the Taft equation indicates[98] that the apparent steric constants have lower values (calculated using Hammett σ-constants) than those reported in the literature (given in brackets): $E_{S_{app}}^{F} = 0.22$ (0.46); $E_{S_{app}}^{Cl} < -1$

(0.18); $E_{S\,app}^{NO_2}$ = −1.56 (−0.75) [calculated for bis(2,4-dinitrophenyl) adipate] [a value of −0.75 has also been adopted for bis-(*o*-nitrophenyl) adipate in calculations]. The reduction in $E_{S\,app}$, which is particularly noticeable when there are two *ortho* chlorine atoms,‡ may be related to the above-mentioned "ortho effect", which creates additional difficulties in the formation of $T^{\pm}$ and shifts this equilibrium to the left, increasing the apparent shielding effect of the *ortho* substituents.

($T^{\pm}$)

Table 2. Apparent constants k_2 for alcoholysis reactions of activated esters at 30 °C.

Results obtained on the alcoholysis and phenolysis of model acetates (Table 2) may also provide an indication of the reality of the "ortho effect". In these reactions an RO^- anion is the nucleophile, so the intermediate has an anionic character (T^-) without intramolecular balance of charge. This enhances the role of this interaction and leads to a substantial change in the relative reactivity of the esters compared to aminolysis reactions. The difference in activity of *p*-nitro- and pentafluoro-phenyl esters is levelled out, the *p*-nitrophenyl ester is more reactive than its *o*-nitro-substituted analogue (in the reaction with aniline in the same medium the opposite occurs, see below) and 2,4,5-trichloro-substituted analogue (according to the literature data the latter is more active in aminolysis)[114] and pentachlorophenyl acetate is less active than *p*-nitrophenyl acetate by a factor of approximately 40 (in the reaction with aniline in chlorobenzene the former is 13 times more active, see Table 3).

‡ While the reduction in $E_{S\,app}$ (increase in steric hindrance) by a factor of 2 in the case of 2,6-dinitro- and pentafluoro-phenyl esters can be attributed to the presence of two *ortho* substituents, the large reduction in $E_{S\,app}^{Cl}$ is difficult to explain solely on the basis of two *ortho* atoms.

However, depending on the properties of the medium, *ortho* substituents can have the opposite effect—a catalytic action on aminolysis processes. Thus, for example, in the reaction with aniline in a weakly polar, proton-inert medium, *o*-nitrophenyl esters are 2–4 times more active than their *para*-substituted analogues,[98] which may be related to the formation of an intramolecular hydrogen bond which stabilises $T^{\pm}$.

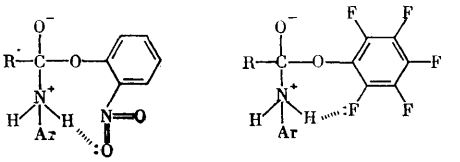

Table 3. Relative reactivity of activated diesters (C_0 = initial concentration of reactants in mol litre^{-1}).

Ester pair (A + B) (C_0)	E_{LUMO}^{*}, eV	Amine (C_0)	Reaction medium (T, °C)	k_1, s^{-1}	k_1^A/k_1^B

* Energy of the lowest unoccupied molecular orbital calculated by the MINDO/3 method.

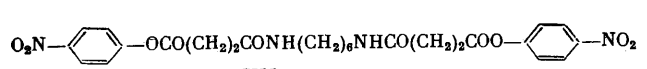
In a proton-active medium such as HMPA, where the formation of strong hydrogen bonds is possible, the catalytic effect from an *ortho*-nitro group is absent (only an inhibiting "ortho effect" seems to occur), and in this case *para*-substituted esters are more active (by a factor of approximately 8).[98] We should note that an intramolecular catalytic effect can be exhibited by *ortho*-fluorine atoms, which may partly explain the high activity of pentafluorophenyl esters in aminolysis reactions (in contrast to reactions with ROH, Table 2).

The nature of the acyl residue has a considerable effect on the relative activity of esters (Table 3). According to the data obtained, esters make up the following series of decreasing activity (other

conditions being equal):

a) Reaction with an arylamine: acetate > methyl phenyl carbonate > benzoate;

b) Reaction with an alkylamine: methyl phenyl carbonate > acetate > benzoate.



The experimental data obtained can be interpreted on the basis of the above-mentioned mechanism.[113] In a reaction with an arylamine that occurs via the intermediate formation of $T^{\pm}$, carbonates are less active since they correspond to a lower ground state energy (because of the mesomeric interaction between the methoxyl oxygen and the carbonyl group),[115] which results in an increase in the energy barrier. In reactions with alkylamines the transition state is reactant-like and in the case of carbonate (which according to the E_{LUMO} value is more electrophilic than acetate, Table 3) is shifted more to the left along the reaction coordinate, thus reducing the barrier. It follows from the results obtained that the difference in rates of aminolysis on changing from an alkylamine to an arylamine is greater for carbonates.

The medium has a considerable effect on the rate of aminolysis, and it was found that the most important of the properties of solvents is their ability to form strong hydrogen bonds (characterised by the value of pK_{HB}, Table 4). Thus, for example, the rate of reaction of *p*-nitrophenyl acetate with aniline is higher by a factor of about 10^3 in DMSO and HMPA than in the proton-inert chlorobenzene and even acetonitrile, which is comparable to the former in terms of polarity and dielectric constant but has a considerably lower pK_{HB}.

Table 4. Effect of medium on apparent pseudo-first-order rate constants (k_1) of reaction between *p*-nitrophenyl acetate (C_0 = 0.05 mol litre^{-1}) and aniline (C_0 = 2.0 mol litre mol^{-1}) and rate constants of imidisation (k_{im}) of the bis(*p*-nitrophenyl) ester of *N,N'*-hexamethylenedisuccinamide (VII) at 30 °C.

Medium	Properties of medium			k_1, s^{-1} (Ref.103)	k_{im}, s^{-1} (Ref.91)
	μ	ε	pK_{HB} (Ref.116)		
C_6H_5Cl	1.69	5.62	–	$4.7\cdot10^{-7}$	does not cyclise
CH_3CN	3.92	36.2	1.05	$5.2\cdot10^{-7}$	»
HMPA	5.37	30.0	3.56	$5.5\cdot10^{-4}$	$4.0\cdot10^{-6}$
DMSO	3.96	49.0	2.53	$1.4\cdot10^{-4}$	$1.6\cdot10^{-6}$

Similarly, the bis(*p*-nitrophenyl) ester of *N,N'*-hexamethylenedisuccinamide (VII)

(VII)

undergoes cyclisation (imidisation) at an appreciable rate only in a medium with a high pK_{HB} value (Table 4). The experimental data obtained can be accounted for by the considerable catalytic effect of these solvents on the aminolysis of esters. We have established that a single molecule of HMPA and three molecules of DMSO participate in catalysis. The reason for the unusual behaviour of DMSO is apparently related to the formation of a solvent-separated ion pair (the formation of which is supported by UV spectroscopy) involving an acyloxysulphonium ion:

$$R{-}COOAr + O{\leftarrow}SMe_2 \longrightarrow R{-}CO{-}O{\leftarrow}\overset{+}{S}Me_2 \ldots O{\leftarrow}SMe_2 \ldots ArO^-.$$

The third DMSO molecule, as with HMPA, participates in proton transfer in $T^{\pm}$.

In proton-inert organic solvents the reaction is catalysed by the amide that is formed[117] (amides have high values of $pK_a \approx 2$)[116] and the initial amine. Under pseudo-first-order reaction conditions (excess amine) the apparent rate constant is given by the familiar equation $k_1 = \sum k_{i+1}[A]^i$, where $i = 1, 2$.[112,113] However, in *n*-heptane the high order term $k_4[A]^3$, with $i = 3$ (Table 5) was first found, which suggests associated (trimeric) forms of the amine take part in the reaction. This result confirms the mechanism according to which catalysis by amine is no different from the action of a specific solvent[117,118] that is capable of forming a strong hydrogen bond, and is given by:

$$R'NH_2 + B \rightleftharpoons R'NH_2 \ldots B,$$

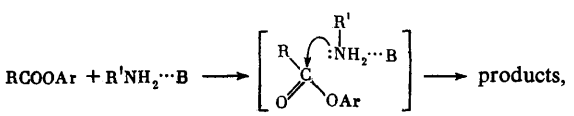


Table 5. Kinetics of the aminolysis of activated *p*-nitrophenyl esters *p*-RCOO–C_6H_4–NO_2 in proton-inert media.

R	(A)	Variation in [A], mol litre^{-1}	Reaction medium	$k_2\times10^2$ litre mol^{-1} s^{-1}	$k_3\times10^2$ litre^2 mol^{-2} s^{-1}	$k_4\times10^2$ litre^3 mol^{-3} s^{-1}
CH_3	BA	0.02–0.35	n-heptane	–	1.3	22.2
	BA	0.04–0.40	benzene	–	3.1	–
	BA	0.01–0.50	1,2-dichloroethane	0.2	9.8	–
	AN	1.5–4.0	chlorobenzene	$1.6\cdot10^{-5}$	$0.4\cdot10^{-5}$	–
CH_3O	BA	0.01–0.42	n-heptane	–	4.6	81.8
	BA	0.04–0.34	benzene	–	9.4	–
	BA	0.04–0.48	1,2-dichloroethane	0.5	22.5	–
	AN	2.0–4.0	chlorobenzene	$0.3\cdot10^{-5}$	$0.2\cdot10^{-5}$	–

	BA	0.07–0.50	benzene	–	0.16	0.7
	BA	0.04–0.54	1,2-dichlorobenzene	–	1.4	3.7

Note. The reaction with aniline (AN) was carried out at 30 °C, that with *n*-butylamine (BA) at 28 °C. Initial concentrations of esters were 0.05 mol litre^{-1} (reaction with AN) and 10^{-4} mol litre^{-1} (reaction with BA).

where B is a molecule of proton-active solvent or the amine itself.

It was established that activated alkyl aryl carbonates react with amines with removal exclusively of a phenoxide ion ArO^- and

formation of the required urethane [route (*a*)]; the alternative route (*b*) does not occur:

$$ROCOOAr + H_2NR' \begin{cases} \xrightarrow[-ArOH]{(a)} ROCONHR' \\ \xrightarrow[-ROH]{(b)} R'NHCOOAr \rightleftharpoons R'-NCO + ArOH \text{ etc.} \end{cases}$$

In other words, aminolysis of activated esters of carboxylic acids and alkyl aryl carbonates occurs by the same "direct" mechanism—either via the formation of $T^{\pm}$ or via a RTS.

In contrast to activated esters, activated carbamates react with amines by a more complicated mechanism, forming an intermediate isocyanate:

$$RNHCOOAr + (H_2NR')_{i-1} \xrightarrow[-ArOH]{} R-NCO \xrightarrow{H_2NR'} RNHCONHR'$$

An indication of this is provided in particular by the constantly occurring term $k_4[A]^3$, regardless of the properties of the medium (see Table 5).

The mechanism of aminolysis of activated diphenyl carbonates consists of a unique combination of both mechanisms

$$ArOCOOAr \xrightarrow{H_2NR} \begin{bmatrix} T^{\pm} \text{ or} \\ RTS \end{bmatrix} \rightarrow ArOCONHR \xrightarrow[-ArOH]{(H_2NR)_{i-1}}$$

$$\rightarrow RNCO \xrightarrow{H_2NR} (RNH)_2CO\ .$$

Thus, aminolysis of activated esters is a complex process and is susceptible to various intra- and inter-molecular influences, which have a considerable effect on the formation of macrochains in activated polycondensation.

3. Possible side reactions

Studies have been conducted on the tendency of activated esters to undergo various side reactions in which traditional activated forms of the monomers are fairly readily involved and which constitute the reason for the restriction on chain propagation and the unit heterogeneity.

It has been established that the majority of activated diesters do not react with alcohols (methanol, ethanol) even on boiling. In the absence of an amine only the most active 2,4-dinitrophenyl esters undergo appreciable alcoholysis.[119,120]

Activated esters are also stable towards amide solvents. Only 2,4-dinitrophenyl esters exhibit relatively low stability; in HMPA at 30 °C about 10% of the ester groups have decomposed after 6 h (when their initial concentration is 0.1 mol litre^{-1}).

Activated esters also exhibit high hydrolytic stability in these weakly basic solvents even in the presence of considerable quantities of water (up to 9%) (see Table 6), with pentafluoro- and *p*-nitrophenyl esters considerably surpassing their 2,4-dinitro-substituted analogues in this respect. It is worth noting that when triethylamine (TEA) is introduced into solution, the pentafluorophenyl ester is the least susceptible to its catalytic action, which may be attributed to the above-mentioned inhibitory effect from two *ortho*-fluorine atoms in attack on an ester by OH^- ions. Alkyl aryl carbonates have similar hydrolytic stability to that of their ester analogues (Table 6).

In contrast to the "conventional" esters (adipates) examined above, the catalytic effect of TEA is absent in the hydrolysis of diester (VII) and only an acceleration of imidisation occurs (see Table 6). This may be related to structural features of diester (VII).

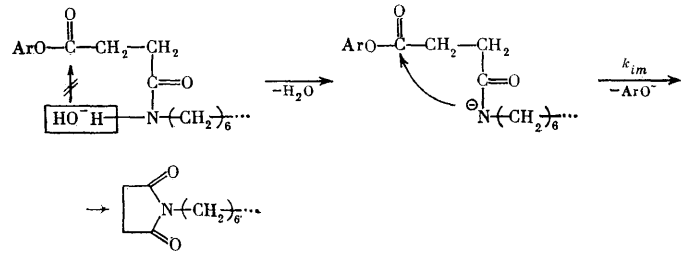

Table 6. Apparent pseudo-first-order rate constants ($k_1^{H_2O}$) of the hydrolysis of activated diesters at 30 °C (not catalysed and catalysed by TEA).

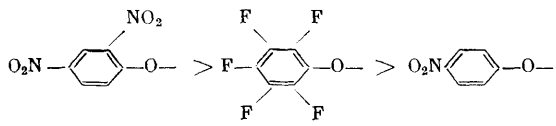
Ester	Solvent	$k_1^{H_2O}$, s^{-1} noncatalytic	$k_1^{H_2O}$, s^{-1} catalytic	$\frac{k_1^{H_2O}(cat)}{k_1^{H_2O}(noncat)}$	$\frac{k_1(aminolysis)^*}{k_1^{H_2O}(noncat)} \cdot 10^{-3}$
$ArOCO(CH_2)_4COOAr$, $ArO = 2,4-(NO_2)_2C_6H_3O-$	HMPA	$1.3 \cdot 10^{-4}$	$4.5 \cdot 10^{-3}$	36	16
$ArO = C_6F_5O-$	HMPA	$8.5 \cdot 10^{-6}$	$2.7 \cdot 10^{-5}$	3	3
$ArO = 4-NO_2C_6H_4O-$	HMPA	$3.5 \cdot 10^{-7}$	$3.2 \cdot 10^{-6}$	9	0.6
	DMSO	$5.2 \cdot 10^{-7}$	$1.6 \cdot 10^{-6}$	3	–
Diester (VII)	DMSO	$1.2 \cdot 10^{-6}$	$1.2 \cdot 10^{-6}$	1	–
		(k_{im} = $1.6 \cdot 10^{-6}$) **	(k_{im} = $5.8 \cdot 10^{-6}$) **	–	–
$CH_3OCOO-C_6H_4-NO_2$	HMPA	$3.8 \cdot 10^{-7}$	$5.3 \cdot 10^{-6}$	14	0.5

Note. Initial concentration of ester groups = 0.1 mol litre^{-1}; molar ratio of [COOR]:[TEA]:[H_2O] = 1:1:50.



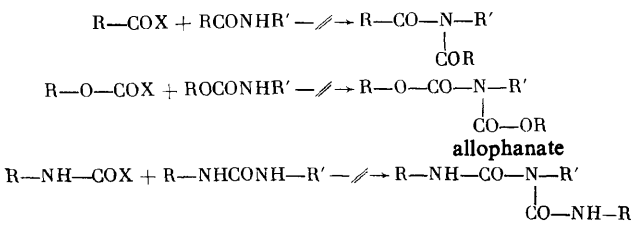
*For k_1 values (aminolysis), see Tables 1 and 3.

**k_{im} = apparent rate constant for imidisation of ester (VII).

In inert organic solvents activated esters hardly react at all with TEA (molar ratio of ester:TEA = 1:2) at 30 °C over a period of more than 24 h. The stability of activated esters towards highly basic tertiary amines is of considerable significance in terms of the synthesis of high-molecular-weight linear heterochain polymers and makes it possible to carry out a number of new polycondensation schemes using a highly basic proton acceptor (see below).

On the whole it may be concluded from the combined results obtained from studying reactions catalysed by TEA that of the possible mechanisms of catalysis—1) nucleophilic catalysis, 2) formation of an intermediate ketene, and 3) general-base catalysis—the latter is the most probable.

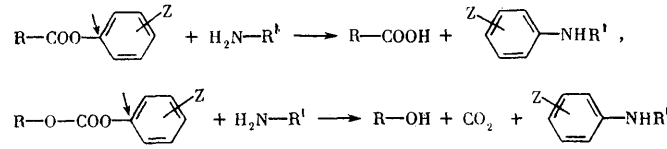
We should note that the hydrolysis of $ArOCO(CH_2)_4COOAr$ occurs at a considerably slower rate than even the slowest of its aminolysis reactions—the reaction with aniline. The ratio of constants k_1 (aminolysis)/$k_1^{H_2O}$ is as high as the order of $10^3-10^4:1$ (see Table 6) and decreases as ArO varies in the series



In other words, an increase in activity of the ester helps to suppress hydrolysis. This is consistent with the results of Menger and Smith,[112] according to which aminolysis is more sensitive to the nature of the leaving group than is hydrolysis. An increase in basicity of the amine has a similar effect; the rate of aminolysis increases by a factor of 10^3-10^5 (see Tables 3 and 5) while side reactions (catalysed by amine) are only accelerated by a factor of 10^1 (see Table 6).

Acid-base processes are of considerable importance in relation to polycondensation in an organic medium. It has been established that the phenols used in weakly polar aprotic media mainly form with amines either molecular complexes $ArOH\cdots H_2NR$ without significant charge separation or hydrogen-bonded ion pairs (in the case of the most acidic phenols) in equilibrium with molecular complexes $ArO^-\cdots H_3N^+R \rightleftarrows ArOH\cdots H_2NR$.[121,122] In weakly basic aprotic media with a high value of pK_{HB} (HMPA, DMF, DMSO) the ion pairs are in equilibrium with strong $ArOH\cdots$solvent complexes.[123,124] All of this makes it possible to carry out the aminolysis of activated esters in any organic medium freely and quantitatively without the use of a proton acceptor.

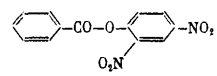
In contrast to phenols, *N*-hydroxysuccinimide forms with primary and secondary amines strong complexes that are insoluble in organic solvents, including polar aprotic ones.[125] However, the amino groups in these complexes are readily acylated by highly active esters. *N*-Hydroxysuccinimide does not form an insoluble complex with tertiary amines.

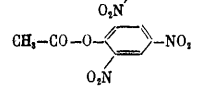


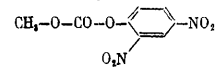
In addition to what has been mentioned, the absence of a reaction between these esters and their aminolysis products should also be considered as an advantage of activated esters (Scheme 4):

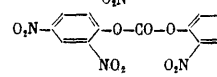
Scheme 4

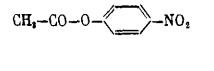
Thus, activated esters differ favourably from the traditional forms of activated polycondensation monomers because of their low tendency to undergo side reactions, which are typical for the latter and lead to a restriction on chain propagation and to unit heterogeneity in the polymers.











It was found by Katsarava et al.[126] that nucleophilic substitution resulting in the loss of ester groups and a restriction on chain propagation, is of considerable significance in the aminolysis of activated phenyl esters

where Z is an electron-withdrawing substituent.

This reaction occurs to the greatest extent when two nitro groups are present in the phenol residue, the yield of product being dependent on the nature of the acyl residue and the amine (Table 7). It was established that a reduction in temperature, dielectric constant and pK_{HB} of the medium helps to suppress nucleophilic substitution.[127]

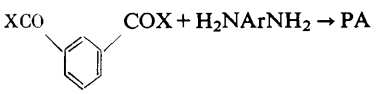
Table 7. Yield of product obtained from nucleophilic substitution in the aminolysis of activated esters in HMPA.

Ester	Amine	Temperature, °C	Yield of product, mol%
	benzylamine	30	1.29
	aniline	80	0.44
	benzylamine	30	0.28
	aniline	80	0.08
	benzylamine	30	1.50
	aniline	30	2.60
	benzylamine	30	0.14
	aniline	30	0.28
	benzylamine	30	trace amounts
	aniline	80	not detected

Note. Initial concentration of ester = 0.6 mol litre^{-1}; molar ratio of ester : amine = 1 : 1.2.

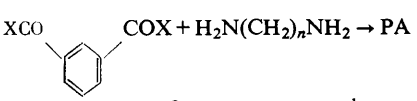
As has been mentioned, the activating groups considered above (see Table 1) make it is possible to control the reactivity of esters over a wide range. A further increase in reactivity of phenyl esters through the introduction of additional electron-withdrawing substituents, in our view, is inappropriate because of the sharp increase in the contribution from nucleophilic substitution.

III. Polycondensation



1. Synthesis of polyamides and polybenzazoles

Bifunctional monomers can be divided into four groups according to their nature and reactivity (see Section II). The effect of the nature of the leaving group of an ester on the molecular weight of



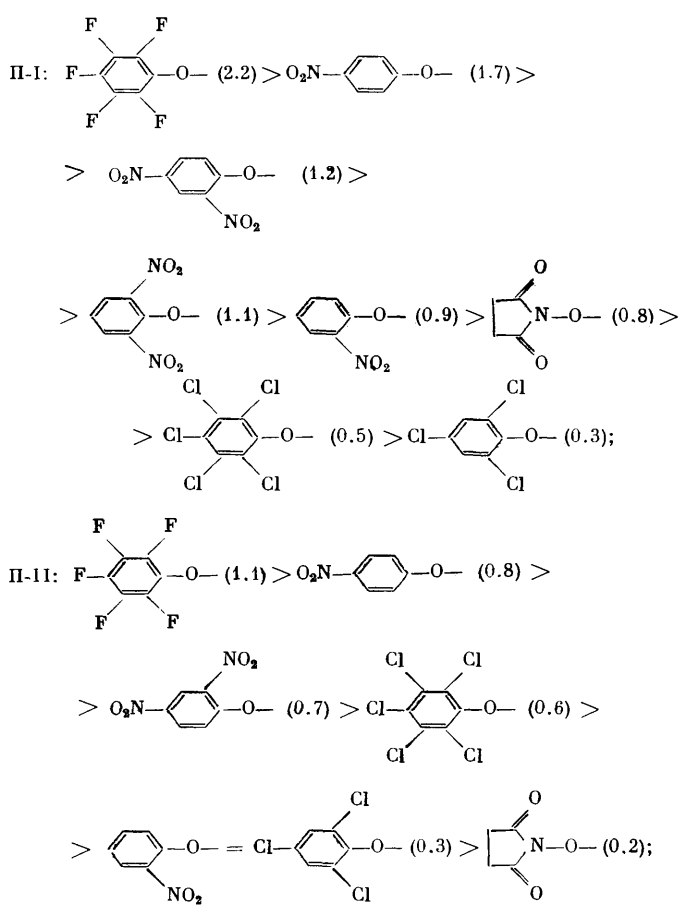
required polyamide (PA) during polycondensation in HMPA has been studied (the conditions of synthesis are given in brackets):[128]

$$XCO(CH_2)_4COX + H_2NArNH_2 \rightarrow PA$$

II-I (80 °C; 0.6 mol litre^{-1})

II-II (80 °C; 0.6 mol litre^{-1})

II-III (30 °C; 0.6 mol litre^{-1})

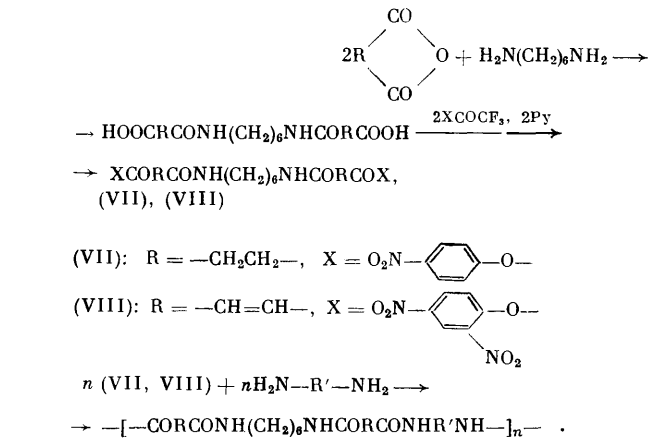


$$XCO(CH_2)_4COX + H_2N(CH_2)_nNH_2 \rightarrow PA$$

II-IV (30 °C; 0.3 mol litre^{-1})

$n = 6, 12$; PA – polyamide .

Polycondensation of pairs II-I to II-III occurs homogeneously, while that of pair II-IV is heterogeneous (polyamide separates out). According to the data obtained, the leaving groups (X) make up the following series with respect to their tendency to form high-molecular-weight polyamides (values of intrinsic viscosity η_{int} at 25 °C and a concentration of polymer solution of 0.5 g dl^{-1} are given in brackets):

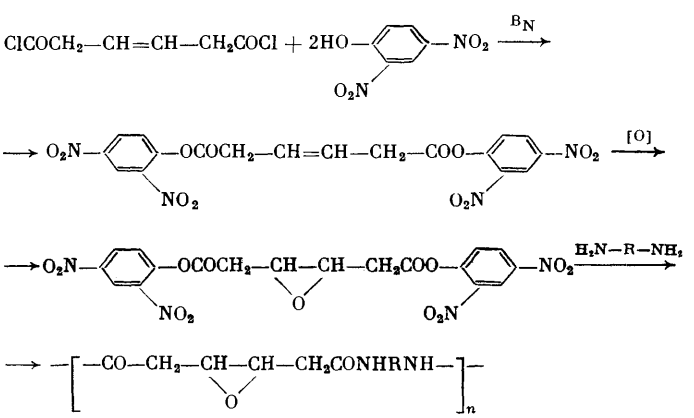


The series obtained do not correlate with the reactivity of the diesters. Under these conditions the pentafluorophenoxide leaving group proved to be more effective in the synthesis of polyamides starting from aromatic diamines (pairs I-II, and II-II), although 2,4-dinitrophenol derivatives lead to good results. When aliphatic diamines are used, one of the best leaving groups is *p*-nitrophenoxide, while in the synthesis of completely aliphatic polyamides the *N*-oxysuccinimide group is one of the best.

A study of the kinetics of polycondensation of pairs II-I to II-III (homogeneous reactions) showed[103] that on the whole its rate is consistent with the reactivity of the monomers [bis(pentachlorophenyl) adipate constitutes an exception, see below]. At the same time the polycondensation of diesters with aliphatic diamines is virtually complete after 1–2 h (at 30 °C), while with aromatic diamines polycondensation lasts from 4 to 40 h depending on the activity of the diester (at 80 °C). The lack of correlation between reactivity of the monomers and the η_{int} value of the resulting polyamides is mainly due to the occurrence of nucleophilic substitution as a side reaction (see Section II.3), resulting in chain termination.

Polycondensation of the monomer pair II-IV, which takes place heterogeneously, is also complete after 1–2 h. The resulting polymers are readily soluble in organic solvents (trifluoroethanol, *m*-cresol), which suggests the absence of intermolecular imide cross-linking which arises when the corresponding acid dichlorides are used.[129]

On the basis of the high stability of intermediate activated amidoesters of the type (VII), which are not very susceptible to imidisation (see Tables 4 and 6), high-molecular-weight polysuccinamides were obtained by reaction of activated succinates with hexamethylenediamine (HMDA) and dodecamethylenediamine (DMDA).[91] The best leaving group for the pair, like II-IV, proved

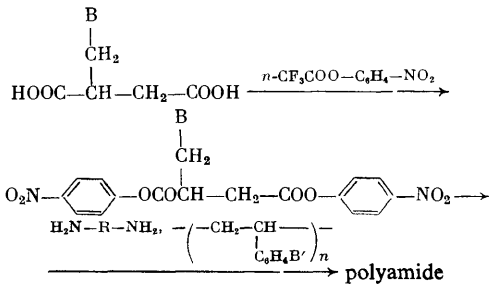


to be *N*-oxysuccinimide. Polysuccinamides were also obtained by a different route using the pure activated bisamidoester (VII):

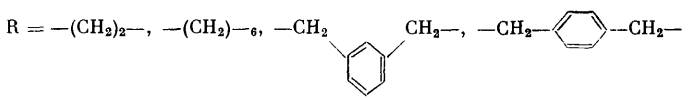
Polyamides with a strict alternation of two diamine residues can be synthesised by this route, and it can be used to prepare polyamides based on "cyclising" dicarboxylic acids (for example, maleic acid) whose activated diesters are difficult to obtain. Thus, polycondensation of diester (VIII) with hexamethylenediamine in HMPA gave polyhexamethylenemaleimide with η_{int} = 0.67 dl g^{-1}).

The use of activated diesters proved fruitful in the synthesis of polyamides starting from indole-containing dicarboxylic acids,[130,131] whose dichlorides in the presence of an acceptor (triethylamine) undergo intermolecular cyclisation to form diketopyrazinoindole residues.[132]

The synthesis of high-molecular-weight epoxypolyamides via an activated diester has been achieved:[19]



η_{int} = 0.42 – 0.48 (R = Alk) and 0.73 – 3.62 (R = Ar) dl g^{-1}.



Lower molecular-weight polyamides ($\eta_{int} \leqslant 0.15$ dl g^{-1}) are formed using the corresponding acid dichloride.

The latter two examples provide support for the view expressed above (see Section II.1) that in a number of specific cases the synthesis of activated diesters is worthwhile even if carried out via the corresponding acid dichlorides.

Activated diesters containing nuclei bases have been used in matrix polycondensation reactions:[59]

where

B = adenine, theophylline, thymine/uracil

B′ = adenine/theophylline.

It was established that in the presence of a polystyrene matrix containing a complementary base B′, polyamidation is accelerated by a factor of more than ten.

We should note that the development of activated polycondensation methods opens up a means of studying matrix polycondensation—a relatively new and little-studied process compared to matrix polymerisation.[133]

We have successfully utilised the highly selective acylating capacity of activated diesters to synthesise soluble polybenzimidazoles. Polycondensation of activated isophthalates with aromatic tetraamines in *N*-methylpyrrolidone gave high-molecular-weight polybenzimidazoles, the best results being achieved when 2,4-dinitrophenyl (η_{int} = 2.2 – 2.4 dl g^{-1}) and 2-mercaptobenzthiazole (η_{int} = 1.1 dl g^{-1}) esters were used. The synthesis of polybenzimidazoles occurs under mild conditions (70 – 100 °C), the polymers obtained form golden-brown coloured films with a tensile strength σ_f = (10 – 12) × 10^7 Pa. The corresponding polybenzoxazoles and polybenzthiazoles (η_{int} = 1.1 – 1.2 dl g^{-1}) were obtained under similar conditions by reaction of bis(2,4-dinitrophenyl) isophthalate and aromatic dihydroxy- and dimercaptodiamines.

2. Synthesis of polyesters

"Activated polyesterification" processes have been carried out in dichloroethane at 25 – 60 °C using trimethylamine as a catalyst (4 moles [Sic. Ed. of Translation) per mole of diol).[134,135] It was established that high-molecular-weight, film-forming polyesters ($\eta_{int} \leqslant 0.9$ dl g^{-1}) are only formed by the polycondensation of activated esters of aliphatic dicarboxylic acids with bisphenols. We should note that it is this class of polyesters that is the most difficult to obtain by means of traditional polycondensation methods using the corresponding aliphatic acid dichlorides, which actively undergo various side reactions, including that with the acceptor (tertiary amine).[5] The best leaving group in the synthesis of the polyesters proved to 2,4-dinitrophenoxide. It was concluded from the results of studying polycondensation and model reactions that "activated polyesterification" occurs by a mechanism involving general base catalysis.

Thus, on the one hand, "activated polyesterification" extends the synthetic opportunities of the polycondensation method for

synthesising polyesters, while on the other hand, it opens up interesting prospects for studying acceptor-catalytic polyesterification processes (usually occurring by two catalytic channels—nucleophilic and general-basic),[136] since it makes it possible to distinguish the general-basic channel in a "pure form".

3. Synthesis of polyurethanes and polyureas

The polycondensation of activated biscarbonates of diols with diamines was carried out according to the scheme:[92]

$$n\ \mathrm{ArOCOO{-}R{-}OCOOAr} + n\ \mathrm{H_2N{-}R'{-}NH_2} \longrightarrow$$
$$\longrightarrow\ \mathrm{-[-COO{-}R{-}OCONHR'NH-]_n-}\ ,$$

where

$$\mathrm{R' = -(CH_2)_6-,\ -(CH_2)_{12}-,\ -NHCO(CH_2)_8CONH-,}$$
$$\mathrm{-C_6H_4-CH_2-C_6H_4-,\ -C_6H_4-O-C_6H_4-.}$$

The effect of the nature of the leaving groups has been studied in the case of the reaction of activated biscarbonates of propane-1,3-diol with hexamethylenediamine in DMF (the best solvent for this monomer pair) at 110 °C and a monomer concentration of 0.6 mol litre^{-1}. According to the results obtained the ArO^- leaving groups make up the following series with respect to their tendency to form high-molecular-weight polyurethanes (the η_{int} values in *m*-xylene, dl g^{-1}, are given in brackets):

$$\mathrm{O_2N{-}C_6H_4{-}O{-}\ (1.4) > O_2N{-}C_6H_3(NO_2){-}O{-} = Cl{-}C_6H_2Cl_2{-}O{-}\ (0.7) >}$$
$$\mathrm{> Cl{-}C_6H_3Cl{-}O{-} = C_6H_4(NO_2){-}O{-}\ (0.6) > C_6H_5{-}O{-}\ (0.3)}\ .$$

Branched butane-1,3-diol derivatives proved more sensitive to the nature of the leaving groups. Thus, for example, while activated carbonates of propane-1,3-diol form high-molecular-weight polyurethanes with virtually all leaving groups, in the case of butane-1,3-diol high-molecular-weight polyurethanes ($\eta_{int} \leqslant 3.8$ dl g^{-1}) are only obtained when the *p*-nitrophenol derivative is used.

Polycondensation of bis(*p*-nitrophenyloxycarbonyl)butane-1,3-diol with hexamethylenediamine in amide solvents (DMF, *N*-methylpyrrolidone) occurs homogeneously at 30 °C, and a high-molecular-weight polyurethane is formed after only 1–2 h, but subsequently the process slows down slightly and the increase in viscosity ceases within 12–24 h depending on the concentration of the initial monomers (1.2–0.3 mol litre^{-1}). The occurrence of a "slow stage" in this case may be related to the reduced activity of the carbonate group formed by the secondary hydroxyl as a result of the shielding effect of the methyl group. The "slow stage" virtually disappears when the temperature is increased to 70 °C.

It is appropriate to note that this example [like the increase in molecular weight of a polyamide that continues for several hours at the fairly high temperature of 80 °C (see Section III.1)] additionally and clearly suggests that activated esters have high stability in an amide solvent (see Section II.3).

The nature of the diamine has a considerable effect on "activated polyurethane formation". Polyurethanes with $\eta_{int} \leqslant 0.5$ dl g^{-1} are obtained with aromatic diamines (at the same time polyamides are formed equally effectively with diamines of both classes, see Section III.1). This may be due to a greater reduction in rate of aminolysis on changing from an aliphatic amine to an aromatic one (see Section II.2).

Activated polyurethane formation occurs by "direct" aminolysis (via $T^{\pm}$ or RTS) without the formation of an intermediate isocyanate (see Section II.2), which excludes the formation of anomalous urea residues, allophanate and biuret branches, and intermolecular cross-linking. It was also established that this reaction is irreversible (like the "activated polyamidation" examined above), and the urethane bond does not react with terminal carbonate groups (see Scheme 4). All this assists the formation of linear polyurethanes. An additional advantage of this method is the lack of necessity for using a proton acceptor or catalyst.

In contrast to urethane formation, the aminolysis of activated carbonates (see Section II.2) occurs via the formation of an intermediate isocyanate:

$$n\ \mathrm{ArOCOOAr} + n\ \mathrm{H_2N{-}R{-}NH_2} \xrightarrow[-\mathrm{HOAr}]{} [\mathrm{ArOCONH{-}R{-}NH_2}] \underset{+\mathrm{HOAr}}{\overset{-\mathrm{HOAr}}{\rightleftharpoons}}$$
$$\rightleftharpoons [\mathrm{O{=}C{=}N{-}R{-}NH_2}] \longrightarrow \mathrm{-[-CONH{-}R{-}NH-]_n-}, \qquad (1)$$

where

$$\mathrm{R = -(CH_2)_6-,\ -C_6H_4-O-C_6H_4-;}$$

$$\mathrm{ArO = O_2N{-}C_6H_4{-}O-,\ O_2N{-}C_6H_3(NO_2){-}O-}\ .$$

Of the two leaving groups—2,4-dinitro- and *p*-nitrophenoxide—the latter proved more effective in the synthesis of polyureas according to the above Scheme.[137] In the polycondensation of bis(*p*-nitrophenyl) carbonate with hexamethylenediamine in dimethylacetamide (DMAA) (containing 15% LiCl) at 90–100 °C, a polyurea with $\eta_{int} = 0.75$ dl g^{-1} was obtained. Under these conditions a high-molecular-weight polyurea is formed even when an aromatic diamine is used ($\eta_{int} = 1.34$ dl g^{-1}). The use of bis(2,4-dinitrophenyl) carbonate in these reactions leads to poorer results (a polymer with $\eta_{int} = 0.2-0.4$ dl g^{-1} is formed), which may be due to its tendency to undergo nucleophilic substitution as a side reaction (see Table 7).

The synthesis of polyureas is also carried out by another method, using the "intermediate" of the aminolysis of a carbonate—the activated carbamate (IX)—as a monomer:[138]

$$n\mathrm{O_2N{-}C_6H_4{-}OCONHRNHCOO{-}C_6H_4{-}NO_2} + n\mathrm{H_2NR'NH_2} \longrightarrow$$
(IX)
$$\longrightarrow \mathrm{-[CONHRNHCONHR'NH-]_n-}$$
$$\mathrm{R, R' = -(CH_2)_2-,\ -(CH_2)_4-,\ -(CH_2)_6-,\ -(CH_2)_{12}-\ \text{etc.}} \qquad (2)$$

Polycondensation of (IX) with diamines occurs under the same conditions as the synthesis of polyureas according to Eqn. (1), giving polymers with $\eta_{int} = 0.5-0.7$ dl g^{-1}.

We should note that the formation of the intermediate isocyanate in the synthesis of polyureas according to Eqns. (1) and (2) does not hinder the preparation of linear soluble polymers. Cross-linked polymers are not formed in this case apparently because of the equilibrium nature of the reaction at the stage involving regeneration of isocyanate. The *p*-nitrophenol that separates out in an amide solvent vigorously reacts with the isocyanate [the equilibrium constants of the dissociation of (IX) with R = $-(CH_2)_6-$ and the

reaction of hexamethylenediisocyanate with *p*-nitrophenol in DMAA are very close to each other and at 30 °C are equal to $(4.5 \pm 0.5) \times 10^{-3}$. This does not prevent the latter reacting with an amino group but it suppresses the formation of biuret.

Thus, the use of the activated polycondensation method considerably simplifies the processes involving formation of linear polyurethanes and polyureas. In terms of synthetic possibilities they are also superior to traditional methods and can be used to obtain polymers in solution under mild conditions without resorting to the synthesis of the corresponding diisocyanates or bischloroformates, which are often difficult or completely impossible to obtain. This circumstance is of particular importance for the preparation of polymers with special properties from those diamines and diols for which the traditional polycondensation methods cannot be used.

4. Some general characteristics of activated polycondensation

We have established in the case of the reaction of activated diesters of dicarboxylic acids and activated biscarbonates of diols with diamines that, in activated polycondensation, polymers with a maximum molecular weight are obtained when there is a strictly equimolar ratio of monomers, regardless of whether the process is homogeneous or heterogeneous.

The dependence of the molecular weight of the polymer in the synthesis of polyamides and polyurethanes on the concentration of monomers for homogeneous processes at 25–30 °C is extremal in nature with a maximum at monomer concentrations of 0.6 and 0.8–1.0 mol litre^{-1} respectively. At higher temperatures (100–120 °C) the results of polycondensation over the concentration range studied (0.2–1.2 mol litre^{-1}) are virtually independent of the initial concentration of the monomers. In heterogeneous polycondensation (the synthesis of aliphatic polyamides in HMPA) the maximum molecular weights are achieved when the reaction solution is diluted to 0.15 mol litre^{-1}, regardless of the nature of the dicarboxylic acid (succinic, adipic) or diamine (hexamethylenediamine, dodecamethylenediamine). The reason for this dependence should be sought in the improved swelling of the polymers when they are diluted, since the polymer grain size decreases on dilution, assisting chain propagation in the heterophase.

The use of amide solvents and DMSO, in which reactions involving both aromatic and aliphatic diamines can occur successfully, as the reaction medium proved the most fruitful. In the case of the latter, other organic solvents such as acetone, dioxan, THF, dichloroethane, etc., in which high-molecular-weight polyamides (regardless of the heterogeneous nature of the process) were obtained at 25–30 °C, are also suitable. Under these temperature conditions in HMPA, diesters with 2,4-dinitro-, 2,6-dinitro-, and pentafluoro-phenoxide leaving groups readily react with aromatic diamines. For esters with other leaving groups the optimum temperature is 80 °C. On comparing these results with the data in Table 1, it may be assumed that for activated polycondensation to be effective the apparent rate of reaction (fundamental stage) must be of the order of $\sim 10^{-2}$ litre mol^{-1} s^{-1}.

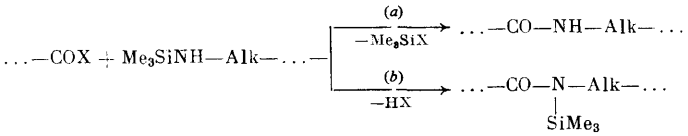
While the synthesis of polyamides and polyurethanes from aliphatic diamines occurs successfully at 25–30 °C, for the preparation of high-molecular-weight polyureas it is necessary to increase the temperature to 90–100 °C in order to change the reaction to homophase conditions. This is due to the equilibrium nature of the process at the stage involving dissociation of the intermediate carbamate to isocyanate. In the swollen precipitate the equilibrium is shifted towards unreactive carbamate, which inhibits chain propagation. After homogenisation of the solution the viscosity of the polyureas increases considerably (from 0.5 to 0.75 dl g^{-1}).

In the synthesis of polyamides and polyurethanes, where equilibrium stages do not occur, separation of the polymer out of solution apparently assists chain propagation through a local increase in concentration of the functional groups and their favourable relative position in space (resembling "liquid-crystalline polycondensation"). If the process occurs in a weakly polar proton-inert solvent, catalysis by an amide (see Section II.2) assumes considerable significance. In the condensed state this catalysis should only have a slight effect because of the high local concentration of the amide groups. The polyamide chain may also fulfil the role of an acceptor of HX (strong hydrogen complexes are formed), although in weakly polar solvents this problem is not so important since salt-like complexes (inactive ammonium cations) are hardly formed at all (see Secton II.3).

Thus, in certain specific cases of activated polycondensation the separation of the polymer out of solution may constitute one of the reasons for a restriction on chain propagation. In other cases, such as in the polycondensation of diamines with pentachlorophenyl diesters of adipic and isophthalic acids in HMPA, the poor solubility of the diesters results in considerable inhibition of the process at the initial stages.[103] After homogenisation of the solution the rate of polycondensation of bis(pentachlorophenyl) adipate with 4,4′-diaminodiphenylmethane is still low and considerably slower than the rate of polycondensation involving bis(*p*-nitrophenyl) adipate, which does not correspond to the expected reactivity of the diesters (see Table 1). The reason for this discrepancy should be sought either in the "immuring" of the terminal ester groups inside the macromolecular coil because of their low affinity for HMPA ("lyophobic effect") or in an increase in the inhibitory "ortho effect" through a reduction in the local dielectric constant of the medium.

Of the other causes of a restriction on chain propagation in the aminolysis of activated diesters, we can single out nucleophilic substitution. The results of model reactions (see Section II.3) are supported by the presence of terminal 2,4-dinitroaniline groups in the corresponding polymers (a characteristic absorption occurs in the region 355–365 nm) at a level of 0.6–1.8 mol%.[126] The contribution of nucleophilic substitution in the reaction between 2,4-dinitrophenyl esters of carboxylic acids, in particular aliphatic acids, and an aromatic amine is comparatively low (see Table 7). The successful synthesis of high-molecular-weight polyamides in the reaction between dinitrophenyl diesters and aromatic amines is considerably dependent on this (see series II-I and II-II). The same diesters actively undergo a nucleophilic substitution reaction with aliphatic diamines and form polyamides that are considerably inferior in terms of viscosity to the samples synthesised via other diesters (series II-III and II-IV). 2,4-Dinitrophenyl diesters have improved behaviour in the synthesis of polyesters and polybenzazoles, which is also an indication of the low contribution of nucleophilic substitution in these processes. In the reaction between 2,4-dinitrophenyl carbonates and an aromatic amine, on the other hand, the yield of the product obtained from nucleophilic substitution is higher than in the reaction with an alkylamine (see Table 7), which inhibits the formation of high-molecular-weight polyurethanes and polyureas based on aromatic diamines ($\eta_{int} \leqslant 0.2–0.4$ dl g^{-1}).

Protonation of the amino groups by low-molecular-weight products of an acidic nature which separate out is known to result in chain termination during low-temperature polycondensation. However, as was demonstrated in Section II.3, in the case of the



weak acids which we have used as phenols, this reaction is not critical. An indication of this is provided by the results given above on polycondensation involving aliphatic diamines without using a proton acceptor in different media—both proton-active and proton-inert.

Polycondensation involving *N*-oxysuccinimide esters occurs in a distinctive manner.[139] The ability of *N*-hydroxysuccinimide to bind with primary aliphatic amines, giving strong insoluble complexes (see Section II.3) has a considerable effect on polycondensation; it inhibits, for example, the reaction between the corresponding isophthalate and hexamethylenediamine. Polycondensation of hexamethylenediamine with a more active adipate readily occurs with the formation of a high-molecular-weight polyamide (series II-IV). In this case triethylamine cannot deprotonate the primary amino group and has no significant effect on the course of the reaction. An increase in temperature to 80–120 °C leads to a marked acceleration of the reaction, but at the same time the side reaction between *N*-hydroxysuccinimide itself and the aliphatic diamine is intensified.[125]

Thus, the various processes for restricting chain propagation are primarily responsible for the lack of a clear relationship between the reactivity of activated diesters and the viscosity properties of the resulting polymers. The role of these processes may be reduced through a choice of suitable reaction conditions or leaving groups.

5. Syntheses using trimethylsilylated derivatives and diamine salts

As an alternative to free aliphatic diamines, their *N,N'*-bis-(trimethylsilyl) derivatives have been used successfully in polycondensation with activated diesters.[90,91,125,137,138,140,141]

Despite the lower nucleophilicity of trimethylsilylated amino groups,[142,143] polycondensation of these derivatives with various activated diesters occurs at sufficiently high rates, resulting in the formation of heterochain polymers that are comparable in terms of molecular weight to the corresponding polymers obtained via the free bases.

Polycondensation of activated diesters with trimethylsilylated diamines mainly takes place with the formation of a "normal" amide [route (*a*)][141] (the eliminated phenol HX acts as a desilylating agent). Even if route (*b*) does occur in this reaction, the number of trimethylsilylated amide groups are either insufficient for formation of cross-linked polymers or the rate of their acylation by activated esters is much lower than the rate of desilylation.[142] Activated diesters differ in this respect favourably from acid dichlorides, which on reacting with trimethylsilylated diamines give cross-linked polymers in a number of cases.[141]

The stability of trimethylsilylated amino groups towards alkyl esters of carboxylic acids (which is important when diamines containing ester groups are used, see below) and also the elimination of the low-molecular-weight silylated reaction product Me_3SiX, which is incapable of protonating an amino group, should be included amongst the advantages of nucleophiles of this class. This is an important factor in the case of polycondensation systems for which a powerful inhibitory reaction between acidic by-products and diamines is typical, such as when bis(*N*-oxysuccinimide) esters of dicarboxylic acids are used as monomers (see Section III.4).[125]

Because of the high stability of the activated diesters towards triethylamine, we were able to use stable diamine salts as monomers in polycondensation.

Y = Cl, CH_3COO.

The reactions examined in this Section are especially useful for the design of macromolecular systems based on diamines that are unstable as free bases. In particular, they have been used successfully for the synthesis of functional heterochain polymers of different classes—polyamides, polyurethanes, and polyureas—from alkyl esters of the natural diaminocarboxylic acids—lysine and cystine—which are of practical interest for medical and biological applications.[144,145]

- - -o0o- - -

In summarising the above material we may conclude that during the last 10–15 years another versatile method for the synthesis of heterochain polymers has been developed. With this method a standardised approach can be made towards the synthesis of heterochain polymers of different classes and to design novel, functional macromolecular systems that were previously unobtainable, including biomedical polymers. This makes the new method particularly promising and attractive for the "fine chemistry" of polymers with special properties. With regard to large-scale production, problems of a practical nature may arise in the future, stimulating the development of new technologies based on the reactions examined above, including efficient methods of regenerating the low-molecular-weight polycondensation products, and corresponding to economic and ecological requirements.

Reactions using nitro-containing monomers for the synthesis of aromatic polymers

A L Rusanov, T Takekoshi
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences
General Electric, USA

ABSTRACT. The progress made in the synthesis of aromatic polymers based on nitro-containing monomers is reviewed. It is shown that the main processes for the synthesis of aromatic polymers using nitro-containing monomers are nucleophilic aromatic polynitrosubstitution reactions, which are effectively used to obtain polymers containing ether groups in the main macromolecular chains. A group of novel reactions that includes thermal and chemical conversion of nitro-containing heterochain polymers is examined.

The bibliography includes 98 references.

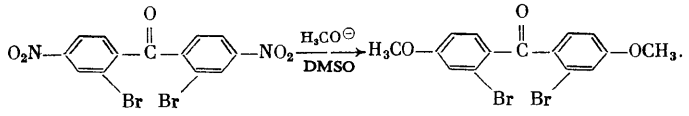
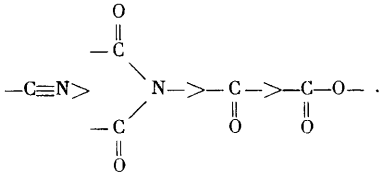
I. Introduction



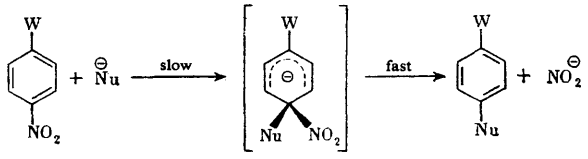
Research into novel functional groups used in polycondensation and the modification of condensation polymers is a topical question in the chemistry of high-molecular-weight compounds. Such groups should establish a sufficiently high reactivity of the monomers, without limiting their availability or increasing their toxicity. Up until recently nitro compounds, which are widespread in organic chemistry,[1,2] have not been used to any appreciable extent in polycondensation processes; however, developments that have occurred over the last 15 years have considerably changed the position in this area. The present review is devoted to an analysis of the principal advances made in the synthesis of condensation polymers based on nitro-containing monomers.

II. Nucleophilic aromatic polynitrosubstitution reactions

Reactions involving nucleophilic substitution of aromatic nitro groups have been known for a long time.[3] Thus, Laubenheimer[4,5] in 1876 described the replacement of the nitro group in 3,4-dinitrochlorobenzene by aniline to form 2-nitro-5-chlorodiphenylamine:



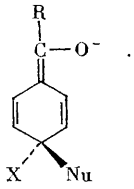
It is interesting to note that very little attention was subsequently given to the application of nitrosubstitution reactions until Gorvin[6] demonstrated the successful reaction between 2,2′-dibromo-5,5′-dinitrobenzophenone and methoxide ion:



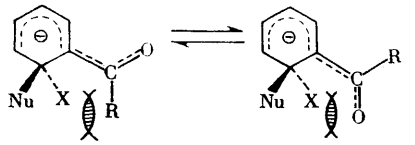
The reaction occurred almost quantitatively, indicating the higher reactivity of nitro groups compared to bromine atoms.

The successful achievement of this reaction was related to the use of a dipolar aprotic solvent. In general the use of dipolar solvents is a necessary condition for the preparation of products in high yield at moderate temperatures.

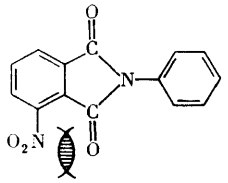
Subsequent studies[7–17] showed that nitrobenzene derivatives containing other electron-withdrawing groups undergo nitrosubstitution. The following series constitutes the rectivity of activating groups:



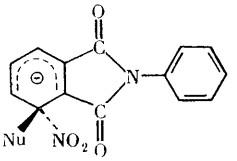
Nucleophilic substitution of a nitro group from an activated system usually occurs by a two-stage addition–elimination mechanism. The first stage is usually, but not always, limiting (determining the rate of the overall process).



When strong electron-withdrawing substituents are present in the ring, nucleophilic substitution reactions occur under mild conditions. The presence of electron-withdrawing groups of the type $-\overset{\overset{O}{\|}}{C}-R$ at



para positions relative to the leaving groups causes the substitution reactions to occur readily because of stabilisation of the Meisenheimer complex as a result of their acceptance of negative charge from the ring:

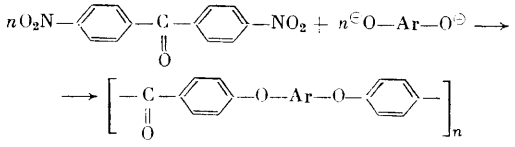


On the other hand, any electron-withdrawing groups situated at *ortho* positions cause a reduction in the rates of the substitution reactions as a result of the formation of high-energy conformers of a Meisenheimer complex:

Steric interactions in the Meisenheimer complexes are less clearly reflected in the case of activated systems containing condensed rings (nitro-substituted *N*-arylphthalimides) where the *ortho* isomers are much more reactive than *para* isomers as a result of the inductive effect, and also the relief of the *peri* interaction

and the absence of steric interaction in the Meisenheimer complex

Moreover, the formation of conformers of the Meisenheimer complex does not occur as a result of ring condensation.

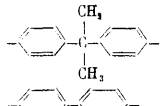


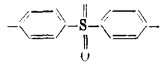
The higher rates of reaction found for nitro groups compared to chlorine groups are due to the greater electrophilicity of the carbon atoms on which substitution occurs, since the nitro group is a stronger electron acceptor than chlorine.

Substitution reactions obey second-order kinetics, being first-order with respect to both the aromatic substrate and the nucleophile.

In general the phenoxides used in nitrosubstitution reactions must be free of moisture. In the presence of the latter, derivatives containing ester and imide groups are readily deactivated as a result of hydrolysis and ring opening respectively. However, it should be noted that derivatives containing nitrile and ketone groups are less sensitive to the presence of small quantities of water. In these cases free phenols can be used in the presence of carbonates or alkali metal hydroxides. Under normal reaction conditions, alkali metal nitrites which are by-products of the reactions do not undergo undesirable conversions. Nevertheless, on increasing the time of the reactions—especially at higher temperatures—nitrite ions can attack other nucleophilic sites of the initial compounds or by-products.[17,18]

The efficiency of activation of the nitro groups by carbonyl "bridges" predetermined the theoretical possibility of using nucleophilic aromatic polysubstitution processes to obtain polyether containing carbonyl groups.[19,20]





It was demonstrated for the first time by Radlmann et al.[21] and by Heath and Wirth[22] that nitrosubstitution reactions occur sufficiently productively to be able to extend them to the synthesis of high-molecular-weight aromatic polyethers. Reaction of 4,4′-dinitrobenzophenone with bisphenols gave different polyetherketones,

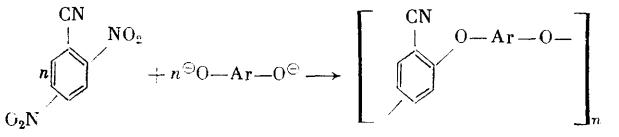
whose individual properties are given in Table 1.

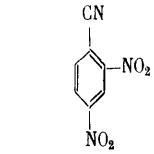
Table 1. Polyetherketones obtained by nitrosubstitution.[21]

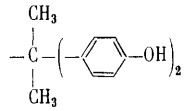
—Ar—	Temperature of polycondensation	Solvent	η_{int} in MP	mp of polymer, °C
	65	DMSO/C_6H_5Cl	1.32	195–220
	145	DMSO	1.18	236–255
	140	DMSO	1.07	201–228

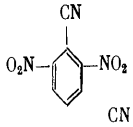
Clendinning and Kwiatkovski[23] also used polynitrosubstitution reactions to obtain polyetherketones.

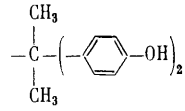
Because of the strong activation effect of the nitrile groups, the two nitro groups in 2,4- and 2,6-dinitrobenzonitriles readily undergo substitution. This make it possible to obtain high-molecular-weight polyethers containing nitrile substituents as a result of the reaction between dinitrobenzonitriles and salts of different bisphenols:[11]

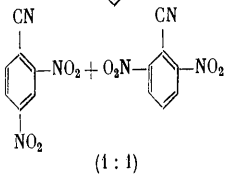


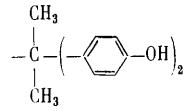


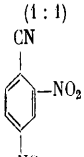


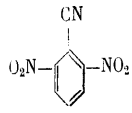


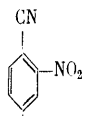


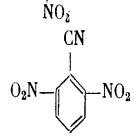


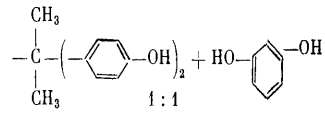


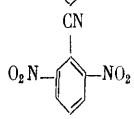


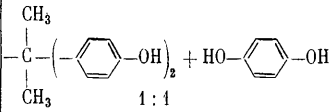


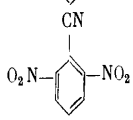


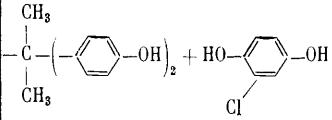


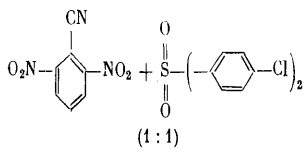












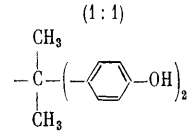


Table 2. Synthesis of polyethers by nitrosubstitution of dinitrobenzonitriles with bisphenol salts.[11]

Dinitro compounds	Bisphenols	Reaction conditions			Thermal properties of polymers		
		solvent/T, °C	yield, %	$[\eta]$, dl g^{-1}	T_g, °C*	T_1, °C**	
						air	N_2
		DMSO/115	81	0,68	141	430	430

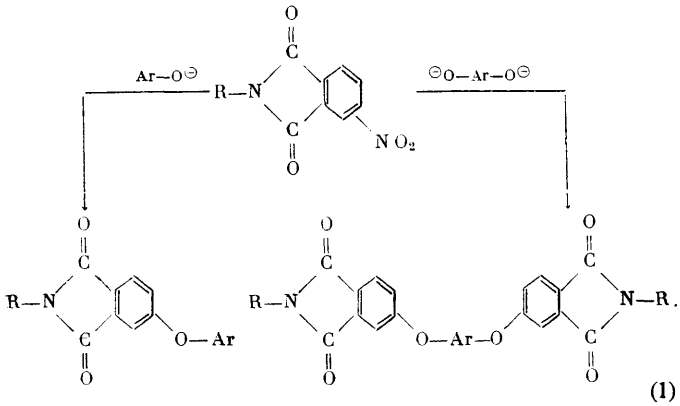
* Glass-transition temperature as determined by differential scanning of calorimetry.



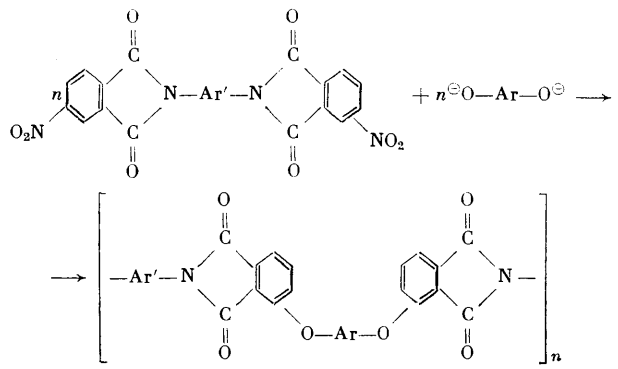
** Temperature of loss of 1% weight as determined by thermogravimetric analysis.

Some properties of the polyethers synthesised are given in Table 2.

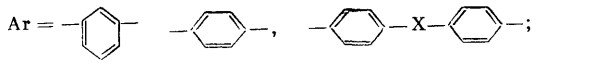
The majority of the nitrile-substituted polyethers obtained are soluble in chlorinated solvents; strong and flexible films are obtained from their solutions. The high glass-transition and thermal-degradation temperatures are caused by the aromaticity of these polymers and the high polarity of the nitrile groups.

The second large family of polymers obtained with the use of polynitrosubstitution processes comprises aromatic polyetherimides.[19]

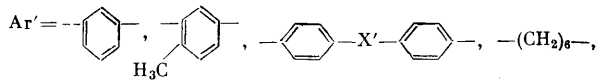
According to several studies,[10,24–27] nitro groups that are activated by two carbonyls undergo nucleophilic substitution. Activation of nitro groups by the two carbonyls contained in cyclic imides is particularly effective.[26,28] Thus, *N*-substituted 3- and 4-nitrophthalimides were converted to mono- and bis-etherimides by reaction with different mono- and bis-phenoxides by means of nitrosubstitution:



(1)



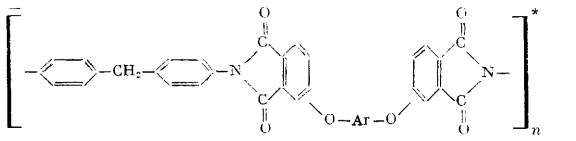
These nitrosubstitution reactions must be carried out in the complete absence of water, since *N*-substituted nitrophthalimides are readily deactivated as a result of hydrolysis and ring opening. Anhydrous solutions of phenoxide salts can be obtained from sodium hydride and the respective phenols or by azeotropic dehydration of aqueous phenoxide salts in DMSO–toluene in a similar manner to the techniques used in the synthesis of polysulphones.[29]

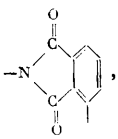


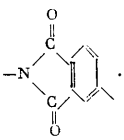
The synthesis of imidoethers is carried out under mild temperature conditions (25–60 °C), it occurs sufficiently rapidly (the reaction time varies from 5 min to several hours), and results in formation of the required products in high yield (>95%).[26]

The high yields of bis(etherimides) predetermined the possibility of extending the reactions depicted in Scheme (1) to the synthesis of polymers, namely, to the preparation of polyetherimides using nitrosubstitution processes[28,30–35]

where







$X' = -CH_2-, -O-, -SO_2-$.

The synthesis of polyetherimides by means of polynitrosubstitution was carried out under modified conditions[29] in the complete absence of moisture.[31,32] The conditions for the synthesis of polyetherimides starting from the dinitrodiphthalimide derivative of 4,4′-diaminodiphenylmethane are given in Table 3 together with certain properties of the polyetherimides.

Table 3. Synthesis conditions and some properties of polyetherimides with the general formula[31,32]

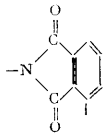
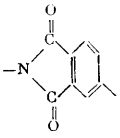
*** T_{deg} = 400 °C.

Polyetherimides based on other dinitrophthalimides were obtained under similar or fairly similar conditions. Some properties of the polymers synthesised are given in Tables 4 and 5.

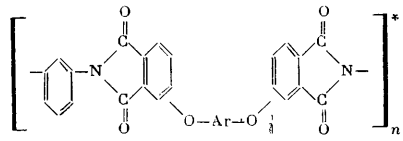




On the whole, polynitrosubstitution reactions occur rapidly even under comparatively mild conditions. When dipolar aprotic solvents or their mixtures with toluene are used, polymers with relatively high molecular weights are formed (M_w up to 123 × 10^3, M_n up to

23×10^3).[32] The most frequently used solvents are DMSO + toluene and DMF, the choice of solvent being determined by the method of obtaining the anhydrous bisphenoxide. The reactivity of dinitrophthalimides used is determined primarily by the position (3- or 4-) of the nitro groups rather than by the nature of the Ar residue. Monomers that contain nitro groups at the 3-position are more reactive than systems containing nitro groups at the 4-position.[26] Consequently, the synthesis of polyetherimides using dinitrophthalimides that contain nitro groups at the 4-position are carried out at higher temperatures and for a longer time. A factor that affects the rate of reaction is the rate of solution of the monomers; this gives rise to the possibility of polymers with relatively high molecular weight being formed when there is some departure from equimolarity of the monomers. The low solubility of bisphenoxides (and/or a low rate of their solution) can be compared with a slow feeding of these monomers into the reaction zone.

Table 4. Synthesis conditions and some properties of polyetherimides with the general formula[31,32]



Compound	—Ar—	Synthesis conditions: solvent	T, °C	time, h	$[\eta]$, dl g^{-1}	Yield, %	T_g/T_{deg}

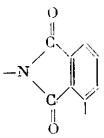
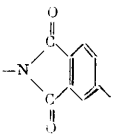
* Compounds 1–7:  , compounds 8 and 9: 

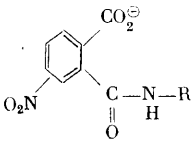




It is advisable to carry out the synthesis at elevated temperatures in order to increase the solubility of the monomers. However, it was found in a number of cases that an increase in temperature and duration of reaction resulted in the formation of products with a lower molecular weight.[32] It is possible that this occurs as a result of side reactions with nitrite ion,[26,28,36] which is eliminated during polynitrosubstitution. Consequently, the optimum temperature for reactions involving 3,3′-dinitrophthalimides is 50 °C, while for reactions involving 4,4′-dinitrophthalimides the optimum temperature is 10 °C higher.[32]

Increasing the concentration of the monomers generally assists the formation of polyetherimides with higher molecular weights, but on reaching very high concentrations (~50%) the rates of solution of the initial compounds decrease—as a result of saturation and an increase in viscosity—which also slows down polynitrosubstitution. The most frequently used concentration range is 20–25%.[32]

Table 5. Synthesis conditions and some properties of polyethermides with the general formula[31,32]



Compound	—Ar	Synthesis conditions: solvent	T, °C	time, h	$[\eta]$, dl g^{-1}	Yield, %	T, °C

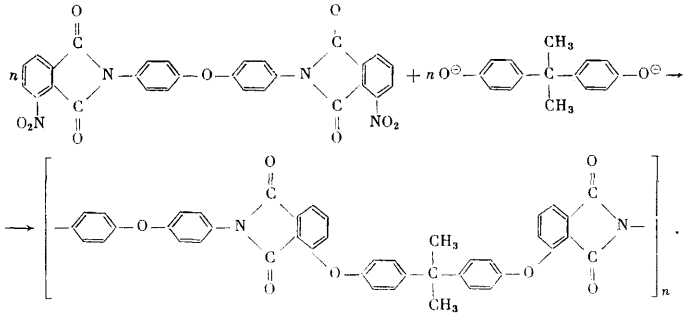
In a number of cases sodium phenoxide or sodium 4-methylphenoxide were introduced into the reaction mixtures after completion of the synthesis processes of polyetherimides in order to replace the terminal nitro groups and increase the thermal stability of the required polymers. At the same time careful control over the course of the reactions was necessary in order to decrease the contribution of exchange reactions between the phenols and the diarylether groups[26] which reduce the molecular weight of the polymers.

By analogy with the synthesis of mono- and bis-etherimides, reactions for the synthesis of polyetherimides by means of polynitrosubstitution are especially sensitive to the presence of moisture in the reaction system. The moisture remaining after formation of a bisphenol and also that contained in the reactants or solvents leads to poor reproducibility of results and to formation of low-molecular-weight polymers. The moisture remaining in the system is in equilibrium with the bisphenoxide, which gives rise to the presence of hydroxide ions in the reaction mixture. The latter

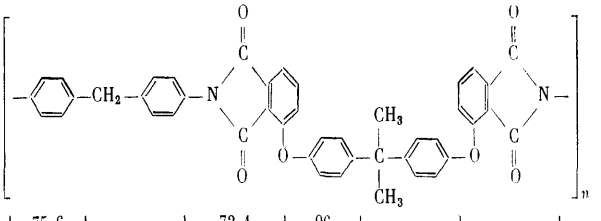
attack the imide rings[37] in the monomers and in the polymers formed. As a result of ring opening, an amino acid

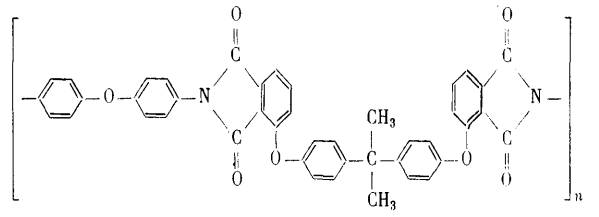


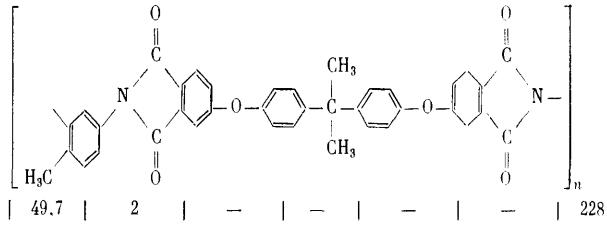
is formed, disrupting the stoichiometry during synthesis of the polymers and causing chain termination, since the nitro group in it is insufficiently activated to undergo substitution.[37] The presence of a hydroxide ion also opens up the possibility of formation of structures of the type

in which the hydroxyl group no longer behaves as a nucleophile.

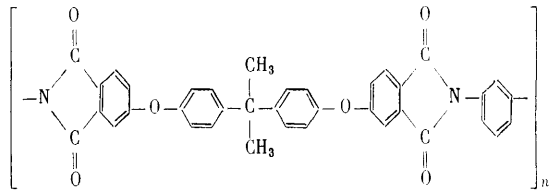
The effect of moisture on the synthesis of a polyetherimide was demonstrated in the case of the synthesis of a polymer in accordance with the following scheme through the addition of a controlled amount of water to the system







It transpired that when the process was carried out in the driest system in DMSO, a polymer with [η] of not less than 0.44 dl g^{-1} was formed, whereas addition of 0.03% water to the solvent (10 mol.% based on the reactants) assists the formation of a polymer with [η] = 0.25 dl g^{-1}, while addition of 0.09% water (30 mol.%) leads to the formation of a polymer with [η] = 0.18 dl g^{-1}.[32]



A study of polyetherimides using gel permeation chromatography showed that they have wide molecular weight ranges, which may also be due to the presence of water in the reaction mixtures. It is this factor that may determine the presence of "open" rings in chains and at the ends of the macromolecules, leading to the possibility of strong carboxylic acids being formed during processing.

Polyetherimides are amorphous in the majority of cases. This factor in combination with the asymmetry of their macromolecular structure and the presence of a considerable number of ether bonds in the latter governs the solubility of the polymers in solvents such as chlorinated hydrocarbons, phenols, and dipolar aprotic solvents. A further characteristic of polyetherimides, which is clearly illustrated in Tables 3–5, is the considerable difference between the glass-transition and degradation temperatures of these polymers, thus making it possible to process them into articles by moulding under pressure. Materials based on polyetherimides have high deformation strength characteristics. Some properties of polyetherimide films obtained from solutions and also those of moulding materials derived from them are given in Table 6.

Table 6. Mechanical properties of materials based on polyetherimides obtained by polynitrosubstitution.[32]

[η], dl g^{-1}	Yield point, MPa	Elongation at yield, %	Break point, MPa	Elongation at break, %	Ultimate flexural strength, MPa	Flexural modulus, MPa	Thermal stability, °C
							
0.42	75.6	—	72.1	96	—	—	—

Of polyetherimides that have been synthesised, the polyetherimide which corresponds to the structural formula

is of the greatest interest in terms of the availability of the starting compounds, processability, and deformation-strength and thermal properties of materials based on it. This polyetherimide, for which 4-nitrophthalic anhydride, *m*-phenylenediamine, and bisphenol A are

the starting compounds, is manufactured by General Electric (USA) under the name Ultem®.[10,34,38–47] Some properties of this polyetherimide are given in Table 7.

Table 7. Properties of Ultem® polyetherimide.[11]

Mechanical properties	
Stress at yield point (yield point)	105 MPa
Modulus of elasticity	3000 MPa
Elongation at break	60–80%
Ultimate flexural strength	145 MPa
Flexural modulus	3300 MPa

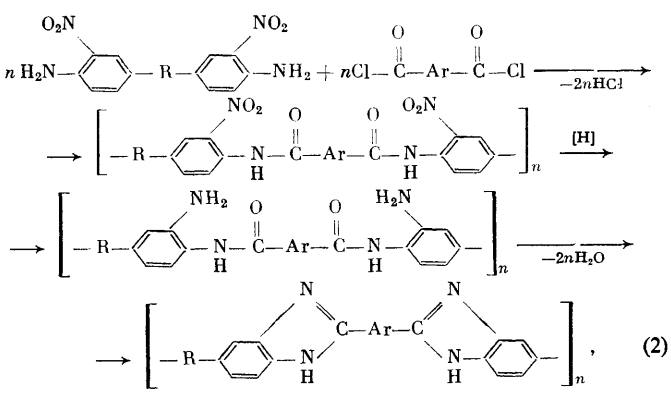
Ultem® is one of the best engineering thermoplastics known at the present time.[40–47] Its distinctive merits are good processability on standard equipment,[43–47] high tensile strength and modulus of elasticity,[34,38,40–43,46,47] good preservation of mechanical properties at elevated temperatures,[38,40,41,43,46,47] valuable electrical properties that remain stable over wide temperature and frequency ranges.[34,38,40,41,43,46,47] The material is distinguished by its high heat resistance and low smoke density. With regard to the latter property it is superior to all known unfilled thermoplastics.[38,40,41,43,44,46,47] The polyetherimide is stable towards solvents[41,45,47] and has high chemical stability.[38,46,47]

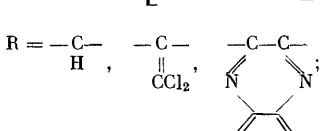
Because of the unique properties of Ultem®, in particular the possibility of using it to obtain articles with a complex configuration, it can be successfully used as a construction material in electrical engineering, electronics, the aerospace industry, ship building, and transportation, including the manufacture of components in the car industry.[38,41,46–48] Moreover, Ultem® and other polyetherimides can be used as heat-resistant adhesives,[50] layers and films for the electronics industry,[51] and foamed plastics for use in heat insultion and vibrational absorption.[52]

Mixtures of polyetherimides with other heterochain and heterocyclic polymers are of considerable interest. Thus, composites based on aromatic polyamides and polyetherimides were obtained with improved impact strength and stability towards chlorinated solvents.[53] Attempts have been made to produce mixtures of polyetherimides and polybenzimidazoles.[54]

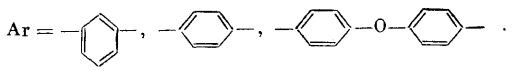
On the whole polyetherimides have attracted the attention of consumers, and according to several studies[3,13,38–49] constitute a significant achievement in the chemistry and technology of condensation polymers.



It was shown by Schaeffer in recent studies[55,56] that not only phenol groups but also aliphatic hydroxyl groups can be used in nitrosubstitution reactions. Thus, polycondensation of 1,4-dinitro-2-(n-hydroxyundecyloxy)benzene in a mixture of THF : DMSO (3 : 1) using phase-transfer catalysts gave polyethers with molecular weights of up to 32 000.



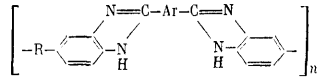
III. Reductive polyheterocyclisation reactions



In contrast to nucleophilic aromatic polynitrosubstitution processes, reductive polyheterocyclisation reactions[57–60] do not assume substitution of nitro groups contained in the monomers used. The nitro groups are retained as *o*-substituents in heterochain polymers, but after their reduction to primary amine groups they participate in processes for the formation of the required aromatic heterocycles.

The evolution of reductive polyheterocyclisation processes in recent years has been due primarily to the development of novel polybenzimidazoles. Novel unsubstituted poybenzimidazoles have been obtained[61–65] from novel bis(*o*-nitroanilines) that are derivatives of chloral and DDT [66–68] by a route that had been proposed previously[57–60,69–71] and which involves the mild reaction between bis(*o*-nitroanilines) and aromatic dicarboxylic acid dichlorides in NMP followed by reduction/cyclisation of the poly(*o*-nitroamides):

(2)

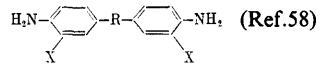


Some properties of the unsubstituted polybenzimidazoles synthesised, which are soluble in MP, DMF, DMAA, and DMSO, are given in Table 8.

It is evident from the properties listed that the majority of the unsubstituted polybenzimidazoles are non-softening polymers with relatively low values of the temperatures of loss of 10% of initial

weight (T_{10}) during differential thermogravimetric analysis (air, ΔT = 5 °C min^{-1}). The unusual series of thermal stability of the polybenzimidazoles in relation to the dicarboxylic acid residue may be due to incomplete reduction of the nitro groups and the subsequent ring-closure reactions of (*o*-nitro)amide residues at high temperatures (see below).

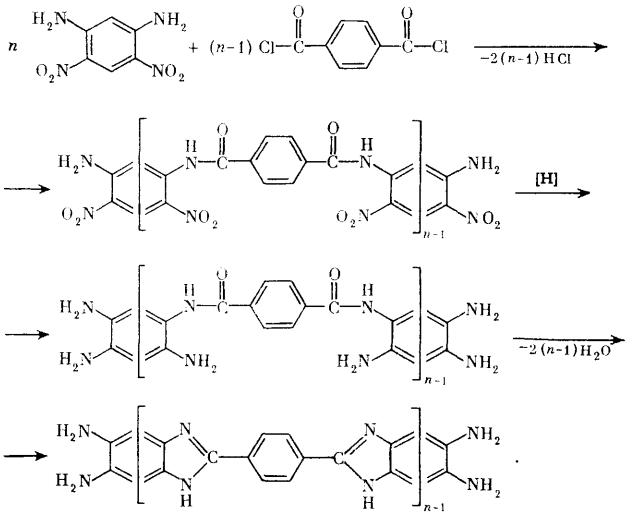
Table 8. Some properties of unsubstituted polybenzimidazoles with the general formula[61,65]



—R—	—Ar—	η_{int} in NMP, dl g^{-1}	T_{soft}, °C	T_{10}, °C
—C(=O)—		0.44	–	360
—C(=O)—		0.30	–	350
—C(=O)—		0.28	300	410
—C(=CCl$_2$)—		0.28	–	380
—C(=CCl$_2$)—		0.46	–	360
—C(=CCl$_2$)—		0.30	–	410
		0.28*	–	475
		0.10*	–	425

*Viscosities determined in *m*-cresol.

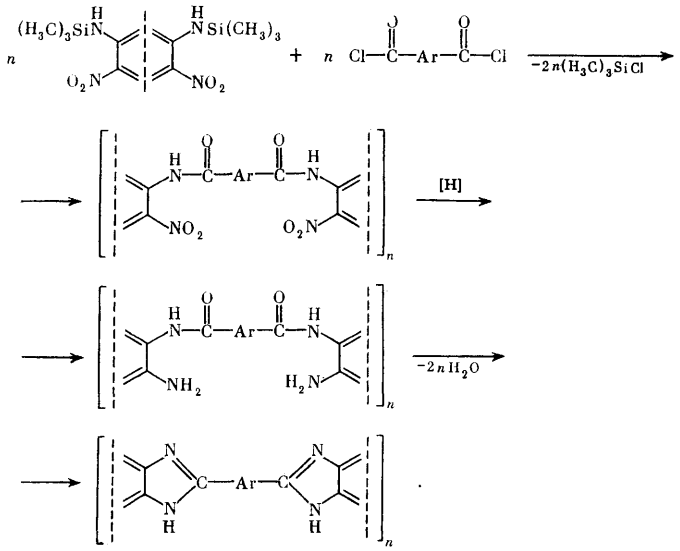
Another characteristic feature of unsubstituted polybenzimidazoles synthesised by means of reductive polyheterocyclisation is provided by their low viscosities and hence molecular-weight characteristics, caused by the lower basicity (Table 9) and correspondingly lower nucleophilicity of bis(*o*-nitroanilines) compared to unsubstituted diamines containing the same "bridging" groups.



The outcome of this situation is evident in the use of reductive polyheterocyclisation processes for the synthesis of oligomeric benzimidazoles rather than polymeric forms,[72] for which it is most suitable to carry out polycondensation with a certain excess of bis(*o*-nitroanilines).

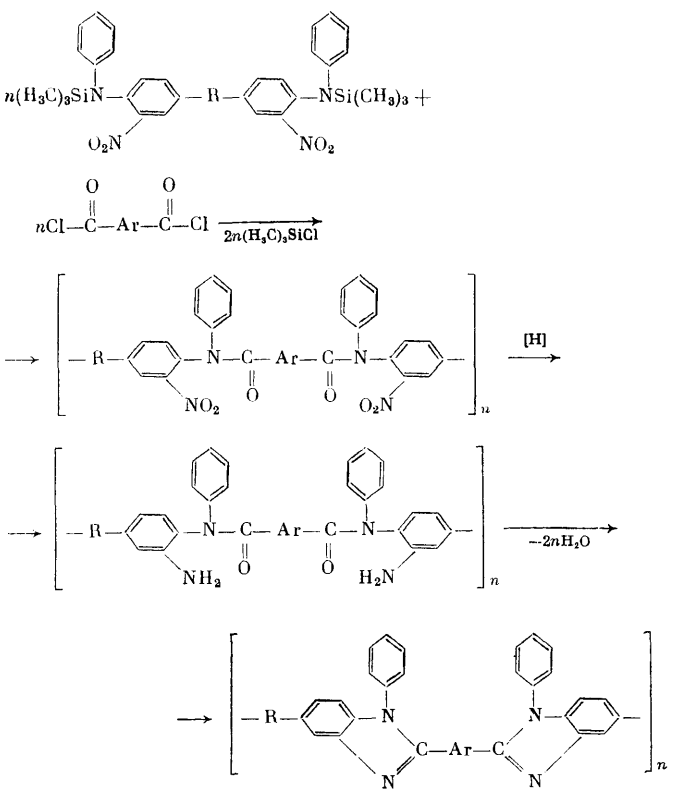
Table 9. Ionisation constants of bis(*o*-nitroanilines) and unsubstituted diamines with a corresponding structure, having the general formula

 (Ref.58)



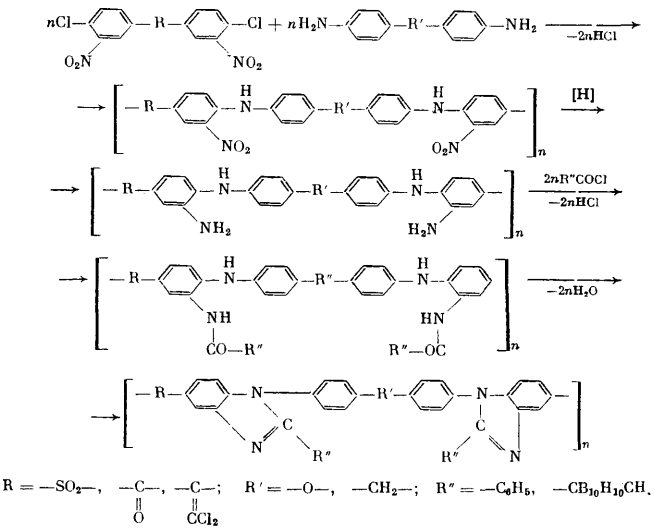
—R—	—X	pK_{a1} (DMF)	pK_{a2} (DMF)	ΔpK_a
—C(=CCl$_2$)—	–H	3.65	3.20	0.45
—C(=CCl$_2$)—	–NO$_2$	2.75	2.50	0.25
—C(=O)—	–H	3.02	2.72	0.30
—C(=O)—	–NO$_2$	2.75	2.45	0.30
	–H	2.95	2.62	0.33
	–NO$_2$	1.88	1.76	0.12

Such an approach is of particular interest in relation to the synthesis of rod-like oligobenzimidazoles starting from 1,3-dinitro-4,6-diaminobenzene and terephthalyl chloride:[72]

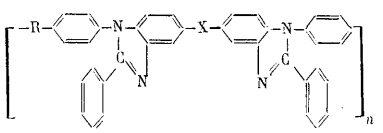


Rod-like oligobenzimidazoles containing *o*-phenylenediamine terminal groups can be used, according to Gordon et al.[73–76] to obtain molecular composites, which have stimulated considerable interest amongst research workers recently.[77–80]

An alternative approach to the use of bis(*o*-nitroanilines) to obtain benzimidazole-containing systems involves increasing the basicity of the amino groups of these monomers by trimethylsilylating them:[81,82]



According to Rusanov and Tugushi,[72] a similar approach can yield relatively high-molecular-weight polybenzimidazoles containing phenyl substituents on the nitrogen atom in the benzimidazole rings, which are synthesised from very weakly basic bis(*o*-nitrodiphenylamines):



R = $-SO_2-$, $-\overset{\overset{O}{\|}}{C}-$, $-\overset{\overset{CCl_2}{\|}}{C}-$.

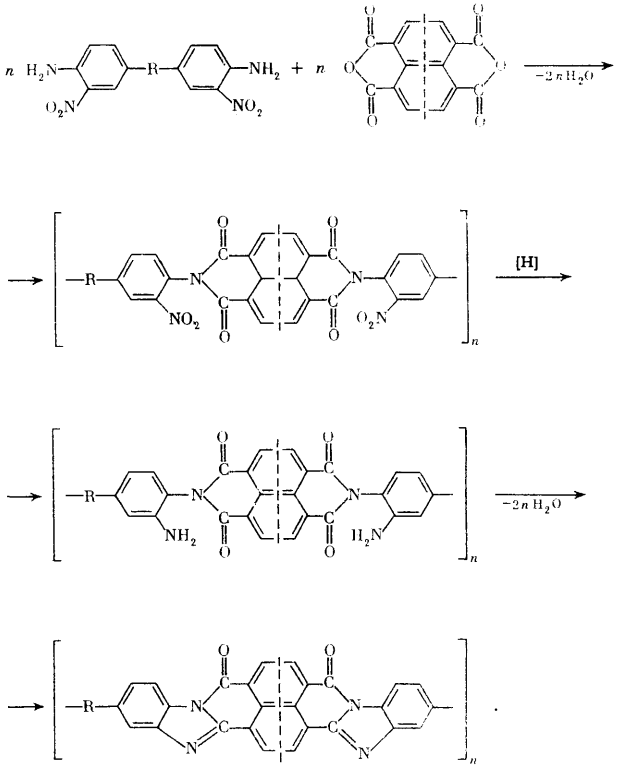
Novel poly(*C*-substituted) benzimidazoles[83–86] were obtained by means of modified reductive polyheterocyclisation processes. According to Rusanov et al.,[87,88] these involved the reaction of activated bis(*o*-nitrohalo)arylenes with aromatic diamines, reduction of the nitro groups in the resulting poly(*o*-nitro)imines to amino groups, acylation of the latter, and catalytic cyclisation of polyimines containing *o*-acylamine substituents:

R = $-SO_2-$, $-\overset{\overset{O}{\|}}{C}-$, $-\overset{\overset{CCl_2}{\|}}{C}-$; R′ = $-O-$, $-CH_2-$; R″ = $-C_6H_5$, $-CB_{10}H_{10}CH-$.

Table 10. Fundamental properties of poly(*C*-phenyl)benzimidazoles with the general formula[83–85]

—R—	—X—	η_{int}, dl g^{-1}	T_{soft},** °C	T_{10}^{*}, °C
$-\overset{\overset{CCl_2}{\|}}{C}-$	—O—	1.30	360	450
$-\overset{\overset{CCl_2}{\|}}{C}-$	$-CH_2-$	1.00	330	410
$-\overset{\overset{O}{\|}}{C}-$	—O—	1.50	310	510
$-\overset{\overset{O}{\|}}{C}-$	$-CH_2-$	1.20	280	470

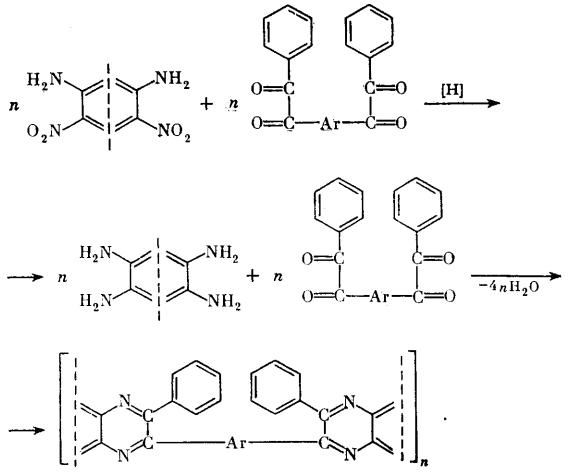
* Determined from thermomechanical curves.
** Differential thermogravimetric analysis, air, ΔT = 4.5 °C min^{-1}.



C-phenyl-substituted polybenzimidazoles that combine high viscosity and thermal properties with solubility in phenolic solvents, MP, and DMF have been obtained using 3,3′-dinitro-4,4′-dichloro-

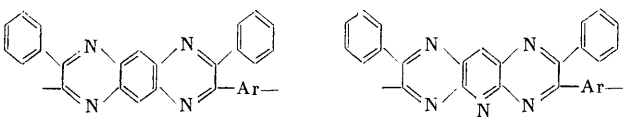
benzophenone and 1,1-dichloro-2,2-bis(3-nitro-4-chlorophenyl)-ethylene,[83–85] which are derivatives of chloral and DDT,[66–68] as activated bis(*o*-nitrohalo)arylenes. Some properties of these polymers are given in Table 10.

C-Carborane-substituted polybenzimidazoles were obtained[86] by reaction of 3,3′-dinitro-4,4′-dichlorodiphenylsulphone with 4,4′-diaminodiphenyl oxide, reduction of the nitro groups in the resulting poly(*o*-nitro)imine to amino groups, acylation of the latter with *m*-carborane-1-carboxylic acid chloride, and catalytic cyclisation of the systems obtained to the required polybenzimidazoles. It is interesting to note that the carborane-containing polybenzimidazoles obtained in this manner are superior in terms of their viscosity and thermal properties as well as the strength of their films to poly(*C*-phenyl)benzimidazoles obtained from *m*-carborane-dicarboxylic acid dichloride.[86]



As well as increasing the range of polybenzimdazoles obtained by means of reductive polyheterocyclisation, the attention of research workers in recent years has been focussed on the possibility of using this process to obtain classes of polyheteroarylenes such as polynaphthoylenebenzimidazoles and polyphenylquinoxalines.

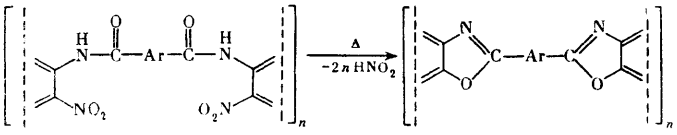
The synthesis of polynaphthoylenebenzimidazoles was carried out in accordance with following scheme:[89]



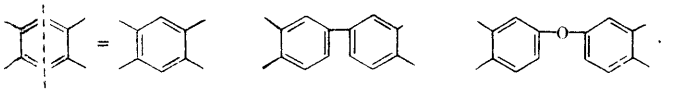
An advantage of this approach to the synthesis of polynaphthoylenebenzimidazoles, in addition to those already known,[57–60] is the possibility of decreasing the number of isomers of the required structures by means of acylation reactions exclusively on the amino groups at the early stages of the reactions. In turn, a decrease in the number of isomers opens up a route to the creation of more regularly formed systems, which have correspondingly higher thermal properties.

The synthesis of polyphenylquinoxalines was carried out in accordance with the following scheme:[90]

This process differs from the previously developed reductive polyheterocyclisation reactions[57–60] in that the stage involving the formation of linear nitro-containing polymers is absent — bis(*o*-nitroanilines) do not react with bis(α-diketones) even under very severe conditions. In actual fact this process essentially involves the reduction of bis(*o*-nitroanilines) to bis(*o*-phenylenediamines) in the presence of bis(α-diketones) and, owing to the specific nature of the reactions leading to polyphenylquinoxalines,[91–94] a polycondensation reaction *in situ* of the resulting bis(*o*-phenylenediamines).



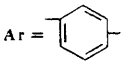
The scheme put forward is attractive as it opens up the possibility of obtaining polyphenylquinoxalines with high heat stability (T_{soft} ~ 400 °C) containing condensed heterocycles starting from 1,3-dinitro-4,6-diaminobenzene instead of the unstable 1,2,4,5-tetraaminobenzene and 3,5-dinitro-2,6-diaminopyridine instead of the unstable 2,3,5,6-tetraaminopyridine.

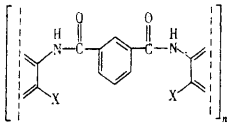


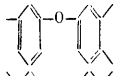
It was reported by Korshak et al.[90] that when processes involving the catalytic reduction with hydrogen over Raney nickel or the reduction with activated iron mixed with HCl were used, only low-molecular-weight polymers ($\eta_{init} \leqslant 0.2$ dl g^{-1}) were obtained. It would appear that under these conditions either the selectivity of reduction is disrupted, i. e., not only is bis(*o*-nitroaniline) reduced but also the bis(α-diketone) is partially reduced, or the reduction of bis(*o*-nitroaniline) to bis(*o*-phenylenediamine) is not quantitative. Further research into the optimum process conditions will most likely lead to considerable progress in the synthesis of polyphenylquinoxalines.

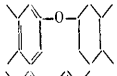
IV. Thermal polyheterocyclisation reactions of poly(*o*-nitroamides)

Poly(*o*-nitroamides) obtained in accordance with Scheme (2) can, according to Kim and Pearce,[95] be regarded as prepolymers for the preparation of polybenzoxazoles:









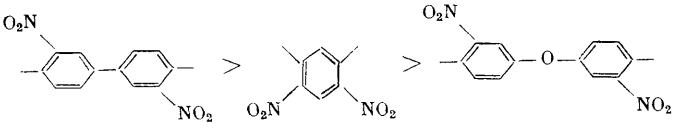


Table 11. Thermal stability and yield of carbon of aromatic polyamides with the general formula:[95]

	–X	T_{sd}, °C	$T_{mr}I$, °C	$T_{mr}II$, °C	Yield of carbon, %
	–H	425	460	–	42
	$-NO_2$	336	351 373	650	35
	–H	440	470	588	37
	$-NO_2$	291	325 390	592	45
	–H	505	542	–	38
	$-NO_2$	386	405	660	52

The series of thermal stability of poly(*o*-nitroamides) in relation to the bis(*o*-nitroaniline) residue takes the following form:

while the yield of carbon is given by the series:

The respective temperatures of start of degradation (T_{sd}), temperatures of maximum rate of weight loss (T_{mr}), and yields of carbon of poly(*o*-nitroamides) and unsaturated polyamides are given in Table 11.

An analysis of the data listed in Table 11 indicates that the temperatures of start of thermal degradation for poly(*o*-nitroamides) are lower than for unsubstituted polyamides in all cases. At the same time, the yield of carbon in the majority of cases is higher for poly(*o*-nitroamides), which confirms that reactions leading to more stable systems occur in poly(*o*-nitroamides).

The occurence of two maxima for the rate of weight loss is a conspicuous feature. In the opinion of Kim and Pearce[95] it is due to the differing ease of elimination of the first and second nitro groups from each fundamental unit of the polymer.

The formation of polybenzoxazoles from poly(*o*-nitroamides) occurs more readily than from the corresponding poly(*o*-chlorophenyl)amides[96–98] and may be regarded as a promising method for the synthesis of these polyheteroarylenes.

Donor-acceptor interactions in polycondensation processes

B A Rozenberg
Branch of the Semenov Institute of Chemical Physics, Chernogolovka

ABSTRACT. **The results of studies on the role of donor-acceptor interactions in polycondensation processes are correlated. The thermodynamic and kinetic aspects of the problem, the features of the reaction mechanism, structure and properties of the resulting polymer that are related to donor-acceptor interactions are examined in examples of the curing of epoxide oligomers.**

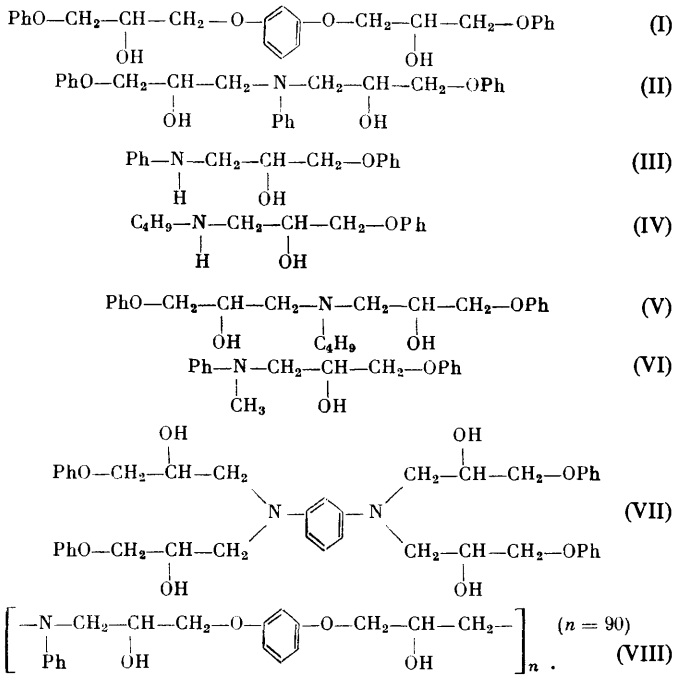
I. Introduction

Monomers containing reactive functional groups of an electrophilic and nucleophilic nature are usually employed as starting compounds in polycondensation processes. These groups can undergo different donor-acceptor interactions between themselves and with other compounds of the reaction system (polymer, solvent, catalyst, impurities or specially introduced components), forming homo- or hetero-associates of a linear or cyclic nature. Thus, both initial and developing systems have a well-defined structural organisation. Although the very fact of such donor-acceptor interactions occurring between polar groups has been known for a long time in organic chemstry, their role in polycondensation processes during the formation of linear and cross-linked polymers, as in similar reactions of low-molecular-weight organic compounds, has until recently remained unclear. Only comparatively recently has this question become the subject of systematic studies, mainly through the efforts of two groups of research workers at the Semenov Institute of Chemical Physics, USSR Academy of Sciences. The first group has studied this question in the case of reactions involving formation of urethanes,[1–12] the second group has studied epoxide curing processes.[13–31] On the basis of these studies it has been possible to formulate sufficiently well-argued ideas about the role of donor-acceptor interactions in the kinetics and mechanism of the processes studied and also in the formation of the structure and properties of the resulting polymers.

The aim of the present article is to classify the results of studies on the effect of donor-acceptor interactions on polycondensation processes, mainly by considering examples of the curing of epoxide oligomers and to draw the attention of research workers to this problem. Elucidation of the role of possible donor-acceptor interactions in the reaction system is a key not only to a more fundamental understanding of the features of the kinetics and mechanism of the formation of a polymer but also to controlling the process and, in individual cases, the structure and properties of the resulting polymer.



II. Composition of the reaction system

The composition of the reaction system is highly complex because of the occurrence of various donor-acceptor interactions, and linear and cyclic homo- and hetero-associates are contained in the system together with the monomer forms of reactive functional groups. As an example we can illustrate the possible forms of the donor-acceptor complexes for epoxyamine systems containing primary, secondary, and tertiary amino groups as well as epoxide, secondary hydroxyl, and ether groups.

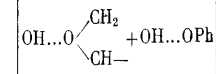
The occurrence of such donor-acceptor interactions as described above was demonstrated using specially synthesised and certain other model compounds by means of IR spectroscopic studies over a

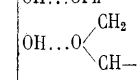
wide concentration range in CCl_4 solution.[13,20,26,27] The model compounds that were synthesised are depicted below:

The values of thermodynamic parameters for the respective complexation reactions have been determined by means of calorimetry and IR spectroscopy (Tables 1 and 2).[13,20,26,31–33]

Table 1. Thermodynamic parameters of reactions for the formation of model donor-acceptor complexes.[20]

Reaction system	$-\Delta H$, kJ mol^{-1}	$-\Delta S$, J mol^{-1} K^{-1}	K_e*, litre mol^{-1}	K_e**, litre mol^{-1}
Cyclohexanol–cyclohexanol (HH)	27.2	98.6	–	–
Cyclohexanol–phenyl glycidyl ether (EH)	14.2	46.0	1.3/0.5	1.5/0.6
Cyclohexanol–aniline (A_1H)	18.8	67.0	1.9/0.5	2.0/0.5
Cyclohexanol–ethylaniline (A_2H)	11.7	41.8	1.4/0.7	1.2/0.6
Cyclohexanol–diethylaniline (A_3H)	3.8	8.4	0.6/0.6	0.3/0.3





* The equilibrium constants K_e (determined by calorimetry) at 22 °C are given by the numerator, while the values of K_e at 98 °C are given by the denominator.

** The values of K_e (determined by IR spectroscopy) at 28 °C are given by the numerator, while the values of K_e at 98 °C are given by the denominator.

Five-membered rings constitute a characteristic form of the cyclic associates. In the molecules of model compounds II and V eight-membered rings with OH...OH hydrogen bonds also occur, but the total proportion of cyclic structures of the associates in the polymer is small and does not exceed 1–2%. A similar conclusion was also drawn from kinetic studies.[20,30]

It is interesting to note that NH groups participate in the formation of hydrogen bonds in both the crystalline and amorphous states of the compound not only as electron donors but also as acceptors.[26,32,33]

Table 2. Thermodynamic parameters of model H-complexes.[26,32,33]

Compound	Reaction system	Type of H-bond in the complex	K_e (at 25 °C), litre mol^{-1}	$-\Delta H$, kJ mol^{-1}
I	Isopropanol–isopropanol	OH...OH	2.45	17.0÷21.0
II	Isopropanol–phenyl glycidyl ether		1.08	–
III	Isopropanol–anisole	OH...OPh	0.33	9.6
IV	From the difference between systems II and III*		0.75	12.5
V	Isopropanol–*N*-diethylaniline		0.38	9.2
VI	*N*-Methylaniline–*N*-methylaniline		0.45	7.5
VII	*N*-Methylaniline–anisole		0.36	7.5
VIII	*N*-Methylaniline–di-n-propyl ether		0.29	13.0

* K_e calculated from the difference in values for systems II and III.

It can be seen from Table 2 that autoassociation of the hydroxyl groups is the predominant form of association at room temperature. As estimates have shown,[26] the proportion of hydroxyl group autoassociates in epoxyamine networks with a stoichiometric composition constitutes 85–90%. Autoassociation of hydroxyl-containing compounds (alcohols, phenols, acids) has been well studied. The extensive literature data, which have been classified in three reviews,[31,33,34] indicate that it is quite a complex process, resulting in the formation of an equilibrium mixture of different linear and cyclic *n*-dimensional autoassociates. With respect to the question that interests us concerning the participation of such structures in the catalysis of the nucleophilic addition of amines to an epoxide ring, the cyclic associates usually exist as trimers and it follows from their structure [see scheme (1)] that they are actually inactive in this process, whereas in linear associates the activity increases significantly relative to the activity of a monomeric hydroxyl-containing compound.

The question as to how information about the thermodynamics of low-molecular-weight model compounds can be applied to real cross-linked epoxyamine polymers is quite natural. A direct comparison between the IR spectra of model compounds and polymers provides a clear answer.[28] The frequencies of the absorption maxima, the line

half-widths, and the relative intensities of vibration bands due to groups participating in the formation of hydrogen bonds for model compounds (melt or glass) virtually match those of linear and cross-linked polymers in a vitreous state. This means that the composition and average values of the hydrogen bond energies for polymer and low-molecular-weight epoxyamine systems are similar. A similar conclusion can be made by comparing the thermodynamic parameters of the model and polymer systems (Tables 1–3).

Table 3. Thermodynamic parameters of complexation reactions for a number of epoxyamine systems.[13,17,18,23,24]

System	$-\Delta H$, kJ mol^{-1}	$-\Delta S$, J mol^{-1} K^{-1}
Phenyl glycidyl ether–aniline (Refs.20, 23)

A_1H	14.2	31.3
A_2H	10.4	41.8
A_3H	4.6	5.0

The processes involving formation of donor-acceptor complexes in oligooxypropylene glycols, hydroxyoligobutadienes, and oligourethanes have been studied using IR spectroscopy and calorimetry.[34–36] It was shown that the thermal parameters of the H-complex in these systems (HO:...H–O, OH...:O<, OH...π-bond, NH...π-bond, NH...:O=C<) do not depend on the molecular weight of the oligomers and almost match those for low-molecular-weight model compounds.

All these results suggest that the approach using model systems to study donor-acceptor interactions is fully justified. Moreover, only with its application is it possible to determine quantitatively the thermodynamic and kinetic properties of the numerous complexes that are formed in a reaction system. At the present time we have only just begun to study the thermodynamics and kinetics of complex systems. For the time being, in fact, it is only possible to determine the apparent values of the thermodynamic and kinetic parameters in the systems (see Section III). The development of an algorithm for both experimental and theoretical approaches to the study of such systems remains an important task.

In studying the thermodynamics of these reactions another problem arises—a correct determination of the exothermicity of opening the epoxide ring and the justification for using calorimetry to study the kinetics of the process.

In fact, during the complexation reactions in the system with constantly varying concentrations of donor and acceptors, the apparent quantity of heat liberated (Q) may have a non-linear dependence on the degree of conversion (α) since in general

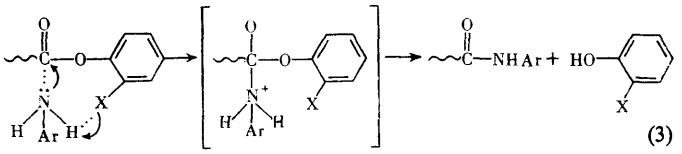
$$Q = q\alpha + \sum q_i(\alpha), \qquad (2)$$

where q is the exothermicity of opening the epoxide ring: $\Sigma q_i(\alpha)$ is the total exothermicity of all the donor-acceptor interactions in the system, which depends non-linearly on the degree of conversion $\alpha = (E_0 - E)/E_0$ (E and E_0 are the current and initial epoxide concentrations respectively).

However, it usually transpires that there is a well-defined linear relationship between Q and α, determined chemically or by means of IR spectroscopy (it is represented graphically as a straight line starting from the origin). Consequently, $\Sigma q_i(\alpha) \to 0$ and $q\alpha \gg \Sigma q_i(\alpha)$, namely, there is a balancing out of the heats of formation and heats of decomposition of the different complexes in the systems during the process. This in turn means that calorimetry can be used as a tool to study the kinetics of these reactions.

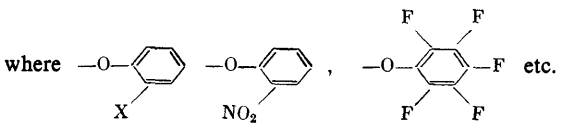
III. Donor-acceptor interactions and reaction kinetics

It is clear that formation of the complexes described above must lead to a change in the reactivity of the initial reactant molecules. At the same time, because the concentrations of the functional groups and hence donor-acceptor complexes are constantly changing throughout polycondensation, the nature of the kinetic effects must also vary with the conversion.



Only on the basis of ideas about the decisive role of complexation processes is it possible to understand such characteristics of the reactions of epoxy compounds with primary and secondary amines as the simultaneous occurrence of autoacceleration and autoinhibition effects, which is very unusual in terms of kinetics,[13,20,30] the catalytic and inhibitor effect of different solvents,[13,20,27–40] the well-defined ortho effect of electron-donating substitutents in aromatic amines and the anomalously low activity of polyoxyethylene primary amines,[37,41] the accelerating effect of added quantities of tertiary amines,[19,42] the high reactivity of aromatic *N*-diglycidylamines and *o*-diglycidyl ethers,[43,44] and certain others.[20,29,45–49]

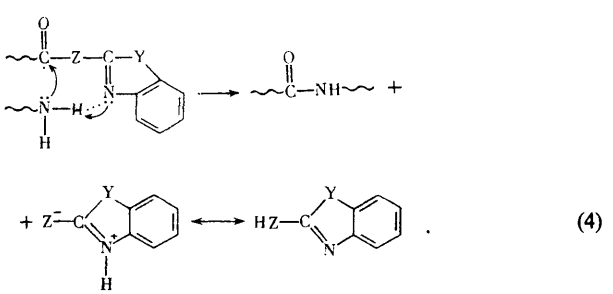
A very typical kinetic feature of polycondensation systems that is related to the occurrence of donor-acceptor interactions is the markedly non-linear, and sometimes even non-monotonic, dependence of the rate of reaction on the concentration of the reactants with a considerable variation of the latter.[3–6,46,48]



In the formation of urethanes during reaction between isocyanates and alcohols catalysed by tetravalent tin compounds, the effect of donor-acceptor interactions manifests itself in the extremal nature of the dependence of the catalytic rate constant on the strength of the complex between catalyst and alcohols,[50] the sharp reduction in the Hammett ρ constant compared to that for a non-catalytic process,[51] and the levelling out of the reactivity of hydroxyl groups that are different in nature.[3,4]

In reactions of the so-called "activated" polycondensation the high activity of *o*-substituted phenyl esters is due not only to and even not so much to stabilisation of the leaving group, which increases with a decrease in pK_a of the corresponding acid, but mainly to the catalytic effect of the *o*-substituent through formation

of an intramolecular hydrogen bond with amines in the preparation of a polyamide:[52,53]

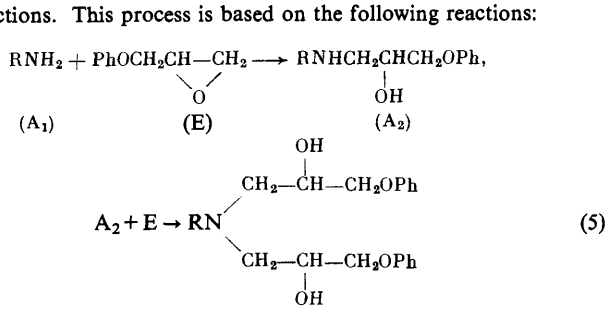


(3)

where  etc.

As expected, the catalytic effect of an *o*-substituent (such as NO_2) is particularly well defined in a proton-inert or weakly proton-accepting medium (chlorobenzene, benzene), where the *o*-nitrophenyl ester is two to four times more active than its *p*-substituted analogue. In a strong proton-donating medium (HMPA), which inhibits the formation of an intramolecular hydrogen bond, the reverse occurs—the *p*-nitrophenyl ester is eight times more active than the *o*-substituted isomer.[53]

It was established in a similar manner that benzene derivatives are very effective as leaving groups because of the formation of an intramolecular hydrogen bond in the reaction between activated esters and amines:[54]

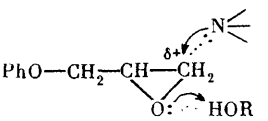


(4)

(Y, Z = —O—, —S—)

In a recently published monograph[55] a large number of examples are given to illustrate the determining role of an intramolecular hydrogen bond and other types of donor-acceptor interactions of reacting groups in the catalysis of different nucleophilic substitution-addition reactions.

Let us examine in greater detail the features of the kinetics of the curing of epoxides by amines that are related to donor-acceptor interactions. This process is based on the following reactions:



(5)

(R = Ar or Alk).

A tertiary amino group that is formed during curing of epoxides by aliphatic amines can in individual cases catalyse the polymerisation of epoxide groups. If aromatic amines are used as curing agents, this reaction does not occur at temperatures below ~150 °C.

It is widely known that added quantities of hydroxyl-containing compounds (water, alcohols, phenols, acids) substantially accelerate the reaction between epoxides and amines and other nucleophilic reactants.[18–24,56–63] In this case considerable activation of the carbon atom of the epoxide ring towards nucleophilic attack takes place. The reaction occurs via a trimolecular transition state, first described by Smith[62,63] for the interaction between epoxide compounds and amines: †

(6)

It is as a result of the build-up of hydroxyl groups during the reaction [see scheme (5)] that the curing of epoxide oligomers by amines has a well-defined autocatalytic nature.

By using a special method for the efficient removal of traces of moisture and other hydroxyl-containing compounds[22] from the initial materials and reaction vessels, it was possible to reduce the concentration of hydroxyl-containing impurities on the basis of water to 10^{-6} mol litre^{-1} or less.

It transpired[22] that under these conditions a reaction occurs between phenyl glycidyl ether (PGE) and aniline, but the initial rate is 40–50 times slower than in the reaction catalysed by proton donors and the dependence on the aniline concentration is quadratic rather than linear. The presence of even small amounts of moisture reduces the order of reaction with respect to amine.

The quadratic dependence of the rate of reaction on the concentration of amine (A_1) signifies that the latter acts both as an electrophile, forming an intermediate complex (A_1E) with an epoxide compound (E)

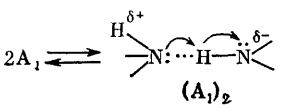
$$A_1 + E \underset{K_-}{\overset{K_+}{\rightleftharpoons}} (A_1E), \qquad (7)$$

and as a nucleophilic reagent

$$(A_1E) + A_1 \xrightarrow{K_1} A_2 + A_1,$$

are a result of which an addition product (A_2) is obtained.

The decrease in the order of reaction with respect to amine in the presence of hydroxyl-containing impurities is related to its taking place partly by a catalytic mechanism, when the hydroxyl-containing compound, which is considerably more acidic than the amine, acts as a proton donor. It should be noted that in the usual method of purification of the reactants and the vessels used, the content of moisture in the reaction mixture is still sufficiently high and the order of reaction with respect to amine is considerably different from quadratic.[23,24] Thus, it was shown by Mutin et al.[25] that the reaction of PGE with butylamine has a fractional order ($1 \leqslant n \leqslant 2$) that is dependent on the reaction temperature. This case is effectively represented if account is taken of the fact that two reactions are taking place simultaneously in the system—one that is first-order with respect to amine (catalytic reaction) and one that is second-order with respect to amine (non-catalytic reaction). The



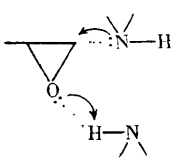
† Not only monomeric but also associated forms of hydroxyl-containing compounds and amines can act as proton donors and nucleophilic reagants.

contribution of each of these to the apparent rate is dependent on temperature, since their energies of activation are different, and on the concentration of the proton-donating impurities.

We should note that on the whole there are no fundamental differences‡ between the catalytic reaction, when activation of the epoxide ring is effected by the hydroxyl-containing component, and the non-catalytic reaction, where the amine itself acts as an electrophilic reagent (proton donor). It is important to note that electrophilic assistance is needed for opening of the epoxide ring by such weakly nucleophilic reagents as amines. This conclusion was also extended to other known nucleophilic addition reactions to an epoxide ring,[13] and it is essential for an understanding of the kinetic mechanisms of such processes.

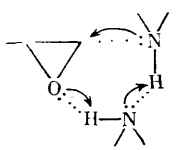
Let us examine in greater detail the mechanism of addition of amines to the epoxide ring. The catalytic addition of amines takes place in two stages: initial formation of quite stable donor-acceptor complexes between the epoxide compound and the hydroxyl-containing reactant; and subsequent nucleophilic attack by amine on this complex, i.e., this quasi-termolecular reaction in fact comprises two successive bimolecular reactions with a push-pull mechanism occurring in the transition state. We should stress that in the donor-acceptor complexes between amine and hydroxyl-containing compounds ($A_i \ldots HOR$) formed in this process the amine is actually deactivated as a nucleophilic reagent and only free, uncomplexed molecules of amine act as the latter.

The question of the detailed mechanism of the non-catalytic reaction between epoxide compounds and amines still remains an open one. Apart from the mechanism shown in scheme (7), we can also put forward an alternative one which involves the initial formation of a more reactive amine dimer



(8)

According to scheme (8) an increase in both the electrophilic and nucleophilic activity of the dimer compared to monomeric amine is to be expected. The kinetic scheme in this case can be given in the form:



$$2A_1 \rightleftharpoons (A_1)_2,$$

$$(A_1)_2 + E \rightleftharpoons [(A_1)_2E] \rightarrow A_2 + A_1. \qquad (9)$$

The respective transition states for the alternative mechanisms (7) and (9) are shown in schemes (10) and (11):

(10)

(11)

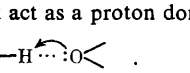
‡ There is only a difference in the degree of activation of the epoxide ring.

It is impossible to distinguish between these mechanisms from the experimental data that are available at the present time. However, the second [scheme (11)] seems preferable to us, since according to this scheme addition of amine occurs via a cyclic transition state and is fully concluded in a single stage, whereas a further proton transfer is required in the realisation of scheme (9).

It is not excluded also that different mechanisms [see schemes (7) and (9)] can precede formation of the same transition state [see scheme (11)]. The question of the nature of the transition state in nucleophilic addition of an amine to an epoxide ring will be considered in greater detail below.

The kinetics of the condensation of primary and secondary amines with epoxides are well represented if account is taken of the fact that the main characteristic of these processes is the formation of different hetero- and auto-complexes that have varying reactivity. An interpretation of the physical significance of the apparent values of the termolecular rate constants that are determined still remains very approximate. This situation is evidently typical for liquid-phase reactions, in which different donor-acceptor interactions of all the components of the reaction system play an important part. For example, even the simplest non-catalytic reaction (in the absence of proton donors) of an epoxide compound with an amine should in general be given by a kinetic scheme that takes into account all the donor-acceptor interactions:

$$A_i^1 + A \underset{a}{\overset{K'_{ai}}{\rightleftharpoons}} A_{i+1}^1,$$



$$A_i^1 + A \underset{b}{\overset{K''_{ai}}{\rightleftharpoons}} (A_iE),$$

$$A_i^1 \underset{c}{\overset{K'''_{ai}}{\rightleftharpoons}} A_i^c,$$

$$A_i^1 + A_i^1 \xrightarrow[d]{K_{ij}} \text{product} + A_{i+j-1}^1, \qquad (12)$$

where A is a primary or secondary amine, the superscripts "l" or "c" indicate linear (reactive) and cyclic (non-reactive) autoassociates respectively. For reactions *a*, *b*, *d*: $i = 1, 2, 3, \ldots$; for reaction *c*: $i = 2, 3, \ldots, j = 1, 2, 3, \ldots$; K''_{ei}, K'_{ei}, K_{ei} are the equilibrium constants; k_{ij} are the true rate constants.

When glycidyl ethers are used as the epoxide compound and the solvent is electron-donating, kinetic scheme (12) will be supplemented by reactions involving complexation between amines and the non-ring oxygen atom in the glycidyl ether molecule and the electron-donating atom of the solvent molecule. In this case the amine must act as a proton donor

(13)

The apparent experimental rate constant of the non-catalytic reaction k_1 is determined from the equation

$$W_0 = k_1 E_0 A_0^2, \qquad (14)$$

where W_0 is the initial rate of reaction, A_0 and E_0 are the concentrations of the respective functional groups: the index "0" relates to the values of the parameters when $t = 0$.

From kinetic scheme (12) the following expression can be derived:

$$W_0 = \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} k_{ij} (A_i^1 E) A_j^1, \qquad (15)$$

where (A_i^1E) and A_j^1 are the equilibrium concentrations of the respective complexes. A solution to this equation, namely, a determination of the composition of the apparent rate constant in general form does not seem possible.

In reality the situation is of course simpler, since the concentration of all the complexes rapidly decreases with an increase in the degree of autoassociation. With regard to the relationship $k_{ij} = f(i, j)$, it can turn out to be non-monotonic since opening of the epoxide ring will occur with the greatest probability via a cyclic transition state that is dependent on the values of i and j.

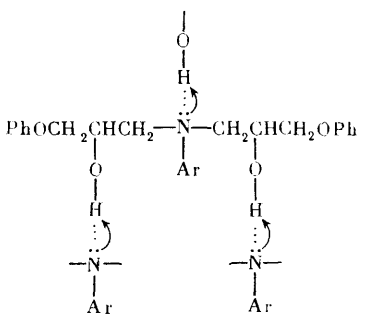
At the present time a definitive answer to the problem concerning the composition of the apparent rate constant in opening of the epoxide ring by amine is not known. As a first approximation the autoassociation reactions of amine can be neglected. In this case the form of the expression for the apparent rate constant of the non-catalytic reaction assuming that $(A_1E) \ll E_0$ is quite clear [see scheme (7)]:

$$k_{app} = k_{tr}K_e, \tag{16}$$

where k_{tr} is the rate constant for the fundamental reaction of opening the epoxide ring [see schemes (10) and (11)], K_e is the equilibrium constant of the reaction $A_1 + E \rightleftarrows (A_1E)$.

The composition of k_{app} will also be similar if it is assumed that the reaction occurs by scheme (9) via a cyclic transition state [see scheme (11)]. Here K_e is the equilibrium constant of the reaction $2A_1 \rightleftarrows (A_1)_2$, in which $A_{1_0} \gg 2(A_1)_2$ and cyclic forms of the dimers are absent.

The treatment given above indicates that we encounter considerable difficulties in interpreting the physical composition of the apparent rate constant, which are related to the absence of valuable quantitative information on the thermodynamics of the reactions for formation of H-complexes and their reactivity. Further detailed studies of the donor-acceptor interactions in these systems would make it possible to find a more precise solution to this problem than we can offer at the present time.



The question of the balancing mechanism which was touched upon above is very closely associated with the problem of the composition of the apparent rate constant. Without establishing this mechanism it is impossible to understand why in a complex system such as the epoxyamine system in question, where many donor-acceptor interactions take place and the reactivity of the H-complexes varies considerably, comparatively simple kinetic mechanisms occur. These are namely: a slight dependence of the apparent rate constant on the degree of conversion, simple dependences of the initial rate on the concentration of reactants, a linear dependence of the total quantity of liberated heat Q on the degree of conversion, and the similarity between the values of Q and the enthalpy for opening the epoxide ring. The latter two problems have been discussed already and the essence of the first two can be revealed, for example, in a study of the non-catalytic reaction.

According to kinetic scheme (12), the initial rate of reaction will decrease compared to that which would occur in the absence of any donor-acceptor interactions as a result of a decrease in the total number of nucleophilic species due to autoassociation of the amino groups and will increase because of an increase in the nucleophilicity of the associated amino groups as well as a certain increase in acidity of the auto-complexes of amine (compared to that for unassociated molecules). This combination of positive and negative factors should lead to a certain levelling out of the role of donor-acceptor interactions in changing the concentrations of reactants and reaction products, namely, a balancing effect. The linear dependence between the current reactant concentrations and the concentrations of their free, uncomplexed forms can also be attributed to its occurrence. In general the magnitude of the balancing effect depends on the nature of the reactants and the specific reaction conditions.

One of the kinetic manifestations of the formation of H-bonds in an epoxyamine system is shown not only in an acceleration but also a deceleration of this reaction at its advanced stages.

The deceleration effect of the advanced stages of conversion is due to the formation of unreactive complexes (A_iH_n). Complexation, on the one hand, reduces the concentration of the reactive complex (EH_n) and, on the other hand, reduces the concentration of free amine and hence leads to a retardation of the process. It should be stressed that deceleration of the reaction can only occur when the basicity of the resulting secondary of tertiary amino groups (or of both of them) is greater than the basicity of the initial primary amino group. Only in this case will a progressive relative decrease in the concentration of free hydroxyl groups, and hence in the rate of overall process, occur.[13,19,20,30]

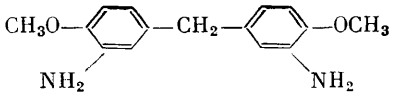
Complexation of the amino groups with the hydroxyl groups is clearly revealed in the fact that the viscosity of the reaction system at the advanced stages of the processes increases substantially as a result of the formation of a network with labile hydrogen bonds at branch points, since the formation of tertiary amino groups gives rise to a trifunctional reaction occurring in the system (one tertiary amino group and two hydroxyl groups):

(17)

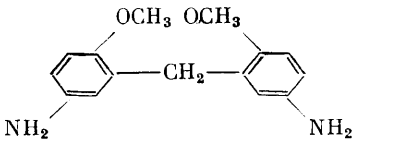
In complete agreement with what is expected, the effect of an increase in viscosity of the system during the reaction increases with a decrease in the ratio of A_{1_0}/E_0, where the index "0" denotes the concentrations of reactants at an initial point in time. In this case the maximum attainable value of the viscosity increases. Thus, when A_{1_0}/E_0 = 1.8; 1.0; 0.45, $\eta_{rel\,t\to 0}$ = 3.5; 14.0; 32.5 respectively. Introduction of a stronger base into the reacting system causes a sharp decrease in viscosity of the system as a result of break-up of the polyfunctional associates.

An increase in reaction temperature leads to a decrease in the proportion of amines associated with hydroxyl groups, and as a result to inhibition of the process starting to occur at a more advanced stage. When the reaction is carried out under adiabatic conditions, 100% conversion of the epoxide groups is achieved without any autoinhibition effect.[23]

Thus, the hydroxyl group has a dual role in this reaction. On the one hand, it leads to considerable activation of the epoxide ring as a result of the formation of a complex (EH_n); on the other hand, in the formation of unreactive complexes (A_iH_n) the rate of reaction is reduced because of a decrease in the concentrations of primary and secondary amines as well as that of free hydroxyl groups not forming (A_iH_n) complexes and which catalyse the reaction. The second factor, naturally, has a much greater effect in reducing the



rate than does the first, which is also borne out by the experimental results.[20,30] Additions of a model secondary alcohol—cyclohexanol—lead not only to an increase in the rate of reaction but also to an increase in the degree of conversion at which a marked inhibition of the reaction occurs.

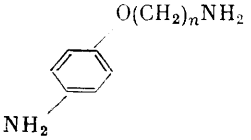


Thus, the results presented above suggest that the mechanism of the reaction of epoxide compounds with amines makes it basically possible for not only autocatalysis but also an autoinhibition effect at advanced stages of the reaction to be exhibited in such systems. However, the latter can only occur when the relative concentration of free hydroxyl groups decreases during the reaction because of the increase in the equilibrium constant for complexation between a hydroxyl group and an amino group on changing from a primary amino group to a secondary and then tertiary amino group.

When electrophilic assistance reagents are introduced into the epoxyamine systems (alcohols, phenols, carboxylic and Lewis acids) in order to activate the epoxide ring, donor-acceptor interactions can cause a dual kinetic effect—both acceleration and inhibition of this reaction depending on the concentration and acidity of the added components.[13,64,65] When activators with quite a high acidity are used (carboxylic and Lewis acids), the dependence of the rate of reaction on the concentration of added component is extremal in nature.

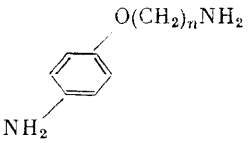
Actually the effect of activating the epoxide ring towards a reaction with nucleophilic reagents increases with an increase in acidity of the electrophilic assistance reagent. At the same time an increase in the acidity and concentration of the added component leads to the amine being bound in an unreactive complex right up to complete inhibition of the reaction when all the amine is bound. This effect is sometimes used to regulate the rate of curing of such systems. These so-called latent systems have considerable viability at low temperatures but start to react at a high rate on heating, which results in decomposition of the unreactive amine–acid complexes.[13]

Consideration of donor-acceptor interactions also makes it possible to understand the kinetic effects related to the structure of the initial reactants. There are a number of facts which attest to the anomalously low reactivity of aromatic amines containing electron-donating groups at the *ortho* position. Thus, the reactivity of an amino group which has SCH_3 as the *ortho* substituent is 21 times lower than for an amino group without this substituent.[56] A similar pattern occurs for aromatic amines with methoxyl groups at the *ortho* position.[37]



(18)

(19)

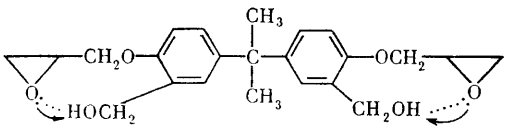


The reactivity of diamine (18) when it reacts with resorcinol diglycidyl ether is approximately 10 times lower than for (19). For both amines containing electron-donating substituents at the *ortho* position the presence of an intramolecular hydrogen bond in which the amine group acts as a proton donor has been established. It would appear that the nucleophilicity of this amino group must increase as a result of both the inductive effect of the electronic substituent and through the formation of an intramolecular donor-acceptor complex, although in reality it decreases. This contradiction can be readily eliminated if it is borne in mind that the hydrogen atoms of the amino group are involved in formation of an associate, namely, the concentration of amine as a proton donor in the reaction system decreases. It is evident that in terms of the ideas being developed concerning obligatory electrophilic assistance for nucleophilic attack on the epoxide ring, this reduction in concentration of proton donors in highly pure systems (when the amine itself acts as a proton donor at the initial stage of the reaction) must lead to a decrease in the rate of reaction. This is what actually occurs.

On the basis of the ideas put forward above, a whole series of aliphatic and mixed (aliphatic-aromatic) liquid oligomers with reduced reactivity was synthesised:[41]

$$ArNHCH_2CH_2(OCH_2CH_2)_mNH_2 \ (m = 1, 2), \tag{20}$$

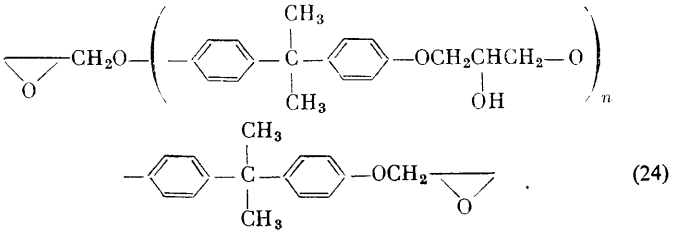
(21)



$(n = 2,3)$

(22)

The use of such amines as curing agents has considerable technological advantages, increasing the viability of composite materials.



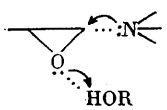
The high reactivity of *o*-diglycidyl ethers of phenols, *o*-diglycidyl esters of aromatic carboxylic acids, and *N*-diglycidylamines can only be explained by assuming that secondary hydroxyl groups, which are present in these compounds as small quantities of impurities, participate in catalysis.[13,43,44,66–67]

The presence of intramolecular hydrogen bonds in the 3,3′-dihydroxymethyl-4,4,′-diglycidyl ether of bisphenol A

(23)

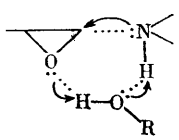
gives rise to its considerably higher reactivity (by a factor of about 10) than that of the diglycidyl ether not containing hydroxymethyl groups at *ortho* positions.[68]

The rate of curing the epoxybisphenol A oligomers (24) increases with an increase in molecular weight of the oligomer, although the concentration of the epoxide groups decreases as this occurs.[13,20,29,45] This result, which appears paradoxical at first glance, is quite obvious when it is borne in mind that with an increase in molecular weight of the oligomer there is an increase in concentration of hydroxyl groups, which leads to an increase in the rate of reaction



(24)

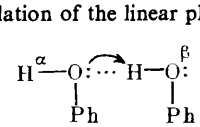
Determination of the reactivity of the epoxide groups in oligomers with varying molecular weights (taking into account the concentration of the hydroxyl groups contained in them) showed that it is the same and does not depend on the molecular weight of the oligomer.



Even in early studies on reactions of epoxides with amines[56–63] it was noted that both proton-donating and electron-donating solvents have a considerable effect on the reaction kinetics. Proton-donating solvents decrease the induction period and increase the rate of reaction to a greater extent the higher the acidity of the solvent, whereas electron-donating solvents reduce both the initial and continuing rate of reaction, and as the degree of conversion of the epoxide groups increases, the inhibition effect increases.[19,20,37,39,40] This type of solvent behaviour is fully consistent with the reaction mechanism considered above. The inhibitory effect of electron-donating solvents is caused by the reduction in concentration of proton donors in the reaction system as a result of their bonding with solvent molecules. At the initial stage amines are bound by solvent while during the reaction hydroxyl groups are bound.[37]

The rate of reaction in strongly associated systems can easily vary over quite a considerable range from the effect not only of the solvent but also of other factors such as temperature and external mechanical or electrical fields, which are capable of changing the degree and nature of association of the reacting groups.[13,69–71]

In concluding this section let us return to the question of the mechanism of addition of amines to an epoxide ring. Possible transition states for non-catalytic opening of the epoxide ring by amine are depicted in schemes (10) and (11). Such schemes can similarly be recorded for a reaction catalysed by any proton donor, such as ROH:



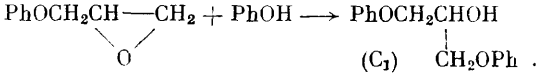
(25)

(26)

It does not appear possible to distinguish these two alternative schemes from the existing kinetic and structural data. At the same time, from detailed kinetic and structural studies of certain other nucleophilic addition reactions to the epoxide ring (phenols and carboxylic acid) it is possible to choose in favour of a cyclic transition state [scheme (26)].[13,46–48]

In the reaction between PGE and phenol[46] a variable order of reaction with respect to phenol was found; at small phenol concentrations it was close to first order, while at large concentrations it increased to fourth order. High values for the order of reaction with respect to the hydroxyl-containing reagent were also obtained in addition of alcohols to propylene oxide[72] or isocyanates,[3] which is due to an increase in reactivity of the hydroxyl-containing compounds on forming autoassociates. A quantum-mechanical calculation of the linear phenol dimer

(27)



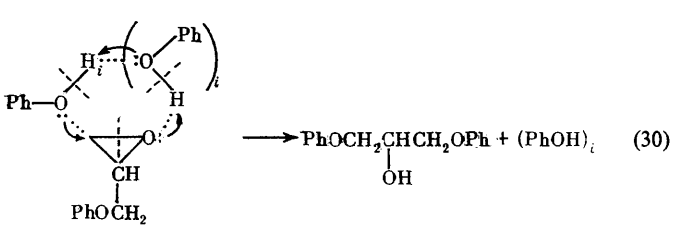
revealed a considerable reduction in electron density on the H^{α} hydrogen atom and an increase in electron density on the O^{β} oxygen atom compared to "monomeric" phenol.[73] Naturally this must result in an increase in proton-donating capacity and nucleophilicity of the phenol dimer. Such changes in the distribution of electron density are even more typical for higher molecular-weight associates.

Taking into account the different possible homo- and hetero-associates, the initial rate of the reaction between phenol (P) and epoxide (E) can be satisfactorily represented by the following simplified scheme, which assumes that all phenol autoassociates have solely a linear structure,

$$P_{i-1} + P \overset{k_i}{\rightleftharpoons} P_i, \quad E + P_i \overset{K_{1i}}{\rightleftharpoons} (EP_i),$$

$$(EP_i) \xrightarrow{k_i} C_1 + P_{i-1}, \qquad (28)$$

where C_1 is the primary product of the addition of PGE to phenol

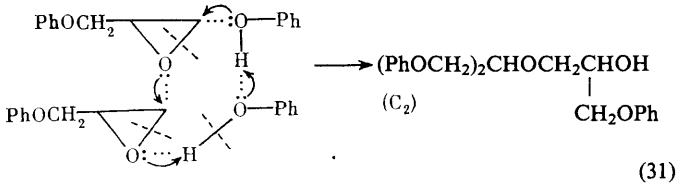


(29)

K_i and K_{1i} are the equilibrium constants for the respective reactions, k_i are the rate constants for formation of C_1.

The unimolecular conversion of the heteroassociates (EP_i) to the reaction product in accordance with scheme (28) in essence assumes a cyclic transition state. The values of the kinetics parameters determined from this scheme showed that the rate of formation of C_1 is mainly determined by processes involving association of the epoxide with higher forms of phenol associates (P_4 and P_5).

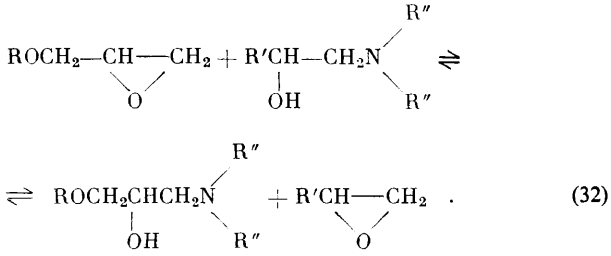
The revelation of the determining role of phenol associates can only be understood in terms of kinetic scheme (28), which assumes the unimolecular decomposition of heteroassociate (EP_i) via a cyclic transition state which is more probable sterically for H-complexes of PGE with higher forms of phenol associates.



(30)

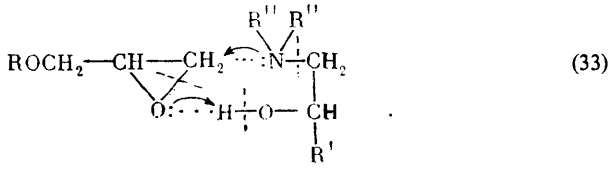
In the transition state the donor-acceptor bonds indicated by arrows are converted into covalent bonds, while the covalent bonds that are intersected by broken lines are cleaved synchronously to form the final reaction products. The formation of the transition state, which comprises a complex cyclic heteroassociate, is preceded by the process of "assembling" its individual fragments, each of which is a simpler homo- or hetero-associate. In this case the principal determining reaction channel, as kinetic studies have shown, is provided by heteroassociates (EP_i), where $i = 4, 5$.

In achieving a cyclic transition state the formation of reaction products occurs simultaneously with the transfer of a proton from the nucleophilic reagent to the molecule which provides electrophilic assistance. In this case the latter essentially fulfils two functions: it activates the epoxide ring towards nucleophilic attack and increases the activity of the nucleophilic reagent, i.e., bifunctional catalysis takes place and a "push-pull" reaction mechanism occurs. It is evident that such a mechanism predicates a lower energy of activation of the reaction than for a non-cyclic transition state, but imposes stricter limits on the entropy factor.



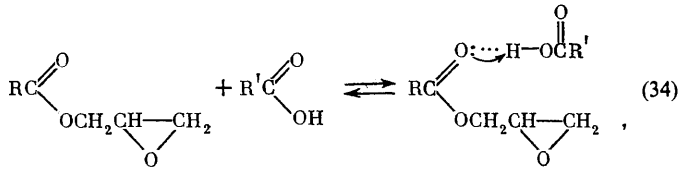
Using the concept of a cyclic transition state it is possible to understand the fact of parallel formation of a secondary addition product (C_2) directly from the initial reactants.[74] This reaction can be depicted as follows:

(31)



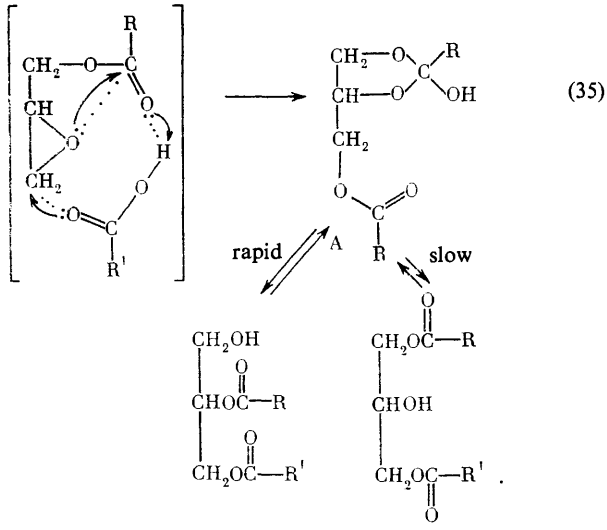
The formation of this type of transition state is evidently preceded by the development of simpler heteroassociates of the type (EP). It is interesting to consider the fact that kinetic studies demonstrate that in all only two molecules of phenol take part in this reaction, and not more as in the formation of C_1.

In fact, similar results were also obtained in the reaction between epoxide compounds and carboxylic acids.[47] Lastly, we shall give two final examples. A novel reaction, namely, amino alcohols on reacting with epoxide compounds can undergo transepoxidation, was recently discovered:[49]



(32)

Evidently the most probable mechanism for this is given by the following:



(33)

Without involving the concept of a cyclic transition state it is also impossible to understand the reaction between carboxylic acid glycidyl esters and carboxylic acids, which results in the formation of an "anomalous" addition product;[74] whereas in the reaction between phenol glycidyl ethers and carboxylic acids, "normal" addition products are obtained. In the first case the product of the donor-acceptor interaction between the hydroxyl group of the acid and the carbonyl group of the ester will evidently become an "active" complex:

(34)

which forms a cyclic transition state

(35)

From the scheme presented it is possible to understand not only the formation of the "anomalous" addition product but also the subsequent slow conversion of the latter to the more stable "normal" addition product via the intermediate A.

Thus, the examples of model reactions for the curing of epoxide oligomers considered above indicate that addition of nucleophilic reagents to the epoxide ring occurs in a very complex manner and involves the initial formation of homo- and hetero-associates. The latter in turn can form even more complex reactive cyclic heteroassociates that act as unique microreactors in which the reaction products are obtained through unimolecular rearrangement with synchronous transfer of electrons in the system.[1–4,13]

The presence of a cyclic transition state is very typical of a large number of reactions in the liquid phase in which various donor-acceptor interactions between the components of the system are possible.[55] The structural organisation of this type of reaction system caused by the donor-acceptor interactions of its components (initial reactants and reaction products) governs, on the one hand, the multiplicity of the routes for passage of the reaction and, on the other hand, the few routes for its favourable development.

Further studies directed at finding a link between the kinetic mechanisms of the chemical reactions and the structural organisation of liquid-phase systems involving polar reactants should lead to a re-examination of the mechanism of many reactions which seem to us at the present time to be well studied.

IV. Donor-acceptor interactions and polymer structure

The donor-acceptor interactions which exist in the reaction system not only govern the kinetic mechanism of the process but also can affect the structure of the resulting polymer in individual cases. Thus, the topological structure of an epoxyamine cross-linked polymer depends to a considerable extent on the occurrence of ineffective cyclisation reactions during its derivation, which lead to the formation of so-called monocycles that in the final analysis reduce the concentration of elastically active chains of the network.[13,15,31,44] The proportion of such ineffective rings is

determined by the ratio of rate constants of intra- and inter-molecular reactions, which in turn depends on the ratio of intra- and inter-molecular hydrogen bonds in diepoxides.

It has been shown in a considerable number of studies[13–16,31,43,76–82] that the *o*-diglycidyl esters of diphenols or *o*-diglycidyl esters of aromatic dicarboxylic acids and also *N*-diglycidylamines have a considerable tendency to form ineffective rings. An important factor that assists the development of ineffective rings in these cases is the formation of a strong intramolecular bond in the products of the primary addition of amine to diepoxide, resulting in activation of the neighbouring epoxide group. The effect of increased reactivity of these diglycidyl ethers and the positive effect of substitution in these monomers are precisely related to this phenomenon.[13,43,44]

The formation of cross-linked polymers with a defect topological structure naturally has an effect on their physical and mechanical properties in the hyperelastic and vitreous states.[77–82] A number of interesting observations about the effect of donor-acceptor interactions on the structure and properties of the polymers formed are made in two studies concerning the processes for formation of polyurethanes.[83,84]

Thus, donor-acceptor interactions between the components of a reaction system during polycondensation processes to a considerable extent determine the reactivity of the resulting homo- and hetero-associates and, as a result, the mechanism of the fundamental stages of condensation and the kinetics of the process. In three-dimensional polycondensation, donor-acceptor interactions can have an effect on reactions leading to intramolecular cyclisation, resulting in the formation of ineffective rings, and hence on the structure and properties of the resulting cross-linked polymers.

Nontraditional methods of synthesising metal-containing polymers

A D Pomogailo, V S Savost'yanov
Branch Institute of Chemical Physics, USSR Academy of Sciences
Associated Institute of Energy Problems of Chemical Physics, USSR Academy of Sciences

ABSTRACT. Complexes of metals with (meth)acrylates and acrylamides are used as examples for examining the application of nontraditional methods for initiating polymerisation of metal-containing monomers: graft, low-temperature, electrochemical, matrix, solid-state (under high pressure with shear deformation), frontal and spontaneous. Such approaches are demonstrated to be very effective for preparing metal-containing polymers with a wide sprectrum of relative molecular masses and with different solubility and stereotacticity. A bibliography containing 39 citations is included.

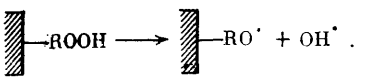
I. Introduction

The synthesis and polymerisation of metal-containing monomers (MCM) has recently advanced at such a rapid pace owing to the efforts of scientists in many countries that a new scientific discipline has formed. It is characterised by novel compositions, methods for their polymerisation, and new approaches to studying the structure of the metal-containing polymers formed.[1-3] The ever increasing interest in such polymers is due to their unusual properties, which are determined not only by the metals in them but also the nature of the polymer matrix. The products of MCM polymerisation are composites with new physicomechanical and operating properties, catalytically and biologically active macromolecules, etc.

Furthermore, considerable attention has been given to polymerisation of MCM by traditional methods (primarily polymerisation in solutions with an initiator, usually a radical, at elevated temperatures). Besides difficulties in choosing a suitable solvent and initiator (which might react with the MCM), problems arise with separating the polymer and removing from it residues from the reaction mixture.



This has led to numerous investigations on nontraditional methods of MCM polymerisation. It was expected that the structures and properties of MCM would facilitate successful application of these methods. Indeed analysis of the data obtained indicates that nontraditional methods of polymerisation have to a large extent been used with nontraditional monomers (MCM are undoubtedly in this class).

Let us recall that MCM are compounds containing an organic moiety with a reactive multiple bond capable of undergoing addition and a metal-containing group chemically bonded to it.[1-3] All MCM can be divided into four groups: monomers with covalent, ionic, donor–acceptor, and π-bonds between the metal and organic part. However, the principal achievements in application of nontraditional methods have involved two groups of MCM: ionic, e.g. metal (meth)acrylates $M(OCOCR=CH_2)_n$ ($R = H$ or CH_3, n is the metal valence), and donor-acceptor, e.g. metal complexes of acrylamides (AAm) $M(H_2NCOCH=CH_2)X_n(H_2O)_p$ ($p = 0$ or 2).

Let us examine the principal nontraditional methods of initiating polymerisation of such MCM.

II. Graft polymerisation of MCM

Graft polymerisation is an effective method for preparing metal-containing polymers that combine properties of the starting polymeric support (film, fibre, powder, etc.) and the grafted polymer. Radiation grafting of MCM, in which the polymer–support is previously irradiated in the presence of oxygen from air, is the most effective approach. This forms hydroperoxide (HP) groups on the surface of the polymer. These can then initiate grafting under the appropriate conditions:

Thus, boiling a suspension of irradiated polyethylene (PE) powder in an alcoholic solution of MCM produces graft polymerisation of acrylates containing the transition metals Cr^{III}, Fe^{III}, Co^{II}, Ni^{II}, and Cu^{II}.[4,5] A distinguishing feature of the grafting of these MCM is the almost complete absence of the homopolymer. Graft polymerisation of potassium acrylate gave 30% homopolymer. A redox-active metal clearly hinders initiation of polymerisation. The kinetic dependences of the process are the same for all acrylates studied. In the first 0.5 h the rate is maximal. It then rapidly drops (Fig. 1). It is interesting that acrylates of divalent metals graft at higher rates than those of trivalent ones. The activity of the acrylates changes in the following order: $Co^{II} > Cu^{II} > Ni^{II} > Cr^{III} > Fe^{III}$. Grafting of Cu^{II} acrylate is characteristically rather effective, in contrast with polymerisation of this MCM in solution. This is obviously due to adsorption of the metal acrylate on the surface of the hydrophobic polymeric support.

The initial rate of graft polymerisation w_0 for all acrylates studied is practically constant for 0.04–0.40 *M* MCM in alcohol. The existence of a limiting rate is probably due to the attainment of a limiting [MCM] on the PE-powder surface. The adsorption isotherm of Co^{II} acrylate confirms this hypothesis (Fig. 2). The amount of adsorbed monomer increases with increasing [acrylate] in solution and reaches the limiting value corresponding to coverage by a monolayer.

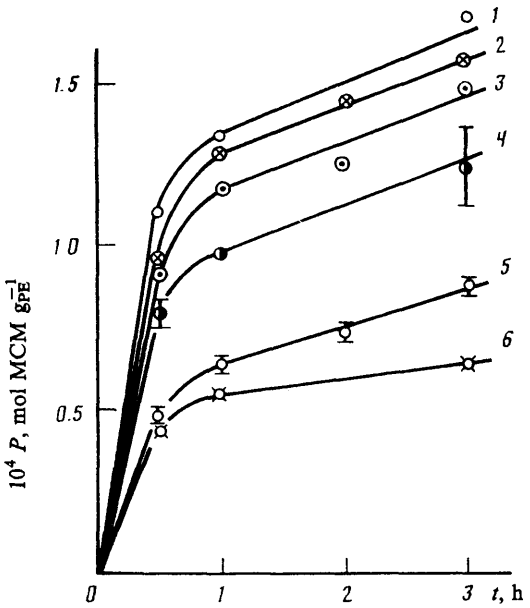


Figure 1. Kinetic curves for yield (*P*) of grafted metal acrylate polymer: *1,3*, Co^{II}; *2*, Ni^{II}; *4*, Cu^{II}; *5*, Cr^{III}, Fe^{III}. The solvent is alcohol. [MCM] = 0.04 mol dm^{-3}, *T* = 79 °C. *1,2,5,6*, *D* = 200 kJ kg^{-1}; *3,4*, *D* = 100 kJ kg^{-1}; *1,3,4*, *I* = 2.8 J kg^{-1} sec^{-1}; *2,5,6*, *I* = 1.4 J kg^{-1} sec^{-1}.

The nature of the transition metal has a substantial influence on the grafting of acrylates. The dependence of the initial rate of grafting on [HP] in irradiated PE can be represented as follows: $w_0 \sim [HP]^{\alpha}$ with α = 0.7, 0.6, 0.5, 1.1 and 1.1 for grafting of Co^{II}, Ni^{II}, Cr^{III}, Cu^{II} and Fe^{III} acrylates, respectively. Such values for α are consistent with predominantly bimolecular termination of the growing chains for Co^{II}, Ni^{II} and Cr^{III} and monomolecular for Cu^{II} and Fe^{III}. The special behaviour of various types of MCM based on Cu^{II} and Fe^{III} has been noted in many other instances[3] and was explained by the increased probability of monomolecular chain termination involving Cu^{II} and Fe^{III}.

Grafting of metal acrylates is characterised by low activation energy E_a from 42 to 55 kJ mol^{-1}. The rate of polymerisation also depends weakly on the presence of radical inhibitors.

The observed dependences are probably general in nature and can be used to examine graft polymerisation of other MCM. Indeed it has been demonstrated that the kinetic curves for grafting of metal chelates of monomers, complexes of metal acrylates with 2,2′-bipyridyl and 1,10-phenanthroline, are analogous.[6] The order of activity for the metals is the same as found in graft polymerisation.

Graft polymerisation after irradiation has been investigated for AAm complexes of metal chlorides and nitrates under conditions analogous to those for acrylates.[5,7] Like for the acrylates, the amount of homopolymer of these MCM in the polymeric products was insignificant. It was 4–8 times less than for grafting of the metal-free analogue, AAm. The only exception was $MnCl_2$, the rate of thermal homopolymerisation of which surpasses that of grafting.

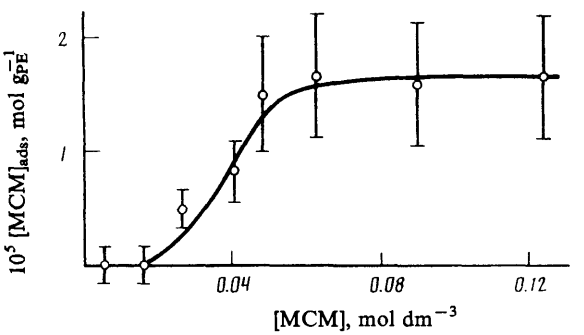

Figure 2. Adsorption isotherm of Co^{II} acrylate on PE powder: MCM in alcohol (15 dm^3), 5 g PE, *D* = 200 kJ kg^{-1}, *I* = 2.8 J kg^{-1} sec^{-1}, *T* = 22 °C.

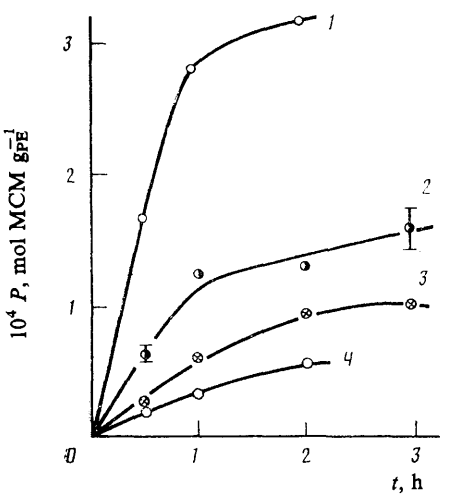

Figure 3. Kinetic curves of yield of grafted polymers of AAm complexes: *1*, $Cr(AAm)_4Cl_3$; *2*, $Co(AAm)_4Cl_2$; *3*, $Ni(AAm)_4Cl_2$; *4*, $Co(AAm)_4(H_2O)_2(NO_3)_2$. In alcohol, [MCM] = 0.1 mol dm^{-3}, *T* = 80 °C, *D* = 200 kJ kg^{-1}, *I* = 1.4 J kg^{-1} sec^{-1}.

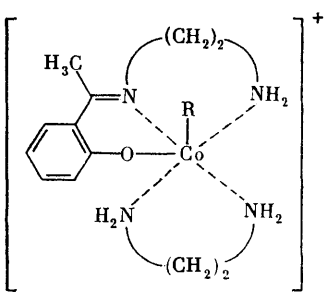

In contrast with graft polymerisation of metal acrylates, the rate of grafting of AAm complexes of metal chlorides varies as follows: Cr^{III} > Co^{II} > Ni^{II} (Fig. 3). This order is opposite that of the metal ion electronegativities. The nature of the anion of the complexant also has a significant effect. Graft polymerisation of

$Co(AAm)_4(H_2O)_2(NO_3)_2$ proceeds with a rate almost three times less than that of $Co(AAm)Cl_2$. Complexes of Cu^{II} with AAm are typically inactive in graft polymerisation.

The rate of grafting of AAm complexes of metals is proportional to [MCM] in solution whereas for grafting of uncoordinated AAm $w_0 \sim [AAm]^{1.7}$. Graft polymerisation of AAm and its complexes is characterised by monomolecular chain termination. The E_a for the complexes $Co(AAm)_4Cl_2$ and $Ni(AAm)_4Cl_2$ are 51 and 60 kJ mol^{-1}, respectively. As in graft polymerisation of acrylates, radical inhibitors had little effect on the reaction of AAm complexes. This is probably due to formation of complexes of the inhibitors with MCM.

III. Low-temperature radical polymerisation

It is difficult to choose an initiator for free-radical polymerisation of MCM at low temperatures. As a rule, traditional initiators are used at elevated temperatures and the redox systems used at low temperatures can lead to side reactions. Therefore, organometallic compounds capable of acting as low-temperature radical initiators are of great interest. For instance, cationic Co^{III} complexes such as

$R = CH_3$, C_2H_5, C_3H_7.

can undergo homolytic cleavage of the Co–R bond.[8] This was used to initiate low-temperature polymerisation of $M[OCOCH=CH_2]_2$, where M = Zn^{II}, Mg^{II}, Pb^{II} and Ba^{II} in methanol.[9] The overall scheme taking into account partial dissociation of the monomer and participation of $[MOCOCH=CH_2]^+$ in the decomposition of the complex can be represented as follows:

$$RCo \xrightarrow{[M(OCOCH=CH_2)]^+} R^{\cdot},$$

$$CH_2=CH + R^{\cdot} \longrightarrow {\sim}CH_2{-}\underset{\displaystyle COOM(OCOCH=CH_2)}{\underset{|}{CH}}{\sim}$$

$$\underset{\displaystyle COOM(OCOCH=CH_2)}{\underset{|}{CH_2=CH}}$$

The kinetics of polymerisation, in addition to the complete inhibition by radical traps, confirm that the process is radical in nature. Such initiators enable polymerisation to be carried out at comparatively low temperatures (from –20 to 10 °C) at sufficiently high rates. The products produced under such conditions are expected to have high relative molecular masses (stereotactic structures may also form).

Another possible method for initiating low-temperature radical polymerisation is irradiation. The post-irradiation polymerisation method has become widespread. The matrix is vitrified, transforming the system from a glass to a supercooled liquid.[10] In a number of instances the process occurs at high rates and the yield of polymers is quantitative. This is due to the sharp change of molecular mobility during phase transitions.

On cooling to –196 °C, Co^{II}, Ni^{II}, Cr^{III}, Mn^{II} and Cu^{II} acrylates in 10% alcohol are completely vitrified. On warming up they devitrify and, with the exception of Ni^{II} acrylate, crystallise and melt (Table 1).[11] On warming up Ni^{II} acrylate that had been vitrified and irradiated at –196 °C in a calorimeter, an exotherm associated with MCM polymerisation is observed immediately after the devitrification step (Fig. 4). The polymer forms a separate phase. As a result, the concentration of monomer decreases. This produces on the calorimetric heating curve an exotherm for crystallisation and an endotherm for melting in addition to the exotherm for polymerisation.

Table 1. Phase-transition temperatures of 10% acrylate salt solutions in ethanol.[11]

Metal acrylate	T_v, °C	T_{cr}, °C	T_m, °C
Ni(II)	–173	–	–
Co(II)	–173	–138	–118
Cu(II)	–171	–143	–118
Mn(II)	–171	–138	–118
Cr(II)	–171	–138	–118

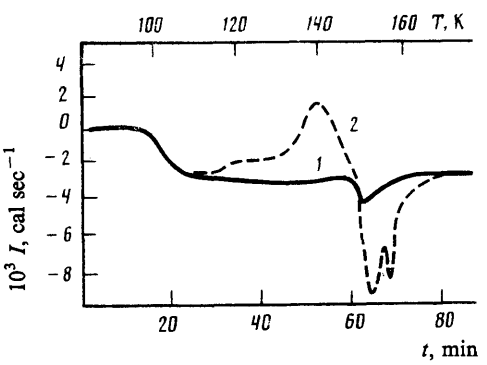

Figure 4. Calorimetric heating curve of 10% Ni^{II} acrylate in alcohol before (*1*) and after (*2*) irradiation. D = 100 kJ kg^{-1}, T = –196 °C.

Post-irradiation polymerisation of AAm complexes of Co^{II} and Ni^{II} chlorides and nitrates proceeds analogously (Fig. 5). It is noteworthy that the calorimetric heating curves of unirradiated MCM differ from the classical curves for the vitreous state. This may be due to the formation and rearrangement of different complexes of the MCM with ethanol. The yield of polymer in this instance reaches 45%. The relative molecular mass was low, $\overline{M}_\eta$ = 5600 (for comparison, $\overline{M}_\eta$ = 8700 for polyacrylamide prepared by polymerisation of AAm under analogous conditions).

Investigation of polymers formed by devitrification of irradiated alcohol matrices revealed that syndiotactic structures are primarily formed. For example, polyacrylic acid prepared by hydrolysis of the product of polymerisation of Co^{II} acrylate contains up to 60% of

the syndiotactic fraction (Table 2). However, the corresponding fraction obtained by polymerisation of acrylic acid under the same conditions gave ony 25–30%.

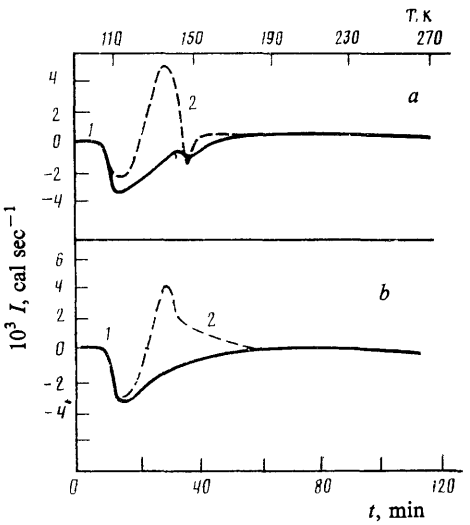

Figure 5. Calorimetric heating curves of 10% $Ni(AAm)_4Cl_2$ (*a*) and $Co(AAm)_4(H_2O)_2(NO_3)_2$ (*b*) in alcohol before (*1*) and after (*2*) irradiation. D = 100 kJ kg^{-1}, I = 100 kJ kg^{-1} h^{-1}, T = –196 °C.

Table 2. Fractional composition of PPA prepared by polymerisation of acrylic acid and isolated from the polymerisation product of Co^{II} acrylate.[11]

Fraction	Selective solvent	Fraction, %	
		PAA	PAA(Co)
Syndiotactic	Dioxane–water (80:20 vol.%)	25–30	45–60
Atactic	Dioxane	60–65	10–20
Insoluble gel	—	10–15	20–30

IV. Solid-state polymerisation under high pressure with shear deformation

Polymerisation under high pressure with shear deformation is performed in a Bridgman anvil cell. It is very effective for converting solid monomers,[12] among which MCM are one of the most interesting. Metal acrylates are so reactive in this process that high degrees of conversion are attained even at pressures from 500 to 1000 MPa and anvil rotation angles from 100 to 200° (Fig. 6).[13,14]

The participation of metal ions in this process was suggested by investigations of the polymerisation of transition metal acrylates under analogous conditions. Thus, the Mössbauer spectrum of Fe^{III} acrylate treated at 2 GPa exhibits two doublets with (shift relative to SnO_2) δ = 1.35 mm sec^{-1} and Δ = 2.22 mm sec^{-1} and δ = 1.44 mm sec^{-1} and Δ = 2.62 mm sec^{-1} (Fig. 7, curves *3* and *4*) in addition to the doublet from starting Fe^{3+} with δ = 0.76 mm sec^{-1} and Δ = 0.65 mm sec^{-1} (Fig. 7, curve *1*).[15] Comparison of Mössbauer spectra of Fe^{3+} and Fe^{2+} demonstrated that the new lines in the spectra of Fe^{III} acrylate that appear after treatment under pressure correspond to Fe^{II} acrylate.

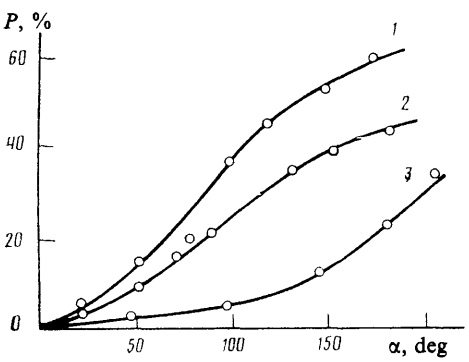

Figure 6. Polymer yield as a function of anvil rotation angle α under high pressure with shear deformation. Pressure, 160 MPa. Metal acrylate monomers: *1*, Ba^{II}; *2*, Pb^{II}; *3*, Zn^{II}.

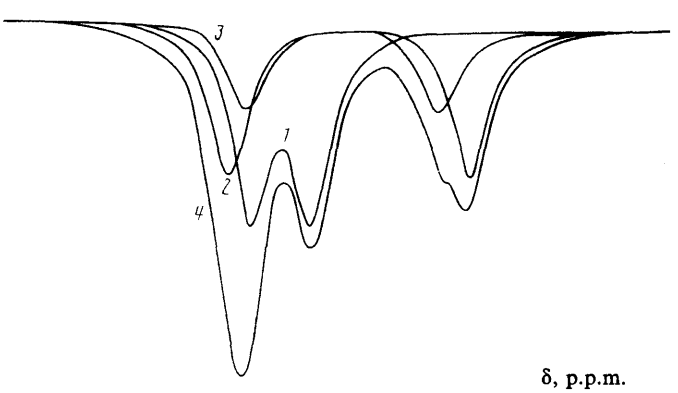

Figure 7. Mössbauer spectra of Fe^{III} acrylate: *1*, before treatment; *2,3*, doublet arising after treatment; *4*, summed spectrum after treatment. Pressure, 2 GPa; anvil rotation angle, 100–200 °C.

As vinyl monomers polymerise during plastic flow under pressure, the flow resistance increases as polymer accumulates.[12] This effect can be used for direct evaluation of the reactivity of monotypic monomers. The flow resistance (σ) as a function of deformation (anvil rotation angle α) for several AAm complexes is plotted in Fig. 8.[16] The data show that the greatest change occurs for $Co(AAm)_4Cl_2$; the least, for $Cu(AAm)_4(NO_3)_2$. The unusual nature of the function for $Fe(AAm)_4(NO_3)_3$ is noteworthy. The AAm complexes can be placed in the following order of

reactivity on the basis of the functions obtained: $Co(AAm)_4Cl_2$ > $Co(AAm)_4(H_2O)_2(NO_3)_2$ > $Ni(AAm)_4(H_2O)_2(NO_3)_2$ > $Mn(AAm)_4$. $.(H_2O)_2(NO_3)_2$ > $Cu(AAm)_4(NO_3)_2$.

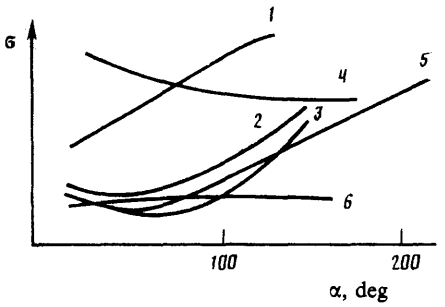

Figure 8. Dependence of flow resistance on deformation for AAm complexes: *1*, $CoCl_2$; *2*, $Co(NO_3)_2$; *3*, $Ni(NO_3)_2$; *4*, $Fe(NO_3)_3$; *5*, $Mn(NO_3)_2$; *6*, $Cu(NO_3)_2$.

This method can also be applied to copolymerisation of MCM. Thus, copolymerisation of acrylates and of AAm complexes of Y^{III}, Ba^{II} and Cu^{II} nitrates is effective.[17] It is noteworthy that high pressure with shear deformation is the only method for introducing into the copolymer MCM based on Cu^{II}, which are usually unreactive in polymerisation. The synthesised ternary copolymers were used as polymeric starting materials for preparing high-temperature superconducting ceramics with good properties.

V. Electrochemical polymerisation

Electrochemical polymerisation of MCM is a unique method for preparing films containing redox centres in each repeating unit. The redox conductivity enables the film to grow continuously since its exterior is active in electron transfer at the film–solution interface.

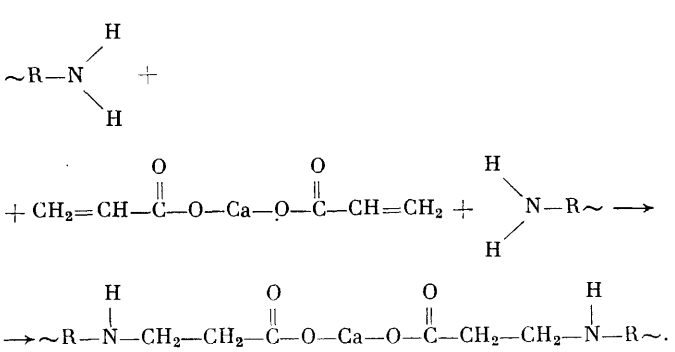
Electrochemical polymerisation can be examined in more detail using the rather numerous mixed-ligand complexes of Ru^{II}, Os^{II} and Fe^{II} perchlorates and hexafluorophosphates as examples.[18–21] The ligands used were 4-vinylpyridine, other more complicated monomers containing pyridine, derivatives of cinnamates, stilbazole, etc., in addition to unsubstituted polypyridyl ligands (2,2′-bipyridyl, 2,2′,2″-terpyridyl, 1,10-phenanthroline, etc.).

The polymerisation was carried out in 0.1 M tetraethylammonium perchlorate in CH_3CN by repeated cycling of a Pt electrode near the reduction potential of the ligand. Homogeneous even polymer films were formed. For the majority of investigated MCM, the first step of electrochemical polymerisation is formation of the anion–radical by electron transfer into the π^*-orbital of the unsubstituted ligand.

$$[Ru(bipy)_2L_2]^{2+} \overset{+e^-}{\rightleftharpoons} [Ru(bipy)(bipy)^{\cdot-})L_2]^{+} \overset{+e^-}{\rightleftharpoons} [Ru(bipy)^{\cdot-})_2L_2]^{0}.$$

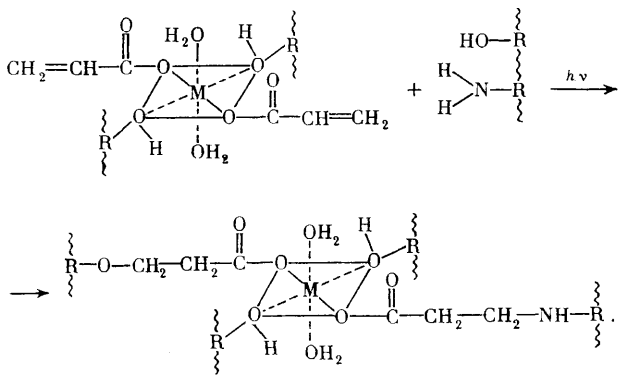
An electron then transfers onto the substituted ligand either by an intramolecular mechanism or by disproportionation. Repetition of these reactions produces the polymer.

Electrochemical polymerisation of complexed AAm is of great interest. However, the majority of studies have been performed using transition metal chlorides such as $ZnCl_2$ and $AlCl_3$.[22–24] Therefore, polymerisation of AAm in aqueous solutions using nitrates, perchlorates and sulphates is impossible. However, effective electrochemical polymerisation of AAm in nonaqueous media in the presence of Co^{II} nitrate and perchlorate was recently reported.[25] The reaction was carried out in DMF, from which the polymer precipitated, and DMSO, in which the reaction mixture remained homogeneous. The rate in DMSO was an order of magnitude greater than that in DMF. The kinetic equation has the following form:



$$w_p = K[AAm]^{1.5}[Co(NO_3)_2]I^{0.5}.$$

This dependence was explained by assuming that two types of monomers, free AAm and that complexed to Co^{II} nitrate, simultaneously participate in chain growth. This was confirmed by the comparatively small amount of $Co(NO_3)_2$ in the polymer, 6–10 mass%. The process can produce polyacrylamide of very high relative molecular mass, greater than 2 500 000. The reaction is inhibited by *p*-benzoquinone, indicative of the radical nature of the process. It is interesting that polymerisation does not occur in the presence of Co^{II}. Most likely this suggests that participation of nitrate in initiation of the process has not been considered.[25]



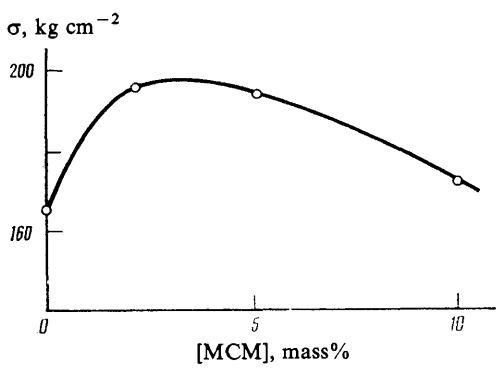
VI. Matrix polymerisation

Polymerisation of MCM in the matrix of a different polymer or compound can lead to dramatic modification of the properties of various materials. Various methods are possible. Among these, polymerisation in the polymer melt is one of the most effective. Thus, polymerisation of acrylates and AAm complexes of Zn^{II} and Ni^{II} nitrates in a high-density PE melt was investigated.[26] The MCM were added to the polymer as a solution in methanol. The mixture was polymerised in a press-form for 5 min at 190 °C and 15 MPa. It was found that adding even 0.5 mass% Zn^{II} acrylate to the PE completely stops the flow at 190 °C. However, adding 10 mass% MCM increases the melting point from 131 to only 135 °C. The crystallinity of the polymer does not change. This is consistent with crosslinking of the amorphous PE during polymerisation of the acrylate. Crosslinking of a polymer is characterised by a sharp drop of the relative expansion (for 0, 2, 5 and 10 mass% Zn^{II} acrylate, its value is 790, 20, 10 and 2%, respectively). The tensile strength of the modified polymer is maximal for 2–5 mass% MCM (Fig. 9).

Interesting results were obtained during investigations of laser-induced polymerisation of Ca^{II}, Co^{II}, Ni^{II} and Cu^{II} acrylates in a gelatin matrix.[27–29] Holographic information can be recorded using laser radiation by adding a metal acrylate to the gelatin matrix. The holograms produced in this manner diffract more efficiently and have better resolution than ordinary holograms. Crosslinking of gelatin by Ca^{II} acrylate can be represented as follows:

The analogous process involving transition metal acrylates is more complicated and includes preliminary formation of macrocomplexes of MCM and gelatin. This is confirmed by IR and electronic spectroscopy. The photochemically induced formation of structures from such complexes is represented by the following scheme:

The sensitivity to absorption of radiation by the macrocomplexes and the degree of crosslinking (number of double bonds reacted) depends on the nature of the transition metal: $Cu^{II} > Ni^{II} > Co^{II}$.



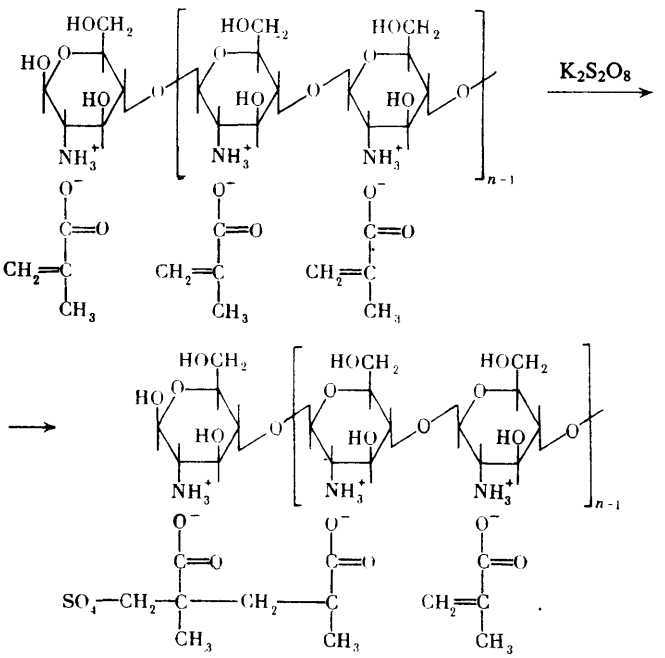


Figure 9. Dependence of tensile strength (σ) of the Zn^{II} polymerisation product in high density PE melt on MCM content.

Matrix effects were detected during an investigation of the polymerisation of aqueous sodium methacrylate in the presence of chitosan acetate (mole ratio chitosan : MCM = 1 : 1) initiated by $K_2S_2O_8$.[30] The rate is described by: $w_p = K[M]^{0.8}[K_2S_2O_8]^0$ up to $[K_2S_2O_8] < 3.5 \times 10^{-3}$ mol dm^{-3} and $w_p = K[M]^{0.8}[K_2S_2O_8]^{1.8}$ for $[K_2S_2O_8] > 3.5 \times 10^{-3}$ mol dm^{-3}. However, w_p changes linearly with initiator concentration in the presence of a chitosan analogue with a low relative molecular mass, glucosamine hydrochloride. The relative molecular mass of the sodium polymethacrylate increases linearly with conversion. The polymerisation is distinguished by a rapid initiation and continuous nature. The polymer contains only one SO_4 group per chain. These data are consistent with the following scheme for matrix polymerisation of MCM owing to inclusion of acrylate bound through ionic and hydrophobic bonds to the polymeric chain of chitosan residues:

VII. Frontal polymerisation in the melt

During an investigation of the properties of $M(AAm)_4 \cdot (H_2O)_2(NO_3)_2$, where M = Mn^{II}, Co^{II}, Ni^{II} and Zn^{II}, it was unexpectedly discovered that these monomers readily undergo polymerisation in a self-propagating (frontal) regime without addition of any initiators or activators.[31] In the frontal polymerisation method, the bottom of the vessel containing the MCM is briefly heated. After the "ignition" is stopped, the boundary where the substance changes colour, the polymerisation front, continues to advance of itself. This effect is the first documented instance of thermally initiated frontal polymerisation. The reaction proceeds under the most mild conditions of any known for such processes: monomer powders pressed at low pressures, the lack of specially added initiator or activator, comparatively low ignition temperature temperatures (120 – 180 °C), and a reaction at normal pressure. The dependences of the front advance rate during polymerisation of $Co(AAm)_4(H_2O)_2(NO_3)_2$ on time from the moment of ignition for various ignition temperatures are plotted in Fig. 10. It is clear that the kinetic functions consist of two parts corresponding to the nonequilibrium and steady-stage regimes of polymerisation front advance. Depending on the ignition temperature, the rate before equilibrium is reached can be higher or lower than the steady-state rate w_{fr}.

Addition of radical inhibitors has a significant influence on frontal polymerisation. Addition of 2,2,4,4-tetramethylpiperidine-1-oxyl to the polymerising system practically linearly decreases w_{fr}. At inhibitor concentrations $\geqslant$ 0.1 mass%, the frontal process is completely stopped. The effective inhibition is consistent with a radical mechanism for thermally initiated frontal polymerisation. An estimate of the number of active centres gives a value less than 3.0×10^{-3} mol per mol of MCM.

A study of the influence of the nature of the metal on the rate of frontal polymerisation of $M(AAm)_4(H_2O)_2(NO_3)_2$ demonstrated that w_{fr} decreases in the order $Co^{II} > Ni^{II} > Mn^{II} > Zn^{II}$.

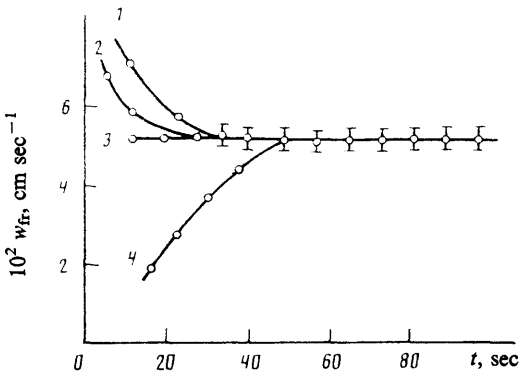

Figure 10. Dependence of front advance rate during polymerisation of $Co(AAm)_4(H_2O)_2(NO_3)_2$ on ignition temperature and process time. Diameter of sample container d = 4 mm, p = 1.02 g cm^{-3}. Ignition temperature, °C: *1*, 300; *2*, 250; *3*, 180; *4*, 120.

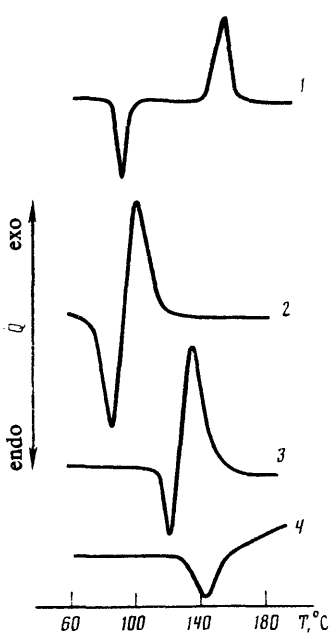

Figure 11. DSC curves of acrylamide and its complexes: *1*, AAm; *2*, $Co(AAm)_4(H_2O)_2(NO_3)_2$; *3*, $Cu(AAm)_4(NO_3)_2$; *4*, $Ni(AAm)_4Cl_2$.

It should be emphasised that frontal polymerisation has been detected only for AAm complexes of Mn^{II}, Co^{II}, Ni^{II} and Zn^{II}. Uncoordinated AAm, AAm complexes of Cu^{II} and Fe^{III} nitrates and transition metal chlorides, bromides and perchlorates, and the complex of 4-vinylpyridine with Co^{II} under analogous conditions do not polymerise in spite of a wide variation of the process parameters. Therefore, this is a unique property of the AAm complexes of Mn^{II}, Co^{II}, Ni^{II} and Zn^{II} nitrates, analogues of which have not yet been found.

Thermal polymerisation of these MCM was investigated by differential scanning calorimetry (DSC). The process was demonstrated to proceed at a high rate with participation of all four unsaturated AAm ligands. The yield of polymer reaches 100%.[32] The reaction occurs at unexpectedly low temperatures (80–100 °C). It characteristically occurs close to the melting point of the complex (Fig. 11, curve *2*). However, heating $Cu(AAm)_4(NO_3)_2$ and $Fe(AAm)_4(NO_3)_3$ effectively oxidises the organic part of the AAm complex. This is apparently initiated by nitrate decomposition (Fig. 11, curve *3*).

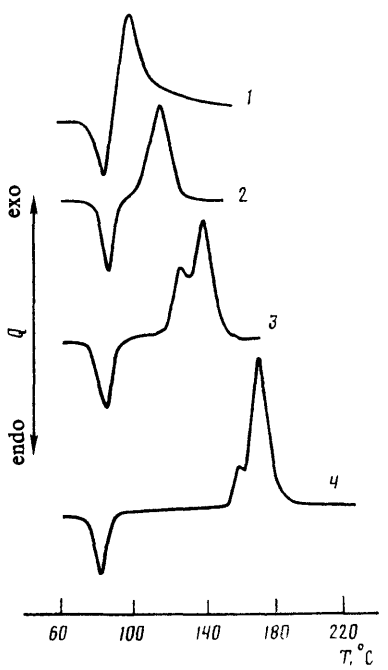

Figure 12. DSC curves of $Ni(AAm)_4(H_2O)_2(NO_3)_2$ with various amounts of 2,2,4,4-tetramethylpiperidine-1-oxyl, mass%: *1*, 0 (no inhibitor); *2*, 0.35; *3*, 0.9; *4*, 8.5.

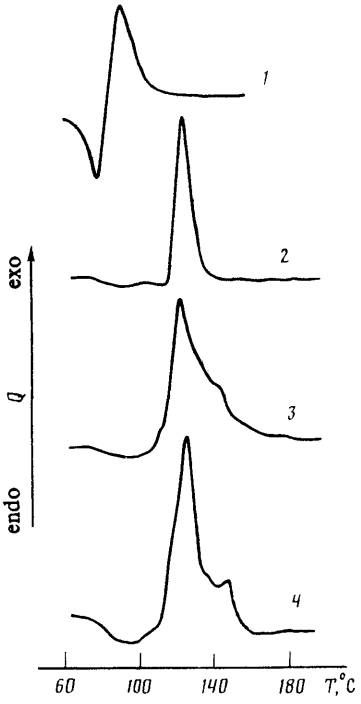
Addition of radical inhibitors to $Ni(AAm)_4(H_2O)_2(NO_3)_2$ prevents polymerisation close to the melting point of the MCM (Fig. 12). However, extensive nitrate decomposition occurs at certain inhibitor concentrations ($\geqslant$0.9 mass%) with oxidation of the organic part of the complex. The two exotherms (Fig. 12, curves *3* and *4*) can probably be explained by two processes, partial polymerisation (the low-temperature peak) and nitrate decomposition with oxidation of the organic part of the complex (high-temperature peak).

It was concluded that Mn^{II}, Co^{II}, Ni^{II}, Zn^{II}, Cu^{II} and Fe^{III} nitrates in monomeric AAm complexes are thermally unstable at

temperatures above 130 °C. However, these complexes, which are incorporated into the polymer matrix during polymerisation, remain stable up to 200 °C, i.e. the polymer matrix to a large extent prevents their decomposition.

It is interesting that AAm complexes of Mn^{II}, Co^{II}, Ni^{II} and Zn^{II} nitrates can undergo thermal copolymerisation with other monomers. Thus, AAm complexes effectively copolymerise with uncoordinated AAm (Fig. 13). At ratios [AAm]:[MCM] < 4, thermal copolymerisation is seen in the thermogram as a single peak (Fig. 13, curve *2*), like for the starting complex (Fig. 13, curve *1*). At [AAm]:[MCM] > 4, the polymerisation region in the thermograms appears as a high-temperature shoulder apparently owing to polymerisation of uncoordinated AAm (Fig. 13, curve *4*).



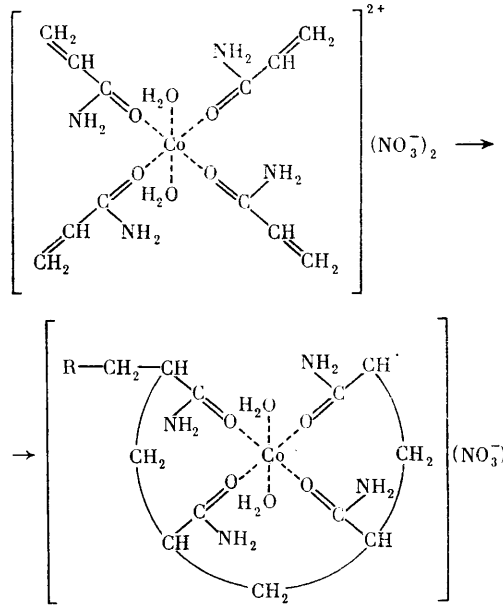


Figure 13. DSC curves of $Ni(AAm)_4(H_2O)_2(NO_3)_2$ and AAm mixtures. [AAm]:[MCM] ratio: *1*, 0; *2*, 2.0; *3*, 4.0; *4*, 7.1.

Elemental analysis of the frontal polymerisation products showed that the polymers produced were practically identical to the starting MCM. The average relative molecular mass of the polyacrylamide isolated from polymeric AAm complexes of Co^{II} and Ni^{II} nitrates after removal of metal compounds was 9.88×10^5 and 4.14×10^5, respectively. This is 100 and 200 times greater than the relative molecular mass of the polymer obtained by radical-initiated polymerisation of $Co(AAm)_4(H_2O)_2(NO_3)_2$ in water.

The following scheme involving nitrate decomposition products was proposed for initiation of the process:

$$Co^{2+}(AAm)_4(H_2O)_2(NO_3^-)_2 \rightleftharpoons$$
$$\rightleftharpoons Co^{3+}O(AAm)_4(H_2O)_2(NO_3^-) \ldots (NO_2).$$

The high rate constant for polymerisation of AAm complexes of these metal nitrates is probably attained owing to a favourable steric position of the AAm molecules in the metal complex. Growth of the polymeric chain can be represented as follows:[33]

The polymeric chain seemingly twists around the four AAm groups of the complex. The chain is then apparently transferred to the next precursor.

VIII. Spontaneous polymerisation

The properties of AAm complexes of metal nitrates are not limited to the ability to undergo thermal polymerisation. Complexes of AAm with such metal nitrates as Cr^{III}, Bi^{III}, Pb^{II}, Ca^{II}, Er^{III} and Nd^{III} spontaneously polymerise in concentrated aqueous solutions even at room temperature during synthesis and cannot be isolated as monomers.[34,35] The water in the starting mixture is retained in the polymer formed. This enables the polymerisation process to be investigated using measurements of the relative permittivity of the system. As seen in Fig. 14, the relative permittivity of reaction mixtures based on AAm and Cr^{III} and Bi^{III} nitrates sharply decreases in the first 10–30 min after complex formation. After this both ε' (real part of the relative permittivity) and ε'' (imaginary part) change slowly.

The kinetics of spontaneous polymerisation were investigated by calorimetry.[36] The composition of the reaction mixture was found to have a substantial influence on the reaction. The kinetic curves plotted in Fig. 15 describe polymerisation of AAm in the presence of $Cr(NO_3)_3.9H_2O$ at various ratios [AAm]:[$Cr(NO_3)_3.9H_2O$]. In the majority of instances, they are analogous, with the exception of 5:1. Here the process occurs at a significantly higher initial rate and a more rapid decrease. A similar path of the curves (although less clearly evident) is observed on addition of a small amount of water (Fig. 15*b*). It can be proposed that the composition of the polymerising complex in this instance has the ratio [AAm]:[$Cr(NO_3)_3.9H_2O$] = 5:1.

It is interesting that the amount of heat released by polymerisation at 20 °C for 3–6 h after the start is only 20–25% of

the calculated value. This may indicate that a comparatively small fraction of the AAm molecules are activated at the start of the reaction. The process is finally finished only after 1–2 days at room temperature. The mixture is already solid. Therefore, its second step cannot be recorded but does become detectable at elevated temperatures where the rate of the process increases (Fig. 16). Thus, the reaction is practically completely finished after 2 h at 60 °C. Increasing the temperature further to 70 °C causes the nitrate to decompose with subsequent oxidation of the organic part of the complex.

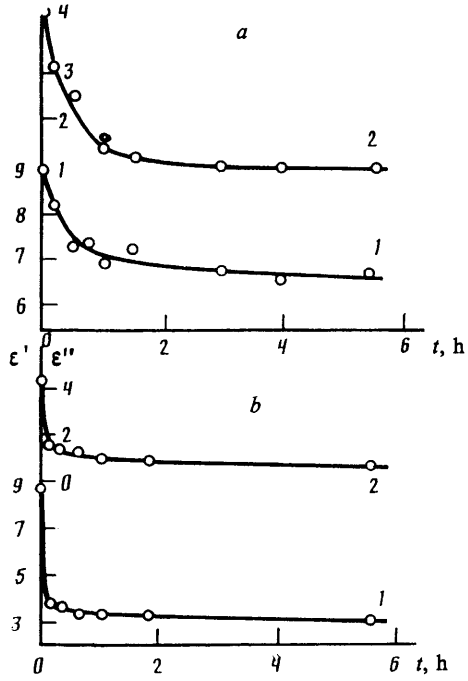

Figure 14. Dependence of change of relative permittivity ε′ (curve *1*) and ε″ (curve *2*) on time during spontaneous polymerisation in the systems [AAm]–[$Cr(NO_3)_3.9H_2O$] (*a*) and [AAm]–[$Bi(NO_3)_3.5H_2O$] (*b*). T = 20 °C. Mole ratio [AAm]:[$M(NO_3)_3.nH_2O$] = 5:1.

Investigation of the spontaneous polymerisation of AAm complexes of Cr^{III} nitrate in the presence of 2,2,4,4-tetramethylpiperidine-1-oxyl demonstrated that this process is radical in nature. The data were used to estimate the rate of initiation of the reaction, equal to 4×10^{-9} mol sec^{-1}. The dependence of the rate on the amount of water added to the system is rather unexpected. Practically the same effects are observed as adding an inhibitor to the system. The start of the reaction shifts. Its initial rate falls. The steric proximity of the polymerising complexes obviously is important for occurrence of spontaneous polymerisation.

Investigation of the properties of the product formed during spontaneous polymerisation of AAm–$Cr(NO_3)_3.9H_2O$ revealed that it contains two fractions. One of these dissolves in water at room temperature, the other does not. The insoluble part is practically pure (without metal compounds) polyacrylamide. It can be assumed that a gigantic molecular polymer forms during spontaneous polymerisation.

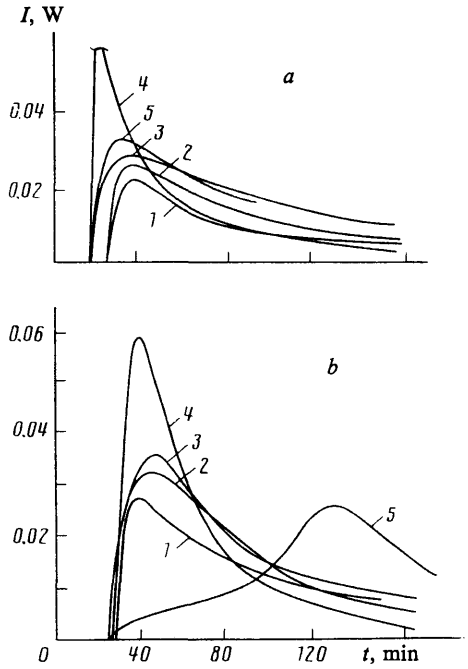

Figure 15. Dependence of rate of heat release on time of spontaneous polymerisation of AAm in the presence of $Cr(NO_3)_3.9H_2O$ with reaction mixtures of various composition: *a*) 20 °C, 0.516 g AAm; [AAm]:[$Cr(NO_3)_3.9H_2O$] ratio: *1*, 2.0; *2*, 3.0; *3*, 4.0; *4*, 5.0; *5*, 6.0. *b*) 20 °C, 0.516 g AAm, 0.10 dm^3 H_2O; [AAm]:[$Cr(NO_3)_3.9H_2O$] ratio: *1*, 3.0; *2*, 4.0; *3*, 5.0; *4*, 6.0; *5*, 8.0.

Addition of other comonomers opens broad possibilities for regulating the properties of the product formed during spontaneous polymerisation of coordinated AAm. This ability was demonstrated using AAm–$Cr(NO_3)_3.9H_2O$–CH_2=CH–CO_2H as an example. Spontaneous polymerisation is slower than homopolymerisation. The reaction is finished only after 5–7 days. However, the product is stronger. The ability to prepare copolymers of the AAm complex of metal nitrates with *N,N*-methylene-*bis*-acrylamide, methacrylic acid and *N*-vinylpyrrolidone has also been demonstrated.

The mechanism of spontaneous polymerisation of AAm complexed with metal nitrates is still largely unclear. However, the fact that the reaction occurs only using the nitrate salts suggests that nitrate is involved in the initiation.

In contrast with the example examined above, spontaneous polymerisation in DMF of vinylazoles complexed with $MnCl_2$, Mn(vinylbenzimidazole)$_2Cl_2$ and Mn(vinylbenztriazole)$_2Cl_2$, stopped after 15% conversion of MCM.[37] The reaction was inhibited by *p*-benzoquinone. Its occurrence depended strongly on the presence in the system of oxygen from air. The reaction rate increased significantly on saturation of the reaction mixture with oxygen. In

the absence of oxygen spontaneous polymerisation was not observed. It was proposed that the reaction is initiated by Mn^{3+} formed by partial oxidation of Mn^{2+}. Manganese(III) coordianted to DMF can probably be reduced by vinylazole to generate radicals that initiate spontaneous polymerisation.

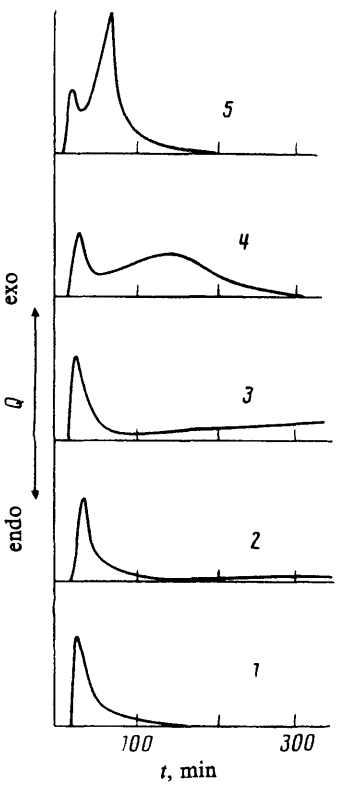

Figure 16. Dependence of rate of heat release on time of spontaneous polymerisation of AAm in the presence of $Cr(NO_3)_3.9H_2O$ at various reaction temperatures, °C: *1*, 20; *2*, 30; *3*, 40; *4*, 50; *5*, 60. m_{AAm} = 0.516 g, $m_{Cr(NO_3)_3.9H_2O}$ = 0.574, [AAm]:[$Cr(NO_3)_3.9H_2O$]= 5:1.

IX. Photopolymerisation with an applied magnetic field

A recent patent[38] claiming photopolymerisation of uranyl acrylate in alcohol with simultaneous application of a high-intensity magnetic field (10 kG) is extremely interesting. As it turned out, the process occurred at a disproportionately greater rate for ^{235}U than for ^{238}U. The insoluble polymer obtained in this way contained up to 50% of the former isotope (natural abundance ^{238}U, 99.3%; ^{235}U, 0.7%). Photopolymerisation typically did not occur without the magnetic field. This was related to the magnetic properties of the U isotopes, including the magnetic dipole of ^{235}U. Therefore, polymerisation of uranyl acrylate can be used to separate U isotopes. It should be noted that this is still the only example where the isotopic composition of the metal in the monomer affects the polymerisation properties of the MCM.

X. Conclusion

A large variety of nontraditional methods have been used to polymerise ionic and donor–acceptor MCM. It is noteworthy that the polymerisation properties of metal (meth)acrylates have been studied rather well. Nevertheless, involvement of such monomers in polymerisation by nontraditional methods enables their polymerisation properties to be more fully described. With respect to acrylamide complexes of metal nitrates, they have been practically ignored until recently. A recent surge of interest in polymerisation of complexes of traditional vinyl monomers with metal nitrates has been noted. This class of MCM is very interesting since the metal cation, the nitrate anion and the reactive double bond coexist in one molecule. Such symbiosis can lead to very unexpected effects, as evident from the material presented above. Hence, MCM based exclusively on metal nitrates participate in frontal and spontaneous polymerisation. It should also be noted that $M(NO_3)_3L_3$, where M = Fe^{III}, Cr^{III} and Co^{III} and L = vinylsulphoxide, can spontaneously explode during synthesis, storage or polymerisation to form oxides of N, S and metals and carbon-containing products.[39] The thermal explosion is caused by spontaneous polymerisation of spatially organised monomeric precursors formed by self-association of MCM through van der Waals and coordinative interactions.

Non-traditional approaches to synthesising metal-containing polymers recently have been extensively developed. This is due primarily to the desire to reduce the influence of extraneous factors that occur with traditional initiation. However, it should be remembered that a differentiated approach to the choice of MCM polymerisation method must be taken in order to account for the specific structures and properties.

Advances in the chemistry of metal chelate monomers

I E Uflyand, A D Pomogailo
Rostov State Pedagogical University
Branch Institute of Chemical Physics, USSR Academy of Sciences, Chernogolovka

ABSTRACT. This review covers the chemistry of metal chelate monomers. Depending on the bonding of the metal to the chelating group, all metal chelate monomers are divided into three main types: molecular chelates, inner-sphere compounds, and macrocyclic complexes. The data are systematised according to methods of preparing similar compounds. Special attention is paid to the specifics of homo- and co-polymerisation of metal chelate monomers. The principal applications of metal chelate monomers and polymers based on them are considered.

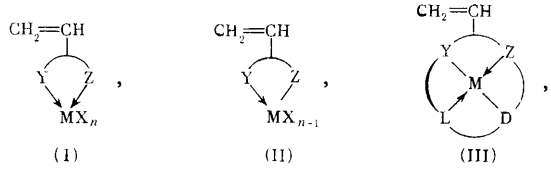
I. Introduction

Problems on the chemistry of macromolecular metal chelates (MMC) have attracted increasing attention over the last few years.[1–8] Polymeric chains and chelating rings are characteristic of MMC. The interest in such compounds is primarily due to their wide use as catalysts,[1–5,9–12] antifriction materials,[13–15] biologically active substances,[16,17] electrically conductive coatings,[18–22] etc. A large number of MMC have already been synthesised (MMC of practically all metals are known). Quantitative characteristics of chelate-formation processes involving polymeric ligands have been defined. Their principal structure features have been revealed.

However, the chelating systems are constructed, as a rule, in many steps including a whole series of successive conversions: the synthesis of the polymeric support, its functionalisation, creation of the chelating groups, synthesis and chelation of the metal complex, and separation of the chemically unbound components. Moreover, chelation in metal–polymer systems is significantly more complicated compared with low molecular weight analogues since both reagents can undergo a variety of reactions. The most important reactions of the transition metal during chelation are redox reactions, dissociation of dimeric complexes, cluster formation, etc. Destruction of the polymer, its conformational transitions, a change in the nature of the functional groups, etc. are also important. It is noteworthy that the compositional inhomogeneity of the MMC, a non-uniform distribution of metal ions on the polymeric support, different valence states, and the modes of coordination of the transition metals significantly affect the properties of the MMC.



In this respect, much of the attention of the last two decades has been directed toward the development of new methods for synthesising MMC. The most promising of these are polymerisation and copolymerisation of metal chelates of monomers (MCM) containing a metal chelate ring and a multiple bond. This enables preparation of MMC in one step. In such MMC each chelating group contains a metal ion and in most instances has a definite spatial configuration in the metal chelate ring.

Chelation is an effective method of stabilising monomer–metal pairs (MMP). Thus, allyltrichlorotitanium is barely stable whereas its complex with 2,2′-bipyridine (bipy) decomposes only at 180 °C.[23] Unsaturated organocobalt compounds are stable only if they contain bulky chelating ligands, in particular, dimethylglyoxime (DH_2).[24,25] Moreover, MCM are independently interesting owing to the influence of the double bond on the stereochemistry of the coordination sphere and the electronic properties of the metal on the one hand and to the influence of the metal on the reactivity of the multiple bond on the other.

In this review, data for the synthesis, homopolymerisation, copolymerisation and graft polymerisation of MCM are summarised. Routes for the most rational development of this area are outlined.

II. Synthesis

Metal chelate monomers include complexes containing a metal chelate ring and a multiple bond capable of undergoing addition. Depending on the type of metal–chelate bonding, MCM can be classified into the following three types: molecular metal chelates (I), inner-sphere compounds (II) and macrocyclic complexes (III).

(I) (II) (III)

where M is the metal, n is the metal valence, X is a ligand, and Y, Z, L and D are the corresponding functional groups.

Type (I) MCM have only coordinate bonds between the metal and the donors of the chelate. Such MCM are formed if the groups have donors positioned to form a metallocycle or are conformationally non-rigid with two or more donors. In type (II) MCM, at least one group forms both a coordinate and covalent bond to the metal. These compounds can be neutral, cationic or anionic and can contain monodentate and chelating ligands. The metal ion in type (III) MCM is bonded to a macrocycle. These three

types of MCM can be further divided into groups depending on the nature of the donors (O,O-; N,N-; N,O-; and P,P-chelates, etc.).

In the modern synthetic chemistry of MCM, general methods and principles for synthesising complexes are widely used.[26,27]

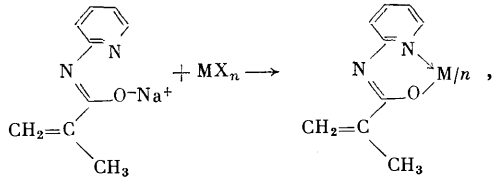
1. Molecular metal chelates

The traditional route for synthesising type (I) MCM is based on reaction of metal compounds (MX_n) with chelating monomers. This method has been used, in particular, to prepare the complex of Cu^{II} chloride with the vinyl ether of monoethanolamine;[28] Ru^{II}, Co^{II} and Fe^{II} complexes with 4-vinyl-, 6-vinyl-, or 4′-vinylterpyridyls;[29] Ru^{II}, Zn^{II} and Ir^{III} complexes with 4-vinyl-4′-methyl-2,2′-bipyridyl;[30–33] the Ru^{II} complex with 6-vinyl-2,2′-bipyridyl;[33] Ni^{II}, Co^{II}, Cd^{II}, Bi^{III}, Hg^{II} and Pd^{II} complexes with 1-allyl-3-(2′-pyridyl)-2-thiourea;[34] Cu^{II}, Ni^{II}, Co^{II}, Mn^{II} and Zn^{II} complexes with 1-vinyl-2-hydroxymethylimidazole and 1-vinyl-2-vinyloxymethylimidazole;[35,36] etc.

A method based on interaction of monofunctional monomers with metal chelates has also been widely employed. For example, chelates of monomers have been prepared for Ru^{II} and Os^{II} with chelates of the type bipy or phen (1,10-phenanthroline) and monofunctional 4-vinylpyridine (4-VP), bis-(4-pyridyl)ethylene, *trans*-4-stilbazole, *N*-(4-pyridyl)-acrylamide, etc.[18–20,37,38]

Molecular metal chelates can be obtained through reaction of metal-containing monomers with chelates. An example of this reaction is the interaction of bipy and phen with transition metal acrylates to give type (IV) MCM:[13,39,40]

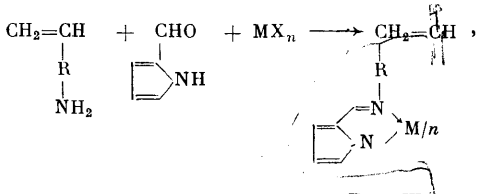
$$M(CH_2{=}CHCOO)_n \cdot mH_2O + L \rightarrow M(CH_2{=}CHCOO)_n \cdot L \cdot pH_2O \quad (IV)$$



where M = Cu^{II}, Ni^{II}, Co^{II}, Cr^{III}, L = bipy or phen, n = 2, 3; and m and p = 0–2.

2. Inner-sphere compounds

Various methods of synthesising type (II) MCM have been developed. The following examples are typical:

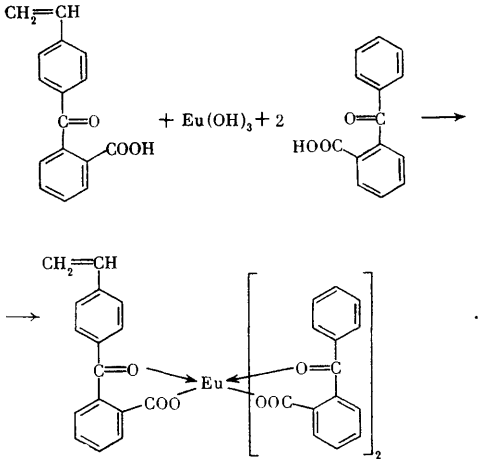


1. direct reaction of MX_n with monomers containing chelating groups. For example, this method was used to prepare Cu^{II} complexes of *N*-vinylsalicylaldimines,[41] complexes of transition[42–44] and rare earth[45] metals with vinyl-β-diketones, chelates of Cu^{II}, Ni^{II}, Co^{II}, Zn^{II} and Cd^{II} with 3-allyl-1-[2-mercapto-4-oxo-3(4*H*)-quinazolinyl]-2-thiopseudourea[46] or 1-isonicotinoyl-4-allyl-3-thiosemicarbazide,[47] a palladiated monomer based on *N*-allylsalicylaldimine,[48] complexes of Cu^{II}, Ni^{II} and Cd^{II} with 5-hydroxyl-5-hydroxy-3-vinyl-3-vinyl-1*H*-benz[*f*]indazole-4,9-dione,[49] etc.

2. Exchange of an alkali or alkaline earth metal in the chelate monomer for a transition metal:[50]

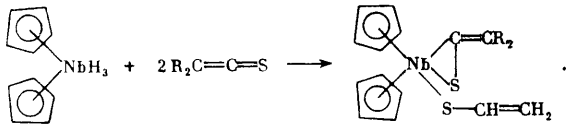
where M = Cu^{II}, Ni^{II}, Co^{II}, Fe^{III}, Cr^{III}; n = 2, 3.

3. Template synthesis of MCM, for example, according to the scheme:[51,52]



where R = $-C_6H_4-$ or $-CH_2-$; M = Cu^{II}, Co^{III}; n = 2, 3.

4. Addition of acetylenic monomers to metal chelates, in particular, phenylacetylene to dimethylglyoxime complexes of Co:[24,25]

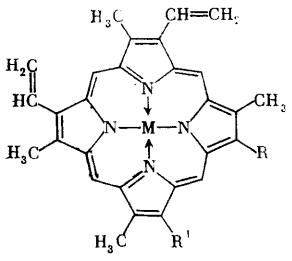


$$HCo(DH)_2 + CH{\equiv}CPh \rightarrow CH_2{=}C(Ph)Co(DH)_2 \ .$$

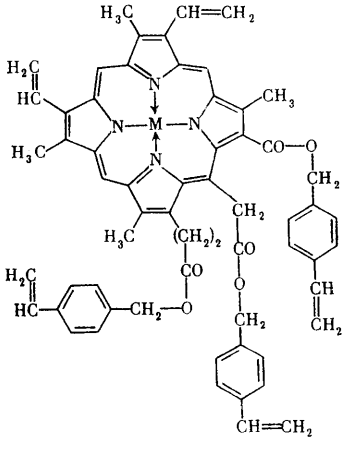
5. Covalent bonding of metal chelates to monomers. An example is the reaction of Co chelates with *p*-chloromethylstyrene to give cobalt chelate monomers with a cobalt–carbon bond.[4]

6. Neutralisation reactions. Thus, the chelate monomer of Eu^{III} was synthesised by neutralisation of $Eu(OH)_3$ by a mixture of 4-vinylbenzoyl-2′-benzoic and 2-benzoylbenzoic acids in a 1:2 mole ratio:[53]

7. Reaction of metal hydrides with thioketenes:[54,55]

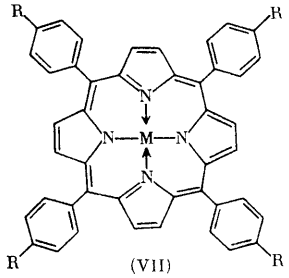


3. Macrocyclic complexes



The macrocyclic type of MCM have been synthesised using a whole range of methods. One of these consists of direct reaction of MX_n with unsaturated macrocycles, for example, reaction of nickel acetate with vinylporphyrin.[56] Other metalloporphyrins, in particular, Co^{II}, Fe^{III}, Fe^{II}, Mg^{II}, Zn^{II}, Cu^{II}, etc. containing one or

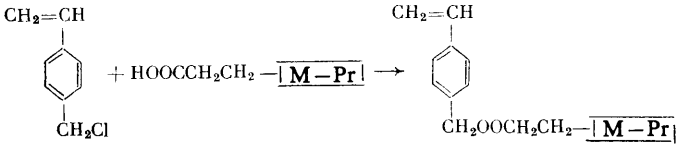
two vinyl substituents were prepared analogously.[57–59] Typical representatives of these are shown in Scheme 1.



Scheme 1

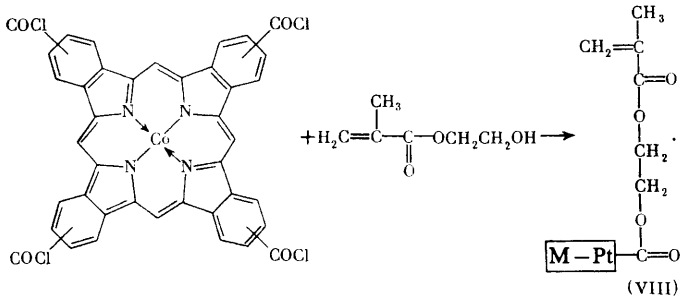
(V)

(VI)



(VII)

where (V) are metal complexes of protoporphyrin-IX [R = R′ = $(CH_2)_2CO_2H$], the dimethyl ester of protoporphyrin-IX [R = R′ = $(CH_2)_2CO_2CH_3$], the vinylbenzyl ester of protoporphyrin-IX [R = R′ = $(CH_2)_2CO_2CH_2C_6H_4CH{=}CH_2$], *N*-(*p*-vinylbenzyl)-*N*′-(imidazolylpropyl)dipropylamidoprotoporphyrin-IX {R = $(CH_2)_2CONHCH_2C_6H_4CH{=}CH_2$, R′ = 1-[$(CH_2)_2CONH.(CH_2)_3$]pyrrole}, and the dimer of protoporphyrin-IX [R = $(CH_2)_2.CONHCH_2-$, R′ = $(CH_2)_2CO_2CH_2C_6H_4CH{=}CH_2$]; (VI) are metal complexes of the porphyrin chlorine; and VII are metal complexes of tetra(*p*-styryl)porphyrin (R = $CH_2{=}CH-$) or acrylamidotetraphenylporphyrin (R = $NHCOCH{=}CH_2$).



Another method is based on the well known ability of planar metalloporphyrins and -phthalocyanines to accept another ligand owing to coordinative unsaturation of the metal. The additional ligands occupy the fifth and sixth sites in the inner sphere of the transition metal.[60] Such ligands can be vinylpyridines, vinylimidazoles, etc.

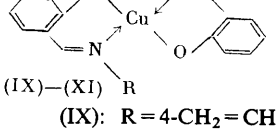
However, the method used most widely to synthesise metalloporphyrin monomers consists of interaction of reactive peripheral groups of transition metal porphyrinates (for example, metal complexes of chlorophyll, chlorine, etc.) with monomers:[58,59,61]

where the symbol M–Pr denotes the metalloporphyrin. The most frequently used peripheral groups are carboxyls, sulpho and amino groups. Analogous MCM can be synthesised by reaction of acryloyl chloride with M^{II} tetra-*p*-aminophenylporphyrinate acetate.[61]

These approaches were also used to synthesise metallophthalocyanine monomers. Thus, synthesis of Co phthalocyaninate (VIII) has been described.[62]

(VIII)

Here the symbol M–Pt denotes the metallophthalocyanine. This can also be accomplished using the reaction of acryloyl or methacryloyl chlorides with metal tetra-*p*-carboxyphenylphthalocyaninates.[63]



Therefore, analysis of the existing data indicates that the synthesis of MCM is rather well developed and continues to be improved. There appear at present to be no significant synthetic difficulties in synthesising MCM of practically any metals in various valence states. However, as for other types of MCM,[64] aspects of homo- and copolymerisation of MCM are largely unstudied.

III. Homopolymerisation

The kinetics of homopolymerisation of MCM and the properties of the MMC formed have begun to be studied only recently. Thus, the first radical polymerisation of haemin dimethyl ester was effected in 1977.[65] The possibility was demonstrated[18] of polymerising 4-VP complexed to Ru^{II} {complexes *cis*-$[Ru(bipy)_2(4\text{-VP})X]^{n+}$, where n = 1, X = Cl, n = 2, X = CO or 4-VP}. However, the properties of the polymers obtained were not described.

Radical polymerisation of the appropriate monomers produces Er^{III} and vanadyl(II) poly(*p*-acryloyloxyphenyltriphenylporphyrinates). The elemental analyses are consistent with 100% occupancy of the coordination sites by metal.[66] In contrast, the usual method (polymerisation of the corresponding chelate monomer with subsequent binding of metal by the macroligand obtained) gives only 50% metal incorporation. It is interesting that, in contrast with the starting chelate monomer of vanadyl with a weak antiferromagnetic exchange interaction (the Curie–Weiss θ value is −25 K), the polymer obtained that is based on it exhibits strong antiferromagnetic interaction (θ = −170 K). This indicates that the polymer chains play an important role in the magnetic interaction.

Salicylaldimine (Salim) chelates of Cu^{II}, CuL_2

(IX)–(XI)

(IX): R = 4-$CH_2{=}CH-C_6H_4-$ (L = Salim′),
(X): R = 4-$CH_2{=}C(CH_3)-CO_2C_6H_4-$ (L = Salim″),
(XI): R = $CH_2{=}C(CH_3)-CO_2-(CH_2)_2-$ (L = Salim‴),

were polymerised in the presence of azobisisobutyronitrile (AIBN) in the ratio AIBN:MCM = 0.12:1.[41] The rate of polymerisation was much less than that for the corresponding salicylaldimines (Table 1). Moreover, homopolymerisation of MCM of Cu^{II} was entirely impossible in a number of other attempts. For example, polymerisation of Cu^{II} methacryloylacetonate in the presence of very different initiators was unsuccessful.[42] Their ineffective homopolymerisation may be due to intramolecular chain termination:

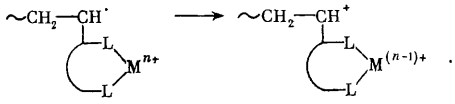


Table 1. Rate of polymerisation of type (IX)–(XI) MCM and the corresponding salicylaldimines.

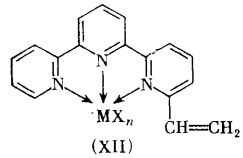
L	CuL_2	W_{tot}, 10^5 mol dm^3 sec^{-1}		W_{sp}, 10^5 (dm^3)^2 sec^{-1}	
		L	CuL_2	L	CuL_2
Salim′	(IX)	2.59	0.23	5.28	2.10
Salim″	(X)	9.26	1.95	18.89	17.73
Salim‴	(XI)	0.34	0.0079	0.69	0.0718

It should be noted that allyl derivatives of metal β-diketonates do not undergo radical homopolymerisation.[44]

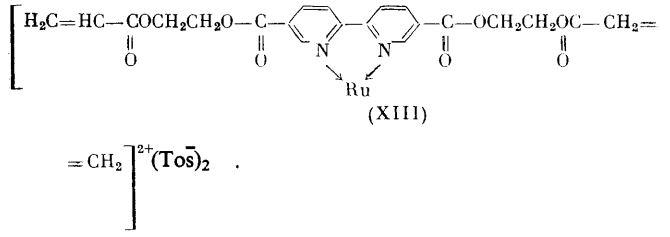
The mechanism of reductive electrochemical polymerisation of Ru^{II}, Os^{II} and Fe^{II} perchlorate and hexafluorophosphate mixed-ligand chelates of monomers has been studied in more detail.[19,20,38,67–69] Such complexes contain a chelating group of the type bipy, phen or terpyridyl (terpy) and a monofunctional monomer of the type 4-VP, *trans*-4-stilbazole, etc. Polymerisation occurs by repeated cycling of the electrode potential (Pt, vitreous carbon, etc.) near values corresponding to ligand reduction. This causes the electrode surface to be covered with an even film of polymer. The MCM in which the vinyl group is bonded to the chelating group polymerise in a similar way (for example, Zn^{II}, Ru^{II} and Ir^{III} complexes of 4-vinyl-4′-methyl-2,2′-bipyridyl).[31] In this instance the film forms much more effectively (the number of moles of polymer per mole of starting MCM).



The mechanism of the electrochemical polymerisation includes formation of an anion–radical, for example, by the following reaction:

$$[Ru(bipy)_2(L)_2]^{2+} + \bar{e} \rightarrow [Ru(bipy)(bipy^{-})(L)_2] + \bar{e} \rightarrow [Ru(bipy^{-})_2(L)_2]^0,$$

where L is a monofunctional monomer. However, polymerisation is initiated by one-electron reduction based on an intramolecular redox equilibrium involving the thermodynamically less stable isomer in which the electron is localised on L;

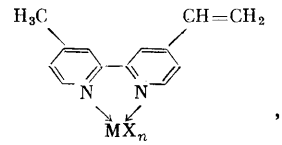


$$[Ru(bipy)(bipy^{-})(L)_2]^+ \rightleftarrows [Ru(bipy)(bipy^0)(L)(L^{-})]^+.$$

The dependence of polymerisation rate on the number of vinyl groups in the MCM and their position relative to the coordinated nitrogen atoms was studied for the example of Co, Fe and Ru complexes of various vinyl derivatives of terpy.[29] In particular, it was found that increasing the number of vinyl groups in the complex leads to significantly increased polymerisation. This was noted in a number of other instances.[64] Also, introduction of a vinyl group in the α-position relative to the nitrogen of the pyridine ring [complex (XII)] inhibits polymerisation of the MCM.

(XII)

Similar metal polymer coatings can be prepared by another method, deposition of MCM solution on the electrode surface with subsequent thermal polymerisation. The effectiveness of such an approach was demonstrated for polymerisation of 5,5′-bis-[(3-acryloyl-1-propoxy)carbonyl]-2,2′-bipyridylruthenium(II) toluenesulphonate (Tos) (XIII).[70–73]

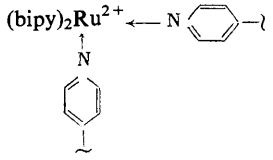


(XIII)

The thickness of the coating is regulated by the polymerisation conditions.

IV. Copolymerisation

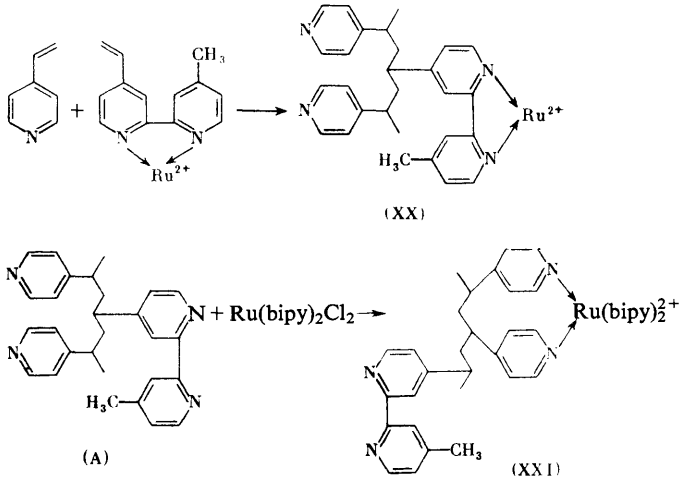
Copolymerisation of MCM with traditional monomers is more common than their homopolymerisation. Thus, copolymers containing complexed rare earths (Eu^{III} and Tb^{III}) were prepared by copolymerisation of MCM of type (XIV)–(XIX) with methylmethacrylate (MMA) in a block or methanol.[45]



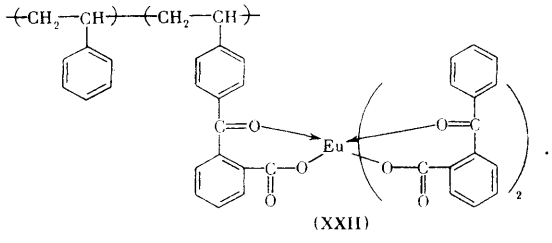
M = Tb^{III}, X = bipy(XIV), phen(XV), terpy(XVI);
M = Eu^{III}, X = bipy(XVII), 1-furyl-4-trifluoroacetylacetone(XVIII), dibenzoylmethane(XIX).

As it turns out the nature of the ligand X had a considerable influence on the fluorescence intensity of the copolymers obtained. In particular, the fluorescence intensity of the Tb complexes decreased in the order: (XVI) > (XIV) > (XV). That for the Eu complexes followed the order: (XIX) > (XVIII) > (XVII). Moreover the fluorescence intensity of the copolymers was much greater than a mixture of the starting monomers. This is consistent with fluorescence quenching by the double bond in the MCM.

Radical copolymerisation of *cis*-$[Ru(bipy)_2(4\text{-}VP)Cl]ClO_4$ and *cis*-$[Ru(bipy)_2(4\text{-}VP)_2](ClO_4)_2$ with styrene (St), MMA and 4-VP has also been achieved.[18] The copolymers based on Ru^{II} complexes



containing one 4-VP molecule were soluble in CH_2Cl_2 and methanol whereas the product of $[Ru(bipy)_2(4\text{-VP})_2](ClO_4)_2$ copolymerisation (comonomer of 4-VP, starting ratio [4-VP]:[MCM] = 20) were insoluble in organic solvents owing to crosslinking through metal atoms:[18]



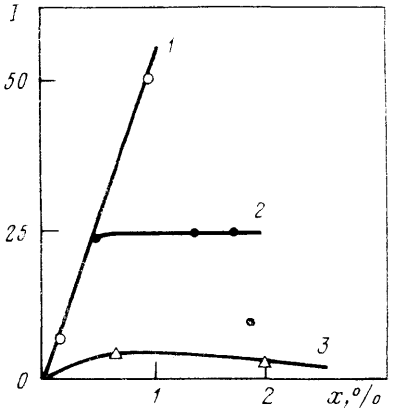
It was demonstrated that MX_n has much less influence if the ratio [4-VP]:[MCM] is increased to 200, for which a soluble product is formed.

It is interesting that copolymerisation of MCM can produce MMC of different structure from those formed by reaction of MX_n with analogous chelating macroligands prepared in advance. For example, copolymerisation of 4-VP with the Ru complex based on 4-vinyl-4′-methyl-2,2′-bipyridyl produces the polymer (XX) (Scheme 2),[31] whereas reaction of the chelating macroligand (A) with $Ru(bipy)_2Cl_2$ gives polymer (XXI).

Scheme 2

Unfortunately, kinetic aspects of the copolymerisation are not treated in the majority of studies of MCM copolymerisation. The mechanism of copolymerisation also is not described in detail for such MCM as Eu[2-(4′-vinylbenzoyl)benzoate]-di(2-benzoylbenzoate) with St to form (XXII).

This MMC characteristically has a high fluorescence intensity proportional to metal content, in contrast with complexes prepared by reaction of $EuCl_3$ with macroligands containing 2-carboxybenzoyl (XXIII) or 2-carboxynaphthoyl (XXIV) groups (Fig. 1).[53] The Eu^{III} complex of 1-(*p*-vinylphenyl)-3-phenylpropane-1,3-dione was copolymerised with MMA in an analogous manner.[45]



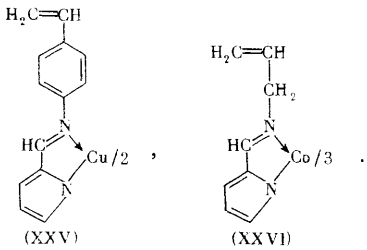


Figure 1. Dependence of fluorescence intensity (*I*) on Eu content (*x*) in complexes (XXII) (curve *1*), (XXIII) (*2*), and (XXIV) (*3*).

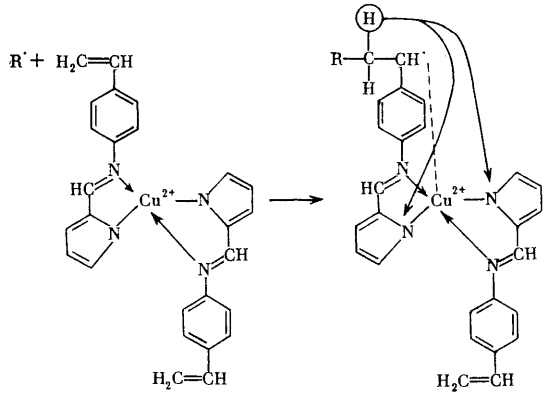
Radical copolymerisation of the Co^{II} complex of *N,N′*-bis-[4′-(*p*-vinylbenzyloxy)salicylaldehyde]-1,2-diaminocyclohexane with St and divinylbenzene (DVB) led to ternary copolymerisation in which 20 St and DVB molecules were added for each MCM.[74]



In contrast with the qualitative work mentioned above, the mechanism of copolymerisation of St, MMA, acrylonitrile (AN) or acrylic acid (monomer M_1) with MCM (monomer M_2), represented by the Cu^{II} complex with pyrrolylmethyleneiminostyrene (PIS) of type (XXV) or the Co^{III} complex with pyrrolylmethyleneiminopropene (PIP) or type (XXVI), has been studied.[51]

As seen from Fig. 2, the mole fraction of monomer M_2 in the copolymers formed is greater for MCM than for its metal-free analogue. The reactivity of the comonomer increases on adding metal (Table 2). This is comparatively rare in the polymerisation and copolymerisation of MCM.[64] Furthermore, only one or two out of the three multiple bonds in the Co^{III} chelate of type (XXVI) are involved in the copolymerisation of MCM. The third multiple bond is incorporated into the copolymer. For the Cu chelate, all vinyl groups are involved in the process. However, the polymerisation of this MCM is initiated along a complicated path (Scheme 3). The primary radical first attacks the vinyl group of the monomer. The free electron then transfers from this group to the central metal ion. This process is enhanced by conjugation (a long coplanar π-electron

system). The chain does not propagate until Cu^{II} is completely reduced to Cu^{I}. β-Elimination of a proton from the vinyl group attacked by the primary radical and addition of the proton to the pyrrole nitrogen atom occur simultaneously.

Scheme 3

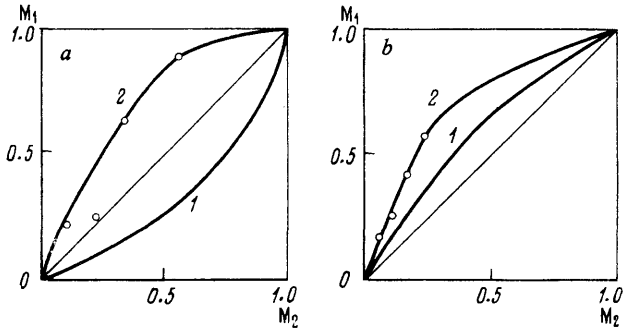


Figure 2. Composition diagram of copolymerisation of MCM (*2*) and their metal-free analogues (*1*) with AN (*a*) and St (*b*). *a* is copolymerisation of complex (XXVI); *b*, complex (XXV).

Copolymerisation of macrocyclic MCM is less well studied. The comonomers used for this are classified according to the *Q* parameter (resonance stabilisation of the monomer during copolymerisation). Monomers with high *Q* values (St, MMA, π-conjugated monomers) copolymerise with haemin and its dimethyl ester. During the copolymerisation Fe^{III} is reduced to Fe^{II}.[75,76] The haemin content in the copolymer with St is basically the same as that in the mixture of monomers (Table 3). As the ratio [MCM]:[St] increases, the yield, relative molecular mass, and viscosity of the polymer decrease owing to the influence of the metalloporphyrin on chain propagation (the coefficient of chain propagation C_s = 2.3).

However, copolymerisation of non-conjugated monomers (with a low *Q* value) does not occur as a result of addition of a radical to haemin to form stable adducts. Therefore, attempts to copolymerise haemin with vinylpyrrolidone (VPr) and vinylimidazole (VIA) were unsuccessful.[75] It is interesting that non-conjugated monomers can be copolymerised with haemin in the presence of a third conjugated comonomer, for example, to form the ternary copolymer haemin–VIA–St.[65,75,76] Copolymerisation of haemin with VPr under the influence of γ-irradiation from ^{60}Co or with 2-hydroxyethylmethacrylate in a buffer (Na_2CO_3–$NaHCO_3$, pH 10) has been described.[77] The MCM obtained through reaction of Mn tetra-*p*-aminophenylporphyrinate-acetate with acryloyl chloride readily copolymerises with MMA or 4-VP to form soluble MMC.[61] Tetra(*p*-vinyl)benzyl esters of the dinuclear Mg^{II} complex with chlorophyll copolymerise through a cationic mechanism (BF_3 etherate) with α-methylstyrene.[78] A three-dimensional structure with the metal monomer immobilised in the bulk of the polymeric gel is formed as a result of copolymerisation of the vinylporphyrin monomers of Co^{II}, Fe^{II} and Ni^{II} containing one or two vinyl substituents with acrylamide or *N*,*N*′-methyl-bis-acrylamide.[57] The parameters of such a networked structure are easily regulated by the ratio of comonomers.

Table 2. Copolymerisation activity of metal chelate monomers (XXVI) and (XXV) and their corresponding free ligands.

* Copolymerisation in pyridine with AIBN at 358 K.
** Block polymerisation with AIBN at 333 K.

Copolymerisation of a type (VIII) monomer with 9-vinylcarbazole is an example of copolymerisation of metallophthalocyanine monomers.[62]

A special type of MCM copolymerisation is graft polymerisation, where the initiators are fixed to a polymeric or other kind of substrate.

Unfortunately, data on graft polymerisation of MCM are very limited, the majority of them being recently obtained.[13,40,79–85] Nevertheless, it is noteworthy that a distinguishing feature of the grafting of these MCM is the nearly complete absence of the homopolymer. The kinetic dependences of polymerisation are similar to those found for other types of MCM.[64,86,87] In particular, the kinetic dependences exhibit an identical nature for all chelates studied (Fig. 3). The rate is maximal during the first 0.5 h and then quickly drops. Moreover, the nature of the transition metal has a substantial effect on the grafting. Absorption bands of the C=C bond at 1640 cm^{-1} in the IR spectra of grated polymers containing metals are consistent with a certain amount of unpolymerised vinyl groups. In other words, only part of the vinyl groups polymerise during grafting of the MCM. The similarity of the spectral and magnetic properties of the monomers and polymers based on them (Table 4) indicates that the valence state and the coordination sphere of the metal do not change during grafting. However, the splitting parameter (Dq) decreases and the Racah interelectron repulsion parameter (B') increases on going from MCM to their polymers. Considering[88] that $Dq \approx d^{-6}$, it can be assumed that the decrease of the splitting parameter indicates an increase of the metal–ligand distance (d) in the indicated order. Moreover, the nephelauxetic parameter β increases in this same order. This indicates a decrease of the covalency of the metal–ligand bond.

V. Applications

Metal chelate monomers and polymers based on them find very diverse applications stimulating the direction of investigations in this area of chemistry.

1. Improvement of operating and physicomechanical properties of polymers

As a rule, polymers based on MCM are stable up to 473–523 K. Introduction of even a small amount of these monomers to copolymers of common monomers leads to crosslinked polymers with increased thermoplasticity and stability toward organic solvents. In particular, bis-(aminoethyleneamido-maleate-tetrahydrate)zinc prepared from zinc maleate and ethylenediamine was used to crosslink polyethylene in order to increase its resistance to thermal ageing and cracking.[89,90]

The reduced products of electrochemical polymerisation of vinyl derivatives of Fe^{II}, Ru^{II} and Os^{II} containing bipy are photoconductive (λ_{max} = 420–520 nm).[91] It should be noted that the metal ions in MMC, as a rule, have the same photophysical properties as in the corresponding MCM. Thus, monomeric Eu^{III} and Tb^{III} complexes with 4-vinyl-4′-methyl-2,2′-bipyridyl, like their copolymers with MMA, are excited at λ_{max} = 335 and λ_{max} = 500–600 nm, respectively. This is characteristic of these ions.[45] It is interesting that the polymeric products exhibit more intense fluorescence than the MCM. These substances may have utility in lasers.

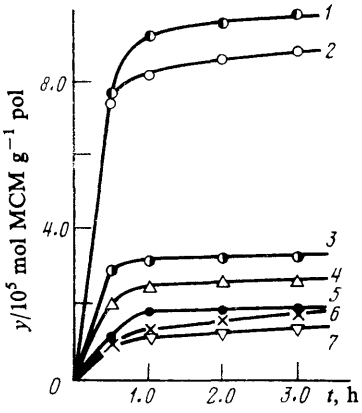

Figure 3. Kinetic curves of yield of grafted MCM polymers based on methacryloylacetophenone: Co^{II} (*1*), Ni^{II} (*2*), Pd^{II} (*3*), Mn^{II} (*4*), Cu^{II} (*5*), Fe^{III} (*6*), Cr^{III} (*7*) (ethylacetate, [MCM] = 0.04 and dm^{-3}, 70 °C, D = 200 kJ kg^{-1}).

Polymer	Co	phen	1639	1608	1565	1016	884	0.911	4.87

Macromolecular metal chelates based on $[Ru(bipy)_2(4\text{-}VP)_2]^{2+}$ and $[Ru(bipy)_2(4\text{-}VP)Cl]^+$ exhibit luminescence in methanol or dilute acids at room temperature.[18] Thus, absorption of the metal ions in poly-$[Ru(bipy)_2(4\text{-}VP)Cl]_n^+$ in methanol at 455 nm leads to a broad emission with a maximum at 615 nm.

Electroactive polymeric coatings are prepared by reductive electrochemical polymerisation of MCM consisting of vinylpyridine derivatives of Fe^{II}, Ru^{II} and Os^{II} complexes with chelates.[19] They are unique in that the redox centres are localised on each monomeric nucleus.

It also seems interesting to use grateful metal chelate polymers as antiwear and anticorrosion additives to lubricants.[15,40] In particular, addition to TsIATIM-201 lubricant of the type (IV) Cu acrylate

complex of bipy grafted to the surface of polytetrafluoroethylene (PTFE) improves its tribiological characteristics (corrosion index, seizing load and weld load) (Fig. 4). Whereas this MMC is more effective than grafted Cu acrylate,[92] this is apparently related to the involvement of the chelating ligand (bipy) in the transfer of Cu from one contacting surface to another. A very thin film of Cu metal (protective film) can be seen on the frictional surface after the tests. This is consistent with a "wearless" regime in these systems.[93,94]

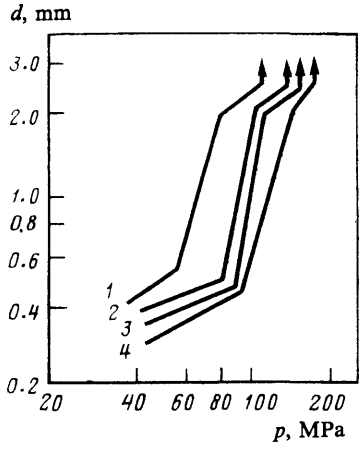

Figure 4. Dependence of average wear-spot diameter (d) of a four-ball machine on applied axial loading (P) for TsIATIM-201 lubricant: without PTFE additive (*1*), with PTFE additive (*2*), with PTFE additive and grafted Cu acrylate (*3*), with PTFE additive and grafted Cu acrylate complex with bipy (*4*).

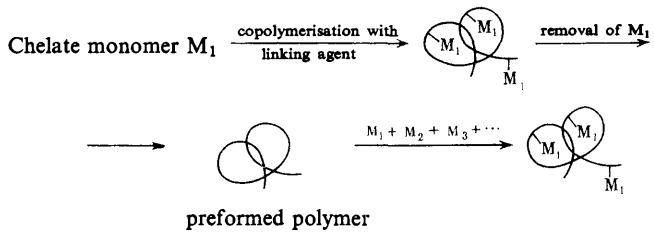
2. Catalytic activity

Macromolecular metal chelates based on chelate monomers include immobilised catalysts[9,10] that combine the high activity and selectivity of homogeneous systems with the technology of heterogeneous ones. Chelation is one of the simplest methods of surmounting the principal drawback of immobilised catalysts, the relatively unstable metal–polymer bond during the catalysed reaction.[12] Moreover, such MMC can be prepared in one step. This is important in planning practical applications of these catalytic systems. Finally, an important advantage of such catalysts is the possibility of rather simple determination of the metal complex structure (the valence and electronic state of the metal, its ligand environment, the geometric structure of the metal chelate group, etc.) in addition to the controlled distribution of metal complexes along the polymer chain. This is due to the ease of separating intermediates at any step of the catalysed reaction.



Examples of the use of MMC based on MCM are numerous. Therefore, let us point out the most typical ones. Soluble metalloporphrin polymers prepared by copolymerisation of MMA or 4-VP with macrocyclic MCM, represented by the product of reacting Mn tetra-*p*-aminophenylporphyrinate-acetate and acryloyl chloride, were capable of catalysing oxidation of olefins by molecular oxygen.[61] The copolymer of acrylamide and *N,N'*-methylene-bis-acrylamide with the Ni^{II} vinylporphyrin complex (in combination with H_2O_2) has been used to create effective redox systems for initiating polymerisation of acrylamide in aqueous medium.[57] Effective catalysts for ethylene dimerisation have been prepared by radical polymerisation of type (IV) Ni^{II} acrylate complexes with bipy and phen.[95]

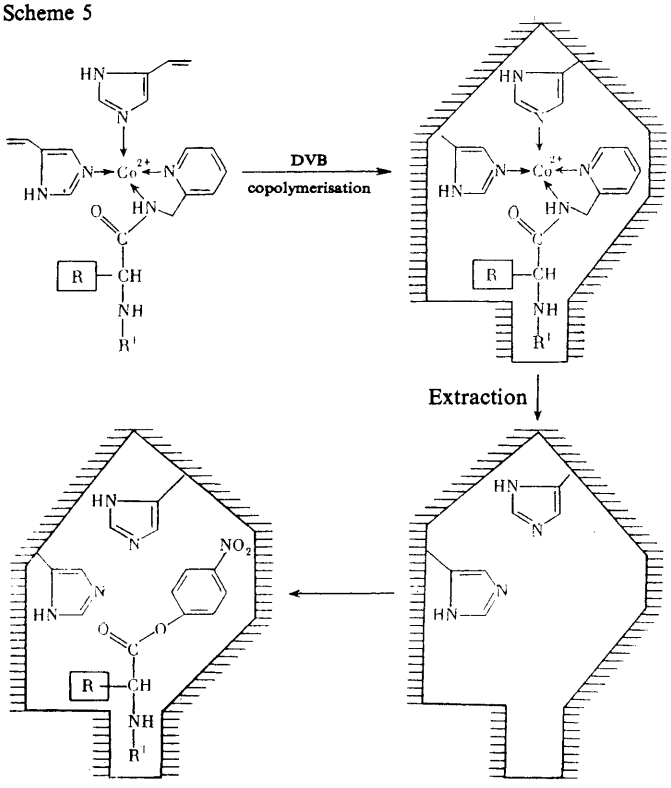
As expected, more active catalysts are obtained by graft polymerisation of MCM since in this instance the catalytically active centres are localised on the support surface. For example, the grafted Pd^{II} chelate of a diketone ligand showed high activity for hydrogenating isomers of chloronitrobenzene.[82] This catalyst remains active for 15 cycles.

3. Template effect in macromolecular metal chelates

As applied to metal polymer systems, the template effect refers to the "recognition" and binding of those metal ions that were used as templates for synthesis of metal polymer complexes.[94,96–99] Ordinary chelate polymers do not selectively bind particular metal ions. As a rule, the selectivity is determined by the formation constants of the corresponding complexes and reaction conditions such as pH, solvent, temperature, etc.[7,8] Also, MMC prepared by copolymerisation of MCM with crosslinking agents exhibit "superstructure". The sorption capacity, sorption rate and selectivity of superstructured polymers increases dramatically after metal ions are removed. The mechanism of this effect is depicted in Scheme 4. The bond length and angle between the central metal ion and the coordinated ligand are strictly determined by their nature. When the chelating groups of the MMC are somehow immobilised and the metal ion is then removed geometrically, i.e., with retention of the preformed structure, the remaining polymeric ligand can have "pockets" specifically disposed to the same metal ions (templates) that were removed from the polymeric matrix.

Scheme 4

Thus, although the copolymer of 4-vinyl-4'-methyl-2,2'-bipyridyl, St and DVB from solutions of Ni^{II} and Cu^{II} salts of identical concentrations to a large extent binds Cu^{II} (as a result of the large binding constant of this complex), this same polymer preformed in the presence of Ni^{II} exhibits a template effect for Ni (Fig. 5).[100]



Polymeric chelates prepared by copolymerisation of dithiophosphate complexes, for example bis-[di(4-vinylphenyl)dithiophosphato].Ni^{II} or -Co^{II} and -Cr^{III}, with St and ethyleneglycolmethacrylate exhibit selectivity for the particular ion after removal of the metal. The enrichment factor (ratio of metal bound by the structured and unstructured polymers) for Ni^{II} is 1.4; for Co^{II}, 2.4.[101]

It should be noted that template syntheses can be effected using MMC. For example, it is possible to separate the racemate of D- and L-phenylalanine.[74] In this instance the separation is carried out as follows. The chelate monomer of Co^{II} with the Schiff base is initially synthesised. Then D-phenylalanine is added. Copolymerisation with St and DVB is carried out. The D-phenylalanine is extracted using HCl. The polymer obtained, structured for the

D-isomer, exhibits a template effect relative to the D-isomer of the racemic mixture (with optical purity 74 ± 1%).

New types of structured polymers that model active group histidine have been synthesised.[102] Complexes of Co^{II} with 4(5)-vinylimidazole and leucine-2-picolinimide or with leucine are copolymerised with DVB in a mixture of water, alcohol and butanol. The polymer particles (200–500 nm) are subjected to extraction with methanol for 12 h. The template molecules are then removed using bipy. The structured polymer formed is used as a catalyst for hydrolysis of *p*-nitrophenyl esters to amino acids (Scheme 5). The hydrolysis rate in the presence of polymers structured for the corresponding methionine or leucine derivatives is significantly greater than in the presence of unstructured ones. This is explained by the creation in the structured polymers of discrete voids with imidazole groups. The effect is retained after repeated use of the structured polymers. This is indicative of the catalytic nature of such action.

Scheme 5

IV. Conclusion

Analysis of existing data on the synthesis, homopolymerisation and copolymerisation of MCM indicates that significant progress has been made in solving several problems on the chemistry of MCM and that extensive investigations are being carried out in this area. Among the most important questions, the solutions of which would reveal general principles of the chemistry of MCM, we note the following:

1) development of new methods for preparing MCM;
2) establishment of the activation pathways of the multiple bonds of MCM, a detailed analysis of the influence of the metal on the separate polymerisation steps, discovery of new methods of initiating polymerisation;
3. investigation of the reactivity of the multiple bonds of MCM in other reactions (hydrogenation, isomerisation, oxidation, ozonolysis, hydroformylation, etc);
4) study of the copolymerisation of MCM with each other and with common monomers;
5) determination of the structures of metal polymer chains, investigation of the changes experienced by the metal ion during polymerisation, and the study of cooperative effects in MMC and their topochemistry;
6) study of the stereoregulation and supermolecular organisation in MMC;
7) discovery of new applications of MCM and polymers based on them, including their industrial use.

The final resolution of these problems requires joint efforts of specialists on the chemistry of polymers, coordination compounds, organic synthesis, catalysis, etc.

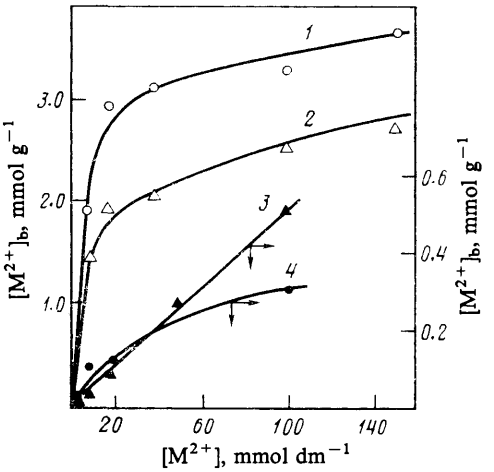


Figure 5. Binding of Cu (curves *1* and *3*) and Ni (curves *2* and *3*) by the copolymer of 4-vinyl-4′-methyl-2,2′-bipyridyl, styrene and divinylbenzene (*1*, *4*) and this same copolymer synthesised with a Ni template (*2*, *3*).

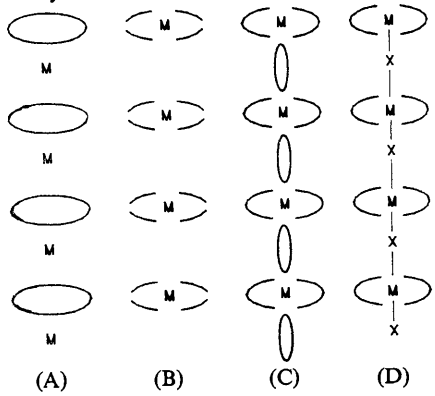
From sandwich and triple-decker to organometallic polymers

W Siebert
Anorganisch-Chemisches Institut der Universität, Heidelberg

ABSTRACT. Several types of organometallic polymers with different backbones are known. Our approach for the construction of metal-containing polymers uses the ability of Lewis-acidic boron heterocycles to interact antifacially with metals. The boron heterocycle 2,3-dihydro-1,3-diborole (*10*) not only allows the formation of sandwich and triple-decker complexes but also the stacking of metal complex fragments to oligodecker and polydecker compounds. This account reviews sandwich and triple-decker complexes as potential building blocks for polymers, and reports on the nickel- and rhodium-2,3-dihydro-1,3-diborolyl polymers *79* and *80*.



The bibliography contains 46 references.

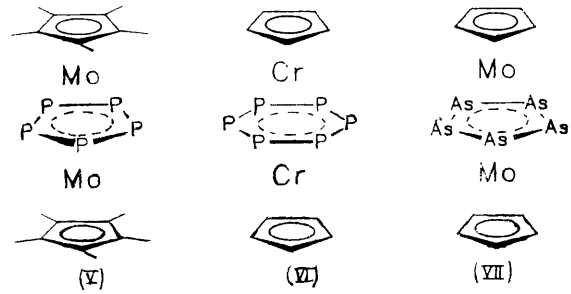
I. Introduction



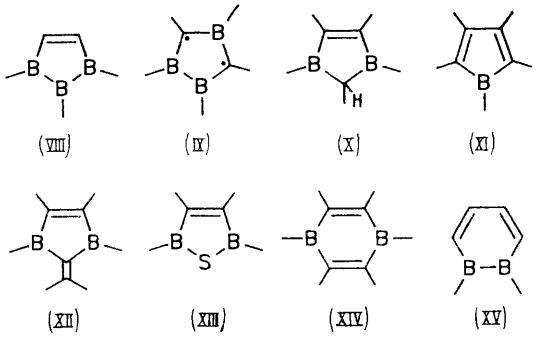
Organometallic polymers may be divided into several classes, depending on the backbone of the polymers. In coordination polymers of type *B*, e.g. in tetracyanoplatinate complexes $M_2Pt(CN)_4$ [1] and in porphyrinmetal complexes[2] the metals have direct contact via the d_{z^2} orbitals. Other polymers may contain heterocycles (type *C*) or chalcogen and halogen atoms (type *D*) as bridging ligands between the metal atoms.[3] Our approach for the construction of organometallic polymers uses electron-poor boron heterocycles in bridging positions (type *A*). They allow antifacial coordination with strong metal-ligand interactions in oligodecker and polydecker sandwich complexes.[4,5] A theoretical study of stacking complex fragments to one-dimensional arrangements has been published by Böhm.[6]

The idea of synthesising polydecker sandwich compounds (stacked cyclic ligands with metal atoms in between) is as old as metallocene chemistry. Early information on triple-decker sandwich species came from mass-spectroscopic studies of ferrocene and nickelocene. Parent ions like $Cp_3Ni_2^+$, Cp_3NiFe^+ and $Cp_3Fe_2^+$ have been detected.[7] It was two decades after the mile-stone discovery of ferrocene when Werner and Salzer[8] obtained the first triple-decker sandwich $Cp_3Ni_2^+BF_4^-$ (*1*) from Cp_2Ni and HBF_4. Only recently the long-sought complexes *2* with M = Fe, Ru, Os; M′ = Fe, Os were synthesised by Rybinskaya, Kudinov, et al.[9] Dinuclear complexes of the types *3* and *4* with arenes in bridging position have been reported by Jonas[10] and Lamanna.[11]

The chemistry of triple-deckers with homocyclic bridging ligands experienced a most interesting addition when Scherer, et al.[12] prepared the first dinuclear compounds *5* and *6* with μ-P_5 and μ-P_6 rings. Another example is the triple-decker *7* with an asymmetric As_5-ring.[13]

Until now all attempts to obtain larger molecules with carbocyclic ligands in bridging positions have failed. In contrast to these findings organoboron heterocycles have not only allowed the construction of a large number of triple-decker complexes, but also the first tetra-, penta- and hexadecker, as well as polydecker sandwich complexes.[4,5] Several reviews have summarised the extensive chemistry of boron heterocycles as ligands in transition metal complexes.[14–16]

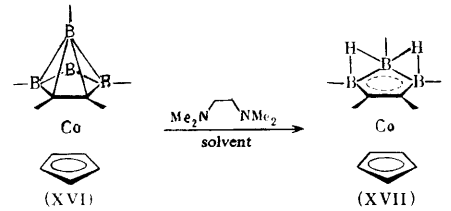
In order to outline the principles for the construction of oligo- and polydecker complexes it is necessary to refer to the electronic situation (HOMO/LUMO) of triple-decker complexes as published by Hoffmann, et al.[17] and by Chesky and Hall.[18] *1* has 34 valence



electrons (Ve, closed shell). In *2*, 30 VE (closed shell) are present. The diamagnetic triple-decker cations *2* are the electronic analogues of ferrocene (18 VE), while *1* is that of nickelocene (20 VE). They are formed when the sandwich complexes are stacked with a CpM^+ moiety. Applying the electron-counting for triple-decker to oligodecker complexes, we proposed that the optimum number of valence electrons is given by $12n + 6$, where n is the number of stacking units, each composed of a cyclic ligand and a metal (ferrocene, $n = 1$, 18 VE; *2*, $n = 2$, 30 VE), for $n = 3$ and 4 the optimum numbers are 42 and 54 VE. The maximum VE number should be given by $14n + 6$; examples are Cp_2Ni ($n = 1$, 20 VE) and *1* ($n = 2$, 34 VE). However, 48 VE for tetradecker ($n = 3$) has not yet been verified.

To date the smallest VE number for a triple-decker is observed in *3* (26 VE) belonging to the series with $10n + 6$ VE. On this basis we expect 36 VE as a minimum number for tetradecker complexes ($n = 3$).

For the design of oligodecker complexes one should focus the synthetic efforts at or near $12n + 6$ VE species, since chances for the realisation of such species are greatest. If we assume that $12n + 6$ species have a closed shell arrangement, then $11n + 6$ VE species have a hole (11 VE), and $13n + 6$ VE have an extra electron (13 VE) per stacking unit. Both should lead to a half filled band in a polydecker arrangement.

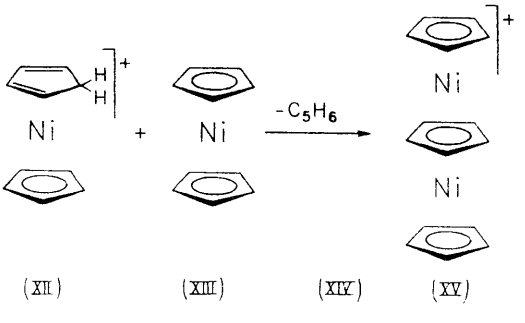


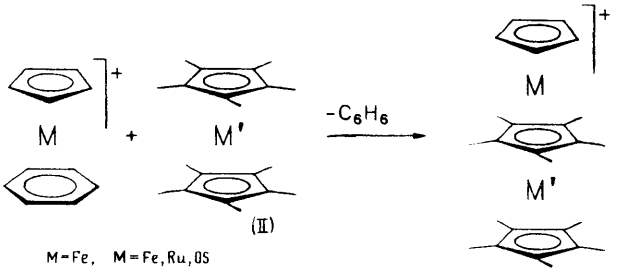
II. Boron heterocycles as ligands[14–16,19,20]

The organic ligands C_5H_5 and C_6H_6 in bridging positions yield complexes with weak interactions between metals and the μ-ligands. This is well documented by the high reactivities of *1–4*. Replacements of CH groups in carbocyclic ligands by BH or BR increase the acceptor properties of the μ-ligands, and thereby strengthen the antifacial interactions to the neighbouring metals. The following boron heterocycles *8–15*, formally derived from cyclopentadiene, fulvene, thiophene, and benzene, have been incorporated as bridging units in various types of complexes.

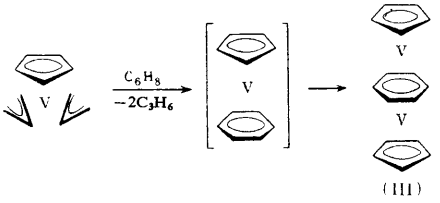
The ligands *8–10* and *15* have no independent stability. They are formed during complexation via activation of B–H or C–H bonds by the metal centre leading to the elimination of hydrogen. *8* and *9* function as 2e donors, *10* as a 3e donor and *11–15* supply 4e for bonding to one or two metal moieties.

Because of its low donor potential, *8* cannot be stabilised in sandwich complexes unless two more hydrogens are incorporated into the C_2B_3 framework. An example is *17*, obtained by the "decapitation" of the sandwich *16* (alternatively described as a *closo* metallo-carborane) with tetramethylethylenediamine. In *17* the two bridging hydrogens function as 2e donors, as does the apex BH group in *16*.[14,20]





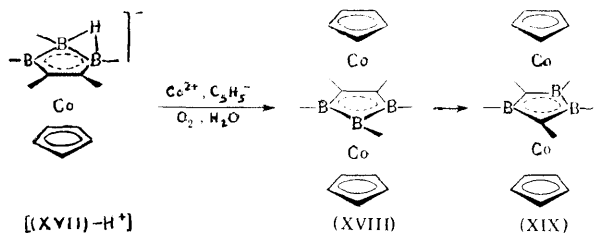
The ligands *10–14* have been used to synthesise various sandwich compounds having good acceptor functions to allow the formation of triple-decker complexes.



III. Triple-decker complexes

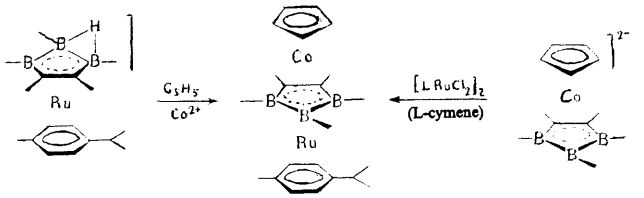
1. Homocyclic ligands in triple-decker complexes

Protonation of nickelocene, with HBF_4 at low temperature occurs at the C_5H_5 ring to give the 18 VE species. This then loses C_5H_6 and the resulting $(C_5H_5)Ni^+$ quantitatively stacks nickelocene to give *1*.[8] A related approach has been used to obtain the diamagnetic species *2* by replacing benzene in $[(C_6H_6)M(C_5H_5)]^+$ complexes with a sandwich molecule.[9] The formation of *3* occurs when $(C_3H_5)V(C_3H_5)_2$ reacts with cyclohexadiene, leading to the $(C_5H_5)V(C_6H_6)$ intermediate, which is stacked to yield *3*.[10]



The formation of *4* via co-condensation of mesitylene and chromium atoms also occurs via stacking of the bis(mesitylene)-chromium with a $Cr(C_6H_3Me_3)$ moiety.[11]

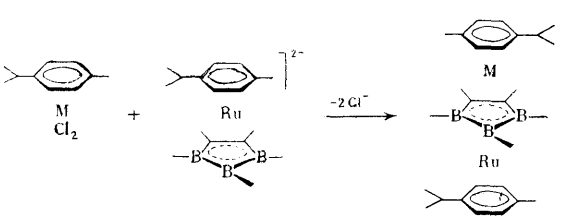
In contrast the triple-deckers *5* and *7* are built from dinuclear species and P_4 molecules, which requires the formation of the P_n ring at the metal centres. A detailed study of *6* has been published.[12]



2. The isomeric μ-$R_2C_2B_3H_3$ ligands *8* and *9*

The synthesis of the first neutral triple-decker sandwich complex *18* has been achieved by Grimes et al.[21] via a three-component reaction of $R_2C_2B_4H_5^-$, Co^{2+} and $C_5H_5^-$, followed by treatment of the reaction mixture with oxygen and water. The sandwich *17* plays the key-role in the stacking reaction leading to *18* in a low yield. A designed synthesis involves a deprotonation of *17* to give [*17*−H^+], which is then reacted with $Co^{2+}/C_5H_5^-$.

[(XVII)−H^+] (XVIII) (XIX)



The red complex *18* (30 VE) quantitative isomerises at 400 °C to give the green 2,4-isomer *19*. Replacing one cobalt atom in *18* by iron leads to a paramagnetic 29 VE species. It is obtained in 20% yield by deprotonation of $(Et_2C_2B_3H_5)Fe(C_8H_{10})$ with NaH followed by reaction with $CoCl_2$ and $C_5H_5Na^+$.[22] For the synthesis of *20* a similar strategy has been applied. *20* is obtained in 40% yield by reacting the Ru sandwich anion [*21*−H^+] with Co^{2+} and $C_5H^-_5$ or by reacting the dianion [*17*−$2H^+$] with $[(cymene)RuCl_2]_2$. In addition the analogous compound *20* with Co and Os has been prepared.

[(XX1)−H^+] (XX) [(XVII)−$2H^+$]

$[(Cymene)MCl_2]_2$ (*22*) and the dianion [*21*−$2H^+$] form the dark orange *23* and yellow *24* in 30−45% yield, respectively. Both complexes have 30 VE.

The results described above prove that for the construction of triple-decker sandwich complexes the sandwich *17* and its anions [*17*−H^+] and [*17*−$2H^+$] as well as *21* and [*21*−H^+] are the best choices to obtain dinuclear species.

(XXIV): M=Os

3. 2,3-Dihydro-1,3-diborole complexes.[4,5,15,19,23]

2,3-Dihydro-1,3-diboroles *10* can function as 3e or 4e donors, depending on the electronic requirement of the $(C_5H_5)M$ moiety. During the formation of yellow-orange *25* a hydrogen atom is lost, whereas in the orange-red cobalt complexes *26* the ligand *10* remains intact and functions as a 4e donor through its C=C and axial C−H group. Both sandwich complexes possess high acceptor properties and they are easily stacked in high yields to give the first complete series of triple-decker sandwich complexes *27*−*31*.[25]

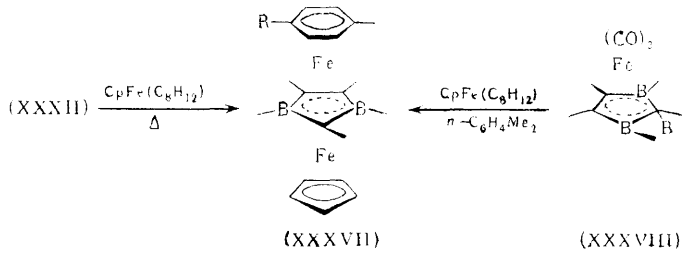
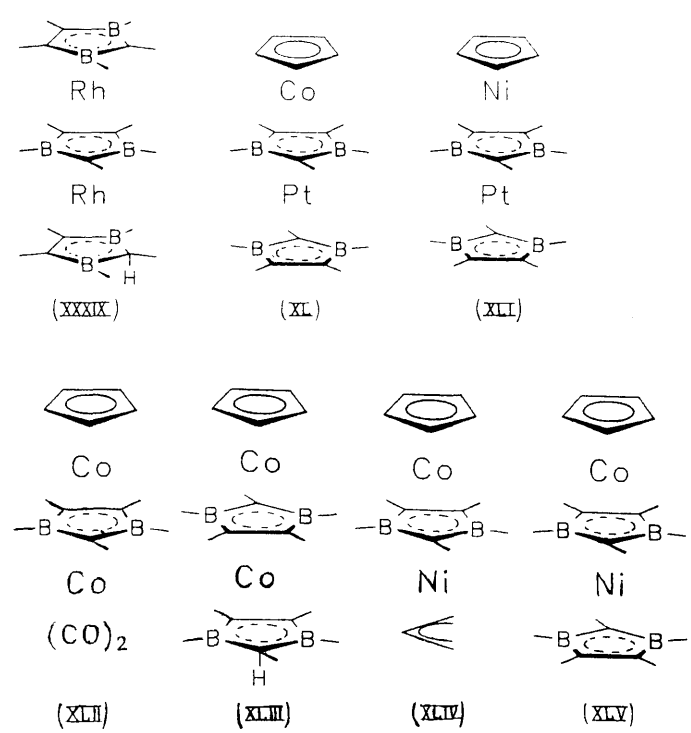
(XXXI)



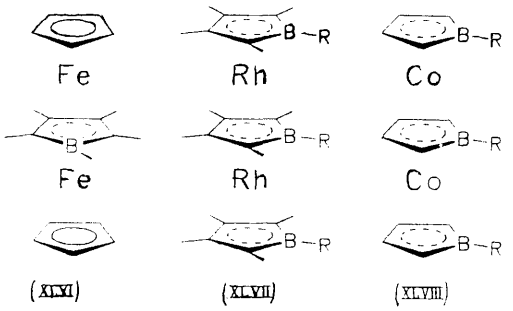
1,3-Dihydro-1,3-diborafulvene derivatives *12*[24] react with Cp_2Ni to give derivatives to *27* with C_5H_5 at the exocyclic C_6 atom. The mixed-valence blue triple-decker *31* is obtained from *10* and $[CpFe(CO)_2]_2$. A three-component reaction between *10*, $CpCo(CO)_2$ and $[CpFe(CO)_2]_2$ only leads in small yields to *30*. Deprotonation of *26* with potassium affords the anion [*26*−H^+], which on reaction with $CpFe(CO)_2I$ gives only a low yield of *30*, since a redox reaction with formation of $[CpFe(CO)_2]_2$ is favoured over the substitution of CO. The magnetic properties of *27*−*31* are in agreement with the number of unpaired electrons as derived from the MO scheme. *27*$^-$ and *30*, are diamagnetic closed-shell species.[25] The former is obtained by reduction of *27* with potassium. Several other sandwich complexes such as *32*−*36* with the 2,3-dihydro-1,3-diborole ligand have been prepared and used as precursors for triple-deckers.[5] *32* is stacked with $CpFe(C_8H_{12})$ to give the 30 VE species *37* (R=H). Another derivative of *37* ($R=CH_3$) is obtained when *38* reacts with $CpFe(C_8H_{12})$ in *p*-xylene.



(XXXII) (XXXIII) (XXXIV), (XXXV) (XXXVI)

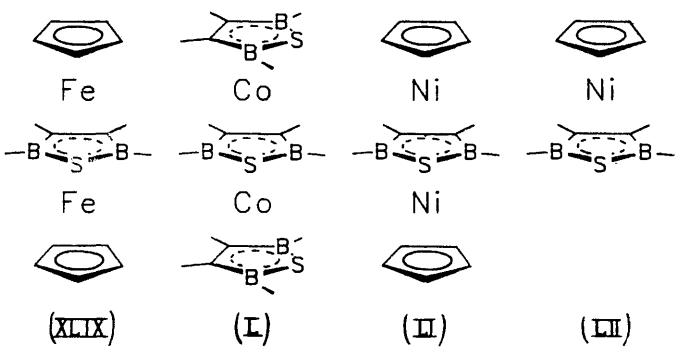
(XXXIV): M=Ni;
(XXXV): M=Pt

On heating the 16 VE sandwich *33* above its melting point, an unusual condensation reaction occurs with elimination of one 2,3-dihydro-1,3-diborole ligand. Red *33* turns into green *39*, a diamagnetic 28 VE triple-decker sandwich.[26] As observed in the sandwich compounds *26*, *32*, *34*, and *35* the axial hydrogen at C2 of the dihydro-diborole ligand of *39* exhibits a high-field ^{1}H NMR signal (δ = 10.1).



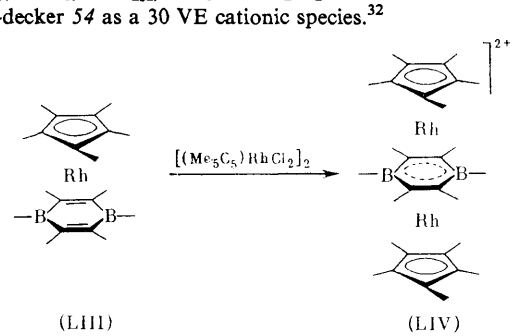
The platinum sandwich *36*, which is formed from *35* by thermal elimination of hydrogen, reacts with $CpCo(C_2H_4)_2$ and $[CpNi(CO)]_2$ to yield the unsymmetrical triple-decker sandwich complexes *40* and *41*, respectively.[27] Two further complexes of this type are obtained when *42* and *44* react with *10* to give *43* and *45*, respectively. Both are 30 VE diamagnetic species which have been used for the construction of penta- and hexadecker sandwich complexes.[29,29]

4. Triple-decker complexes with borole ligands[16]



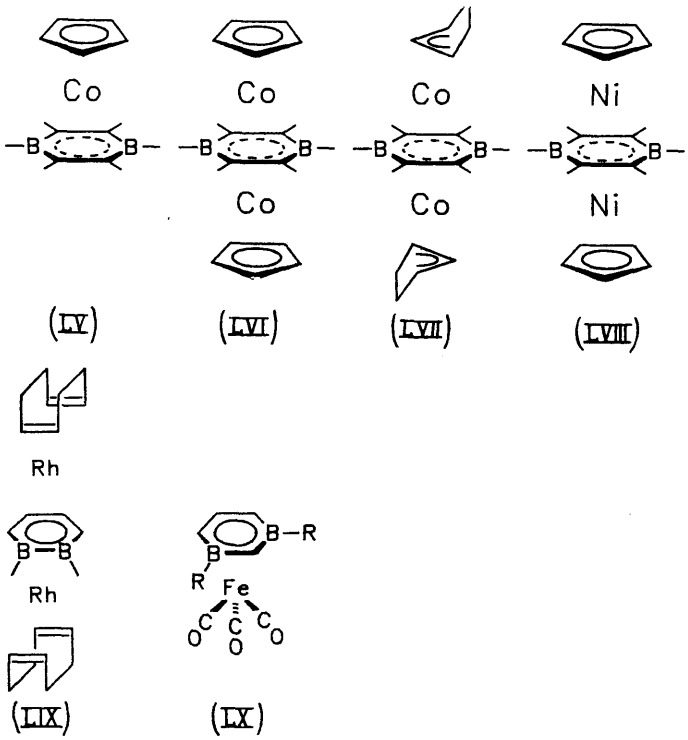
The borole ligand *11* functions as a 4e donor and a 2e acceptor to complete a η^6-system. A number of 18 VE metal complexes of *11* are known, and stacking of sandwich complexes analogous to that of *25* have been reported. Reaction of $[CpFe(CO)_2]_2$ with *11* leads to *46*, a diamagnetic 30 VE complex.

Dehydrogenative complexation of borolenes C_4H_6BR (R = Me, Ph) with $[Rh(C_2H_4)_2Cl]_2$ gives the 30 VE triple-decker *47*.[30] Its reaction with C_5H_5.Na leads to $(C_5H_5)Rh(C_4H_4BR)$ and $[(C_4H_4BR)_2Rh^+]Na^+$. $Co_2(CO)_8$ and the borole ligand form the dinuclear complex $[(C_4H_4BR)Co(CO)_2]_2$, which on thermal treatment results in the formation of *48* (R = Me). The borole rings in *48* are nearly coplanar with torsional angles of 59.8° and 72.2°.



5. Triple-decker complexes with 2.5-dihydro-1,2,5-thiadiborole ligands[15]

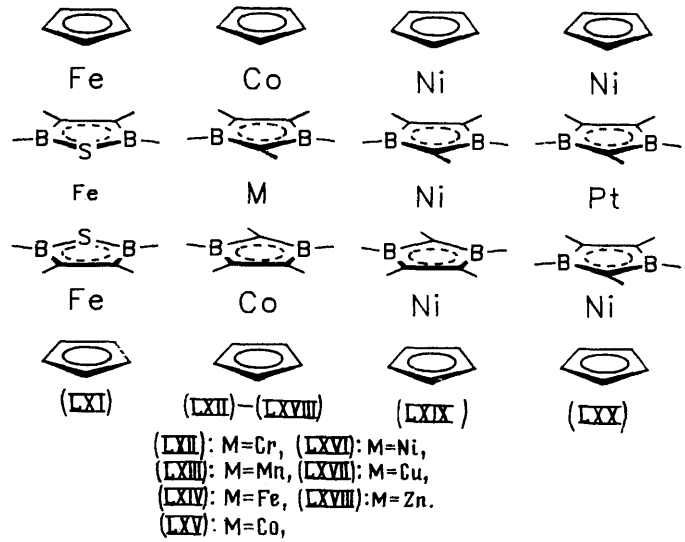
The heterocycle *13* [31] allows the formation of various complexes, however none of the mononuclear species could be stacked to a triple-decker. *13* reacts with $[CpFe(CO)_2]_2$ and $Co_2(CO)_8$ to give the triple-decker sandwich complexes *49* and *50*. Attempts to obtain the 34 VE complex *51* only led to the paramagnetic sandwich *52*, which decomposes at 100 °C to Cp_2Ni and $(13)_2Ni$.



6. 1,4-Diboracyclohexadiene triple-decker complexes[16]

The 1,4-diboracyclohexadiene ligand *14* is related to the borole ligand *11* in its donor properties, and to the 2,3-dihydro-1,3-diborolyl in its acceptor properties. Treating the sandwich *53* with $[(Me_5C_5)RhCl_2]_2/AlCl_3$ in CH_2Cl_2 leads to the formation of the triple-decker *54* as a 30 VE cationic species.[32]

For the construction of the triple-deckers *56*–*58* alkyl derivatives of the 1,4-diboracyclohexene ring have been used. Dehydrogenative complexations of $C_4B_2R_4H_4$ with $(C_5H_5)Co(C_2H_4)_2$ and $[(C_5H_5)Ni(CO)]_2$ lead to the complexes *55*–*58*.[5,33,34]



56 and *58* have 32 and 34 VE, respectively. *57* is a remarkable case, as the hydrogen atoms of $C_4B_2R_4H_6$ are transferred to the cyclopentadienyl groups to form the cyclopentenyl ligands. The constitutions of *57* and *58* have been studied by X-ray structure analyses.

7. 1-2-$B_2C_4R_6$ and 1,3-$B_2C_4R_6$ ligands

Herberich, et al.[35,36] have obtained the first examples of the title ligands stabilised in metal complexes such as *59* and *60*.

Both boron ligands in *59* and *60* should be capable of bridging two $(CH)_nM$ moieties to yield triple-decker sandwich complexes.

reaction between $[(C_5H_5Fe(COD)]_2Zn$ [38] and *13* leads to the 46 VE tetradecker $[(C_5H_5)Fe(13)]_2Zn$, which after reductive cleavage and reaction with Fe^{2+} yields the 42 VE tetradecker sandwich *61*.

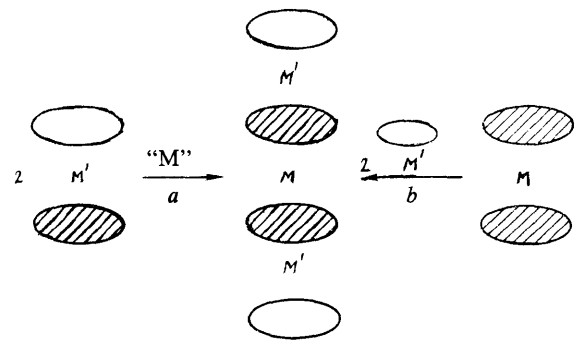


Figure 1. Routes of formation for oligodecker compounds.

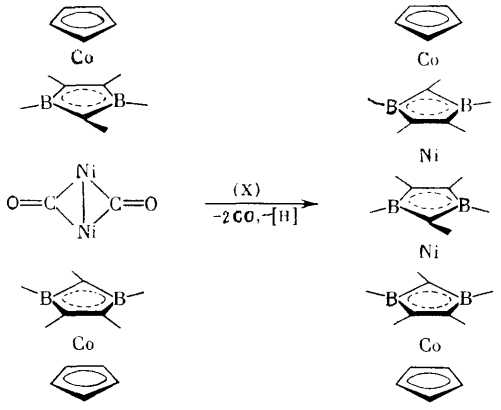
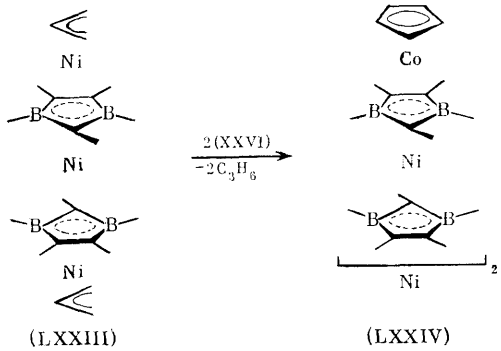


IV. Oligodecker complexes[4,5]

As outlined above the formation of triple-decker compounds can be achieved via several routes. For the construction of oligodecker complexes two reaction principles have been applied: a) reaction of two sandwich anions with a metal cation and b) stacking of a Lewis-acidic sandwich with two $(C_5H_5)M^+$ complex fragments (Fig. 1).

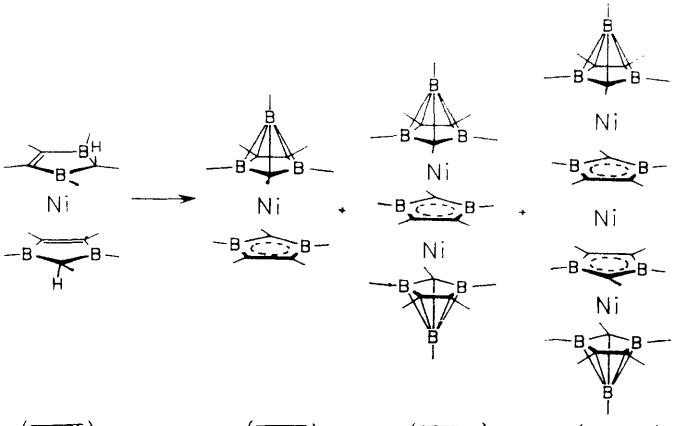
We synthesised and structurally characterised the first example of a tetradecker complex with the 1,2,5-thiadiborole ligand *13* in the bridging position. The diamagnetic, 42 VE hexacarbonyl dimanganese-iron complex $[(CO)_3Mn(C_2H_2B_2R_2S)]_2Fe$ was obtained in low yield by cleaving the triple-decker $[(CO)_3Mn]_2(13)$ with $C_5H_5^-$ and reacting the formed anion $[(CO)_3Mn(13)]^-$ with Fe^{2+}.[37] The



The first series of tetradecker complexes has been obtained from the deprotonated cobalt sandwich $[26-H^+]$ and the metal dications Cr(*62*), Mn(*63*), Fe(*64*), Co(*65*), Ni(*66*), Cu(*67*), and Zn(*68*).[39,40] With the exception of *68* (M = Zn) the highly coloured trinuclear species are paramagnetic; the compounds *62*–*65* have a high-spin configuration. All complexes are structurally characterised: the 2,3-dihydro-1,3-diborolyl rings adopt an antiperiplanar arrangement, and the central metal to ring distances correlate well with the Shannon–Prewitt ionic radii for octahedrally coordinated M^{2+} ions. Considerable deviations from the ideal tetradecker sandwich structure are observed due to a slip of the central metal away from the position above the centroid of the heterocycle towards the C2 carbon (between the two boron atoms). In contrast to the antiperiplanar arrangement of the boron heterocycles in the

diamagnetic 46 VE tetradecker *69*,[4] the isoelectronic platinum complex *70*,[27] obtained via reaction type *b*) in Fig. 1, exhibits a synclinal conformation.

(LXXI) (LXXII)



To extend the number of stacks, we have explored routes to pentadecker and hexadecker complexes. The pentadecker *72* was first obtained upon reaction of the tetranuclear complex *71* with the ligand *10*, which replaces the two CO groups of the diamagnetic, 58 VE *71* to yield the paramagnetic, 57 VE *72*. Alternatively, *72* is formed when the allyl groups in the triple-decker *44* is susbtituted for *10* to give the unsymmetrical triple-decker sandwich *45*. Its reaction with *44* leads to the pentadecker *72*.[41] This compound has been studied by X-ray, ESR, paramagnetic NMR and cyclic voltammetry. It was shown that paramagnetic *72* can be reduced to the diamagnetic, 58 VE anion and to the paramagnetic, 59 VE dianion. The next step led us to the synthesis of the first hexadecker sandwich complex via the reaction of the bis(allyl)tetradecker *73* with two sandwich molecules *26* in refluxing mesitylene. Besides the diamagnetic 70 VE hexadecker *74* paramagnetic triple-decker and tetra-decker were also formed.[42] The second route leading to *74* involves stacking at both ends of the bis(2,3-dihydro-1,3-diborole)nickel sandwich *34* with the allyl-triple-decker *44* at 160 °C. Again several by-products are formed, which can be separated by column chromatography. Due to the poor quality of the crystals structural determination of the red-violet *74* was unsuccessful.

(LXXIII) (LXXIV)

V. Carboranyl sandwich complexes

The bis(2,3-dihydro-1,3-diborole)nickel sandwich *34* exhibits an unusual reactivity: at room temperature it is slowly transformed into *75* and a series of carboranyl nickel oligodecker complexes *76*, *77* and higher molecular species (determined by FAB mass spectra up to the decadecker complex).[43]

(XXXIV) (LXXV) (LXXVI) (LXXVII)

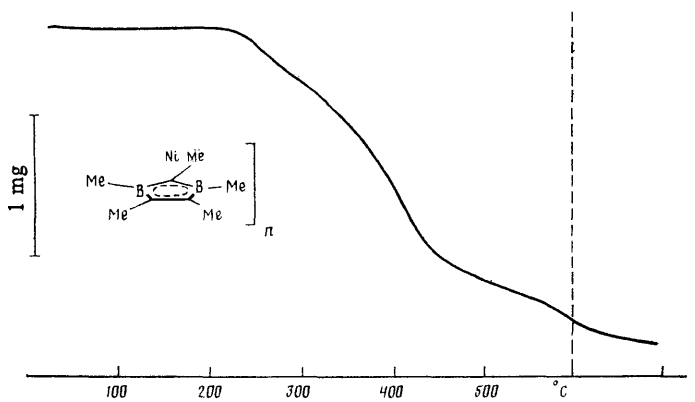
Its formation occurs via capping of the diborolyl ring with a boranediyl fragment (R−B:) to give *75* after elimination of the two axial hydrogen atoms from *34*. Besides capping, a stacking to oligodecker takes place, which leads to *76*, *77* and higher oligodeckers. Several of the new carboranylnickel complexes have been structurally characterised.[43,44] This unusual finding of capping and stacking at room temperature clearly indicated a route to polydecker formation. The problem was to prevent the capping reaction, because it stops the one-dimensional system from growing.

VI. Polydecker sandwich complexes

For the synthesis of polydecker compounds reactive monomers and/or dimers are required. Reactions of sandwich complex dianions with metal dications shoud lead to polymers. However, the only complex dianion $[(C_3H_3B_2)_2Pt]^{2-}$ [*36*]$^{2-}$ was oxidised by Fe^{2+} to neutral *36* in an attempt to build a mixed-metal polymer, *78*−*79*.

The unusual reaction sequence of capping and stacking when the nickel sandwich *34* is heated to 80 °C for one hour in benzene to give *75*−*77* and higher oligomers indicated that the combination of Ni(d^{10}) and the 2,3-dihydro-1,3-diborolyl [*10*−H] leads to stacked products. This "self-organisation" of stacks (which also occurs slowly at room temperature) has the disadvantage of the capping reaction (tricarbahexaboranyl formation) and therefore prevents the oligomers from growing to polymers. Therefore we have studied polycondensation reactions of tris(allyl)dinickel-(μ-2,3-dihydro-1,3-diborolyl) complexes *78*, which on heating slowly to 200 °C *in vacuo* yield black polymeric products *79*, bis(allyl)nickel and hexadiene.[5,45] The material is readily attacked by oxygen at ambient temperature. It does not dissolve in toluene, tetrahydrofuran or methylene chloride. A TGA study of three polymeric products with different substituents at the 1,3-diborolyl ring showed that on heating from 200 to 450 °C the polymers lose weight (almost linearly with increasing temperature). Above 450 °C the loss of mass is

reduced (Fig. 2, heating was carried out under an atmosphere of nitrogen, 10 °C/min, up to 600 °C). The absolute mass losses of three polymers (in the range 200–600 °C) amount to 26–27%.



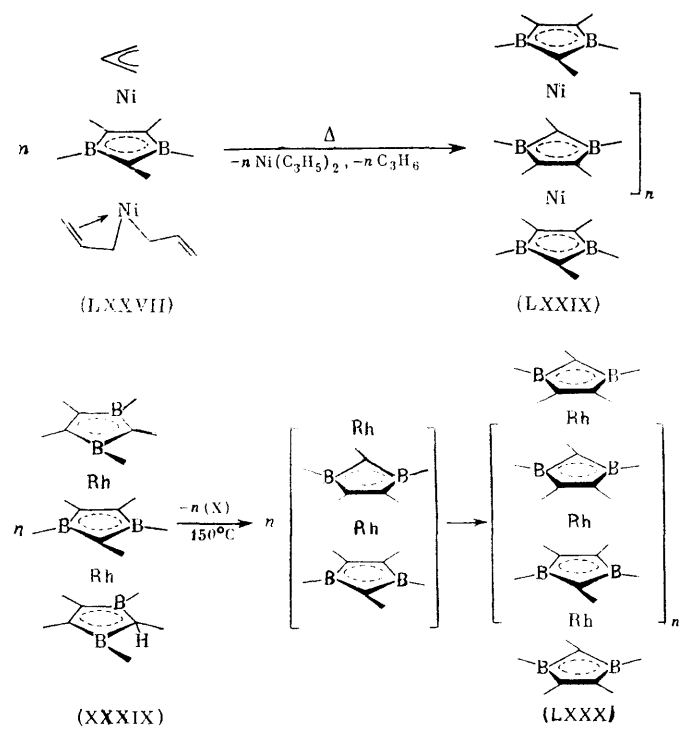


Figure 2. TGA study of compound (LXXIX).

The second polymer was formed by heating the red sandwich *33* to give the green rhodium triple-decker *39*. Elimination of the terminal 2,3-dihydro-1,3-diborole ligand *10* occurs, leaving the reactive double stack behind, which undergoes stacking to the black polymer. *12a* is less sensitive to oxygen than *79*.

The nickel and rhodium polydeckers are amoprhous and insoluble in organic solvents. Therefore a determination of the average molecular weight is not possible. EXAFS studies of *79* at 120, 300 and 340 K confirm the polydecker sandwich structure.[45,46] A 1:1 ratio of Ni to ligand and a Ni...Ni distance of 3.35 Å was observed. Preliminary results of an EXAFS study of the rhodium polymer *80* indicate a Rh...Rh distance of 3.6 Å.

Conductivity measurement on the nickel polymer gave results which are characteristic for a semiconductor (hopping mechanism). The four-probe measurements at room temperature yielded a conductivity of 10^{-2} Scm^{-1} which is similar to that of germanium. In contrast the rhodium polymer is an insulator, the conductivity is 10^{-10} Scm^{-1}. The high sensitivity toward oxygen results in a drop of the conductivity when the sample is exposed to air or doped with iodine. However, chemical alteration of the ligand and the switch to less electronic-rich metals (e.g. iron) may have stabilising effects.

Acknowledgements

I wish to thank my co-workers for their valuable contributions in developing this field of oligodecker and polydecker sandwich complexes. Our research reported here was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the State of Baden-Württemberg and the BASF AG.

Equilibria in interpolyelectrolyte reactions and the phenomenon of molecular "recognition" in solutions of interpolyelectrolyte complexes

V A Izumrudov, A B Zezin, V A Kabanov
Lomonosov Moscow State University

ABSTRACT. The results of studies on the equilibria in interpolyelectrolyte reactions occurring in homogeneous aqueous solutions of linear synthetic polyelectrolytes bearing unlike charges and accompanied by the transfer of polyions are described. The influence of the chemical nature of low-molecular-weight ions and also of the chemical nature, linear charge density, and the degree of polymerisation of polyelectrolytes on equilibria in interpolyelectrolyte exchange and substitution is analysed. The phenomenon of the molecular "recognition" of one set of polyions by others is described and the factors leading to the selective binding of polyelectrolytes are indicated.

The bibliography includes 93 references.

I. Introduction

The study of the reactions betweem chemically complementary linear macromolecules and also the structures and properties of the interpolymer complexes (IPC) formed constitute one of the most interesting and promising aspects of the development of the physical chemistry of macromolecular compounds. The knowledge of the main features of the occurrence of such interpolymer reactions (IPR) is essential for the creation and further development of a general theory of interpolymer reactions and interpolymer complexes. This refers fully also to interpolyelectrolyte reactions involving polyelectrolyte complexes (PEC). Cooperative interpolymer reactions are convenient models for the study of the processes in which biopolymers participate, for example, the self-assembly of complex structures such as viruses, for a deeper understanding of the mechanism of the self-regulation of enzyme systems, and for the elucidation of the principles of the action of artificial antigens and the creation of fundamentally new vaccines based on synthetic polyelectrolytes.

The study of the equilibria in interpolyelectrolyte reactions is also essential for the specific synthesis and the optimisation of the application of polyelectrolyte complexes in various branches of the national economy, for example as highly effective flocculants, stabilisers of colloidal dispersions, ion-exchange materials, membranes, binders, sorbents, structure-forming agents, physiologically active compounds, etc. This task is of particularly great current interest in connection with the prospects of using water-soluble polyelectrolyte complexes as carriers of biologically active substances, in particular enzymes, and their use in this state in biotechnology and medicine.

This review gives an account of the results of our systematic studies of the equilibria in interpolymer reactions accompanied by the transfer of polyions. The most important factors determining the direction of these reactions and the high selectivity of the interpolyelectrolyte interaction are specified and discussed.

II. Reactions involving interpolymer complexes

The reactions between chemically complementary polymers, i.e. polymers whose functional groups have an affinity for one another and whose geometrical structure does not hinder the formation of a fairly large number of intermolecular bonds per chain, have now been investigated in fair detail.[1–3] The reactive groups can be located both in the main chain and in the side groups and also on the surfaces of globular or other particles. The products of such reactions have come to be referred to as interpolymer complexes.

The nature of the forces by virtue of which interpolymer complexes exist can be various: hydrogen bonds [complexes of polycarboxylic acids with polyvinylpyrrolidinone, poly(vinyl alcohol), and poly(ethylene glycol);[4–9] complexes of biopolymers—for example, the native form of DNA [10]], electrostatic interactions (polyelectrolyte complexes[2,11,12]), van der Waals interactions [stereocomplexes of iso- and syndiotactic poly(methyl methacrylates)[13–15]], and donor–acceptor interactions (charge-transfer complexes[16]). Hydrophobic interactions may play a significant role in the stabilisation of interpolymer complexes in aqueous solutions.[17,18] The reason for the stability of such complexes is the cooperative nature of the interaction of the polymers with one another. The formation of interpolymer complexes is accompanied by an appreciable entropy gain compared with the analogous reactions involving low-molecular-weight reactants (for equal degrees of reaction) because after the formation of one bond between the units of the reacting macromolecules, the formation of all the subsequent bonds no longer entails the loss of additional translational degrees of freedom.

The physicochemical, mechanical, and other properties of interpolymer complexes differ significantly from those of their constituent components.[19] These polymeric compounds exist both in dilute solutions and in block and can be obtained either by mixing

the solutions of macromolecular reactants or as a result of matrix polymer reactions.[20–23]

One of the important properties of interpolymer complexes is their ability to enter into interpolymer exchange and substitution reactions in aqueous solutions. The essential feature of these reactions is the transfer of macromolecules from one interpolymer complex species to another. Interpolymer reactions involving interpolymer complexes stabilised by a system of hydrogen bonds were discovered and investigated systematically in the 1970s.[1,3,4–9,17–19,23–32]

The selectivity of the polymer–polymer interactions in systems containing more than two types of polymer molecules is also directly related to the interpolymer reactions. Such selectivity is a characteristic evolution-dependent property of the components of living organisms.[33,34] The selectivity of interactions is characteristic also of simpler polymer systems.[3,24,25]

III. Intermacromolecular reactions in solutions of polyelectrolytes bearing unlike charges

The formation of complexes between ionogenic polymers, manifested by a phase separation of the liquid–liquid type in their solutions, was discovered as early as the 1890s.[35] Such phase separation in solutions of polyelectrolytes, incorporating in their composition hydrophilic non-ionogenic groups for a low content of ionogenic groups, has been called complex coacervation.[36,37] According to modern ideas, coacervation is none other than the formation of polyelectrolyte complexes. The thermodynamic description of the phase separation process in the formation of a coacervate complex has been achieved, the composition and concentration of the complex have been predicted, and the influence of salts and various low-molecular-weight substances on its stability has been investigated.[38–41] The importance of the study of these questions arises from the fact that the coacervation phenomenon is used in various technological processes, for example in microencapsulation[42] or in the creation of medicinal preparations. Complex coacervation has been considered as a possible mechanism of the prebiological compartmentalisation, which constitutes an important stage in the prebiological evolution of organic compounds.[43] It therefore became necessary to investigate the interaction of such coacervate complexes with polyelectrolytes.[44–46]

The attempts to investigate complex formation in solutions of polyions bearing unlike charges with a high linear charge density were undertaken as early as the 1960s.[47–49] It was established that the precipitate of the polymeric complex formed as a result of the macromolecular reaction contains virtually equimolar amounts of polymeric components, while the precipitate itself is insoluble in any of the known individual solvents. Admittedly it is possible to dissolve it in ternary systems of the acetone–water–NaBr type, but this process takes place as a result of the decomposition of the complex — the polyelectrolytes in such systems hardly interact with one another. The combination of insolubility in familiar simple solvents with a high swellability in water, selectivity in the sorption of ions, and high biological compatibility have led to the application of such complexes as materials for medical-biological purposes.[50] However, the insolubility of stoichiometric complexes, formed by strong polyelectrolytes, as well as the insolubility of the coacervate complexes hinder the study of the structure of such species and also of the interpolymer reactions involving them.

The study of the cooperative interpolymer reactions in solutions of synthetic polyelectrolytes became possible after the discovery of non-stoichiometric polyelectrolyte complexes (NPEC) formed by polyions with a high charge density. Notable properties of non-stoichiometric polyelectrolyte complexes are their ability to dissolve in water and to participate in interpolyelectrolyte reactions occurring in homogeneous aqueous solutions. This factor gave rise to the possibility of using various physicochemical methods for the study of polymer solutions in order to investigate such reactions (light scattering, high-speed sedimentation in the analytical version, viscometry, etc.) and made it possible to avoid many complications which arise in the study of colloidal dispersions of insoluble stoichiometric polyelectrolyte complexes (SPEC).

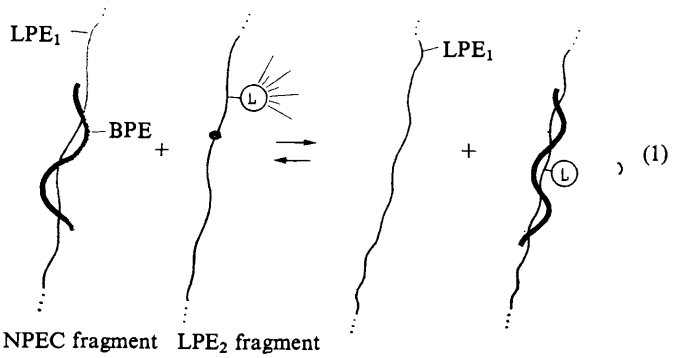
IV. Water-soluble non-stoichiometric polyelectrolyte complexes

The procedure used to obtain water-soluble non-stoichiomdtric polyelectrolyte complexes was first described in detail by Tsuchida et al.[51] It consisted in mixing aqueous solutions of aromatic ionenes and sodium polystyrenesulphonate (NaPSS) in non-equivalent proportions. The complete dissolution of the polyelectrolyte complex is observed in the presence of a three-fold excess of the charged units of sodium polystyrenesulphonate relative to the charged units of ionene. After the introduction of excess amounts of ionene into a solution of sodium polystyrenesulphonate, an insoluble stoichiometric polyelectrolyte complex is obtained instead of the non-stoichiometric one, while the excess ionene remains in solution. These observations led the authors[51] to the conclusion that polymers of the ionene series have a special capacity for the formation of soluble non-stoichiometric polyelectrolyte complexes, which is in their view associated with the location of the charged groups in the ridge of the macromolecules. This conclusion was confirmed by the failure of the attempt to obtain water-soluble non-stoichiometric polyelectrolyte complexes from sodium polystyrenesulphonate and polytrimethylbenzylvinylammonium chloride, i.e. from a pair of electrolytes in which the ionogenic groups are located in the lateral substituents. It was soon shown for the reaction between sodium polyacrylate and 5,6-ionene bromide that aliphatic ionenes are also capable of forming water-soluble non-stoichiometric polyelectrolyte complexes.[52] This finding was also seemingly consistent with the hypothesis of the exceptional properties of ionenes, which, if one agreed with the conclusions of Gulyaeva et al.,[52] are due to the steric "accessibility" of the positively charged quaternary nitrogen atoms.

It was shown later that water-soluble non-stoichiometric polyelectrolyte complexes can be obtained, whilst maintaining certain conditions, from polyelectrolytes bearing unlike charges and having a wide variety of chemical structures.[53–55] It has been established[53] in relation to the sodium polymethacrylate (NaPMA)–poly-*N*-ethyl-4-vinylpyridinium bromide (PEVP) system that water-soluble non-stoichiometric polyelectrolyte complexes can be obtained for polyions each of which contains charged groups in their lateral substituents. In this case, i.e. when at least one weak polyelectrolyte (sodium polymethacrylate) is incorporated in the composition of the non-stoichiometric polyelectrolyte complex, there is a possibility of the formation of non-stoichiometric polyelectrolyte complexes under conditions where the interpolymer reaction is still far from completion. Such non-stoichiometric polyelectrolyte complexes, formed in acid media in the reaction of polymethacrylic acid

(PMAA) with poly-*N*-ethyl-4-vinylpyridinium bromide, are insoluble in water. The addition of alkali leads to the ionisation of the free carboxy-groups of the polymethacrylic acid, incorporated in the non-stoichiometric polyelectrolyte complex in excess, and to the dissolution of the non-stoichiometric polyelectrolyte complex.

In conformity with the terminology adopted nowadays,[2] the non-stoichiometric polyelectrolyte complex species contains a lyophilising polyelectrolyte (LPE) and the oppositely charged blocking polyelectrolyte (BPE). The units of the lyophilising polyelectrolyte are incorporated in the non-stoichiometric polyelectrolyte complex species in excess relative to the units of the blocking polyelectrolyte, i.e. the composition of the non-stoichiometric polyelectrolyte complex is φ = [BPE]/[LPE] and φ is less than unity. The fragments of the lyophilising polyelectrolyte chains and of the blocking polyelectrolyte chain, linked by interpolymer salt bonds, form relatively hydrophobic double-stranded sequences, which tend to segregate in aqueous solutions. The tails and loops of the lyophilising polyelectrolyte (see the left-hand side of Scheme 1) ensure the solubility of the non-stoichiometric polyelectrolyte species as a whole.



A simple and universal method of preparation of non-stoichiometric polyelectrolyte complexes consists in the direct mixing of aqueous solutions of polyelectrolytes bearing unlike charges taken in non-equivalent proportions in the pH range where they are both fully charged and in the presence of small amounts of a low-molecular-weight electrolyte.

Clearly in this synthetic method polymeric complexes of different composition, including complexes insoluble in water, should be formed as a consequence of inevitable local supersaturation. However, the final product—a water-soluble non-stoichiometric polyelectrolyte—is homogeneous as regards composition. The study of aqueous salt solutions of various non-stoichiometric polyelectrolytes by light scattering[55] showed that the macromolecular characteristics of the non-stoichiometric polyelectrolyte species are independent of the method of preparation, i.e. such complexes are equilibrium compounds. These findings show that interpolyelectrolyte reactions accompanied by the transfer of polyions do indeed take place in aqueous solutions.

Evidently, the observed[51] dissolution of the suspension of a stoichiometric polyelectrolyte complex incorporating sodium polystyrenesulphonate and ionene, which occurred after the addition of an excess of sodium polystyrenesulphonate, is also caused by the transfer of ionene chains from the stoichiometric polyelectrolyte complex species to the sodium polystyrenesulphonate chains introduced and by the appearance of new water-soluble non-stoichiometric polyelectrolyte species. However, the transfer of polyions, which occurs in this system also in salt-free media, is not due to structural-chemical characteristics[51] but is caused by the low linear charge density of ionene. The breakdown of the electrostatic complementarity of the interacting chains, as a result of both a change in the linear charge density and the introduction of low-molecular-weight ions capable of being bound specifically to the charged units of the macromolecules incorporated in the non-stoichiometric polyelectrolyte complex, accelerates the interpolyelectrolyte exchange.[56] In dilute salt-free solutions of electrostatically complementary polyelectrolytes, for example, in mixtures of sodium polymethacrylate and poly-*N*-ethyl-4-vinylpyridinium bromide,[57] the transfer of polyions hardly occurs, but, after the addition of low-molecular-weight electrolytes its rate increases sharply. The formation of soluble non-stoichiometric polyelectrolyte complexes is not observed in mixtures of salt-free solutions of electrostatically complementary polyions apparently for the same reason.[51]

V. Interpolyelectrolyte reactions

Cooperative interpolyelectrolyte reactions of various types, occurring in solutions of linear synthetic polyelectrolytes bearing unlike charges, are presented below in a generalised schematic form:

NPEC fragment LPE_2 fragment

where LPE_1 and LPE_2 are lyophilising polyelectrolytes competing for binding with the blocking polyelectrolyte. Predominantly the literature has reported interpolyelectrolyte reactions in solutions of non-stoichiometric polyelectrolyte complexes, where polyanions play the role of the lyophilising polyelectrolyte, while the blocking polyelectrolyte consists of polycations.

The transfer of the blocking polyelectrolyte to the lyophilising polyelectrolyte of the same chemical nature as that incorporated in the composition of the initial non-stoichiometric polyelectrolyte (in this case the initial and resulting non-stoichiometric polyelectrolytes are stabilised by interpolyelectrolyte salt bonds of the same kind) is referred to as the interpolyelectrolyte exchange reaction. Otherwise, if LPE_1 and LPE_2 have different chemical structures, then the transfer of the blocking polyelectrolyte to LPE_2 is called an interpolyelectrolyte substitution reaction. Apart from these two main types of interpolyelectrolyte reactions, the reaction involving the coupling of polyions bearing unlike charges has been investigated. The interpolyelectrolyte reactions described in this review take place in homogeneous aqueous solutions.

The occurrence of interpolyelectrolyte reactions involving a wide range of polyions has been established by various methods. The formation of products was detected on the sedimentograms for solutions of reaction mixtures in both the normal and scanning versions.[54,58–61] The molecular characteristics of the non-stoichiometric polyelectrolyte species—the products of the interpolyelectrolyte exchange—were measured by the light scattering method.[55,62–64] The interpolyelectrolyte substitution reaction was accompanied in individual instances by a change in viscosity or by the phase separation of the reaction mixtures, which made it possible to use viscometric and turbidimetric titration for their detection and investigation.[58,61] The rate of formation and decomposition of polymer–polymer complexes was recorded directly by the luminescence quenching method.[65] The advantages of this method include high sensitivity, which makes it possible to work with highly dilute polymer solutions, the possibility of studying opalescent solutions, the absence of a need for the introduction of a supporting low-molecular-weight electrolyte into the system, as happens, for example when light scattering and the high-speed sedimentation

method are used, and the possibility of continuous recording of rapid processes and hence the possibility of studying their kinetics.

The essential feature of the luminescence quenching method as applied to the study of interpolyelectrolyte reactions is as follows. A luminescent label L (see Scheme 1) is introduced into one of the polyelectrolytes, for example LPE_2. A blocking polyelectrolyte whose units are luminescence quenching agents, is selected. The formation (or decomposition) of the lyophilising polyelectrolyte LPE* carrying a luminescent label on reaction with the blocking polyelectrolyte is accompanied by a decrease (or increase) in the relative intensity of the luminescence of the solution I/I_0 (I_0 is the intensity of the luminescence of the LPE* solution). The degree of quenching is determined by the composition of the complex φ. By recording the change in I/I_0 in the reaction mixture containing all three polyelectrolytes, it is possible to follow the interpolyelectrolyte reaction.

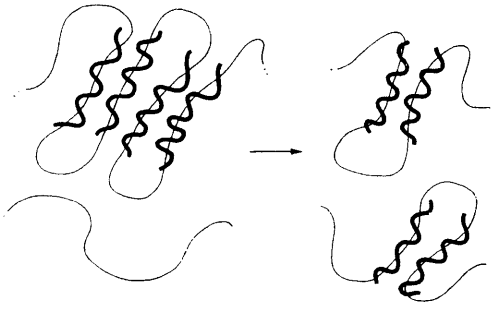
The change in the quenching of the luminescence observed in the experiments constitutes direct evidence for the replacement of the LPE_1-BPE contacts by LPE_2-BPE contacts as a result of the interpolyelectrolyte reaction (1).

Salts of polycarboxylic acids — polymethacrylic and polyacrylic — bearing a luminescent label were used as the LPE*. The introduction of luminescent anthracene or pyrene groups into their chains was achieved by the interaction of fractions of the polyacids with anthryl- or pyrenyl-diazomethane by the method of Krakovyak et al.[66] In contrast to the copolymerisation method,[67] this procedure makes it possible to obtain specimens of labelled and unlabelled polyacids with the same molecular weight distribution (MWD). Polymeric amines played the role of blocking polycationic quenching agents. Polycations with pyridinium groups, which effectively quench luminescence, have been most widely used:[68] poly-*N*-ethyl-4-vinylpyridinium bromide together with its statistical copolymers and poly-4-vinylpyridine (PEVP-β).[69]

The question of the validity of the application of the luminescence quenching method in the study of interpolyelectrolyte reactions with selected polyelectrolytes is important. The kinetics of the quenching of luminescence in solutions of complexes of lyophilising polyelectrolytes bearing a luminescent label and polycationic quenching agents were investigated with the aid of a pulsed fluorimeter using single photon counting. The identity of the kinetics of the quenching of the luminescence of the NPEC* and the initial NaPMA* with the simultaneous decrease in luminescence intensity shows that the static quenching mechanism predominates in NPEC* solutions.[70]

This picture has been observed in solutions of various NPEC*, regardless of the composition of the latter, at different concentrations of the low-molecular-weight electrolytes introduced into the system and for different linear charge densities and degrees of polymerisation of the polyions. This means that in all the systems investigated the quenching mechanism is static, i.e. the lifetime of the contacts between the units of the polyions forming the NPEC* under the conditions investigated is significantly greater than the lifetime of the excited state of the label.[71]

VI. Equilibria in interpolyelectrolyte reactions



Before proceeding to the description of the results of the study of equilibria in interpolyelectrolyte exchange and substitution reactions, it is necessary to make the following comments. Low-molecular-weight electrolytes are known to exert an enormous influence on the behaviour and state of the polyelectrolyte complex species in solutions. At a high ionic strength of the solution, at which extensive decomposition of the cooperative system of interpolyelectrolyte salt bonds takes place, the uniform distribution of the blocking polyelectrolyte with respect to the lyophilising polyelectrolyte breaks down (the so called disproportionation is observed[63]), while in concentrated solutions of simple salts polyelectrolyte complexes are fully dissociated into the constituent polyions.[65] The results described below refer to interpolyelectrolyte reactions occurring under conditions far from such far-reaching action on polyelectrolyte complex species. In the dilute solutions of low-molecular-weight electrolytes investigated, the cooperative system of interpolyelectrolyte salt bonds in the initial polyelectrolyte complexes is still entirely stable as are those formed subsequently.

1. The equilibrium in an interpolyelectrolyte exchange reaction

(a) The uniform distribution of the blocking polyelectrolyte among the non-stoichiometric polyelectrolyte species

It follows from the results of the study of aqueous salt solutions of non-stoichiometric polyelectrolyte complexes by the light scattering method[55] that the molecular characteristic of the species of such complexes are independent of the method of synthesis, i.e. the non-stoichiometric polyelectrolyte complexes are equilibrium interpolymer compounds. The determination of the equilibrium distribution of the blocking polyelectrolyte among the polymeric complex species presupposes the transfer of blocking polyelectrolyte chains from one set of lyophilising polyelectrolyte chains to another, i.e. the occurrence of reaction (1) in the $LPE_1 = LPE_2$ version. We investigated the equilibrium in such an exchange reaction between a non-stoichiometric polyelectrolyte complex and a free lyophilising polyelectrolyte and also between non-stoichiometric polyelectrolyte complexes of different composition.

We shall consider initially the case where the degrees of polymerisation of the lyophilising and blocking polyelectrolytes $\overline{P}$ satisfy the condition $\overline{P}_{LPE} > \overline{P}_{BPE}$ and each non-stoichiometric polyelectrolyte complex species incorporates a considerable number of relatively short blocking polyelectrolyte chains. At the present time, this is the situation most frequently encountered in practice. The properties of such non-stoichiometric polyelectrolytes have been studied in detail and such complexes have in fact been used for the solution of many important problems, in particular for the creation of reversibly soluble immobilised enzymes.[72] The results of sedimentation studies[59] have shown that the transfer of blocking polyelectrolyte macromolecules from the non-stoichiometric polyelectrolyte complex to the free polyions of the lyophilising polyelectrolyte does indeed occur and results in the formation of a new non-stoichiometric polyelectrolyte whose composition is identical with that of the mixture of polyelectrolytes [reaction (2)]:

(2)

It follows from the comparison of the sedimentograms that in the solution of a mixture of a non-stoichiometric polyelectrolyte and a lyophilising polyelectrolyte a single component NPEC* is observed, its sedimentation coefficient not differing from that of a specially prepared non-stoichiometric polyelectrolyte complex having the same composition as the reaction mixture. The areas of the peaks on both sedimentograms also agree. The latter fact demonstrates convincingly that the interpolyelectrolyte exchange reaction (2) reaches completion during the experiment.

The results of the study of the same system by the luminescence quenching method using labelled NaPMA* (containing on average one anthrylmethyl methacrylate unit per 900 chain units) agree with the above conclusion. The relative luminescence intensity of aqueous salt solution of a mixture of NPEC* (NaPMA*–PEVP) having the composition $\varphi = 0.45$ and NaPMA with [NaPMA*] = [NaPMA] agrees with the value of I/I_0 for the solution of a non-stoichiometric polyelectrolyte (NaPMA*–PEVP) having the composition $\varphi = 0.23$ and incorporating half the amount of the polycationic quenching agent. The addition of an aqueous solution of the labelled NaPMA* to the solution of the non-stoichiometric polyelectrolyte complex (NaPMA–PEVP) leads to the same result.

Similar phenomena have been observed also on mixing solutions of non-stoichiometric polyelectrolyte complexes formed by a pair of the same polyelectrolytes but in different proportions.[59]

Thus interpolyelectrolyte exchange reactions lead to the appearance of non-stoichiometric polyelectrolyte complexes characterised by a uniform distribution of the blocking polyelectrolyte chains among the non-stoichiometric polyelectrolyte complex species, whose composition is identical to that of the mixture of polyelectrolytes formed ultimately. This has been explained[59] by the fact that, for a constant total number of interchain salt bonds and with retention of solubility, a higher entropy corresponds to a uniform distribution of the blocking polyelectrolyte among the non-stoichiometric polyelectrolyte complex species, i.e. the driving force of the transfer of polyions is the increase in the entropy of the systems. This constitutes a significant difference between the reactions investigated and those between linear polyelectrolytes and globular proteins[73–75] and also the reactions between polymethacrylic acid and poly(ethylene glycol) or poly-*N*-vinylpyrrolidinone[76] in which disproportionation is clearly manifested, i.e. there is a significantly non-uniform distribution of one of the macromolecular components among the species of the corresponding polymeric complexes.

The important question of the state and behaviour of the products of the interpolymer reactions—non-stoichiometric polyelectrolyte complexes whose composition is identical with that of the reaction mixture—remains obscure in the study of the exchange reaction. In particular, it is not clear whether the exchange of chains of the blocking polyelectrolyte between the non-stoichiometric polyelectrolyte complex species of the same composition, which are illustrated on the right-hand side of scheme (2), does occur. Evidently, this problem cannot be solved solely by studying the system examined above in the $\overline{P}_{LPE} \gg \overline{P}_{BPE}$ version. Even if such mutual exchange of the blocking polyelectrolyte chains between the non-stoichiometric polyelectrolyte complex species does occur, it is not accompanied by a change in the properties of the species themselves; in particular, it should not lead to an alteration of the luminescence intensity because it is not accompanied by a change in the number of label–quenching agent contacts.

However, it was found that such reactions are characteristic of non-stoichiometric polyelectrolyte complexes formed by pairs of polyelectrolytes with not unduly different degrees of polymerisation of the lyophilising and blocking polyelectrolytes. The ratio of the degrees of polymerisation of the lyophilising and blocking polyelectrolytes can be specified in such a way that it coincides with the ratio of the numbers of units [BPE]/[LPE] incorporated in the non-stoichiometric polyelectrolyte complex, i.e. $\overline{P}_{BPE}/\overline{P}_{LPE}$ = [BPE]/[LPE]. In a non-stoichiometric polyelectrolyte complex of this composition, there is on average only one blocking polyelectrolyte chain per lyophilising polyelectrolyte chain. If a free lyophilising polyelectrolyte is added to the solution of the given non-stoichiometric polyelectrolyte, then the "migration" of the blocking polyelectrolyte chains from the non-stoichiometric polyelectrolyte complex species to the chains introduced will naturally not be accompanied by a change in composition and such a process would correspond entirely to the conditions formulated above for the reaction involving the mutual exchange of blocking polyelectrolyte chains between the non-stoichiometric polyelectrolyte complex species.

We investigated the behaviour of the system obtained on mixing aqueous solutions of a free lyophilising polyelectrolyte and a non-stoichiometric polyelectrolyte complex formed by sodium polymethacrylate ($\overline{P}_{LPE} = 3000$) and poly-*N*-ethyl-4-vinylpyridinium bromide ($\overline{P}_{BPE} = 1300$) for which $\overline{P}_{BPE}/\overline{P}_{LPE} = 0.4$.[77] It follows from the results of high-speed sedimentation that free lyophilising polyelectrolyte polyions and non-stoichiometric polyelectrolyte complex species, whose composition is identical with that of the initial non-stoichiometric polyelectrolyte complex, do indeed coexist in the mixtures obtained.

The "migration" of the blocking polyelectrolyte chains derived from the species of the initial non-stoichiometric polyelectrolyte to the chain of the free lyophilising polyelectrolyte has been established also for the above system. The luminescent-labelled NaPMA* chain with the same degree of polymerisation as the sodium polymethyacrylate incorporated in the initial non-stoichiometric polyelectrolyte was used as the free lyophilising polyelectrolyte. The results of the study of this system by the high-speed sedimentation method indicate unambiguously the occurrence of reaction (2). Scanning at the wavelength corresponding to the absorption by the luminescent (anthryl) label make it possible to detect the LPE* in both fractions. The results presented demonstrate unambiguously that the interpolyelectrolyte exchange is completed before the end of the experiment, the latter requiring 3 h. It might be thought that similar exchange reactions occur also in solutions of a non-stoichiometric polyelectrolyte complex whose species contain more than one blocking polyelectrolyte chain; an example may be provided by the mutual exchange reactions between non-stoichiometric polyelectrolyte complex species illustrated on the right-hand side of scheme (2).

A similar picture has been observed also in mixtures of non-stoichiometric polyelectrolyte complexes formed by the same lyophilising high-molecular-weight sodium polymethacrylate and different blocking polycations—5,6-ionene bromide and poly-*N*-ethyl-4-vinylpyridinium bromide.[78] High speed sedimentation data show that a solution of a mixture of these two non-stoichiometric polyelectrolyte complexes contains one component which has a rate of sedimentation intermediate between the rates of sedimentation of the initial non-stoichiometric polyelectrolyte complexes. The occurrence of interpolyelectrolyte exchange is also confirmed by the behaviour of the mixture of non-stoichiometric polyelectrolyte complexes in solutions of low-molecular-weight electrolytes. The curve for the turbidimetric titration of a mixture of

non-stoichiometric polyelectrolytes does not coincide with the titration curves for either non-stoichiometric polyelectrolyte complex and occupies an intermediate position on the ionic strength scale for the solution. There is a single distinct jump on the turbidimetric titration curve. Mixtures of such polyelectrolyte complexes having other compositions behave similarly.

Thus the species of different non-stoichiometric polyelectrolyte complexes exchange in solution the blocking polyelectrolyte chains incorporated in their composition and the equilibrium in the exchange reaction shifts under the experimental conditions, i.e. at pH 7.5 and [NaCl] = 0.06 M, towards the formation of the final reaction product—a new soluble non-stoichiometric polyelectrolyte complex which incorporates both BPE_1 and BPE_2.

The variation of the degree of exchange can be followed by the luminescence quenching method because the introduction of ionene into the test solutions is accompanied by only a slight decrease in the luminescence intensity, whereas poly-*N*-ethyl-4-vinylpyridinium bromide effectively quenches the labels on the polyanion in the NPEC* species. The relative luminescence intensities I/I_0 of a solution of the mixture of non-stoichiometric polyelectrolyte complexes, which does not coincide with the values of I/I_0 for solutions of the individual non-stoichiometric polyelectrolyte complexes, occupies an intermediate position on the NaCl concentration scale, which agrees with the formation of mixed non-stoichiometric polyelectrolyte complexes in which some of the LPE* units are blocked by ionene, which is not a luminescence quenching agent.

The results show that the mutual exchange reactions investigated take place continuously, i.e. that the species of the non-stoichiometric polyelectrolyte complexes whose composition coincides with that of the reaction mixture exchange continuously the blocking polyelectrolyte chains with one another, the rate of exchange being controlled by the ionic strength of the solution. The reactions observed are none other than a form of thermal motion in polyelectrolyte complexes which are the products of reversible ionic reactions between polyelectrolytes.

(b) The influence of the degree of polymerisation of the lyophilising polyelectrolyte on the equilibrium in the interpolyelectrolyte exchange reaction

The influence of the length of the lyophilising polyelectrolyte chains on the equilibrium in the interpolyelectrolyte exchange reaction was investigated in solutions of non-stoichiometric polyelectrolyte complexes formed by sodium polymethacrylate and poly-*N*-ethyl-4-vinylpyridinium bromide fractions with different molecular weights.[79] We shall consider the results obtained when the three most characteristic conditions are fulfilled:

$$\overline{P}_{LPE} \gg \overline{P}_{BPE}, \quad \overline{P}_{LPE} \simeq P_{BPE}, \quad \text{and } \overline{P}_{LPE} \ll \overline{P}_{BPE}.$$

Sodium polymethacrylate (NaPMA*) specimens with $\overline{P}_W$ = 4100 and 500 and $\overline{P}_n$ = 50, which will henceforth be referred to as long, moderately long, and short polyanions respectively, and the poly-*N*-ethyl-4-vinylpyridinium bromide specimen with $\overline{P}_W$ = 500 satisfy these conditions. It is important to note that the labelled polymers NaPMA* were obtained by the reaction of chemically activated derivatives of the labels with sodium polymethacrylate fractions. This eliminates the question of the inconsistency between the $\overline{M}_W$ and the MWD for the labelled and unlabelled specimens.

The influence of the chain length of the lyophilising polyelectrolyte on the equilibrium in the exchange reaction

$$\text{NPEC(NaPMA}-\text{PEVP)} + \text{NaPMA*} \Leftrightarrow \text{NPEC*(NaPMA*}-\text{PEVP)} + \text{NaPMA}, \quad (3)$$

is manifested particularly strikingly in systems containing lyophilising polyelectrolyte chains of different length. This follows from the results of the study by the luminescence quenching method of mixtures of polyions, prepared in different ways and containing long and short polyanions (Fig. 1). As can be seen from Figs. 2 and 3, reaction (3) does not occur in the absence of a low-molecular-weight electrolyte. The introduction of even insignificant amounts of a simple salt leads to the complete displacement of the short chains into the solution from their complexes with poly-*N*-ethyl-4-vinylpyridinium bromide (curves *2* and *3*). The reverse reaction, i.e. the insertion of short chains in the non-stoichiometric polyelectrolyte species with long lyophilising polyelectrolytes, does not occur under these conditions (curve *1*).

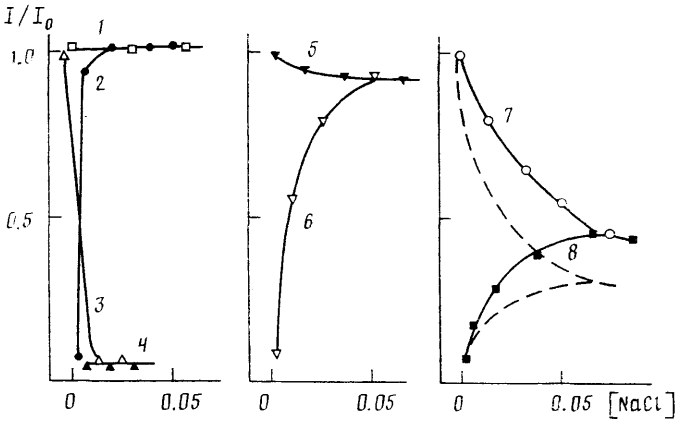


Figure 1. Dependence of I/I_0 on the NaCl concentration in mixtures of solutions of polyions containing polyanions polymerised to different extents: *1*, NPEC(P = 4100) and NaPMA*(P = 50); *2*, NPEC*(P = 50) and NaPMA (P = 4100); *3*, NPEC(P = 50) and NaPMA*(P = 4100); *4*, NPEC*(P = 4100); *5*, NPEC(P = 500) and NaPMA*(P = 50); *6*, NPEC*(P = 500) and NaPMA(P = 500); *7*, NPEC(P = 4100) and NaPMA*(P = 500); *8*, NPEC*(P = 500) and NaPMA(P = 4100).[79]

This result shows that in systems containing lyophilising polyelectrolytes of the same chemical nature, interpolyelectrolyte substitution of one set of chains by another can in essence occur. The displacement of short chains into the solution is accompanied by an entropy gain as a consequence of the liberation of a large number of short lyophilising polyelectrolyte chains previously immobilised in the NPEC or NPEC* species, which is apparently the reason for the virtual completion of reaction (3).

Very similar results were obtained in the study of mixtures containing moderately long and short polyanions (Fig. 1, curves *5* and *6*). In the absence of a salt, reaction (3) does not occur in this styrene either, while in aqueous salt solutions the displacement of short chains into the solution is observed. However, the differences

between the chain lengths and hence also the amounts of the chains in the non-stoichiometric polyelectrolyte species are insufficient to ensure such a high entropy gain when short lyophilising polyelectrolyte chains are displaced from the non-stoichiometric polyelectrolyte into the solution, so that a proportion of them, albeit extremely small, remains bound in the initial non-stoichiometric polyelectrolyte complex; $I/I_0 \neq 1$ at [NaCl] = 0.03 M.

This trend is manifested distinctly also in systems containing long and moderately long polyanions (Fig. 1, curves *7* and *8*). On attainment of equlibrium, which occurs at [NaCl] = 0.05 M, an appreciable proportion of the moderately long lyophilising polyelectrolyte chains remain in the non-stoichiometric polyelectrolyte complex. However, in this case too an appreciable amount of them pass into the solution. This is indicated by a higher value of I/I_0 corresponding to the state of equilibrium at [NaCl] = 0.05 M compared with I/I_0 for the NaPMA ($\overline{P}_W$ = 500)–PEVP–NaPMA* ($\overline{P}_W$ = 500) mixture at equilibrium (dashed curves).

Thus the ratio of the chain lengths of the competing lyophilising polyelectrolytes determines the direction of the interpolyelectrolyte exchange reaction in aqueous salt solutions.

(c) The influence of groups capable of stabilising additionally the polyelectrolyte complex on the exchange reaction equilibrium

It has been shown[80] that the presence in the polyanion of a small number of groups (one per hundreds of chain units) capable of interacting specifically with the polycation units in the non-stoichiometric polyelectrolyte complex formed can ensure the "recognition" by the polycation of such modified chains among unmodified polyanions.

Aqueous salt solutions of the non-stoichiometric polyelectrolyte complex formed by sodium polymethacrylate having $\overline{P}_W$ = 4100 and poly-*N*-ethyl-4-vinylpyridinium bromide having $\overline{P}_W$ = 600 were studied. Modified sodium polymethacrylate (NaPMA*) containing anthrylmethylmethacrylate (Ant-NA) groups or pyrenylmethyl methacrylate (Pyr-MA) units was used as the competing polyanion. The presence of the luminescent Ant-MA or Pyr-MA groups in the NaPMA* chains makes it possible to record the interpolyelectrolyte reaction by the luminescence quenching method:

$$\text{NPEC(NaPMA – PEVP)} + \text{NaPMA*} \overset{K_e}{\Leftrightarrow} \Leftrightarrow \text{NPEC*(NaPMA* – PEVP)} + \text{NaPMA}. \quad (4)$$

The experiments were carried out as follows. A solution of the non-stoichiometric polyelectrolyte complex (NaPMA–PEVP), in which there is on average one polycation chain per polyanion chain, was prepared initially. The non-stoichiometric polyelectrolyte complex having the composition

$$\varphi = [\text{PEVP}]/[\text{NaPMA}] = \overline{P}_{\text{PEVP}}/\overline{P}_{\text{NaPMA}} = 0.147$$

corresponds to this condition. An aqueous salt solution of NaPMA was then added to the resulting solution so that the amounts of NaPMA and NaPMA* in the reaction mixture were identical and the time variation of I was recorded. The degree of completion of the reaction was judged from the value of I/I_0, where I_0 is the intensity of the luminescence of the aqueous solutions of NaPMA* at the same concentration as in the initial mixture. In the study of the reverse reaction, a solution of a labelled non-stoichiometric polyelectrolyte complex NPEC* (NaPMA*–PEVP), having the composition φ = 0.147, was prepared by a similar procedure and was treated with an aqueous salt solution of sodium polymethacrylate.

It was found that that presence in the NaPMA* chain on average of only three Pyr-MA units per 4100 methacrylate (MA) units already leads to the predominant binding of the polycation to the labelled polyanion, i.e. to an appreciable shift of the equilibrium in the exchange reaction (4) to the right. The equilibrium value of I/I_0, obtained in both the forward (Fig. 2, curve *1*) and reverse (curve *2*) reactions, is lower than expected on the assumption of a uniform distribution of poly-*N*-ethyl-4-vinylpyridinium bromide between the labelled and unlabelled polyanions (the dashed arrow in Fig. 2 indicates the value of I/I_0 for the NPEC* having the composition $\varphi = 0.5 \times 0.147 = 0.073$). With increase in the average number of Pyr-Ma units to 12 per 4100 MA units (Fig. 2, curves *3* and *4*), a virtually complete selectivity of the binding is attained: the vast majority of the sodium polymethacrylate polyanions in the non-stoichiometric polyelectrolyte complex are substituted by the NaPMA* polyanions and I/I_0 at equilibrium is identical with I/I_0 for the NPEC* solution having the composition φ = 0.147 (Fig. 2, continuous arrow).

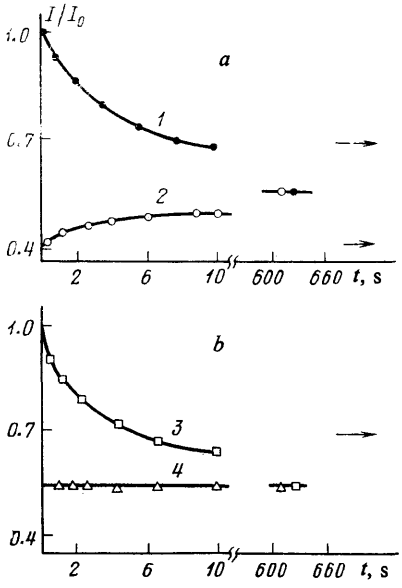

Figure 2. Kinetic curves for reaction (*4*); *1* and *3*, mixtures of the non-stoichiometric polyelectrolyte complexes NaPMA–PEVP and NaPMA*; *2* and *4*, mixtures of labelled non-stoichiometric polyelectrolyte complexes (NPEC*) NaPMA*–PEVP and NaPMA; [NaPMA*] = [NaPMA] = 1.3×10^{-4} M (curves *1* and *2*) and 3.2×10^{-5} M (curves *3* and *4*); [NaCl] = 0.08 M.[80]

The equilibrium constant of reaction (4) under the experimental conditions, involving the transfer of one polycation chain, i.e. [NaPMA] = [NaPMA*], is given by

$$K_e = X^2/(1-X)^2, \quad (5)$$

where X is the fraction of the NPEC* (NaPMA*–PEVP) species formed as a result of reaction (4). If preferential binding of the polycation by the modified polyanion is observed (Fig. 2), X varies in the range $0.5 < X < 1$, which corresponds to the variation of the

equilibrium constant in the range $1 < K_e < \infty$. In the range $0.5 < X < 1$ in which we are interested, the relative luminescence intensity I/I_0 decreases linearly with increase in X. This makes it possible to determine X experimentally using the equation

$$X=0.5+0.5(I_l-I)/(I_l-I_\infty), \quad (6)$$

where I_l and I_∞ are the intensities of the luminescence of solutions of poly-*N*-ethyl-4-vinylpyridinium bromide and NaPMA* having the composition $\varphi = 0.073$ and $\varphi = 0.147$ respectively. Thus the determination of the equilibrium constant of reaction (4) reduces to the measurement of the quantities I, I_l, and I_∞, the calculation of X by Eqn. (6), and the calculation of K_e by Eqn. (5).

The equilibrium constants K_e of the interpolyelectrolyte reaction (4) involving NaPMA* with $\overline{P}_W = 4100$, differing in the number of Ant-MA and Pyr-MA units, are presented in Table 1.

Table 1. The quantities $\overline{M}_k$ and K_e for the exchange reaction (4) involving NaPMA* modified by different numbers of pyrenyl or anthryl groups {$\overline{P}_{NaPMA} = \overline{P}_{NaPMA^*} = 4100$, $\overline{P}_{PEVP} = 600$, [NaCl] = 0.08 M}.

No. of groups in NaPMA*	5	9	3	12
Chemical nature of groups	Ant-MA	Ant-MA	Pyr-MA	Pyr-MA
$\overline{M}_k$	2.5	3.5	1.5	5.5
K_e*	≃1	10	10	>200

* The accuracy of the determination of K_e is to within 10–15%.

The average number of labelled units $\overline{M}_k$ in contact with the units of the polycationic quenching agent in the NPEC* formed was calculated from the experimental values of I/I_0 for solutions of NPEC* having the composition $\varphi = 0.147$ by the formula

$$\overline{M}_k=\overline{M}(1-I/I_0), \quad (7)$$

where $\overline{M}$ is the average number of labelled units in the NaPMA* chain and the expression in brackets corresponds to the fraction of quenched labels.

Table 1 shows that the experimental values of $\overline{M}_k$ in the NPEC* with the composition $\varphi = 0.14$ are greater than the calculated values $\overline{M}_k = \overline{M}\varphi$, i.e. the average number of labels in the NaPMA* chains per contour length of the poly-*N*-ethyl-4-vinylpyridinium bromide chains bound electrostatically to them. It follows also from Table 1 that the equilibrium constant of reaction (4) is determined by the number of labels in the polyanion chain and their chemical nature. For example, the presence of five anthryl groups per 4100 MA units in the NaPMA* chains hardly disturbs the uniform distribution of poly-*N*-ethyl-4-vinylpyridinium bromide among all the polyanions present in solution ($K_e \simeq 1$) and does not therefore introduce perturbations into the occurrence of the corresponding interpolyelectrolyte reactions.[57,60,65,77] An increase in the number of anthryl labels to nine already displaces the equilibrium of reaction (4) appreciably to the right. Other conditions being equal, the pyrenyl labels influence K_e much more strongly than the anthryl labels. The "recognition" of the labelled polyanions by the polycations is probably determined by the decrease in free energy which is attained after the immersion of hydrophobic anthryl (pyrenyl) groups in the hydrophobic clusters formed by sections of the oppositely charged chains of the polymeric complex bound to one another. The free energy changes on transfer of anthracene and pyrene from octanol to water are respectively 24.9 and 29.0 kJ mol^{-1}.[82] This difference is apparently responsible for the better "recognition" of the pyrenyl groups compared with the anthryl groups. The stabilisation of the NPEC* (NaPMA*–PEVP) probably promotes also the formation of charge-transfer complexes (CTC) between the anthryl or pyrenyl groups (donors) and the pyridinium units (acceptors). Such charge-transfer complexes can be detected directly in the absorption spectra of the corresponding solutions.[81]

The higher experimental values of $\overline{M}_k$ compared with the calculated values can probably be accounted for by the same factors.

Thus a small number of molecular "anchors" with energies of the order of several kT is apparently sufficient to ensure a decided advantage for the labelled polyanion, whose length is greater by a factor of several hundreds than the length of the "anchor", in the competition with its unlabelled analogue for the binding of the polycation. In our view, this result is of fundamental importance for the understanding of the mechanisms of the selective biological action *in vivo* of functionalised polyelectrolytes (in particular, artificial immunogens—conjugates of high-molecular-weight linear polyions with a small number of antigens or antigen determinants[83]).

(d) The influence of the linear charge density of the blocking polyelectrolytes on the equilibrium in the interpolyelectrolyte exchange reaction

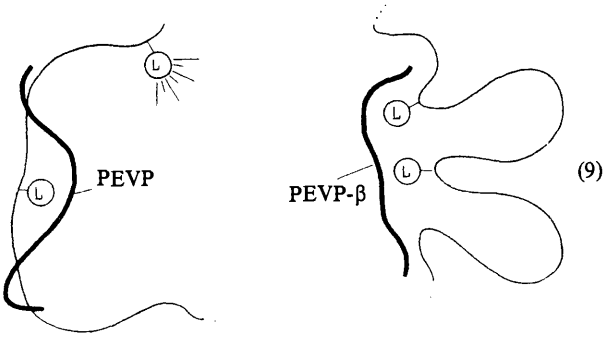
The influence of the linear charge density of the blocking polyelectrolyte on the equilibrium in the exchange reaction was investigated in solutions of non-stoichiometric polyelectrolyte complexes formed by sodium polymethacrylate and partly quaternised poly-4-vinylpyridines (PEVP-β).[84] The PEVP-β specimens, obtained by alkylating poly-4-vinylpyridine with ethyl bromide, were alkylated to different extents, the degree of alkylation being $\beta(\%) = 100n/(n + m)$, where n and m are respectively the mole fractions of the alkylated and non-alkylated units.

Under the experimental conditions, the non-alkylated units, distributed statistically along the polycation chain, are uncharged. The molar extinction coefficient at $\lambda = 257$ nm is $\varepsilon = 1800$ litre mol^{-1} cm^{-1} for the above pyridine units and $\varepsilon = 3600$ litre mol^{-1} cm^{-1} for the charged pyridinium units. Comparison of the UV spectra of solutions of the non-stoichiometric polyelectrolyte complex and PEVP-β at identical concentrations showed that the optical densities at $\lambda = 257$ nm are identical, i.e. under experimental conditions at pH 10 the charge on the PEVP-β chains is determined solely by the alkylated units, while the pyridine units of PEVP-β, incorporated in the non-stoichiometric polyelectrolyte complex species, disturb the continuity of the sequence of the charged quaternised unit. The study of the alkylation of poly-4-vinylpyridine by ethyl bromide showed that the reaction proceeds without the "neighbour effect", all three alkylation rate constants, calculated from the kinetic curve, being virtually identical.† This means that,

† The constants were calculated by L B Stroganov and A N Olonovskii—members of the Department of Macromolecular Compounds in the Faculty of Chemistry of Moscow State University.

up to the attainment of high degrees of quaternisation, the non-alkylated units are arranged along the chain in accordance with the statistical law.

The equilibrium constant of the exchange reaction



$$\text{NPEC(NaPMA} - \text{PEVP} - \beta) + \text{NaPMA}^* \overset{K_e}{\Leftrightarrow}$$
$$\Leftrightarrow \text{NPEC}^*(\text{NaPMA}^* - \text{PEVP} - \beta) + \text{NaPMA} \quad (8)$$

increases with decrease in the degree of quaternisation β. This follows from the results of the study of solutions of mixtures of polyelectrolyte by the luminescence quenching method[84] (Table 2). The quantities K_e were determined as described above for non-stoichiometric polyelectrolyte complexes incorporating the exhaustively alkylated poly-*N*-ethyl-4-vinylpyridinium bromide.

The sharp increase in K_e with decrease in the degree of alkylation of the polycation is accompanied by an increase in the number of labels covered by a single chain of the blocking polyelectrolyte in the NPEC*, which follows from the increase in $1 - I/I_0$ with decrease in β (Table 2).

An increase in the number of labels quenched by the blocking polyelectrolyte chain is accompanied by a decrease in the size of the non-stoichiometric polyelectrolyte complex species. This follows from the measurements by the quasi-elastic light scattering method of the effective sizes of the non-stoichiometric polyelectrolyte complex species incorporating PEVP-β alkylated to different extents.[84] It is important to note that the values of $\overline{M}_W$ measured by the light scattering method for all the test specimens proved to be constant and amounted to 445 000, which indicates the absence of associated species in the solutions.

Thus the increase in the number of defects in the structure of the non-stoichiometric polyelectrolyte complex with decrease in β, caused by the disturbance of the continuity of the sequence of quaternised blocking polyelectrolyte units, promotes the compaction of the non-stoichiometric polyelectrolyte complex and an increase in the number of labels covered by the polycationic quenching agent [Scheme (9)]. The appreciable decrease in the free energy of the system when an additional number of labels are immersed in the hydrophobic region of the NPEC* species is in fact the cause of the increase in K_e for reaction (8) with decrease in the degree of alkylation of the polycation.

(9)

Similar conformational transformations of the non-stoichiometric polyelectrolyte species have been observed on rupture of a proportion of the interpolymer salt linkages, stabilising the non-stoichiometric polyelectrolyte complex, under the influence of the low-molecular-weight electrolyte.[85] According to the authors,[85] the driving force of this process is the increase in the combinatorial entropy caused by the contribution of structures of the type illustrated on the right-hand side of Scheme (9). Evidently, the endeavour of the labels located on the LPE* to become immersed in the hydrophobic regions of the NPEC* species should promote still further such compaction. This is also indicated by the sharp decrease in the luminescence intensity of NPEC* solution when low-molecular-weight electrolytes are introduced into them.[71]

Table 2. The values of $1 - I/I_0$ and K_e for the exchange reaction (8) involving PEVP-β for different degrees of alkylation β:[84] $\overline{P}_{NaPMA} = \overline{P}_{NaPMA^*} = 4400$, $\overline{P}_{PEVP} = 500$, [NaCl] = 0.10 M; pH 10; in NaPMA* there is on average one Pyr-MA unit per 1400 methacrylate (MA) units.

β, %	40	55	80	90
$1-I/I_0$	0.74	0.78	0.62	0.59
K_e*	>200	160	60	7

* The accuracy of the determination of K_e is to within 10–15%.

Thus non-stoichiometric polyelectrolyte complexes should be regarded as compounds which are extremely resistant to the disrupting effect of low-molecular-weight electrolytes and which are capable of exchanging their constituent polyions in aqueous salt media. Such exchange results in a uniform distribution of relatively short blocking polyelectrolyte chains among all the long lyophilising polyelectrolyte chains present in the solution. However, highly selective interaction of the polyions with the oppositely charged chains can be achieved, for example, by changing the degree of polymerisation or by slight chemical modification of the polyions. Thus in mixtures of relatively long and short sodium polymethacrylate chains the poly-*N*-ethyl-4-vinylpyridinium polycation is bound preferentially to the long sodium polymethacrylate chains. When the degrees of polymerisation of sodium polymethacrylate are significantly different, this competing interaction can lead to the complete displacement of short chains from the polyelectrolyte complex by long sodium polymethacrylate chains. The cation selects from the mixture of modified and unmodified polyanions macromolecules containing groups capable of additional stabilisation of the polyelectrolyte complex and binds them preferentially. This is manifested even in the presence of only one hydrophobic pyrene group per hundreds of sodium polymethacrylate chain units, whereupon such labelled chains are selected for incorporation in the polyelectrolyte complex almost without error.

2. Equilibrium in the interpolyelectrolyte substitution reaction

The previous section gave an account of the principal results of studies on equilibria in interpolyelectrolyte exchange reactions where the transfer of polyions is accompanied by the disruption and formation of interpolyelectrolyte contacts of the same type. This section will deal with the equilibria in interpolyelectrolyte substitution reactions where lyophilising polyelectrolytes of different chemical nature participate as competing polyanions. The effect involving the molecular "recognition" of polyions of a definite kind proves as a rule to be very pronounced in such systems. This effect has a bearing on the selective biological action of polyelectrolytes *in vivo* and can be used for the creation of systems for the specific transport of biologically active substances. Therefore, before

proceeding to the discussion of the experimental results, we shall consider briefly the available literature data on the selectivity of interpolymer substitution reactions.

(a) Molecular selectivity of interpolymer substitution reactions

The principal feature of interpolymer reactions is their cooperative character. The sharp increase in the stability constant of the polymeric complex as a function of the degree of polymerisation of the reacting macromolecules may serve as proof of this. It is described by the equation[29,30]

$$K_\nu = K_1^\nu = \exp(-\nu\Delta G_1^\circ/RT), \quad (10)$$

where K_ν is the equilibrium constant for the binding of the oligomer incorporating ν chains of the long chemically complementary chain-matrix and $K_1 = \exp(-\Delta G_1^\circ/RT)$ is the effective constant for the binding of the oligomer unit to the matrix unit. The term "oligomer" is conventional and indicates merely the fact that its chains are shorter than those of the matrix. Since the binding constant K_ν increases rapidly with increase in the degree of polymerisation of the oligomer, it follows that, in a system containing oligomer chains of identical structure but of different lengths, one should expect the manifestation of selective binding of the longest chains. Such a case has been analysed theoretically.

Experimental confirmation of the model examined by Papisov and Litmanovich[29] has been obtained.[28] It was found that the fraction with the highest molecular weight participates in the reaction between polymethacrylic acid (PMAA) and a mixture of three fractions of poly(ethylene glycol (PEG) having different degrees of polymerisation $\overline{P}$:

$$\text{PEG}(\overline{P}=32\,000)+\text{PEG}(\overline{P}=180)+\text{PEG}(\overline{P}=30)+\text{PMAA} \Leftrightarrow$$
$$\Leftrightarrow \text{IPC[PMAA}-\text{PEG}(\overline{P}=32\,000)]+\text{PEG}(\overline{P}=30\,180). \quad (11)$$

The "selective complex formation" reaction (11) can be regarded in essence as an interpolymer substitution reaction. Indeed, at the instant of the mixing of the reactants, interpolymer complexes incorporating different oligomers are apparently formed and, as a result of the substitution of the relatively short oligomer chains by long ones, are converted into stable interpolymer complexes containing oligomer molecules. The selectivity of the binding of oligomers of the same chemical nature but with different degrees of polymerisation examined above, manifested strikingly in interpolymer reactions, is one of the fundamental features of polymer chemistry and has no analogue in the chemistry of low-molecular-weight compounds.

Apart from chain lengths, factors such as the chemical nature of the reactants, the structural complementarity of the interacting chains, the pH of the medium, etc. exert a significant influence on the occurrence and nature of the interpolymer reactions. We shall consider in what way each of these factors influences the equilibrium in reactions with participation of polymeric complexes.

The polymeric complex formation reactions in a system containing simultaneously high-molecular-weight chains and two kinds of complementary oligomers of different chemical structure were first investigated by Papisov et al.[26] and Bednar et al.[32] The objects of study were a high-molecular-weight polymethacrylic acid and the relatively short chains of poly(ethylene glycol), poly-*N*-vinylpyrrolidinone (PVPD), and poly(vinyl alcohol) (PVA). The interpolymer complexes formed in aqueous media in such systems are stabilised by the hydrogen bonds between the protonated carboxy-groups of the polymeric acid and the hydroxy-groups of poly(vinyl alcohol) or the corresponding nucleophilic groups of poly(ethylene glycol) and poly-*N*-vinylpyrrolidinone.[86] Hydrophobic interactions also play a significant role in the stabilisation of such interpolymer complexes.[18] In systems of this kind, the equilibria in the interpolymer substitution reactions (12) and (13) are displaced almost wholly to the right:

$$\text{PC(PMAA}-\text{PEG})+\text{PVPD} \rightleftarrows \text{PC(PMAA}-\text{PVPD})+\text{PEG}, \quad (12)$$

$$\text{PC(PMAA}-\text{PVA})+\text{PVPD} \rightleftarrows \text{PC(PMAA}-\text{PVPD})+\text{PVA}. \quad (13)$$

The highly selective binding of poly-*N*-vinylpyrrolidinone to polymethylacrylic acid in the multicomponent systems indicated is strikingly manifested in the processes involving the matrix polymerisation of methacrylic acid in a mixture of poly(vinyl alcohol) and poly-*N*-vinylpyrrolidinone [or a mixture of poly-(ethylene glycol) and poly-*N*-vinylpyrrolidinone]. In each of these cases, the rate of polymerisation of methacrylic acid is equal to its rate of polymerisation in the presence of poly-*N*-vinylpyrrolidinone alone and is independent of the presence of either poly(ethylene glycol) or poly(vinyl alcohol) in the polymerising system.[26] Under these conditions, the selectivity of the binding of polymethacrylic acid decreases in the sequence PVPD > PEG > PVA.

The substitution reactions can also be observed in systems containing two types of macromolecular matrices of different chemical nature and an oligomer capable of being bound to either of them. An example of such interpolymer reactions is provided by the substitution reactions in solutions of polymethacrylic acid of the interpolymer complex formed by polyacrylic acid (PAA) and poly(ethylene glycol):[27]

$$\text{IPC(PAA}-\text{PEG})+\text{PMA} \rightleftarrows \text{IPC(PMAA}-\text{PEG})+\text{PAA}. \quad (14)$$

The formation of a new interpolymer complex (PMAA–PEG) and the quantitative displacement into the solution of the polyacrylic acid previously incorporated in the initial interpolymer complex were observed in such a system by IR and NMR spectroscopic methods and also by the polarised luminescence method. Reaction (14) is endothermic and is accompanied by a gain in the entropy of the solvent (water). This can be explained by the fact that hydrophobic interactions play a decisive role in the stabilisation of the interpolymer complex (PMAA–PEG).[18] The important conclusion has also been reached that the matrix polymerisation of methacrylic acid in the presence of the interpolymer complex (PAA–PEG) is accompanied by a substitution reaction of type (14), whose rate is comparable to the rate of the polymethacrylic chain propagation in radical polymerisation, i.e. the substitution reaction takes place over a period of the order of 1 s.[27]

The influence of the chemical structure of the macromolecules on the selectivity of the interpolymer interaction in multicomponent systems has been examined.[28] Macromolecules capable of reacting with polymethacrylic acid with formation of the corresponding interpolymer complexes can be arranged in the following sequence in conformity with their ability to compete in substitution reactions:

$$\text{PEG}(\overline{P}=32\,000) > \text{polyacrylamide}\ (\overline{P}=80) > \text{PVPD}(\overline{P}=100) > \text{PEG}(\overline{P}=70) > \text{PVA}(\overline{P}=1000). \quad (15)$$

As can be seen, the influence of the molecular weight and of the chemical nature of the chain are manifested simultaneously in the intermacromolecular reactions. Thus, depending on the molecular weight, poly(ethylene glycol) can exhibit different reactivities in substitution reactions.

Systems in which the influences of both factors — the chemical nature and length of the chain — are manifested simultaneously lead to the possibility of the fine regulation of the matrix polymerisation processes. Cases of matrix polymerisation in the presence of two types of matrices differing in their chemical nature, namely "short" but "strong" and "long" but "weak", have been examined theoretically.[87] Model calculation showed that an interpolymer complex of the daughter chain with the shorter but "strong" matrix should be formed initially. Subsequently the daughter chain attains a length comparable to that of the matrix and an interpolymer reaction accompanied by the formation of a more stable interpolymer complex of the daughter chain with the long but "weak" matrix should take place.

The pH of the medium can play an important role in the selective interpolymer interaction. The influence of the pH on reactions of this type has been investigated[28] in relation to a three-component system containing a weak polymeric acid (polymethacrylic acid), a weak polymer base [poly-2-vinylpyridine (P2VP) or oligoethyleneimine (OEI)], and a non-ionogenic polymer [poly(ethylene glycol) or poly-*N*-vinylpyrrolidinone]. In an acid medium, the weak polymeric acid (polymethacrylic acid) exists predominantly in the unionised form, as a result of which an interpolymer complex between polymethacrylic acid and poly-*N*-vinylpyrrolidinone or poly(ethylene glycol), stabilised by a hydrogen bond, is mainly formed. In a neutral medium, both the polymeric acid and the polymeric bases are partly charged, so that a polyelectrolyte complex stabilised by salt bonds is produced. In an alkaline medium, where polymethacrylic acid is fully dissociated while the weak base is uncharged, the formation of both a polyelectrolyte complex and an interpolymer complex stabilised by hydrogen bonds is impossible, i.e. the interpolymer reaction does not occur at all. Thus the pH of the medium influences significantly both the ability of polymer chains to react with one another and the nature of the interactions stabilising the interpolymer complex.

Yet another important factor influencing the nature of the selective interpolymer interaction is the structural complementarity of the reacting chains. It has been shown[28] that the steric disposition of the functional groups is a decisive factor in the selective interaction in the following systems:

$$\text{P4VP} + \text{P2VP} + \text{PMAA} \rightleftarrows \text{IPC(PMAA} - \text{P4VP}) + \text{P2VP}, \quad (16)$$

$$\text{PGA} + \text{PEG} + \text{PMAA} \rightleftarrows \text{IPC(PMAA} - \text{PEG}) + \text{PGA}, \quad (17)$$

where P4VP is poly-4-vinylpyridine and PGA is polyglutamic acid. A characteristic feature of system (16) is the possibility of the formation of an interpolymer complex both as a result of electrostatic interpolymer interactions and as a consequence of the formation of interpolymer hydrogen bonds. Bearing this factor in mind, the formation of the interpolymer complex (PMAA–P4VP) in the presence of P2VP was explained precisely by the impossibility of the formation of strong hydrogen bonds between the polymethacrylic acid and poly-2-vinylpyridine units owing to steric hindrance. For the same reason the electrostatic interactions between the oppositely charged groups in the interpolymer complex PMAA–P2VP are much weaker than in the interpolymer complex PMAA–P4VP. The conformation of the polymeric reactants plays a decisive role in the reaction. In acid media, where reaction (17) was carried out, polyglutamic acid exists in the α-helical conformation, where the distance between the carboxy-groups of the acid does not correspond to the distance between the oxygen atoms in the neighbouring poly(ethylene glycol) units. The steric correspondence between the polymethacrylic acid and poly(ethylene glycol) chains is much better, as a result of which the insoluble interpolymer complex PMAA–PEG is formed predominantly in the PMAA–PEG–PGA ternary system. This is indicated by the results of the analysis of the supernatant, which contained almost the entire polyglutamic acid in the α-helical conformation introduced into the reaction.

(b) The influence of the degree of polymerisation of the polyions and of the chemical nature of the small ions on the equilibria in interpolyelectrolyte substitution reactions

We shall now proceed to the consideration of the equilibria in interpolyelectrolyte substitution reactions. An example may be provided by the reaction occurring in mixtures of solutions of the NPEC* formed by the high-molecular-weight labelled NaPMA* (P_W = 4100) and poly-*N*-ethyl-4-vinylpyridinium bromide (P_W = 170), and sodium polyphosphate (NaPP):[88–90]

$$\text{NPEC*(NaPMA*} - \text{PEVP}) + \text{NaPP} \rightleftarrows$$

$$\rightleftarrows \text{NPEC(NaPP} - \text{PEVP}) + \text{NaPMA*}. \quad (18)$$

The position of the chemical equilibrium in reactions of type (18) varies markedly, changing the direction of the process as a consequence of the change in the free energy of contact between a pair of units of the chemically complementary macromolecules. As already stated above, this is due to the cooperative nature of the interpolymer reaction.

Fig. 3 illustrates the dependence of the degree of conversion q on the NaCl concentration in reaction (18), which was carried out by mixing solutions of the NPEC* with sodium polyphosphate fractions with different $\overline{P}_n$. On addition of a salt-free solution of sodium polyphosphate to a salt-free solution of the NPEC*, the luminescence intensity does not change, i.e. in the absence of a low-molecular-weight electrolyte reaction (18) hardly occurs. The introduction of even insignificant amounts of NaCl into a system containing sodium polyphosphate with $\overline{P}_n$ = 230 leads to an appreciable increase in I (curve *1*). Hence it follows that the high-molecular-weight sodium polyphosphate substitutes NaPMA* in the initial NPEC*. However, with decrease in the length of the sodium polyphosphate chains, the rate of increase in I diminishes (curves *2*

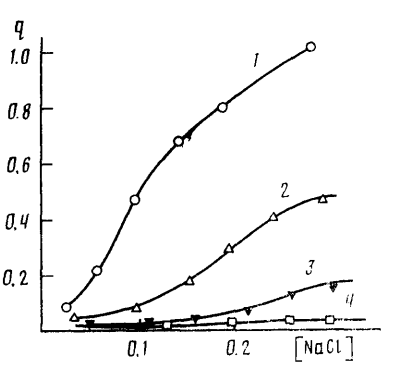


Figure 3. Dependence of the extent of reaction q in reaction (18) on the salt concentration in mixtures of solutions of the labelled non-stoichiometric polyelectrolyte complexes (NPEC*) NaPMA*–PEVP and sodium polyphosphate having different degrees of polymerisation: *1*, 230; *2*, 70; *3*, 50; *4*, 20; pH 10; [NaPMA*] = [NaPP]; φ = [PEVP]/[NaPMA*] = 0.33.[88]

and *3*) and finally does not change at all in solutions containing sodium polyphosphate with $\overline{P}_n$ = 20 (curve *4*). This means that in the last case reaction (18) hardly proceeds from left to right.

In order to elucidate the question whether kinetic or thermodynamic factors limit the occurrence of reaction (18), a study was made of the reverse reaction. It was found that, when [NaCl] > 0.05 M, the values of *I* for mixtures of the non-stoichiometric polyelectrolyte complex NaPP–PEVP and NaPMA* are identical with the values of *I* for mixtures having the same composition but obtained by adding sodium polyphosphate to NPEC*. This means that, when the ionic strength exceeds 0.05 M, reaction (18) is kinetically unhindered and equilibrium is established during the experiment. Consequently the observed dependence of *q* on the degree of polymerisation of sodium polyphosphate is determined by thermodynamic factors.

Fig. 4 shows that, by replacing one alkali metal cation, playing the role of the counterion in relation to PMA* and polyphosphate anions, by another alkali metal cation, it is possible to alter the direction of reaction (18) for fixed degrees of polymerisation of the polyelectrolytes. The addition of sodium polyphosphate ($\overline{P}_n$ = 70) to a solution of NPEC* in the presence of KCl does not alter *I* (curve *3*), i.e. the equilibrium in reaction (18) is fully displaced to the left. On the other hand, in LiCl solutions for [LiCl] > 0.05 M, equilibrium (18) is fully displaced to the right (curve *1*). An intermediate solution occurs in NaCl solutions (curve *2*).

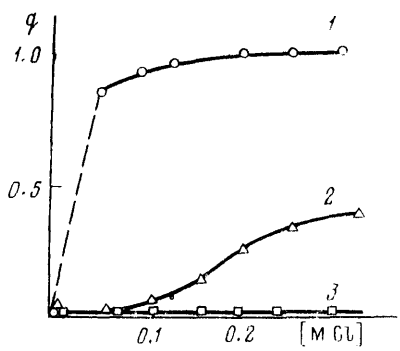

Figure 4. Dependence of the extent of reaction *q* in reaction (18) on the salt concentration [MCl] in mixtures of solutions of labelled non-stoichiometric polyelectrolyte complexes (NPEC*) NaPMA*–PEVP and sodium polyphosphate (P = 70) in the presence of various salts MCl: *1*, M = Li; *2*, M = Na; *3*, M = K; the conditions are the same as in Fig. 3.[88]

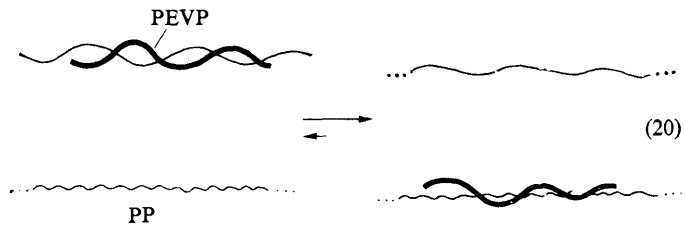


It must be emphasised that, over the entire range of variation of the concentrations of the salts and for any equilibrium position in reaction (18), almost all the units of the polycation are linked to the units of NaPMA* and sodium polyphosphate.

In order to account for the observed effects, we shall represent the free energy change in reaction (18) as the sum of two components:

$$\Delta G = \Delta G_r + \Delta G_s, \qquad (19)$$

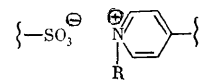
where ΔG_r is the free energy change on replacement of the NaPMA*–PEVP contacts by the NaPP–PEVP contacts, while ΔG_s is the difference between the free energies of the reaction of the counterion with sections of the chains of the PMA* and polyphosphate polyanions.

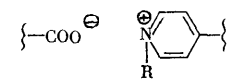
If the degree of polymerisation of both polyanions is greater than that of the polycation, then the number of species in the system remains constant;

(20)

It follows from Fig. 3 that in NaCl solutions (curve 2) the equilibrium in such a reaction is displaced to the right, i.e. $\Delta G' = \Delta G'_r + \Delta G'_s < 0$. However, the decrease in the sodium polyphosphate chain length displaces the reaction equilibrium in the opposite direction, i.e. the overall free energy change in reaction (21) becomes positive: $\Delta G'' = \Delta G''_r + \Delta G''_s > 0$.

(21)





Since ΔG_s is independent of the chain length, i.e. $\Delta G'_s = \Delta G''_s$, the observed effect should be explained by the increase in $\Delta G''_r$, i.e. $\Delta G''_r > \Delta G'_r$. When the total number of salt bonds between the polyions is retained, the occurrence of reaction (21) is less favourable from the standpoint of entropy than that of reaction (20) owing to the decrease in the number of polymeric species in solution. This is correlated with data concerning the influence of the degree of polymerisation of sodium polyphosphate on the stability of the stoichiometric polyelectrolyte complexes NaPP–PEVP in salt media.[89]

For a fixed degree of polymerisation of the polyelectrolytes, ΔG_r remains unchanged on replacement of the alkali metal cation introduced into the system by another and it follows from the comparison of curves *1*, *2*, and *3* in Fig. 4 that the change of sign of ΔG is caused by the change in ΔG_s. The observed effect should be attributed to the difference between the free energies of the reaction of the PMA* and polyphosphate anions with different alkali metal cations. It follows from the turbidimetric titration curve[89] that the critical salt concentration at which the polyelectrolyte complex NaPMA*–PEVP dissociates decreases in the sequence KCl > NaCl > LiCl. In the case of the polyelectrolyte complex NaPP–PEVP, the series is reversed.

By replacing the counterion, it is possible to increase the reactivity of the short chains of the polyphosphate anion. In solution in LiCl, the polyphosphate anions with $\overline{P}_n$ = 20 are already capable of competing with the polymethacrylate anions in reaction (21). On the other hand, in KCl solution even long chains of polyphosphate anions with $\overline{P}_n$ = 230 are almost totally lacking in the ability to replace the polymethacrylate anions.

Thus the equilibrium in the interpolyelectrolyte reaction can be effectively regulated by the simple dissociation or growing of

polyion chains, i.e. by altering the degree of polymerisation. The replacement of one alkali metal cation by another can also induce a qualitative change in the state of multicomponent polyelectrolyte systems. The observed phenomena have no analogues in polymer systems. Presumably such cooperative effects constitute the basis of the regulatory processes in natural biopolymer systems.

The differences between the free energies of the reaction of polyanions of different chemical nature with the polycation as well as the differences mentioned above, observed in the interaction of the polyanions with different alkali metal cations, are evidently caused by the contribution of specific interactions together with the usual Coulombic forces. When such differences become considerable, they actually determine the direction of the inter-polyelectrolyte reaction. Thus polyanions containing sulpho-groups, including heparin, sodium polystyrenesulphonate, sodium polyanetholesulphonate, potassium polyvinylsulphate, etc., almost wholly substitute polymeric carboxylate anions in their polyelectrolyte complexes with different polycations.[58,61,91] This is a consequence of the greater stability of the cooperative system of contacts of the type  compared with the contacts  in aqueous salt media (NaCl solutions) in which substitution reactions were investigated. Indeed, the dissociation of polyelectrolyte complexes formed by polyanions with sulpho-groups and by poly-*N*-ethyl-4-vinylpyridinium bromide requires a NaCl concentration higher by a factor of 4 than for the dissociation of the polyelectrolyte complex NaPMA–PEVP.[58]

(d) The influence of the length of the *N*-alkyl substituent in the poly-4-vinylpyridinium cation on the equilibrium in the substitution reaction

It has been observed[92] that the direction of the substitution reaction

$$\text{NPEC*(NaPMA*}-\text{PVPAlk)}+\text{NaPP} \rightleftarrows \text{NPEC(NaPP}-\text{PVPAlk)}+\text{NaPMA*} \qquad (22)$$

is determined, other conditions being equal, by the number of carbon atoms in the *N*-alkyl substituents of quaternised poly-4-vinylpyridines (PVPAlk). Virtually completely quaternised ($\beta > 90\%$) PVPAlk with $\overline{P}_W = 130$ as well as NaPMA* containing 11 pyrene labels and having $\overline{P}_W = 4100$ and sodium polyphosphate with $\overline{P}_W = 250$ were used in the experiments. Fig. 5 presents the dependence of the degree of conversion q in reaction (22) on the concentration of the added salt NaCl for PVPAlk with *N*-alkyl substituents for Alk = Me, Et, or Pr. The points on the curves correspond to equilibrium values. It follows from Fig. 5 that the number of carbon atoms in the *N*-alkyl substituent in PVPAlk determines the direction of reaction (22) at a fixed ionic strength of the solution. Thus the introduction of sodium polyphosphate into a solution of NPEC* incorporating PVPPr leads to a very slight alteration of q (curve *3*), i.e. equilibrium (22) is displaced to the left. On the other hand, in NPEC* solutions containing PVPMe the equilibrium is significantly displaced to the right (curve *1*), while an intermediate situation arises in solutions of a non-stoichiometric polyelectrolyte complex with PVPEt (curve *2*).

Such alteration of the direction of the interpolyelectrolyte substitution reaction (22) agrees with the difference between the stabilities of the corresponding initial polyelectrolyte complexes and the reaction products in aqueous salt solutions. In sodium chloride solutions, the stabilities of both the complexes NaPP–PVPAlk and the complexes NaPMA–PVPAlk diminish consistently in the sequence PVPMe > PVPEt > PVPPr.[93] Such decrease in the ability of the complexes to resist the disruptive effect of the salts in the homologous series of PVPAlk can apparently be accounted for by the steric shielding of the oppositely charged groups of polyions. However, it is significant that this effect is more marked in the case of the complexes NaPP–PVPAlk, where the replacement of one *N*-alkyl substituent in poly-4-vinylpyridine by another leads to more significant changes in stability. For the same reason, with increase in the length of the *N*-alkyl substituent in PVPAlk, the difference between the stabilities of the corresponding complexes decreases, which agrees with the decrease in the degree of conversion q in the substitution reaction (22) in the sequence PVPMe > PVPEt > PVPPr (Fig. 5).

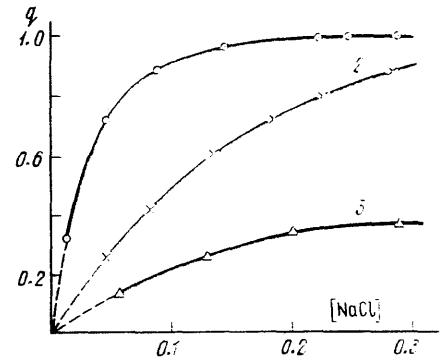


Figure 5. Dependence of the extent of reaction q in reaction (22) on the salt concentration in solutions containing different alkylated poly-4-vinylpyridines: *1*, PVPMe; *2*, PVPEt; *3*, PVPPr; φ = [PVPAlk]/[NaPMA*] = 0.2; [NaPP] = [NaPMA*]; pH 10.[92]

Thus, by virtue of the cooperative nature of the inter-polyelectrolyte reactions, even very slight differences between the free energies of the interaction between pairs of units of chemically complementary chains is entirely sufficient to alter completely the direction of such processes. In many instances, a strikingly high selectivity of the interaction of the oppositely charged chains is manifested in systems of this kind. In a solution containing relatively long and relatively short polyanions with the same chemical structure, the polycation prefers to combine with long chains. By the method of trial and error, the cation recognises and selects that of the two cations which forms with it a more stable polyelectrolyte complex even if the difference between the energies of reaction per pair of oppositely charged units is very small. By adding different alkali metal salts to the reaction mixture (i.e. by varying the nature of the low-molecular-weight counterions), it is possible to alter the affinity of the competing polyanions for the polycation and to regulate thereby the direction and equilibrium position of the interpolyelectrolyte substitution reaction. The presence in the polyanion of a small number of groups (1 per hundreds of chain units), capable of interacting specifically with the units of the complementary chain in the non-stoichiometric polyelectrolyte

complex formed, can ensure the preferential binding, i.e. "recognition", by the polycation of a modified polyanion of this kind among the unmodified macromolecules.

This is responsible for the exceptionally high selectivity of the interpolypolymer interactions and the striking tendency of such systems to undergo self-organisation and also ensures the "self-assembly" of the non-stoichiometric polyelectrolyte complex species in aqueous salt solutions. The factors influencing the direction of the reactions investigated can be an effective means for regulating the interpolyelectrolyte exchange and substitution.

Three-dimensionally growing polyorganosiloxanes. Possibilities of molecular construction in highly functional systems.

A M Muzafarov, E A Rebrov, V S Papkov
Institute of Synthetic Polymeric Materials, USSR Academy of Sciences
Institute of Organoelement Compounds, USSR Academy of Sciences

ABSTRACT. An analysis is carried out of general aspects of the construction of three-dimensionally growing structures with an organic or an inorganic skeleton. Problems in the synthesis of novel polymeric forms based on organosilicon monomers are examined. Ways are discussed for overcoming steric effects in the surface layer, caused by the characteristics of the formation of three-dimensionally growing structure.

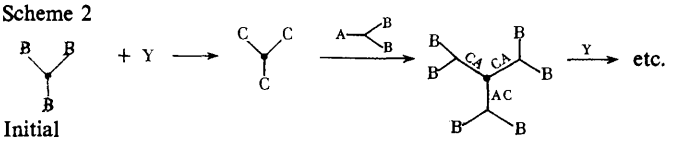
I. Introduction

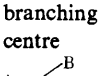
The present review is based primarily on the material of a report which was presented at the first international school-seminar on non-traditional methods of polymer synthesis.[1] However, a considerable amount of work in this area has appeared recently, as a result of which it can be said that polymer chemistry has developed in a new direction which may be described as the "synthesis of dendrimers" or, more poetically, of polymers of the "starbust" type. The principal achievements and problems and also the characteristics of formation of these structures, including theoretical prerequisites for the emergence of the new polymeric forms, have been reviewed by Tomalia et al.[2] Publication of this detailed review simplified our task to a considerable extent. Here we shall consider only the results and problems arising in the course of the synthesis of three-dimensionally growing organosiloxanes or organosilicon dendrimers. Data for the organic analogues will be used only to the extent that is necessary for an understanding of the similarities in the problems investigated and of the differences in the synthetic approach to their solution.

II. Basic prerequisites, concepts, and general schemes

The basic prerequisites for the creation of macromolecular dendritic systems can be traced back to the work of Flory,[3] who suggested that highly functional systems could lead to the formation of highly branched polymers rather than cross-linked or polycyclic types. To achieve such a result, one main condition, specified by Flory, must be satisfied. Thus, if a monomer contains two or more functional groups, one of which is A, and the others are of type B, and if A does not react with A, or B with B, but the interaction of A with B results in the formation of a chemical bond A–B, then it is possible that a non-crosslinked and non-polycyclic polymer will be formed, as shown in Scheme 1.



Scheme 1



A + A ⇸
B + B ⇸
A + B ⟶ AB

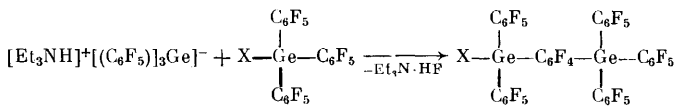
If, however, in the initially formed oligomer itself, not only does A not interact with A, or B with B, but A also does not interact with B; and if it is possible at a certain stage to convert B into C, a group which can form a chemical bond by interaction with A, then such a scheme can be used to obtain completely controlled growth of the molecule (Scheme 2):

Scheme 2

Initial branching centre

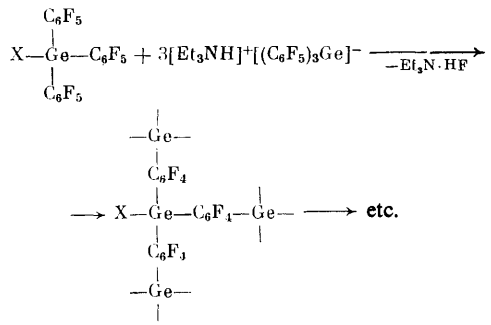
main reagent

A + B ⇸
A + A ⇸
B + B ⇸
B + Y ⟶ C
C + A ⟶ AC



Practically all systems synthesised at the present time can be described in general form by means of Schemes 1 and 2 and we shall therefore make use of these frequently for appraisal of the characteristics of one or another real system.

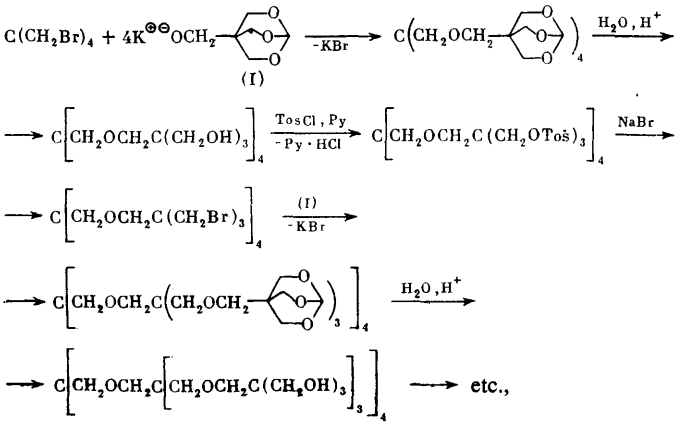
III. Examples of real structures, and corresponding general schemes



Scheme 1 is well illustrated by work[4,5] using organoelement compounds. During a study of the chemical characteristics of the hydrides of germanium and silicon, with perfluorophenyl substituents at the heteroatom, an interesting fact was discovered. The presence of three perfluorophenyl substituents at the atom of the element leads to such a significant redistribution of the electron density in the molecule, such that on the addition of a base, triethylamine, charge separation occurs with the separation of hydrogen as a proton rather than hydride.

$$(C_6F_5)_3GeH+Et_3N\rightarrow[Et_3NH]^+[(C_6F_5)_3Ge]^-.$$

This fact, in combination with the reactivity of the *p*−F atoms of the perfluorophenyl substituents at the atom of the element, in particular germanium, leads under these conditions to a process at every reaction centre, which can be depicted by the following general scheme:



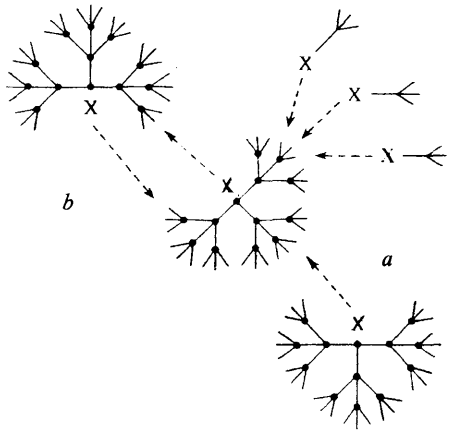
or, bearing in mind the molecule as a whole:

In this system the germanyl hydride grouping (in accordance with the condition of Flory) is the functional group A, and the atom of fluorine in the *para* position of all three perfluorophenyl groupings is the functional group B (Scheme 1).

Let us consider briefly the remarkable properties of this system. First of all, the ease with which reaction occurs at room temperature should be noted: from the moment of introduction of triethylamine to the completion of the reaction and the formation of a polymer, less than a minute elapses. As a result a "live" polymer is formed. The reaction may be resumed again after separation of the precipitate of triethylamine hydrofluoride and the introduction of new portions of reagents. Such an operation can be repeated more than once. In addition, it is possible to obtain a polymer with a molecular mass of several millions, as determined by light scattering. From electron microscope data, the polymeric molecules obtained are seen to be spherical.

The most complete illustration of the general Scheme 2 is possible by a consideration of the following system:[6]

in which the basic reagent is the potassium salt of the tricyclo-orthoester, 4-(hydroxymethyl)-2,6,7-trioxabicyclo[2.2.2]octane (I). Conversion of the functional group B:



into the form C[−C(−CH_2Br)$_3$] occurs in three stages—hydrolysis, tosylation, and bromination, after which the process is repeated again. As a result, branched dendrimers are obtained (Fig. 1).[6]

Comparing the two basic schemes for the construction of three-dimensionally growing systems, or dendrimers, several principal points should be noted. Scheme 1 occurs in a single step and does not involve regulation of the structure at the molecular level. On the other hand, in accordance with Scheme 2 (and this is confirmed both theoretically and in practice) it is possible to form the structure of the molecule layer by layer with the possibility of termination at any stage. However, such a delicate control of the structure and dimensions of the molecule at the molecular level demands certain sacrifices, both in terms of the purely synthetic target (since a complex and multistage synthesis is involved), and also in general scientific terms (since the molecule grows in an orderly fashion to a definite size, after which there is a rapid reduction in rate on account of steric hindrance). The fact is, that the surface of the molecule grows more slowly than the number of functional groups, leading at a certain stage to steric difficulties.[6] At the same time, the unregulated system (Scheme 1) controls its own growth and therefore in every layer as many functional groups as possible are used without steric complications. In accordance with Scheme 1, polymers can be obtained with a molecular weight of > 1,000,000 a.m.u. The authors[4,5] did not analyse certain additional, purely structural processes, which can take place during the unregulated formation of three-dimensional structures. The basic difference between systems 1 and 2, as schemes for the formation for these structures, is that in the regulated version, if the interaction of the growing molecules between themselves is excluded then growth of the macromolecule is accomplished only by the addition of monomeric units at the growing centre, whereas in the non-regulated variant, the growing molecules are fully able to interact between themselves, especially in the early stages. On the one hand, therefore, it is possible that entire regions of the surface of the growing molecule may become

shielded (Scheme 3, process *a*), but on the other, cyclisation may occur (Scheme 3, process *b*):

Scheme 3

The principles and basic schemes for obtaining macromolecular dendrimeric systems have thus been considered and attention will now be turned to the main subject of this brief review: three-dimensionally growing polyorganosiloxanes.

IV. Three-dimensionally growing polyorganosiloxanes

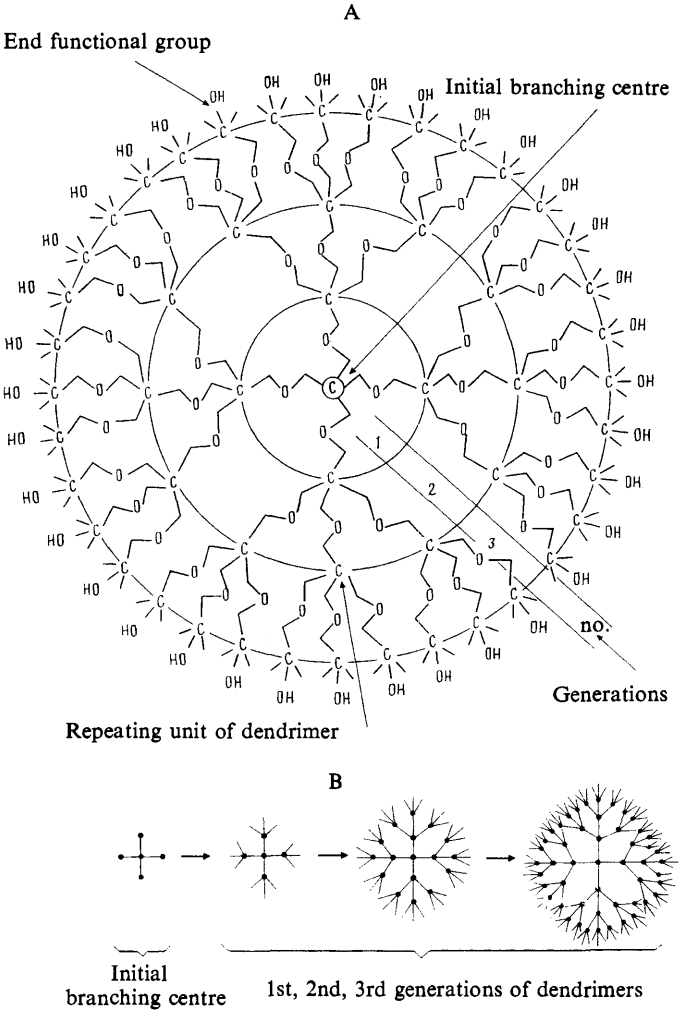
With the whole expansion of possibilities for controlling the structures of organosilicon polymers, and so also to a certain extent the properties of materials based on them, a search was carried out for new, convenient methods for the synthesis of organosilicon polyfunctional oligomers with reactive functional groups.

From the point of view of choice of reagents, suitable for the construction of three-dimensionally growing systems, organosilicon monomers are not themselves convenient, because of the limited choice of functional groups in comparison with normal organic monomers. This applies especially to the construction of polymers with a purely siloxane skeleton. Analysis of data in the literature showed, in particular, that amongst the organosilicon monomers reported, there were none which could have met the necessary requirements sufficiently (i.e. would have allowed the aim of conversion by general Scheme 2 to be achieved). The majority of traditional monomers employed for obtaining siloxane polymers by polycondensation methods contain functional groups that are the same, undergo exchange with each other, are insufficiently stable, or enter into reaction with one and the same reagent.

The basic reaction, therefore, is not sufficiently selective for the preparation of simple branched oligomers by the use of such organosilicon monomers, or for the subsequent development of the functional system.[7–15] All of these facts stimulated work on the creation of monomers containing two or more differing functional groups. In this connection, our attention was attracted to the alkoxysilane-alkali metal hydroxide system, which, in spite of conflicting reports in the literature,[16–19] allowed one to hope that monomers with independent functional groups could be obtained, containing simultaneously sodiumoxy- and alkoxy-groupings attached to atoms of silicon. The synthesis of such compounds proved to be very simple and the yield of the main substance in the majority of cases reached 95%.[20]

$$\mathrm{RO{-}Si{-}OR} + \mathrm{NaOH} \longrightarrow \mathrm{RO{-}Si{-}ONa} + \mathrm{ROH},$$

R=Et; R′=R″=Me; R′=R″=OEt; R′=Me, R″=OEt.



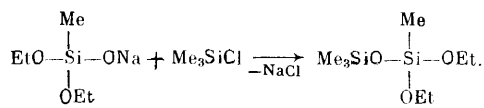


Figure 1. Planar projection of "starbust dendrimer" (A) and scheme for its formation (B).

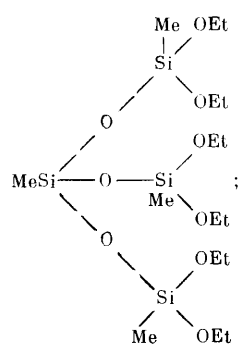
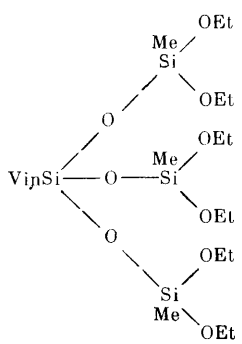
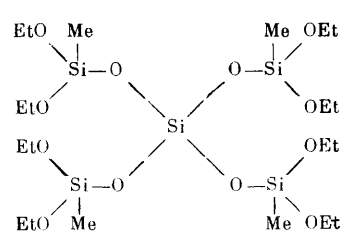


Although it was initially apparent that the presence of two or more identical functional groups in a molecule of alkoxysilane does not permit high selectivity to be achieved in this reaction, a more detailed study of the NaOH–$(RO)_2SiR'R''$ system showed subsequently, that selectivity is an entirely natural result of the marked redistribution of electron density in the molecule of

alkoxysilane that follows the introduction of sodiumoxy-groupings into its structure.[21] A study of the properties of the sodiumoxy-organoalkoxysilanes that were obtained led us to the conclusion that under certain conditions, alkoxy groupings can be considered as latent functional groups or as protected groups that may be activated to become reaction centres ($\geq$Si—Cl). These assumptions were most simply confirmed and utilised by a one-step transformation of the alkoxysilyl grouping into chlorosilyl (Scheme 4). The transformation of $\geq$Si—OR into $\geq$Si—Cl allowed the primary cycle of conversion to be completed and the molecular construction of siloxane systems to commence immediately.

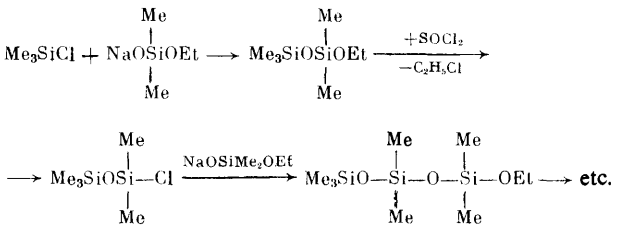


In contrast to the majority of sodiumoxy-derivatives or organosilicon monomers, sodiumoxyorganoalkoxysilanes dissolve readily in practically all organic solvents including those such as hexane, toluene, diethyl ether, etc. The first reactions carried out with the use of the novel reagents have already demonstrated the "independence" of their functional groups; in particular, we have shown that it is possible to carry out the reaction between organochlorosilanes and sodiumoxy groupings with formation of a siloxane bond, whilst preserving the inviolability of the alkoxy groupings. Thus, during treatment of the monomers with trimethylsilyl chloride (a process used by us for the identification of synthesised compounds and estimation of their yield) the formation of by-products was not observed.

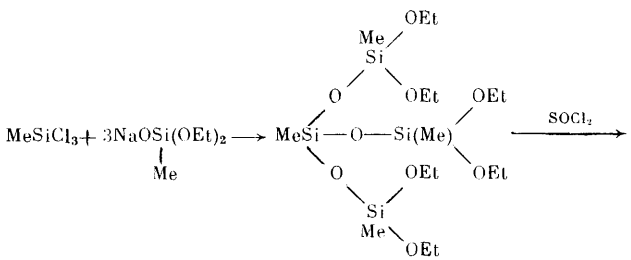


The use of tri- or tetra-functional silanes such as $RSiCl_3$ (R = Me, vinyl) and $SiCl_4$ in these reactions, instead of trimethylchlorosilane, allows the first generation of oligomers to be obtained.

62%

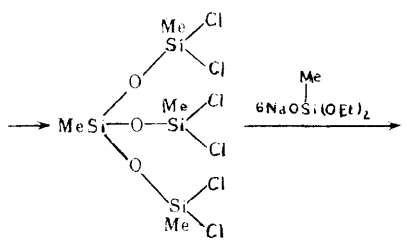


65%

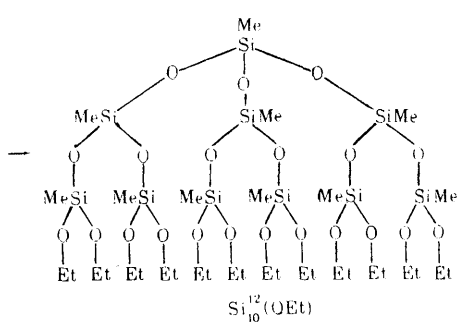


30%

Differences in the yields are explained by the different stabilities of the central, branching centres towards nucleophilic reagents. Further development of the process—conversion of the functional groups from the form B into C (in accordance with the general Scheme 2)—was carried out through replacement of the alkoxy groupings by chlorosilyl as in the scheme:



Scheme 4



or by use of a trifunctional branching centre.

$Si_4^6(OEt)$

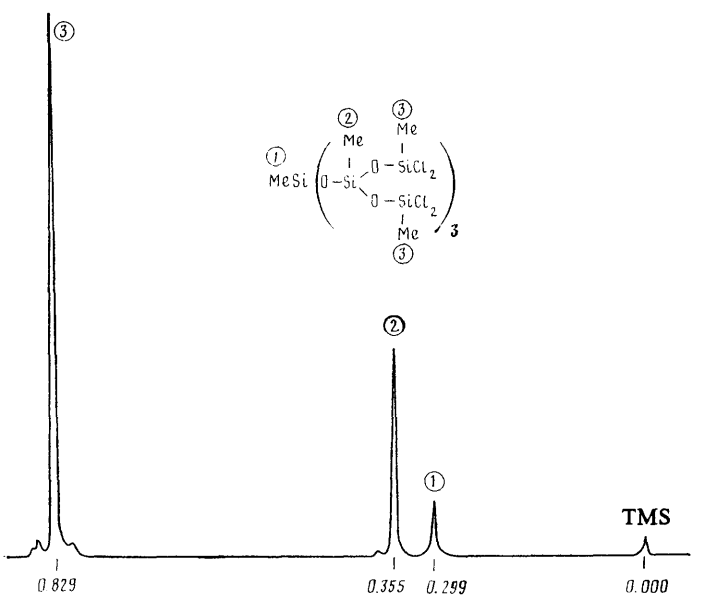
$Si_4^6(Cl)$

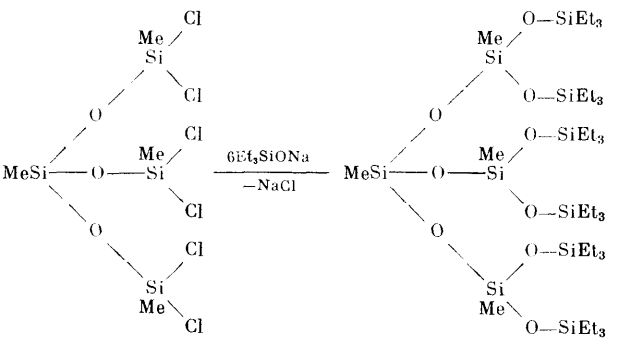
$Si_{10}^{12}(OEt)$

In the accepted designation of three-dimensionally growing oligomers the upper index shows the functionality of the oligomer, the lower index shows the number of silicon atoms in the structure of the oligomer, and the type of functional group is shown in brackets.

The high yields of first and second generation oligomers and the absence in the reaction mixture of products resulting from fission of the siloxane bond, show that the reaction conditions chosen were suitable. Since compounds with chlorosilyl groupings were already used in the first stage of reaction (by interaction with sodium-oxyorganoalkoxysilanes), then the process for obtaining second generation oligomers did not give rise to special difficulties. It was also found that the yield of the oligomer $Si_{10}^{12}(OEt)$, was significantly higher than the yield of $Si_4^6(OEt)$ and that this tendency was repeated for the conversion of $Si_{10}^{12}(OEt)$ to $Si_{22}^{24}(OEt)$, facts that may be

accounted for, apparently, by the characteristics of the structure of the synthesised oligomers and, in particular, the extensive screening of the siloxane skeleton by the surface functional groups. Thus, if the primary branching centre and the surface reaction centres are chemically identical, there is less possibility of fission of the siloxane bonds under the action of sodiumoxy-derivatives. Four generations of oligomer, $Si_4^6(OEt)$, $Si_{10}^{12}(OEt)$, $Si_{22}^{24}(OEt)$ and $Si_{46}^{48}(OEt)$ are reported,[22] providing indisputable evidence of correspondence with the cited Scheme 4 and the conditions for formation of three-dimensionally growing systems mentioned above. From Scheme 4 it is possible to see all stages of formation of the molecular structure by the use of methyltrichloro-silane as the branching centre and sodiumoxymethyldiethoxysilane as the basic reagent. The reaction of chain growth (accumulation of layers) proceeds by the interaction of sodiumoxy groupings with chlorosilane groupings at the branching centre, whilst the ethoxy groups act as protecting groups for the future reaction centres at which, after their conversion into the active form, a new "layer" in the structure of the growing molecule will be formed.





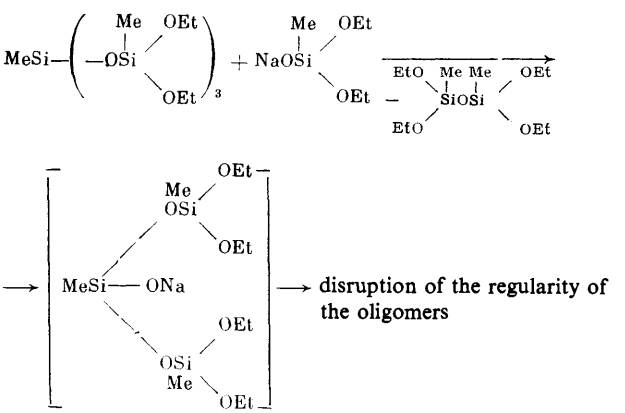


Figure 2. ^1H nmr spectrum of the oligomer $Si_{10}^{12}(Cl)$ in CCl_4 (spectrum recorded on Bruker WP-200 instrument).

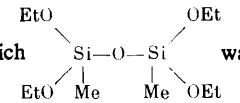
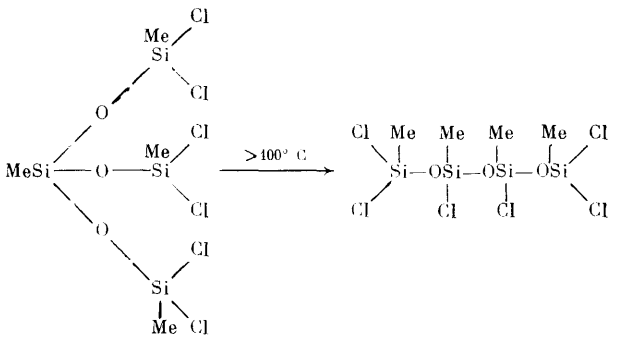
The three-dimensionally growing oligomers are obtained as transparent mobile liquids. For identification of the synthesised oligomers a number of methods were used, including functional and elemental analysis, ^1H and ^{29}Si nmr spectroscopy, and high performance liquid chromatography (HPLC). In Fig. 2, the ^1H nmr spectrum of the oligomer $Si_{10}^{12}(Cl)$ is given as an example, showing well resolved signals for three species of methyl group attached to silicon in the central, first and second (external) layers. The integration ratio for the intensities of these signals (1 : 3 : 6) is in complete accordance with calculation. Still more informative is the ^{29}Si nmr spectrum. In particular, for the oligomer $Si_{10}^{12}(OEt)$, three signals are observed in the regions $\delta_1 = -67.91$, $\delta_2 = 67.44$, and $\delta_2 = 51.47$ ppm, corresponding to the central silicon atom and the atoms of silicon of the first and second layers.

At the same time, in the analysis of the oligomers that were obtained, account was taken of the specific character of the highly-functional and very reactive systems under investigation. Because of the high reactivity of chlorosilyl derivatives, the use of HPLC for confirmation of purity was preceded by an additional step involving blocking of the functional groups by triethylsilyl groups to give non-functional derivatives:



These non-functional derivatives of the three-dimensionally growing oligomers were studied by the method of HPLC and it was shown that the resolving ability of the apparatus, with a column efficiency of 24 000 theoretical plates, was sufficient for the separation of oligomers of the 1st, 2nd, 3rd and 4th generations. HPLC was used to confirm the purity of the standard obtained by Scheme 4 and also proved to be helpful in the selection of optimum reaction conditions for the basic synthetic scheme. The latter circumstance is especially important, as it is known that the siloxane bonds which form the skeleton are sensitive to both the nucleophilic reagent (sodiumoxy-organoalkoxysilane) and the electrophilic reagent (thionyl chloride) which are used at different stages of the synthesis. It was shown that to carry out the synthesis under non-optimum conditions can lead to disruption of the ordered structure of the oligomers as in the following scheme:



i.e. the fear that the siloxane skeleton of the oligomers may not be stable is not without foundation. Indeed, under certain conditions the fission of the grouping $\diagdown Si-OC \diagup$ by sodiumoxyorgano-alkoxysilanes can proceed quantitatively. Concerning fission of the

$\diagdown$Si—O—Si$\diagup$, grouping, interaction of the sodiumoxy-derivative $NaOSiMe(OEt)_2$ with the oligomer $PhSi[OSiMe(OEt)_2]_3$, gave

products among which  was identified, showing

clearly that this type of interaction should also be borne in mind in the systems under investigation.

There are further experimental factors confirming the instability of the siloxane skeleton. Thus, for example, we have shown[24] that to heat oligomers which contain chlorosilyl functional groups above 100 °C is extremely undesirable, as it can lead to rearrangement.

However, in the presence of chlorosilyl groupings, the oligomer shows desirable stability both of the siloxane skeleton and of the molecule as a whole. It is sufficient to say that the oligomer $Si^{24}_{22}(OEt)$, which has a molecular mass of 2356, was distilled under vacuum without showing any tendency to rearrangement. A knowledge of these processes, of the temperature ranges at which they occur, and of their characteristics, ensures the possibility of accurate control of the formation of products. As a result, the majority of oligomers were made and characterised as individual chemical compounds. It can therefore be affirmed, that by carrying out the reactions under optimum conditions, the synthetic schemes shown can be realised without any perceptible side reactions.

V. Separate problems of synthesis of three-dimensionally growing siloxanes

In spite of considerable differences in methods of synthesis for three-dimensionally growing polyorganosiloxanes and their organic analogues, systems of the type under examination develop according to general and objective rules. It was therefore natural to consider the question of saturation of the surface layer by functional groups and the negative consequence of this phenomenon for regular growth of the molecule. We first encountered this in the course of the synthesis of three-dimensionally growing siloxanes, having found that at a definite stage in the progress of the synthesis, the characteristics of the products obtained began to change in a way that was not in accordance with previously observed tendencies. Thus, in Fig. 3, the relationship is given of refractive index, specific viscosity and density for three-dimensionally growing oligomers with ethoxy functional groups, to the ordinal number of the oligomer. It is easy to see that in all cases of change from oligomers of the 6th generation to those of the 7th, these curves show a break, which we believe to be associated with a loss of regularity in the oligomer, on account of arising steric difficulties. The same phenomenon was encountered but at an earlier stage in the blocking of functional oligomers. Thus in the case of the 4th generation oligomer, Si^{48}_{46}, we found that the number of blocked end groups which could be introduced did not correspond to that calculated theoretically. For this reason we do not have available the corresponding chromatograms, confirming the individuality of synthesised oligomers that contain more than 46 atoms of silicon. This earlier breach of the regularity of the system is explained, first of all, by the use of monomeric reagents, and it is not therefore surprising that the increase in the functionality of the oligomer quite quickly outstrips the increase of the surface at which they may be able to attach themselves.

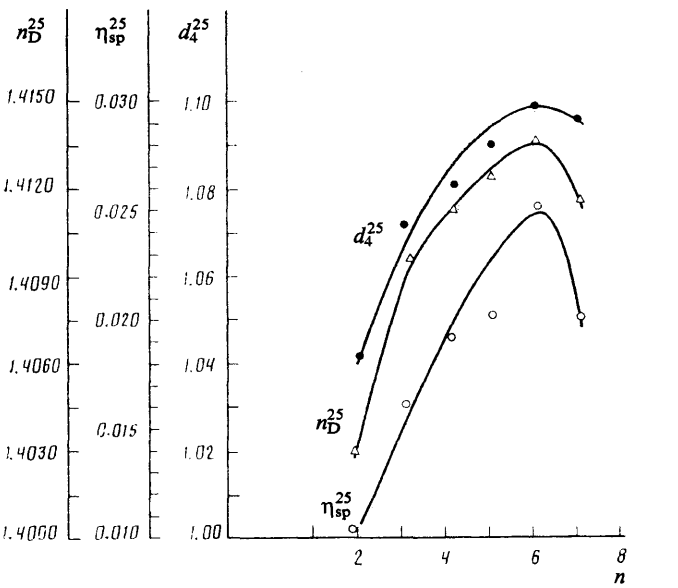


Figure 3. Relationship of density, (d_4^{25}), specific viscosity (η_{sp}^{25} for a 1% solution in toluene) and refractive index (n_D^{25}) for three-dimensionally growing polyethoxymethylsilsesquioxanes to the ordinal number of the oligomer in the homologous series.

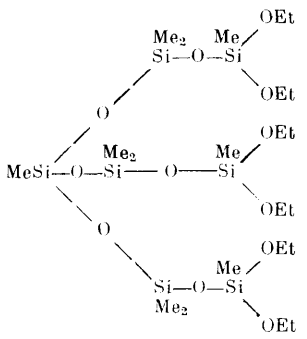
The limit to the regular growth of dendrimers should not, however, be considered as an insurmountable problem but should rather stimulate efforts to overcome these difficulties in the field of molecular construction of such polymers. In principle this is possible. A mathematical correlation can be made between the length of the linear section of an oligomer and its functionality, for which steric difficulties on the synthetic pathway for oligomers of a definite size will not arise. There is also another way for solving this problem. In particular, we have shown that during accumulation of

a further layer of monomer, it is possible to use a structure which is different from that of the basic structure.[22]



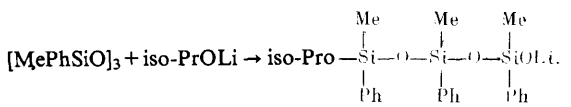


Table 1. Properties of blocked oligomers.

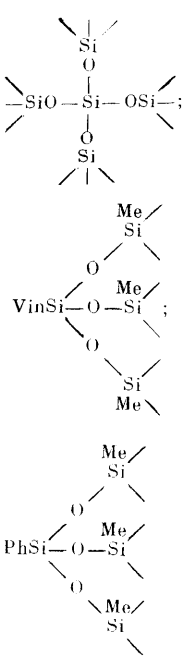
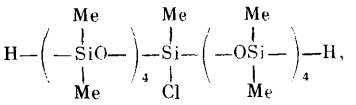
Unit blocked	Blocking group	t_{vit}, °C	η Pa s
$MeSiCl_3$	Et_3SiO-	−138.4	$2.5\cdot10^{-3}$
$Si_4^6(Cl)$	Et_3SiO-	−133.0	$2.5\cdot10^{-2}$
$Si_{10}^{12}(Cl)$	Et_3SiO-	−120.0	0.1
$Si_{10}^{12}(Cl)$	$Me_3SiOSiO-$ (Me, Me)	−110	–
$Si_{22}^{24}(Cl)$	Et_3SiO-	−101.0	6.5
$Si_{46}^{48}(Cl)$	$C_{10}H_{11}-$	−48.0	$2\cdot10^{-2}$
$Si_{46}^{48}(Cl)$	$(CF_3CH_2CH_2)_3SiO-$	−63.8	0.28
$Si_{46}^{48}(Cl)$	Me_3CO-	−85.0	–
$Si_{46}^{48}(Cl)$	$CH_2=CH-SiO-$ (Me, Me)	–	–



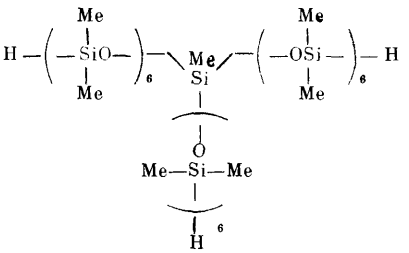
From the chemical formula given, it is seen that the use of a difunctional monomer leads to an increase in the size of the oligomer and consequently also, in the size of its surface, with preservation of the number of functional groups. Such an operation can be described as a distinct "thinning out" of the reaction centres, averting the onset of steric difficulties. Undoubtedly, the effectiveness of such a thinning out is proportional to the length of the linear section between the last branch in the structure and the functional groups. In such a scheme for the siloxane systems considered, there is the prospect of using individual oligomers, synthesised as follows.[25]

It is necessary at once to make the reservation, that the operation of "thinning out" of the functional groups is closely connected with a change in the intramolecular packing of the three-dimensionally growing molecules, and at present it is not clear whether such thinning out has any effect on the properties of the oligomer as a whole. The influence of the surface layer on the properties of the oligomer, especially in blocked oligomers, is considerable, since the blocking groups constitute 50% of the structure of three-dimensionally growing oligomers (out of the total number of monomeric units) and being concentrated in the surface have an independent significance.

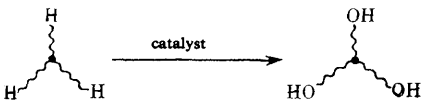


It appeared to be possible within fairly wide limits to change the intermolecular interaction of the oligomers by the use of different organic substituents at the atoms of silicon in the surface layer. For this purpose it was shown to be possible to use blocking compounds such as Me_3CONa, $Me_3SiOSiMe_2OH$, $(CF_3CH_2CH_2)_3SiONa$, and $C_{10}H_{11}MgBr$.[23] For illustration we can use the data in the Table 1, which shows oligomers having identical molecular skeletons but differing in the features of the surface layer as a direct consequence of the use of different blocking agents. From the data that are presented it is seen that both the viscosity of the oligomers and also their temperatures of vitrification vary widely.

The problem of molecular construction in such systems are not exhausted by a guarantee of the possibility of layered growth but require maximum flexibility of approach in order to control the form and density of intramolecular packing and also the quantitative and qualitative composition of the functional groups in the surface layer of the oligomer. Comparing the schemes for dendrimers with organic and inorganic skeletons, it can be noted that in both cases it is possible to use different initial branching centres. Thus Newkome[26] demonstrates tri- tetra- and hexa-functional branching centres for organic systems. For organosiloxane systems in the same way it is possible to use various compounds, for example;[22]



As regards the choice of reagents that meet the requirements for the use of general Scheme 2 for the construction of regular dendritic structures, it can be noted that the number of organosilicon monomers exceeds that of the organic analogues, although at the



present time they are almost all of the same type. Organic reagents are notable for their diversity, making it possible to obtain amidoamino and polyoxyalkylenic oligomers, in addition to those based purely on carbon. Furthermore, it is clear, that in the use of siloxane systems both the process of building up of the layers, and the conversion of functional groups into the active form involve two reactions, whereas in the majority of organic systems that have been investigated, the conversion of functional groups into the active form requires four different chemical reactions.[6,26] More recently a short communication[27] has appeared on the synthesis of polyorganosiloxanes of the starburst type using a different functional basis and reagents of a larger size than were considered by us above. In this case, the following was taken as a particular reagent:

and as a branching centre:

Conversion of form B into form C was carried out according to the following scheme:

This example also shows that in the field of organosilicon polymers, three-dimensionally growing systems are not excluded and that the reagents which are used can themselves be diverse.

In conclusion let us refer to possible trends in the uses of three-dimensionally growing polyorganosiloxanes. Firstly they find application, as do the organic analogues,[2] as standards for HPLC, electron microscopy, and the calibration of membranes. There are prospective uses in biology and medicine for three-dimensionally growing polyorganosiloxanes as soluble polyfunctional matrices, with variable characteristics in the surface layer at which different biomolecular assemblages can be attached. There are also good prospects for the use of new polymers in the fields of microelectronics, conducting materials, and membrane separation technology, etc. However, in the course of making these new materials, still wider investigations will be necessary into the development of the necessary basic reagents, the properties of three-dimensionally growing polymers of different structure and composition, and new synthetic approaches to the control of structure and properties.

Steric effects: the problem of their quantitative assessment and manifestation in the reactivity of hetero-organic compounds

V I Galkin, R D Sayakhov, R A Cherkasov
V I Ul'yanov-Lenin Kazan State University

ABSTRACT. Literature data on the methods of quantitatively assessing steric effects and their manifestation in the reactivity of various hetero-organic compounds is systematised. The authors' own results are considered in the light of a model of frontal steric effects and of a calculated scale of steric constants R_s, the high effectiveness of which has been demonstrated in more than 100 reaction series involving organic and hetero-organic compounds.

The bibliography contains 202 references.

I. Introduction

Current ideas on the effects of the spatial structure of molecules on their reactivity embrace many diverse phenomena. The overall interaction of substituents with a reaction centre is assumed to be subdivided into inductive, resonance and steric components.

When attempting a quantitative assessment of the steric component investigators have frequently encountered a problem when choosing parameters reflecting the steric effect of substituents. The presence of many steric scales complicates such a choice. The assessment of spatial effects in the chemistry of hetero-organic compounds (HOC) was problematical until recently owing to the uncertainty of its overall theoretical character. Whether steric effects actually influence the reactivity of HOC was still in question.

The present review is devoted to a discussion of studies affecting both aspects of the problem. In addition to an analysis and comparison of the existing methods of calculating steric effects attempts will be made to use these methods for the analysis of the reactivity of HOC. In those cases when the material of the present review partially overlaps reviews published already the appropriate references are given.

II. Quantitative methods of assessing steric effects

1. General concepts of steric effects

a) History of their development

It is considered (see Ref. 1 and literature therein) that the idea of a steric effect was introduced for the first time by Khermann in the mid-nineteenth century to explain the chemical inertness of substituted quinones by the steric effect of *ortho* substituents. Up to the thirties of the present century the concept of a steric effect was widely drawn upon by Hofman, Menshutkin, Holleman, Conant and other authors to explain chemical phenomena. However the development of steric effect theory later went into a decline caused by the predominant attention paid by investigators to the inductive effect of substituents.

Subsequently the reactivation and blossoming of steric effect theory was linked mainly with the precise quantitative investigations carried out by Ingold, Brown and Taft (see Ref. 2 and literature therein).

At present the steric effect shown by a substituent is recognised as steric hindrance or cooperation in the course of a reaction as a result of which there is a change in valence angles and coordination number of the reaction centre during the reaction or on activation.[3] The concept of a substituent shielding a reaction centre is widely used.[4] The drawing together of molecules in space is considered to be the most important factor determining the energy of activation.[5,6] According to contemporary ideas[7–9] steric effects for processes occurring in solution reduce in many cases to the hindrance which a substituent creates for solvation of the reaction centre. Finally, steric effects of substituents may be manifested by the inhibition of resonance structure formation.[4]

These factors of structure and reactivity have been considered in adequate detail for organic compounds in the review literature.[3,10–13] For hetero-organic compounds these aspects have not as yet been generalised in any appreciable manner although there are individual reviews concerning compounds of phosphorus, silicon and nitrogen[9,14–18] and a whole series of individual papers and series of papers on the chemistry of other elements in which some aspects of the spatial effect of substituents are considered. It must be noted that the possibility of the actual manifestation of steric effects in HOC chemistry was discussed comparatively recently,[19] although there are numerous investigations, including some carried out at the quantitative level,[20,21] pointing in favour of the existence of such an effect.

An extremely important factor moderating the study of steric effects until now has been the absence, in spite of many experimental data, of a satisfactory physical model of steric interactions, although the latter are linked in a sense with the spatial structure of

molecules.[3] Taft, for example, considers that the more bulky (or more branched) the interacting group is and the closer it is located to the reaction centre then the stronger these interactions will be. It is assumed that these correspond to repulsive forces.[13,22]

At the present time quantitative methods of calculating the steric effect comprise quantochemical, topological, structural and experimental approaches.

2. Methods of molecular mechanics and quantum chemistry

In the theoretical approach to the study of steric effects it is most important[3] to consider the combination of phenomena united by the term 'spatial effects of substituents' as a part of the more general problem of conformational analysis. Consequently a quantitative calculated–theoretical approach to the study of spatial effects must be based on the achievements of theories of conformational analysis,[4] i.e. on quantochemical calculations of the total energy of a molecule as a function of the angles of rotation, which enable the most stable conformation to be established.

It is accepted (see Ref. 2 and literature therein) that the general theory of spatial effects was first formulated in 1946 by Hill who showed that the energy of any molecule (or activated complex) may be described as the sum of the van der Waals potential energy (for the interaction of non-valently linked atoms) and the energy required for the deformation of bond lengths and valency angles of the molecule.

$$SE=E_r(r)+E_\theta(\theta)+E_\varphi(\varphi)+E_{nb}(d), \quad (1)$$

where SE is the system energy, E_r is the energy for deformation of bond length, E_θ is the energy for deformation of valency angles, E_φ is the torsional energy and E_{nb} the energy of non-bonding interactions.

The energy minimum corresponds to the optimum conformation of the molecule. The mathematical problem therefore reduces to varying the structural parameters in the search for the energy minimum.

The approaches of various authors have differed, as a rule, by ignoring some or other of the components of Eqn. (1) or by including additional terms and by the form of the potential function, the force field and by the mathematics and programs provided.

The method,[23] which has received the name atom–atom potential functions, was first applied to the calculation of the spatial influence of substituents in substitution reactions at a saturated carbon atom.[24] The agreement of calculated and experimental data was fairly satisfactory considering that the calculations were carried out manually. After a twenty-year break the studies were continued using computers (see Ref. 2 and literature therein). Initially the calculation plans were most simple, being stepwise, and were then improved by considering an analysis of the energy differences linked with a change in each coordinate of a mobile atom. The Engler 73 and Allinger 71 force field programs were developed.

The approach modified in this way, called the force-field or molecular-mechanics method, is better than previous methods since the set of structural parameters and deformation values used is appreciably improved, the choice of potential function is easier and the calculation procedure for the user is simplified.

The method of molecular mechanics has been used in various branches of organic chemistry. The results of the previous studies of Ingold on the S_N2 process have been re-examined (see Ref. 2 and literature therein) using more precise models. The method proved to be applicable to explain the processes of solvolysis of carbocations and their rearrangements and for conformational calculations of molecules and certain reactions.

DeTar[25] has proposed assessing steric effects using hydrocarbon models. The method considered afforded an explanation of the results of certain reactions[26] and proof of the steric sense of the experimental Taft constants, E_S.[27]

In a series of studies Kalamov and Kuzmin[28–32] developed and verified an approach to the assessment of the steric factors of reactivity based on calculation of the energy of the various conformations of a substrate and an intermediate within the framework of a force field model. By varying the torsion angle and the distance to a reactant a picture was constructed of the potential surfaces which enabled the reactivity of the compounds investigated to be analysed qualitatively and the stereochemical result of a reaction to be explained.

The steric index of reactivity (SIR) was introduced by these authors[28–32] for the quantitative description of the steric effects. This correlates satisfactorily with the E_S constants of alkyl groups and also with the rate constants for the hydrolysis of various esters. Such an approach also enables the stereochemical result of the reduction of α-substituted β- and γ-ketoesters to be explained.

Another approach[33] to the quantitative assessment of steric effects is based on the analysis of the overlap volumes of van der Waals shells of pairs of reactants. A good agreement of calculated and experimental data was achieved. This and methods similar to it are applied mainly to the correlation of biochemical data and biological activity (see Ref. 2 and literature therein).

Recently *ab initio* quantum methods have been developed for the calculation of potential barriers to internal rotation and of the total energy of a molecule as a function of the angles of internal rotation.

The approach proposed by Becker[34–36] is considered to be the most fundamental among this group of methods. Steric effects of substituents are proposed as the manifestation of particular conformational relationships.[34–36] However at the basis of Becker's method there are complex mathematical calculations and parameters which are difficult to determine and which hamper its practical use. It is necessary to mention the work of Bohle[37] on the development of optimisation programs based on Becker's approach in which a satisfactory description of the steric effect of alkyl substituents was achieved with specific assumptions. However it is also unlikely that this modification will be successful in the short term.

Periodically studies have appeared using various methods of disregarding differential overlap in calculations, such as CNDO, CNDO/2, MNDO, CS-INDO.[38–42] However the results of calculations did not always agree with the experimental data.

Various MO methods have been applied with varying success to the calculation of rotational barriers[43,44] and the investigation of various reactions.[45,46]

3. Topological methods

Topological indices have been applied in chemistry comparatively recently and have already acquired a wide reputation (see Refs. 2 and 47 and literature therein).

The development of topological approaches is linked with the application of graph theory. Usually an abstract mathematical structure, the so-called 'molecular graph', is characterised by two matrices, a proximity matrix A and a distance matrix D. The topological indices are quantitative characteristics of such graphs and represent various combinations of the elements of both matrices and reflect some aspect of the structure of the molecule.

The topological index was first introduced by Weiner (see Ref. 2 and literature therein). He introduced the W index denoting the number of edges connecting all pairs of apices to one another and showing the extent of branching of the molecule. Like W the I indices, the Platt index f, and the index N_2 derived from it, depend on the number of linking edges but in a different manner. The Hosoi index Z reflects the distance between all the unconnected apices. The indices of Gutman (M_I), Randic (χ) and Kier–Hall (h_x) are indicators of the extent of substitution at each apex.

A new group of informational indices I_{PC} and $\bar{I}_{PC}$ was introduced by Bonchev. These indices are combinations of indices W, Z and χ.

The group of centric indices of Balaban reflect the structure of a tree-like graph and is also linked with the geometric structure of the molecule.

The topological indices represented above and certain others are considered in a more detailed manner in the review[2] and in the literature cited in it.

Topological indices are intuitively linked with the structural parameters of molecules[2] but there are very few quantitative investigations of them. Recently Balaban[48] has correlated 14 known topological indices with molecular refraction and van der Waals volume. The best correlations were obtained for the indices W, I, χ and the informational indices I_D^W and I_D^E. This enabled a conclusion to be drawn on the similarity of these indices with the experimental constants E_S and v_X. In addition it turned out that all 14 of the indices investigated were linked linearly to one another which prevented the creation of a new superindex of the linear combination of several of the known indices. However in several cases the correlation of experimental data with the indices of Randic[49] and Kier–Hall[50] proved to be successful. A linear connection between the Randic indices and steric constants has also been recorded.[49]

The lack of consideration of the conformation of a molecule is a considerable drawback to the use of the indices mentioned. This drawback is removed when using the DARC system of Dubois (see Ref. 2 and literature therein). However this system is an order of magnitude more complicated than the 'disordered' topological indices.

The topological indices may be and already are being used for the calculation of steric effects, for example in computer synthesis programs. However the absence of a clear physical and geometric meaning and also the lack of consideration of the conformation of molecules restrains their application.

4. Structural and geometric scales

The approaches to the modelling of steric effects using various structural, geometric and physical parameters differ from the previous two by the considerable simplification of the mathematics used, by its more graphic nature and by a clear geometric meaning. As a rule available structural parameters, such as valence angles, atomic, covalent, van der Waals radii of atoms and bond lengths, are used as the initial data.

Attempts to create similar accessible methods for the calculation of steric effects were undertaken long ago and were unsuccessful initially. For example some authors compared distances between chemically unbonded atoms with the sum of their van der Waals radii.[51] Such a comparison was usually uninformative but sometimes this method gave acceptable results.

Intramolecular covalent radii, proposed by Bartell[52] as a measure of steric effects, have also not been widely applied.

Tolman's method of cone angles has proved to be more popular. The plane angle subtended at the apex of a cone tangential to the whole ligand was proposed as a measure of the steric effect of the ligand in transition metal complexes.[14,53] However the precision of the measurements conducted at the scale of the model was not high and the method has not enabled linear relationships to be obtained between the stability of complexes and the steric effect of ligands. It succeeded only in explaining qualitatively the effect of some ligands and in placing them in a series according to the order of increasing steric effect.

$$(CH_3)P < (C_2H_5)_3P < (C_3H_7)_3P < (C_6H_5)_3P < (\text{iso-}C_3H_7)_3P < < (\text{sec-}C_4H_9)_3P < (\text{t-}C_4H_9)_3P < [2,4,6\text{-}(CH_3)_3C_6H_2]_3P.$$

Tolman's cone angle model has been further developed in a series of studies[54–59] which has appeared recently. It is proposed to use the idea of 'coordination space' for the quantitative description of steric effects in the coordination sphere of a metal atom in complexes. This space is set by the Tolman cone angles of the ligand at a fixed (ionic) radius of the metal and the van der Waals radii of the atoms in the ligand. The concept of a packing function characterising the density of packing of ligands was also introduced.

This approach has enabled the molecular structure of several complexes to be explained. Rules have emerged for packing saturation, the geometrical parameters of complexes have been calculated and agree with data of X-ray structural analysis. Based on an analysis of the packing function the course of certain reactions has been successfully explained, such as the disproportionation and ligand insertion reactions.

The Tolman cone angle concept has also been extended to cluster systems.[60]

Tolman cone angles have been recalculated by Imyanutov[61,62] using a simple mathematical device and new values have been obtained. The more recent individual values for the extent of screening Λ_c of a central atom, characterising the part of the sphere occupied by the cone angle, proved to be applicable in coordination and organic chemistry and served (for a while) as a basis for a new scale of Λ_c constants.[63] However this scale does not always correlate well with the experimental E_S scale; the authors confined themselves only to a graphical correlation.

Tolman's approach served as a basis for the creation of the solid angle method. Initially[64,65] the steric hindrance generated by a substituent at a carbon atom was assessed on a semiquantitative basis. The solid angles cast by the atoms of a substituent on the sphere of the central atom was used as a measure of the hindrance. The method was used at the quantitative level more recently[66–69] by applying a computer for the calculations. A good correlation was obtained between the stability of a complex and the total solid angles of the ligand. The method also proved to be suitable for the assessment of the screening of individual atomic fragments (such as an individual chemical bond or individual atoms) of the remaining portion of the molecule.[66–69]

The concept of screening a reaction centre by a substituent has been used in many studies. It is thus considered obvious that any substituent screens a reaction centre but the extent of screening is determined by the area cast by the substituent. Approaches to the actual assessment of this area vary.

It was proposed[51,70] to assess the area of screening by the solid angle describing the substituent. The measure of the steric effect is the sum of the ratios $S_L/4\pi R^2$ where S_L is the area screened and R is the distance from each atom to the reaction centre. The equality

of this sum to unity indicates coordination saturation has been reached.

This approach is close in essence to the frontal steric effect model proposed by us two years previously[71] which is based on kinetic collision theory. In it the procedure for calculating the screened area is simpler. A scale of steric constants R_S is proposed which are linked linearly with the available experimental scales. More detail on this method and the different aspects of its application will be considered below.

An ideology almost identical to the ideology of the frontal steric effect served as a basis for the generation in 1989 of a scale of Ω_S constants.[72] This scale differs from the R_S scale only in the use of more complicated methods of calculation. It also correlates well with the E_S constants, but in contrast to the R_S scale gives distinct relationships for primary, secondary and tertiary alkyls. The Ω_S constants also correlate with certain experimental data.

Another direction for assessing steric effects is in essence close to the use of topological indices. Here the number of α-, β-, γ-, etc. carbon atoms is used to characterise the shape of the molecule.[73,74] This is less convenient since it requires several numbers for the description of a substituent[73] and it does not have such a clear geometric and physical sense as is possessed by scales based on the screening of a reaction centre by a substituent. For the same reason it is inconvenient to use parameters characterising the geometric shape of the molecule, such as the length and width in various directions proposed independently by Balaban[75] and by Verloop (see Ref. 2 and literature therein).

The number of carbon atoms in the sixth position in relation to the reaction centre in reactions of addition to an unsaturated system known as the 'six-number' of Newman[76] is used fairly widely (see Ref. 2 and literature therein) and is linked with the E'_S constants of Dubois.[77]

Steric effects are also characterised by parameters reflecting the size and shape of a molecule such as molecular weight or van der Waals volume. However these methods have not had particular success.

Structural methods, as a rule, describe fairly precisely the steric effect of a substituent. Their drawbacks are considered to be that they calculate for only one conformation, they have a static character and they ignore the second reactant. For the usual investigational purposes this is frequently not necessary. Special problems linked with a dynamic change in conformation may occasionally be resolved within the framework of these methods but requires other approaches. The solution of some of these problems will be considered below using the frontal steric effect model.

5. Experimental methods

Experimental methods of determining the steric effect developed completely by another independent route have been applied widely. These methods, proposed by Ingold and Taft,[3,13,78] are based on the principle of the linearity of free energies (LFE). This has been carried out for an enormous number of chemical processes and among them it is possible to pick out those in which the influence of one of the effects predominates. Taft[13,22] proposed that in aliphatic compounds there are powerful steric effects of substituents which must be separated from the electronic. He proposed assessing steric effects using the hydrolysis of carboxylic acid esters.[79] The inductive constants of aliphatic substituents were assessed at the same time.

$$\sigma^* = \frac{1}{2.48}[\lg (k/k_0)_B - \lg (k/k_0)_A],$$

$$E_S = \lg (k/k_0)_A,$$

where σ^* is the constant for a substituent depending exclusively on the overall polar effect of the substituent (corresponding rate constant k), k_0 is the rate constant for a standard compound with substituent CH_3, E_S is the constant of the substituent reflecting its steric effect, the indices A and B refer to the reaction of alkaline and acidic hydrolysis of carboxylic acid esters identical in all other respects. The factor 2.48 is a constant introduced with the aim of making the polar scale of σ^* within the limits of the same scale as applied by Hammett.

The E_S constants have been and still are widely applied in contemporary chemistry in reactions of nucleophilic substitution and fission at a saturated carbon atom (their use is possible both in reaction series analogues to the standard and in very different series) and in unsaturated systems, in catalysis and polymerisation processes, in the chemistry of free radicals, in processes of association in solution and in the gas phase and in spectroscopy. Periodically refined values of constants appear for certain substituents.[80] Correlations of E_S have been obtained with steric energy (ΔSE) calculated by the method of molecular mechanics[27] which, in the authors' opinion,[27] neatly proves the steric nature of the E_S constants.

The Taft E_S scale has been modified by Hancock[81] using a value of $h = 0.306$, calculated by MO methods, for the reaction series of ester hydrolysis, with the aim of calculating the contribution of the hyperconjugation of C–H bonds. The corrected values of the steric constants E_S^c, obtained in this way are linked with the Taft E_S values by the following expression:

$$E_S^c = E_S + 0.306(n-3),$$

where n is the number of hydrogen atoms on the first carbon atom of the substituent being considered and 3 is the same figure for the standard substituent CH_3.

The values of E_S^c lead in several cases to a marked improvement in correlations[82–84] compared with results obtained using E_S constants.

Pal'm has proposed taking into consideration the hyperconjugation of C–C bonds as well.[85]

$$E_S^0 = E_S - 0.33(3-n_H) + 0.13n_C.$$

Several scales similar to E_S have also been introduced. One of them (E_N) is based on the principle of isostericity for substituents at a nitrogen atom,[86] a second on the approach of DeTar[87] and a third on the E_S(Si) constants of Cartiedge.[88] Particular mention must be made of the E'_S scale (MacPhee, Panaye and Dubois[89–91]) determined from the acid esterification of carboxylic acids.

$$RCOOH + CH_3OH \xrightarrow{H^+,\ 40^\circ C} RCOOCH_3.$$

The E'_S scale is similar to the E_S scale for all substituents, except for the very bulky.

An E_S^* scale of constants, similar to the E'_S scale, has been introduced for reactions the transition state of which is analogous to that in hydroboration reactions.[92]

The scale of v_X constants, proposed by Charton,[93] is based on several other principles. The Charton scale may be described as semiempirical since v_X constants may be calculated fairly simply from

the following equation for monoatomic and for highly symmetrical substituents of the A_3B type.

$$v_X = r_{v_X} - r_{v_H} = r_{v_X} - 1.20,$$

where r_{v_X} and r_{v_H} are the van der Waals radii of the groups X and atom H. In addition an equation has been obtained within the framework of the standard reaction series of hydrolysis of carboxylic acid esters

$$\lg k_X = \varphi v_X + h,$$

permitting an empirical route for determining v_X constants for complex unsymmetrical substituents. Charton gave values for 61 v_X constants and also carried out an analysis of the correlation ratios between the experimental data and v_X, E_S, E_S^c and E_S^0 constants for data on 22 reactions of esterification and acidic hydrolysis. It turned out that v_X constants gave the best correlation.

The insignificance of electronic effects of substituents was shown[94] in a continuation of the study of alkaline hydrolysis of esters. Correlation with v_X constants again gave excellent results.

In reactions occurring by an S_N2 mechanism,[95] the use of v_X constants did not lead to a very good result since in this case the type of reaction centre, and consequently the structure of the activated complex, is changed. Introduction of a v' scale of constants for substituents at a sp^2-hybridised reaction centre enabled successful application of correlation analysis to these systems. It transpired that the sizes of the steric effects in S_N2 reactions are greater than in esterification reactions.

Finally v_X constants have been used in the study of the kinetics of $E1$ and $E2$ processes, of internal rotational barriers, the hydrolysis of amides and the racemisation of chiral biphenyls (see Ref. 73 and literature therein).

The v_X constants have been shown to be additive.[96] In addition they proved to be applicable to the study of reactions with substituents present on atoms of oxygen, nitrogen, sulphur and phosphorus (see Ref. 97 and literature therein).

The investigation of the effect of branching in a substituent on the value of v_X constants is a logical completion of the studies on v_X constants.[73] The steric v_X parameters of alkyl, alkoxyl, thioalkyl and dialkylamino groups and also values of v' for alkyl groups have been described using Eqn. (2) with a good correlation.

$$v_X(v') = an_\alpha + bn_\beta + cn_\gamma + dn_\delta + i. \qquad (2)$$

Here the parameters n_α, n_β, n_γ and n_δ reflect the number of α-, β-, γ- and δ-carbon atoms. The correlation Eqn. (2) enables assessment of values of the v_X constants of a very large number of groups. In this scheme the E_S^c constants of Hancock and the E_S^0 constants of Pal'm are simpler steric parameters correlating only with the value of n_α, the coefficients a in which are different from those for v_X.

In spite of the wide and fairly successful application of the empirical scales they are constantly subjected to critical analysis and are occasionally disputed. The main attention of critics is paid to the E_S scale of Taft and the scales derived from it.

In particular it has been shown[98] that the observed rate constant for the standard ester hydrolysis reaction is an effective (but not a simple) constant. The dissecting out of the rate constant for the primary bimolecular stage enabled E_S^b constants to be determined based on it, the values of which are different from the values of the Taft E_S constants. A dependence was also detected for the E_S constants on σ* constants having the form of several straight lines with the same slope for each individual number of α-hydrogen atoms.[99] This led investigators to the concept of the non-electronic nature of σ* constants, although σ* constants work successfully in many cases.[100] On analysis of the experimental data on the hydrolysis of carboxylic acid amides it was proposed[101] that the Taft σ* constants for alkyl groups do not reflect the electronic effect of alkyl groups. More recently Charton[102] discovered that the Taft constants correlate well with the degree of branching of the alkyl group at the α and β positions. From this it was concluded that the σ* constants reflect principally the steric effect of substituents.

Other authors have arrived at the same conclusion. When investigating σ*, σ_I and E_S constants DeTar[103] drew the following notable conclusions. The σ* constants of alkyl groups are inaccurate values which comprise a residual steric effect and experimental error. The use of any other nonsteric values for alkyl groups is also erroneous. References to the nonsteric effects of alkyl groups are based on incorrect data. The alternative scales, such as E_S^c and v_X have no special merit and should be rejected.

One of the main errors of Taft when determining the E_S scale has been considered[90] to be the *a priori* assumption that the various reaction series (acidic and alkaline hydrolysis) used for calculations have identical sensitivities to steric effects.

The lack of consideration of the conformational state of a substituent is described[2] as an appreciable drawback of the E_S scale although the importance of the influence of conformation on the steric effect of a substituent has been recognised by many authors.[73,104–106]

Much attention has been paid to the problem of the additivity of E_S constants. Taft himself recorded[13] that E_S constants were nonadditive but show a telescoping effect (the change of a constant in relation to the position of the substituent at the reaction centre). However certain authors[107,108] use ΣE_S in correlation analysis.

There is another possible approach to the consideration of the additivity of the constants. The following equation has been proposed.[107]

$$E_S(C_{XYZ}) = aE_S(X) + bE_S(Y) + cE_S(Z),$$

which enables various conformations of substituents to be taken into account and the E_S constants of any complex group to be calculated.

Much work has been devoted to a study of the physical significance of the E_S scale. Numerous attempts have been made to find the interconnection between the E_S constants and the various geometric and structural parameters of a molecule. For example, a linear relationship was discovered between E_S constants and the φ_{R_1} scale,[109] reflecting the contribution of the spatial stress built up by α, β and γ C–H bonds. Attempts to link the E_S values directly with the number of α, β and γ carbon atoms were not particularly successful[73] since a correlation was detected only with the number of α carbon atoms. Inherent geometric parameters of a substituent such as its length or width in two orthogonal directions proved to be completely unconnected with the E_S scale.[75]

Taking the results of all these investigations into account and also the recent work of Kramer[110,111] on the nature and additivity of E_S constants, it may be regarded as established that the E_S scale has on the whole a steric nature, its successful use in correlations is well founded in principle but it does not have a clear physical and geometric sense. It is not known which of the aspects or what proportions of steric effects it reflects. Certain actual values of the E_S constants need refinement, such as the E_S constants for the

t-BuMe$_2$C and t-Bu(t-BuCH$_2$)MeC substituents.[90] Recent achievements in solvation theory enable consideration of the appreciable contribution of solvation effects to the size of E_S constants. Thus the conclusion of Motoc and Balaban[75] on the need to create a new scale of spatial constants with a clearer physical, geometric or topological meaning is entirely well founded.

The E_S^c and E_S^0 scales, being derived from the E_S scale, have absorbed all of its drawbacks and virtues. In addition they proved to have their own specific defects. It has been made clear[90] that the size of the hyperconjugation coefficient h on both scales depends appreciably on the choice of reaction series and solvent which significantly reduces their universal nature. Pal'm[3] was guided by these same considerations when justifyng the need for the correction of the E_S^c constants. However it has been considered[90] that the E_S^0 scale is not completely free from the indicated drawbacks.

Even in the early studies of Charton doubt was expressed on the expediency of estimating the hyperconjugation components in the E_S^c and E_S^0 scales.[112,113] More recently these doubts became stronger[93] and then grew in confidence.[114] It was shown that all the results previously explainable by hyperconjugation may be interpreted by drawing on electronic, steric and polarisation effects alone and there is no need to use the E_S^c and E_S^0 scales. Istomin and Baranskii arrived at the same conclusion almost simultaneously.[115]

The ν_X scale being semiempirical has nonetheless acquired the drawbacks of the experimental scales, namely a dependence on the conditions and precision of the experiment. In its calculated portion it is also not completely reliable for large and unsymmetrical substituents.[90] Charton himself acknowledged that the values of ν_X for such groups may have not one but at least two values, a minimum and a maximum.[112] It turned out that neither correlates with the value of log k determined experimentally or with the experimental ν_X constants.

In conclusion it must be noted that in spite of a proposal to give up the use of experimental scales,[116] they still remain a common and useful instrument in correlation analysis and are a good basis for creating, testing and developing a new generation of steric constants.

III. Steric effects in the chemistry of hetero-organic compounds

Historically organic chemistry was the first area where the theory of steric effects was applied. There are examples demonstrating the influence of steric effects on the course of the nucleophilic substitution reaction.[117,118] The majority of the existing methods for the quantitative estimation of steric effects are based on the data of organic chemistry. The literature data on this theme are contained in numerous reviews.[3,10–12] Some of these studies have been referred to by us above so we will not consider them in more detail.

There is also the question of estimating steric effects in hetero-organic chemistry. For a long time it was considered[19,119] that steric effects were insignificant in the chemistry of phosphorus and the majority of other elements in view of the large size of the atoms of these elements. Information on steric effects was vague, sketchy and only at the qualitative level.[120,121]

However the experimental results accumulated up to the present indicate that the role of steric effects in the reactivity of HOC is far more substantial than was supposed previously. It is sufficient to note the opinion which is now established in the literature[17,94] that alkyl substituents in general do not exert any effect other than steric.

Numerous studies have appeared (see for example Refs. 15, 16, 53) in which there is a description of a steric effect at the qualitative level in the chemistry of boron, silicon, phosphorus and other elements.

It is recorded[4] that steric effects play a more varied role in HOC chemistry than in carbon chemistry. Spatial effects have an influence in three areas, viz. reactivity, complex-forming ability and conjugation. The majority of the existing steric scales of substituents are applicable only to the first area. Consequently it is probable that the literature data concerning the chemistry of various elements describe mainly the effect of substituents on the acid–base properties of HOC and on their reactivity in reactions of various types. On varying the nature of the reaction centre the problem inevitably arises of the possibility of applying the carbon scales of steric constants. Opinions are divided concerning this. On the one hand it is considered[3] that the carbon experimental scales of the E_S type are inapplicable for describing steric effects in HOC chemistry and the introduction of special scales is required. On the other hand Charton (see Ref. 97 and literature therein), when obtaining scales of ν_X constants for nitrogen, oxygen, sulphur and phosphorus, discovered their linear interrelation and concluded that special calculations were unnecessary and that the carbon steric ν_X constants for substituents may be used to describe the reactivity of any HOC (see Ref. 73 and literature therein). The E_S constants have proved to be applicable in phosphorus chemistry.[20]

Steric Λ_C constants have been calculated for more than 20 atoms[122] and an empirical link has been discovered between the scales obtained, which is characterised by discrete parameters unconnected with dimensions or with any characteristics of reaction centres.

On the whole the situation remains unclear and the same variety of scales of steric constants are applied for the estimation of steric effects in HOC chemistry. The main bulk of data relates to the description of steric effects in the chemistry of nitrogen, sulphur, phosphorus and arsenic.

1. Steric effects of substituents at a nitrogen atom

When studying steric effects in nitrogen chemistry two predominant directions of investigation stand out, viz. effects on the basicity of amines and effects on the reactivity of amines, amides and related compounds in various reactions.

The study of the basicity of amines was begun in the forties with the work of Brown and co-workers. The results of these studies have been published in a review,[1] consequently we will not analyse these results, we mention only that they led mainly to the determination of basicity constants and the discovery of the anomalous order of the change in basicity of the methylamines.

$$NH_3 < CH_3NH_2 < (CH_3)_2NH > (CH_3)_3N.$$

It has been recorded (see Ref. 9 and literature therein) that the changes in basicity of various classes of amines in all solvents are governed by the same rules and are linked with structural changes and special features of the molecule. This is caused mainly by the electronic effects of substituents and the effects of the medium, actual steric effects only apply to branched residues.

However there are examples of successful correlations of pK_B with σ^* and E_S constants (see Ref. 9 and literature therein). A scale of steric constants for alkyl substituents has even been developed[123] and differs from the Taft scale.

According to a contemporary concept[124] the mechanism of the steric influence on the basicity of amines is included in the steric hindrance of solvation. However for a complete solution of the problem of steric influence (including anomalous changes in basicity) it is necessary to think of the change in the configuration of the atomic orbitals of nitrogen, and in the state of the unshared electron pair responsible for basicity, being connected with the change in nature and number of alkyl groups and the symmetry of the alkylamine.[9]

The influence of the structure of amines on their reactivity was even recorded by Menshutkin[125] but attempts to assess steric effects quantitatively were undertaken relatively recently. Carbon scales were also used and new scales of steric constants have been introduced.

However the latter are, as a rule, only modifications or extensions of scales known already. Examples are the constants of Charton $\nu_X(NR^1R^2)$ which correlate well with various experimental data.[126]

A new standard reaction series has been proposed[127] for determining the steric influence in iodo-lactonisation of (*R*)-*N*-allyl-aminoacetic acids but no new scale was built up based on this series.

The best known is the scale of E_N constants,[86] which were obtained using the isostericity principle and are the constants of the corresponding carbon analogue. The E_N constants are applied widely to describe the various reactions of amines with alkyl halides,[128–132] such as the Menshutkin reaction,[133,134] and also nucleophilic addition reactions[135–140] and in the study of catalytic activity.[141]

At the same time the equation generally used

$$\lg k = \lg k_0 + \rho\Sigma\sigma^* + \delta\Sigma E_N,$$

does not enable the reactivity of all amines to be described. The deviations observed are taken[142] to be explained by two reasons, viz. by the imperfections of the principle of isostericity and by the presence of specific non-steric interactions of certain substituents with the reaction centre (by the formation of an intramolecular hydrogen bond for example).

It has been proposed[142] that a third and most important reason may be an incorrect allowance for electronic effects. In view of the combined opinion[87,103] on equating the inductive effects of all alkyl groups to that of a methyl group it was proposed[142] to take only the steric effect into consideration. In this case

$$\lg k = \lg k_0 + \delta E_S' + \rho_H^* n_H \sigma_H^*,$$

where n_H is the number of hydrogen atoms on the nitrogen, $\sigma_H^* = 0.49$ the inductive constant for the H atom, ρ_H^* is a coefficient showing the sensitivity of the reaction centre to substitution of a hydrogen by an alkyl group, E_S' is the modified MacPhee scale,[90] differing from the E_S scale by the larger range of substituents and better self-consistency.

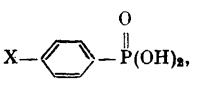
The classical E_S constants have been used for calculations of steric effects in some correlations[143–146] and the E_S^0 constants in a further study.[147]

2. Steric effects in the chemistry of organosilicon compounds

The influence of steric effects of substituents on the reactivity of the most varied organosilicon compounds at the qualitative level has been discussed very widely in the literature. One of the first investigators who attempted a quantitative description of steric effects was Sommer[148] when recording the combined influence of steric and electronic effects in solvolysis and chlorination reactions in compounds containing the R_3Si fragment. The E_S constants for the alkyl substituents on the silicon atom were calculated on the basis of literature and the authors' own kinetic data. Sizes of the deviation from the dependence of log k on σ^* for various reactions taken from the E_S constants were not mutually consistent and had no particular practical importance.

The conclusion has been drawn (see Ref. 149 and literature therein) on the basis of a comprehensive analysis of literature data that the manifestation of steric effects of substituents was important in many reactions of compounds of the R_3SiX and even R_2SiX_2 types (R is an organic substituent and X a functional group). In all cases steric effects were suitable for describing compounds with three alkyl substituents on silicon. Occasionally such an approach is also applied for substituents having iso-structures. In certain reaction series the reaction kinetics were interpreted successfully only using the steric constants E_S^c and E_S^0, for example in the hydrolysis of R_3SiH, the methanolysis of siloxanes, the ozonolysis of silanes and in the hydrosilylation reactions of 1-hexyne.

It has been emphasised[149] that the absence of a direct correlation of reactivity with steric constants does not imply that the steric effect makes an unimportant contribution since in these cases, as a rule, substituents are used which differ little in their steric characteristics.



The use of scales based on the degree of branching of substituents[150] and the E_S(Si) steric scale of Cartiedge[88] must also be noted. A series of acid hydrolyses was used as the model.

$$R_3SiOR + H_2O \xrightarrow[-ROH]{EtOH,\ HCl,\ 25^\circ C} R_3SiOH.$$

The E_S(Si) constants obtained correlated best of all with the Charton ν_X constants and possessed the property of additivity. However these scales are not used widely and in several cases (see Ref. 151 for example) correlation with E_S constants was significantly better than with E_S(Si).

3. Steric effects in the chemistry of organophosphorus compounds

Study of the quantitative interrelation between the structure of organophosphorus compounds (OPC) and their reactivity began around 1953. The first studies[152–154] showed that the Hammett equation was applicable to the ionisation of phosphonic acids of the form

where X is the substituent being varied. The Hammett constants and the Taft σ^* constants were used to characterise the influence of the substituent X. With the purpose of building up a scale of similar constants for radicals joined to phosphorus (σ^P), Kabachnik[119] subjected the literature data on the pK_a values of the phosphorus acids $RPO(OH)_2$, $R^1R^2P(S)OH$, $R^1R^2PO_2H$ to quantitative treatment using the Hammett equation in the form

$$pK_a = pK_a' - \rho\Sigma\sigma^P.$$

It must be noted that in all cases only the electronic effects of substituents were taken into account. It was proposed[19,119] that steric effects were insignificant in view of the large size of the phosphorus (or other element) atom.

This opinion has been held for a fairly long time.[120,121] However with the subsequent accumulation of new experimental data the σ^P scale has been subjected to careful analysis and its relation to steric effects has been reconsidered.

It has been shown[115] that the σ^P constants of alkyl groups and electronegative substituents having no α,β multiple bonds or unshared electron pairs on the α atom are combined values and contain inductive and steric components. The inductive and steric components are described adequately by the scales accepted in correlation analysis for the corresponding types of interactions using the σ^* and E_S scales, i.e. the phosphorus atom does not require any special scales.

Consideration of the standard reaction series used as a basis of the σ^P scale also showed[156] that the experimental values are described adequately by a single correlation equation using the σ^* and E_S scales. It was noted that the principal difficulty when considering such broad sets of data obtained by different authors was the lack of self-consistency.[157]

In a review[20] of the results of a correlation analysis of organic derivatives of pentavalent four-coordinate phosphorus it was shown that the σ^P constants widely used in the chemistry of OPC are complex and include contributions from the inductive, steric and resonance interactions of substituents with the reaction centre. The σ^P scale is applicable to those cases when the proportions of the various contributions to the overall effect of a substituent and the structure of the reaction centre in the series of compounds being studied are the same as or close to the values on which these constants are based in the standard reaction series. In other cases a different approach must be sought.

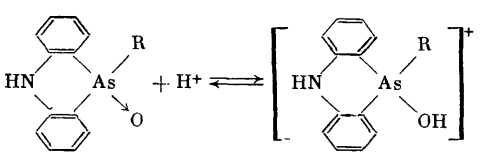
The $\nu_X(P)$ scale of Charton obtained for substituents at a phosphorus atom may serve as one of such approaches to the assessment of spatial effects.[97] The successful use of the carbon ν_X scale in OPC chemistry is also possible. There are also data on the successful application of E_S constants in correlations with pK_b values of alkyldiphenylphosphines.[158]

Relying on data of recent years[101,159] regarding the electrical neutrality of alkyl groups an approach has been suggested[17,21] involving the separation of the σ^P constants into inductive (σ_i^P), resonance (σ_r^Φ) and steric (σ_s^Φ) components. The σ_s^Φ scale was then used successfully to correlate the chemical and biological activity of OPC[160–164] and evidently the approach must be acknowledged to be totally fruitful.

At the same time when separating the σ^P constant into its primary components the authors[17] used certain assumptions which from our point of view were not completely argued through. For example the E_s^0 constants of alkoxyl groups were estimated on the basis of isostericity (from the E_s^0 constants of the isosteric alkyls) and these values were then included in the overall correlation with alkyl substituents virtually giving the isosteric constant the significance of the true constants. In a way this may be one of the reasons for the low quality of the correlation (r = 0.92) in the overall reaction series including alkyl and alkoxyl residues.[17]

Various approaches and combinations of scales are used when describing the influence of steric effects on the reactivity of OPC. The carbon scales are frequently used which is quite understandable because of the discovered similarity of the influence of substituents on the reactivity of compounds of phosphorus and carbon[165] and of phosphorus and silicon.[166]

The stability of complexes of $(RO)_3P$ with R_FI, as has been shown,[167] correlates poorly with the value of σ^P, particularly for branched substituents, the reason for which[167] is the lack of consideration of steric effects. A satisfactory correlation was achieved with the joint use of E_s and $\Sigma(\sigma_i^P + \sigma_r^P)$ constants. At the same time the acid–base properties of R_3PO with alkyl and alkoxyl substituents correlate quite successfully with the σ^P constants.[168] Consequently the σ^P scale works well in some cases[169,170] but must be replaced by different scales in others.[171]



Occasionally it has been proposed in discussion to discard the apparatus of correlation in general and to replace it by methods of linear algebra.[172] However it is doubtful whether this suggestion meets with wide response.

In general the variety of quantitative approaches and the unpredictability of the importance of one or other parameter in the various correlations is extremely inconvenient in practice. A search is needed for a universal scale enabling description as far as possible of all cases of steric interactions in OPC chemistry.

As will be shown below the use of the calculated R_s scale, proposed on the basis of a model of the frontal steric effect,[71] gives good results when describing the very varied reaction series involving OPC.

4. Steric effects in the chemistry of organoarsenic compounds

Steric effects have not been considered in the few quantitative studies of the properties (mainly acid–base) or organoarsenic compounds up to the present time. The available data on the acidity of certain alkyl- and arylphosphonic acids and on arsinic acids in water[173] and in DMF[174] and data on the basicity of tertiary arsine oxides[175] correlated either with the σ^* constants or with σ^P constants. Correlation was better with the Taft inductive constants (σ^*). Analysis of the basicity of 10-alkyl-5,10-dihydrophenarsazines showed a very unusual dependence of pK_b on the σ^* constants.[176]

The values of pK_b for the alkyl-containing compounds in the series R = CH_3, C_2H_5, iso-C_3H_7, t-C_4H_9, $CH_2{=}CH{-}CH_2$, Ph, Ph–C≡C, OH lie on a separate straight line with a positive ρ coefficient although when the inductive influence predominates the value of ρ must be negative. A link was also detected between pK_b and parameters characterising the branching of a substituent. It was concluded[176] that another effect, which requires clarification, exerts an influence.

In our opinion, allowing for all the above-mentioned it may be deduced that the effect in question has a steric nature, although confirmation of this must finally be obtained experimentally. Regrettably there are still very few investigations of that type.

A Japanese study[158] is devoted to the examination of the nucleophilicity of a wide range of alkyldiphenylphosphines and -arsines (reaction with methyl iodide for example). A linear correlation was established between the nucleophility of phosphines and arsines expressed by the equation

$$\lg k_{As} = 0.49 \lg k_P - 3.14.$$

Phosphines are three orders of magnitude more nucleophilic than arsines. The nucleophilicity of both types of compound is described by a two-parameter Taft equation using σ^* and E_S constants.

Similar compounds of arsenic were investigated previously by Soviet authors.[177,178] It was shown that the nucleophilicity of arsines correlates with σ^* constants but does not correlate with σ^P, which the authors link with the possible manifestation of steric effects.

5. Steric effects in the chemistry of organosulphur compounds

The influence of steric effects on the reactivity of sulphur compounds was considered by Charton[97] who showed that the AlkS group possessed a constant electronic effect. The ν_x(SR) parameter for SR substituents was determined using the hydrolysis of alkylthioacetates in 40% aqueous dioxan as the reaction series. The ν_X parameters obtained were used in the analysis of 24 sets of acidic and alkaline hydrolysis. This enabled the conclusion that the effect of alkyl groups joined to sulphur was fairly large and had a predominantly steric nature.

The constants obtained have been used by other authors, for example in the investigation of the catalytic activity of thiols.[179]

The E_S scale is also widely applied in addition to the ν_X parameters. Processes successfully described with it are the oxidation of alkyl aryl sulphides,[180] the electron donating properties of sulphides,[181] the chemoselectivity of alkanesulphonates[182] and the catalytic sulphonylation of phenol with a sterically hindered sulphonyl chloride.[183]

$$RC_6H_4SO_2Cl + HOC_6H_5 \xrightarrow[-HCl]{(C_2H_5)_3N,\ C_6H_6,\ 40^\circ C} RC_6H_4SO_2OC_6H_5,$$

$$R = 2\text{-}CH_3,\ 2\text{-}C_2H_5,\ 4\text{-t-}C_4H_9,\ 2,4,6\text{-}(C_2H_5)_3,\ 2,4,6\text{-(iso-}C_3H_7)_3.$$

In the latter case, in fact, the E_S^0 constants were used.

Regrettably the limited amount of experimental data enabled a conclusion to be drawn only on the appreciable influence of steric effects in the chemistry of organic sulphur compounds but did not enable a comparative analysis to be carried out with compounds of other elements.

6. Steric effects in the chemistry of organometallic compounds

Literally a single study is devoted to steric effects in the chemistry of organometallic compounds (the chemistry of complex compounds is not considered here). Pal'm[3] has drawn attention to the reaction of alkylmagnesium bromide with pinacolin.[184]

$$RMgBr + CH_3\overset{\overset{O}{\|}}{C}C_4H_9\text{-t} \xrightarrow{\text{ether}} \begin{matrix} & CH_3 & & OMgBr \\ & \diagdown & \diagup & \\ & & C & \\ & \diagup & \diagdown & \\ & R & & C_4H_9\text{-t} \end{matrix},$$

which, in his opinion, might be used for obtaining a new scale of 'pure' steric constants. However this was not sustained.[184,185] Of the three parallel processes, viz. reduction, addition and enolisation, taking place in the reaction of pinacolin with RMgBr only the last two are linked with steric effects. The addition reaction is linked predominantly only with the steric effects of alkyl substituents and correlates with the E_S^0 constants. The rate of the uncatalysed reaction of $R_3SnOCOC_2H_5$ with phenyl glycidyl ether[186] and the rate of electroreduction of titanium and zirconium bis-(cyclopentadienyl) chlorides[187] are linked linearly with the same constants.

IV. A model of the frontal steric effect and its application to the analysis of the reactivity of organic and hetero-organic compounds

The numerous approaches to the assessment of the steric effect to describe the reactivity of organic and hetero-organic compounds indicates the need to search for a universal scale of steric constants ready for use in any region of organic and hetero-organic chemistry. Such a scale must probably be based on calculated structural methods such as the experimental scales linked to actual conditions and to the precision of an experiment. It must also consider the conformational state of a substituent. It is necessary, when changing the conformation of a substituent, to obtain refined values of the steric constants fairly simply. Finally, the universal nature of this scale must be subject to broad experimental verification. It is necessary that such a scale should describe, as far as possible, the maximum amount of experimental data correlated by other scales, while retaining a high degree of correlation.

We have attempted to create such a scale and verify it in a large number of different reaction series, including hetero-organic compounds.

1. A model of frontal steric effects and the R_S scale

A model of frontal steric effects and its mathematics have been presented in a fairly detailed manner[71,188] consequently a short description only will be given here. The basis of the model is the concept of the frontal character of the steric effect, i.e. simple mechanical shielding of the reaction centre by a substituent (Fig. 1). This model enables the steric effect of any substituent at any reaction centre to be described, proceeding only from its structure and conformation. Parameters describing the structure of a molecule, i.e. bond lengths and valence angles, are used as the initial data.

It is easy to show, within the framework of kinetic collision theory and a simple mathematical procedure, that the steric effect of a substituent is proportional to the area which it occupies on the sphere separating it from a reaction centre. The final expression for the reaction rate constant of a compound with a particular substituent has the following form:

$$k_R = \left(1 - \sum_{i=1}^{n} r_i^2/4R_i^2\right) Z \exp(-E/RT),$$

where r_i is the radius of each actual atom in a multiatomic substituent, R_i is the distance of this atom from the reaction centre, Z is the frequency of twin collisions and E the activation energy.

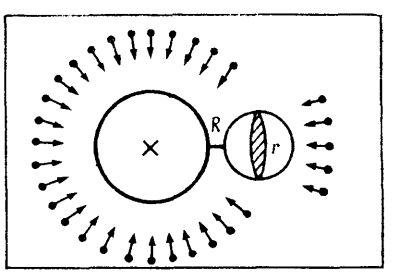


Figure 1. Attack at a substituted reaction centre.

The correctness of the model proposed was verified[71] by comparing values of the steric effect for substituents (first for alkyl and then others), calculated theoretically on its basis, with the existing steric scales E_S, E_S^0 and ν_X, which are based on hundreds of reaction series with steric control. An excellent correlation ($r \approx 0.99$) was obtained in every case covering the whole possible range of variation of steric effects (from +1.24 to −4.0 on the E_S scale), which indicates that proposed model describes steric effects in an adequately correct manner. In order to solve problems insoluble or soluble with difficulty within the framework of the existing experimental scales, a purely calculated steric R_S scale has been proposed which, for the reasons detailed,[71] has been introduced as

$$R_S = 30 \lg \left(1 - \sum_{i=1}^{n} r_i^2/4R_i^2\right).$$

This scale correlates well with the empirical scales and describes adequately the steric effect of the most varied substituents. For example the majority of halogen, hydroxy, alkylthio and alkoxy substituents are described satisfactorily by the relationship of R_S and E_S which applies to alkyl substituents.[71]

$$R_S = (-1.702 \pm 0.032) + (0.730 \pm 0.022) E_S, \quad n=35, \quad r=0.9854, \quad S_0=0.141. \qquad (3)$$

At the same time it must be emphasised that a strict physical interpretation cannot be conferred on such a limitingly simplified steric model.[71,188] In spite of the fact that the better quality of correlation as in (3) would justify assumptions to be made, the steric effects of a substituent undoubtedly cannot lead only to screening of a reaction centre, ignoring completely the energy contributions of other types of steric interactions. The screening effect must be considered as only one component of the steric effect which for some reason (possibly simply formal) is linked linearly with the total effect.

The proposed model is therefore more formal rather than physical. At the same time it represents a fairly successful means for the correct calculation of the steric effects of various substituents and may be extremely useful in solving the most varied problems. This will be illustrated below with some examples.

2. The principle of isostericity

The standard reaction series forming the basis of the empirical scales impose some serious limitations on the possibility of determining the steric constants of substituents. In the E_S scale, and the E_S^c and E_S^0 scales derived from it, the standard reaction series, viz. the hydrolysis of esters, does not permit determination of the steric constants of hetero-atomic substituents such as OR, SR, NR_2, etc.

In practice the isostericity principle is used in these cases, which means that the steric effect of any heteroatomic substituent is equated to the effect of the corresponding (isosteric) alkyl substituent.[3]

Since the model considered above enables direct calculation of the steric effect of any hetero-atomic substituent there is the possibility of verifying to what extent the indicated principle remains within this framework and what are the limits of its applicability. This was carried out[71] using as example a set of alkoxyl and thioalkyl substituents by comparing the R_S constants calculated for them with those for the isosteric hydrocarbon analogues.

It turned out that in each series excellent linear relationships were satisfied.

$$R_S(\mathrm{OR}) = (0.812 \pm 0.115) + (1.256 \pm 0.053) R_S(\mathrm{CH_2R}), \quad n=8, \quad r=0.9954, \quad S_0=0.058;$$

$$R_S(\mathrm{SR}) = (-0.459 \pm 0.039) + (0.976 \pm 0.018) R_S(\mathrm{CH_2R}), \quad n=8, \quad r=0.9991, \quad S_0=0.019.$$

It follows from the correlation equations obtained that the steric constants for OR and SR substituents are linearly related to the constants of the CH_2R group but are not equal to them. Hence it is evident that the isostericity principle must work well in sets of substituents of the same type (for example, only OR or only SR) but will not be effective in mixed sets.

Within the framework of the present model the application of the isostericity principle has a mathematical foundation but at the same time its limitations are clearly evident. However since it is possible to calculate directly the R_S constants for any heteroatomic substituent, the principle of isostericity in general loses its value in this scale.

3. The steric effect of substituents at non-carbon atoms

As was indicated above more data have appeared in the literature recently which indicate the appreciable contribution of steric effects in the reactivity of many hetero-organic compounds. In some studies the presence of a linear relationship between the steric effect of substituents at a heteroatom and at carbon has been suggested.

The R_S constants for 25 substituents at phosphorus, sulphur, arsenic and antimony have been compared with the constants for the same substituents as carbon with the aim of clarifying the sensitivity of various atoms to steric effects and detecting the presence or absence of linear relationships between the steric effects of substituents at these atoms and of the same substituents at a carbon atom.[189] This series has been extended more recently to 43 substituents at 20 elements (from hydrogen to lead).

It has been established[189] that the steric effect of a substituent is reduced uniformly with an increase in the size of the central atom. At the same time there was a strict linear relationship ($r > 0.99$) between the steric effects of substituents at each heteroatom studied and the steric effects of the substituents at a carbon atom.

$$R_S(\mathrm{E}) = A_0 + A_1 R_S(\mathrm{C}),$$

where $R_S(\mathrm{E})$ are the steric constants for substituents at any element and $R_S(\mathrm{C})$ are the steric constants for the same substituents at a carbon atom.

The results obtained are completely in agreement with the literature data mentioned above according to which the steric effects of substituents at various heteroatoms (particularly at atoms of phosphorus, sulphur, oxygen, nitrogen and silicon) are described well by correlation equations using the constants for carbon.

The linear dependence established between the steric effects of substituents at various atoms and at a carbon atom removes the problem of determining the steric constants for substituents for each individual element since it is possible, when analysing the reactivity of hetero-organic compounds, to use the steric constants for substituents at a carbon atom with equal success.

4. Steric effects and the conformation of a substituent

It is evident that the steric effect of any substituent within the framework of the model being considered is linked directly and in an extremely effective manner with its conformation. In particular the parameter R_i in the expression $\sum_{i=1}^{n} r_i^2/4R_i^2$, which corresponds to the distance from each of the atoms contained in the substituent to the reaction centre, is sensitive to conformation. On the one hand this points in favour of the adequacy of the model since the dependence of steric effects on conformation actually occurs.[2,73,104–106] On the other hand such a conformational sensitivity may seem to be an undesirable factor because the conformation may not be known precisely for each substituent. For the majority of substituents the problem of conformational uncertainty is either completely absent or one of several possible conformations is known to be obviously in existence. In such a case it is possible to go over to the reverse procedure, i.e. to determine which conformation exists in those substituents in which the proportion of conformational uncertainty is large. For this it is sufficient to compare the theoretical values of R_S for each of the possible conformations (as a rule there are no more than two) with the experimental parameter log k and to select that which is best described in coordinates of log k and R_S for the general series (a reaction series composed of conformationally unequivocal substituents).

An actual example of such an unusual conformational analysis has been described[71] for the substituents CH_2OCH_3 and CH_2SCH_3. Two of the possible types of orientation of these substituents relative to the reaction centre were examined, viz. the transoid and the conformation with free rotation about the CH_2-E bond. Comparison of the theoretically calculated values of R_S for each orientation with the values calculated according to the correlation Eqn. (3) from the experimental values of E_S showed that the methylthiomethyl substituent has a clearly expressed transoid orientation while it is impossible to exclude free rotation or the existence of a *gauche* form for the methoxymethyl substituent.

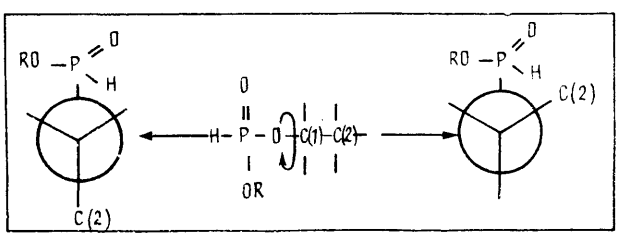

Figure 2. Conformations of alkoxy substituents in the Pudovik and Abramov reactions.

The dynamic stereochemistry of dialkyl phosphorus acids and their anions have been investigated in an analogous manner in the Pudovik and Abramov reactions.[190,191] It was shown that the reactivity and acid properties of the free dialkyl phosphites were well described by a choice of R_S constant corresponding to the least sterically hindered *trans* orientation of the P–O and C(1)–C(2) bonds in both alkoxyl groups on the phosphorus atom. At the same time the best correlation for the dialkyl phosphite anion was observed on proposing a *gauche* orientation for the P–O and C(1)–C(2) bonds in one of the alkoxyl substituents (Fig. 2). It is possible to explain such an orientation for the substituent by the electrostatic interaction of the anion and the alkyl group polarised by it.

Conformational sensitivity is therefore not a drawback of the proposed model but on the contrary makes it more flexible and more useful in a practical sense.

Table 1. Some types of reaction series described using R_S steric constants.

Series number	Type of reaction series	Q	N_{av}	R_{av}	Refs.
1	Existing scales of steric constants E_s, E_s^0, v_x	3	35	>0.98	[71]
2	Reactions of organic compounds of nitrogen	19	6	~0.99	[192]
3	Reactions of organic compounds of oxygen	8	5	~0.96	[192]
4	Reactions of organosilicon compounds	5	7	~0.98	[192]
5	Reactions of organophosphorus compounds	22	5	~0.99	[192]
6	Reactions of organic compounds of sulphur	4	5	~0.98	[192]
7	Reactions of organic compounds of arsenic	4	4	~0.98	[192]
8	Reactions of organomagnesium compounds	1	5	0.958	[192]
9	Dissociation of phosphoric, phosphonic and phosphinic acids in water and in aqueous alcoholic media	9	9	>0.99	[193]
10	Dissociation of dialkyl phosphites in absolute isopropanol	1	5	0.966	[190]
11	Addition of dialkyl phosphites to an unsaturated compound (Pudovik and Abramov reactions)	10	8	>0.98	[190, 191, 194, 195]
12	Complex formation of nickel and cobalt ions with cyclic and acyclic dithio acids of phosphorus	8	7	~0.97	[196]
13	Reactions of cyclic and acyclic isocyanatophosphites with diphenylcarbodiimide	2	4	>0.99	[197, 198]
14	1,3-Dipolar cycloaddition reactions to a phosphorylated allene and an acetylene	2	6	>0.98	[199]
15	Reaction of dithio acids of phosphorus with cumene hydroperoxide	4	66	>0.97	[200]
16	Williamson reaction in the chloromethylphosphine oxide series	2	24	~0.99	[201]
17	Reaction of gelatine with aldehydes	1	6	0.989	[202]
18	*cis-trans*-Isomerism of ethylenes	2	6	>0.97	[188]

Footnote. Symbols used: Q is the number of reaction series, N_{av} the average number of points in the correlation and R_{av} the mean correlation coefficient.

5. Analysis of the reactivity of organic and hetero-organic compounds

Since the proposed model enables steric effects to be calculated fairly simply for any substituent at any reaction centre it is natural that the largest area for its application is the analysis of steric interactions in the reaction series varying most widely and firstly

where the steric effects of substituents are not expressed adequately by the existing scales. This applies primarily to hetero-organic compounds although recently more data have appeared on purely organic reaction series containing complex branched or heteroatomic substituents, the steric effect of which may not be described in the empirical scales. In this case the theoretical calculation of the steric effect remains the only possibility for an effective analysis and prediction of reactivity.

Attempts to apply the proposed approach indicate its high effectiveness in describing the most varied reaction series both under purely steric control and with a mixed influence of electronic and steric factors within the framework of a multiparameter regression analysis.

Certain types of organic and hetero-organic reaction series which are described successfully using R_S constants are shown in Table 1.

The first 8 types of reaction series in Table 1 are literature data which have been processed previously using other steric scales. Comparative analysis of the quality of the correlations shows that the R_S scale describes the given reaction series in every case no worse than the various scales [E_S, E_S^0, ν_X, $\nu_X(NR^1R^2)$, $\nu_X(P)$, $\nu_X(SR)$, $E_S(Si)$, etc.] which were used in the original correlations. Experimental investigation of the remaining reaction series (series 9–18) were carried out by us either independently or in collaboration which is reflected in the corresponding literature references. It follows from Table 1 that the R_S scale gives good results when describing the reactivity of the most varied HOC in different types of reaction, from acid–base properties to processes of complex formation. In this way regularities often became apparent which could not be detected within the framework of the existing experimental scales. For example, on repeating the experimental study of the dissociation of various types of phosphorus acids (phosphoric, phosphonic and phosphinic)[193] not only were the pK_α values of certain acids successfully refined but it was also discovered that there were distinct relationships between pK_a and R_S for these types of acid, i.e. a given reaction series selected as a standard in HOC chemistry was not a single reaction series. This conclusion was also confirmed by studying the Brønsted relationships.

The approach proposed therefore turned out to be extremely effective in the analysis of the most varied chemical processes and also in solving theoretical problems connected with steric effects. Although simple it provides a fairly correct description of the steric interactions developing to a certain extent and of their nature. Using simple and available mathematics it enables calculation of the steric effects of any substituent at any reaction centre, starting from its structure and conformation, and may be useful in understanding and predicting interrelationships between the structure and reactivity of organic and hetero-organic compounds.

Progress in the chemistry of perhalomethanesulphenyl halides

I V Koval'
F E Dzerzhinskii Dnepropetrovsk Institute of Chemical Engineering

ABSTRACT. Results of investigations on perhalomethanesulphenyl halides are systematised and correlated in the review. Methods of obtaining perhalomethanesulphenyl halides are reviewed and their nucleophilic, electrophilic and radical substitution, addition, oxidation and reduction reactions are discussed.

The bibliography contains 232 references.

I. Introduction

The chemistry of perhalomethanesulphenyl halides began with the synthesis of trichloromethanesulphenyl chloride by Rathke.[1,2] However this region of hetero-organic chemistry had its most rapid development at the beginning of the sixties of the present century after the discovery by Kittleson[3] of the fungicidal properties of *N*-trichloromethanesulphenyl phthalimide and *N*-trichloromethanesulphenyl 1,2,5,6-tetrahydrophthalimide, which have been widely used as standard fungicidal preparations under the commercial names Ftalan and Captan. Trichloromethanesulphenyl chloride is at present the most widely studied perhalomethanesulphenyl halide. Convenient preparative methods (both laboratory and industrial) have been developed for obtaining it, its properties have been studied in detail and areas have been found for its application in practice. The structure of the trichloromethanesulphenyl chloride molecule has been investigated in the gas phase by electron diffraction,[4] from which it was established that the chlorine atom Cl(1) on the sulphur atom and one of the chlorine atoms of the trichloromethanesulphenyl group Cl(4) are in *trans*-disposition. The latter chlorine atom and the sulphur atom are drawn together somewhat because of the deviation of the C–S bond from the three-fold axis of the trichloromethyl residue as a result of which the SCCl(4) bond angle is 102° 5′. Such a peculiarity in the structure of the trichloromethanesulphenyl chloride molecule sets a stamp on its chemical properties. Thus the nonequivalence of one of the chlorine atoms in the trichloromethyl group [as a result of the deviation of the SCCl(4) angle from 109°] is displayed in the increased reactivity of Cl(1) and Cl(4) in free radical processes. The deformation of the SCCl(4) angle also facilitates intramolecular nucleophilic attack of Cl(1) on the carbon atom and makes the generation of dichlorocarbene possible. The other perhalomethanesulphenyl halides known at present have been investigated less and require further study. The interest displayed in the chemistry of perhalomethanesulphenyl halides by many investigators is explained primarily by the synthetic value of these compounds The high lability of the sulphur–halogen bond, its tendency towards heterolytic and homolytic fission, and also two reaction centres (sulphur and carbon) impart the properties of valuable synthons to the perhalomethanesulphenyl halides. On the other hand certain representatives of this class of compound, trichloromethanesulphenyl chloride and dichlorofluoromethanesulphenyl chloride in particular, are widely used in the manufacture of biologically active preparations which are of interest.

Several reviews[3,5–11] partially cover the chemistry of perhalomethylsulphenyl halides up to 1970, however, regretably there are no exhaustive studies. In our view the proferred review may compensate for this omission to some extent. The literature is covered up to 1990.

II. Methods of synthesis of perhalomethanesulphenyl halides

1. Perchloromethanesulphenyl halides

a) Trichloromethanesulphenyl chloride

Trichloromethanesulphenyl chloride was obtained for the first time in 1870 by the chlorination of carbon disulphide with chlorine in the presence of iodine as catalyst.[1,2] For a long time this reaction was the subject of investigation by many scientists with the aim of optimising the process of obtaining trichloromethanesulphenyl chloride both in the laboratory and in industry. This is linked primarily with the fact that in the chlorination of carbon disulphide with chlorine other products are formed in addition to trichloromethanesulphenyl chloride, particularly sulphur mono- and dichlorides and carbon tetrachloride. The probability of forming any particular product is due to a series of factors, mainly by the ratio of reactants, the chlorination conditions and the nature of the solvent. Depending on the ratio of reactants sulphur mono- and dichlorides are formed in addition to trichloromethanesulphenyl chloride in the chlorination of carbon disulphide, as illustrated by the following reactions.

$$2CS_2+5Cl_2\longrightarrow 2CCl_3SCl+S_2Cl_2,$$

$$CS_2+3Cl_2\rightarrow CCl_3SCl+SCl_2.$$

Sulphur mono- and dichloride are formed in the reaction of chlorine with carbon disulphide, the dichloride practically always predominating.[3] The formation of trichloromethanesulphenyl chloride by the reaction of chlorine with carbon disulphide at a ratio

of 2:5 occurs by the following conversions in the opinion of certain authors.[12]

$$2CS_2+2Cl_2\longrightarrow 2ClC(S)SCl,$$
$$2ClC(S)SCl+Cl_2\longrightarrow 2Cl_2C{=}S+S_2Cl_2,$$
$$2Cl_2C{=}S+2Cl_2\longrightarrow 2CCl_3SCl.$$

Although such a mechanism for the chlorination of carbon disulphide is confirmed to a certain extent by the formation of trichloromethanesulphenyl chloride in the reaction of thiophosgene with chlorine,[12,13] it has nevertheless been questioned.[14] These authors[14] considered that the addition of chlorine occurs at the two C=S bonds of carbon disulphide simultaneously with the formation of dichloromethanedisulphenyl chloride, the further chlorination of which leads to the formation of trichloromethanesulphenyl chloride.

$$2CS_2+4Cl_2\longrightarrow 2\left[\begin{array}{c}Cl\\|\\ClS{-}C{-}SCl\\|\\Cl\end{array}\right]\xrightarrow[-S_2Cl_2]{Cl_2}2CCl_3SCl.$$

A change in the ratio of the initial reactants in the direction of increasing the quantity of chlorine leads to a reduction in the yield of trichloromethanesulphenyl chloride and the formation of carbon tetrachloride which arises from the following reaction.[3,15]

$$2CCl_3SCl_2+Cl_2\longrightarrow 2CCl_4+S_2Cl_2.$$

The conversion of trichloromethanesulphenyl chloride into carbon tetrachloride is assisted by sunlight,[3] and also by the presence in the reaction mixture of such metals as iron, tin and copper.[3,5] It is recommended to carry out the chlorination of carbon disulphide with chlorine in the temperature range from 15 to 30 °C.[5] Carrying out this process at higher temperatures assists the formation of carbon tetrachloride, while a reduction in the temperature of the process slows down the rate of chlorination of carbon disulphide. Water,[5] carbon disulphide,[16] organic solvents such as heptane, carbon tetrachloride, etc.[17] are used as reaction medium. In view of the relatively high stability of trichloromethanesulphenyl chloride towards hydrolysis the chlorination of carbon disulphide in an aqueous emulsion is more preferred since the sulphur mono- and disulphides formed in the process are partially decomposed by water to water-soluble products which assists their separation from trichloromethanesulphenyl chloride. Purification of trichloromethanesulphenyl chloride from byproducts is a relatively complex operation. The low-boiling sulphur dichloride and carbon tetrachloride are separated from trichloromethanesulphenyl chloride, which has bp 147 °C, by simple distillation but it is practically impossible to separate sulphur monochloride (bp 136 °C) by simple distillation. Several methods have been developed for purifying trichloromethanesulphenyl chloride from sulphur monochloride. The most widespread are methods comprising steam distillation of trichloromethanesulphenyl chloride[18] and washing trichloromethanesulphenyl chloride with water,[5] or with aqueous solutions of reducing[19] or oxidising[3] agents which convert sulphur monochloride into compounds readily soluble in water. After chlorination the reaction mixture is treated with a fresh portion of carbon disulphide with the aim of converting sulphur mono- and dichlorides to trichloromethanesulphenyl chloride.[3]

$$2S_2Cl_2+CS_2\longrightarrow CCl_3SCl+5S,$$
$$2SCl_2+CS_2\longrightarrow CCl_3SCl+2S.$$

After chlorination, treatment of the reaction mixture with sulphur dioxide has been proposed.[3] This converts sulphur monochloride into thionyl chloride which is readily separable from trichloromethanesulphenyl chloride by simple distillation.

$$S_2Cl_2+SO_2\longrightarrow SOCl_2+S+SO_2.$$

It was reported[3] that the chlorination of carbon disulphide with chlorine in hydrochloric acid leads to the formation of practically pure trichloromethanesulphenyl chloride since sulphur mono- and dichlorides are readily hydrolysed in hydrochloric acid.

$$CS_2+5Cl_2+4H_2O\xrightarrow{HCl}CCl_3SCl+H_2SO_4+6HCl.$$

Other means of obtaining trichloromethanesulphenyl chloride are based on the reaction of chlorine with methane-, chloromethane- or dichloromethanesulphenyl chloride,[3] with dimethyl disulphide,[3] with methyl trichloromethyl sulphide,[3] methyl thiocyanate,[5] dimethyl sulphide,[20] chloromethyltrichloromethyl sulphide,[20] and carbon selenosulphide.[21] However these methods are not widely used due to the low availability of the starting materials, the low yields of trichloromethanesulphenyl chloride and the complexity of isolating it.

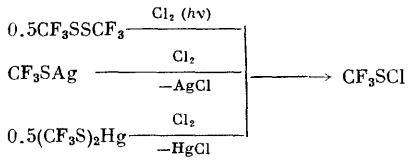
b) Trichloromethanesulphenyl bromide

Trichloromethanesulphenyl bromide is formed in quantitative yield by the reaction of trichloromethanesulphenyl chloride with 48% hydrobromic acid at 23–25 °C.[22–24]

$$CCl_3SCl+HBr\longrightarrow CCl_3SBr+HCl.$$

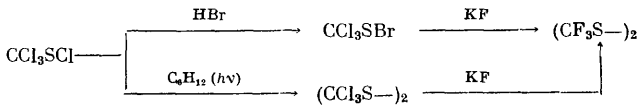
c) Trichloromethanesulphenyl fluoride

The unstable trichloromethanesulphenyl fluoride is formed on heating trichloromethanesulphenyl chloride with activated potassium fluoride and is converted under the reaction conditions into dichlorofluoromethanesulphenyl chloride.[25,26]



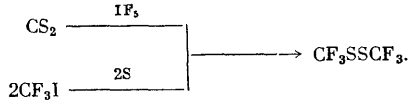
Of the perbromomethanesulphenyl halides only tribromomethanesulphenyl bromide is known and is formed on reaction of dibromochloromethanesulphenyl bromide with 48% hydrobromic acid[22] and by the reaction of bromine with carbon disulphide[8] and carbon selenosulphide.[21]

The formation of the unstable triiodomethanesulphenyl iodide on reaction of carbon disulphide with iodine has been presumed in the literature.[27]



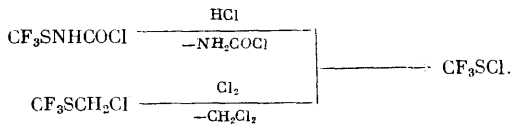
2. Perfluoromethanesulphenyl halides

a) Trifluoromethanesulphenyl chloride



Trifluoromethanesulphenyl chloride is formed in relatively good yield by the reaction of chlorine with hexafluorodimethyldisulphide[8,27] and also with silver[28] and mercury[8,29] trifluoromethylmercaptides.

Replacement of the chlorine atoms by fluorine in trichloromethanesulphenyl chloride by the action on it of sodium fluoride,[30] potassium fluoride[31] or hydrogen fluoride[32] also leads to the formation of trifluoromethanesulphenyl chloride, but in low yield, since fission of the C–S bond occurs with the formation of various products in addition to the chlorine–fluorine exchange. Because of this it is more rational to convert trichloromethanesulphenyl chloride into hexafluorodimethyldisulphide as follows.[23]

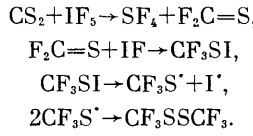


Hexafluorodimethyl disulphide may also be obtained by the fluorination of carbon disulphide or by the reaction of trifluoroiodomethane with sulphur.

Replacement of chlorine by fluorine in chlorodifluoromethanesulphenyl chloride may be effected with antimony trifluoride.[34]

Fission of the S–N bond of trifluoromethanesulphenamides[35] and also of the S–C bond of trifluoromethyl sulphides[36] by reaction with hydrogen chloride and chlorine also leads to the formation of trifluoromethanesulphenyl chloride.

In the latter case the ease of fission of the S–C bond is explained by the structure of the initial sulphide. Consequently there is great interest in the radical perfluorination of thiols[37–39] as a result of which trifluoromethylsulphides themselves of various structure may be obtained.

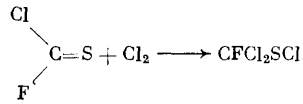


b) Trifluoromethanesulphenyl bromide

Trifluoromethanesulphenyl bromide is obtained in 40% yield by the reaction of bromodifluoromethanesulphenyl bromide with antimony trifluoride in the presence of antimony pentachloride.[34]

c) Trifluoromethanesulphenyl iodide

The unstable trifluoromethanesulphenyl iodide, which readily converts into hexafluorodimethyl disulphide, is formed as an intermediate in the fluorination of carbon disulphide with iodine pentafluoride between 60 and 200 °C.[27]



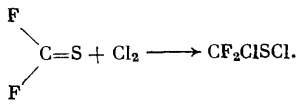
d) Trifluoromethanesulphenyl fluoride

Trifluoromethanesulphenyl fluoride is formed in low yield on exhaustive fluorination of trichloromethanesulphenyl chloride with activated potassium fluoride.[26]

3. Mixed perhalomethanesulphenyl halides

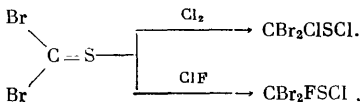
a) Dichlorofluoromethanesulphenyl chloride

Several methods have been developed for obtaining dichlorofluoromethanesulphenyl chloride, however they do not provide a high yield. One of these methods comprises replacement of one of the chlorine atoms in trichloromethanesulphenyl chloride by reaction with potassium fluoride[25,26,31,40] or hydrogen fluoride.[56] Another method is based on the addition of chlorine to the C=S bond of thiocarbonyl chlorofluoride.[24]



More promising from a preparative standpoint is the replacement of one of the chlorine atoms by fluorine in *N*-(diethyl)-trichloromethanesulphenamide with subsequent fission of the S–N bond in the resulting *N*-(diethyl)dichlorofluoromethanesulphenamide by reaction with hydrogen chloride.[41] A maximum yield (37%) of dichlorofluoromethanesulphenyl chloride was observed at a reactant ratio of 1 : 1, a temperature for fluorination of 55 °C and duration 105 min.

b) Chlorodifluoromethanesulphenyl chloride

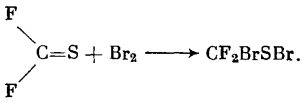


Chlorodifluoromethanesulphenyl chloride is formed in 22% yield on replacing two chlorine atoms by fluorine in *N*-(diethyl)chlorodifluoromethanesulphenamide with subsequent fission of the S–N bond in the resulting *N*-(diethyl)chlorodifluoromethanesulphenamide by reaction with hydrogen chloride.[41] This compound may also be

obtained by the partial fluorination of trichloromethanesulphenyl chloride with potassium fluoride[24] and by the addition of chlorine to the C=S bond of thiocarbonyl difluoride.[8]

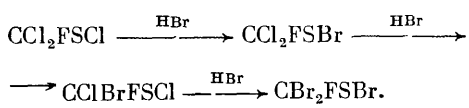
c) Dibromochloromethane- and dibromofluoromethanesulphenyl chlorides

The addition of chlorine or chlorine fluoride to the C=S bond of thiocarbonyl dibromide leads to the formation of dibromochloromethanesulphenyl chloride or dibromofluoromethanesulphenyl chloride in yields of 34 and 18% respectively.[42]



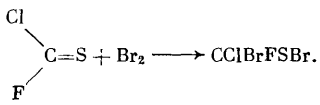
d) Bromodichloromethanesulphenyl bromide

Bromodichloromethanesulphenyl bromide is formed by the reaction of trichloromethanesulphenyl chloride with 48% hydrobromic acid.[3] The formation of this compound has also been mentioned in the reaction of trichloromethanesulphinic acid with thionyl bromide.[43]



e) Bromodifluoromethanesulphenyl bromide

The addition of bromine to the C=S bond of thiocarbonyl difluoride leads to the formation of bromodifluoromethanesulphenyl bromide in relatively good yield.[44]

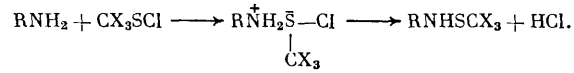


f) Dichlorofluoromethane, dibromofluoromethane- and bromochlorofluoromethanesulphenyl bromides

It has been shown that dichlorofluoromethanesulphenyl chloride is converted by step-wise bromine–chlorine exchange into dichlorofluoromethanesulphenyl bromide, bromochlorofluoromethanesulphenyl bromide and dibromofluoromethanesulphenyl bromide.[24]

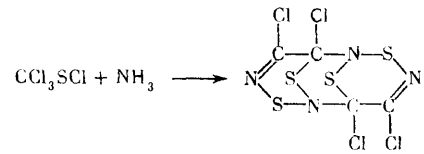
Bromochlorofluoromethanesulphenyl bromide is also formed by the addition of bromine to the C=S bond of thiocarbonyl chlorofluoride.[24,44]

III. Reactions of perhalomethanesulphenyl halides



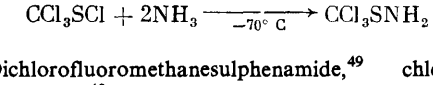
1. Nucleophilic substitution reactions

Perhalomethanesulphenyl halides react vigorously with amines, alcohols, thiols and other nucleophiles with the formation of various perhalomethylthio derivatives. Some of these reactions are fairly unusual compared with the analogous reactions of alkanesulphenyl halides containing no halogen in the alkyl group. In the majority of cases these reactions proceed by an S_N2 mechanism with the formation of a transition state in which the entering and leaving groups are at apices of a trigonal bipyramid.[45]



X = Hal.

The possibility of some reactions occurring by an addition–elimination mechanism is not excluded.[45]

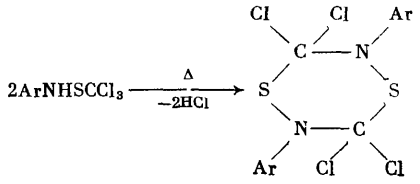


a) Interaction with *N*-nucleophiles

Interaction with ammonia. The vigorous reaction of trichloromethanesulphenyl chloride with ammonia was remarked upon even by Rathke,[1] however the structure of the resulting product was not determined. Significantly more recently the reaction of trichloromethanesulphenyl chloride with ammonia was studied in a heterogeneous medium of benzene and water.[46] The product formed in this reaction was assigned the structure of 3,6-dichloro-1,4-dithia-2,5-diazine, but proved to be more complex.[47] The reaction of trichloromethanesulphenyl chloride with 25% aqueous ammonia solution in a two-phase benzene–water system leads to the formation of 2,3,7,8-tetrachloro-5,10,11,12-tetrathio-1,4,6,9-tetraazatricylo[5,3,11^{2,6}]dodeca-3,8-diene.

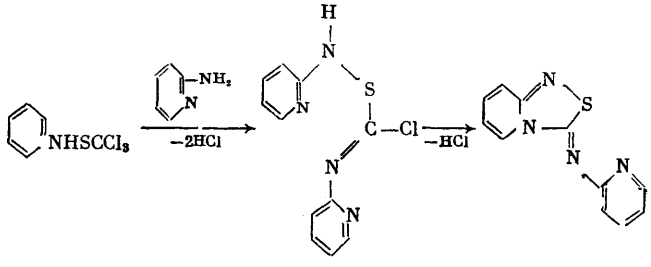
Trichloromethanesulphenamide has been proposed[47] as an intermediate in this reaction and was obtained more recently by the reaction of trichloromethanesulphenyl chloride with liquid ammonia in pentane at –70 °C.[48] This unstable compound, which decomposes at room temperature, is preserved at –80 °C without decomposition for 7 days.

Dichlorofluoromethanesulphenamide,[49] chlorodifluoromethanesulphenamide[49] and trifluoromethanesulphenamide,[50] formed by the reaction of the corresponding sulphenyl chlorides with liquid ammonia at –60 °C in trichlorofluoromethane, proved to be more stable. Further reaction of perhalomethanesulphenamides with one



or two moles of perhalomethanesulphenyl chloride leads to the formation of bis-(perhalomethanesulphen)amides and tris-(perhalomethanesulphen)amides.[49,51–53]

$$RSNH_2 + RSCl \xrightarrow[-HCl]{} (RS)_2NH \xrightarrow[-HCl]{RSCl} (RS)_3N,$$
$$R=CCl_2F,\ CClF_2,\ CF_3.$$



Interaction with amines. The reaction of perhalomethanesulphenyl halides with primary and secondary amines leads to the formation of *N*-substituted amides of perhalomethanesulphenic acids. *N*-Substituted amides have been described for trichloromethanesulphenic,[3,5] trifluoromethanesulphenic,[3,54] dichlorofluoromethanesulphenic,[3,10,55] chlorofluoromethanesulphenic[3,41] and bromochlorofluoromethanesulphenic[3] acids. The formation of *N*-disubstituted trichloromethanesulphenamides has been established in the reaction of trichloromethanesulphenyl chloride with aminals.[56] The instability of *N*-substituted trichloromethanesulphenamides formed by the reaction of trichloromethanesulphenyl chloride with primary amines has been recorded.[10] For example *N*-alkyltrichloromethanesulphenamides are converted into *N*-trialkylguanidines in the presence of alkylamines.

$$AlkNHSCCl_3 + 4AlkNH_2 \xrightarrow[-2AlkNH_2\cdot HCl]{} AlkN{=}C(NHAlk)_2$$

N-Aryltrichloromethanesulphenamides are converted on heating in the presence of alkali into 2,5-diaryl-3,3,6,6-tetrachloro-1,4-dithia-2,5-diazines.[10]

2-(*N*-Trichloromethanesulphenamino)pyridine, formed by the reaction of trichloromethanesulphenyl chloride and 2-aminopyridine, is converted by an excess of the latter into (2-pyridylamino)-3H-1,2,4-thiadiazolo[4,3-α]pyridine.[10,57]

The reaction of perhalomethanesulphenyl halides with tertiary amines proceeds in a more complex manner. For example, the reaction of trichloromethanesulphenyl chloride with triethylamine in benzene at 20 °C leads to the formation of 1,1-bis(trichloromethanesulphenyl)-2-(*N*,*N*-diethylamino)ethylene.[58]

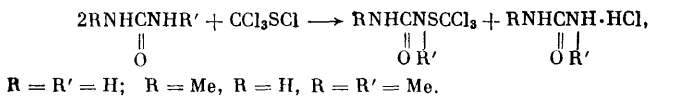
$$2CCl_3SCl + CH_3CH_2N(CH_2CH_3)_2 \xrightarrow[-HCl]{} (CCl_3S)_2C{=}CHN(CH_2CH_3)_2.$$

Interaction with hydrazine derivatives. The reaction of perhalomethanesulphenyl halides with hydrazine derivatives has been studied mainly for trichloromethanesulphenyl chloride. Reactions have been described for trichloromethanesulphenyl chloride with alkylhydrazines,[59–61] arylhydrazines[61] and alkane(arene)sulphohydrazides.[61] Nucleophilic attack at the sulphur atom is, as a rule, effected by the NH_2 group. However, participation of the NH group in such attack has also been recorded. For example the reaction of trichloromethanesulphenyl chloride with benzenesulphonohydrazide in dimethoxyethane leads to the formation of two products, viz. *N*-benzenesulphono-*N'*-trichloromethanesulphenohydrazide and *N*-benzenesulpho-*N*-trichloromethanesulphenohydrazide.[61]

$$PhSO_2NH{-}NH_2 + CCl_3SCl \rightarrow \begin{cases} PhSO_2NH{-}NHSCCl_3 \\ PhSO_2N(SCCl_3){-}NH_2 \end{cases}$$

The trichloromethanesulphenylation of diacylhydrazines has been carried out in aqueous alkaline medium.[61] Replacement of two hydrogen atoms by trichloromethanesulphenyl groups occurs in this way:

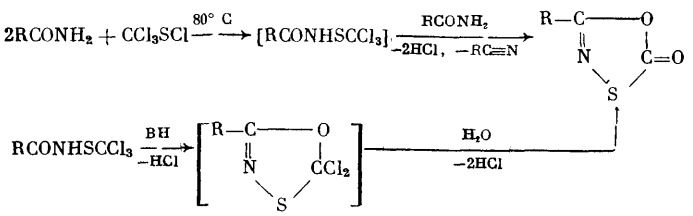
$$RCNH{-}NHCR + 2CCl_3SCl \xrightarrow[-2NaCl]{NaOH} RCON(CCl_3S){-}NCOR(SCCl_3),$$



R = H, Me, Et, Ph.

Interaction with amides and amidines of carboxylic acids. Replacement of a hydrogen atom on the nitrogen atom of a carboxylic acid amide takes place with significantly more difficulty than in the case of amines. The structure of the starting material, the nature of the solvent and the sulphenylation conditions play an appreciable role. The presence of strongly electron-accepting groups in the acyl fragment hinder the sulphenylation process, but the presence in the acyl fragment of other reactive functional groups frequently leads to sulphenylation of the acyl fragment and not the amide group, as has been mentioned.[3,62] Strongly basic polar solvents such as dioxan, dimethoxyethane, dimethylformamide, etc. are used as reaction medium. An excess of the amide or an organic base (pyridine, triethylamine, etc.) is used as acceptor of hydrogen halide. The trichloromethanesulphenylation of certain carboxylic acid *N*-monosubstituted amides is effected via the sodium salt.[3] It was shown[63] that the reaction of trichloromethanesulphenyl chloride with amides of aliphatic carboxylic acids in dimethoxyethane or dioxan at room temperature leads to the formation of *N*-alkanoyltrichloromethanesulphenamides in 5–22% yield.

$$2RCON(R')H + CCl_3SCl \rightarrow RCON(R')SCCl_3 + RCON(R')H\cdot HCl.$$



R = R' = H; R = Me, R' = H; R = Et, R' = H; R = n-Pr, R' = H; R = PhCH = CH_2, R' = H; R = H, R' = Et; R = H, R' = n-Pr; R = R' = Me; R = Me, R' = n-Pr; R = Me, R' = n-Bu.

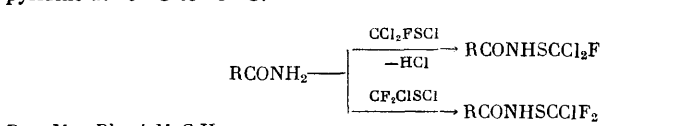
Trichloromethanesulphenyl chloride reacts under analogous conditions with urea and its homologues with the formation of the corresponding *N*-trichloromethanesulphenyl derivatives.[63]

$R = R' = H$; $R = Me$, $R = H$, $R = R' = Me$.

Amides of aromatic carboxylic acids do not react under these conditions but heating the reaction mixture leads to 5-aryl-1,3,4-oxathiazol-2-ones,[64] the formation of which was also observed on reacting *N*-aroyltrichloromethanesulphenamides with bases (NaOH, triethylamine, pyridine, etc.).[65–68]

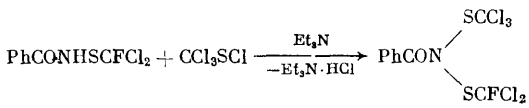
R = Ph; 3-MeC_6H_4; 4-MeC_6H_4; 4-PhC_6H_4; 2-ClC_6H_4; 3-ClC_6H_4; 4-ClC_6H_4; 2,4-$(Cl)_2C_6H_3$; 3,4-$(Cl)_2C_6H_3$; 2-$NO_2C_6H_4$; 3-$NO_2C_6H_4$; 3,4,5-$(MeO)_3C_6H_2$.

It was established[69–71] that the reaction of trichloromethanesulphenyl chloride with amides of aliphatic and aromatic carboxylic acids in dimethylformamide in the presence of pyridine at –10 °C to 0 °C leads to the formation of *N*-acyltrichloromethanesulphenamides in 39–86% yield.

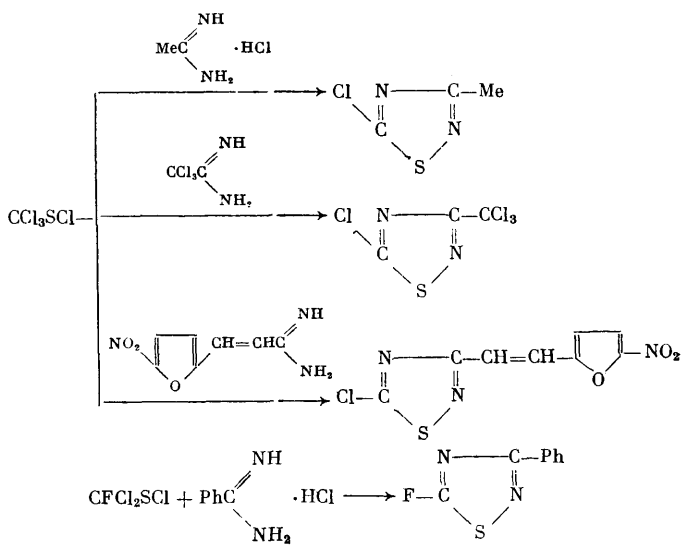


R = Me; n-Pr; n-Bu; iso-Bu; Ph; 3-MeC_6H_4; 4-MeC_6H_4; 3.5$(Me)_2C_6H_3$; 3-$MeOC_6H_4$; 4-$MeOC_6H_4$.

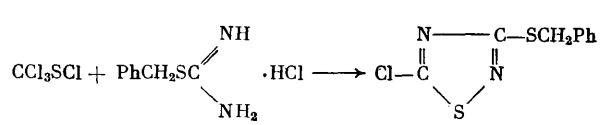
Trichoromethanesulphenyl chloride reacts under analogous conditions with urethane with the formation of *N,N*-bis-(trichloromethanesulphenyl)urethane[72] which is evidently explained by the fact that the rate of trichloromethanesulphenylation of urethane is less than the rate of trichloromethanesulphenylation of the *N*-trichloromethanesulphenylurethane formed as an intermediate.



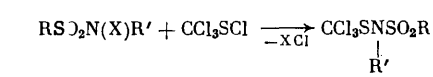
Dichlorofluoromethanesulphenyl chloride is more reactive than trichloromethanesulphenyl chloride in relation to carboxylic acid amides.[3] For example according to the patent literature[73] the reaction of dichlorofluoromethanesulphenyl chloride with carboxylic acids on heating in dioxan leads to the smooth formation of the corresponding *N*-acyldichlorofluoromethanesulphenamides in relatively good yield. Dichlorofluoromethanesulphenyl and chlorodifluoro-methanesulphenyl chloride also react readily with carboxylic acid amides in dimethylformamide in the presence of pyridine at –5° C to –3 °C.[72,74,75]



R = Me, Ph, 4-MeC_6H_3.

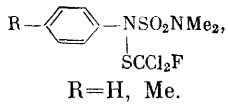


N-Benzoyldichlorofluoromethanesulphenamide reacts with trichloromethanesulphenyl chloride in the presence of triethylamine with the formation of *N*-(dichlorofluoromethylthio)-*N*-(trichloromethylthio)benzamide.[10]



Amidines of carboxylic acids possess a higher reactivity towards perhalomethanesulphenyl halides than do carboxylic acid amides. As a rule both reaction centres (sulphur and carbon) of the perhalomethanesulphenyl halide participate in nucleophilic substitution reactions as a result of which 1,2,4-thiadiazole derivatives are formed.[10,77,78]

S-Alkylisothiouronium salts react like amidines with the formation of 1,2,4-thiadiazole derivatives.

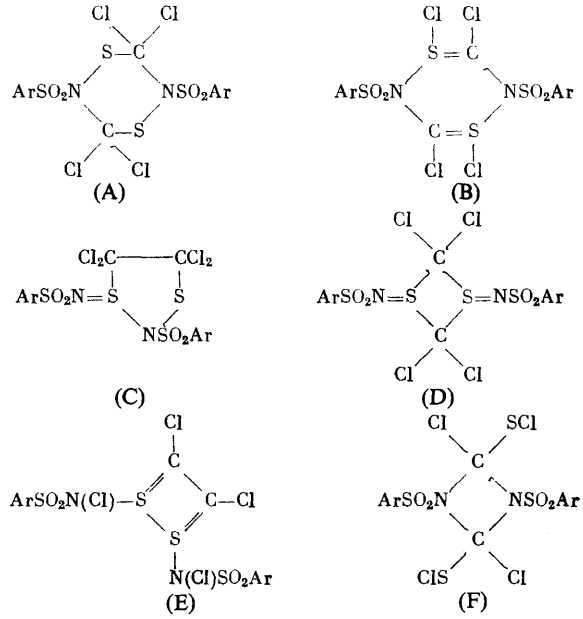


Interaction with sulphonamides. *N*-Substituted amides of alkane- and arenesulphonic acids containing alkyl,[3,80,81] aryl,[3,82] acyl[83] and arenesulphonyl[84,85] groups as substituents react relatively easily with trichloromethanesulphenyl chloride with the formation of *N,N*-disubstituted amides of trichloromethanesulphenic acid. Sulphenylation is carried out in nonaqueous organic solvent (benzene, toluene, chlorobenzene, diethyl ether, etc.) in the presence of organic bases. Occasionally in place of sulphonamides their sodium, lithium or silver salts are used.

R=Alk, Ar; R'=Alk, Ar, RCO, $ArSO_2$, X=H, Na, Li, Ag.

N-Substituted alkane- and arenesulphonamides and also *N,N,N'*-trisubstituted sulphonamides react in a similar manner with dichlorofluoromethanesulphenyl chloride, bromochlorofluoromethanesulphenyl chloride and dibromofluoromethanesulphenyl bromide.[3,86] *N,N*-Dimethyl-*N'*-phenyl-*N'*-dichlorofluoromethylthiosulphonamide and *N,N*-dimethyl-*N'*-*p*-tolyl-*N'*-dichlorofluoromethylthiosulphonamide are the most studied of the *N*-perhalomethylthiosulphonamides formed and are widely used as fungicides under the commercial names "Euparen" and "Euparen-M".[118]

R=H, Me.



The composition and structure of the products of the reaction of unsubstituted arenesulphonamides with trichloromethanesulphenyl chloride depend on the reaction conditions. It was recorded[87] that the main products of the reaction of arensulphonamides with trichloromethane-sulphenyl chloride in boiling tetrachloroethylene were diaryl disulphides, ammonium chloride and sulphur *N,N*-bis-(arenesulphonyl)diimine. The reaction of arenesulphonamides with trichloromethanesulphenyl chloride in anhydrous benzene in the presence of triethylamine leads to the formation of *N*-arenesulphonyltrichloromethanesulphenamides in 40–60% yield.[88]

$$ArSO_2NH_2 + CCl_3SCl \xrightarrow[-Et_3N\cdot HCl]{20-30^\circ C,\ Et_3N} ArSO_2NHSCCl_3.$$

Arenesulphonamides react similarly with trichloromethanesulphenyl chloride in dimethylformamide in the presence of pyridine at −10 to 0 °C.[67,89] The reaction of arenesulphonamide sodium salts with trichloromethanesulphenyl chloride in carbon tetrachloride at −17 to −10 °C leads to *N,N*-bis(trichloromethanesulphenyl)arenesulphonamides the formation of which was also observed on reaction of *N*-arenesulphonyltrichloromethanesulphenamides with trichloromethanesulphenyl chloride in benzene in the presence of triethylamine.[88]

$$2ArSO_2NHNa + 2CCl_3SCl \xrightarrow[-ArSO_2NH_2,\ -2NaCl]{} ArSO_2N(SCCl_3)_2$$
$$ArSO_2NHSCCl_3 + CCl_3SCl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} \uparrow$$

The reaction of arenesulphonamides with trichloromethanesulphenyl chloride in aqueous alkaline medium leads to the formation of cyclic compounds which were assigned the structure of 2,4-dichloro-2,4-bis(chlorothio)-1,3-bis(arenesulphonyl)-1,3-diazetidines [structure (F)] after analysis of several alternative structures (A–F).[88,90]

These compounds are also formed on reaction of arenesulphonamide sodium salts with trichloromethanesulphenyl chloride in carbon tetrachloride at −1 to +3 °C and also on reaction of *N*-arenesulphonyltrichloromethanesulphenamides with triethylamine.[90]

$$4ArSO_2NH_2 + CCl_3SCl + 4NaOH \xrightarrow[-2ArSO_2NH_2,\ -4NaCl,\ -4H_2O]{-1 \text{ to } 0\ ^\circ C} (E)$$
$$4ArSO_2NHNa + 2CCl_3SCl \xrightarrow[-2ArSO_2NH_2,\ -2NaCl]{-1 \text{ to } 3\ ^\circ C} \uparrow$$
$$2ArSO_2NHSCCl_3 + 2Et_3N \xrightarrow[-2Et_3N\cdot HCl]{} \uparrow$$

Interaction with nitrogen-containing heterocyclic compounds. The reaction of perhalomethanesulphenyl halides with heterocyclic compounds containing an N–H bond leads to the formation of *N*-perhalomethylthio derivatives of the heterocyclic compounds which possess biological activity as a rule. These investigations were particularly widely developed after the discovery in 1951 of the fungicidal properties of *N*-trichloromethylthiophthalimide and *N*-trichloromethylthio-1,2,5,6-tetrahydrophthalimide. As a rule the sulphenylation of heterocyclic compounds is carried out in anhydrous organic solvent in the presence of an organic base (pyridine, triethylamine, etc.). In the case of strongly basic heterocycles an excess of the heterocyclic compound is used as an acceptor of hydrogen halide. Heterocyclic compounds possessing an acidic character are sulphenylated as the sodium salts in aqueous, aqueous-alcoholic or alcoholic solution. *N*-Trichloromethylthio derivatives of the following are known: maleimide,[72] succinimide and its homologues,[91] hexahydrophthalimide and its homologues,[92] pyromellitimide,[93] 2,2-disubstituted malonimide,[94] homologues of

glutarimide,[3] aziridine,[3] caprolactam,[72] pyrrolidine,[95] indole,[3] isatin and its homologues,[96] piperidine,[95] pyrazole and its homologues,[13] imidazole,[3] hydantoin and its homologues,[99,100] uracil,[101] piperazine,[95] benzotriazole and its homologues,[3] benzo-1,2,3-triazin-4-one,[102] oxazolidine-2,4-dione and its homologues,[103] benzoxazolone and its homologues,[3] morpholine,[104] thiazolidine-2,4-dione and its homologues,[103] benzothiazolone,[3] benzoisothiazolone and its homologues,[105] benzoisothiazolone 1,1-dioxide and its homologues,[3] 5-methylthio-1,3,4-thiadiazol-2-one,[3] 5-phenylthio-1,3,4-thiadiazol-2-one,[3] 5-phenyl-1,3,4-thiadiazole-2-thione,[3] phenothiazine[3] and homologues of tetrahydro-1,3-thiazine.[106] The *N*-dichlorofluoromethylthio derivatives of the following have been described:[3,24] phthalimide and 1,2,5,6-tetrahydrophthalimide, hexahydrophthalimide, succinimide, pyrrolidine, homologues of isatin, imidazolin-2-one, benzotriazole, benzoxazolone, 3-methylbenzimidazolone, 1,3,4-oxadiazol-2-one, thiazolidine-2,4-dione, benzothiazolone and benzoisothiazolone 1,1-dioxide and also the *N*-trifluoromethylthio, *N*-dibromofluoromethylthio, *N*-bromodichloromethylthio and *N*-bromochlorofluoromethylthio derivatives of phthalimide and 1,2,5,6-tetrahydrophthalimide. It was shown[107] that the reaction of trichloromethanesulphenyl chloride with hexamethylenetetramine may lead to various products depending on the solvent used. For example 1,3-bis(trichloromethanesulphenyl)hexahydro-1,3,5-triazine is formed in alcohol and 3,7-bistrichloromethanesulphenyl-1,3,5,7-tetraazabicyclo[3,3,1]nonane in dimethoxyethane.

Interaction with other *N*-nucleophiles. The reaction of trichloromethanesulphenyl chloride with an *N*-(trimethylsilyl)-bis(arenesulphonyl)imide[85] or with sulphur *N,N'*-bis(trimethylsilyl)diimine[108] is accompanied by replacement of the trimethylsilyl group on the nitrogen atom by trichloromethanesulphenyl.

$$CCl_3SCl \begin{cases} \xrightarrow[-Me_3SiCl]{Me_3SiN(SO_2Ar)_2} CCl_3SN(SO_2Ar)_2 \\ \xrightarrow[-Me_3SiCl]{(Me_3SiN=)_2S} CCl_3SN{=}S{=}NSiMe_3 \end{cases}$$

b) Reactions with *O*-nucleophiles

Hydrolysis. Trichloromethanesulphenyl chloride is relatively stable towards hydrolysis and may be steam distilled without decomposition. Partial hydrolysis occurs in concentrated sulphuric acid in the presence of a calculated quantity of water with the formation of a chlorocarbonylsulphenyl chloride.[7,8]

$$CCl_3SCl + H_2O \xrightarrow[-2HCl]{(H_2SO_4)} ClC(O)SCl.$$

It was established[109] that the intermediate in this reaction is dichloromethylene sulphoxide, which readily rearranges in concentrated sulphuric acid into chlorocarbonylsulphenyl chloride.

$$Cl_2C{=}S{=}O \xrightarrow{(H_2SO_4)} ClC(O)SCl.$$

Hydrolysis of trichloromethanesulphenyl chloride in the presence of alkali may, depending on the quantity of the latter, lead to the *S*-trichloromethyl ester of dichloromethanethiosulphonic acid[110] or to the sodium salt of dichloromethanethiosulphonic acid.[111] The formation of the *S*-trichloromethyl ester of dichloromethanethiosulphonic acid occurs as follows.

$$2CCl_2SCl + 3NaOH \xrightarrow[-H_2O]{} Cl_2CHSO_2SCCl_3 + 3NaCl.$$

It was proposed[110] that initially hydrolysis of trichloromethanesulphenyl chloride occurs with the participation of the sulphur atom.

$$2CCl_3SCl + 2NaOH \rightarrow 2CCl_3SOH + 2NaCl.$$

Disproportionation of the unstable trichloromethanesulphenic acid then occurs giving trichloromethanesulphinic acid and trichloromethanethiol.

$$2CCl_3CSOH \rightarrow CCl_3SO_2H + CCl_3SH.$$

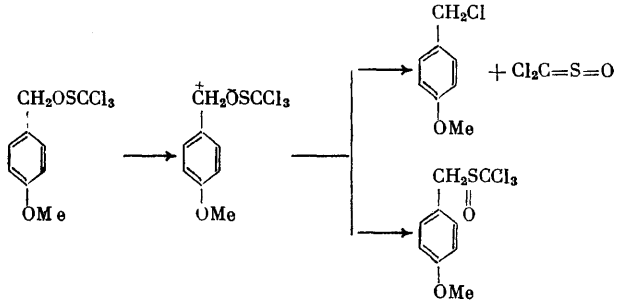
In its turn the trichloromethanesulphinic acid is converted into dichloromethylene sulphoxide by elimination of hydrogen chloride and subsequent addition of trichloromethanethiol giving the *S*-trichloromethyl ester of dichloromethanethiosulphonic acid.

$$CCl_3SO_2H \xrightarrow[-HCl]{} Cl_2C{=}SO_2 \xrightarrow{CCl_3SH} Cl_2CHSO_2SCCl_3.$$

An excess of alkali obviously leads to saponification of the *S*-trichloromethyl ester of dichloromethanethiosulphonic acid one of the products of which is the sodium salt of dichloromethanesulphonic acid as has been observed.[111] Controlled hydrolysis of trifluoromethanesulphenyl chloride by alkali leads to the formation of the *S*-trifluoromethyl ester of trifluoromethanethiosulphonic acid and hexafluorodimethyl disulphide.[112]

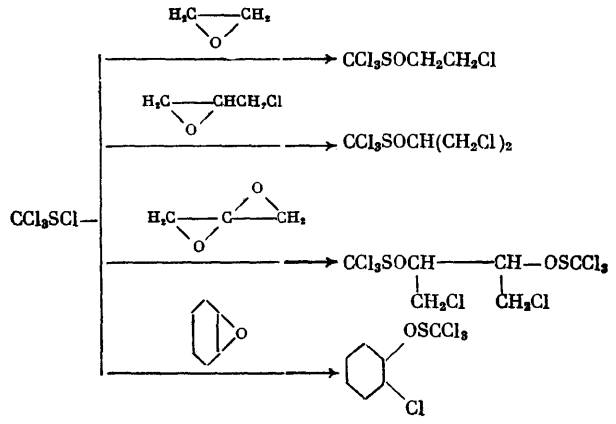
$$4CF_3SCl + 2H_2O \xrightarrow[-4HCl]{} CF_3SO_2SCF_3 + CF_3SSCF_3.$$

Interaction with alcohols and phenols. The reaction of perhalomethanesulphenyl halides with alcohols and phenols leads to the formation of alkyl and aryl esters of perhalomethanesulphenic acids. The esters of trichloromethanesulphenic,[3,112–116] dichlorofluoromethanesulphenic[3] and trifluoromethanesulphenic[3] acids have been described. Sulphenylation of alcohols is carried out in an excess of alcohol or in another organic solvent in the presence of pyridine or triethylamine. Sulphenylation of phenols or naphthols is better carried out as the sodium salts which prevents the competing electrophilic substitution of hydrogen atoms of the benzene ring.[117,118] Reaction of alkoxides instead of alcohols with trichloromethanesulphenyl chloride, especially an excess of the former, leads to the formation of alkyl orthocarbonates.[119] On reaction of trichloromethanesulphenyl chloride with allyl alcohol the resulting allyl ester of trichloromethanesulphenic acid is converted into allyl trichloromethyl sulphoxide as a result of a [2,3] sigmatropic rearrangement.[120–123]



$$CCl_3SCl + HOCH_2CH{=}CH_2 \xrightarrow[-HCl]{C_5H_5N} \left[CCl_3S \begin{matrix} \diagup \\ \diagdown \end{matrix} \begin{matrix} CH \\ O \end{matrix} \begin{matrix} \diagup CH_2 \\ \diagdown \end{matrix} \right] \longrightarrow$$

$$\longrightarrow CCl_3S\underset{\underset{O}{\|}}{CH_2}{-}CH{=}CH_2$$



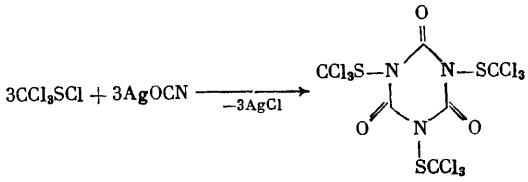
At higher temperatures rearrangement of trichloromethanesulphenic acid allyl ester proceeds without the 1,3-allyl shift with the formation of allyl chloride and dichloromethylene sulphoxide.

$$[CCl_3SOCH_2CH{=}CH_2] \rightarrow CH_2{=}CH{-}CH_2Cl + Cl_2C{=}S{=}O.$$

The propargyl ester of trichloromethanesulphenic acid undergoes an analogous rearrangement.[63] It was noted[123] that trichloromethanesulphenic acid benzyl ester is relatively stable but anisyl esters are rearranged into the sulphoxide and hexane even at 20 °C. Reaction of trichloromethanesulphenyl chloride with anisyl alcohol gives *p*-anisyl chloride and dichloromethylene sulphoxide but trichloromethyl *p*-anisyl sulphoxide is not an intermediate in the process.[123] It was proposed[124] that both rearrangements of anisyl esters proceed according to an ionisation–recombination mechanism by separate schemes.

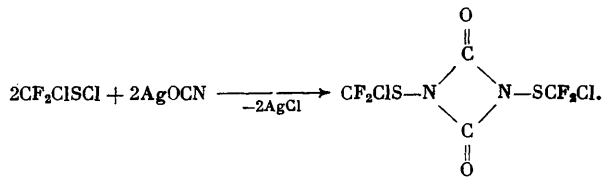
On reacting trichloromethanesulphenyl chloride with 1,2-epoxides a *trans*-scission of the ring takes place with the formation of β-chloroalkyl sulphenates.[11,125]

Interaction with salts of organic and mineral acids. The reaction of trichloromethanesulphenyl chloride with silver[3,11] and sodium[125,126] salts of carboxylic acids leads to the formation of mixed anhydrides of trichloromethanesulphenic acid and the carboxylic acid.



$$RCOOM + CCl_3SCl \rightarrow RCOOSCCl_3,$$

R = Me, Ph, CF_3, *p*-$MeCONHC_6H_4$; M = Ag, Na.



Trifluoromethanesulphenyl chloride reacts ambiguously with silver salts of carboxylic acids. Reaction of it with the silver salt of trifluoroacetic acid leads to the mixed anhydride of trifluoroacetic and trifluoromethanesulphenic acids but a mixture of various products is formed on reaction with the silver salts of chlorodifluoroacetic and pentafluorobenzoic acids.[11,127] Reaction of trichloromethanesulphenyl chloride with silver nitrate leads to the formation of trichloromethanesulphenyl nitrate.[128]

$$CCl_3SCl + AgNO_3 \xrightarrow[-AgCl]{} CCl_3SONO_2.$$

Silver isocyanate reacts with perhalomethanesulphenyl halides with a shift of the reaction centre, i.e. with nitrogen and not oxygen participating in the nucleophilic attack. The character of the reaction products is therefore determined by the form of the perhalomethanesulphenyl halide. For example the product of the reaction of trichloromethanesulphenyl chloride and silver isocyanate is 2,4,6-trioxo-1,3,5-tris(trichloromethanesulphenyl)-1,3,5-triazine which is formed by trimerisation of the unstable trichloromethanesulphenyl isocyanate.[129]

Chlorodifluoromethanesulphenyl chloride reacts with silver isocyanate with the formation of 1,3-bis(chlorodifluoromethanesulphenyl)-2,4-dioxo-1,3-diazetidine.[130,131]

The reaction of trifluoromethanesulphenyl chloride with silver isocyanate leads to the relatively stable trifluoromethanesulphenyl isocyanate.[130,131]

$$CF_3SCl + AgOCN \xrightarrow[-AgCl]{} CF_3SNCO.$$

Interaction with other *O*-nucleophiles. It has been shown[132] that the reaction of trichloromethanesulphenyl chloride with *N*,*N*-diacylhydroxylamines leads to the formation of *N*,*N*-diacyl-*O*-(trichloromethylthio)hydroxylamines.

$$CCl_3SCl + HON(COR)_2 \xrightarrow[-HCl]{} CCl_3SON(COR)_2.$$

c) Reactions with *S*-nucleophiles

Interactions with inorganic sulphur-containing reagents. Perhalomethanesulphenyl halides react with elementary sulphur in the presence of triethyl phosphate with the formation of perhalomethanethiosulphenyl halides.[8]

$$RSCl + S \xrightarrow{140-150\,^\circ C} RSSCl,$$

R = CCl_3, CCl_2Br, CCl_2F.

The interaction of trifluoromethanesulphenyl chloride with hydrogen sulphide leads to the formation of hexafluorodimethyl trisulphide.[133,134]

$$2CF_3SCl + H_2S \xrightarrow[-2HCl]{} CF_3SSSCF_3.$$

In contrast to silver isocyanate silver isothiocyanate reacts with perhalomethanesulphenyl halides with the participation of the sulphur and not the nitrogen atom.[11,135]

$$RSCl + AgSCN \xrightarrow[-AgCl]{} RSSCN,$$
$$R=CCl_3,\ CF_3.$$

Silver isoselenocyanate reacts with perhalomethanesulphenyl halides in a similar manner.[11] The reaction of trichloromethanesulphenyl chloride with sodium trithiocarbonate leads to the formation of bis(trichloromethyl) trithiocarbonate which is converted into thiophosgene on heating.[136,137]

$$Na_2CS_3 + CCl_3SCl \xrightarrow[-2NaCl]{} CCl_3SC(S)SCCl_3 \xrightarrow{130-190^\circ C} 3ClCCl.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \| \qquad\qquad\qquad\qquad\quad \|$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad S \qquad\qquad\qquad\qquad\quad S$$

Interaction with compounds containing thiol and thione groups. Trichloromethanesulphenyl chloride reacts relatively readily with compounds containing thiol or thione groups with the formation of unsymmetrical disulphides.[119,137–149]

$$XSH(M) + CCl_3SCl \xrightarrow[-H(M)Cl]{} XSSCCl_3,$$
$$X=Alk,\ Ar,\ Het,\ HOCH_2CH_2,\ MeC(O)OCH_2CH_2,$$
$$ROC(S),\ RSC(O),\ NH_2C(O),\ RNHC(O),\ R_2NC(O),$$
$$PhC(S),\ (RO)_2P(O),\ (RO)_2P(S),\ (RS)_2P(S),$$
$$Et_2NC_2H_4;\ M=Na,\ MgBr.$$

In contrast to dithiobenzoic acid which forms an unsymmetrical disulphide with trichloromethanesulphenyl chloride,[137] thiobenzoic acid reacts with trichloromethanesulphenyl chloride with the formation of hexachlorodimethyl disulphide and dibenzoyl disulphide.[150] Esters such as *O*-alkyl thiocarbamates[151] and *O,S*-dialkyl dithiocarbonates[152] react with trichloromethanesulphenyl chloride with the participation of the thione sulphur and elimination of alkyl chloride.

$$XC(S)OAlk + CCl_3SCl \xrightarrow[-AlkCl]{} XC(O)SSCCl_3,$$
$$X=R_2N,\ RS.$$

Thioamides also react with trichloromethanesulphenyl chloride with the participation of the thione sulphur and the formation of unsymmetrical disulphides,[150,153] but the reaction of thiourea and its derivatives with trichloromethanesulphenyl chloride proceeds in a more complex manner.[154,155]

$$RC(S)NH_2 + CCl_3SCl \longrightarrow RC(NH)SSCCl_3 + HCl.$$

In the reaction of trichloromethanesulphenyl chloride with thiiranes a *trans*-fission of the ring occurs and β-chloroalkyl trichloromethyl disulphides are formed.[156,157]

$$RCH(S)CH_2 + CCl_3SCl \longrightarrow R-CH(Cl)-CH_2SSCCl_3.$$

Interactions with sulphinic acids and their derivatives. The reaction of trichloromethanesulphenyl chloride with the sodium salts of sulphinic acids leads to trichloromethyl esters of thiosulphonic acids.[158,159]

$$CCl_3SCl + RSO_2Na \xrightarrow[-NaCl]{} CCl_3SSO_2R,$$
$$R=Alk,\ Ar.$$

Aryl esters of thiosulphinic acids react with trichloromethanesulphenyl chloride with the formation of a mixture of various products.[160]

$$ArS(O)SAr + CCl_3SCl \rightarrow ArSO_2SAr + ArSSCCl_3 + ArSCl.$$

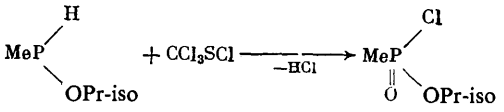
d) Reactions with *P*-nucleophiles

Interaction with inorganic phosphorus-containing reagents. Perhalomethanesulphenyl halides react even at –80 °C with white phosphorus in anhydrous carbon disulphide forming mainly chlorobis(trichloromethylthio)phosphine.[161] The formation of other products has also been recorded, the quantity of which is determined by the perhalomethanesulphenyl halide.

$$CF_nCl_{3-n}SCl + P \rightarrow (CF_3Cl_{3-n}S)_2PCl +$$
$$+ (CF_nCl_{3-n}S)_xPCl_{3-x} + (CF_nCl_{3-n}S)_2 + F_nCl_{2-n}C{=}S.$$

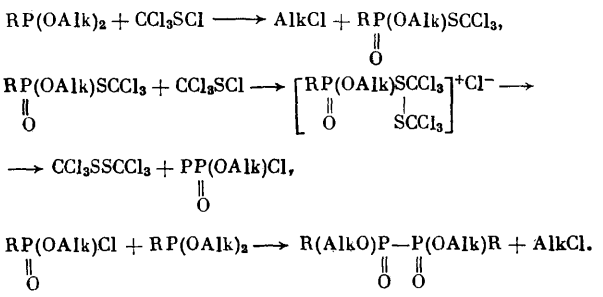
Reaction of trichloromethanesulphenyl chloride with phosphorus trisulphide at 80 °C leads to a mixture of several products including dichloro(trichloromethylthiol)phosphine, *S*-trichloromethyl dithiophosphoric dichloride and bis(S-trichloromethyl) dithiophosphoric chloride.[162]

$$CCl_3SCl + P_2S_3 \longrightarrow CCl_3SPCl_2 + CCl_3SPCl_2 + (CCl_3S)_2PCl.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \| \qquad\qquad\qquad\quad \|$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad S \qquad\qquad\qquad\quad O$$



The main product of the reaction of trichloromethanesulphenyl chloride with phosphorus pentasulphide is *S*-trichloromethyl *S*-chloro dithiophosphoric chloride.[8]

$$CCl_3SP(S)(Cl)SCl.$$



Trifluoromethanesulphenyl chloride reacts readily with phosphine with the formation of bis(trifluoromethylthio)phosphine or tris(trifluoromethylthio)phosphine depending on the ratio of reactants.[50]

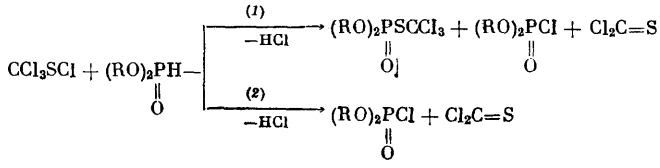
$$PH_3 \xrightarrow{2CF_3SCl} (CF_3S)_2PH + 2HCl$$
$$PH_3 \xrightarrow{3CF_3SCl} (CF_3S)_3P + 3HCl$$

The main products of the reaction of isopropyl methylphosphinite with trichloromethanesulphenyl chloride are isopropyl methylphosphonic chloride and thiophosgene.[163]

The reaction of trichloromethanesulphenyl chloride with dialkyl esters of alkylphosphonous acids proceeds in a more complex manner with the formation of a mixture of various products.[164] As was proposed,[164] in the first stage of this reaction the dialkyl esters of alkylphosphonous acids react with trichloromethanesulphenyl chloride by a type of Arbuzov rearrangement with the formation of alkyl halide and an *O*-alkyl *S*-trichloromethyl thiophosphonate which then reacts with the excess of trichloromethanesulphenyl chloride with the formation of the other reaction products.

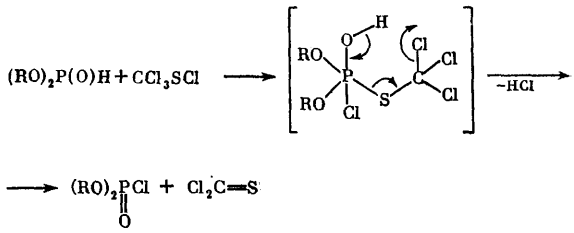
This process was investigated in a more detailed manner using as example the reaction of trichloromethanesulphenyl chloride with the diethyl and diisopropyl esters of methylphosphonous acid.[163] The authors came to the conclusion that the route of this reaction depends on the reactant ratio, the order of mixing them and the structure of the initial ester. For example, on adding diisopropyl methylphosphonite to trichloromethanesulphenyl chloride at a ratio of 1:1 at −50 °C a mixture of products is formed from which the acid chloride of isopropyl methylphosphonous acid, hexachlorodimethyl disulphide and isopropyl chloride were isolated.

$$CCl_3SCl + MeP(OPr\text{-}iso)_2 \rightarrow MeP(O)(Cl)OPr\text{-}iso +$$



$$+ (CCl_3S-)_2 + iso\text{-}PrCl.$$

On adding one mole trichloromethanesulphenyl chloride to four moles of the diethyl ester of methylphosphonous acid the product formed in 80% yield is that of replacement of all four chlorine atoms.



$$4MeP(OEt)_2 + CCl_3SCl \rightarrow$$
$$\rightarrow MeP(O)(OEt)SC[P(O)(Me)OEt]_3 + 4EtCl.$$

In a monograph[165] it was shown that in the case of the diisopropyl ester of methylphosphonous acid no reaction took place due to steric hindrance.

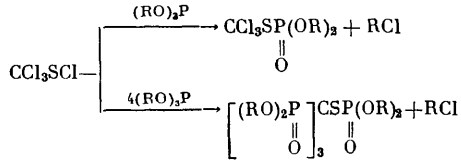
Interaction with dialkyl and trialkyl phosphites. Trichloromethanesulphenyl chloride reacts with dialkyl phosphites according to two alternative routes.[166,167]

The formation of the products of the second route is due to the initially formed phosphorane decomposing according to a six-centre mechanism.[166]

In another study[168] the formation of products by the second route is explained by decomposition of the intermediate salt formed by attack of the dialkyl phosphite at a chlorine atom of trichloromethanesulphenyl chloride.

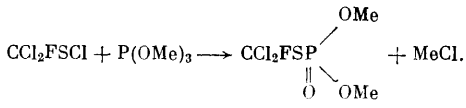
$$(RO)_2P(O)H + CCl_3SCl \rightarrow [(RO)_2P(OH)Cl]^+(SCCl_3)^- \rightarrow$$

$$\rightarrow (RO)_2P(O)Cl + Cl_2CS + HCl.$$



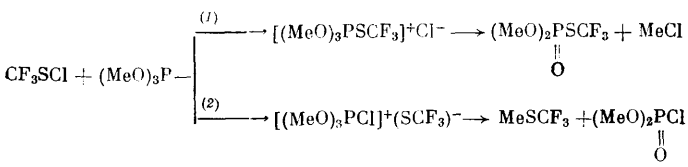
It was shown[169] that reaction of other perhalomethanesulphenyl halides with dialkyl phosphites forms *O,O'*-dialkyl *S*-trihalomethyl thiophosphates mixed with products formed by other routes and with the starting materials which it was impossible to separate by distillation due to the thermal instability of the main products. However reaction of the same sulphenyl chlorides with bis(trimethylsilyl) phosphite or diisopropyl phosphite in anhydrous benzene or toluene at room temperature and a reactant ratio of 2:1 leads to the corresponding *S*-trihalomethyl thiophosphate in quantitative yield.

$$(RO)_2P(O)H + CCl_{3-n}F_nSCl \rightarrow (RO)_2P(O)SCCl_{3-n}F_n,$$

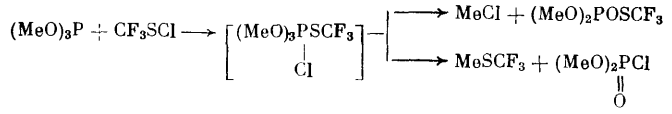


$R = (Me)_3Si$, iso-Pr.

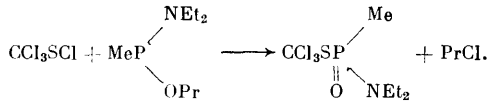
The results of this study formed a basis for the authors[165] to propose that the formation of products of the second reaction route for trichloromethanesulphenyl chloride with dialkyl phosphites may occur during subsequent treatments and not during the reaction. Perhalomethanesulphenyl halides react ambiguously with trialkyl phosphites. For example it was recorded[170–174] that the reaction of trichloromethanesulphenyl chloride with trialkyl phosphites leads to



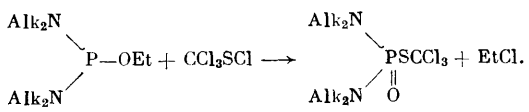
various products, depending on the ratio of reactants, including compounds with three phosphoryl groups.



However in more recent work[175] the possibility of forming compounds with three phosphoryl groups on one carbon atom is doubtful based on PMR spectroscopic data. Dichlorofluoromethanesulphenyl chloride reacts with trimethyl phosphite by an Arbuzov rearrangement with the formation of *O,O'*-dimethyl *S*-dichlorofluoromethyl thiophosphate and methyl chloride.[176]



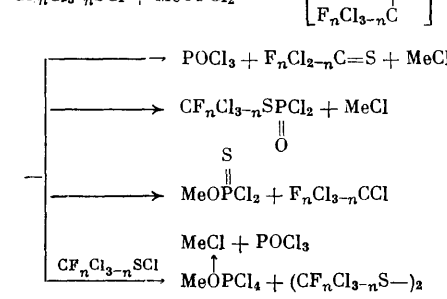
The reaction of trichloromethanesulphenyl chloride with trimethyl phosphite[177] leads to a mixture of four compounds which are formed in pairs as a result of nucleophilic attack of phosphite either at the sulphur atom or at a chlorine atom effecting the two alternative mechanisms (*1*) and (*2*).



The possibility of forming a compound of five-coordinate phosphorus as an intermediate, which then eliminates methyl chloride or methyl trifluoromethyl sulphide, is not excluded.[177]

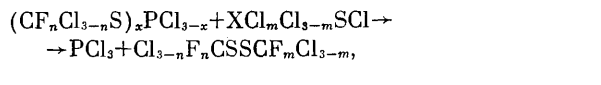
Interaction with amidoesters of alkylphosphonous acids, alkoxydiaminophosphines and diamino(hydroxy)phosphines. Trichloromethanesulphenyl chloride reacts with the propyl ester of (diethylamino)methylphosphonous acid according to an Arbuzov rearrangement mechanism.[164]

Trichloromethanesulphenyl chloride reacts with alkoxydiaminophosphines in a similar manner.[3]



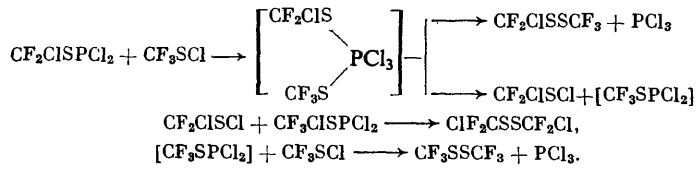
Perhalomethanesulphenyl halides react with tetraalkyldiamino(hydroxy)phosphines with the formation of *S*-trihalomethyl tetraalkyldiaminothiophosphates.[176]

Interaction with chlorodialkoxyphosphines and chlorodi(alkylthio)phosphines. *O,O'*-Diaryl *S*-trichloromethyl thiophosphates, which possess pesticidal properties and are additives for lubricating oils, are formed by the sequential addition of acetic anhydride and trichloromethanesulphenyl chloride to chlorodiaryloxyphosphines.[178]



R=H, Me, Cl.

The main products of the reaction of perhalomethanesulphenyl halides $CF_nCl_{3-n}SCl$ (n = 0 to 3) with alkoxydichlorophosphines at −30 to 20 °C are *S*-trihalomethyl thiophosphoryl dichlorides formed in 50% yield.[162] In addition to these compounds *O*-alkyl thiophosphoryl dichlorides, phosphorus oxychloride, alkyl chlorides, bis(trihalomethyl) disulphides, halomethanes (CF_nCl_{4-n}) and thiocarbonyl dihalides ($F_nCl_{2-n}C{=}S$, n = 0 to 2) are formed, the quantity of which varies depending on the ratio of chlorine and fluorine atoms in the sulphenyl chloride molecule. For example it was recorded that on going sequentially from trifluoromethane- to trichloromethanesulphenyl chloride an increase occurred in the yield of *O*-alkylthiophosphoryl dichloride and a decrease in the yield of the corresponding disulphide. It was shown[162] by NMR spectroscopy (^{31}P, ^{19}F) for the reaction of trichloromethanesulphenyl chloride with methoxydichloro-phosphine that an unstable phosphorane was formed as an intermediate, the further conversions of which readily explain the formation of all the reaction products.



On reacting perhalomethanesulphenyl chlorides with (trihalomethylthio)chlorophosphines at 22−70 °C fission of all the P−S bonds occurs with the formation of unsymmetrical disulphides and phosphorus trichloride.[162]

n, m = 0 to 3; x = 1 to 3.

The formation has also been recorded of a small quantity of symmetrical disulphide and a second sulphenyl chloride which is explained by the formation of a phosphorane intermediate with two perhalomethanethio groups.

$$CF_2ClSPCl_2 + CF_3SCl \longrightarrow \left[\begin{array}{c} CF_2ClS \\ \diagdown \\ PCl_3 \\ \diagup \\ CF_3S \end{array}\right] \begin{array}{l} \longrightarrow CF_2ClSSCF_3 + PCl_3 \\ \longrightarrow CF_2ClSCl + [CF_3SPCl_2] \end{array}$$

$$CF_2ClSCl + CF_3ClSPCl_2 \longrightarrow ClF_2CSSCF_2Cl,$$

$$[CF_3SPCl_2] + CF_3SCl \longrightarrow CF_3SSCF_3 + PCl_3.$$

e) Reactions with *C*-nucleophiles

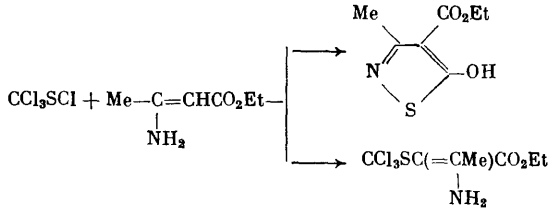
Interaction with organometallic compounds. Perhalomethanesulphenyl halides react energetically with organomagnesium compounds by a nucleophilic mechanism of substitution of the halogen atom at sulphur by the hydrocarbon radical.

$$CX_3SCl + RMgX \rightarrow CX_3SR + MgXCl,$$

$$X = Hal.$$

As a rule a small quantity (up to 15%) of alkyl halide is formed which hinders isolation of the resulting sulphide. Reactions described include trichloromethanesulphenyl choride with ethylmagnesium bromide[179] and also trichloromethanesulphenyl chloride with alkynylmagnesium halides[180] and arylmagnesium halides.[181] Organomercury compounds react with trifluoromethanesulphenyl chloride in a similar manner to organomagnesium compounds.[182] Simultaneously with substitution of the chlorine atom at sulphur by the hydrocarbon radical, replacement of the mercury halide fragment by chlorine and also demercuration occur.

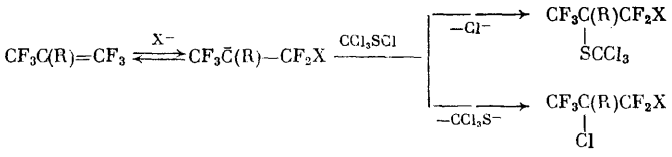
$$p\text{-}RC_6H_4HgCl + CF_3SCl \rightarrow p\text{-}RC_6H_4SCF_3 + p\text{-}RC_6H_4Cl + PhR,$$



$$R = MeO,\ Me,\ H,\ Cl,\ NO_2.$$

Electron-accepting groups R aid the formation of trifluoromethylthio derivatives and electron-donating groups aid the formation of halogen derivatives.

Interaction with CH-acids and their anions. Perhalomethanesulphenyl halides react relatively easily with compounds containing active methyl, methylene or methine groups with the formation of the corresponding sulphides. For example trichloromethanesulphenyl chloride reacts with nitromethane in an aqueous alkaline medium in the cold with the formation of trichloromethyl nitromethyl sulphide.[182]



$$CCl_3SCl + CH_3NO_2 \xrightarrow[-NaCl]{0^\circ C,\ NaOH} CCl_3SCH_2NO_2.$$

Depending on the conditions the amino group[183] or the methine group[184] of β-aminocrotonic acid ethyl ester may participate in nucleophilic attack on the sulphur atom of trichloromethanesulphenyl chloride.

$$CCl_3SCl + Me{-}C(NH_2){=}CHCO_2Et \longrightarrow \begin{array}{l} \longrightarrow \text{2-hydroxy-4-ethoxycarbonyl-5-methylthiazole} \\ \longrightarrow CCl_3SC(=CMe)CO_2Et \\ \qquad\qquad | \\ \qquad\qquad NH_2 \end{array}$$

It has been shown[185] that trifluoromethanesulphenylation of CH-acids $RCXCH_2R'$ (X = O, NH; R = Ph, Me; R' = $CONH_2$, CN, $C(S)NHC_6H_4Br$-4) at 0–20 °C in anhydrous chloroform occurs selectively at the α-carbon atom. The reaction of perhalomethanesulphenyl halides with *C*-anions generated by various means occurs by two alternative routes, viz. with the formation of products either of *C*-sulphenylation or of *C*-chlorination. For example the reaction of trichloromethanesulphenyl chloride with carbanions generated by adding fluoride or chloride anions to the multiple bond of fluoroolefins leads to the formation of products of *C*-sulphenylation and *C*-chlorination.

$$CF_3C(R){=}CF_3 \overset{X^-}{\rightleftharpoons} CF_3\bar{C}(R){-}CF_2X \xrightarrow{CCl_3SCl} \begin{array}{l} \xrightarrow[-Cl^-]{} CF_3C(R)CF_2X \\ \qquad\qquad | \\ \qquad\qquad SCCl_3 \\ \xrightarrow[-CCl_3S^-]{} CF_3C(R)CF_2X \\ \qquad\qquad | \\ \qquad\qquad Cl \end{array}$$

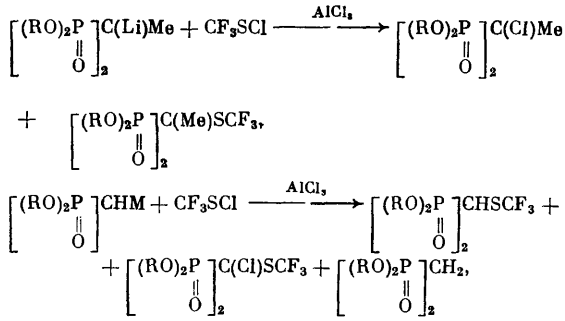
The reaction of perhalomethanesulphenyl chlorides with anions of tetraalkyl methylenephosphonates has been investigated.[187] The anions were generated by the action of butyllithium, sodium hydride or metallic sodium on tetraalkyl methylenephosphonates. It was established that products of sulphenylation and of chlorination were formed both in the presence of $AlCl_3$ and in its absence. In the case of dichlorofluoro- and chlorodifluoromethanesulphenyl chloride sulphenylation products were obtained in which the trihalosulphenyl groups were enriched with fluorine compared with the initial sulphenyl chlorides.

$$[(RO_2)P(O)]_2CHM + CCl_{3-n}F_nSCl \xrightarrow{AlCl_3} \longrightarrow [(RO)_2P(O)]_2CHSCCl_{3-n}F_n + [(RO)_2P(O)]_2CHCl +$$

$$+ [(RO)_2P(O)]_2CHSCCl_{2-n}F_{n+1} + [(RO)_2P(O)]_2CHSCF_3,$$

$$R = \text{iso-Pr};\ M = Li,\ Na$$

The formation of products enriched with fluorine in the trihalomethanesulphenyl group occurs, as discussed,[187] by replacement of chlorine atoms by fluorine in the initial sulphenyl chloride and not in the products of sulphenylation. Fluoride anion acts as a fluorinating agent and arises on decomposition of the trihalomethylthio anion which is a byproduct of the chlorination of tetraalkyl methylenephosphonate anion.

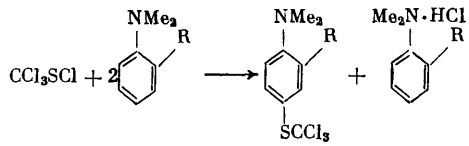


$$[(RO)_2P(O)]_2CHM + CCl_{3-n}F_nSCl \rightarrow$$

$$\rightarrow [(RO)_2P(O)]_2CHCl + CCl_{3-n}F_nS^-,$$

$$CCl_{3-n}F_nS^- \rightarrow Cl_{3-n}F_{n-1}C{=}S + F^-$$

$$CCl_{3-n}F_nSCl + F^- \rightarrow CCl_{2-n}F_{n+1}SCl + Cl^-$$

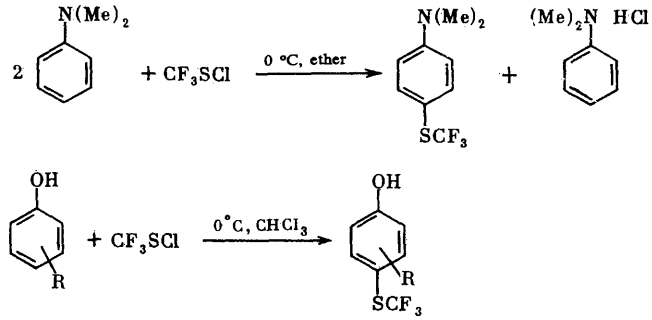


The proportion of chlorination products increases in the sequence $CF_3SCl < CF_2ClSCl \ll CFCl_2SCl$ which is caused[165,187] by the increase in steric hindrance to nucleophilic attack on the sulphur atom by the carbanion. In favour of this explanation is the formation of the product of replacement of a second H atom of the methylene group by chlorine and not by a second trifluoromethylthio group in the reaction with trifluoromethanesulphenyl chloride. In addition, in the reaction of the lithium derivative of tetraisopropyl ethylidenediphosphonate with trifluoromethanesulphenyl chloride in the presence of aluminium chloride products of chlorination and sulphenylation are formed in a 2:1 ratio while in the case of the tetraisopropyl methylenediphosphonate anion under the same conditions the ratio of (trifluoromethylthio)methylene- and (trifluoromethylthio)chloromethylenediphosphonates was 4.6:1.

R = iso-Pr; M = Li, Na.

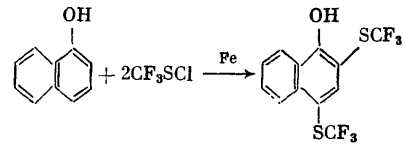
2. Electrophilic substitution reactions

Perhalomethanesulphenyl chlorides react with aromatic compounds by an S_E2 electrophilic substitution mechanism with the formation of trihalomethyl aryl sulphides. The reaction occurs relatively easily with derivatives of benzene and naphthalene containing electron-donating substituents [$N(CH_3)_2$, OH, OCH_3, etc.] but other aromatic compounds react with perhalomethanesulphenyl halides under forcing conditions in the presence of catalysts. For example, trichloromethanesulphenyl chloride reacts relatively easily with dimethylaniline[188] and its derivatives[189] with the formation of the corresponding trichloromethyl aryl sulphides.

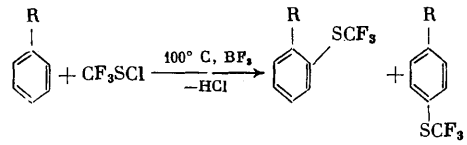


R = H, Me; MeO, MeCOO, $PhCH_2O$.

Trichloromethanesulphenyl chloride reacts anomalously with benzene in the presence of $AlCl_3$ with the formation of diphenyl thioketone.[190]

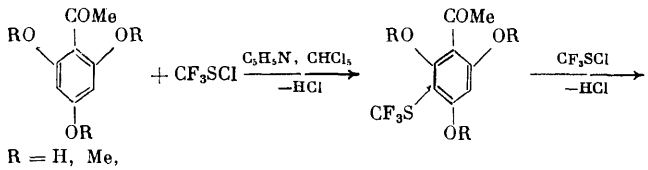


The mechanism of this reaction was not investigated[190] however it is not excluded that thiophosgene is an intermediate in this reaction and as is known,[45] reacts with benzene in the presence of $AlCl_3$ with the formation of diphenyl thioketone. Trifluoromethanesulphenyl chloride reacts with dimethylaniline,[117] and also with phenol and its homologues[118,191] even at 0 °C. The trifluoromethylthio group is directed to the positions *ortho* or *para* to the substituent.

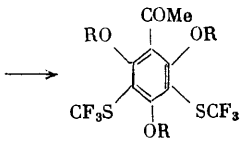


R = H, 2-Me, 3-Me, 2-OH.

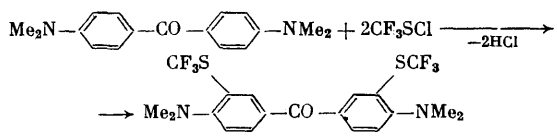
Trifluoromethanesulphenyl chloride reacts with α-naphthol in the presence of iron with the formation of 2,4-bis(trifluoromethylthio)-naphthol.[118]



Trifluoromethanesulphenyl chloride reacts with benzene and toluene at 100 °C in an autoclave in the presence of BF_3 with the formation of trifluoromethyl phenyl sulphide and a mixture of 2- and 4-tolyl trifluoromethyl sulphides.

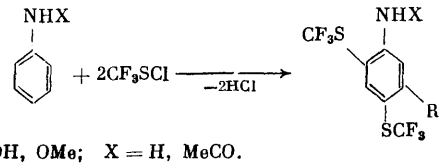


R = H, Me.

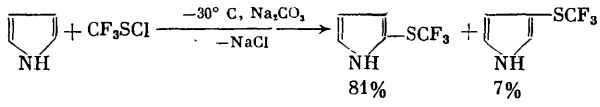


Trifluoromethanesulphonic acid is a more efficient catalyst for the trifluoromethanesulphenylation of benzene, its use enables reduction of the reaction temperature to 20 °C.[192] Introduction of a second trifluoromethylthio group into the benzene nucleus is difficult even in the presence of trifluoromethanesulphonic acid. Trifluoromethanesulphenyl chloride reacts with chlorobenzene under forcing conditions with the formation fo the two isomeric *p*-chloro- and *o*-chlorophenyl trifluoromethyl sulphides.[192] However if there are electron-donating groups (OH, OMe, NMe_2) present in the molecule in addition to electron-accepting groups [MeCO, PhCO, MeOCO, C(O)H], then depending on the conditions one, and in the presence

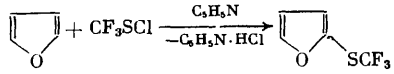
of iron powder, two or even three trifluoromethylthio groups may be introduced.[191,193]



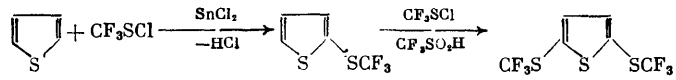
R = H, Me.



Derivatives of aniline and acetanilide containing the electron-donating groups OH or OMe in the *meta* position also react readily with trifluoromethanesulphenyl chloride with the formation of bis(trifluoromethylthio) derivatives.[194]



R = OH, OMe; X = H, MeCO.



A set of rules has been established[193,195–198] for the electrophilic substitution of hydrogen atoms by the trifluoromethylthio group in heterocycles. For example pyrrole reacts even at –30 °C with trifluoromethanesulphenyl chloride with the formation of 2-trifluoromethylthiopyrrole and a small quantity of 3-trifluoromethylthiopyrrole.[193]

Under the same conditions trifluoromethanesulphenyl chloride reacts with indole with the formation of 3-trifluoromethylthioindole.[193] In the presence of trifluoromethanesulphonic acid two, three or even four hydrogen atoms in the pyrrole ring may be replaced by trifluoromethylthio groups.[195,196] Trifluoromethanesulphenyl chloride reacts with furan in the presence of pyridine with the formation of 2-trifluoromethylthiofuran.[197]

With thiopen, depending on the catalyst used, trifluoromethanesulphenyl chloride forms 2-trifluoromethylthiothiophen or 2,5-bis-(trifluoromethylthio)thiophen.[193,197,198]

3. Radical substitution reactions

Perhalomethanesulphenyl halides react with alkanes and cycloalkanes by a mechanism of radical substitution of hydrogen atom by halogen. For example, trichloromethanesulphenyl chloride reacts in the presence of catalysts of radical processes or under UV irradiation with cyclohexane,[199] n-hexane,[199] n-heptane and other saturated hydrocarbons[200–204] with the formation of the corresponding halogen derivatives and hexachlorodimethyl disulphide.

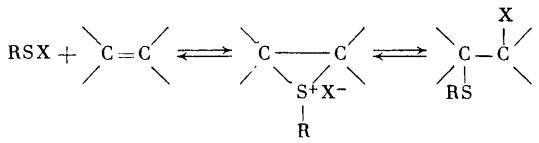
$$RH + 2CCl_3SCl \xrightarrow{h\nu} RCl + CCl_3SSCCl_3 + HCl.$$

A mechanism has been proposed[199] for the radical chlorination of hydrocarbons with trichloromethanesulphenyl chloride which includes the generation of a trichloromethylthio radical which acts as a chain propagating agent.

$$CCl_3SCl \rightarrow \dot{C}l + \dot{S}CCl_3,$$
$$RH + \dot{C}l \rightarrow R^{\cdot} + HCl,$$
$$R^{\cdot} + CCl_3SCl \rightarrow RCl + \dot{S}CCl_3,$$
$$RH + \dot{S}CCl_3 \rightarrow R^{\cdot} + CCl_3SH,$$
$$CCl_3SH + CCl_3SCl \rightarrow CCl_3SSCCl_3 + HCl.$$

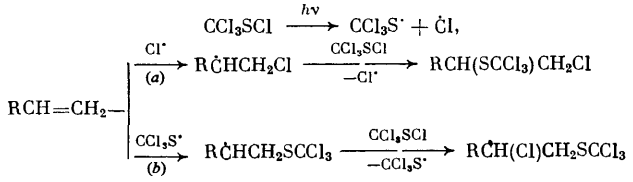
Chain termination may occur by the following processes:

$$R^{\cdot} + R^{\cdot} \rightarrow R{-}R,$$
$$Cl^{\cdot} + Cl^{\cdot} \rightarrow Cl{-}Cl,$$
$$R^{\cdot} + Cl^{\cdot} \rightarrow R{-}Cl,$$
$$R^{\cdot} + \dot{\bar{S}}CCl_3 \rightarrow RSCCl_3,$$
$$CCl_3S^{\cdot} + CCl_3S^{\cdot} \rightarrow CCl_3SSCCl_3.$$



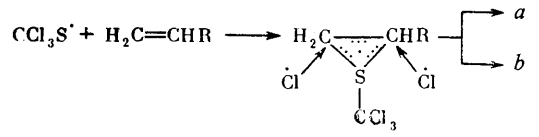
The composition of the mixture of products formed on chlorination of n-heptane with chlorine and trichloromethanesulphenyl chloride has been studied by gas chromatography.[201] It was noted that trichloromethanesulphenyl chloride possesses a higher selectivity than chlorine. Trifluoromethanesulphenyl chloride reacts with saturated hydrocarbons in the same manner as trichloromethanesulphenyl chloride.[199,203,205]

4. Addition reactions

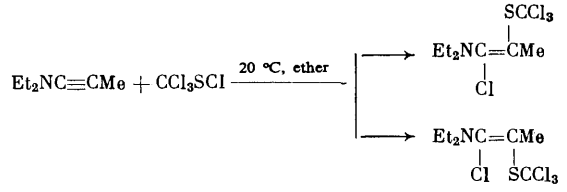


a) Addition to multiple bonds $\diagdown C{=}C \diagup$ and $-C{\equiv}C-$

In contrast to alkanesulphenyl halides the perhalomethanesulphenyl halides react with olefins with difficulty with the formation of β-halogenated sulphides containing a trihalomethyl group. For example, trichloromethanesulphenyl chloride reacts with cyclohexene only on extended heating at 120 °C.[206] Trichloromethanesulphenyl

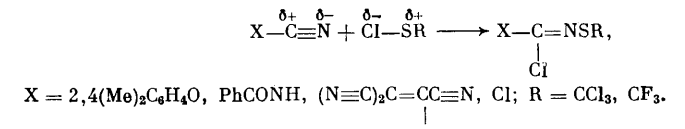


chloride reacts in an even worse manner with allyl chloride and adds to propylene only at 100–110 °C and a pressure of 100 atm. Trichloromethanesulphenyl chloride adds to bicylo[2.2.1]heptene at 100 °C by an ionic mechanism with the formation of *trans*-2-*endo*-chloro-3-*exo*-trichloromethylthiobicyclo[2.2.1]heptane.[207] Addition of trichloromethanesulphenyl chloride to 2,3-dihydrofuran proceeds only in the presence of concentrated hydrochloric acid.[208] Trifluoromethanesulphenyl chloride also adds to vinyl chloride under forcing conditions.[209,210] It was considered[45] that addition of sulphenyl halides to alkenes proceeds by an Ad_E2 mechanism including formation of an episulphonium ion as an intermediate the thermal stability of which, and consequently the thermodynamic advantage, is caused by the character of the R group on the sulphur atom.

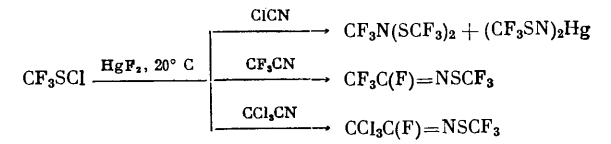


Strongly electron-accepting groups, which trichloro- and trifluoromethyl groups are, reduce the stability and therefore the thermodynamic advantage of the episulphonium ion, which hinders its formation, and consequently the addition reaction. The free radical addition of trichloromethanesulphenyl chloride to cyclohexene, n-hexene, allyl chloride, styrene[211] and aryl vinyl ether[212] proceed readily in the presence of UV light. Depending on the olefin, addition occurs according to two alternative routes with the participation of chlorine radical or of trichloromethylthio radical.

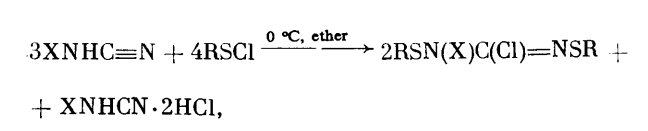
The addition of trichloromethanesulphenyl chloride to styrene, n-hexene and allyl chloride proceeds according to scheme (a)[211] while addition of trichloromethanesulphenyl chloride to aryl vinyl ether, in the opinion of the authors,[212] proceeds by scheme (b). The possibility of forming a non-classical adduct-radical, leading to loss of regioselectivity, is not excluded.[45]



Addition of trichloromethanesulphenyl chloride to the triple bond of ynamines proceeds with the formation of *cis* and *trans* isomers.[213]



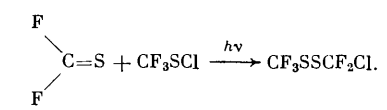
b) Addition to $-C\equiv N$ and $-N\equiv C$ bonds



Perhalomethanesulphenyl halides add relatively readily to the polar $-C\equiv N$ bond. As a rule the chlorine atom adds to the electron-deficient carbon atom while the trihalomethylthio group adds to nitrogen with the formation of a S–N sulphenamide bond. Trichloromethanesulphenyl chloride reacts according to this scheme with 2,4-dimethylphenyl cyanate[9] and *N*-benzoylcyanimide,[214] dichlorofluoromethanesulphenyl chloride reacts with cyanogen chloride,[9] trifluoromethanesulphenyl chloride with tetracyanoethylene[215] and cyanogen chloride.[216]

Trichloromethanesulphenyl chloride readily adds to the $C\equiv N$ bond of cyanogen chloride and the nitriles of trichloroacetic and trifluoroacetic acids in the presence of mercury difluoride.[217] Replacement of chlorine by fluorine occurs together with the addition.

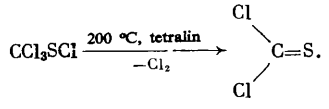
Addition of perhalomethanesulphenyl chlorides to the $C\equiv N$ bond of cyanamide and its *N*-alkyl derivatives is accompanied by sulphenylation of the amide group.[218,219]



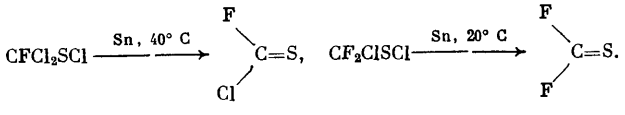
In the case of the reaction of trichloromethanesulphenyl chloride with isonitriles the chlorine atom and the trichloromethylthio group are added to the carbon atom of the isonitrile group.[9]

c) Addition to the C=S bond

Photochemical addition of trifluoromethanesulphenyl chloride to the C=S bond of thiocarbonyl difluoride leads to the formation of trifluoromethyl chlorodifluoromethyl sulphide.[220,221]



5. Oxidation reactions



The oxidation of trichloromethanesulphenyl chloride with various oxidising agents is used as a preparative method for obtaining trichloromethanesulphonyl chloride. Oxidising agents include chlorine in aqueous medium,[222,223] chlorine in acetic acid,[224] nitric acid[225] and hydrogen peroxide.[226] These same oxidising agents may be used for converting trifluoromethanesulphenyl chloride into trifluoromethanesulphonyl chloride.[227] *m*-Chloroperbenzoic acid is used for converting trichloromethanesulphenamides into trichloromethanesulphonamides[228] and trichloromethanesulphenates into trichloromethanesulphinates.[229] On heating with nitric acid trifluoro-methyl aryl sulphides are oxidised to trifluoromethyl aryl sulphoxides.[230]

6. Reduction reactions

On reaction with various reducing agents perhalomethanesulphenyl halides are readily reduced to the corresponding thiocarbonyl dihalides. For example heating trichloromethanesulphenyl chloride with tetralin leads to the formation of thiophosgene.[231]

Sulphur dioxide, hydrogen sulphide[232] and tin[44] are also used as reducing agents. In the presence of tin dichlorofluoromethanesulphenyl chloride and chlorodifluoromethanesulphenyl chloride are readily reduced to thiocarbonyl chlorofluoride and thiocarbonyl difluoride respectively.[44]

An attempt has been made in the present review to systematise the available literature data on the methods of synthesis and reactivity of perhalomethanesulphenyl halides in view of the considerable synthetic possibilities which this class of heteroorganic compounds conceals.

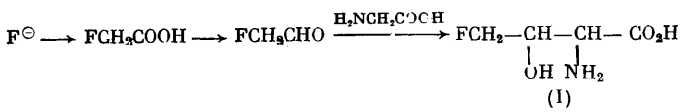
Aliphatic fluorine-containing amino acids

V P Kukhar', V A Soloshonok
Institute of Bioorganic Chemistry and Petrochemistry
Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. Data on the methods of synthesising fluorine-substituted analogues of the natural aliphatic amino acids are systematised in the review. The increased interest in these amino acids is explained by the wide spectrum of their biological action and also by the possibility of using them to solve theoretical and practical problems in medicine, biochemistry, enzymology, biotechnology and other related scientific areas. Particular attention is paid in the review to preparative methods of synthesis of the fluorine-containing aliphatic amino acids and to the means of obtaining these compounds in an optically pure state.



The bibliography contains 120 references.

I. Introduction

Until recently fluorine-containing amino acids (FAA) were a unique type of halogen-containing amino acid (AA), having no representatives in nature. Only in 1986 did Japanese investigators[1] describe the first example of FAA biosynthesis, viz. 4-fluorothreonine (I) by the microorganism *Streptomyces cattleya*. It was shown that (I) is a secondary metabolite of monofluoroacetic acid and is formed as follows.

(I)

Chlorine-containing AA, which are the closest analogues of the FAA among halogen-substituted AA, are in contrast fairly widely represented among natural products.[2] The biological activity of chlorine-substituted AA is extremely specific. Many of them are antibiotics or form part of natural peptide or glycopeptide antibiotics. Examples are armentomycin (II), isolated from *Streptomyces armentosus*,[3] 5-chlorotryptophan (III), discovered in the antibiotic longicatenamycin[4] and β-(3-chloro-4-hydroxyphenyl)serine (IV), a structural fragment of the antibiotics actaplanin,[5] vancomycin[6] and aridicin.[7]

(II) (III)

(IV)

All this is a stimulus for broad investigations of other halogen-containing AA.

The most interesting results in the area of halogen-containing AA were obtained when using fluorine atoms for modification, which is explained by the special features of this element compared with the other halogens. Fluorine is the smallest atom after hydrogen and this enables FAA to be incorporated into the metabolism of natural AA (disguise effect).[8,9] On the other hand, the fluorine atom possesses the greatest electronegativity (4.0) of all the elements of the periodic system which is shown in the change of polarisation and an increase in the strength of the C–F bond (451–485 kJ mol^{-1}) compared to the C–H bond (410 kJ mol^{-1}). As a result FAA, incorporated in metabolic processes by organisms by mistake, may in many cases inhibit various metabolic processes partially or completely (blocking effect). The consequences of introducing fluorine atoms into an AA molecule are a change in the acid–base properties of their functional groups and an appreciable increase in the lipophilicity of these compounds, particularly clearly marked when perfluorinated groups are introduced. The manifestation of these factors in the various biochemical processes involving FAA leads to the development of a wide spectrum of biological action. The most important aspects of the biological action of FAA, such as the suicide inhibition of enzymes, the carcinostatic, bactericidal and antiviral activity have been correlated.[10–17]

In addition FAA open the promise of successful application of ^{19}F NMR spectroscopy for the conformational investigation of proteins containing them, of the interaction of AA with receptors, the study of the mechanisms of enzymic reactions,[18,19] and also new routes in biotechnology when selecting microorganisms.[20,21] One rapidly developing use of FAA in medicine is the use of AA labelled with radioactive ^{18}F for the diagnosis of various diseases, the study of pharmacokinetics, the distribution of AA and the products of their metabolism in the tissue and organs of animals and man.[9,22,23]

Intensive study of the biological activity of FAA continually presents synthetic chemists with the problem of developing methods for the synthesis of previously unknown FAA for the testing of biochemical concepts. A second problem is the improvement of methods for obtaining known FAA which may be required in large quantity or in optically pure form.

The methods of synthesis of FAA published up to 1969 have been reviewed.[24,25] The methods of obtaining FAA containing fluorine atoms in the β-position to the amino group have been considered in a recently published review.[26] In addition methods of obtaining FAA have been discussed in studies[10–17] in addition to data on the biological properties of certain FAA. Work discussed in the present review includes the synthesis of fluorine-containing analogues of the natural aliphatic aminocarboxylic acids containing fluorine atoms or fluoroalkyl groups in the carbon skeleton of the AA molecule with the exception of β-fluorine-substituted amino acids.

II. Preparation of fluorine-containing amino acids using classical methods of amino acid synthesis

The possibility of applying classical methods of synthesising AA to obtain aliphatic FAA is determined by the disposition and extent of the effect of the fluorine atoms or fluorine-containing groups on the reaction centres of the molecule and also by the stability of these substituents towards the electrophilic or nucleophilic reagents used. In several cases the influence of fluorine and fluorine-containing groups, which possess a strong electron-accepting effect,[27] proved to be critical for reactions proceeding through the formation of carbocations. However in the majority of cases, when fluorine or the fluorine-containing groups are separated from the reaction centre of the molecule by two or more simple C–C bonds their electronic effects have practically no influence on the course of the reaction. Consequently the classical methods of AA synthesis proved to be suitable for obtaining the majority of fluorine-containing AA.

1. Alkylation of 2-acylaminomalonic acid esters

The classical method of synthesising AA, the alkylation of diethyl 2-acylaminomalonates (AAM) with alkyl halides, has been used for obtaining aliphatic FAA from the first. Alkylation of formamidomalonic ester with 4,4,4-trifluorobutyl iodide or 4,4,4-trifluoro-3-methylbutyl iodide gives the corresponding 6,6,6-trifluoronorleucine (VI) and 6,6,6-trifluoro-5-methylnorleucine (VII).[28]

$$R(CH_2)_2{-}X + R^1{-}CONHCH(COOC_2H_5)_2 \longrightarrow$$
(AAM)

$$\longrightarrow R(CH_2)_2C(COOC_2H_5)_2{-}NH{-}COR^1 \longrightarrow R(CH_2)_2{-}CH(NH_2){-}COOH;$$
(V) (VI)–(XI)

X = Br, I; R^1 = H, CH_3, C_6H_5; R = CF_3CH_2 (VI), $CF_3CH(CH_3)$ (VII), F (VIII), CH_2F (IX), $F(CH_2)_2$ (X), CH_3CHF (XI).

The use of this method for the synthesis of α-amino-ω-fluorocarboxylic acids such as 2-amino-4-fluorobutyric acid (VIII), 5-fluoronorvaline (IX) and 6-fluoronorleucine (X) is complicated. Partial replacement of the fluorine atom by a hydroxyl group occurs with the formation of corresponding α-amino-ω-hydroxycarboxylic acid at the stage of hydrolysing the product of alkylation of the acylmalonic esters (V) with mineral acid.[29,30] Acid hydrolysis of the product (V, R = F) gives a mixture of various quantities of 2-amino-5-fluorobutyric (VIII) and 2-amino-5-hydroxybutyric acids which are separated by crystallisation from aqueous ethanol.[29] It has been shown[30] that on hydrolysis of (V, R = F) a mixture is obtained with a fluorine content from 8 to 39% of the theoretical value for the FAA (VIII).

Replacement of a fluorine atom by an OH group also occurs in the fluoromethylene group and is shown in the preparation of 5-fluoronorleucine (XI).[31,32] 5-Hydroxynorleucine was isolated as well and became the main reaction product on extended heating of compound (V, R = CH_3CHF) with dilute mineral acid.

The synthesis of FAA (IX)–(XI) without contamination by the corresponding hydroxy acids was successfully achieved by hydrolysing the alkylation products (V) with 48% hydrofluoric acid. This approach also enables the preparation of unsaturated aliphatic FAA as was shown in the synthesis of 2-amino-5-fluoro-4,5-dehydroadipic acid (XII).[33]

$$BrCH_2{-}CH{=}CF{-}COOC_2H_5 \xrightarrow[2)\ H_3O]{1)\ AAM} HOOC{-}CF{=}CH{-}CH_2{-}CH(NH_2){-}COOH$$
(XII)

2-Amino-4,4,4-trifluorobutyric acid (XIII), first synthesised[34] in four stages from diazoacetic ester and trifluoroacetic anhydride, may be obtained by the direct alkylation of 2-acetamidomalonic ester with 2,2,2-trifluoroethyl triflate.[35] Attempts to use 2,2,2-trifluoroethyl iodide or 2,2,2-trifluoroethyl tosylate proved to be unsuccessful.

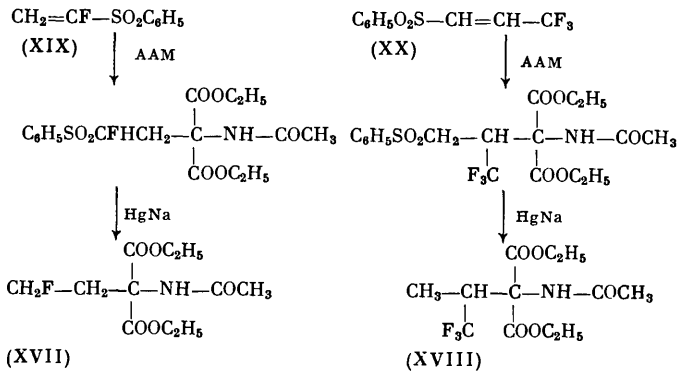
$$CF_3(CH_2)_nOSO_3R \xrightarrow{AAM} CF_3(CH_2)_n{-}C(COOC_2H_5)_2{-}NH{-}COCH_3 \xrightarrow{H_3O^{\oplus}}$$

$$\longrightarrow CF_3(CH_2)_n{-}CH(NH_2){-}COOH$$
(VI), (XIII), (XIV)

n = 1 (XIII), 2 (XIV), 3 (VI); R = CF_3, 4-$CH_3C_6H_4$

5,5,5-Trifluoronorvaline (XIV) is formed similarly from 3,3,3-trifluoropropyl triflate. However, 6,6,6-trifluoronorleucine (VI) is not obtained by the alkylation of 2-acetamidomalonate ester with 4,4,4-trifluorobutyl tosylate. The free (*R*)- and (*S*)-enantiomers of FAA (VI), (XIII), and (XIV) are obtained by enantioselective hydrolysis of their *N*-acetyl derivatives with acylase.

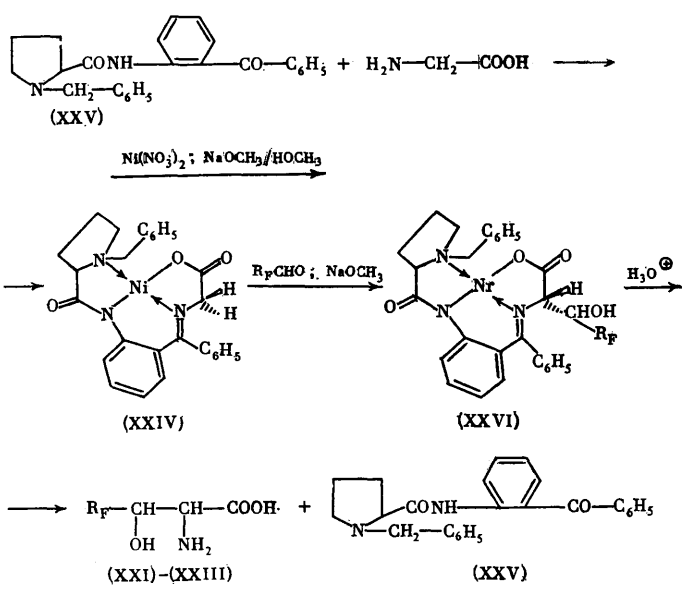
One further method of alkylating acylaminomalonate esters has been used for the synthesis of certain FAA, viz. the Michael addition of activated olefins. 4-Fluoroglutamic acid (XV) is obtained by the condensation of acetamidomalonic ester with the ethyl or methyl esters of 2-fluoroacrylic acid with subsequent acid hydrolysis of the resulting product.[35–38]



$$CH_2{=}CF{-}COOR \xrightarrow{AAM} C_2H_5OOC{-}CHF{-}CH_2{-}C(COOC_2H_5)_2{-}HN{-}COCH_3 \longrightarrow$$

$$\longrightarrow HOOC{-}CHF{-}CH_2{-}CH(NH_2){-}COOH;\quad HOOC{-}CHF{-}CH_2{-}CH(NH_2){-}CONH_2,$$
(XV) (XVI)

R = CH_3, C_2H_5

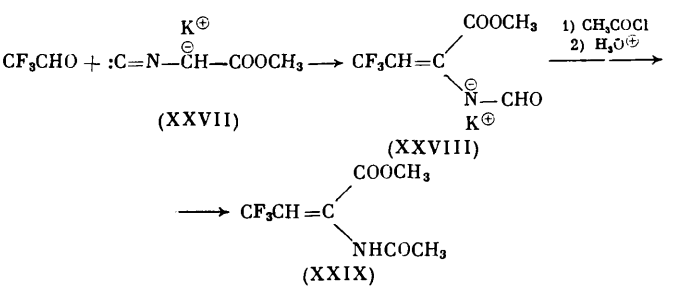


Treatment of the monomethyl ester of 4-fluoroglutamic acid with ammonia gives the corresponding 4-fluoroglutamine (XVI) in low yield.[33]

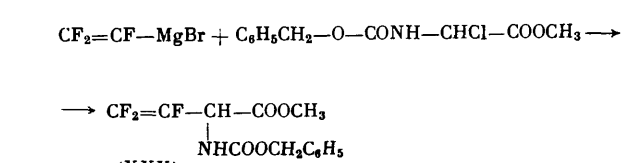
The ease of removing the benzenesulphonyl group by the action of sodium amalgam on phenyl alkyl sulphones[39] is used in the last stage of synthesising protected 2-amino-4-fluorobutyric acid (XVII)[40] and 4,4,4-trifluorovaline (XVIII).[41] The fluorine-containing vinyl sulphones (XIX) and (XX), readily obtained by the Emmons–Horner reaction from the corresponding benzenesulphonylmethanephosphonates and carbonyl compounds, undergo Michael condensation with 2-acetamidomalonic ester. Subsequent desulphurisation of the resulting products gave FAA derivatives (XVII) and (XVIII) in 40% yield.

2. Alkylation of glycine or its derivatives

A preparative method has been developed recently for the diastereo- and enantioselective synthesis of (*S*)-4,4,4-trifluorothreonine (XXI), (*S*)-*threo*-β-nonafluorobutyl (XXII) and (*S*)-*threo*-β-(ω-hydrododecafluorohexyl)serines (XXIII) using the hydroxyalkylation of the glycine fragment in the chiral Ni(II) complex of its Schiff's base (XXIV) with the appropriate aldehydes.[42]



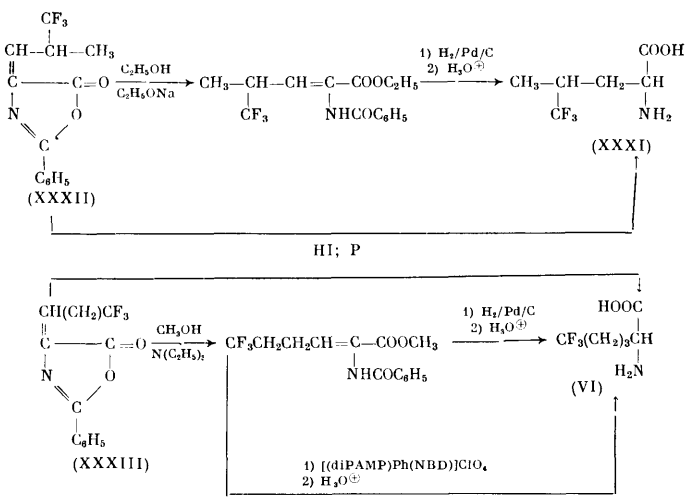
R_F = CF_3(XXI), C_4F_9(XXII), $H(CF_2)_6$(XXIII).



The chiral Ni(II) complex of the glycine Schiff's base is readily assembled from the available (*S*)-2-*N*-(*N*^{1}-benzylprolyl)-*o*-aminobenzophenone (XXV), glycine and nickel nitrate in the presence of sodium methoxide.[43] The hydroxyalkylation of the complex (XXIV) with fluorine-containing aliphatic aldehydes in the presence of sodium methoxide proceeds with high stereoselectivity forming the complex (XXVI) in 70% chemical yield. It was established by X-ray structural analysis that the corresponding FAA (XXI)–(XXIII) with a (2*S*,3*S*)-configuration of the chiral carbon atoms were contained in the complexes (XXVI).

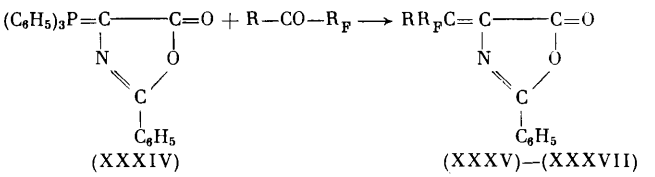
Decomposition of the Ni(II) complexes (XXVI) with 2 N hydrochloric acid gives the free fluorine-containing serines (XXI)–(XXIII) and regenerates the chiral inducing reagent (XXV). It is interesting to record that acetaldehyde gives (*R*)-threonine in the analogous reaction.[44] The total inversion of the stereochemical result of the reaction on using fluorine-containing aldehydes with the complex (XXIV) is apparently linked with the strong influence of the electron-accepting perfluoroalkyl groups on the geminal hydroxyl in the AA fragment formed. In place of the free fluoroaldehydes it is possible to use stable derivatives, such as hydrates or hemiacetals, for the hydroxyalkylation of the glycine-Ni(II) complex. This significantly improves the conduct of the experiment. The diastereoselectivity of the hydroxyalkylation of complex (XXIV) is about 90%. FAA (XXI)–(XXIII) may be obtained with an optical purity of more than 99% after further purification of complexes (XXVI) by chromatography on SiO_2 or by crystallisation.

An interesting example of obtaining fluorine-containing dehydroalanine is shown in the reaction of fluoral with the potassium salt of the isonitrile (XXVII). Acetylation of the intermediate anion (XXVIII) gives a stable imide which is successfully converted regioselectively into the methyl ester of *N*-acetyl-3-trifluoromethyldehydroalanine (XXIX).[45] The electrophilic C=C bond in (XXIX) enables it to be used as a structural unit for obtaining precursors of other FAA.



In all the reactions considered above α-anions of glycine or its derivatives and electrophilic fluorine-containing reagents are used. Special mention must also be made of the first example of the use of 'electrophilic glycine' in FAA synthesis. A derivative of α-trifluorovinylglycine (XXX) is obtained in 85% yield by the alkylation of *N*-carbobenzoxy-α-chloroglycine methyl ester with trifluorovinylmagnesium bromide in THF.[46]

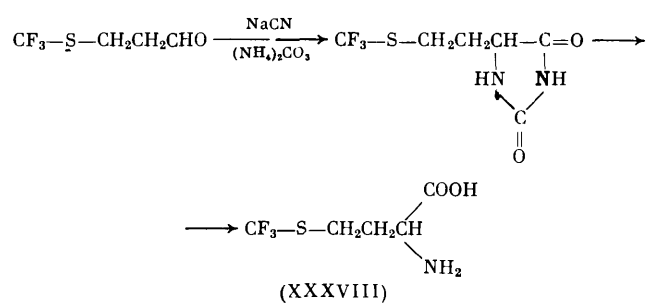
3. Azlactone synthesis (the Erlenmeyer reaction)



The use of the Erlenmeyer reaction in the synthesis of aliphatic FAA is shown by the preparation of 5,5,5-trifluoroleucine (XXXI) and 6,6,6-trifluoronorleucine (VI).

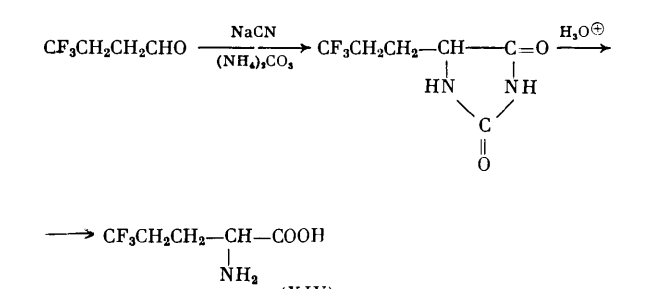
diPAMP = (1*R*,2*R*)-1,2-bis[(*o*-anisylphenyl)phosphino]ethane, NBD = norborndiene.

A mixture of lead acetate and acetic anhydride in THF is used to form the appropriate azlactones from 2-trifluoromethylpropionic and 4,4,4-trifluorobutyric aldehydes and hippuric acid. This modification enables azlactones (XXXII) and (XXXIII) to be obtained in 100 and 60% yield respectively[47,48] as mixtures of the (*E*)- and (*Z*)-isomers [*E*/*Z* = 13/87 for (XXXII) and *E*/*Z* = 12/88 for (XXXIII)]. The pure (*Z*)-isomers of (XXXII) and (XXXIII) were obtained in 70% yield by crystallisation of the reaction mixture. The pure (*E*)-isomers were isolated by chromatography on SiO_2. The azlactones (XXXII) and (XXXIII) were readily converted by ethanol or methanol in the presence of base into the dehydroaminoacids from which the FAA (XXXI) and (VI) were obtained by reduction with an HI/P mixture. The use of H_2/Pd/C at the reduction stage enabled 5,5,5-trifluoroleucine to be obtained with an 80% excess of the (*S**,*S**)-isomer.[49,50] The optically active methyl ester of *N*-benzoyl-6,6,6-trifluoroleucine was obtained in quantitative yield by the asymmetric hydrogenation of the methyl ester of (*Z*)-*N*-benzoyl-6,6,6-trifluorodehydronorleucine in the presence of a chiral rhodium complex.[48,50] The enantiomeric excess of the corresponding (*S*)-isomer was about 90%.



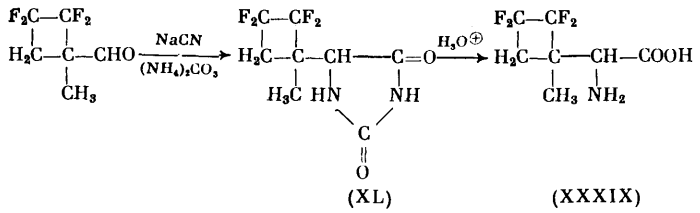
It is possible to use the Wittig reaction between 5-oxo-2-phenyl-4H-oxazolidenetriphenylphosphorane and perfluoroalkyl-containing carbonyl compounds in the synthesis of perfluoroalkyl-containing azlactones.[51] The use of the reagent (XXXIV)[52] enables preparation of the fluorine-containing azlactones (XXXV)–(XXXVII) in far higher yields than using the Erlenmeyer reaction due to the unusual ease of the hydrolytic fission of the azlactone ring in these compounds.[53]

R = R_F = CF_3 (XXXV); R = $COOCH_3$, R_F = CF_3 (XXXVI); R = H, R_F = $CF_2CF_2CF_2CF_2H$ (XXXVII)



4. Hydantoin synthesis (Bucherer-Bergs reaction)

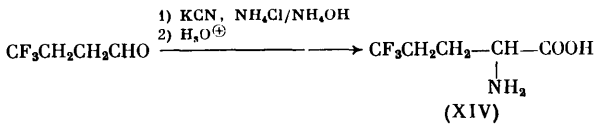
The synthesis of trifluoromethionine (XXXVIII), a fluorinated analogue of methionine, has been effected with the Bucherer-Bergs reaction.[54] The initial 3-(trifluoromethylthio)propionaldehyde was obtained by addition of trifluoromethyl mercaptan to acrolein.



Biological testing showed that trifluoromethionine (XXXVIII) retards the growth of several microorganisms,[55] and is capable of forming *in vivo* the corresponding adenosyl derivative thus inhibiting the demethylation of *S*-adenosylmethionine.[56]

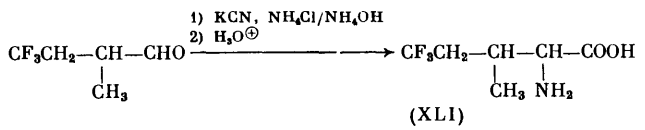
The use of 4,4,4-trifluorobutyraldehyde in the hydantoin synthesis enables preparation of the corresponding 5,5,5-trifluoronorvaline (XIV) in 30% yield.[28]

This approach gives a better result than the Strecker reaction, however in preparative capability it is surpassed by the hydroformylation method, the amidocarbonylation of 3,3,3-trifluoropropene, which is discussed in Section IV.



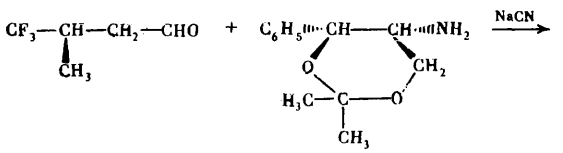
The Bucherer-Bergs reaction has also been used for the synthesis of an unusual AA with a tetrafluorocyclobutyl substituent (XXXIX),[29] in which the hydantoin (XL) is obtained from the corresponding aldehyde in 49% yield. Hydrolysis of hydantoin (XL) with 60% aqueous sulphuric acid gives the FAA (XXXIX).

(XL) (XXXIX)

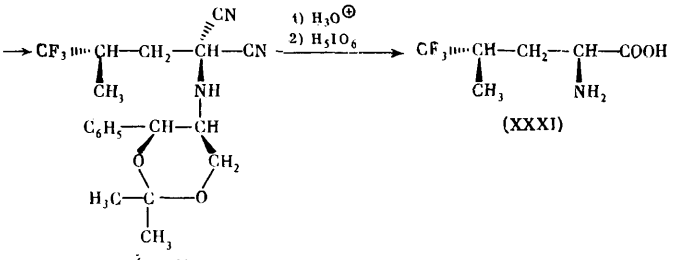


5. Cyanohydrin synthesis (Strecker reaction)

Only β-trifluoromethyl-substituted aldehydes take part in the Strecker reaction. The yield in this case is so low that it does not have the practical value of some of the reactions studied. Thus, 5,5,5-trifluoronorvaline (XIV) is obtained in 4.6% yield by the cyanohydrin method from 4,4,4-trifluorobutyraldehyde.[28]



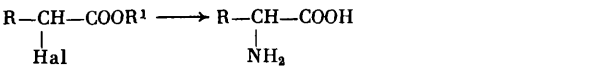
(XIV)



Several methods have been suggested for the preparation of 5,5,5-trifluoroisoleucine (XLI), including the cyanohydrin synthesis based on 2-methyl-4,4,4-trifluorobutyraldehyde.[57] Trifluoroisoleucine (XLI) obtained in this way contains equal quantities of *threo* and *allo* isomers.

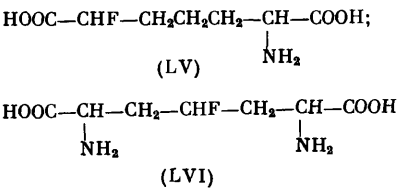
(XLI)

The asymmetric synthesis of (2*S*,4*R*)- and (2*S*,4*S*)-5,5,5-trifluoroleucines (XXXI) has been carried out by the Strecker reaction from optically pure 4,4,4-trifluoro-3-methylbutan-1-al and (4*S*,5*S*)-5-amino-2,2-dimethyl-4-phenyl-1,3-dioxan.[58] The ratio of the (2*S*,4*R*)- and (2*R*,4*R*)-diastereomeric aminonitriles (XLII) was 8:2 (60% enantiomeric excess).



(XLII) (XXXI)

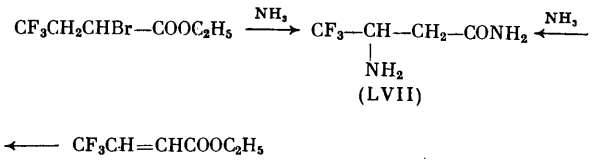
6. Replacement of halogen or hydroxyl group by an amino group.



The amination of α-halogen-substituted carboxylic acids is a general method of synthesis for aliphatic FAA. Variants of this approach are manifold. A two stage process is most frequently used. The fluorine-containing α-bromocarboxylic acid or ester is reacted with sodium azide and the azido group is subsequently hydrogenated to an amino group. Another variant is the direct aminolysis of fluorine-substituted α-chloro- or α-iodocarboxylic acids or reaction of them with potassium phthalimide. The choice of experimental conditions is governed by the availability of the fluorine-containing starting material and also by the stability of the functional groups to the action of the reagents used. The following have been obtained by this route: 4-fluoroleucine (XLIII),[59] 4-fluoroisoleucine (XLIV),[60] 5,5,5-trifluoroisoleucine (XLI),[57] β-chlorofluoromethyl- (XLV) and β-chlorodifluoromethylalanine (XLVI),[61] 2-amino-4,4,4-trifluorobutyric acid (XIII),[62] 4,4,4-trifluorovaline (XLVII),[63] 5,5,5,5′,5′,5′-hexafluoroleucine (XLVIII),[64] 2-amino-4-fluorobutyric acid (VIII), 4,4′-difluorovaline (XLIX), 5,5′-difluoroleucine (L), 4-fluorothreonine (I),[65] and several β-perfluoroalkylalanines (LI)–(LIII)[66] and polyfluoronorvalines (LIV) containing in addition bromine or chlorine.[67]

(I), (VIII), (XIII), (XLI), (XLIII)–(LIV

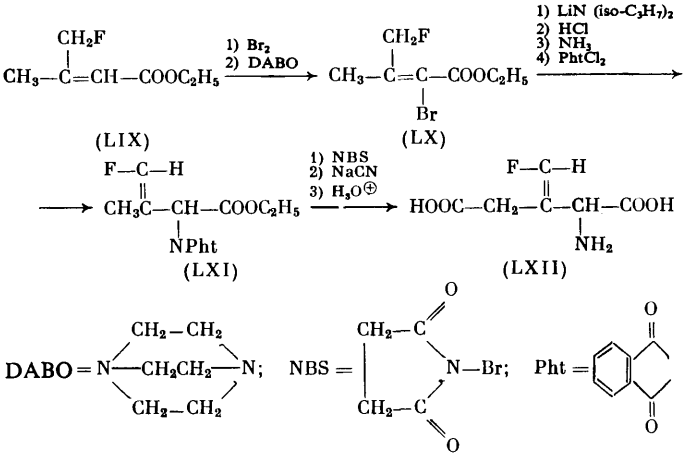
R = $(CH_3)_2CFCH_2$ (XLIII), $CH_3CHFCH(CH_3)$ (XLIV), $CF_3CH_2CH(CH_3)$ (XLI), $CHClFCH_2$ (XLV), $CClF_2CH_2$ (XLVI), CF_3CH_2 (XIII), $CF_3CH(CH_3)$ (XLVII), $(CF_3)_2CHCH_2$ (XLVIII), CH_2FCH_2 (VIII), $(CH_2F)_2CH$ (XLIX), $(CH_2F)_2CHCH_2$ (L), $CH_2FCH(OH)$ (I), $C_2F_5CH_2$ (LI), $C_3F_7CH_2$ (LII), iso-$C_3F_7CH_2$ (LIII), $CF_2XCFXCH_2$, X = Cl, Br, X′ = F, Cl, H (LIV); Hal = Br, Cl, I; R′ = H, C_2H_5.



The fluorine-substituted aminodicarboxylic acids 2-amino-6-fluoropimelic (LV) and 2,6-diamino-4-fluoropimelic (LVI) acids may also be obtained by this method.[68]

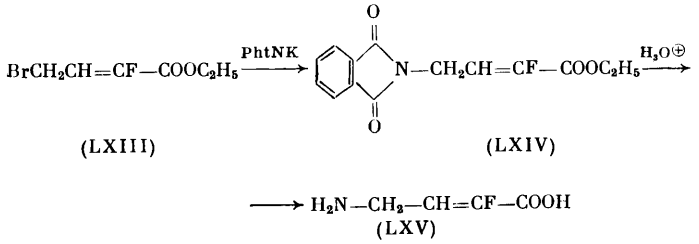
(LV)

(LVI)



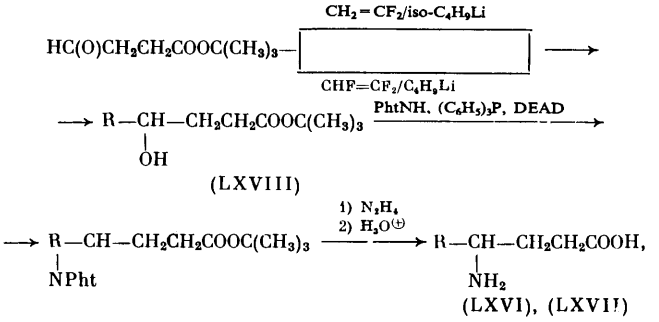
It must be noted that attempts to obtain 2-amino-4,4,4-trifluorobutyric acid (XIII) by the direct aminolysis of ethyl 2-bromo-4,4,4-trifluorobutyrate led to an unexpected product, viz. 3-amino-4,4,4-trifluorobutyramide (LVII),[62] which was obtained by an alternative synthesis from ethyl 4,4,4-trifluorocrotonate (LVIII) and ammonia.[69] The formation of the β-aminoacid (LVII) probably occurs as a result of the dehydrobromination of ethyl 2-bromo-4,4,4-trifluorobutyrate to the ethyl crotonate (LVIII) and subsequent addition of ammonia.[62]

(LVII) (LVIII)



The synthesis of 2-amino-4,4,4-trifluorobutyric acid (XIII) was successfully effected by replacing the bromine atom in ethyl 2-bromo-4,4,4-trifluorobutyrate by an azide group with subsequent reduction over a palladium catalyst.[62]

Replacement of a bromine atom by an amino group has also been used as one of the stages of forming an amino acid molecule in the multistage synthesis of (*E*)-3-fluoromethyleneglutamic acid (LXII).[70]

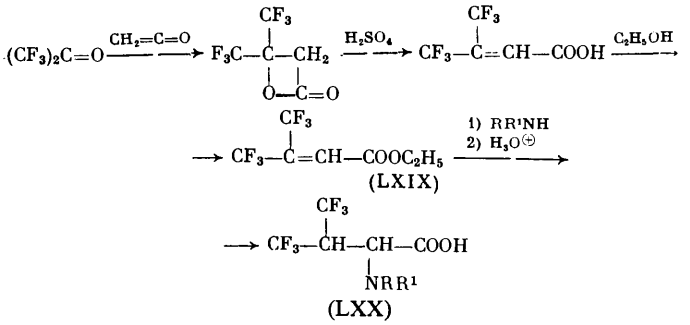


(LIX) (LX) (LXI) (LXII)

Fluorine-containing aliphatic α-amino acids are generally obtained by replacing a halogen atom by an amino group. Obviously this method is also acceptable for the synthesis of other types of FAA as is shown for the example of obtaining 4-amino-2-fluorocrotonic acid (LXIV) from ethyl 4-bromo-2-fluorocrotonate and potassium phthalimide with subsequent acidic hydrolysis of the product (LXIV).[33]

(LXIII) (LXIV) (LXV)

Replacement of an OH group by an amino group by the Mitsunobu reaction was used successfully in the synthesis of the γ-difluorovinyl- and γ-trifluorovinyl-substituted γ-aminobutyric acids (LXVI) and (LXVII).[71] The initial hydroxy derivatives (LXVIII) were obtained by the condensation of t-butyl 4-ketobutyrate with difluoro- and trifluoroethylene by the action of iso-butyl- and butyllithium respectively.

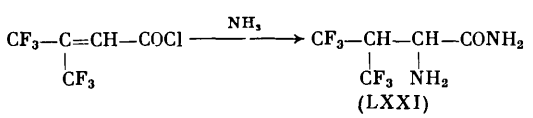


(LXVIII) (LXVI), (LXVII)

DEAD = $H_5C_2OOC-N=N-COOC_2H_5$; R = $CF_2=CF$ (LXVII), $CF_2=CH$ (LXVI)

7. Addition of ammonia or its derivatives to the double bond of acrylate systems

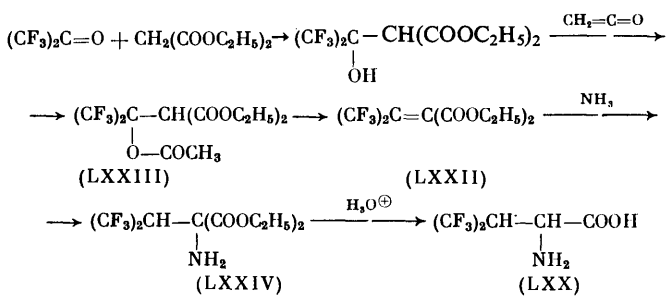
The addition of ammonia or one of its derivatives to a fluorine-containing acrylic acid, as the final stage in the construction of a FAA molecule, is used mainly to obtain derivatives of hexafluorovaline and α-trifluoromethyl-β-alanine due to the fairly high electrophilicity of the C=C bond in the initial unsaturated acid. Hexafluorovaline (LXX) was synthesised for the first time[72] in preparative yield (80–90%) by the addition of ammonia in ether at −80 °C to ethyl β,β-bis(trifluoromethyl)acrylate (LXIX), which was obtained in three steps from hexafluoroacetone and ketene or by the Wittig reaction.[73]



(LXIX) (LXX)

R = R¹ = H (LXX), CH_3, $(CH_2)_4$, $(CH_2)_5$, $CH_2C(CH_3)_2$, $CH_2CHCOOCH_3$; R = H, R¹ = OH; R = H, R¹ = $N(CH_3)_2$; R = H, R¹ = $CH(CH_3)C_6H_5$

Attempts to resolve the hexafluorovaline racemate with enzymes proved unsuccessful.[35,74] This aim was achieved by the crystallisation of the salt of hexafluorovaline (LXX) with *D*-camphor-10-sulphonic acid.[75] Asymmetric synthesis of hexafluorovaline (LXX) in low optical yield may be effected by adding benzylamine to the ester (LXIX) in a solution of methyl *L*-lactate or by the reaction of the optically active *N*-(α-phenylethyl)amide of β,β-bis(trifluoromethyl)-acrylic acid with α-phenylethylamine.[75] It is



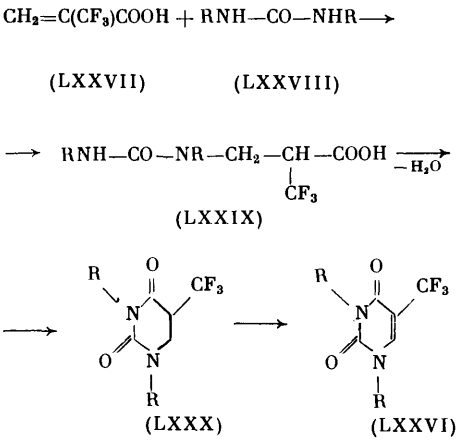
possible to use secondary amines, hydroxylamine and derivatives of hydrazine and aziridine in addition to ammonia in the condensation with the ester (LXIX).[76–79]

Attempts to obtain hexafluorvaline amide (LXXI) by the reaction of ester (LXIX) and ammonia were in vain. Compound (LXXI) was successfully synthesised only by the reaction of ammonia on β,β-bis-(trifluoromethyl)acrylic acid chloride.[72]

(LXXI)

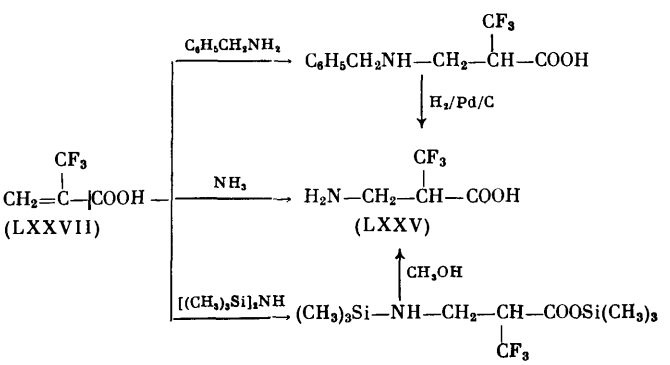
It is possible to use ethyl α-ethoxycarbonyl-β,β-bis(trifluoromethyl)acrylate (LXXII) instead of ethyl β,β-bis(trifluoromethyl)-acrylate (LXIX) in the synthesis of hexafluorovaline (LXX). The ester (LXXII) is obtained by the low temperature pyrolysis of the *O*-acetyl derivative of the adduct of hexafluoroacetone with ethyl malonate (LXXIII).[80] The addition of ammonia to the diester (LXXII) occurs regioselectively at the α-carbon atom giving the aminodiester (LXXIV), hydrolysis of which gives hexafluorovaline.

(LXXIII) (LXXII) (LXXIV) (LXX)



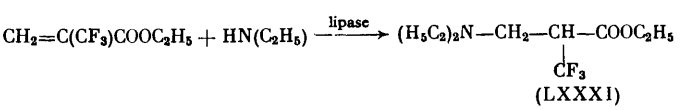
It is interesting to note that in the diester (LXXII) the influence of the two trifluoromethyl groups on the polarisation of the C=C bond proved to be stronger than the action of the two ethoxycarbonyl groups while in ethyl β-trifluoromethylacrylate (LVIII) the reverse polarisation of the C=C bond occurred.[80]

(LXXII) (LVIII)



The presence of two trifluoromethyl groups in hexafluorovaline (LXX) is displayed in its physical properties as well as in its biological action. For example hexafluorovaline hydrochloride is insoluble in water.

The development of methods of obtaining α-trifluoromethyl-β-alanine (LXXV) was stimulated by the prospect of synthesising 5-trifluorouracil (LXXVI) from this AA. 5-Trifluorouracil is a fluorinated analogue of thymine and may be used in the synthesis of nucleic acids. The most convenient synthon for obtaining α-trifluoromethyl-β-alanine and its derivatives is seemingly α-trifluoromethylacrylic acid (LXXVII) obtained by the carboxylation of 2-bromo-3,3,3-trifluoropropene. Heating acid (LXXVII) with the ureas (LXXVIII) readily leads to the formation of derivatives of α-trifluoromethyl-β-alanine (LXXIX) which cyclise in the presence of dehydrating agents into the 5-trifluoromethyl-dihydrouracils (LXXX). The conversion of the dihydrouracils (LXXX) into 5-trifluoromethyluracils is effected by bromination and dehydrobromination of the compounds (LXXX).[81,82] Biological testing showed that the derivatives of 5-trifluoromethyluracil possess antiviral activity.

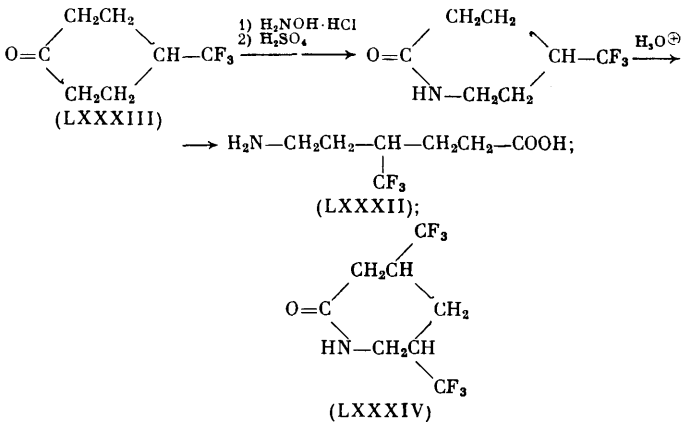


(LXXVII) (LXXVIII) (LXXIX) (LXXX) (LXXVI)

Free α-trifluoromethyl-β-alanine (LXXV) is obtained in high yield by the direct reaction of ammonia with the acid (LXXVII) in methylene chloride at 0–5 °C. Two-stage syntheses through the formation of *N*-benzyl or *N*-trimethylsilyl derivatives have also been studied.[48,50]

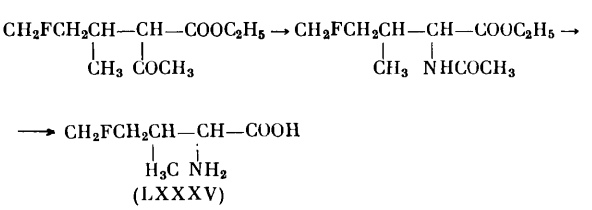
(LXXVII) (LXXV)

Asymmetric synthesis of *N,N*-diethyl-α-trifluoromethyl-β-alanine ethyl ester (LXXXI) with a 35% enantiomeric excess has been effected by the condensation of ethyl α-trifluoromethylacrylate with diethylamine in benzene in the presence of lipase modified with lipophilic fluorine-containing compounds.[83]



(LXXXI)

8. Beckmann rearrangement

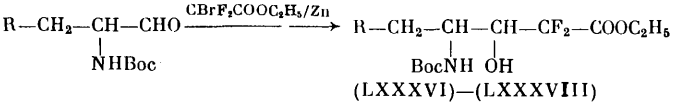


The synthesis of 6-amino-4-trifluoromethylcaproic acid (LXXXII) has been effected from 4-trifluoromethylphenol, which was converted by reduction and oxidation of the resulting alcohol into

4-trifluoromethylcyclohexanone (LXXXIII). The corresponding trifluoromethylcaprolactam was obtained from the ketone (LXXXIII) by the usual scheme of the Beckmann reaction and formed FAA (LXXXII) on acid hydrolysis.[84] The lactam of 6-amino-3,5-bis(trifluoromethyl)caproic acid was obtained from 3,5-bis(trifluoromethyl)phenol in a similar manner.

9. Schmidt rearrangement

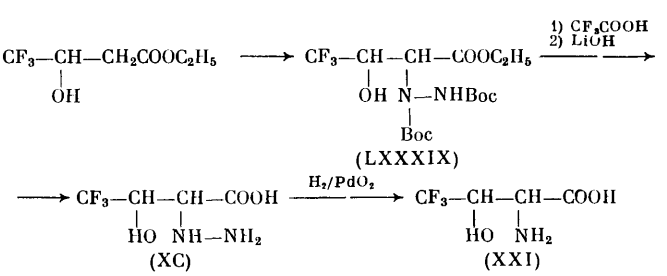
The stereoselective synthesis of 5-fluoro-*allo*-isoleucine (LXXXV) has been effected by a Schmidt rearrangement from ethyl 2-acetyl-5-fluoro-3-methylvalerate, which is readily obtained by the alkylation of acetoacetic ester with 3-bromo-1-fluorobutane.[85]



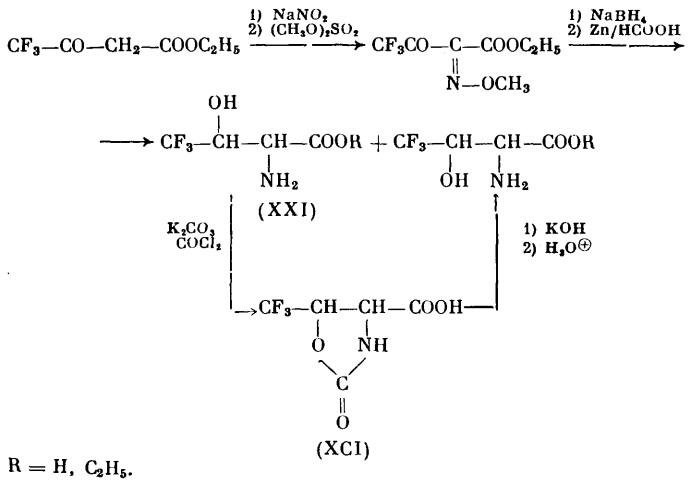
The enantioselective enzymic hydrolysis (using acylase) of the *N*-acetyl derivative of isoleucine (LXXXV) enables the preparation of only the *D*-form of AA (LXXXV) since the *L*-isomer is cyclised under the reaction conditions with replacement of the fluorine atom into *cis*-3-methyl-*L*-proline. It is interesting to note that the preparation of monofluoroisoleucine (LXXXV) by the alkylation of sodium acetamidomalonate with 3-bromo-1-fluorobutane was unsuccessful.[31]

10. Reformatskii reaction

The introduction of ethyl bromodifluoroacetate into the Reformatskii reaction[86] was used in an elegant manner in the synthesis of a 2,2-disubstituted analogue of the unusual AA statin which forms part of the natural pentapeptide pepstatin.[87] Two methods were proposed for the condensation of *N*-t-butyloxycarbonyl-(*S*)-leucinal with bromodifluoroacetic ester in the presence of activated zinc.[88,89] Boiling the reactants in THF gave the *threo*-isomer of (LXXXVI) alone. However partial racemisation (~10%) was observed at the α-carbon atom of the initial leucinal. Conducting the reaction at low temperatures by ultrasound proved to be more preferable and led to the formation of a mixture of the (3*R*,4*S*)- and (3*S*,4*S*)-diastereoisomers of (LXXXVI) (ratio 7 : 3) which was easily separated into the individual isomers. The optically pure diastereoisomers were used in the synthesis of tetrapeptides for study of their ability to inhibit renin, an enzyme playing an important role in the regulation of blood pressure.



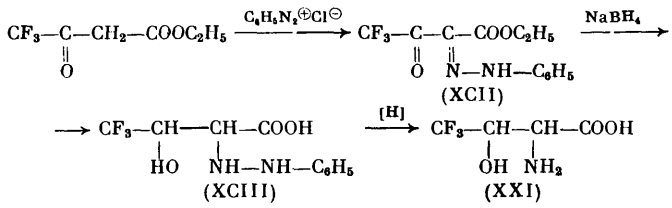
Analogues of difluorostatin containing phenyl (LXXXVII) and cyclohexyl (LXXXVIII) groups in place of the isopropyl group were obtained in a similar manner.[88,89] These compounds were made in order to determine the influence of the lipophilicity of substituents in the *gem* position to the amino group of statin on the biological activity of peptides containing these AA.



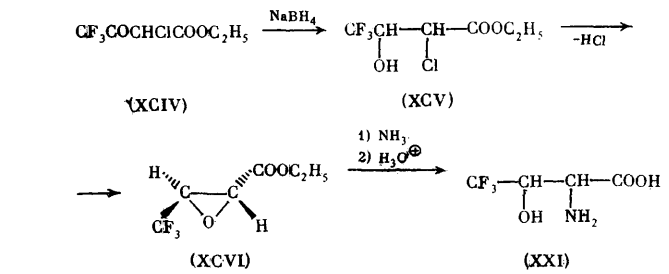
R = iso-C_3H_7 (LXXXVI), C_6H_5 (LXXXVII), cyclo-C_6H_{11} (LXXXVIII); Boc = $COOC(CH_3)_3$

11. Use of other classical methods of AA synthesis to obtain FAA

Several methods have been proposed for the synthesis of trifluorothreonine (XXI) in which 4,4,4-trifluoroacetoacetic ester or products one stage removed from it are used as starting materials. Thus by the sequential action of lithium diisopropylamide and di-t-butyl azodicarboxylate on ethyl 4,4,4-trifluoro-3-hydroxybutyrate a mixture is obtained of diastereoisomers (6 : 1) of protected 4,4,4-trifluoro-2-hydrazino-3-hydroxybutyric acid (LXXXIX), the first representative of the fluorine-containing hydrazinoacids.[90] The free hydrazinoacid (XC), obtained by the hydrolysis of compound (LXXXIX), may be converted readily into trifluorothreonine (XXI) by reduction of the hydrazino group.

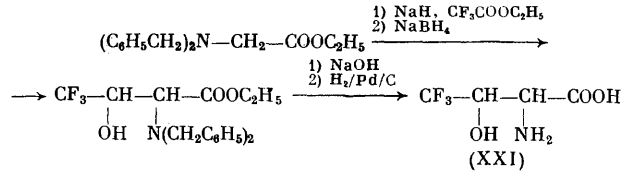


Racemic trifluorothreonine (XXI) has been obtained by the nitrosation of ethyl trifluoroacetoacetate with subsequent methylation of the resulting oxime and reduction of the C=O and C=N bonds.[91] The ratio of *threo* and *allo* isomers in trifluorothreonine (XXI) was 1.5 to 1. Trifluoro-*allo*-threonine may readily be epimerised into the corresponding *threo* isomer through the formation and breakdown of the oxazolidinone (XCI).

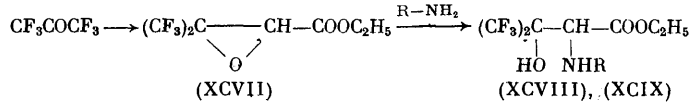


R = H, C_2H_5.

The conversion of the methylene group of 4,4,4-trifluoroacetoacetic ester into an azomethine for subsequent conversion into an amino group may also be carried out by the Japp-Klingeman reaction between 4,4,4-trifluoroacetoacetic ester and phenyldiazonium chloride.

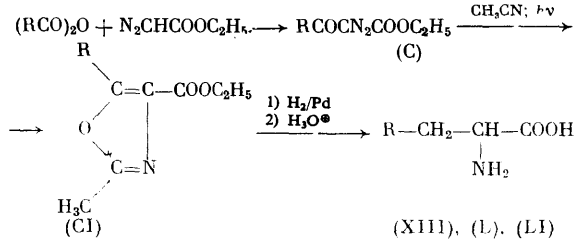


The preparation of 4,4,4-trifluorothreonine (XXI) from phenylhydrazone (XCII) is effected into three stages, viz. reduction of the carbonyl group and azomethine bond, saponification of the ester group and catalytic hydrogenation of the phenylhydrazine (XCIII).[91]



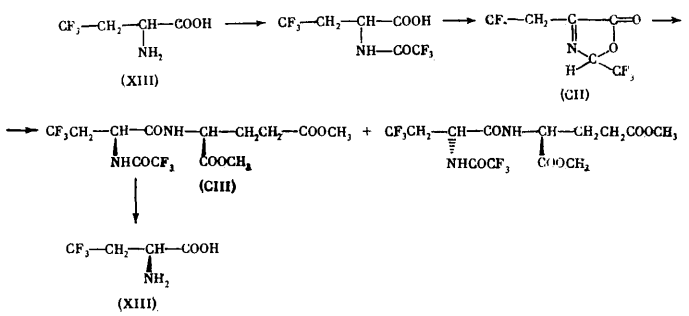
The diastereoselective synthesis of 4,4,4-trifluorothreonine (XXI) is carried out using as precursor ethyl 2-chloro-4,4,4-trifluoroacetoacetate (XCIV), which is readily obtained by the chlorination of 4,4,4-trifluoroacetoacetic ester.[91] The reduction of the carbonyl group of the ester (XCIV) leads to the formation of a mixture of diastereoisomers of ethyl 2-chloro-4,4,4-trifluoro-3-hydroxybutyrate (XCV) in a ratio of 7:4. Dehydrochlorination of hydroxyester (XCV) gives a single compound, the α-oxime (XCVI) to which the *trans*-configuration has been assigned.[91] Decomposition of the oxirane ring of the ester (XCVI) occurs mainly at the α-carbon atom leading to the formation of 4,4,4-trifluoro-*allo*-threonine as an ester or amide depending on the reaction conditions.

An alternative approach, comprising the condensation of ethyl *N,N*-dibenzylglycinate with ethyl trifluoroacetate under the action of sodium hydride and subsequent reduction of the carbonyl group and hydrogenolysis of the *N*-benzyl groups, gave a mixture of the diastereoisomers of trifluorothreonine (XXI) with a predominance of the *allo* form.[92]



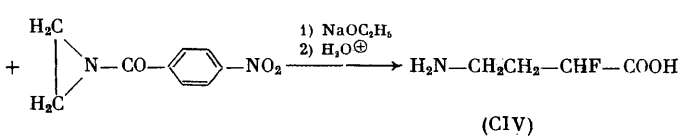
Opening of the oxirane ring with benzylamine or aniline in the bis(trifluoromethyl)glycidic ester (XCVII), obtained from hexafluoroacetone and diazoacetic ester,[93] leads to the formation of the ethyl esters of *N*-benzyl- and *N*-phenyl-4,4,4,4′,4′,4′-hexafluoro-3-hydroxyvaline (XCVIII) and (XCIX) respectively.[94]

R = $C_6H_5CH_2$ (XCVIII), C_6H_5 (XCIX)



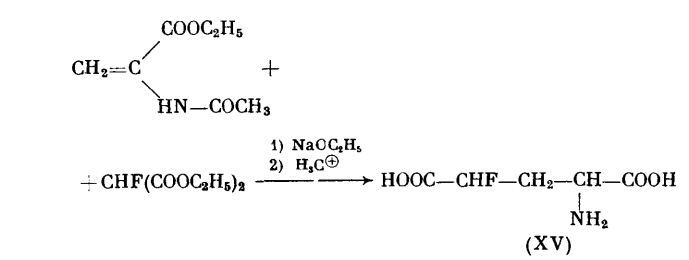
A general method has been developed for the synthesis of β-perfluoroalkylalanines based on the photochemical conversion of the perfluoroacyldiazoacetic esters (C).[34]

R = CF_3 (XIII), C_2F_5 (L), C_3F_7 (LI).



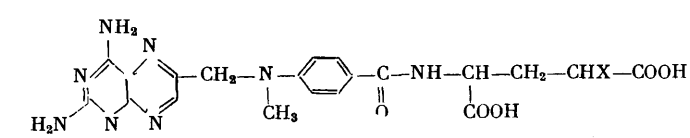
Irradiation of the compounds (C) leads to the formation of the ethyl esters of 2-methyl-5-perfluoroalkyloxazole-4-carboxylic acids (CI) the catalytic hydrogenation of which is accompanied by hydrogenolysis of the C—O bond giving the corresponding esters of *N*-acetyl-AA. Acid hydrolysis of the ethyl esters of *N*-acetyl-3-perfluoroalkylalanines gives 2-amino-4,4,4-trifluorobutyric acid (XIII), 4,4,5,5,5-pentafluoronorvaline (L) and 4,4,5,5,6,6,6-heptafluoronorleucine (LI).

An asymmetric process has been proposed to obtain the *L*-enantiomer of 2-amino-4,4,4-trifluorobutyric acid (XIII) using the racemic FAA (XIII) as starting material. *DL*-2-Amino-4,4,4-trifluorobutyric acid (XIII) was converted into 4-(2,2,2-trifluoroethyl)-2-trifluoromethyl-Δ^3-oxazolin-5-one (CII) by sequential trifluoroacetylation and dehydration by dicyclohexylcarbodiimide.[34]



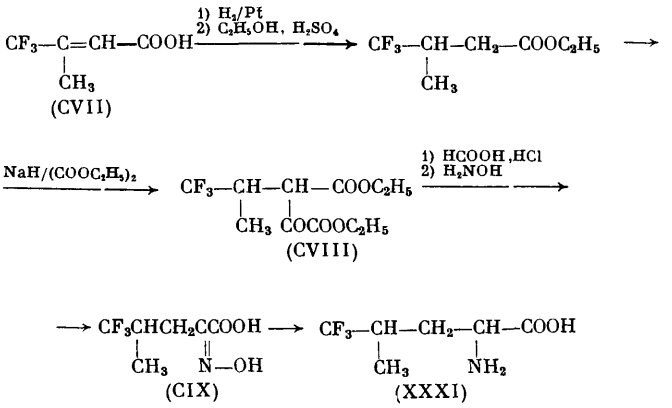
Opening of the oxazolinone ring of (CII) with dimethyl *L*-glutamate gives a mixture of the diastereoisomeric dipeptides (CIII) in a ratio $(L,L):(D,L) = 83:17$. Enantiomerically pure *L*-2-amino-4,4,4-trifluorobutyric acid (XIII) was obtained after numerous crystallisations of the mixture (CIII) with subsequent removal of the *L*-glutamic acid residue.

A convenient method of synthesising γ-amino-α-fluorobutyric acid (CIV) is based on the nucleophilic fission of the *N*-(4-nitrobenzoyl)aziridine anion with monofluoromalonic ester and subsequent saponification of the resulting condensation product.[95]

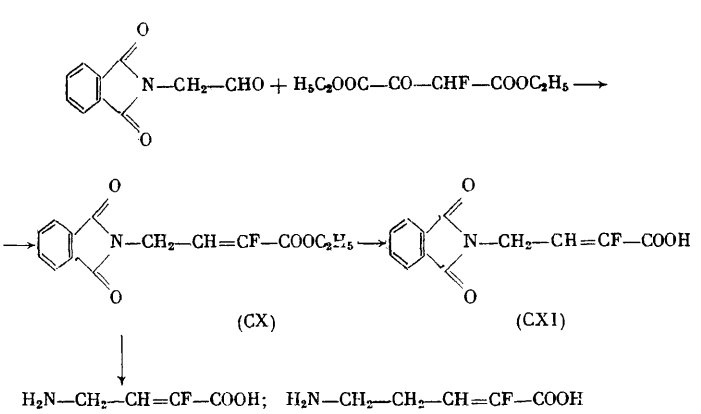


(CIV)

4-Fluoroglutamic acid (XV), obtained by the addition of fluoromalonic ester to ethyl 2-acetylaminoacrylate, has been used for the synthesis of the fluorinated analogue (CVI, X = F) of the known antitumour compound methotrexate (CVI, X = H) [35,38,96,97] which has been proposed for the treatment of leukaemia.[98]



(XV)

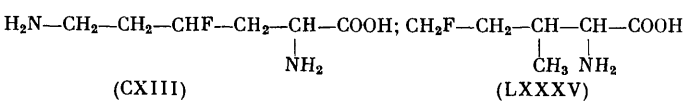


(CVI), X = H, F

It must be noted that this method gives a higher yield of FAA (XV) than the alternative Michael addition of ethyl 2-fluoroacrylate of acetamidomalonate.[35–37]

A multistage method has been proposed for obtaining 5,5,5-trifluoroleucine (XXXI) in which 4,4,4-trifluorocrotonic acid (CVII) is used as starting material.[99] The ketoester (CVIII) is synthesised from it by hydrogenation, esterification and condensation with diethyl oxalate. This is converted into the oxime (CIX) after hydrolysis of the ester groups and decarboxylation. Catalytic hydrogenation of the oxime (CIX) gives the desired AA, 5,5,5-trifluoroleucine (XXXI).

4-Amino-2-fluorocrotonic acid (LXIII) is obtained by boiling phthalimidoacetaldehyde with the sodium derivative of diethyl 2-fluoro-3-ketosuccinate in xylene, as a result of which compound (CX) is formed. Hydrolysis of it with dilute hydrochloric acid gives 2-fluoro-4-phthalimidocrotonic acid (CXI) but the use of concentrated HCl leads to the FAA hydrochloride (LXIII).

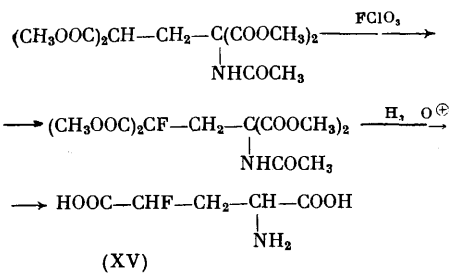


3-Phthalimidopropanal may be converted into 5-amino-2-fluoropent-2-enoic acid hydrochloride (CXII) in a similar manner.[100]

III. Application of methods of organofluorine chemistry to the synthesis of fluorine-containing amino acids

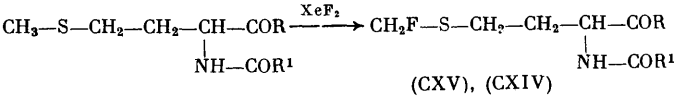
The application of the methods of organofluorine chemistry to the synthesis of aliphatic FAA is linked mainly with the possibility of introducing fluorine atoms and fluorine-containing groups directly into an already prepared AA and has certain advantages in some cases over the classical AA syntheses. For example replacement of hydrogen atoms by fluorine or fluoroalkyl groups in the side chain of an AA may be effected without affecting the chiral α-carbon atom of the AA. Consequently the use of enantiomerically pure AA in these syntheses enables optically active FAA to be obtained.

1. Replacement of hydrogen by fluorine



The use of methods for the direct fluorination of organic compounds to obtain aliphatic FAA is represented in the literature by only a few examples. This is evidently linked with the fact that aliphatic AA molecules are far less stable than aromatic AA towards the action of fluorine or its equivalents and also with the large quantity of reactive C–H bonds which is the reason for the very low regioselectivity of these processes. Thus after treatment of a solution of *L*-lysine in liquid HF with trifluoromethyl hypofluorite *L*-4-fluorolysine (CXIII) was isolated in low yield by ion exchange chromatography from the mixture of products. Compound (CXIII) has been used in a synthesis of a cyclic hexapeptide analogue of somatostatin.[101]

(CXIII) (LXXXV)

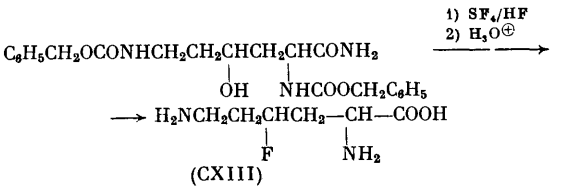


There are data on the formation of 5-fluoroisoleucine (LXXXV) by fluorinating isoleucine with trifluoromethyl hypofluorite. However its isolation was unsuccessful due to the ready heterocyclisation into 3-methylproline.[102]

4-Fluoroglutamic acid (XV) was obtained by replacing a hydrogen atom in the γ-position of tetramethyl 2-acetamido-2,4-dicarboxylglutarate with fluorine by reaction with perchloryl fluoride with subsequent hydrolysis and decarboxylation.[103–105]

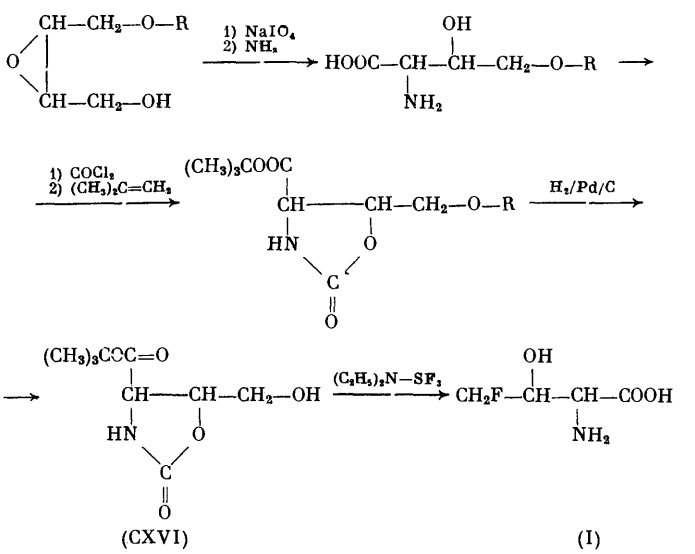
(XV)

The differences in reactivity of the C–H bonds of methionine enabled the development of a preparative method for the monofluoro derivative of methionine (CXIV) and of the dipeptide methionyl-glycine (CXV) using XeF_2 as fluorinating agent.[106] It must be recorded that no products of more extensive fluorination, di- and trisubstituted compounds, were detected.



(CXV), (CXIV)

R = OCH_3, R^1 = CF_3 (CXIV); R = $NHCH_2COOC_2H_5$, R^1 = $OCH_2C_6H_5$ (CXV).

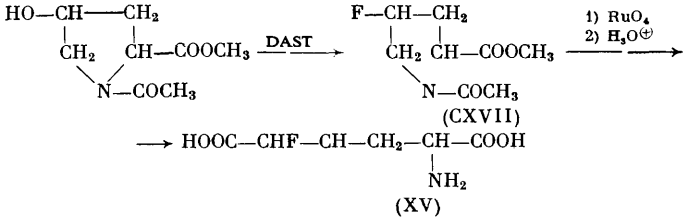


2. Replacement of a hydroxyl group by fluorine

The fluorodehydroxylation of protected 4-hydroxylysine by sulphur tetrafluoride in liquid HF proved to be a more efficient method of obtaining 4-fluorolysine (CXIII) than the direct fluorination of lysine with trifluoromethyl hypofluorite discussed above.[101]

(CXIII)

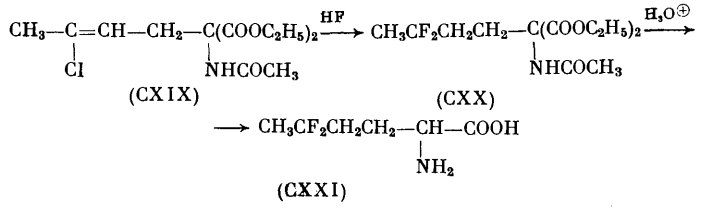
Optically pure (2*S*,3*S*)-4-fluorothreonine (I) is synthesised by the replacement of an OH group by fluorine by the reaction of diethylaminosulphur trifluoride (DAST) and the (4*S*,5*S*)-oxazolone (CXVI), which was obtained from (2*S*,3*R*)-3-benzyloxymethyl-2-hydroxymethyloxirane.[92]



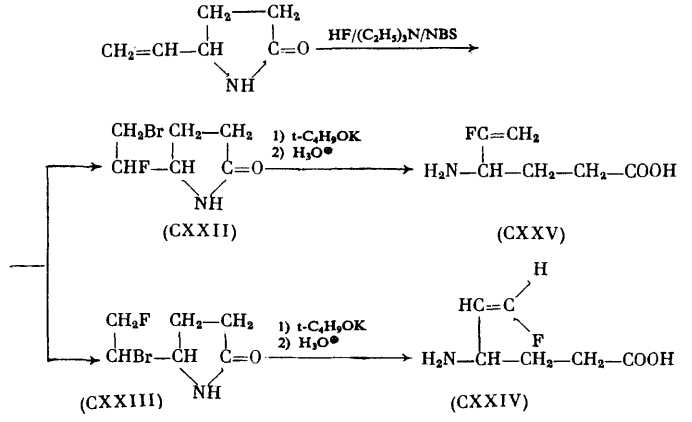
(CXVI) (I)

R = $CH_2C_6H_5$

The possibility of converting hydroxyproline into glutamic acid was used recently for the synthesis of optically pure (2*S*,4*S*)-4-fluoroglutamic acid (XV).[107] The fluorodehydroxylation of (–)-*N*-acetyl-*trans*-4-hydroxy-(*S*)-proline methyl ester by the action of DAST proceeds stereoselectively with the formation of a derivative of optically active 4-fluoroproline (CXVII). Compound

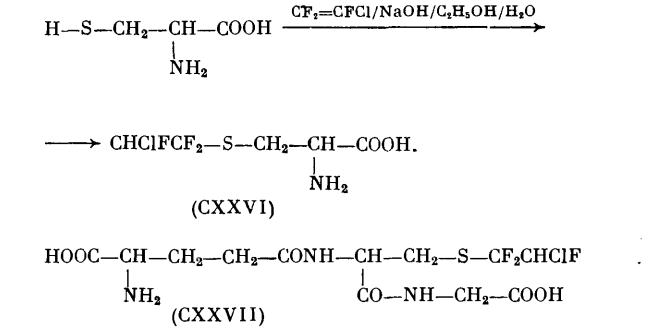


(CXVII) is oxidised regioselectively at the C(5) methylene group of the pyrrolidine ring and subsequent hydrolysis of the lactam (CXVIII) gives (2*S*,4*S*)-4-fluoroglutamic acid (XV).

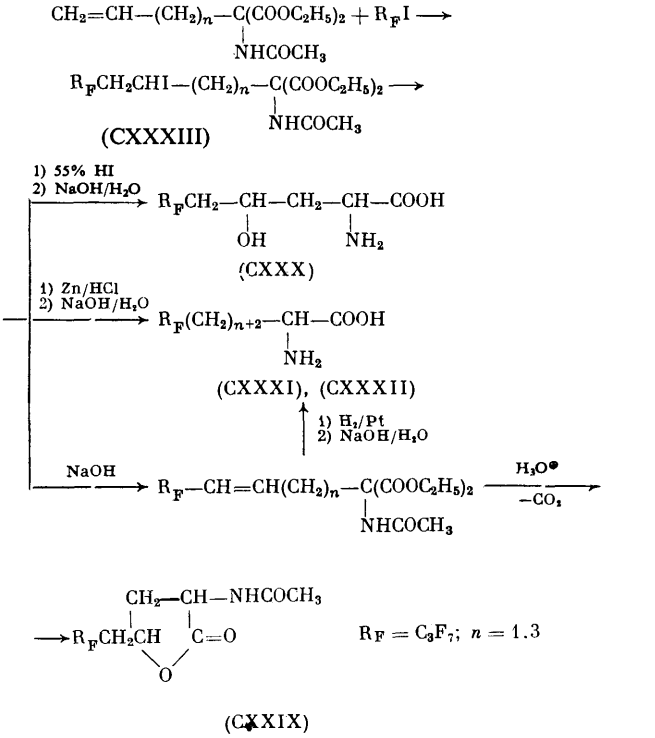


In view of the ease of *cis,trans*-isomerism of the 4-hydroxyprolines and the reduced cost of (+)-*cis*-4-hydroxy-*R*-proline it may be suggested that this method will be convenient for obtaining all four stereoisomers of 4-fluoroglutamic acid (XV).

3. Application of other methods of organofluorine chemistry to the synthesis of FAA



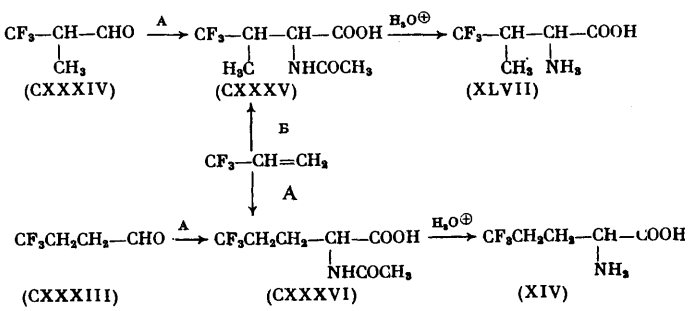
The action of hydrogen fluoride on the acetamidomalonic ester derivative (CXIX) leads to simultaneous addition of hydrogen fluoride to the C=C bond and replacement of the chlorine atom by fluorine. After hydrolysis of the product (CXX) a 50% yield of 5,5-difluoronorleucine (CXXI) is obtained.[108]



The combined addition of fluorine and bromine atoms to 5-vinylpyrrolid-2-one gives a mixture of the isomeric 5-(bromofluoroethyl)pyrrolidones (CXXIII), which is readily separated by chromatography. Dehydrobromination of compounds (CXXII) and (CXXIII) and subsequent hydrolysis leads to the formation of the γ-amino-γ-fluorovinylbutyric acids (CXXIV) and (CXXV). (*Z*)-γ-amino-γ-(2-fluoroethenyl)butyric acid (CXXIV) proved to be the strongest inhibitor of γ-aminobutyric acid (GABA) transaminase of the series of γ-fluorovinyl-substituted GABA (LXVI), (LXXVII), (CXXIV) and (CXXV).[71]

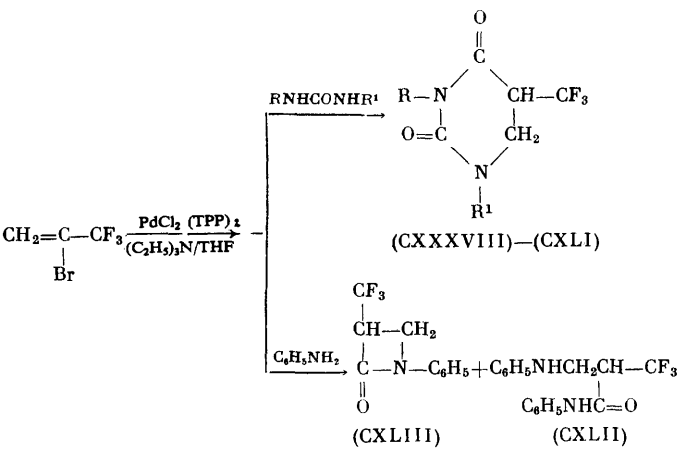
The direct chlorotrifluoroethylation of cysteine is effected by the reaction of chlorotrifluoroethylene and the disodium salt of *N*-t-butyloxycarbonyl-(*S*)-cysteine at 25 °C in aqueous ethanol.[109] (*S*)-*S*-Chlorotrifluoroethylcysteine (CXXVI) may be obtained by this reaction and from unsubstituted cysteine. The regioselectivity of the chlorotrifluoroethylation of the RS^- anion in the presence of RNH^- enables use of this approach for the direct chlorotrifluoroethylation of glutathione. The fluorinated analogues of cysteine (CXXVI) and of glutathione (CXXVII) proved to be nephrotoxic.

Progress in the area of free radical addition of perfluoroalkyl iodides to alkenic acids with a terminal C=C bond[110] has enabled development of a general method of synthesis of long chain FAA containing perfluoroalkyl groups.[111] The addition of perfluoropropyl iodide to diethyl 2-acetamido-2-allylmalonate ester or to diethyl 2-acetamido-2-(pent-4-enyl)malonate in the presence of the initiator azo-bis(isobutyronitrile) gives the products (CXXXVIII) in high yield.



Subsequent hydrolysis of the acetamidomalonate (CXXVIII, $n = 1$) with 55% HI proceeds with simultaneous replacement of the iodine atom by hydroxyl, probably through the lactone (CXXIX), forming 2-amino-6,6,7,7,8,8,8-heptafluoro-4-hydroxyoctanoic acid (CXXX). In order to obtain free 2-amino-6,6,7,7,8,8,8-heptafluorooctanoic (CXXXI) and 2-amino-8,8,9,9,10,10,10-heptafluorodecanoic acids (CXXXII) the iodine atom is replaced by hydrogen, either directly in compound (CXXVIII) by the action of zinc and hydrochloric acid or by a two-stage process of dehydroiodination and catalytic hydrogenation, with subsequent removal of protecting groups and decarboxylation of one carboxyl group. This method is distinguished by high yields at each stage and by the availability of the starting materials. The FAA (CXXXI) and (CXXXII) may also be obtained from the corresponding α-bromocarboxylic acids.[111]

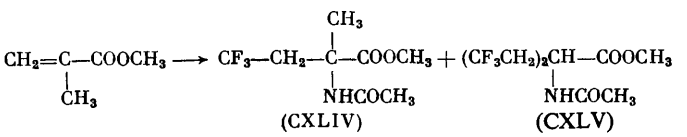
IV. Special methods of obtaining fluorine-containing amino acids



1. Amidocarbonylation of fluorine-containing amino acids

Trifluorovaline (XLVII) and trifluoronorvaline (XIV) are obtained by the amidocarbonylation of 4,4,4-trifluorobutyric (CXXXIII) and 3,3,3-trifluoroisobutyric (CXXXIV) aldehydes respectively. The amidocarbonylation of aldehydes (CXXXIII) and (CXXXIV) with acetamide in the presence of cobalt carbonyl and a mixture of carbon monoxide and hydrogen is carried under a pressure of about 100 atm on heating to 120 °C. Hydrolysis of the acetamides (CXXXV) and (CXXXVI) formed in high yield gives the free FAA (XLVII) and (XIV).[48,50,112] The trifluorovaline formed in this way is a mixture of two diastereoisomers in a ratio 38 : 62. Since the synthesis of the aldehyde (CXXXIII) from 3,3,3-trifluoropropene requires the same catalyst, viz. $Co_2(CO)_8$ and a CO/H_2 mixture,[47,113] the process of making trifluoronorvaline (XIV) in 94% purity may be effected directly from 3,3,3-trifluoropropene through the step of forming aldehyde (CXXXIII) *in situ*. Addition of small quantities of rhodium carbonyl to $Co_2(CO)_8$ leads to a change in the regioselectivity of the reaction giving *N*-acetyl-3,3,3-trifluorovaline (CXXXV) as the main reaction product (96% pure). Thus the regioselectivity of the preparation of trifluorovaline (CXXXV) or trifluoronorvaline (XIV) from trifluoropropene through the two steps of hydroformylation and amidocarbonylation is determined only by the nature of the catalyst.[114–116] The FAA (XLVII) and (XIV) are obtained in pure form by crystallisation of the crude product. Racemic trifluoronorvaline (XIV) has been separated into its (*S*)- and (*R*)-enantiomers by enzymic hydrolysis of its *N*-acetyl derivative.[50]

A = CO, H_2, CH_3CONH_2, $Co(CO)_8$; B = A + $Rh_6(CO)_{16}$.



3,3,3-Trifluoropropene also proved to be a convenient starting material for the synthesis of α-trifluoromethyl-β-alanine derivatives. Trifluoropropene is converted in two stages (bromination, dehydrobromination) into 2-bromo-3,3,3-trifluoropropene (CXXXVII) in high yield.[117] Ureidocarbonylation of the propene (CXXXVII) with 1,3-dimethylurea and carbon monoxide on a catalyst consisting of the complex of palladium chloride with triphenylphosphine leads to the formation of 5-trifluoro-1,3-dimethyl-5,6-dihydrouracil (CXXXVIII) in 70% yield. The use of methylurea in this reaction gives a mixture of the 1-methyl- (CXXXIX) and 3-methyl-substituted (CXL) dihydrouracils in a ratio of 1 : 5. Unsubstituted urea forms 5-trifluormethyldihydrouracil (CXLI) (26%),[48,118,119] from which it is possible to obtain free α-trifluoromethyl-β-alanine (LXXVII) by hydrolysis. The use of aniline instead of urea enables the amide (CXLII) and β-lactam (CXLIII) of *N*-phenyl-α-trifluoromethyl-β-alanine to be obtained.[48]

TPP = $(C_6H_5)_3P$; R = R^1 = CH_3 (CXXXVIII); R = CH_3, R^1 = H (CXXXIX); R = H, R^1 = CH_3 (CXL); R = R^1 = H (CXLI)

2. The trifluoromethyl-acetamidation of olefins

The electrolysis of a mixture of trifluoroacetic acid and methyl methacrylate in aqueous acetonitrile leads to the formation of a complex mixture of products. From this the methyl esters of β-trifluoromethyl-α-methylalanine (CXLIV) and bis(trifluoroethyl)-glycine (CXLV) are isolated in 20 and 5% yield respectively.[120] As suggested, the electrochemical trifluoromethyl-acetamidation of methyl methacrylate may be used for the preparation of FAA (CXLIV).

At present the synthesis of fluorine-containing amino acids is a component of the approach to the solution of one of the basic problems of bio-organic chemistry, namely the purpose-directed modification of the natural bioregulators (mainly peptidic in nature)

to adjust their functions and properties (activities) in the required direction. Amino acids with one or more fluorine atoms on their carbon skeleton are required for the solution of this problem. As is seen from the literature data considered in this review the known methods of synthesis of aliphatic FAA enable practically any AA containing one fluorine atom or perfluoroalkyl groups to be obtained. However, the methods cited in the present review are not all of preparative value. Fluorine-containing amino acids, including the aliphatic AA, still remain difficultly accessible compounds, paticularly as pure diastereo- and/or enantiomers, for the majority of biochemical laboratories. The problem of the asymmetric synthesis of FAA must be taken separately and with certain exceptions has no optimal solution at present. Consequently it must be expected that further work in the area of FAA synthesis will be directed mainly to the creation of preparative methods of synthesis of these compounds from available organofluorine compounds using the latest achievements of organometallic chemistry, engineered enzymology and asymmetric synthesis.

Structure and spectral-luminescent properties of polymethine dyes

A A Ishchenko
Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. The review considers the influence of the length of the polymethine chain, the structures of the hetero-radicals, the nature of substituents, electronic asymmetry, interactions of chromophores, structures of ion-pairs, photochemical reactions with proton transfer, and concentration, on the spectral-luminescent properties of polymethine dyes. The characteristic features of these properties in low-polarity media, including polymeric matrices, are discussed. Solvatochroism and solvatofluorochroism of polymethines are considered. Major factors influencing changes in the spectral-luminescent properties of cyanines, in relation to their structure and the nature of the medium, are revealed. Possible applications of polymethines to the solution of various problems connected with the transformation of light energy are discussed.

The bibliography includes 231 references.

I. Introduction

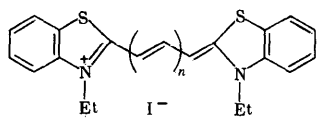
Polymethine (cyanine) dyes (PD) are unique agents for the transformation of light energy in the visible and near infrared region of the spectrum.[1] They are able to strengthen and to weaken radiation, to change its wave length and to sensitise and desensitise various photo-processes,[2–6] and are thus suitable for wide application in various areas of science and technology.[7] In order to search effectively for PD that are specifically able to transform light energy, it became necessary to establish a relationship between their chemical structure and spectral-luminescent properties.

In the course of the long history of investigations of PD, fundamental relationships were obtained linking coloration with structure, making possible the synthesis of dyes with desired absorption maxima λ^{a}_{max}.[8–10] In spite of such a long history of investigation, interest in PD has revived strongly in recent times. This has been caused primarily by the fact, that in addition to their traditional application in the photographic industry,[10,11] PD have found wide application from the mid-seventies in other fields of technology, especially in the rapidly growing area of quantum electronics.[2,5,12,13] Only by the application of PD as passive locks has it been possible to obtain laser impulses of extremely short duration: femtoseconds (using jet dye lasers) in the visible region (487–508,[14] 553–570,[15] 576–615,[16] 652–694 nm[17]) and picoseconds (using solid state lasers) in the near infrared region (750–790,[18] 1060,[19] 1320,[20] and 1540 nm[21]). New possibilities have thereby been opened up for the investigation of ultra-fast photo-processes in chemistry and biology.[22] At the present time, PD are the only organic dyes which can be used as active laser media to provide generation (i.e. to change the wave length of laser radiation) in the region >1000 nm: 1080–1170,[23] 1150–1240,[24] 1200–1320,[25] 1425,[26] 1550, 1600, and 1800 nm.[27] The passive synchronisation and generation of radiation in this region are of great interest in the fields of optical fibres and medicine.[28,29]

However, the specific search for cyanines for use in quantum electronics cannot be carried out effectively on the basis of a relationship linking only λ^{a}_{max} and structure of the PD.[8–10]. It became necessary to establish an analogous relationship for luminescence. But this was also soon found to be insufficient in the effective search for PD with the required properties, since identical values of λ^{a}_{max} and of λ^{f}_{max} may be associated with different dyes, which differ distinctly in such spectral-luminescent properties as quantum yield of fluorescence, φ, life time of the excited state, τ, and shape of the bands (especially their width, σ). These differences determine the assignment of the PD to the solution of one or another problem. Thus, dyes with small values of σ, φ, and τ are used as passive locks for quality modulation and mode synchronisation of optical quantum generators.[30,31] On the other hand, dyes with large values of these parameters are applied as active media for frequency conversion in lasers.[2,12] New spheres of application for PD have stimulated the investigation of their spectral-luminescent properties and have led to the appearance of numerous publications in the literature. However, there are no reviews of this work†.

In the present review, a systematic analysis of literature data, including work of the author in the field of spectral-luminescent properties of PD, is first carried out. Considerable attention is given to problems of directional change of the Stokes shift (ΔS) and quantum yields of fluorescence of PD, the characteristics of their spectral-luminescent properties in low polarity media (including

† Reviews are available on analogous topics for aromatic[32] and heterocyclic compounds.[33]



polymeric matrices), and the application of PD for the transformation of light energy. Prospects for future investigations of the spectral-luminescent properties of PD are considered.

II. Influence of the structure of the chromophore on the spectral-luminescent properties of polymethine dyes

Spectral-luminescent properties of polymethine dyes are due principally to their long-wave $\pi-\pi^*$ transition, the dipole moment of which is directed along the chain of conjugation from one heteroradical to the other. The probability of this transition is strongly dependent on structural changes in the chromophore. Therefore, the structure of the chromophore has an essential influence on the spectral-luminescent properties of PD.

1. Influence of the length of the polymethine chain on the spectral-luminescent properties of polymethine dyes

The polymethine chain (PC) is the major structural factor determining the spectral-luminescent properties of PD. In the example of the classical cyanine series of benzthiazoles, (I)–(V), it is seen that a change in chain length of only one vinylene group gives rise in symmetrical PD to a corresponding change in both λ^a_{max} [34] and λ^f_{max} [35] of about 100 nm. This agrees well with theoretical predictions of the change in position of electronic bands, with the length of the PC.[36,37]

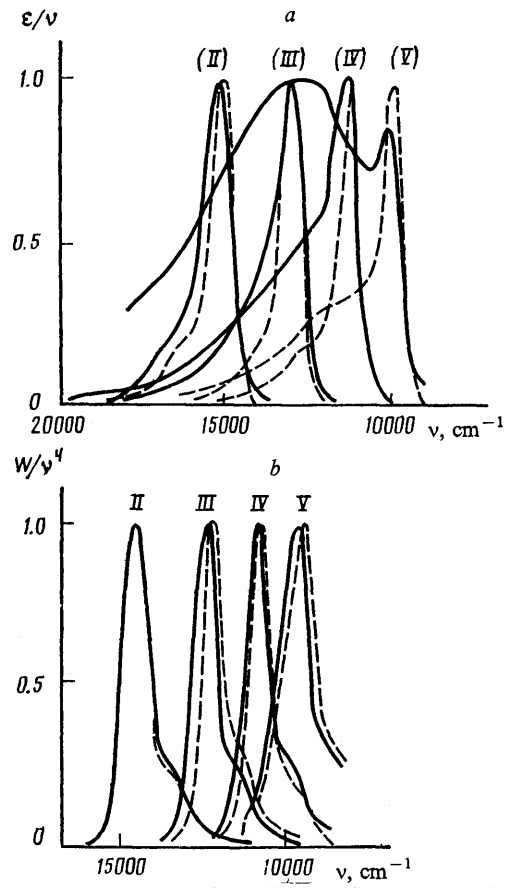
(I) - (V)

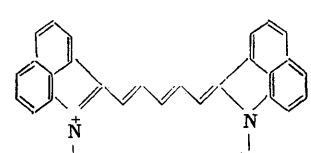
Dye	n	λ^a_{max}, nm	λ^a_{max}, nm (CH_2Cl_2)
(I)	1	560	580
(II)	2	665	683
(III)	3	770	793
(IV)	4	895	918
(V)	5	1000	1023

The shapes of the bands in the absorption and fluorescence spectra, in contrast to their maxima, change in different ways with increase of n (Fig. 1*a*, *b*). Lengthening of the PC leads to a sharp fall in the selectivity of absorption (to a decrease in intensity and widening of the bands).[34] In addition, the dependence of the shape of the absorption bands on the nature of the solvent is increased (Fig. 1*a*). Conversely, the fluorescence bands become narrower with increase of n, and their shape is practically independent of the nature of the solvent[38] (Fig. 1*b*).

The shapes of the absorption and fluorescence bands of PD are determined mainly by vibrational and intermolecular interactions.[34,39] With increase of n in symmetrical cyanines, the former gradually become less, but the latter increase in strength.[34] A decrease in vibrational interactions leads to a narrowing of the bands, and an increase in intermolecular interaction leads, conversely, to broadening.[34] In the spectra of the thiocyanines (I)–(V), the described effects are explained by the dominant role of intermolecular interactions in absorption and of vibrational interactions in fluorescence.[38]

The length of the PC has a considerable effect on the quantum yield of fluorescence. Thus, for the symmetrical thiocyanines (I)–(V) and their analogues with benzoxazole and indolene radicals, the magnitude of φ increases with increase of n from 0 to 2–3.[35] For $n > 3$ the quantum yield for these PD decreases sharply.[35] For $n = 0$ and $n \geqslant 4$, the magnitude of φ is $< 1\%$. In the case of di- and tri-carbocyanines, φ varies within the range 25–58%.[35]





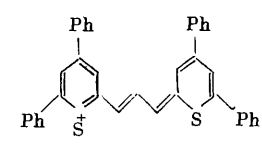


Figure 1. Absorption (*a*) and fluorescence (*b*) spectra for PD (II)–(V) in CH_2Cl_2 (dotted lines) and in DMF (continuous lines).

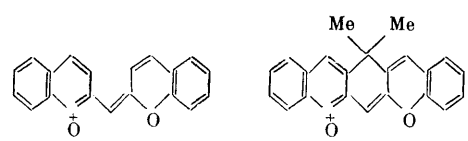
Small values of φ for the lower vinylogues are caused by effects arising from the close proximity of the nuclei, leading either to deviation from coplanarity,[40] or to interaction between the non-bonded heteroatoms.[41] The fall in the quantum yield of fluorescence with the higher vinylogues is caused, apparently, by the increased probability of internal conversion with increase of n, on account of a decrease in the energy difference between the ground (S_0) and first excited (S_1) states.[43,44] Such an assertion accords well with the fact that cyanines (VI) (λ^a_{max} = 876 nm, φ = 0.1%) and (VII) (λ^a_{max} = 865 nm, φ = 0.2%), with much shorter PC than the tetracarbocyanine (IV) whilst absorbing in practically the same region,[35] have almost the same values of φ.

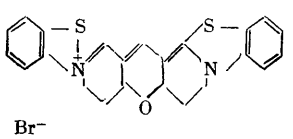
(VI)



(VII)

The life times of the excited states of PD vary with increase in n in the same way as the quantum yields of fluorescence, since the change in τ[45–47] with lengthening of the PC results from the same causes as the change in φ.

Attention is drawn to the fact that for PD with an open PC, even in the optimum region of absorption in which internal conversion is a minimum, the quantum yields of fluorescence are mainly in the region of 20–40% and only in the case of oxatricarbocyanine, φ = 58%.[35] Moreover, it is possible that the latter value is overestimated, as are the values of φ for thio- and indotricarbocyanines, since later measurements on these PD by other authors[48] gave smaller magnitudes for φ on the second occasion. These facts indicate that low values of quantum yields for PD with open PC are linked not only with internal conversion but also with the nature of the chain.

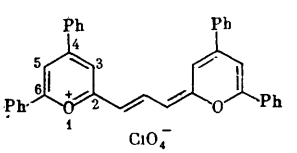


In symmetrical PD, the lengths of the carbon–carbon bonds are to a large extent equalised, as in aromatic compounds, and approximate to a bond order of one and a half.[49] Therefore rotation about these bonds is difficult by comparison with ordinary bonds. Nevertheless, the energy required is not large (33–63 kJ mol^{-1}).[40] In the ground state, dyes having no substituents in the PC and with $n \geqslant 1$ exist mainly as all-*trans* isomers.[4,40] With the introduction of bulky substituents into the PC, rotation about the bonds occurs, leading to the formation of various types of *cis*-isomer.[4,40]

With electronic excitation, the order of the carbon–carbon bonds decreases considerably,[50] so that rotation becomes easier. Therefore PD easily form photoisomers, which serve as basic "channels" for deactivation of the electronic excitation energy of cyanines.[4] The formation of photoisomers causes a sharp reduction in both the quantum yield and the life-time of the excited state.[3,51–53] Therefore, in spite of the fact that the oxygen analogue of PD (II), widely known as DODCI, possesses a nanosecond τ in its normal state, it is effective for passive mode synchronisation in dye lasers under pico- and even femto-second conditions[54] (it works as a short-life photoisomer[55,56]). It should be noted, that deactivation of the excited state will occur not only through rotations about the carbon–carbon bonds of the PC, but also through torsional vibrations about them.[3,4] If these rotations or vibrations are not hindered, then no structural changes whatever, which favour an increase in φ, wil be able to raise it to a value approaching 100%.

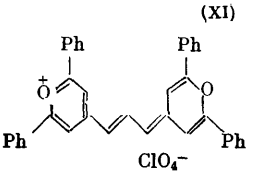
(VIII) (φ = 4%)

(IX) (φ = 97%)



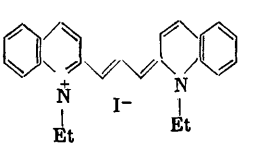
(X) (φ = 53%)

One way to solve this problem is by fixing the links of the PC rigidly with the aid of saturated bridging groups. Thus, for the monomethine cyanine (VIII), with an open PC, fluorescence is not visibly observed because of the low value of φ.[57] In the case of its analogue (IX), which has a rigidly fixed chromophore, such a strong golden-yellow luminescence is "kindled", that it masks the true crimsom colour of the dye which is like that of the compound (VIII). A sharp increase in φ is also observed by fixing the links of the PC of trimethine cyanines as, for example, in the case of PD (X).[58–60] In its benzoxazole analogues, φ = 80–90%.[58–60] Cyanines with completely fixed PC, containing five or more methine groups, are not known at present. There are certain PD with long PC, in which some of the groups form part of a saturated cyclic grouping,[61] but the fixing of separate parts of the PC only does not have such a significant effect on the value of φ,[62–65] as in the cases considered above.[58–60]

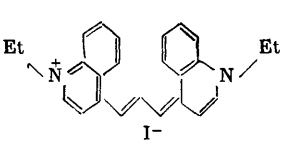


2. Influence of the structures of hetero-radicals on the spectro-luminescent properties of polymethine dyes

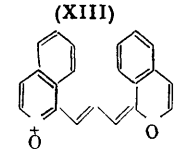
The structures of the hetero-radicals exert a very strong influence on the spectral-luminescent properties of PD. Thus, replacement of the benzthiazole nucleus in the dyes (I) and (II) with thiopyran or benz[*c*,*d*]indole groups [PD (VI) and (VII) respectively] gives rise to practically the same change in the absorption and fluorescence bands as does lengthening of the PC by two (*ca.* 200 nm) and three (*ca.* 300 nm) vinylene groups. In this way it is possible to obtain deeply coloured luminophores with short PC. Interest in such PD depends firstly on the fact that they are much more stable than dyes with long PC.[8,9]



Isomeric change in the hetero-radicals has a significant effect on the spectral-luminescent properties of PD. Thus, cyanines in which the pyranyl or thiopyranyl heterocycles are linked to the chromophore by atom C(2) [PD (XI)], absorb or luminesce in a significantly longer wavelength region of the spectrum than their isomers, the pyran-4-yl (or thiopyran-4-yl) cyanines [PD (XII)].[41] For the nitrogen analogues of PD (XI) and (XII)[41] and the quinocyanine PD (XIII) and (XIV)[66] the opposite is true.



(XI)



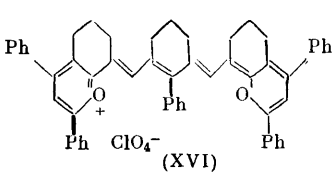
(XII)

(XIII)

(XIV)

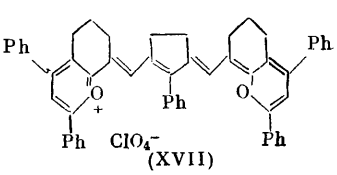
(XV)

PD	λ^{a}_{max}, nm (CH_2Cl_2)	σ, cm^{-1}	φ, %	τ, ps	δ
(XI)	800	1176	1	—	0.176
(XII)	686	801	9	—	0.116
(XIII)	607	975	$\leqslant$0.01	9	0.182
(XIV)	713	769	2	37	0.083
(XV)	706	964	5	—	0.142



This is due to the fact that in pyran-2-yl- and thiopyran-2-yl-cyanines the carbon–carbon bonds in the hetero-radicals participate less in the general system of conjugation than in the pyrid-2-ylcyanines because of the smaller tendency to conjugation of atoms of oxygen and sulphur in comparison with atoms of nitrogen.[41]

Isomerism of the hetero-radicals is also strongly reflected in the shapes of the electronic bands of PD. The majority of symmetrical cyanines, including (XII) and (XIV) have characteristic spectral curves of similar shape, with vibrational maxima in their short-wave region.[67,68] For pyran-2-ylcyanines and their analogues there are anomalies. At room temperature the spectral curves of these compounds [for example, for (IX), (XI), and (XIII)] have four vibrational maxima[57,69,70] which is not uncommon for complex organic dyes.[71,72] For the 2-isomers, the absorption and luminescence bands are quite broad,[41,66,73–75] but the magnitudes of φ and of τ[76,77] are substantially less than for PD of types (XII) and (XIV).



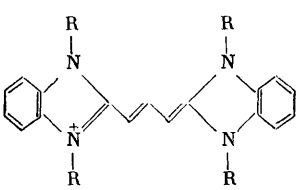
On the basis of quantum mechanical calculations using the squares of the changes in bond order (δ) on excitation[78] as a quantitative measure of the vibrational interactions in the PD chromophores, it was shown that there is an intensification of the vibrational structure, and a consequent widening of the bands, on going from the 4- to the 2-isomer in the pyranylcyanine series and their analogues.[79] Such an intensification is caused primarily by a sharp reduction in bond order between atoms C(3) and C(4) on excitation, a change which considerably exceeds that for all other bonds and which accounts for a significant contribution to the total magnitude of δ.[79]

Hence it follows that any structural modifications of the hetero-radicals of pyran-2-ylcyanines and their analogues, which hinder a change in the length of the bond between atoms C(3) and C(4), must lead to a weakening of the vibrational interactions. This can be achieved quite effectively as a result of annelation involving this bond, since a lowering of its order in the ground state decreases the extent to which it can change on excitation. Indeed, the bond between atoms C(3) and C(4) in cyanine (XV) contributes only 4% to the total magnitude of δ, whereas the analogous bond in the dye (XI) contributes 33%.[79] As a result, for PD (XV), a weakening of the vibrational interactions occurs, accompanied by a narrowing of the absorption bands in comparison to the analogous bands for compound (XI).

Vibrational interactions in molecules of PD are among the fundamental factors giving rise to a reduction in φ and τ.[80,81] It is very likely, therefore, that attenuation of their magnitude on going from the 4- to the 2-isomers is caused by an intensification of vibrational interactions. This assertion accords with the fact, that the excited states for pyran-2-yltricarbocyanines (XVI) and (XVII) have unusually short life times ($\leqslant 3$ ps).[19,77] Such small values of τ have made it possible to use PD (XVI) and (XVII) and their analogues as passive locks for lasers, with λ = 1060 nm, in order to generate impulses of extremely short duration.[19,77,82,83]

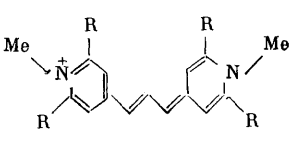
(XVI)

(XVII)



It should be noted, however, that the pyran-2-yl- and thiopyran-2-yl-cyanines are much more deeply coloured than the 4-isomers (by *ca.* 100–110 nm).[41] It can therefore be assumed that the reduction in φ and τ, on going from the latter to the former, is caused[43,44] by an increase in internal conversions. However, for the isomeric quinocyanines (XIII) and (XIV), the same tendency is observed in the changes in φ and in τ, in spite of the fact that pinacyanol (XIII) absorbs in a considerably more short-wave region (at 106 nm), than cryptocyanine (XIV). It can therefore be assumed that vibrational interactions play a dominant role in the reduction of φ and τ, on going from the 2- to the 4-isomer.

3. Influence of the nature of the substituents on the spectral-luminescent properties of polymethine dyes



To regulate the extent of vibrational interactions in molecules of PD it is possible to introduce substituents with various electronic characteristics[84] into different positions of the heteroradicals[85–90] and into the PC.[91,92] For example, additional intensification of the vibrational interactions and a consequent shortening of the life time of the excited state of the pyran-2-yltricarbocyanines (XVI) and (XVII) is achieved on account of the electron-donating saturated cyclic groupings.[92]

Substituents containing heavy atoms, for example bromine and iodine,[4] have a considerable influence on the deactivation of electronically-excited states. They significantly increase the probability of intersystem crossing $S_1 \rightsquigarrow T$, because of the sharply decreasing values of φ and τ corresponding to the PD.[93] The role of such substituents in PC is more important than in the hetero-radicals.[93]

Substituents with their own conjugated electron system, such as those that are able to increase the Stokes shift of the PD molecules significantly, are of great interest.[93] Thus, the replacement of ethyl groups in the cyanine (XVIII) by phenyl [PD (XIX)], or better still by a heterocycle [PD (XX)], leads to an increase in ΔS and in φ.[94]

(XVIII)—(XX)

(XXI), (XXII)

PD	R	λ^a_{max}, nm	λ^f_{max}, nm	φ, % (ethanol)
(XVIII)	Et	500	515	0.5
(XIX)	Ph	519	563	5
(XX)	Py	530	593	25

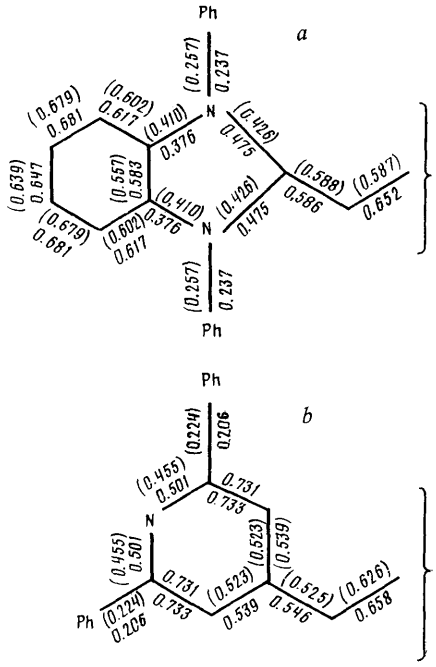
PD	R	λ^a_{max}, nm	λ^f_{max}, nm (CH_2Cl_2)
(XXI)	Me	610	620
(XXII)	Ph	644	673

These effects have been shown to be associated with intramolecular processes. The increase in φ, by the introduction of substituents with their own π-system, is thought to be due to a decrease in the probability of the formation of stereoisomers, on account of "weighting" of the PD molecule with these substituents.[94] The increase of the Stokes shifts in the cited work is not explained. However, an explanation may easily be given on the basis of an analysis of the change in electronic structure of PD (XIX) and (XX) on excitation.

In the ground state of cyanine molecules (XIX) and (XX), the phenyl and pyridyl groups are displaced from the plane of the basic chromophore to a considerable extent, on account of steric hindrance by the atoms of hydrogen in positions 4,4′; 7,7′; and

8,8′. In the excited state, it follows from simple Hückel molecular orbital calculations for PD (XIX) (Fig. 2), that the bonds between N and C(2); C(4) and C(3*a*); C(7) and C(7*a*) are lengthened significantly. (In the calculations the parameters used were taken from Ref. 95, the angle of rotation of the phenyl group being represented by a value of $\beta_{C-Ph} = 0.7$). The steric hindrance to rotation of the phenyl groups is thereby reduced and they can therefore become much more nearly coplanar on excitation. Approach to coplanarity will also be favoured by the fact that in the excited state the N–Ph bond order is increased. A more planar structure for the phenyl (or pyridyl) substituted PD, (XIX) and (XX), in the excited state, compared with the ground state, leads to a larger bathochromic shift of the fluorescence bands than for the absorption bands. Therefore, a change from cyanine (XVIII) to (XIX) or (XX), is accompanied by an increase in ΔS.

On the basis of the above, it can be concluded that the introduction into a PD molecule of substituents with their own conjugated electron systems, capable of becoming more nearly coplanar on excitation, brings about an increase in the Stokes shift. Indeed, the replacement of methyl groups in the cyanine (XXI) by phenyl [PD (XXII)], increases ΔS. This arises from the fact that steric hindrance between the Ph and methyl groups in the ground state gives rise to a considerable departure from coplanarity with the chromophore,[96] but in the excited state, as a result of a decrease in the bond order of the bonds between the atoms of C and N and an increase in the order of the Ph–C bonds (Fig. 2), the groups becomes much more nearly coplanar.



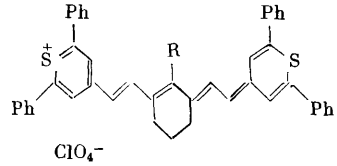


Figure 2. Orders of the π-bonds in the cations of PD (XIX) (*a*) and (XXII) (*b*) in the ground state and (in brackets) the excited state.

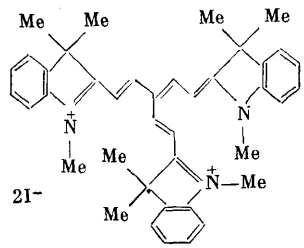
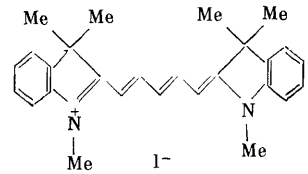
An analogous change in the conformation of the phenyl groups on excitation explains the anomalous Stokes shifts for 2,6-diphenyl substituted pyridine salts.[97–100]

In the *meso*-position of tricarbocyanines, the phenyl group also deviates considerably from the plane of the chromophore in the ground state.[101] However, replacement of the hydrogen atom in this position in the thiopyran-4-yltricarbocyanine (XXIII) with a phenyl group (compound XXIV) does not in practice increase ΔS.[102] The phenyl group in PD (XXIV) moves little towards coplanarity in the excited state.



(XXIII), (XXIV)

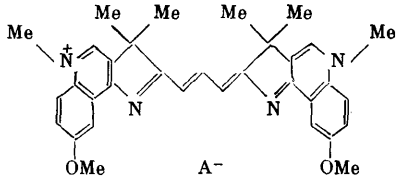


PD	R	λ^a_{max}, nm	λ^f_{max}, nm (CH_2Cl_2)
(XXIII)	H	1035	1090
(XXIV)	Ph	1040	1097

Especially large increases in Stokes shifts occur with the introduction into the *meso*-position of substituents that lead to branching of the PC, i.e. to the formation of tricyclic PD, for example (XXV), and its analogues.[103,104]

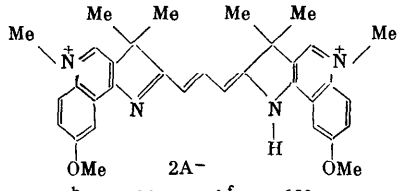
The magnitude of ΔS for the tricyclic dye (XXV) (1597 cm^{-1}) is almost twice that for the corresponding bicyclic PD (XXVI) (632 cm^{-1}).

(XXV): $\lambda^a_{max} = 636$ nm, $\lambda^f_{max} = 698$ nm



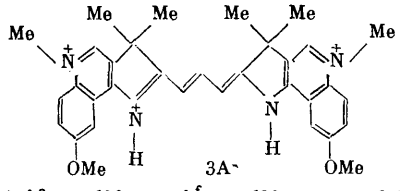
(XXVI): $\lambda^a_{max} = 640$ nm, $\lambda^f_{max} = 667$ nm.

Such a marked effect depends on the considerable change in geometry that occurs on excitation of the molecule (XXV) compared to (XXVI). In the ground state, tricyclic dyes have a propellor-like structure but in the excited state each of their nuclei in turn becomes perpendicular to the plane of the other two.[103,104] In bicyclic cyanines, excitation mainly brings about a change in bond lengths.



An increase in the Stokes shifts for PD (XXV) and its analogues is accompanied, in contrast to cyanines (XVIII)–(XX), by a marked lowering of φ.[104,105] This is linked with the fact that for tricyclic dyes the coplanarity is disturbed and there is a much more pronounced alternation of the bonds in the PC, than in the corresponding bicyclic dyes.[103,104] Consequently, the vibrational interactions and conformational processes are intensified in the former by comparison with the latter, with the result that PD (XXV) fluoresces much more weakly than (XXVI).

4. Photochemical reactions with proton transfer



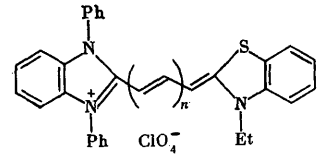
Large values of Stokes shifts and high quantum yields of fluorescence can be achieved for certain PD, for example (XXVII), through reversible photochemical reactions with proton transfer.[106,107] In absolute ethanol, this dye exists in the monocationic form (XXVII, a). On acidification with weak acids the protonated, dicationic form (XXVII, b), is produced. As a result, the electronic symmetry is disturbed and the conjugation of the chain is shortened, so that it absorbs in a considerably more short-wave region of the spectrum, than (XXVII, a). In strongly acidic solutions, compound (XXVII)

(XXVII, a): $\lambda^a_{max}=710$ nm; $\lambda^f_{max}=735$ nm; $\varphi=24\%$,

(XXVII, b): $\lambda^b_{max}=530$ nm; $\lambda^f_{max}=650$ nm; $\varphi=7\%$,

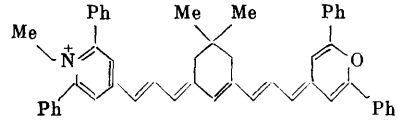
(XXVII, c): $\lambda^a_{max}=600$ nm; $\lambda^f_{max}=620$ nm; $\varphi=3.5\%$,

exists in the diprotonated, tricationic form, (XXVII, c). In this case the electronic symmetry of the molecule is restored, but the chain of conjugation becomes shorter. The absorption band of form (XVII, c) is therefore found in an intermediate region between the forms (XXVII, a) and (XXVII, b). For the PD (XVII) in the ground state there is an equilibrium (XXVII, a)$\rightleftharpoons$(XVII, b) or (XVII, b)$\rightleftharpoons$(XXVII, c), depending on the pH.



On excitation form (XXVII, b) results, with the loss of a proton, on account of redistribution of electron density in the chromophore. Therefore in the fluorescence spectra, in addition to the band of the dication (XXVII, c) the band responsible for the form (XXVII, a) appears, with a high value of φ, providing a large Stoke shift relative to the absorption of form (XXVII, b). This has made it possibe to use the equilibrium (XXVII, b)$\rightleftharpoons$(XXVII, a) for the generation of laser emission in the region of 720–810 nm, i.e. with a large shift relative to the wave length pumped, λ_P (λ_P = 530 nm).[106,107]

The form (XXVII, c) does not generate emission, most probably because of the low value of φ. In addition, it does not change on excitation into form (XXVII, b), or into form (XXVII, a). The first transformation does not occur because dissociation of the diprotonated form with formation of the excited monoprotonated form is energetically unfavourable, and the second is of low probability since it requires the simultaneous transfer of two protons.



Photochemical reactions with proton transfer are highly sensitive to change in pH of the medium and are only characteristic of a small number of PD. These circumstances give rise to their wide application for the transformation of light energy.

5. Electronic asymmetry and spectral-luminescent properties of polymethine dyes

Asymmetrical PD are far more promising for the transformation of light energy.

(XXVIII) – (XXX)

(XXXI)

PD	n	Solvent	λ^a_{max}, nm	D^a_λ, nm	λ^f_{max}, nm	D^f_λ, nm
(XXVIII)	1	DMF	528	13	567	7.5
(XXIX)	2	DMF	618	22	670	2.5
(XXX)	3	DMF	645	95	779	5.0
(XXXI)	—	MeCN	610	387.5	1020	35.0

In the ground state of these cations the charge is mainly localised on the more electron-donating nucleus,[108–111] so that an alternation of single and double bonds arises in the PC leading, in the absorption spectra, to a rise in the deviation (D^a_λ), attenuation of the vinylenic shifts, and broadening of the bands.[108–111]

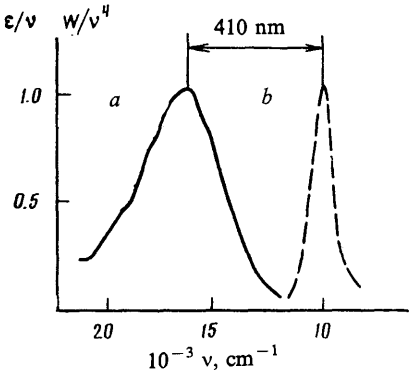
In the excited state, the nuclei of the hetero-radicals become equivalent to a considerable extent. For example, in the S_1-state of PD (XXX),[111] the total charges on the benzimidazole and benzthiazole radicals amount to 0.640 and 0.631, whereas in the S_0 state they are 0.858 and 0.388 respectively. Equalisation of the charges on the hetero-radicals and, consequently, equalisation of their electron-donating abilities, greatly reduces the alternation in the bond order in the PC of the cation in the excited state. Thus, for example, a measure of their alternation, calculated as described[57] for the dye (XXX) in the excited state, is 0.098 but in the ground state is 0.126. Consequently, typical electronically-asymmetric PD tend towards electronic symmetry in the excited state. This leads to a sharp decrease in the deviation in the fluorescence spectra (D^f_λ), a narrowing of their bands, and a rise in the vinylenic shifts of approximately 100 nm, i.e. to values characteristic of symmetrical PD. Asymmetric PD also retain high values of φ, at the level of the symmetrical PD.[112]

A marked difference in the electronic structure of asymmetric PD in the ground and excited states causes a large Stokes shift. Since this occurs for high values of φ, then highly effective generation of radiation was obtained for solutions of asymmetric cyanines in the near infrared region (650–900 nm).[112,113] It is significant, that in view of their wide absorption bands,[111-113] the generation of emission by PD of types (XXVIII)–(XXX) occurs with a pump of different

wave length from the most used sources of radiation in the visible range (510, 530, 578, 694 nm).[112,113] Asymmetric PD are advantageously different in this respect from the wide range of active media based on coumarins, rhodamines and oxazines.[112,114]

Variations between the absorption and fluorescence spectra of asymmetrical PD are more significant, the greater their electronic asymmetry. The latter increases regularly with increase in the difference in electron donating ability of the hetero-radicals and with the length of the PC.[109–111]

Pyrid-4-yl-pyran-4-yl-tetra- and -pentacarbocyanines have been described,[115] with the highest electronic asymmetry amongst organic dyes. In their absorption spectra, the deviation amounts to 545 nm (7450 cm^{-1}). However, these PD approach the symmetrical cyanines to a considerable extent in their luminescent properties in the excited state.[115] In the fluorescence spectra, the deviation falls to 35–65 nm (320–650 cm^{-1}).[115] The Stokes shift for PD (XXXI) amounts to 410 nm (6590 cm^{-1}), the highest value for all known dyes (Fig. 3). Unfortunately, the quantum yield of fluorescence is extremely small (< 0.01%) because, apparently, of strong vibrational interactions.[115]



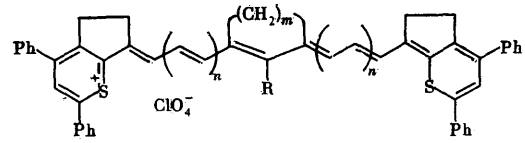


Figure 3. Absorption (*a*) and fluorescence (*b*) spectra of PD (XXXI) in MeCN.

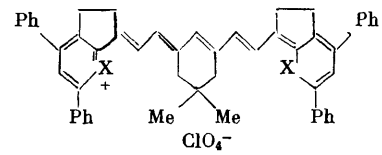


6. Spectral-luminescent properties of polymethine dyes in highly concentrated solutions

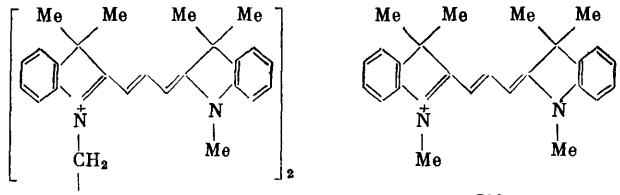
Highly concentrated solutions of the tri-, tetra-, and pentacarbocyanines (XXXII)–(XXXVI), absorbing in the region 1270–1500 nm, have interesting spectral-luminescent properties.[27,116,117] Thus, with increase in the concentration of the dye (XXXII) to 10^{-3} mol L^{-1} and above, in parallel with quenching of its principal fluorescence band at λ^{f}_{max} = 1283 nm, a new long-wave emission band is observed of approximately three times the intensity and with λ_{max} = 1613 nm.[116,117] The absorption spectrum of this compound remains unchanged for the whole working range of concentrations (10^{-5}–10^{-2} mol L^{-1}). On the basis of these data, longwave luminescence is explained by the formation and decomposition of associations of excited molecules.[116,117] In the ground state, molecules of PD (XXXII) are not associated, because the bulky phenyl groups that are present, displaced from the plane of the heteroradicals,[96] do not allow the molecules to approach sufficiently. On excitation of the pyran-2-ylcyanines and their hetero analogues, a considerable elongation of the carbon–heteroatom bonds occurs.[79,118] This decreases the steric hindrance between the heteroatoms and phenyl groups considerably. The orders of the C–C(Ph) bonds in the excited state are increased.[118] Both circumstances allow the phenyl groups to move into the plane significantly in the excited state and considerably facilitate the formation of associations.

(XXXII)–(XXXIV)

PD	*n*	*m*	R
(XXXII)	0	2	Ph
(XXXIII)	0	2	H
(XXXIV)	1	3	Ph

(XXXV), (XXXVI)

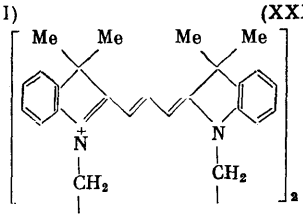
X = S (XXXV), X = Se (XXXVI).



Highly concentrated solutions of PD (XXXII)–(XXXV) generate emission in the most longwave region 1400–1800 nm, with λ_P = 1060 nm.[27,117] This method should be promising for the generation of emission in the near infrared range, since it makes possible a considerable increase in both ΔS and φ. To bring about a significant increase in the quantum yield of fluorescence for monomeric organic dyes that absorb at more than 1200 nm, by means of structural changes, is highly problematical [for PD (XXXII)–(XXXVI), φ = 0.01–0.1%],[27] since small energy intervals and the effective promoting roles of high frequency CH-vibrations in this region, make internal conversion a powerful channel for the decay of electronic excitation.[44,119]

7. Spectral-luminescent properties of polymethine dyes with two chromophores

Much attention has been given recently to the investigation of spectral-luminescent properties of compounds with two chromophores,[120–123] since the intramolecular transfer of absorbed light energy from one chromophore to the other allows them to re-emit it effectively with a large red shift. Polymethine dyes with two chromophores (biscyanines) became known in 1965.[124] Fundamental relationships between the absorption spectra of PD and their chemical structure have been established.[125] Only the first steps have been taken towards the establishment of analogous relationships for the luminescence spectra of biscyanines.[126–129] Luminescence has previously been taken only as evidence for the structure of PD with two chromophores.[130,131]



In the case of the biscyanines, resonance interaction of the chromophores, according to exciton theory,[132] causes splitting of the S_1-level into levels with higher energy S'_1 and lower energy S''_1.[125–128] In a number of cases, splitting into a *T*-level is also possible.[133] Electronic transitions $S_0 \rightarrow S'_1$ and $S_0 \rightarrow S''_1$ give rise to short- and long-wave bands respectively in the absorption spectra of biscyanines, compared to the bands associated with the $S_0 \rightarrow S_1$ transition in the monomeric (parent) dyes.[125–128] For illustration,

the spectra of the bisindocarbocyanine (XXXVII) and the parent indocarbocyanine (XXXVIII) can be compared.[128,134]

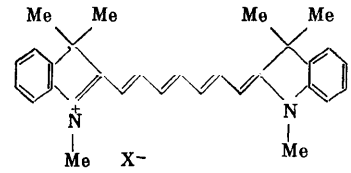
ClO_4^- (XXXVII)

ClO_4^- (XXXVIII)

ClO_4^- (XXXIX)

PD	λ^a_{max}, nm	λ^f_{max}, nm (CH_2Cl_2)
(XXXVII)	508, 570*	581
(XXXVIII)	550	570
(XXXIX)	506*, 590	662

*The more intense absorption band.

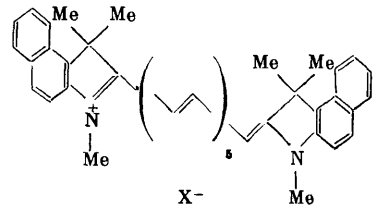


The transition $S'_1 \rightsquigarrow S''_1$ in the dimers is non-radiative.[135] Therefore, on excitation of the biscyanines, for both the short- and long-wave absorption bands, fluorescence is seen only from the S''_1-level. This situation gives rise to an increase in the shift of the emission bands relative to the shortwave absorption bands and the increase is greater, the more sharply the bands in the absorption spectra of the biscyanines move apart. According to exciton theory, the absorption bands move apart to a maximum for parallel orientations of the chromophores.[132] Therefore the change from the bis-dye (XXXVII) to (XXXIX) is accompanied by a sharp increase in the bathochromic shift of the fluorescence band relative to the short-wave absorption band.

It should, however, be borne in mind that long wave transition is forbidden for parallel orientations of the chromophores.[132–135] Luminescence occurs as a result of partial remission of the band, because of distortion of the "sandwich" structure (of the dye XXXIX) and slight displacement of the chromophores relative to each other, because they have a step-like form.[131] Therefore the luminescence of the dimers of such a structure is weak. It is also weak in the biscyanines with angular dispositions of the chromophores, for example in (XXXVII), by comparison with the monomeric PD (XXXVIII).[129] This, first of all, gives rise to an increase in the probability of intersystem crossing with change from the parent compounds to the bis-dyes.[136] This increase takes place on account of the decrease in energy difference between the S''_1 and T levels in the dimers in comparison with the S' and T levels in the monomers.

It appears to be possible to increase the luminescence of the dimers, as also of associations of some organic dyes, by the "kindling" of delayed luminescence.[137] In the dimers, it must in fact occur more easily than in the monomers, because of the increase in the probability of both $S_1 \rightsquigarrow T$ and the reverse $T \rightsquigarrow S_1$ transitions.[138]

III. The influence of the nature of the counter-ion on the spectral-luminescent properties of polymethine dyes



It has traditionally been thought that the spectral-luminescent properties of PD are not dependent on the nature of the colourless counter-ion but are determined only by the structure of the chromophore.[8–11] In the example of the caitonic indotricarbocyanines (XL) and (XLI) it has been shown[139] that in solvents of low polarity, as opposed to polar, the anion has a strong influence on the position, intensity and shape of the absorption bands.

(XL), (XLI)

PD	X	Solvent	λ^a_{max}, nm
(XL)	ClO_4	benzene	734*, 790
		ethanol	744
(XLI)	I	benzene	730, 790*
		ethanol	744

*The more intense band

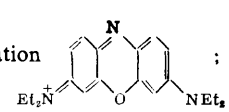
(XLII)—(XLIV)

PD	X	λ^a_{max}, nm	λ^f_{max}, nm	τ, ps (dichloroethane)
(XLII)	I	1035	1075	97
(XLIII)	ClO_4	1035	1120	75
(XLIV)	BF_4	1035	1150	55

In the light of these published results, a wide range of investigations into the spectral-luminescent, nonlinear-optical, photophysical, and photochemical properties of cyanines in low polarity media, has subsequently been developed. On the basis of a study of ionic equilibria, the influence of salt addition, temperature, and the addition of polar ionising solvents, it was confirmed that solutions of indotricarbocyanines (XL) and (XLI) follow the Lambert-Beer law, and that the dependence of their absorption spectra on the nature of the counter-ion is caused by the formation of various types of ion pair. This conclusion was later confirmed by electroconductivity data.[140] Further investigations showed that the formation of such pairs can also give rise to marked changes in the spectral-luminescent properties of other types of salt-like PD.[141–144] A need arose to establish the structures of polymethine ion pairs.

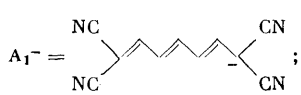
The structures of ion pairs of dyes of the indolene and benz[*c,d*]indole series have been studied by means of ^1H, ^{14}N, and ^{15}N NMR spectroscopy[143,145,146] and by NMR with lanthanide shift reagents. It was shown for these PD that the anion is located in the

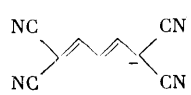
region of the nitrogen heteroradical, at which the maximum positive charge is shown, by quantum chemical calculations, to be concentrated.[143,144] On electronic excitation, a redistribution of charge occurs in the cations of the dye. Therefore the probabilities of formation of ion pairs in the ground and excited states are different. Thus, the positive charge on the cation of the pentacarbocyanines (XLII)–(XLIV) is more localised on the heteroradical in the S_1-state than in the S_0.[147] In the excited state, therefore, they form ion pairs more readily than in the ground state. Indeed, in dichloroethane, the position of the absorption band of PD (XLII)–(XLIV) does not depend on the nature of the anion. Conversely, the fluorescence band is displaced into the longwave region for the series of anions $I^- \rightarrow ClO_4^- \rightarrow BF_4^-$.[147] In this same series the values of φ and τ decrease regularly.[147]



The described effects are caused by an intensification of electrostatic interactions and consequently, the formation of tighter ion pairs in the above mentioned sequence of anions in agreement with equivalent electroconductivity and dissociation constant data for pentacarbocyanines.[148] Intensification of electrostatic interactions on changing from I^- to ClO_4^- and BF_4^-, lowers the energy of the activated state,[147] and leads to a bathochromic shift of λ_{max}^{ϕ}.[147] In addition, the localisation of the anion at one of the heteroradicals gives rise to a disturbance of the electronic symmetry of the dye, leading to a displacement of the positive charge in this state. As a result, an alternation of bond order in the PC arises for the pentacarbocyanines (XLII)–(XLIV), and also for the asymmetric cyanines.[111] This, on the one hand, intensifies the vibrational interactions[110,111] but, on the other, increases the probability of isomerisation or, to a lesser extent, intensifies the critical vibrations around the bonds of the chain.[4] Both of these processes lead to an attenuation of the magnitude of φ and τ. Vibrational interactions and the probability of rotation about the bonds is greater, the tighter the ion-pairs that are formed. Therefore in the series of PD (XLII)–(XLIV) there is a regular decrease in the quantum yield of fluorescence and the life time of the excited state.[147]

A still greater effect on these values in low polarity media is caused by coloured organic anions, having their own system of π-bonds[149] as, for example, in the dyes (XLV), (XLVI) and (L).





PD	Dye*	Solvent	λ_{max}^{a}, nm
(XLV)	$K_1^+A_1^+$	benzene	549, 763
(XLVI)	$K_2^+A_1^-$	,,	535, 663
(L)	$K_3^+A_2^-$	dichloroethane	448, 1030

PD	Dye*	Solvent	λ_{max}^{a}, nm
(XLVII)	$K^+{}_1C(CN)_3^-$	benzene	753
(XLVIII)	$K^+{}_2ClO_4^-$	,,	658
(XLIX)	$\overset{+}{N}(CH_3)_4A_1^-$	,,	551
(LI)	$Na^+A_2^-$	dichloroethane	448

*Designation adopted:

K_1^+ = cation of dye (XLI); K_2^+ = cation  ;

K_3^+ = cation of Pd (XLII)–(XLIV);

A_1^- =  ; A_2^- = 

Cation-anion dyes (XLV) and (XLVI) form ion-pairs in solvents of low polarity as do the corresponding cationic types.[149] In these ion-pairs, on account of the electrostatic forces of attraction, the two chromophores which have different electronic structures become "associated", in contrast to the chromophores of the biscyanines considered above. If the initial cationic and anionic dyes absorb in similar regions then the formation of a cationic-anionic compound will be accompanied by resonance interactions of the chromophores, leading to a change in the position of the electronic bands, as in the case of the biscyanines. For the cationic-anionic compounds (XLV) and (XLVI) in benzene, the absorption bands move apart: the longwave bands moving bathochromically and the shortwave bands hypsochromically, relative to the absorption bands of the corresponding cationic (XLVII), (XLVIII) and anionic (XLIX) dyes.[149]

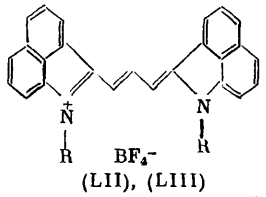
For compound (XLVI) the absorption bands move apart to a greater extent than for (XLV), since (XLVIII) and (XLIX) absorb light at closer wave lengths than compounds (XLVII) and (XLIX).

For the cationic-anionic dye (L) there are also two absorption bands, but these do not move apart in comparison with those of the corresponding cationic and anionic cyanines.[150,151] This is due to the fact that the regions of absorption for the cationic and anionic chromophores differ sharply. Therefore resonance interactions, leading to splitting of the S_1-level and, consequently, to separation of the bands for PD (L), do not take place. Absorption bands for the cationic-anionic compound (L) are characterised by a significantly smaller integral intensity and greater width than the absorption bands of the corresponding cationic (XLII) and anionic (LI) dyes,[150,151] as the result of the formation of an ion pair, disturbing the electronic symmetry of the chromophore for the former more strongly than for the latter. Such a difference is due to the presence of a system of easily polarisable conjugated bonds and alternating positive and negative charges in the anions of cationic-anionic dyes, in contrast to the anions of the cationic types. It is able to increase the electronic asymmetry of the chromophores on account of non-resonance interactions with the analogous system of bonds of its cation and therefore cationic-anionic dyes have lower values of φ and τ than the corresponding cationic dyes.[150,151] For compound (L) in dichloroethane, τ = 49 ps, and for its analogue with the trimethineoxanine anion it falls to 24 ps.[150,151]

In polar solvents, the spectral-luminescent properties of PD (XL)–(LI) are independent of the nature of the anion, since these dyes are completely dissociated in these solvents.

Such a large reduction of τ in cationic-anionic compounds, with practically complete transparency at λ = 1060 nm, allows their use as effective passive locks for solid state lasers.[150] Cationic PD (XLII), widely known in the USSR under the number 3955 and having a large value of τ, works well in quality modulation.[152]

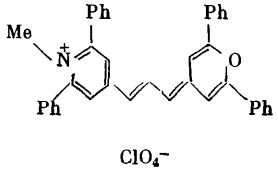
Cationic-anionic compounds, like mixtures of PD with other classes of dye, for example PD (II) plus rhodamine S[153] or PD (XLI) plus oxazine 750,[155] may also be used successfully for the transformation of light energy, with a large red shift. This shift, as in the case of the biscyanines, is achieved on account of the separation of the short- and long-wave bands of their ion pairs as a result of interaction of the chromophores. They are more promising than mixtures of dyes as transformers of light energy, since transfer of energy within ion pairs may occur in dilute solutions and is not dependent on the concentration of the dye, as is the case for the original components of mixtures. The latter circumstance may lead to undesirable concentration effects in mixtures of dyes.[156–158]



IV. Structure of associations of ion pairs of polymethine dyes

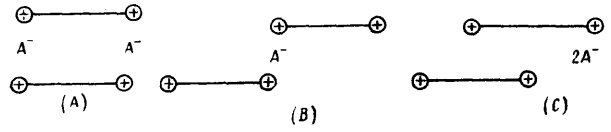
Salt-like cyanines with simple anions can also prove to be excellent transformers of light energy when they are associated. The association of PD in silver halide photographic emulsions has been widely investigated, since they have a considerable effect on the sensitising ability of cyanines in these emulsions.[10,159] Until recently, therefore, attention was given primarily to the problem of aggregation of dyes in aqueous solvents.[160] In these solutions, associations of cyanines are of low stability. They dissociate easily on warming.[161] In water and especially in other polar solvents aggregation of dyes occurs at high concentrations. This leads to concentration quenching of luminescence.[156]

Conversely, in low polarity media, cyanines easily associate in dilute solutions ($10^{-7}-10^{-5}$ molL^{-1}) at room temperature.[141,143] This is caused by the fact that the association of PD in low polarity media, in contrast to polar, comes about on account of both dispersion interactions and electrostatic interactions of different charges in the ion pairs according to the scheme $K^+A^-...K^+A^-$.[141-143]



The study of association of salt-like dyes in low polarity solutions is frequently very difficult because of their low solubility. However for PD this problem can be solved by the introduction of aliphatic hydrocarbon radicals into their molecules.[143] Recently, interest in such PD has revived sharply in connection with their ability to form a Langmuir-Blodgett poly-layer,[162-170] which finds wide application in various fields of science and technology.[171]

The influence of processes of association in low polarity media on the spectral-luminescent properties of salt-like cyanines have been investigated in detail.[141-144]



(LII), (LIII)

R = $C_{10}H_{21}$ (LII); R = $CH_2C_6H_4$ (LIII)

(LIV)

It has been shown that PD with a planar structure, not containing bulky substituents, for example (LII), easily form associations of ion pairs with a "sandwich" structure on lowering the polarity of the solution.[141-144] The formation of a "sandwich" structure favours the localisation of the anion in the region of the nitrogen heterocycle.[143] This is due to the fact that the terminal cations on both sides attach "rigidly" to the anions, because of the electrostatic attraction of the differing charges of the monomers of the ion pairs (Structure A).[143] Structure A is also advantageous from the point of view of dispersion interactions, since these are maximum for parallel orientations of the chromophores.[135] Therefore "sandwich" salt-like cyanines have high strength in low polarity media. They do not decompose on boiling even in high-boiling point, low polarity solvents,[143] in contrast to cyanines in polar, particularly aqueous, solvents.

(A) (B) (C)

The formation of associations with structure (A) is acompanied by a fall in the intensity of the absorption and luminescence bands of monomeric PD molecules to practically complete extinction and the appearance of new short-wave absorption bands (Fig. 4*a*, *b*). Thus for compound (LII) in low polarity media, the absorption band of its "sandwich" structure is shifted hypsochromically by 100 nm more than is the absorption band of the monomer.[141-144]

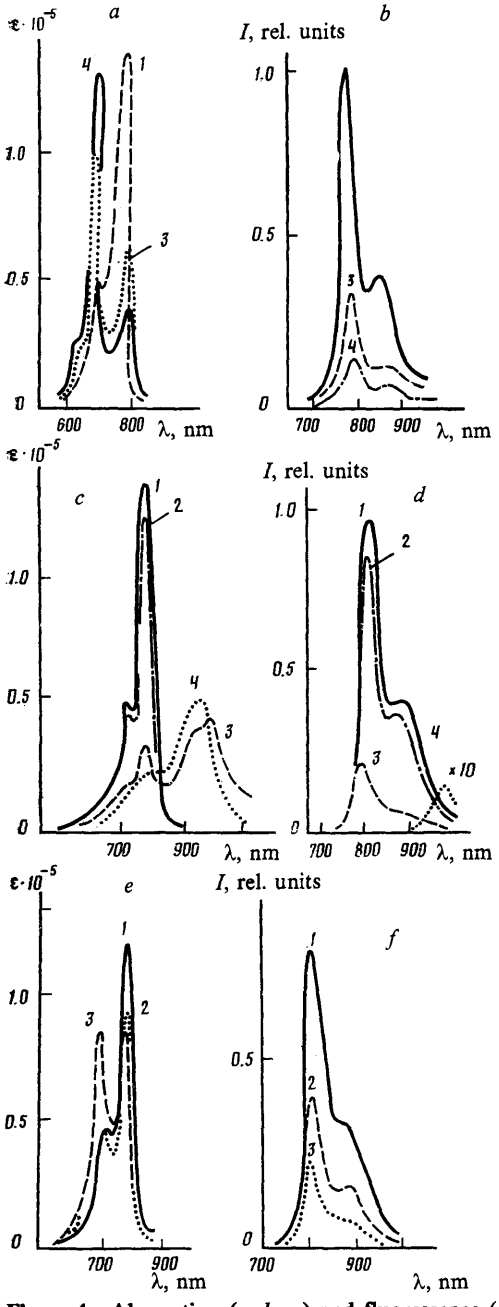


Figure 4. Absorption (*a*, *b*, *c*) and fluorescence (*d*, *e*, *f*) spectra of PD (LII) (*a*, *b*) and (LIII) (*c*–*f*) for $C = 10^{-5}$ mol L^{-1} in mixtures of CH_2Cl_2 and hexane (*a*–*d*) (CH_2Cl_2 content in %): *1*, 100; *2*, 50; *3*, 20; *4*, 10) and in DMF–water (*e*, *f*) (DMF content in %): *1*, 100; *2*, 20; *3*, 10. Fluorescence spectra standardised against the spectra of (LII) in CH_2Cl_2.

The introduction of bulky substituents hinders the formation of associations with structure (A). They are especially effective in the region of the heteroradicals, where the maximum positive charge is concentrated, since they hinder the "rigid" attachment of cations of dyes in the type (A) structure. However, in this case, it is possible for the cations to be attached at one end in a "head-to-tail" structure (Structure B), in which the angle between the direction of the chromophores is close to 180°.[143,144] The formation of associations with structure (B) is accompanied by the appearance of electronic spectra with new long-wave bands.[135,160] For example, replacement of the decyl groups in the hetero-radicals of the dye (LII) by tolyl groups (compound LIII), which deviate significantly from the plane of the chromophore, [as in the case of cyanine (XIX)] leads to the appearance of these bands (Fig. 4*c*) on reduction of the polarity of the medium (i.e. with increase in the content of hexane in the hexane–methylene chloride mixture).

The magnitude of the shift of the absorption and luminescence bands of associated molecules of PD, with respect to the corresponding bands of the unassociated molecules, deserves special attention. This magnitude is *ca.* 200 nm, which is equivalent to lengthening of the PC of the dye by two vinylene groups. Since dyes with long chains are much less photochemically stable than those with short chains, it may be hoped that associations of type (B) will be promising for the transformation of light energy from the visible into the near infrared region of the spectrum, especially as these large shifts of the electronic bands occur in even dilute solutions. This ease of association of salt-like cyanines in low polarity solutions depends on strong electrostatic attraction between the differing charges in the ion pairs of the monomers.[143,144]

It is significant, that association of the dye (LIII) in polar solutions is accompanied by opposite changes.[144] As for the cyanine (LII), in parallel with a drop in absorption ability and quenching of the luminescence, there is a characteristic appearance of a new short-wave absorption band at a distance >100 nm from the absorption band of the monomer (Fig. 4*e*, *f*). This difference depends on the fact that in polar solutions the anion does not take part in association. Under these conditions, therefore, the chromophore does not need to be so precisely fixed in the "sandwich" structure as in low polarity media. In this connection, the PD (LIII) in the DMF–water system is able to form some deformed "sandwich" structures in which the chromophores are displaced with respect to each other (structure C), on account of dispersion interactions,[144] allowing a reduction in steric hindrance between the $N-C_6H_4CH_3$ groups. Deformation of the "sandwich" structure in a DMF–water mixture is associated with greater intensity of the forbidden long-wave absorption band (Fig. 4*e*, *f*) by comparison with a solution of the same dye in a methylene chloride–hexane mixture (Fig. 4*c*, *d*).[144]

Changes in spectral-luminescent properties according to the polarity of the medium, as observed for the associated forms of compound (LIII), occur also for other PD.[172]

In low polarity media, various types of salt-like cyanines are able to associate, in particular to form dimers.[141–144] It is convenient to take advantage of this fact in those cases in which chemically bonded dimers—biscyanines—cannot be synthesised. The latter are interesting targets for use in the study of problems of chromaticity and luminescence in organic dyes, but they are frequently difficult to obtain. This is due firstly to the fact that their synthesis is accompanied by the formation of traces of monomeric dyes which are difficult to separate, especially in terms of luminescent purity. Furthermore, not all heterocycles yield bi-quaternary salts for use as starting materials in the synthesis of biscyanines.

The bis-dyes themselves associated considerably more easily than the parent dyes in low polarity solutions.[126,128] This is due to the presence of two anions in the biscyanines, so that the probability of association of their ion pairs is increased by comparison with monomeric PD.[126,128]

In polar solutions the anion does not take part in aggregation. Nevertheless, in this case, as also in low polarity solvents, biscyanines associate more easily than the parent dyes. This is due to the fact that aggregation occurs in polar solutions on account of dispersion interactions of the π-systems of the PD. For compounds with two chromophores, these systems are more extended than in those with one chromophore. The former, therefore, associate more easily than the latter.[126,127]

V. Spectral-luminescent properties of polymethine dyes in polymeric matrices

Polymeric matrices also can be regarded as low polarity media. Coloured polymeric materials are especially widely used at present in quantum electronics,[173–175] helioenergetics,[176,177] and as agents for recording information.[178,179] Polymeric matrices have a number of operational advantages by comparison with liquid media,[173–175] although these advantages may only be realised if, in addition, the spectral-luminescent properties of the dye do not deteriorate under these conditions.

The first attempt to introduce PD into polymeric matrices led to a marked distortion of their spectral-luminescent properties.[180,181] In addition, a new band appears for many PD at the short-wave end of the absorption spectrum and the intensity of the long-wave band decreases, for example in the case of thiopyranyltricarbocyanine (XXIII) when dichloroethane is replaced by poly(methyl methacrylate) (PMMA).[181–184] These changes are accompanied by the quenching of luminescence.[185] It has been shown[182–185] that the described spectral-luminescent effects are caused by the formation of ion pairs and by their association in the type (A) "sandwich" structure, in the same way as in low polarity liquid solutions.[141–143] It has also been shown that such association leads to a fall in the photochemical stability of coloured polymeric matrices.[181,183]

It is difficult to avoid the association of PD in polymers, as it is in low polarity liquids, since association occurs at even low concentrations of cyanines.[183,184] The situation is also complicated by the fact that for a number of purposes highly delicate films are required, for example for passive laser locks.[186] For achieving the required degree of transmission of such films it is necessary to use a concentration of dye that is some orders of magnitude higher than that used for measurement of the absorption spectra in a 1 cm cell.

In order to reduce the tendency of salt-like PD to the formation of ion pairs, and also therefore association, it is necessary to use polymers with high values of dielectric permeability, ε. However, the preparation of such polymers is difficult. For the majority of polymeric materials ε is <10,[187] and dyes are therefore not completely dissociated in these materials. It is possible to facilitate the dissociation of PD in matrices which have low values of ε by the use of polymers containing polar groups. The role of such groups is to solvate the charges of the chromophore of the dye, separating them from the counterions, and to some extent hinder the formation of tight ion pairs.[147] Solvent separated ion pairs have practically the same electronic spectra as the solvated ions.[148] Therefore the formation of such pairs in a polymer does not cause a substantial

change in the spectro-luminescent properties of salt-like PD from those found in liquids, even if the cyanines are fully dissociated in liquids. Specific solvation of the charges of PD by polar groups of the polymer also reduces the electrostatic and dispersion interactions between the chromophores of the dye, making association of the latter more difficult.[126,142]

For cationic PD, which undergo mainly nucleophilic solvation,[188] it is necessary to use polymeric matrices that contain strongly nucleophilic groups, for example polyvinylbutyral, polyepoxides, and polyurethanes. The latter are especially promising, since they not only have strongly nucleophilic groups (comparable in nucleophilicity to DMF), but also they also have some of the highest values of ε for polymeric media.[187] The absorption spectra of thiopyranyltricarbocyanine (XXIII) in these polymers, in contrast to PMMA which has a lower value of ε, have the same form as in liquid solvents (Fig. 5).[183,184] Conversely, in polystyrene, which is characterised by minimum values of ε and nucleophilicity *B* (both of which are comparable to those of toluene) the form of the spectral curve of the same dye is altered considerably more than it is in PMMA (Fig. 5).

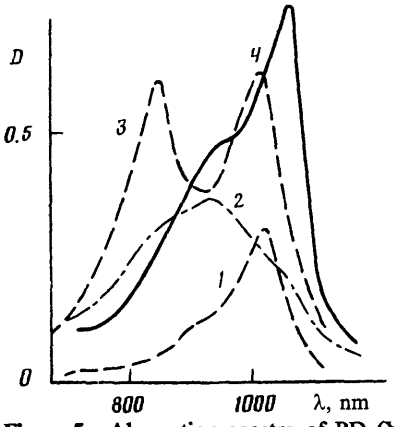

Figure 5. Absorption spectra of PD (XXIII). *1*, in dichloroethane ($C = 10^{-4}$ mol L^{-1}, *1* = 69 mm); *2*, in polystyrene; *3*, in poly(methyl methacrylate); *4*, in polyurethane (*2*–*4*, $C = 5 \times 10^{-7}$ mol g^{-1}, *1* - 70 mm).

However, a change in the nature of the matrix is not always justified. Thus, for example, for use in luminescent solar concentrators (LSC) the most preferred polymer is PMMA, which possesses excellent optico-mechanical properties[189] and is also extremely accessible and cheap.

In order to avoid the association of polymethines in PMMA, it is therefore necessary to modify them. For example, in the molecule of thiopyranyltricarbocyanine (XXIII) it is possible to introduce bulky substituents in order to prevent the formation of associations with structure (A).[185] Thus, if a hydrogen atom in the *meso*-position [dye (XXIII)] is replaced by a phenyl group [dye (XXIV)], the shape of the spectral curve remains the same in both dichloroethane and PMMA. An analogous result is also obtained with the introduction of other bulky substituents, such as CH_3, Cl, or *iso*-C_3H_7 into the *meso*-positon.[183] The formation of "sandwich" structures can be prevented, not only by the introduction of bulky groups into the polymethine chain, but also by their introduction into the heteroradicals.[183]

The above-mentioned substituents, having decreased the tendency to association of thiopyranylcyanines in polymers, substantially increased the photochemical and radiation stability of coloured matrices.[185] It allowed them to be used as the basis for the production of highy effective passive film locks, working in synchronised mode and guaranteeing the generation of ultra-short impulses of picosecond duration.[185,190]

If the association of PD in polymeric matrices is reduced to a minimum, it is possible to increase their quantum yields of fluorescence substantially. This is due to the fact that the polymer, being a "rigid" medium, impedes isomerisation processes which reduce the magnitude of φ significantly.[4] It has been shown that the quantum yields of fluorescence for a series of PD are increased more strongly by their introduction into a polymeric matrix, than by complete cyclisation of their PC. For example, on going from thiacarbocyanine (I) with an open chain to its analogue (X) with a rigidly fixed PC chain the value of φ is increased from 5 to 53%, whereas with the introduction of PD (I) into a polymer this value increases to 72%.[191]

A greater increase in the quantum yield of fluorescence of the thiacarbocyanine (I) by its introduction into a matrix, than by "chemical" fixing of its chain, is most probably due to the fact that not only are isomerisation processes hindered in "rigid" media, but also the quenching of luminescence, due to diffusion-controlled collision with molecules of oxygen and other quenching impurities, is decreased.[192–194] This fact also leads to a significant rise in the photochemical stability of coloured polymeric matrices based on PD. The latter are, in fact, able to sensitise the formation of singlet oxygen,[192–194] which is one of the basic factors in the photochemical destruction of cyanines.[195–197] In a polymer, because of weak diffusion, the generation of singlet oxygen is of low probability and cyanines are therefore more stable in these than in liquid solutions.

In luminescent ability and photochemical stability many PD in polymeric matrices are comparable with a wide range of luminophores, such as rhodamine 6G, POPOP, and various coumarins, etc.[198] In matrices, therefore, even those cyanines which are unsuitable as active laser media in liquid solutions can be used for the highly effective generation of emission.[199] In a polymer, the effectiveness of generation of emission is increased not only because of the increase in φ, but also as the result of a decrease in the losses that are caused by the induced absorption of the isomer in the intensified band.[200]

It should be noted that in "rigid" media the Stokes shift frequently falls. Thus, for the pyridylpyranyltetracarbocyanine (XXXI), which has one of the highest ΔS values, the Stokes shift decreases by 820 cm^{-1} on going from acetonitrile solution to polyurethane film, although its magnitude nevertheless remains rather significant. In general, if a decrease in ΔS occurs in polymers, then it does not decrease to the same extent as for completely fixed PC, with saturated cyclic groupings.[191] Small values of ΔS are also characteristic of other classes of structurally rigid luminophores.[198]

The possibility of achieving large Stokes shifts and quantum yields of fluorescence, together with high photochemical stability, makes coloured matrices based on PD more promising than the above named luminophores for the solution of problems connected with the transformation of light energy. One of these is helioenergetics.[191,201] The use of PD as LSC has been proposed.[191,201] It was shown that cyanines, that are not even the most suitable, can have larger coefficients of energy concentration than the widely used rhodamine 6G.[191,202]

It should be emphasised that a considerable increase in φ can be achieved, not only by the introduction of PD into polymeric matrices but also by increasing the viscosity of the medium.[59,60,203,204] It has therefore been possible to produce highly effective fluorescent probes, based on polymethines, for the determination of the microviscosity of phospholipid membranes.[205]

It was recently found that a sharp increase in the quantum yield of fluorescence of PD can also occur in low viscosity aqueous solutions in the presence of DNA.[206] This fact is of particular interest, since quenching of luminescence normally occurs in water because of the high tendency of PD to aggregation especially with the formation of "sandwich" structures, under these conditions.[156,160] Furthermore, the concentration of DNA employed does not increase the viscosity of the solution sufficiently for this be the cause of an appreciable increase in φ. The role of DNA in the case decribed is different. On the one hand, DNAs are surface active substances which hinder the association of dyes in aqueous solutions,[207] but on the other they form complexes with molecules of PD, most probably on account of electrostatic interactions which fix the dye rigidly in one isomeric form only. If this form is the *trans*-isomer, which usually has good luminescence, then fluorscence of the cyanine is enhanced in the presence of DNA. Conversely, in the case of the *cis*-isomer, quenching occurs.[4] Depending on the type of DNA and PD the formation of one or other of isomer occurs and, consequently, the enhancement or quenching of luminescence. Polymethines can therefore be used successfully in aqueous solutions as fluorescent probes for the recognition of types of DNA.[206]

VI. Influence of the nature of the solvent on the spectral-luminescent properties of polymethine dyes

It has been generally accepted that the solvent cannot have a significant effect on the spectral-luminescent properties of salt-like PD, since in contrast to intraionic (merocyanine) dyes, their dipole moment should change little on excitation.[208,209] It has been shown[34,110,111,188] that cyanines, depending on their chemical structure, may undergo strong solvation that becomes distinctly apparent from the position, intensity, and form of the electronic bands. For the exact quantitative estimation of these changes the moments method is applied,[210,211] as used in probability theory for the determination of functional parameters of various distributions, for example intensities in absorption and luminescence spectra.[210,211]

This method was used to calculate the mean frequencies (centres of gravity) of the bands ($\bar{\nu}$), oscillator strengths (f), band widths (σ), coefficients of asymmetry (γ_1), excess (γ_2), and fine structure (F). The magnitude of $\bar{\nu}$ has an advantage over the band maximum, in that its position in the series becomes determined more precisely and it more strictly characterises the vertical change in energy.[210] The magnitude of σ, being proportional to the dispersion of the band, allows an objective comparison of the widths of curves of different shapes to be made, in contrast to the half-widths (widths at half height) that are traditionally used for these purposes. The coefficients γ_1, γ_2, and F give additional information relating to changes in symmetry, steepness, and the degree of fine structure that is observed with widening or narrowing of the spectral curves. It has been shown possible to use these coefficients for analysis of the mechanisms of broading (uniform or otherwise) of the electronic bands.[211]

Moments of the absorption bands are determined by the coordinates ε/ν, and of the fluorescence bands by the coordinates W/ν^4, since these coordinates follow the law of mirror symmetry for the named spectra most exactly.[212]

1. Solvatochroism

In the examples of the dyes (XL) and (LIV), which differ sharply in chemical properties and in the regions of absorption and shape of their spectral curves, a study was made of the influence of various parameters of solvent polarity on the position, intensity, and shape of the absorption bands.[188] For this purpose the same range of solvents were used, that made it possible to obtain objective information on the influence of intermolecular interactions on the spectroluminescent properties of dyes. For a series of solvents with similar properties it was concluded[213] that a change in the position of the absorption band maximum for symmetrical cyanines correlates well with the Bayliss refractive index function: $(n_D^2-1)/(2n_D^2+1)$. However the inclusion of even a small number of solvents of other types at once led to a breakdown of the relationship,[214] i.e. the correlation is only satisfactory for a series of solvents of the same type.[214] Indeed, as seen for the example of the indotricarbocyanine (XL) (Fig. 6) neither ν^a_{max} (correlation coefficient $r = 0.912$) nor $\bar{\nu}^a$ ($r = 0.807$) correlate with the mentioned Bayliss function if different classes of solvent are used. The picture is not improved substantially by the use of the two-paramter function $f(n_D, \varepsilon)$.

Hence it follows, that solvation of the PD cations depends not only on macro- but also on microscopic properties of the medium. It has been shown for cyanines of the types (XL) and (LIV), and in general for polymethines that do not contain functional groups able to form hydrogen bonds, that the microscopic properties are determined by specific electrostatic interactions of the charges of the PD molecules and the solvent.[188] On the basis of an analysis of solvatochroism effects for cyanines (XL) and (LIV) and their dependence on empirical parameters of solvent polarity. viz. nucleophilicity (B) and electrophilicity (E), it was established for cationic PD that these interactions are significantly more sensitive to changes in parameter B than E. In other words, specific solvation of these dyes is determined mainly by nucleophilic solvation of the positive charges of their cations with the negative charges of the solvent molecules. Specific solvation becomes stronger with increasing unevenness in the distribution of charge in the cyanine molecules[34] and this in its turn increases with lengthening of the PC, deviation of the electron-donating abilities of the terminal heterocyclic groups from average values,[34,215] and increase in the electronic asymmetry.[111] Thus, for thiapentacarbocyanine (V), containing two benzthiazole nuclei, the electron-donating ability of which is above average, replacement of weakly nucleophilic methylene chloride by strongly nucleophilic DMF gives rise to such marked changes in the absorption spectra, that they do not appear to be caused by the change in the nature of the solvent but by the presence of two different dyes (see Fig. 1*a*). Equally strong effects, with change in the nucleophilicity of the medium, are observed for cyanines having weakly electron-donating radicals.[216] In both cases these effects are shown more distinctly for PD with longer PC (see Fig. 1).

It has been established that the nucleophilicity of a solvent has a significantly greater influence on the shape of the band (especially width), than on its position. The latter is more sensitive to change in the refractive index of the medium.

On the basis of an analysis of the moments of the absorption bands of PD in pairs of solvents, for which one parameter of

polarity was the same but the other different, the following law was formulated[188] concerning the influence of the solvent on the characteristics of the absorption bands of these dyes: in order to maximally deepen the coloration, to narrow the band and to increase the peak intensity, it is necessary to use, as media, solvents which have as large refractive indices as possible (a necessary condition for deepening of the coloration) and as low nucleophilicities as possible. Conversely, the largest increase in coloration, widening of the bands, and decrease in their extinction occurs in solvents with maximum B (a necessary condition for the creation of wide bands) and minimum n_D.

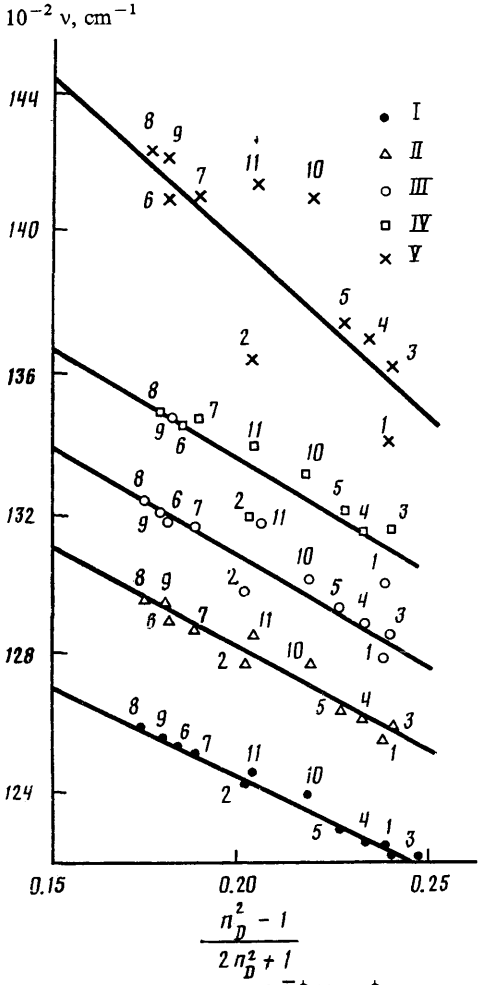

Figure 6. Dependence of $\bar{\nu}^{\Phi}$(I), ν^{Φ}_{max}(II), ν_{00}(III), ν^{a}_{max}(IV), and $\bar{\nu}^{a}$(V) for the dye (XL) on the Bayliss function. *1*, *o*-dichlorobenzene; *2*, methylene chloride; *3*, nitrobenzene; *4*, benzonitrile; *5*, pyridine; *6*, ethanol; *7*, nitromethane; *8*, acetonitrile; *9*, acetone; *10*, DMSO; *11*, DMF.

2. Solvatofluorochroism

The first report of the solvatofluorochroism of cyanines appeared only in 1987.[217] In this publication, and subsequently in others,[38,211] the influence of the nature of the solvent on the moments of the fluorescence bands of PD (XXVI), (XXXVIII) and (XL) was investigated. It was shown that the magnitudes of solvatofluorochroism effects were significantly less than those of solvatochroism. For example, the replacement of *o*-dichlorobenzene by DMF (these solvents differ considerably in the magnitude of n_D and B)[188] leads to a hypsochromic shift of the maximum and mean frequencies of the fluorescence bands of indotricarbocyanine (XL) of 400 and 361 cm^{-1} respectively, whereas the analogous values for absorption are 470 and 818 cm^{-1}. Still more contrasting is the influence of the solvent on the magnitudes of α^a and σ^f. Thus, in the above mentioned pair of solvents, the change in band width in the emission spectra amounts to only 58 cm^{-1} but in the absorption spectra to 414 cm^{-1}.[38,217] It was shown that the solvent has very little effect on the shape of the fluorescence band, in contrast to that of absorption, even for the strongly solvatochromic thia- (see Fig. 1*b*) and thio-pyranylcyanines with log PC. It has been found that the magnitudes of σ, γ_1, γ_2 and F for fluorescence bands are significantly less than the corresponding values for the absorption bands (especially σ).[211,217] This shows that the law of mirror symmetry for absorption and emission spectra is not observed. This conclusion is fairly important, since it was traditionally considered from the appearance of the spectral curves, that the above mentioned law is observed for the cyanine (XL) and for many other PD.[68,69] Only the application of the moments method revealed the considerable deviation from this law.

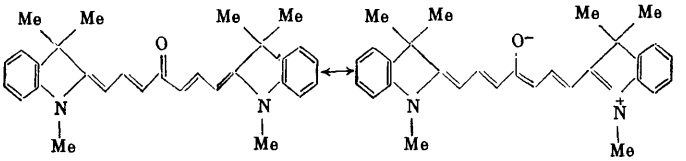
Deviation from mirror symmetry, and also a decrease in the magnitude of solvatofluorochromic effects by comparison with solvatochromic, witnesses to a weakening of the solvation of dyes in the excited state by comparison with the ground state.

From the data obtained by quantum chemical calculations for the molecule of indotricarbocyanine (XL), it follows[217] that the charges in the S_1-state have, as a rule, smaller numerical values than in the S_0-state. The total positive charge responsible for nucleophilic solvation also decreases with excitation (in the ground state it is 1.616 and in the excited state, 1.324).[217] In the excited state, therefore, electrostatic interactions (nucleophilic solvation), in contrast to dispersion interactions, must become significantly weaker, causing a decrease in the solvatofluorochromic effects by comparison with the solvatochromic.

With electronic excitation of the cyanine cations a marked redistribution of charge occurs. Specifically solvated forms of the dyes (SSFD), which are formed on account of nucleophilic solvation in the ground state, will therefore become unstable in the excited state and will seek to undergo reorganisation, with some dissociating completely. The probability of formation of SSFD in the excited state also falls because of a decrease in the absolute magnitude of the majority of the charges in this state by comparison with the ground state. As a result, the solvent will have a smaller effect on the shape of the absorption band than on the fluorescence band. Weakening of nucleophilic solvation leads also to a large decrease in the magnitudes of σ^{Φ}, γ_1^{Φ}, γ_2^{Φ} and F^{Φ}, by comparison with σ^a, γ_1^a, γ_2^a and F^a,[211] giving rise to deviation from mirror symmetry.

Additional narrowing of the fluorescence bands, by comparison with the absorption bands and a decrease in the influence of the solvent on the magnitudes of σ^{Φ}, γ_1^{Φ}, γ_2^{Φ} and F^{Φ}, occurs because of radiationless, directed transfer of light energy from the "blue" to the "red" solvate.[218,219] As a result, not all SSFD take part in such a transfer in emission in contrast to absorption, but mainly long-wave and non-specific solvates, absorbing in the still more "red" region than SSFD.[38,217]

The occurrence of radiationless directed transfer of energy also accords with the fact that quantum yields of fluorescence and life-



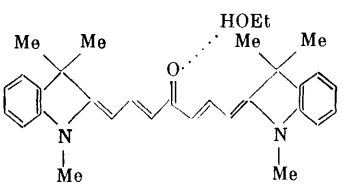
times of the excited states in a group of strongly nucleophilic solvents are, as a rule, lower than in weakly nucleophilic solvents,[38] since the probability of the formation of SSFD and, consequently, degradation of the excitation energy of the former is higher. This is due to the fact that the quantum yield and life time depend not only on the nucleophilicity of the medium, but also on its other properties, for example on viscosity. Therefore, in the highly viscous DMSO, in spite of its high nucleophilicity, a fairly high quantum yield of fluorescence is achieved.[38]

In alcohols, for PD absorbing in the region >1000 nm, the value of τ is minimal.[220] This is because there are additional routes of degradation for the energy, as a result of an overlap of the long-wave absorption bands of the cyanines with the overtone bands of the valence vibrations of the alcoholic OH groups. By deuteriation of these alcoholic groups, the magnitude of τ increases. Thus, for thiopyranylcyanine (XXIV), the values of τ in C_2H_5OH and C_2H_5OD are 14 and 23 ps respectively.

The Stokes shifts increase in almost the same way in a series of solvents, as the band widths. This is explained by the fact that ΔS is caused by an increase in hypsochromic band shifts, which result from a large reduction in the energy of the ground state of the dye, by comparison with the excited state, on account of an increase in nucleophilic solvation of the former.

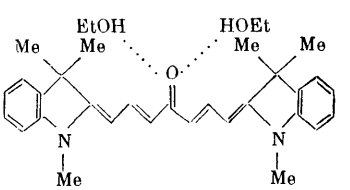
This solvation is so significant, that the characteristic positions of the absorption bands, as already noted, do not correlate satisfactorily with the Bayliss function of refractive index (Fig. 6). This is specially clear for $\bar{\nu}^a$ since the average frequency, being at the centre of gravity of the band, is extremely sensitive to changes in band shape. A change in the latter, under the influence of solvent, is due mainly to specific rather than general electrostatic interactions, leading to a breakdown of the correlation mentioned above. Solvatochromic shift of the band maxima is more dependent on the polarisability of the solvent, than on its nucleophilicity. There is therefore an approximate correlation ($r = 0.912$) between ν^a_{max} and the Bayliss function. The picture is improved to some extent by the closeness of the $0-0$ transition, ν_{00} (Fig. 6). This is because the vibrational transition corresponding to the band maximum, is partially removed under the influence of solvent because of the formation of SSFD.[221] The extent of this removal changes according to the nature of the solvent. Therefore the band maximum, in contrast to the magnitude of ν_{00}, may be dependent in different solvents on various vibrational transitions in a sub-level of the excited state of the SSFD. But in spite of the advantage of the closeness of the $0-0$ transition, a satisfactory correlation between this and the refractive index function is not acheived ($r = 0.942$). This once again shows the significant contribution of specific interactions in solvated cationic dyes. Indeed, a satisfactory relationship of the above mentioned characteristics of the electronic bands and refractive index is only obtained for uncharged compounds.[222,223] The excellent correlation shown between $\bar{\nu}^\Phi$ and the refractive index ($r = 0.993$) for fluorescence of the dye (XL) is therefore striking; it is better than for ν^a_{max} ($r = 0.974$), although the latter is extremely satisfactory. These facts convincingly confirm the conclusion that nucleophilic solvation is significantly weakened in the exicted state, in comparison with the ground state.

The opposite is true of the analogue of dye (XL), indotricarbo-ketocyanine (LV).[224,225]



(LV)

(LV): $\lambda^a_{max} = 465$ nm; $\lambda^f_{max} = 475$ nm (heptane).



Compound (LV), being intra-ionic, is shown as a nonpolar-bipolar borderline structure. The latter predominates in the excited state. Therefore in the molecule (LV) in the S_1-state, in contrast to the cationic indotricarbocyanine (XL), the specific electrostatic interactions are intensified. This is shown by the fact that an increase in the nucleophilicity of the medium does not give rise to a bathochromic shift rather than a hypsochromic shift, as takes place for compound (XL).[224] Such changes in the spectra are caused by the fact that nucleophilic solvation of the ketocyanine (LV) increases in the excited state and reduces its energy more than for the ground state.

In the S_1-state of compound (LV), electrophilic solvation is also increased. This becomes especially apparent in protic solvents, in which the ketocyanine (LV) forms two types of complex (LVa) and (LVb).[224,225]

(LVa)

(LVa): $\lambda^a_{max} = 487$ nm; $\lambda^f_{max} = 540$ nm

(LV6)

(LVb): $\lambda^a_{max} = 565$ nm; $\lambda^f_{max} = 620$ nm.

The probability of their formation is increased in the excited state, since the negative charge on the oxygen atom increases on excitation. This leads to a rise in ΔS in protic solvents by comparison with aprotic. In addition, there is an excellent increase in the order of the quantum yield. This is caused by saturation of the carbonyl with hydrogen bonds, leading to an increase in rigidity of the complexes, fixed in the all *trans*-conformation.[225]

Owing to the high values of ΔS and φ, alcoholic solutions of ketocyanines generate emission effectively with both laser[226] and lamp[227] pumping.

VII. Conclusion

PD are seen to possess unique and widely ranging spectral-luminescent properties.

Depending on structure, cyanines may absorb and luminesce in the whole visible and near infrared regions of the spectrum. At the present time, PD have the most interesting long-wave (1600 nm)[1] $\pi-\pi^*$ transitions among all the dyes investigated, with extinction reaching 5.10^5 l mol^{-1} cm^{-1}.[126]

Band shape may change from being strongly structured to being completely diffuse, from the most narrow ($\sigma \leqslant 700$ cm^{-1})[126,215] to the most wide (σ 3000 cm^{-1}).[115]

The quantum yield of fluorescence and the life-time lie within the limits 0.01–100% and $10^{-12}-10^{-9}$ s respectively.[3,4] Stokes shifts change from unity to 100 nm (from 200 to 7000 cm^{-1}).[112,115]

The spectral-luminescent properties of some PD are strongly sensitive to change in the nature of the medium, and others significantly so.[34,216]

No one class of organic dyes possesses such contrasting properties. Furthermore, a change from one class to another, is not always accompanied by such strong effects. PD are therefore ideal subjects for answering the main question of photoluminescence, formulated by S I Vavilov as follows: "...why does one molecule luminesce and others not?".[228] Further investigations of the spectral-luminescent properties of cyanines and the factors which determine them, should answer this question to a large extent. Special attention will be given to non-radiative processes in the region > 1000 nm, since only PD show interesting absorptions in this region. It will assist in the simple resolution of the question of the roles of internal conversion and high frequency vibrations in processes of deactivation of the excited states of the molecules.

Their solution may be most facilitated by the preparation of fully deuteriated PD with $\lambda^{a}_{max} > 1000$ nm. Since, in this region, the gap between the S_1- and T-levels decreases, an increase in the role of triplets in deactivation of the excited state can be expected. Elucidation of their role in deactivation is very necessary for the creation of stable PD which absorb and luminesce in the near infrared region. Singlet oxygen luminesces in this region (λ^{ϕ}_{max} = 1270 and 1590 nm).[119] PD with $\lambda_{max} > 1000$ nm should therefore occupy a fundamental place in the study of problems of energy transfer from themselves to singlet oxygen and *vice versa*. As a result of such a study, effective quenchers and sensitisers for singlet oxygen may be discovered.

In future, much greater attention will apparently be given to the investigation of the spectral-luminescent properties of the highly excited state of PD. Practical applications of cyanines are, in fact, frequently based on interactions of their molecules with intensive light fields. Such interactions give rise to non-linear optical effects in molecules of PD, with the participation of highly excited states.[229] Until recent times, the study of the latter was very difficult because of their very short life times. However, with the appearance of multi-photon laser spectrosocpy[230] this aim has become practicable for PD.[231]

Investigations in all these areas will make it possible to search still more effectively and purposefully for cyanines that are suitable for the solution of the problems of the transformation of light energy.

S-alkynyl esters of phosphorus thioacids as inhibitors of cholinesterases and as promising physiologically active compounds

ABSTRACT. Data are given in the review on the anticholinesterase activity of 58 specially synthesised esters of phosphorus thioacids containing an actylenic bond in the thioester group. It was established that compounds containing an acetylenic group in the β and especially in the α position of the thioester residue display an inhibitory action many times greater than that of their saturated analogues. A phosphorylated enzyme is formed by the reaction of the actylenic organophosphorus inhibitors (OPIs) with the enzymes as in the case of reaction with the saturated analogues. It was shown that the acetylenic organophosphorus inhibitors possess high biological activity both for mammals and for arthropods. On replacing the phosphoryl oxygen (P=O) by sulphur (P=S) the toxicity of the acetylenic organophosphorus inhibitors for mammals was sharply reduced but was little changed for arthropods. This raises the possibility of obtaining highly selective insecto-acaricides. The mechanism of the antienzymic action of the acetylenic OPIs and the mechanism of detoxication of diethyl *S*-hexynyl dithiophosphate are considered.

The bibliography includes 44 references.

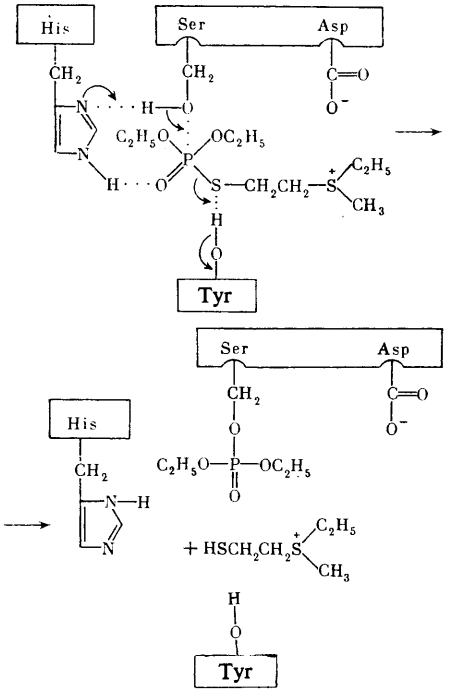
I. Introduction

Among the substances influencing the transmission of nervous excitation in cholinergic synapses a significant place is occupied by derivatives (esters, amides, etc.) of phosphorus acids, many of which are used as insectoacaricides. Their bioligical action consists mainly of the inhibition of acetylcholinesterase (ACE), the enzyme causing the hydrolysis of acetylcholine (AC), the mediator of nervous excitation. It is well known[1] that under the stimulus of a nervous impulse, AC enters the synaptic gap and is reversily adsorbed onto a receptor which leads to excitation of the innervated cell. Due to the hydrolytic action of ACE the receptor is freed from AC and is transformed into its initial state acquiring the ability to take up a further portion of mediator. When ACE is inhibited the removal of AC from the receptor occurs very slowly, by diffusion alone, and the transmission of nervous impulses is disturbed which gives rise to serious disorders in the vital activity of organisms.



In addition to nervous tissue there are cholinesterases (CE) in erythrocytes and in the serum of many animals, in muscular tissue, etc. There are several varieties of CE which differ from one another not only in substrate specificity, i.e. the ability to hydrolyse choline esters of carboxylic acids, but also in sensitivity to inhibitors.[2,3]

Many derivatives of phosphoric, phosphonic and phosphinic acids of the following general formula are organophosphorus inhibitors (OPI) of cholinesterase.

where A and B are the same or different substituents at the phosphorus atom (alkyl, alkoxyl, amide, aryl, etc.) and X is a residue of an organic or inorganic acid (fluoride, cyano, phenol, mercaptan, etc.).

It has been demonstrated[4] that on reaction with cholinesterase these inhibitors phosphorylate the hydroxyl group of a serine residue which forms part of the catalytic centre of the enzyme. According to current ideas[5] the activation of the serine hydroxyl required to carry out this process occurs with the direct participation of the OPI by the following scheme.

The above scheme explains why thione OPI do not phosphorylate these enzymes. Unlike oxygen the sulphur atom is unable to form a stable hydrogen bond.[1,5]

The phosphorylated enzyme formed is a fairly stable compound. Spontaneous dephosphorylation takes place extremely slowly. Significant dephosphorylation occasionally leading to almost complete restoration of the cholinesterase catalytic activity (reactivation) is effected only by aromatic or aliphatic oximes.[6]

There is an anionic site in the active centre of the cholinesterases at a distance of 4–5 Å from the esterase site which interacts with the onium groups of substrates and of organophosphorus inhibitors increasing their adsorption to the active surface of the enzyme. Presumably[1] the anionic site is a carboxylate ion of a dibasic amino acid, such as aspartic or glutamic acid, forming part of the polypeptide chain of the enzyme. Both the esterase and the anionic sites are surrounded by hydrophobic regions on which hydrophobic adsorption of hydrocarbon radicals of substrates or inhibitors is effected thereby enabling the appropriate processes to occur at a higher rate.[7]

The anticholinesterase (anti-CE) activity of an OPI is characterised quantitatively by the bimolecular rate constant for the inhibition of the enzyme (k_{II}). In addition to the reaction conditions (pH, ionic strength, temperature and composition of the reaction medium) this activity depends on the nature of the enzyme and also on the structure of the substituents A and B and the fissile grouping.[7,8]

The presence of an onium atom in the β position of a thioalkyl radical, as in the compound Gd-42, viz. $(C_2H_5O)CH_3P(O)SCH_2CH_2\overset{+}{S}(C_2H_5)CH_3$, causes extremely high anti-CE activity sometimes exceeding the activity of its non-ionic analogue $(C_2H_5O)CH_3P(O).SCH_2CH_2SC_2H_5$ by a thousandfold.[1,2] Hydrophobic adsorption exerts a large effect on anti-CE activity. The value of k_{II} for the inhibition of human erythrocyte ACE by the compounds $(C_2H_5O).CH_3P(O)SC_nH_{2n+1}$ and $(C_nH_{2n+1}O)CH_3P(O)SC_4H_9$ is raised a hundredfold on increasing n from 1 to 7.[7]

Table 1. ω-Chlorobutynyl esters of phosphorus thioacids $RR'P(O)SCH_2C{\equiv}CCH_2Cl$.[18,19]

It was shown recently[9,10] that a significant increase in the anti-CE activity of an OPI may be achieved by introducing an acetylenic grouping into the thioester residue. In some cases such phosphorus thioacid *S*-alkynyl esters supersede their saturated analogues in inhibitory activity by thousands and millions of times. Some of them inhibit the CE of arthropods more strongly than the CE of mammals, which is one source of selective toxicity. There is considerable practical interest in the *S*-alkynyl esters of dialkyl dithiophosphoric acids which acquire anti-CE activity by conversion into esters of monothiophosphoric acids by microsomal monooxidases. Such dithiophosphates display very high selective toxicity for arthropods and therefore are promising insecto-acaricides.[11]

To date a relatively large quantity of experimental data has been accumulated on the acetylenic OPIs which may be used for further study of the anti-CE activity and toxicity of this new and extremely intersting class of biologically active compounds.[9–17] The data presented in this review indicate the route for a purpose-directed search for highly selective insecto-acaricides. They are also of interest for the clarification of the mechanism of the interaction of the acetylenic OPIs with CEs.

II. Methods of synthesis of acetylenic organophosphorus inhibitors

The *S*-alkynyl esters of thiophosphoric and dithiophosphoric acids were synthesised by methods developed specially for this investigation.[13–15,18–28]

***S*-Butynyl esters of phosphorus thioacids** containing a triple bond in the β-position and a functional group in the ω-position of the thioester residue were obtained in the following way. The ω-chlorobutynyl esters of these acids were obtained initially by the reaction of the sodium or potassium salts of the appropriate phosphorus monothioacids with a 5-fold excess of 1,4-dichlorobutyne in alcohol (Table 1).[18]

$$RR'PSOM+ClCH_2C{\equiv}CCH_2Cl \rightarrow RR'P(O)SCH_2C{\equiv}CCH_2Cl,$$

R = CH_3, C_6H_5, CH_3O, C_2H_5, iso-C_3H_7O; R′ = CH_3O, C_2H_5O. iso-C_3H_7O, M = K or Na.

The products were subsequently converted by reaction with various nucleophilic reagents into ω-substituted *S*-butynyl esters of phsophorus monothioacids (Table 2). Sodium alkylmercaptides, dimethyl sulphide, dimethylamine, trimethylamine, triphenylphosphine and potassium dialkyl thiophosphate or thioacetate were used as nucleophilic reagents.[19]

$RR'P(O)SCH_2C{\equiv}CCH_2Cl \rightarrow$

- $\xrightarrow{R''SNa}$ $RR'P(O)SCH_2C{\equiv}CCH_2SR''$
- $\xrightarrow{S(CH_3)_2}$ $RR'P(O)SCH_2C{\equiv}CCH_2\overset{+}{S}(CH_3)_2Cl^-$
- $\xrightarrow{HN(CH_3)_2}$ $RR'P(O)SCH_2C{\equiv}CCH_2N(CH_3)_2$

- $\xrightarrow{CH_3C(O)SK}$ $RR'P(O)SCH_2C{\equiv}CCH_2SC(O)CH_3$

O,O-Dimethyl and *O,O*-diethyl *S*-(4-acetoxybut-2-ynyl) thiophosphates (Table 2) were obtained by the reaction of 4-chlorobut-2-ynyl acetate with potassium dimethyl or diethyl thiophosphate.[20]

$$(RO)_2PSOK+ClCH_2C{\equiv}CCH_2OC(O)CH_3 \rightarrow$$
$$\rightarrow (RO)_2P(O)SCH_2C{\equiv}CCH_2OC(O)CH_3.$$

S-Propargyl esters of diethyl thiophosphoric acid were obtained by the reaction of the *O,O*-diethyl thiophosphates of potassium or monovalent copper with the appropriate propargyl halides.[12,21]

$$(C_2H_5O)_2PSOM + XCH_2C{\equiv}CR \rightarrow (C_2H_5O)_2P(O)SCH_2C{\equiv}CR,$$

R=H, Pr, Br; M=K, Cu; X=Cl, Br.

***S*-Hex-1-ynyl thioacetate** was obtained in one stage in the following way.[30] Hex-1-ynyllithium was obtained by the reaction of a freshly prepared soluton of butyllithium in ether with 1-hexyne and was then converted into the corresponding lithium mercaptide by reaction with sulphur.

$$C_4H_9C{\equiv}CH \xrightarrow{C_4H_9Li} C_4H_9C{\equiv}CLi,$$
$$C_4H_9C{\equiv}CLi \xrightarrow{S} C_4H_9C{\equiv}CSLi.$$

Reaction with acetyl bromide then gives *S*-hex-1-ynyl thioacetate.

$$C_4H_9C{\equiv}CSLi+CH_3C(O)Br\rightarrow CH_3C(O)SC{\equiv}CC_4H_9.$$

III. Anticholinesterase activity of acetylenic organophosphorus inhibitors

Partially purified water-soluble preparations of acetylcholinesterase of human erythrocytes (ACE) and butyrylcholinesterase of horse serum (BuCE) served as enzyme sources. In addition a brain homogenate from white mice (mouse CE), a homogenate of the heads of the fly *Musca domestica L.* (fly CE), homogenates of whole beet aphids *Aphis fabae Scop.* and grass aphids *Schizaphis gramina Rond.* (aphid CE) and spider mites *Tetranychus urticae Koch* (mite CE) were also used. The rates of cholinesterase hydrolysis of acetylthiocholine (ATC) before (v_0) and after (v_i) reaction with the various inhibitors were determined at 25 °C and pH 7.5 by Ellman's method.[31] Ellman's reagent was added after stopping the enzymic reaction in experiments with aphid CE.[32] The bimolecular rate constant (k_{II}) for the reaction of a cholinesterase with an OPI was determined at 25 °C and pH 7.5 by known methods[7,8] and was calculated from the formula:

$$k_{II}=\frac{2.303}{t[I]}\lg\frac{v_0}{v_i}(M^{-1}\,min^{-1}),$$

where v_i is the rate of enzymic hydrolysis of ATC after t min incubation of the CE with the OPI at a concentration [I] many times greater than the concentration of enzyme active centres; v_0 is the rate of enzymic hydrolysis of ATC in the absence of the OPI. The rate constant for the alkaline hyrolysis of the OPI (k_{OH}) was determined at 25 °C and pH 9.2 by a known method.[14]

Table 9. Anticholinesterase activity (k_{II}, M^{-1} min^{-1}) of acetylenic OPI $(RO)_2P(O)SCH_2C{\equiv}CCH_2R'$ and their saturated analogues $(RO)_2P(O)SCH_2CH_2CH_2CH_2R'$ (compounds numbered 'a').[8,9]

1. *S*-Butynyl esters of phosphorus thioacids containing an acetylenic bond in the β-position of the thioester residue

The esters investigated were of *O,O*-dialkyl thiophosphoric acid, viz $(RO)_2P(O)SCH_2C{\equiv}CCH_2R'$, where R = CH_3, C_2H_5, C_3H_7, and R' = Cl, OH, SC_2H_5, SC_4H_9, $OC(O)CH_3$, $SC(O)CH_3$, and $\overset{+}{N}(CH_3)_3Cl^-$ (Table 9) and of *O*-ethyl thiophosphoric acids, viz. $(C_2H_5O)RP(O)SCH_2C{\equiv}CCH_2R'$, where R = CH_3, C_6H_5, and R' = Cl, SC_2H_5, $SC(O)CH_3$, $\overset{+}{N}(CH_3)_3Cl^-$ (Table 10). In these compounds the acetylenic group is at approximately the same distance from the

phosphorus atom as the sulphonium sulphur atom in the preparation Gd-42 (see above for formula). It was assumed that this highly reactive group may react with the anionic centre in cholinesterases and thereby affect the inhibitory activity of these compounds.

Table 10. Anticholinesterase activity (k_{II}, M^{-1} min^{-1}) of acetylenic OPI $R(C_2H_5O)P(O)SCH_2C{\equiv}CCH_2R'$ and their saturated analogues $R(C_2H_5O)P(O)SCH_2CH_2CH_2CH_2R'$ (compounds numbered 'a').[9]

Footnote. Values of the acetylene effect q are given in parentheses.

Parallel experiments were carried out with saturated analogues of some of the acetylenic inhibitors in order to assess objectively the effect of the acetylenic group on the anticholinesterase (anti-CE) activity of the compounds. This effect was assessed quantitatively by the size of the 'acetylene effect' (q) which shows how many times the bimolecular rate constant for cholinesterase inhibition by the acetylenic compound was greater than the same inhibition constant of its saturated analogue.

It follows from the data of Tables 9 and 10 that the acetylenic compounds (I)–(IV) and (XIII)–(XVI) possess higher anti-CE activity than their saturated analogues. This is observed for all compounds without exception but varies within very wide limits depending on the nature of the enzyme and the structure of the inhibitor. The ethylmercapto-substituted thiophosphates (III) and (IV) exceed the chloro-substituted compounds (I) and (II) in the size of the acetylenic effect. This is linked with the fact that the inhibitory activity of an acetylenic OPI is practically independent of the nature of the substituent but for the saturated analogues the chloro-substituted compounds possess a higher anti-CE activity than the ethylmercapto-substituted compounds. It is characteristic that the structure of the phosphoryl portion of the inhibitor molecule shows a smaller influence on the acetylenic effect. Relatively close values of q were observed for mouse CE, fly CE and ACE both for the chloro-substituted esters of dimethyl and diethyl thiophosphoric acids (I) and (II) and for the ethylmercapto-subtituted derivatives of these acids (III) and (IV). The dimethyl thiophosphates surpassed by a little the corresponding diethyl thiophosphates in the size of q for the other CE.

There were no saturated analogues for compounds (V)–(XII). Experiments with them gave additional information on the link between the structure of the acetylenic OPI and their anti-CE activity. Dimethyl and diethyl esters of thiophosphoric acids with an $OC(O)CH_3$ substituent (VI) and (VII) displayed close inhibitory activity towards each of the CE investigated as was also seen in experiments with chloro- and ethylmercapto-substituted derivatives of these acids. Appreciable differences were also not observed in their anti-CE activity for various CE. For example the size of the inhibition constant for compound (VI) for fly CE, the most sensitive, was 3.0×10^5 M^{-1} min^{-1}, and for mouse CE, the least sensitive, was 1.0×10^5 M^{-1} min^{-1}, i.e. a threefold difference.

On the other hand a clearly marked dependence of inhibitory activity was shown by the acetylenic OPIs with a $SC(O)CH_3$ substituent (VIII)–(X) on the structure of the phosphoryl portion of the molecule for each CE and on the nature of the CE for each compound. Thus mammalian and aphid CE proved to be the most sensitive to the ester of dipropyl thiophosphoric acid and fly CE to the ester of diethyl thiophosphoric acid. In difference to the other enzymes mite CE displayed an extremely low sensitivity towards the ester of dipropyl thiophosphoric acid (X) $k_{II} = 1.3 \times 10^3$ M^{-1} min^{-1} which is 30 000 times less than k_{II} for BuCE, 3.8×10^7 M^{-1} min^{-1}. A large difference was detected in the sensitivity of the CEs investigated towards a diethyl thiophosphate with an OH susbtituent (XI). In the inhibition of ACE $k_{II} = 2.9 \times 10^4$ M^{-1} min^{-1} but in the inhibition of aphid CE $k_{II} = 4.8 \times 10^6$ M^{-1} min^{-1}.

The butylmercapto derivative (V) possesses a higher anti-CE activity than the methylmercapto derivative (IV) in relation to mammalian CE. Consequently in addition to the acetylenic group, the length of the hydrocarbon chain, which provides hydrophobic adsorption to the corresponding portion of the catalytic centre of the enzyme, enhances the anti-CE activity. Compound (XII), having a trimethylammonium group, surpasses all the other compounds, except for compound (X), in its anti-CE activity on reaction with mouse CE. The sensitivity of the other CEs to compound (XII) differed little from their sensitivity to certain uncharged actylenic OPIs.

Two general regularities must be mentioned in relation to the selectivity of the inhibitory action of the actylenic OPIs investigated. a) Among the mammalian enzymes BuCE proved to be the most sensitive to each of the OPIs investigated which is in agreement with numerous literature data on the higher inhibitory activity of phosphates in relation to BuCE than to ACE.[2] b) Among the arthropod enzymes, fly CE possesses the highest sensitivity towards the OPIs investigated with few exceptions.

It follows from the data of Table 10 that a sharp increase in anti-CE activity is also observed for the thiophosphonates on introducing an acetylenic group into the OPI molecule. Thus for the methyl esters (XIII) and (XV) the size of k_{II} in relation to fly CE proved to be exceptionally high (10^9 M^{-1} min^{-1}) and these compounds may be considered to be highly selective inhibitors of this enzyme. Such an enormous increase in anti-CE activity over the saturated analogues (XIIIa) and (XVa) cannot be explained by the higher phosphorylating ability of the acetylenic compounds since the introduction of an acetylenic group into the β-position of the thioalkyl residue increases the rate constant for alkaline hydrolysis by only 5–6 times. It must be noted that the saturated methylthiophosphonates strongly inhibit not fly CE but the other CEs, compound (XIIIa) inhibits the aphid CE and mite CE and compound (XVa) inhibits mouse CE and ACE.

In contrast to the thiophosphates, the nature of the substituent for the methylthiophosphonates (XIII) and (XV) showed a less clear influence on the acetylene effect. On reacting these compounds with ACE, fly CE and mouse CE the size of q varied little with the nature of the substituent. For aphid CE and mite CE the size of q was greater than when reacting these enzymes with ethylmercapto-substituted derivatives, and for BuCE than with chloro-substituted compounds.

With few exceptions the *S*-butyl esters of phenylthiophosphonic acid (XIV) and (XVI), in comparison with similar esters of methylphosphonic acid (XIII) and (XV), proved to be less strong inhibitors of the CEs investigated. For example, a large difference was observed towards esters of these acids for mite CE for all three substituents. There was a particularly large difference in the sensitivity of fly CE to compounds with substituents Cl and SC_2H_5. For the chloro-substituted derivatives (XIII) and (XIV) this difference was 10000 times and for the ethylmercapto-substituted derivatives (XV) and (XVI) 2500 times.

The thioesters of phenylthiophosphonic acid were surpassed by the corresponding methylthiophosphonates in the size of the acetylene effect. For the majority of the CEs investigated the size of q did not exceed 50 (Table 10), and only for aphid CE were they relatively large, viz. 310 for chloro-substituted and 670 for ethylmercapto-substituted compounds. As for the methylthiophosphonates, the influence of the substituent on the acetylene effect for phenylthiophosphonates is displayed in different ways for the investigated CEs. For arthropod and mouse CE the size of q is greater for ethylmercapto-substituted compounds [(XIV) and (XV)], on the other hand for ACE the size of q is greater for chloro-substituted compounds and for BuCE there is no difference in the values of q for these compounds.

From the experimental data given in this section the problem arises as to which position of the acetylenic bond in the *S*-butynyl group provides the greatest anti-CE activity. The acetylenic group, with its high π-electron density, may react by forming a type of π-complex not only with the carboxyl group of the anionic site of the CE, but also with other groups such as alcohols, amino groups, etc. Consequently the optimum effect of the acetylenic grouping may not necessarily be displayed at the β-position.

2. *S*-Alkynyl esters of diethyl phosphoric acid with the acetylenic group at various positions in the thioester residue

The anti-CE activity of two sets of compounds of general formula $(C_2H_5O)_2P(O)SX$ has been investigated (Table 11). In compounds (XVII)–(XIX), the first set, the group X is a hexynyl group C_6H_9 in which the acetylenic bond is found in the α-, β- or γ-positions relative to the sulphur atom, i.e. X = $-C\equiv CC_4H_9$, $-CH_2.C\equiv CC_3H_7$, $-CH_2CH_2C\equiv CC_2H_5$. In compounds (XX)–(XXII), the second set, the position of the acetylenic bond and the length of the *S*-alkynyl chain are chained. i.e. X = $-C\equiv CH$, $-CH_2C\equiv CH$, $-CH_2CH_2C\equiv CH$. The anti-CE activity of the saturated analogues of these compounds was studied. Compound $(C_2H_5O)_2P(O)SC_6H_{13}$ is the saturated analogue for the three compounds of the first set, each compound of the second set has its own analogue.

It follows from the data of Table 11 that inhibitors with an actylenic bond in the α-position possess the greatest anti-CE activity. In their ability to inhibit CEs they surpassed such strong OPIs as the onium compounds, such as the methylsulphomethylate of *O,O*-diethyl S-[β-(phenylmethylamino)ethyl] thiophosphate.[35] The k_{II} for this compound when inhibiting ACE was 2.5×10^7 M^{-1} min^{-1}, and when inhibiting BuCE was 6.8×10^7 M^{-1} min^{-1}. Compound (XX) gave the same value for the constant when inhibiting ACE, viz. 2.3×10^7 M^{-1} min^{-1}, but compound (XVII) gave the even larger value of 1.0×10^8 M^{-1} min^{-1} when inhibiting BuCE (Table 11).

Table 11. Anticholinesterase activity (k_{II}, M^{-1} min^{-1}) of OPIs of structure $(C_2H_5O)_2P(O)SX$ with various positions of the acetylenic group in the thioether residue.[10,12]

*Grass aphid CE was used in this experiment.
Footnote. Values of the acetylene effect q are given in parentheses.

Moving the acetylenic bond in the thioalkynyl group from the α- to the β-position leads to a sharp fall in the inhibition rate constant for the CE investigated extending to two to three orders of magnitude (Table 11). In line with this the sizes of the acetylene effect were also sharply reduced. The values of q for compound (XVII) of the first series with the acetylenic bond in the α-position were in the thousands but with the acetylenic bond in the β-position [compound (XVIII)] q was in the range 2.4–34.

A large difference in values of q was also observed for the corresponding compounds of the second series. Thus for compound (XX) the size of q when inhibiting fly CE ws 2.7×10^6 but for compound (XXI) with the acetylenic bond in the β-position q was 3000. Further movement of the triple bond to the γ-position of the thioester residue showed a less marked effect in the compounds of both the first and second series.

It seemed of interest to compare the anti-CE activity of compounds (XVII) and (XX) and also compounds (XVIII) and (XXI). Replacement of a hydrogen atom in compound (XX) by a C_4H_9 group [(compound (XVII)] leads to an increase in the inhibitory activity in relation to arthropod CE and BuCE and caused a small reduction in this activity in relation to mouse CE and ACE. Replacement of the acetylenic hydrogen in compound (XXI) by a C_3H_7 group [compound (XVIII)] and replacement of two other hydrogen atoms in the alkylthio residue of this compound by methyl groups [compound (XXIII)] proved to have a weak effect. Here also

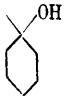
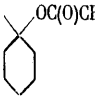
*Grass aphid CE was used in experiments.
Footnote. Values of the acetylene effect q are given in parentheses.

a small reduction was observed in the anti-CE activity in relation to ACE. It is characteristic that compound (XXII) with the acetylenic bond in the γ-position is a weaker inhibitor than its saturated analogue in relation to arthropod CEs, giving a value of $q < 1$.





3. *S*-Alkynyl esters of dialkyl thiophosphoric acids containing hydrophobic or onium groups in the alkylthio residue

OPIs of general formula $(RO)_2P(O)SC{\equiv}CR'$ have been investigated where the acyclic hydrophobic group R' = C_4H_9, $CH_2SC_2H_5$, $CH_2SC_4H_9$, $CH_2CH_2SC_2H_5$, $CH_2SC(O)CH_3$, $CH_2OC(O)CH_3$, $CH_2OC_2H_5$, $CH_2OC_3H_7$, $CH_2OC_4H_9$, $CH_2CH(COOC_2H_5)_2$, and R = CH_3, C_2H_5, C_3H_7, C_4H_9 (Table 12). In the experiments with these compounds a study was made of the dependence of their anti-CE activity on the structure of the group R' which is capable of hydrophobic adsorption onto appropriate portions of the enzyme active surface. In addition, comparison of the anti-CE activity of compounds with various R but with the same R' made it possible to assess the effect of the structure of the phosphoryl group of the OPIs. These same problems were also investigated in experiments with compounds containing cyclic hydrophobic groups R', such as phenyl, cyclohexenyl and cyclohexyl and groups R = CH_3 and C_2H_5 (Table 13). The influence of onium groups was investigated in experiments with the inhibitor $(C_2H_5O)_2P(O)SC{\equiv}CCH_2CH_2\overset{+}{S}(CH_3)C_2H_5$ (Table 12).

It follows from the data of Table 12 that replacement of the hydrogen atom of the acetylenic group in the alkylthio residue of compound (XX) with various acyclic hydrophobic groups leads to a significant increase in the anti-CE activity in relation to BuCE. Only the substituents $-CH_2CH(COOC_2H_5)_2$ and $-CH_2SC_4H_9$ did not increase it but reduced the inhibitory action on this CE a little [compounds (XXXV) and (XXXVII)]. In the majority of cases the substituent reduced or did not change the anti-CE activity in relation to the other CE.

For example, compound (XXXVIII) inhibits these CE more weakly than compound (XX). In this case the hydrophobic t-butyl group does not aid but seemingly hinders absorption of the acetylenic inhibitor molecule to the active surface of the enzyme. Only a few substituents increased the anti-CE activity of an inhibitor for certain CE. Thus compound (XX) is surpassed in anti-CE activity by compounds (XVII) and (XXXVII) in experiments with fly, beet aphid and spider mite CE, by compound (XXVII) in experiments with aphid and mite CE and by compound (XXXVIII) in experiments with fly and aphid CE.

Table 13. Anticholinesterase activity (k_{II}, M^{-1} min^{-1}) of acetylenic OPI $(RO)_2P(O)SC{\equiv}CR'$ and their saturated analogues $(RO)_2P(O)SCH_2CH_2R'$ (compounds numbered 'a').[9,12]

*Beet aphid CE was used in experiments.

Footnote. Values of the acetylene effect q are given in parentheses.

Replacement of a hydrogen atom in compound (XX) by phenyl [compound (XLIV)] and cyclohexenyl [compound (XLV)] residues led to an increase in the anti-CE activity for BuCE and to a decrease for mouse CE, aphid CE and ACE (Table 13). Compound (XLIV) proved to be less strong in relation to fly CE, but compound (XLV) was a stronger inhibitor than compound (XX). Again, replacement of hydrogen on the acetylenic bond in compound (XX) by a cyclohexenyl group [compound (XLVI)] is accompanied by a significant strengthening of the inhibitory activity in relation to all the CE investigated. For aphid CE the size of k_{II} for this compound was 1.4×10^9 M^{-1} min^{-1}, which is two orders of magnitude greater than for compound (XX). It is characteristic that compounds (XLVII) and (XLVIII), into the cyclohexyl residue of which OH and $OC(O)CH_3$ groups respectively have been introduced, possess many times lower anti-CE activity than compound (XLVI).

A reduction in k_{II} is observed in many cases on replacing the acetylenic hydrogen atom by hydrophobic susbtituents but an appreciable increase always occurred in the value of k_{II} on analogous replacement of hydrogen in the saturated analogue (XXa) [i.e. compounds (XVIIa), (XXXVa), (XXXVIIIa), (XXXIXa), (XLa), (XLIVa), (XLVa), (XLVIa)], seemingly as a result of the increase in the adsorption rate of inhibitors onto the active surface of the CE caused by the hydrophobic adsorption of substituents onto the correpsonding hydrophobic portions of this surface. The cyclohexenyl derivative (XLVa), and not the cyclohexyl compound (XLVIa), was the strongest inhibitor, in relation to all the CE, of the saturated analogues with cyclic substituents [Table 13, compounds

(XXIVa), (XLVa), (XLVIa)] in contrast to the acetylenic compounds. This occurred in spite of the high hydrophobicity of cyclohexyl groups.

It is possible that the difference noted in the effectiveness of substituents is explained by the fact that when many acetylenic compounds are adsorbed onto the enzymes these substituents do not make contact with the hydrophobic portions of the active surface. The linear acetylenic group orients the acetylenic compound on the enzyme differently from the orientation of the saturated analogue. Overall the impression is created that the interaction with the anionic centre of the CE active site does not play a major role in the inhibition process in the case of the acetylenic OPIs.

It is seen from the data shown in Tables 12 and 13 that the values of the acetylenic effect vary between very wide limits and depend on both the structure of the compound and on the source of the enzyme. As already mentioned above the value of q for compound (XX) was very high. Replacement of the hydrogen atom on the acetylenic bond of this compound by groups of various structure led, as a rule, to a reduction in the size of q. Only on replacing the hydrogen atom by a cyclohexyl group [compound (XLVI)] was there an increase in q for the inhibition of mouse and aphid CE. The absence of a correlation between the change in the size of k_{II} and q for an acetylenic analogue is worthy of attention. For example on replacing the hydrogen atom in compound (XX) by a cyclohexyl group [compound (XLVI)] the size of k_{II} for fly CE was increased almost threefold (3×10^8 M^{-1} min^{-1} and 8×10^8 M^{-1} min^{-1} respectively) but the size of q was reduced by more than 100 times (2 700 000 and 24 000 respectively). The same picture was observed on replacing the hydrogen atom in compound (XX) by a butyl group [compound (XVII)] when inhibiting BuCE and arthropod CE. These divergences between the changes of k_{II} and q are explained by the fact that replacement of the hydrogen atom by certain groups in the saturated analogue (XXa) causes an increase in k_{II} several times greater than the analogous replacement in the acetylenic compound (XX). For example, replacement by a cyclohexyl group [compound (XLVI)] in the acetylenic compound (XX) leads to an increase in k_{II} for fly CE of less than threefold but replacement of hydrogen by this group [compound (XLVIa)] in the saturated compound (XXa) leads to an increase of k_{II} for the same enzyme of 300-fold.

The dependence of inhibiting ability on the length of the alkyl chain in the phosphoryl portion of the OPI molecule has been investigated for certain compounds. It must be noted first that the esters of dimethyl thiophosphoric acid, both acetylenic [(XXVI), (XXX), (XLI)–(XLIII)] and saturated [(XLIa), (XLIIa), (XLIIIa)], display in the majority of cases a lower anti-CE activity than their diethyl homologues (XXVII), (XXXI), (XLIV), (XLV), (XLVI), (XLIVa), (XLVa) and (XLVIa). Only in the case of the cyclohexyl derivatives (XLIII) and (XLVI) and only for fly CE and BuCE was the ratio reversed. These two compounds surpass significantly all the known acetylenic OPIs in anti-CE activity. Further lengthening of the alkyl chain in the phosphoryl portion of the OPI molecule leads to a different result depending on the enzyme and on the structure of the group R′ on the acetylene. On investigating a series of acetylenic OPIs with R′ = H [compounds (XX), (XXIV), (XXV)] it was discovered that the diethyl thiophosphate possesses the greatest activity in relation to mouse CE and ACE but the dipropyl thiophosphate possessed the greatest in relation to BuCE. This agrees with the results obtained previously for ACE and BuCE in experiments with $(RO)_2P(O)SC_2H_4\overset{+}{N}(CH_3)_2C_6H_{11}$, where R = C_2H_5, C_3H_7, C_4H_9 and $(RO)_2P(O)SC_2H_4\overset{+}{S}(CH_3)C_2H_5$, where R = C_2H_5, C_3H_7.[34] It was characteristic that grass aphid CE proved to be the more sensitive to the diethyl thiophosphate.[35]

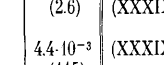
However, in the series of OPIs with R′ = $CH_2OC(O)CH_3$ the diethyl thiophosphate (XXVII) was a more active inhibitor of all the CE, except for ACE, than the dimethyl thiophosphate (XXVI) and the dipropyl thiophosphate (XXIII). Among the compounds with R′ = $CH_2OC_4H_9$ the ester of diethyl thiophsophoric acid [compound (XXXIII)] inhibits mite CE more strongly, the ester of dipropyl thiophosphoric acid [compound (XXXIV)] BuCE and aphid CE, but mouse and fly CE and ACE were equally sensitive to both OPIs. The dipropyl derivative [compound (XLIX)] of the OPI series with R′ = C_6H_5 was a stronger CE inhibitor than the diethyl derivative (XLIV) in all cases.

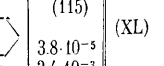
The anti-CE activity of compounds therefore depends on the nature of the enzyme and on the structure of the OPI in both the phosphoryl and the cleavable portions of the molecule.

The change in anti-CE activity on converting the acetylenic compound (XXXIX) with a sulphide sulphur atom into the derivative (XL) with a sulphonium sulphur atom was unusual. In this case the cationic group provides a reduction in the size of k_{II} for warm-blooded CE and an insignificant increase (2–4 times) for fly CE and aphid CE while the rate constant for alkaline hydrolysis of the sulphonium derivative was many times greater than that for the sulphide (2.9×10^{-1} and 4.4×10^{-4} min^{-1} respectively).

It was characteristic that the acetylenic effect for compounds with a sulphide sulphur atom (XXXIX) was significantly greater than for the derivative with sulphonium sulphur atom (XL) for all CEs. This is linked with the fact that replacement of sulphide sulphur atom in the saturated prototype [compound (XXXIXa)] by sulphonium [compound (XLa)] leads to a strengthening of the anti-CE activity in relation to each CE. The k_{II} constants are increased 10–25 times, the alkaline hydrolysis constant is increased 75 times.

The low effect on introducing an onium grouping is explained to a significant extent by the fact that in compounds (XL) and (XLa) the onium atom is placed at a significantly large distance from the phosphorylmercapto group ($-CH_2CH_2CH_2CH_2\overset{+}{S}=$), compared with the optimum distance ($-CH_2CH_2\overset{+}{S}=$) for example in preparation Gd-42 mentioned above. The rigidity of the *S*-alkynyl residue also plays a particular role in the case of the acetylenic OPIs. It is possible that the hypothesis on the absence or small extent of reaction with the anionic site of a CE for all groups of acetylenic OPIs is correct.





4. Analysis of the mechanism of the anticholinesterase action of acetylenic OPIs

a) Alkaline hydrolysis

The mechanism of the interaction of acetylenic OPIs with the cholinesterases is an extremely important problem. It might have been thought that the acetylenic group, which shows an electron-accepting effect, increases the electrophilicity of the phosphorus atom and thereby increases the phosphorylating ability of a compound. The rate constant for alkaline hydrolysis (k_{OH}) of the organophosphorus inhibitors is a fairly reliable measure of this ability. Experiments have shown that the values of k_{OH} for the acetylenic OPIs are in reality higher than the values for their saturated analogues (Table 14). They are particularly high for compounds with an acetylenic bond in the α-position. For compound (XX) $k_{OH} = 2.2 \times 10^{-3}$ min^{-1} but for its saturated analogue (XXa) this constant was 290 times smaller.

Such a strengthening of the phosphorylating ability does not agree quantitatively in any way with the enormous size of the acetylene effect which ranges from 82 000 for ACE to 2 700 000 for fly CE for the same compound (XX) (Table 11). In addition the colossal difference observed in the values of the acetylene effect for a single compound against several CEs cannot be explained by the change in k_{OH}.

Table 14. Rate constants for the alkaline hydrolysis (k_{OH}, min^{-1}) of the acetylenic OPIs $(C_2H_5O)_2P(O)SR$ and their saturated analogues (compounds number 'a').[12–14]

OPI		k_{OH}, min^{-1}	OPI		k_{OH}, min^{-1}

(XLVIa)	$CH_2CH_2C_6H_{11}$-cyclo	$3.4\cdot10^{-5}$			

Footnote. Values of the acetylene effect q are given in parentheses.

At first glance the non-correspondence between the acetylene effects in the alkaline hydrolysis reaction and in the reaction with CE may be a reason to propose a different mechanism for the irreversible inhibition of enzymes by acetylenic OPIs, for example not phosphorylation but alkylation of the active site. It is well known[36] that derivatives of α-propynylamine inhibit monoamine-oxidases irreversibly by alkylation of the enzyme. However such a hypothesis encounters serious objections. It was established previously[7] that on increasing the thioalkyl residue from SCH_3 to SC_7H_{15} in compounds $(C_2H_5O)CH_3P(O)SR$ the anti-CE activity was significantly increased but the size of k_{OH} was practically unchanged. This was explained by the fact that the size of the bimolecular rate constant for the reaction of OPIs with CE is determined mainly by the rate of formation of the enzyme–inhibitor complex which is the first stage of the reaction and not by the rate of phosphorylation which is the second stage. According to this analogy it is also obvious that the observed non-correspondence between the increase of k_{II} and k_{OH} on replacing an ethylenic by an acetylenic group in the S-alkyl residue may be explained by the significant acceleration of the adsorption of an acetylenic OPI onto the CE active surface. This increase of the adsorption rate may not be the same for the various CEs which differ in the structure of their active centres.

b) Change of anticholinesterase activity of acetylenic OPIs under various conditions

Specially conducted investigations[36] have shown that acetylenic OPIs possess some properties characteristic of typical OPIs. One of such properties is the loss of the ability of an OPI to inhibit a CE irreversibly on replacement of the phosphoryl oxygen by a sulphur atom, which was mentioned in the introduction. It has been established[11] that in contrast to compound (XVII) its dithio analogue $(C_2H_5O)_2P(S)SC\equiv CC_4H_9$ does not inhibit CE. Another acetylenic dithio derivative $(CH_3O)_2P(S)SC\equiv CC_4H_9$ does not possess anti-CE activity.

Considerable similarity has been observed between acetylenic and the usual OPIs in the character of the change in k_{II} vlaue on changing the pH and in the action of tetraalkylammonium ions.

The effect of tetraalkylammonium ions on the bimolecular rate constant for the reaction of ACE with an OPI was investigated at 25 °C and pH 7.5 and was assessed by the value of the inhibition constant K_i[37] which was found from the equation

$$k_{II,\,i} = k_{II}\frac{1}{(1+[I]/K_i)},$$

where [I] is the concentration of the irreversible inhibitor. Experimental points plotted on a graph having coordinates $1/k_{II}$ and [I] lay on a straight line cutting the abscissa axis at a distance equal to $-K_i$.

The effect of pH on the rate of interaction of cholinesterase with OPI was investigated at various values from 3 to 11.

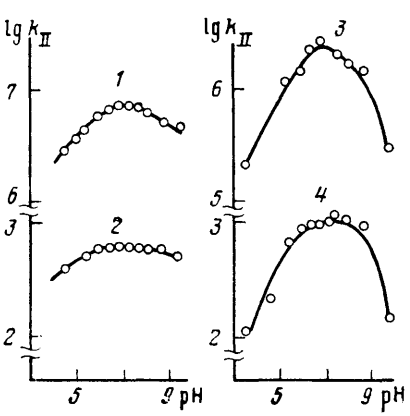

Figure 1. Dependence of the reaction rate of OPIs with ACE on pH; *1*, $(C_2H_5O)_2P(O)SC\equiv CC_2H_4SC_2H_5$; *2*, $(C_2H_5O)_2P(O)SCH_2.CH_2C_2H_4SC_2H_5$; *3*, $(C_2H_5O)_2P(O)SC\equiv CC_6H_{11}$-cyclo; *4*, $(C_2H_5O)_2.P(O)SCH_2CH_2C_6H_{11}$-cyclo.

The dependence of the size of k_{II} on pH when inhibiting ACE with an acetylenic compound and its saturated analogue is expressed by similar curves but the values of the pH optima of these curves were close and were in the pH range 7–8 (Fig. 1). It was established in experiments with ACE[38] that tetraalkylammonium ions reduced to a varying degree the interaction of this enzyme with the acetylenic OPIs (XXXIX) and (XLIV) and with their saturated

analogues (XXXIXa) and (XLIVa). The values of K_i proved to be practically identical for the tetraalkylammonium ions investigated (Table 15). It is evident that the changes in conformation and the degree of ionisation of the functional groups on the active surface of the enzyme occurring on changing pH or by the action of tetraalkylammonium ions proved to be the same when reacting cholinesterases with acetylenic OPI and with their saturated analogues. This indicates that the introduction of an acetylenic bond into the OPI molecule does not change the main features of the mechanism of inhibition of CE.

Table 15. Reversible inhibition constants (K_i, M) for ACE of human blood erythrocytes by tetraalkylammonium ions on reacting the enzyme with acetylenic OPI or their saturated analogues.[38]

OPI		K_i, M		
Compound No.	Formula	$(CH_3)_3N^+$	$(C_2H_5)_4N^+$	$(C_4H_9)_4N^+$
(XXXIX)	$(C_2H_5O)_2P(O)SC{\equiv}CC_2H_4SC_2H_5$	$1.2\cdot10^{-3}$	$1.6\cdot10^{-3}$	$5.1\cdot10^{-5}$
(XXXIXa)	$(C_2H_5O)_2P(O)S(CH_2)_4SC_2H_5$	$1.5\cdot10^{-3}$	$1.8\cdot10^{-3}$	$5.6\cdot10^{-5}$
(XLIV)	$(C_2H_5O)_2P(O)SC{\equiv}C-C_6H_5$	$4.0\cdot10^{-3}$	$3.3\cdot10^{-3}$	$7.2\cdot10^{-5}$
(XLIVa)	$(C_2H_5O)_2P(O)SC_2H_4-C_6H_5$	$6.1\cdot10^{-3}$	$5.0\cdot10^{-3}$	$6.0\cdot10^{-5}$

c) Reactivation

The bimolecular rate constant for reactivation ($k_{II,re}$ M^{-1} min^{-1}) was determined at 25 °C and pH 7.5 and calculated from the formula:

$$k_{II,re} = 2.303/\tau[R]\ \lg(v_0 - v_i)/(v_0 - v_\tau),$$

where v_0 is the initial rate of the enzymic hydrolysis of substrate, v_i the residual rate of hydrolysis after reaction of the enzyme with the OPI, v_τ the rate of hydrolysis of substrate after τ min reaction of the inhibited enzyme with reactivator of concentration [R]. In this formula $(v_0 - v_i)$ is directly proportional to the initial quantity of phosphorylated enzyme and $(v_0 - v_\tau)$ to the quantity of phosphorylated enzyme remaining after partial reactivation at time τ. 1,1-Trimethylene bis(4-pyridinaldoxime) dibromide (TMB-4)[38] was used as reactivator.

The most convincing proof of the phosphorylation of CEs on reaction with acetylenic OPI are the results of experiments on the reactivation of ACE inhibited by various OPIs. It follows from the data of Table 16 that ACE, inhibited by derivatives of diethyl phosphoric acid such as the acetylenic inhibitors (XXXIX) and (XLVI) and their saturated analogue (XXXIXa) and by the well known OPI paroxon, are reactivated by TMB-4 at identical rates. The observed similarity of the reactivation rate constants indicates that a phosphorylated enzyme of the same structure $E-O-P(O)(OC_2H_5)_2$ is formed by reaction of ACE with these compounds which differ markedly in structure. Similar results were also obtained in experiments with the acetylenic derivatives of dimethyl phosphoric acid (XLIII) and (XLIV) and with methylparoxon. In this case the reactivation rate constants were a little greater than in the experiments with the derivatives of diethyl phosphoric acid.

Table 16. Bimolecular rate constants ($k_{II,r}$) for the reactivation of inhibited acetylcholinesterase [reactivator was TMB-4, 1,1-trimethylene-bis(4-pyridinaldoxime) dibromide].[38]

d) Anticholinesterase activity of hexynyltrimethylammonium ions

The results obtained form a basis for considering that the inactivation of cholinesterase by acetylenic OPIs is brought about by esterification of a serine hydroxyl by the appropriate phosphoric acid. Experiments seemed to confirm the initial conclusion that the origin of the acetylene effect should be sought in the effect of the acetylenic bond on the first stage of the inhibition, viz. on the rate of formation of the enzyme–inhibitor complex. Consequently the possibility of an interaction of the C≡C triple bond with structures located either in the region of the anionic site of the enzyme or near the phosphorylated serine hydroxyl has been investigated.[12]

It is known that tetraalkylammonium ions are reversible inhibitors of CE. It is highly probable that their action is effected by adsorption with the formation of simple ion pairs with the carboxylate anion at the anionic point of the enzyme. It has to be clarified whether the triple bond shows a strengthening action on the adsorption of such compounds. Quaternary ammonium ions containing alkynyl groups have been investigated.[14] However the experiments carried out on the inhibition of ACE and BuCE by such quaternary ammonium ions (Table 17) show that the introduction of an acetylenic bond into any position of the hexyl group [compound (LIII)] had practically no effect on the ability of hexynyltrimethylammonium ions [compounds (L)–(LII)] to inhibit reversibly the catalytic activity of the enzymes. The same values of I_{50} were obtained in experiments with trimethylpropynylammonium salts (LIV) and (LV). In reality there is no binding of the acetylenic group in the region of the anionic site of a CE.

The serine hydroxyl may be a binding region. Many authors have proposed its presence in the esterase site of cholinesterase.[1] This hypothesis will be considered below.

e) Cholinesterase hydrolysis of acetylenic substrates

It was mentioned above that acetylenic OPIs, like typical OPIs, phosphorylate the active site of CEs. Further, experiments with ammonium salts show that the acetylenic group does not show any effect on processes occurring in the region of the anionic site of the

enzyme. Nevertheless the acetylene effect (q) is present. Two alternative hypotheses may be proposed. Either the acetylenic group accelerates the formation of the enzyme–inhibitor complex by being adsorbed onto the active surface of the enzyme elsewhere than in the region of the anionic site and this adsorption improves the steric conditions for the attack by the phosphorus atom on the serine hydroxyl of the enzyme very effectively, or the triple bond participates directly in the phosphorylation of the enzyme, i.e. by reducing appreciably the energy of activation in this part of the reaction but not changing the final result. In both cases it remains unclear what occurs to the *S*-alkynyl residue after fission of the thioester bond. Does it remain bound to the enzyme or is it transferred into the reaction medium? The fact that the reactivation rate constants for ACE inhibited by acetylenic OPIs are practically equal to the reactivation rate constants for ACE inhibited by their saturated analogues does not rule out the possibility of forming a product of interaction of the acetylenic bond with any portion of the active surface of the enzyme. If the rate of freeing ACE from the remainder of the *S*-alkynyl group by the action of the reactivator is significantly greater than the rate of dephosphorylation then the presence of a product from the reaction of this group with the enzyme is by no means reflected in the size of the reactivation rate constant.

Table 17. Anticholinesterase activity (I_{50}, M) of trimethylhexynylammonium ions, with the acetylenic bond at different positions in the hexynyl chain, and of their saturated analogue.[14]

Inhibitor		I_{50}, M	
Compound No.	formula	ACE	BuCE
(L)	$(CH_3)_3\overset{+}{N}C{\equiv}CC_4H_9Br^-$	$1.0\cdot10^{-3}$	$2.7\cdot10^{-3}$
(LI)	$(CH_3)_3\overset{+}{N}CH_2C{\equiv}CC_3H_7\cdot Br^-$	$3.0\cdot10^{-4}$	$2.0\cdot10^{-4}$
(LII)	$(CH_3)_3\overset{+}{N}C_2H_4C{\equiv}CC_2H_5\cdot Br^-$	$1.1\cdot10^{-3}$	$7.4\cdot10^{-2}$
(LIII)	$(CH_3)_3\overset{+}{N}C_6H_{13}Br^-$	$2.1\cdot10^{-3}$	$6.5\cdot10^{-3}$
(LIV)	$(CH_3)_3\overset{+}{N}CH_2C{\equiv}CH\cdot Br^-$	$3.5\cdot10^{-3}$	$7.5\cdot10^{-3}$
(LV)	$(CH_3)_3\overset{+}{N}CH_2C{\equiv}CH\cdot I^-$	$1.3\cdot10^{-3}$	$1.5\cdot10^{-2}$

The experiments carried out on the reactivation of the enzyme showed convincingly that the acetylenic OPIs, like the usual OPIs, phosphorylate cholinesterases but they do not give an answer to the problem of the fate of the *S*-alkynyl group.

There are considerable methodological difficulties in the detection in the reaction medium of an acetylenic mercaptan or a product of its conversion during experiments on the inhibition of CE by acetylenic OPIs. In these experiments the concentration of CE active centres in the reaction medium usually does not exceed 1×10^{-9} M and consequently the possible concentration of the *S*-alkynyl residue or its conversion product may not be more than the value indicated. This is a thousand times less than the minimum concentration of SH groups which can be determined by contemporary chemical methods.

The interaction of cholinesterase with *S*-alkynyl esters of thioacetic acid, viz. $CH_3C(O)SCH_2C{\equiv}CH$ [compound (LVII)] and $CH_3C(O)SC{\equiv}CC_4H_9$ [compound (LVIII)] has been investigated in order to clarify this problem.[38]

If the acetylenic group forms a stable complex with the enzyme then these compounds should be irreversible inhibitors. Experiments showed that both compounds were hydrolysed, although slowly, by both ACE and BuCE. Ellman's reagent, present during the enzymic hydrolysis, pointed to the formation of a compound possessing an SH group in the reaction medium. It is possible that this compound is either an acetylenic mercaptan, which reacts with the Ellman reagent at the moment of fission from the substrate molecule, or a product of its conversion. Control experiments, in which the Ellman reagent is added after the end of enzymic hydrolyis, also showed the presence of a product with an SH group. When such a reaction mixture was protected from access to oxygen of the air the concentration of SH groups remained practically unchanged for an extended period. Consequently a stable product with an SH group is formed from the unstable *S*-alkynyl group split off from the substrate molecule or from the acetylenic OPI molecule. It is possible that the conversion of the *S*-alkynyl group occurs by the following scheme:

$$HS{-}C{\equiv}C{-}R \rightarrow S{=}C{=}CHR \xrightarrow{H_2O}$$
$$\rightarrow S{=}C(OH){-}CH_2R \rightarrow HS{-}C(O){-}CH_2R,$$

$$HSCH_2C{\equiv}CH \rightarrow HSC{\equiv}C{-}CH_3 \rightarrow S{=}C{=}CH{-}CH_3 \xrightarrow{H_2O}$$
$$\rightarrow HSC(O){-}CH_2CH_3.$$

Evidently such conversion products of the *S*-alkynyl group are also obtained on alkaline hydrolysis of both acetylenic OPIs and of the acetylenic substrates.

As was established in experiments on the alkaline hydrolysis of acetylenic OPI and substrates,[38] the number of micromoles of alkali spent in the neutralisation of the products formed was almost twice the number of micromoles taken in the experiments on the compounds, i.e. the alkali is bound not only by the appropriate phosphoric or acetic acid but also by the conversion product of the acetylenic mercaptan. According to the data obtained the acid properties of this product exceed those of the usual mercaptans, which is confirmation of the scheme shown.

It was established further[38] that the catalytic activity of the cholinesterases was unchanged during enzymic hyrolysis of the acetylenic substrate. As follows from Fig. 2, the quantity of compound (LVIII) taken is hydrolysed completely by BuCE. A new portion of this compound added to the reaction mixture at the same concentration is hydrolysed at the same rate. The slopes of the curves in coordinates of 'concentration of thiol product formed' against 'time' in the initial period of enzymic hydrolysis for the two portions of substrate proved to be equal. Analogous results were obtained in experiments with compound (LVII). Consequently the products of enzymic hydrolysis do not cause irreversible inhibition of the catalytic activity of the enzyme.

The *S*-alkynyl esters of thioacetic acid therefore act only as substrates in relation to the cholinesterases. The low rate for enzymic hydrolysis is most likely caused by slow desorption of the resulting mercaptan. Evidently among the numerous examples of cholinesterase hydrolysis of various carboxylic acid esters the

hydrolysis of acetylenic substrates is a rare case in which the rate of enzymic hydrolysis is limited by the desorption of the reaction product.[39]

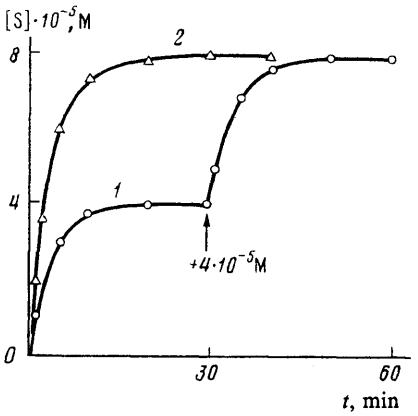

Figure 2. Cholinesterase hydrolysis of substrate $CH_3C(O).SC{\equiv}CC_4H_9$ (S) at different initial concentrations: *1*, 8 × 10^{-5} M, *2*, 4 × 10^{-5} M with subsequent addition of a new portion of substrate (indicated by the arrow).[38]

IV. Toxicity of acetylenic organophosphorus inhibitors

The method of determining the toxicity of OPIs for white mice on subcutaneous administration and the method of determining the contact toxicity for the beet aphid *Aphis fabae Scop.*, the rice weevil *Calandra oryzae L.*, the imago and larvae of the fourth instar of the Colorado beetle *Leptinotarsa decemlineata Say.*, larvae of the second instar of the Podisus bug *Podisus maculiventris Say.* and the spider mite *Tetranychus urticae Koch* have been described previously.[15] The mouse toxicity was characterised by the LD_{50}, the dose of the substance in mg kg^{-1} causing death of 50% specimens, and the toxicity for arthropods by the size of the LC_{50}, the concentration of compound in mg $litre^{-1}$ causing death of 50% specimens also 24 h after applying the OPI.

Only a small proportion of the compounds shown in Tables 12 and 13 were used in the toxicological investigation. Mostly these were compounds with high anti-CE activity (Table 18). The test objects for the toxic action of these compounds were white mice, beet aphids, rice weevils and spider mites. It follows from the data of Table 18 that the *S*-ethynyl esters of dialkyl thiophosphoric acids possess high insecticidal activity, exceeding that of the standard (chlorofos for beetles, carbofos for aphids) 10–100 times in certain cases. At the same time their saturated analogues proved to have low toxicity for arthropods. The introduction into the OPI molecule of an acetylenic bond in the α-position relative to the phosphoryl-mercapto group leads to a significant enhancement of the anti-CE activity and of the insecticidal properties. The efficiency of such enhancement depends on the OPI structure and is manifested in a different way for each compound for the arthropods investigated.

It is generally acknowledged that CE inhibition is the main reason for the toxic action of the organophosphorus insecto-acaricides.[40] However a direct link between the toxicity of the organophosphorus compounds and their inhibitory activity towards the CE of the given representatives of the arthropods or mammals exists in those fairly rare cases when compounds close in structure are investigated. The absence of such a link is explained chiefly by differences in losses of compound during the time taken to be transferred from the site of administration in the organism to the synaptic CE and in non-uniform conversions during metabolism.[40,41]

Table 18. Toxicity of *S*-ethynyl esters of dialkyl thio- and dithiophosphoric acids $(RO)_2P(Y)SC{\equiv}CX$ and their saturated analogues $(RO)_2P(Y)SCH_2CH_2X$ (compounds numbered 'a').[15]

*Compounds of low toxicity for arthropods. Death of test objects at concentration of 500 mg $litre^{-1}$ for mites and 100 mg $litre^{-1}$ for aphids were only 5–10%.

Footnote. Values of the thione effect *T* are given in parentheses [for mammals $T = LD_{50}$ (Y = S)/LD_{50} (Y = O) and for arthropods $T = LC_{50}$(Y = S)/LC_{50} (Y = O)].

It follows from Tables 12 and 13 that of the *S*-ethynyl esters of diethyl phosphoric acid the strongest inhibitors of CE are compounds (XXVII) and (XLVI), while compound (XLVI) (Table 18) is surpassed by compound (XVII) in its toxic action on mice. Compounds (XVII), (XXXVI) and (XXXVII) surpass compound (XXVII) in their toxic action on mites, although these compounds are weaker than compound (XXVII) in anti-CE activity by a ratio of 30–80. Only for aphids was a satisfactory link

observed between the anti-CE activity and toxicity of these compounds.

Since the toxicities of the investigated thiophosphoric acid esters for mice are relatively large these compounds do not satisfy contemporary requirements for highly selective insecto-acaricides. It is known that replacement of a phosphoryl (P=O) group by a thiophosphoryl (P=S) group in an OPI leads to a reduction in toxicity since thione derivatives are devoid of anti-CE activity and their toxic action *in vivo* is brought about only after enzymic oxidative desulphurisation which occurs at different rates in different forms of animal.[40,41] This reaction is provided in the system by microsomal oxygenases with cytochrome P-450 as the central unit. This process is usually accomplished significantly more rapidly in arthropods than in mammals, which possess a relatively low activity of these enzymes.[41] As a result the replacement of a phosphoryl group in OPIs by a thiophosphoryl group markedly reduces their toxicity for mammals and in the same way increases the selectivity of their action on arthropods. The selective toxicity of compounds in this case is assessed most graphically (Table 18) by the size of the 'thione effect' (T) which is the ratio of the toxicity of the thione compound ($LD_{50,S}$ and $LC_{50,S}$) to the toxicity of its oxygen analogue ($LD_{50,O}$ and $LC_{50,O}$).

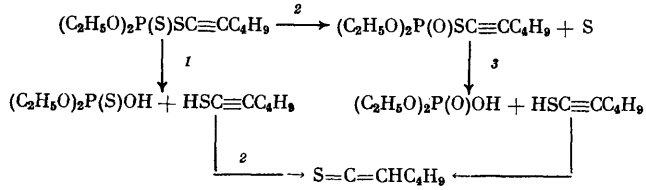
Acetylenic (8) and saturated (3) derivatives of dithiophosphoric acids, which are analogues of the monothio compounds, have been synthesised and investigated.[15] In the text they will be referred to by the number of the oxygen compound with the index S. Their toxicities and the size of the thione effect are given in the same Table 18. The thione derivatives investigated differ from one another in toxicity to a larger degree than do the oxygen analogues. For example, for beetles the toxicity of compound (XLVI,S) has a $LC_{50,S}$ value of 1 mg litre^{-1}, but the toxicity of compound (XXVII,S) has a value of 7000 mg litre^{-1}.

It was extremely important and unexpected that on replacing a phosphoryl by a thiophosphoryl group in the acetylenic compounds the toxicity was changed very little for arthropods but was strongly reduced for mammals. Some acetylenic derivatives of dithiophosphoric acid proved to be 100 times less toxic for mice than the corresponding derivatives of monothiophosphoric acid. The size of the thione effect for compounds (XVII), (XXVII) and (XLVI) was more than 400. This sharp fall in toxicity for mammals on replacing the phosphoryl oxygen by sulphur in OPIs is observed for the first time. In contrast to the acetylenic compounds the saturated analogues are characterised by significantly smaller values of the thione effect. Values of T were from 2 to 12 which is natural for the usual organophosphorus insecto-acaricides.

The size of the thione effect for arthropods was in the range 0.5 to 1 in all cases. A thione effect equal to 1 might be regarded as the result of complete conversion of the dithio into the monothio compound by oxidative desulphurisation by certain isoenzymes of cytochrome P-450. Obviously such a assumption is naive as values of the thione effect of less than 1 contradict this conclusion. Such low values for the thione effect may be explained by the presence in addition of further oxidative desulphurisation and deocmposition processes which are catalysed both by oxidases and by other enzymes.[41] Low values for the thione effect were detected for compounds (LVI) and (LVI,S) in experiments with other representatives of the arthropods, viz. Colorado beetle and Podisus bug. It follows from Table 19 that in all cases the size of the thione effect was less than 1, particularly in experiments with Podisus (T = 0.09).

In order to clarify the mechanism of the thione effect for the acetylenic organophosphorus compounds the interaction has been studied[38] of compounds of general formula $(C_2H_5O)_2P(Y)R$, where R = $C{\equiv}CC_4H_9$, $SC{\equiv}CC_4H_9$, and Y = O or S, and also of their saturated analogues with cytochrome P-450 from Wistar rat liver microsomes and from the abdomen of houseflies. The effect of the OPIs on cytochrome P-450 was studied by a known procedure.[17]

Table 19. Toxicity (LC_{50}, mg litre^{-1}) of compounds $(CH_3O)_2P(Y).SC{\equiv}CC_4H_9$ for Colorado beetles and for Podisus bugs.[41]



Y	LC_{50}, mg litre^{-1}		
	Colorado beetle		Podisus bug
	imago	larvae IV instar	larvae II instar
O	1900	1500	75
S	790	1050	6.5
	(0.42)	(0.7)	(0.09)

Table 20. Reaction of compounds $(C_2H_5O)_2P(Y)R$ with cytochrome P-450.[17]

OPI			Decrease in cytochrome P-450 content, %	
compound No.	R	Y	rat liver microsomes	fly abdomen microsomes
(XXXVII, S)	$SC{\equiv}CC_4H_9$	S	22.2±2.5	60±6.5
(XXXVII)	$SC{\equiv}C_4H_9$	O	22.2±1.7	27.5±1.5
(XXXVIIa, S)	$SCH_2CH_2C_4H_9$	S	0	10.5±3.7
(XXXVIIa)	$SCH_2CH_2C_4H_9$	O	0	0
(LVII)	$C{\equiv}CC_4H_9$	O	0	0
(LVIIa)	$CH_2CH_2C_4H_9$	O	0	0

It is seen from Table 20 that after incubation of cytochrome P-450 from rat liver microsomal fractions in the presence of NADPH, destruction of enzyme occurs only by the action of the acetylenic thioesters of monothio- and dithiophosphoric acids (XXXVII) and (XXXVII,S) but in the case of cytochrome P-450 from fly abdomen destruction also occurs in the presence of the saturated compound, the *S*-hexyl dithiophosphate (XXXVIIa,S). The analogous *S*-hexyl monothiophosphate (XXXVIIa), having no thiol group like the esters of the phosphonic acids (LVII) and (LVIIa), does not react with the microsomal cytochrome P-450. It is obvious that the destructive action is not possessed by the compounds (XXXVII), (XXXVII,S) and (XXXVIIa,S) themselves but by products of their conversion. One of the most probable conversion routes for esters of phosphorus thioacids may be cleavage of the thioester bond by certain cytochrome P-450 isoenzymes. A normal mercaptan is formed from thioesters with a saturated R group. The mercaptans formed in the case of the acetylenic

thioesters are unstable and are readily converted into thioketenes as shown in the scheme.

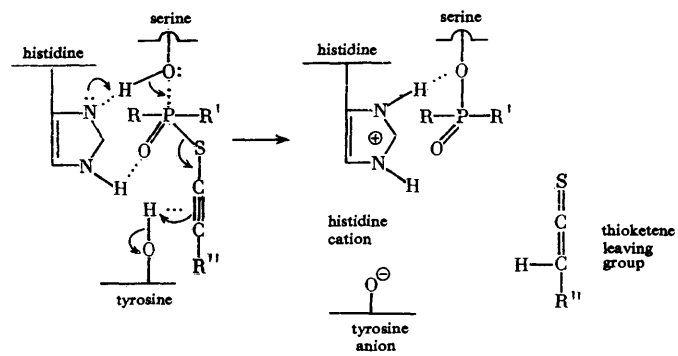
The ability of thioketenes to react with any compound containing a labile hydrogen atom is well known.[17] It may therefore be taken that butylthioketene, formed by the metabolism of the acetylenic compounds (XXXVII) and (XXXVII,S), reacts with the appropriate groups in the haem region of cytochrome P-450 causing its destruction. It is known from the literature[42] that destruction of cytochrome P-450 is observed when organic compounds with unsaturated bonds add to the protoporphyrin ring of haem. The thioketene formed causes destruction of the monooxygenase and in this way reduces the rate of detoxification of acetylenic OPIs thereby aiding the retention of their toxicity. The saturated mercaptans formed on deactivation of the saturated analogues (XXXVIIa) and (XXXVIIa,S) are incapable of destroying the enzyme.

Another metabolic route for the thione esters of phosphorus acids is their activation by the process of oxidative desulphurisation. It is also effected in a microsomal monooxygenase system but seemingly by other cytochrome P-450 isoenzymes. A sulphur atom is formed which it is claimed is able to bind covalently with the cytochrome active centre causing its degradation.[43] In actual fact diethyl *S*-hexyldithiophosphate (XXXVIIa,S) displays a destructive action on fly abdomen cytochrome P-450. Only the sulphur atom formed in the oxidative desulphurisation of this compound may possess this action in this case since the other metabolite, hexylmercaptan, cannot exert a degradative action on a cytochrome as follows from the experiments with compound (XXXVIa). In addition it is evident from Table 20 that compound (XXXVIIa,S) does not possess a destructive action on the family of isoenzymes of rat liver cytochrome P-450, which evidently indicates the insignificant content of the isoenzyme effecting the oxidative desulphurisation in rat liver microsomes compared with fly abdomen microsomes.

Insect cytochrome P-450 is therefore able to activate the dithio derivatives used but rat cytochrome P-450 is less well suited for this.

The reasons stated explain logically why compound (XXXVII) reduces the content of cytochrome P-450 to the same extent in rat liver microsomes and in fly abdomen microsomes but compound (XXXVII,S) acts more strongly on the cytochrome P-450 from fly abdomen microsomes.

The introduction of a thioethynyl group into an OPI molecule, which contains a phosphoryl group, leads to high toxicity not only as a result of an increase in anticholinesterase activity but also by reducing its detoxification rate by destroying specific cytochrome P-450 isoenzymes. These processes proceed at approximately the same rate in mammals and arthropods.



The activation of *S*-ethynyl esters of dialkyl dithiophosphoric acid by specific cytochrome P-450 isoenzymes in mammals and arthropods proceeds at different rates. These processes occur at a higher rate in arthropods than in mammals. Evidently these are the chief factors in the display of the thione effect observed by us.

V. Conclusion

The results of the investigations carried out show that thioesters of monothioacids of phosphorus containing an acetylenic bond in the thioester group are a new class of organophosphorus inhibitors possessing very high anticholinesterase activity.

Analysis of the mechanism of action of these OPIs on CE leads to the conclusion that the role of the acetylenic group consists of the formation of an enzyme–inhibitor complex which is then converted into a phosphorylated enzyme or of the significant acceleration of the phosphorylation step leading to the same phosphorylated enzyme. In connection with the first hypothesis it must be said that to date there are no clear data on the location of the binding portion. It may only be assumed that it is not in the region of the anionic site but is a small distance from the esterase centre. It is probably impossible to consider the binding zone as strictly fixed, its location may vary within known limits when reacting the enzyme with inhibitors of various structure. This follows from Koshland's theory[44] on the induced fit of an enzyme active centre to the structure of susbtrates and inhibitors when reacting with them. The correctness of this conclusion is indicated by the fact that OPIs with an acetylenic bond in the β-position are characterised by high values for the acetylenic effect. For example compound (XV), $CH_3(C_2H_5O)P(O)SCH_2C\equiv CCH_2SC_2H_5$, on reaction with arthropod CE gives inhibition rate constants k_{II} of 2.5×10^7 to 1.1×10^9 M^{-1} min^{-1} and values of the acetylene effect q of 590 to 38 000. Consequently the part of the enzyme binding the actylenic group to the active surface is accessible not only to compounds with the acetylenic group in the α-position but also to compounds with a β-acetylenic group. In the latter case it is evident that there are definite restrictions since the disposition of the functional portions of the binding onto the active surface of the enzyme corresponding to a compound with an α-positioned acetylenic bond will not correspond to a compound with a β-acetylenic bond.

It is possible to represent the second hypothesis by an extended scheme of phosphorylation of the esterase site of the enzyme, comprising a serine hydroxyl group, a histidine imidazole ring and a tyrosine phenolic hyroxyl with the inhibitor acetylenic group forming a π-complex bond with the tyrosine proton.

Lengthening of the conjugation chain in which transfer of a proton from tyrosine to the acetylenic bond and from serine to histidine occurs and there is remote transfer of an electron pair from the histidine nitrogen to the tyrosine oxygen must sharply reduce the activation energy of the phosphorylation. It is possible that at such an orientation of the OPI at the moment of attack adsorption onto the anionic point of the CE loses its value. It is understood that the

normally phosphorylated enzyme must be formed as a result of such a process but the rate of its formation must be appreciably higher.

It is not ruled out that these two hypotheses do not contradict one another. All depends on the time (moment) of forming the π-complex of the tyrosine phenolic hydroxyl with the acetylenic π-bond.

The effect of the acetylenic bond depends markedly on the structure of the compound. Compound (XX), $(C_2H_5O)_2$.P(O)SC≡CH, the simplest of the acetylenic OPIs investigated, possesses very high anti-CE activity. Replacement of the acetylenic hydrogen in this compound by various hydrocarbon residues does not increase but reduces anti-CE activity in relation to many CE in the majority of cases. A substituent with a sulphonium grouping proved to be weakly effective. Consequently the acetylenic OPIs with the substituents indicated above are not oriented on the catalytic centre of the enzyme in the best way. As is known[44] the complementarity of the inhibitor molecule with the enzyme active surface, which causes 'productive' adsorption in the final account, depends generally on the compatibility of the various forms of their interaction such as ion–ion, ion–dipole, dipole–dipole, hydrophobic and, in our case, on the orientation of the acetylenic group as well. When these interactions are compatible the adsorbed OPI molecule is oriented on the active centre so that the phosphorus atom and the serine hydroxyl of the enzyme are spatially drawn together and phosphorylation occurs. When the interactions are 'incompatible' the inhibitor molecule is disposed so that the phosphorus atom and the serine hydroxyl are spatially separate, the acetylenic bond is unable to participate and phosphorylation is hindered.

High physiological activity and selectivity of action are characteristics of acetylenic OPIs. Selectivity in relation to arthropods is sharply increased on replacing the phosphoryl group in them by a thiophosphoryl. The toxicity for mice is thereby reduced, occasionally by a hundredfold, while for OPIs without an acetylenic group it is reduced by no more than 20 times.[40] The toxicity of the same acetylenic OPI for arthropods is changed very little by this and in several cases the opposite effect is observed. The toxicity of esters of dithiophosphoric acid exceeds the toxicity of esters of monothiophosphoric acid.

The properties of the acetylenic organophosphorus compounds which are so unusual require further study of the metabolic features of these compounds in mammals and arthropods.

Lectins in the investigation of receptors

V M Lakhtin, I A Yamskov

Institute of Foodstuffs, Academy of Sciences of the USSR, Moscow

ABSTRACT. Problems of the purification and characterisation are considered for approximately 270 receptors (including cell surface and organelle enzymes), which are glycoconjugates (mainly glycoproteins) from animals, plants and microorganisms, using various lectins (mainly lectin sorbents). An analysis has been carried out of the stages of lectin affinity chromatography of receptors (choice of detergent, use of organic solvents, elution with carbohydrates, etc.). Examples are given of procedures for the purification of receptors, including the use of paired columns and combination chromatography on lectins. The possibility of separating sub-populations of receptors using lectins has been demonstrated. Examples are given of the use of lectins in the analysis of the oligosaccharide structure of receptors. Cases are recorded of the interaction of receptors with endogenous lectins and of receptor lectins with endogenous glycoconjugates. It has been shown that lectins, in combination with glycosidases and antibodies, may be useful in the investigation of receptors.

The bibliography contains 406 references.

I. Introduction

In recent years the study of receptors has been at the centre of investigators' attention due to their participation in biorecognition at various levels of the organisation of living systems.[1–9] It has been established that key (important in the metabolic sense) interactions between receptors and external agents (endogenous and exogenous, soluble and bound to cell surfaces or cell organelles) proceed in many cases by specific bonding between lectins (carbohydrate-binding proteins) and glycoconjugates.[10–22] The problems of purifying and characterising receptors with a selection of lectin sorbents or labelled lectins are therefore of interest to biologists and chemists. A large number of publications has appeared since the publication of the review by Lotan and Nicolson[23] on the purification of membrane glycoproteins by lectin affinity chromatography. These have extended our ideas on the possible use of lectins in the study of receptors and enzymes bound to cellular structures (see reviews[21,22,24–27] for example).

The aim of the present review is to examine the purification and characterisation of receptors of various types using lectins, chiefly lectin sorbents.

II. Interaction of immobilised lectins with receptors

Results are summarised in Tables 1 and 2 of the use of lectin affinity chromatography for the purification of receptor glycoproteins, including enzymes bound to cellular structures (see also reviews[22–24,26]). It is evident from Tables 1 and 2 that receptors possess an affinity for a wide range of lectins. Wheat-germ lectin (WL) is the most frequently used which is explained by the widespread distribution on its receptor glycoproteins of polyantenna sialylated glycans, branched residues of *N*-acetyl-D-glucosamine, *O*-glycoside-bound *N*-acetyl-D-glucosamine residues, hybrid oligosaccharides and glycans of the polylactosamine type (see below for investigations of receptor structure with lectins).

1. Results of the use of lectin affinity chromatography for the purification of receptors

It is evident from the data shown in Tables 1 and 2 that the use of wheat lectin enables 50–100-fold purification of Ca-channels, opioid receptors and glycoproteins of olfactory neurones.[47,61,74,90,117,193] Concanavalin A (Con A) is highly effective in the purification of phospholipase A_1 (165 times, based on enzyme activation[269,270]) and pea (*Pisum sativum*) lectin in the purification of fibroblast glycoproteins (58 times, by affinity HPLC [187]). Some lectins, which are relatively rarely used in lectin affinity chromatography, may also prove to be extremely useful, e.g. castor-oil plant (*Ricinus communis*) lectin (CL) in the purification of the glycoproteins induced by Epstein–Barr virus and of the cholecystokinin receptor [144 and 440 times respectively,[98,223] gorse (*Ulex europaeus*) lectin-I (GL-I) in the purification of the cholecystokinin receptor (300 times)[99]] and the lectin from seeds of *Vicia bungei* which is specific for α-mannose in the purification of opioid receptors (200 times[60]). Lectin affinity chromatography is the most efficient step in receptor purification in these and in other cases (see Tables 1 and 2).

Stabilisation of receptor preparations is achieved by lectin affinity chromatography. This is important for their preservation (for example, in the case of dopamine receptors[76]). This is evidently linked with the removal of contaminating hydrolases and oxidases.[92] Occasionally investigators have found activation of receptors in eluates from the lectin sorbent, as in the case of receptors of insulin,[91] phospholipase A_1 [269] or Ca^{2+}-dependent peptidase.[295] Activation of the glycoconjugates indicated above may occur both by the removal (separation in eluates) of inhibitors (glycoconjugates and proteins) and by the stabilisation of receptors in comparison with an unstable control (before purification). An appreciable

increase in the yield of receptors, up to 150% of the initial activity, is achieved in specially selected cases.[269]

Simple immobilisation of glycoconjugates (low yield at a high percentage of binding) with their simultaneous purification from contaminants is possible during affinity chromatography on lectins. This occurs in the case of α_1-adrenergic and lactogenic receptors, epitectin (Ca-antigen), receptors of thyrotropin and interleukin 4 and sulphotransferase.[65,108,112,163,214,256] As in other cases of oligomeric receptors, subunits with a predominant affinity for the given lectin (glycosylated subunits) are bound primarily with the lectin sorbent and provide subsequent directed assembly of the receptor (the addition, for example, of non-glycosylated subunits) as in the case of receptors of α-latrotoxin, fibronectin, insulin-like growth hormone, cGMP-channel, Na^+,K^+-ATPase and antigens of trypanosomes[43,123,134,201,235,302,303] and also receptor complexes.[51,126,202]

Octopamine R/neurohormone R/adenyl cyclase activator R from luminescing organs of the glow-worm *Photinus Pyralis*, SU 75 + 79 kD	Affinity for Con A**(blotting)***	[82]
Muscarinic acetylcholine R from porcine atrium cordis	WL (55%; 20 times)	[83]
Acetylcholine R from bovine brain cortex, 73 kD	WL (b 90%; yield up to 65%)** Con A**	[84]
Acetylcholine R from rat muscle fibres	WL (b)	[85]
Acetylcholine R from rat brain cortex	WL better than Con A**	[86, 87]
Acetylcholine R from the electric organ of the eel, α + β + γ + δ (SU)	Labelled*** L-FGA (b δ- and γ-SU) WL (b δ-SU) Con A (b all SU)	[88]
Ryanodine R from rabbit brain and muscle	WL (no b) Con A (no b) LL (no b)	[51a, 88a]

Receptors of peptide and protein hormones and growth factors from animal tissues and cells

Insulin R from human placenta WL → LL → CL-1	WL (98%; 22 times) PL (45%; 14 times) LL (30%; 15 times) Con A (20%; 5 times) CL-1 (15%; 7 times)	[89]
Insulin R from human placenta WL → Insulin; Con A → Insulin	WL (54%; 7.5 times) WL (40%; 5 times)	[90, 90a]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
Insulin R from human IM9 lymphocytes WL → CL-1 → PL	WL (70%; 21 times) CL-1 (50%; 50 times) CL-2 (30%; 50 times) PL (25%; 26 times) LL (20%; 15 times) Con A (10%; 5 times)	[89]
Insulin R from rat skeletal muscle	WL (80%; 70 times)	[90a]
WL → Insulin	WL (94 – 120%; 7 times)	[91]
Insulin R from rat brain and liver, SU 135 + 95 kD DEAE → Con A → Insulin → WL	Con A (93%; 36 times) WL (94%; 2.3 times; removal of insulinase)	[92]
Formyl-peptide R from rabbit peritoneal neutrophils, 50 – 70 kD (fMet-Leu-Phe) → WL	AC → WL (74%; 203 times)	[93]
Vasopressin V1 R from rat liver, 58 – 68 kD, GF → WL → HA → DEAE	WL (84%; 6 times)	[94]
Peptide transporter from rabbit small intestinal brush border membranes, 127 kD, WL → DEAE	WL (b)	[95]
Vasoactive intestinal peptide R (neurotransmitting hormone R) from rat liver, 80 + 56 kD	WL (b 50%;)**, but not Con A	[96]
Vasoactive intestinal hormonal peptide R from rat lung, 58 kD	WL (b)	[97]
Cholecystokinin R from rat pancreas, 80 – 90 kD, CL-2 → Affigel	CL-2 (about 100%; 440 times)	[98]
Cholecystokinin R from rat pancreas, 95 kD S-Sepharose → GL-1 → GF	GL-1 (47%; 300 times) better than WL	[99]
Cholecystokinin R from rat pancreas, 85 – 95 kD	WL (b)**	[100]
R from liver bile duct cells, 110 kD	WL (b)	[101]
R of luteinising hormone and choriogonadotropin from rat ovary, 73 kD or 90 – 93 kD, WL → Choriogonadotropin	WL (70%; 18 times)**	[102 – 104]
R of luteinising hormone and choriogonadotropin from porcine ovary Sepharose 6B → Con A	Con A (30 – 40%; 4 – 10 times)	[105]
Lutropin R from porcine ovary, 22 + 40 + 66 kD Hormone → Con A	Con A (50 – 75% b)	[106]
Folliotropin R from bovine testes, 240 kD (SU 60 kD) DEAE → WL	WL (92%; 3.7 times) two types of GP	[107]
Thyrotropin R from bovine thyroid, 316 + 115 + 54 kD Thyrotropin → GrL	Thyrotropin → GrL (3%; 808 times) GrL (84% b) WL (70% b) CL-1 (69% b) Con A (60% b)	[108]
Thyrotropin R from thyroids of patients with Graves' disease, 70 + 50 + 35 kD WL → Thyrotropin	WL (26%; 4.7 times; b more than 90%)	[109]
Somatostatin R from rat pancreas, 400 kD (100 + 56 + 21 kD, SU)	WL (75%; 7 times)	[110]
Somatostatin R from rat brain	WL (50% b; yield 67% of bound form)	[111]
Lactogenic R from mouse liver, SU 62 + 100 kD (in complex with human growth hormone 20 kD)	Con A (95% b; yield 30%) CL-1 (81% b; yield 69%) LL (52% b; yield 38%) WL (27% b)	[112]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
Lactogenic R from rat ovary Con A → Choriogonadotropin	Con A (yield 60%)	[113, 114]
Corticotropin releasing factor R from rat anterior pituitary and brain, SU 75 and 58 kD respectively	WL 20% (b)** Con A (b)	[115]
Growth β-transforming factor R from chick and human tissue, mouse 3T3 cells	WL (b)	[116]
Platelet growth factor R from porcine uterus WL → Mono Q → (Ab to phosphotyrosine)	WL (99%; 90 times)*	[117]
Fibroblast growth factor R from bovine brain, 125–165 kD DEAE → Mono Q → WL → (Growth factor)	WL (100% b), to remove heparin	[118]
Insulin-like growth factor I R from phaeochromocytoma PC12 cells and bovine adrenals	WL (Purification 36–72 times)	[119]
Insulin-like growth factor I R from human placenta	WL (b)	[120]
R for platelet-derived growth factor from cat brain, 145 kD	WL (b)**	[121]
Growth hormone R from cultured human lymphocytes	WL better than Con A, LL, CL-1, CL-2	[122]
Insulin-like growth factor II R from human lipid cells, 260 kD (SU 87+60 kD)	WL (b)	[123]
Heparin-binding growth factor R from human hepatoma Hep G2 cells, 130 kD	WL (b)**	[124]
Macrophage and granulocyte colony-stimulating factor R from human placenta, neutrophils and leukemic cells lines, 84 kD	WL (b)	[124a]
α-Interferon R from human lymphoblastoid *Namalva* cells	WL (47%; 13 times)*	[125]
Human β-interferon R, 110 kD WL → Ab	WL (90% b; yield 68%)	[126]
γ-Interferon R from human foreskin fibroblasts Interferon → CL-1	CL-1 (100%; 2.6 times)	[127]
γ-Interferon R from human placenta, 90 kD WL → Interferon	WL (b)**	[128]
Other receptors and animal antigens		
Complement CR1 R from human peripheral nerve myelin, 190 kD	LL (b)	[129]
Immunoglobulin Fc-fragment R from lymphocytes of patients with chronic leukemia LL → GF	LL (b)	[130]
α_2-Macroglobulin R from human placenta, 420 kD GF → Macroglobulin → Mono Q → WL	WL (b)	[131]
Mouse lactotransferrin R, 130 kD	Con A, L-FGA (b)**	[132]
Fibronectin R from rat hepatocytes and fibroblasts, 155+115 kD WL → (Fibronectin hexapeptide)	WL (b)	[133]
β-SU R of mouse sarcoma fibronectin, 135 kD LL → WL → AC → HA	WL (no b, purified by filtration)	[134]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
R of fibronectin/integrin from rat liver parenchymal cells, SU 110 kD WL → Fibronectin	WL (b)**	[135]
Antigen associated with integrins from plasma membranes of human placenta cells, SU 50 kD WL → γ-Interferon → B6H12 (Ab)	WL (b)	[136]
β_1-SU of integrin (R of fibronectin from larvae of amphibian *Pleurodeles waltl* GF → Con A	Con A (b)	[137]
Transferrin R from mouse NS-1 plasmacytoma cells, SU 90–95 kD	4 L (b GP)**	[138]
Transferrin R from chicken oviduct, 180 kD (SU 91 kD)	4 L (b GP)	[139]
Vitronectin R from human M21 melanoma cells	Con A, LL (b)	[140]
Vitronectin R/integrin $\alpha_v\beta_3$/fibronectin R from human placenta LM 609 (Ab) → WL	WL (b)	[141]
Integrin $\alpha_1\beta_5$ (adhesion R of vitronectin) from human placenta LM 6–9→MN142→WL	WL (b)	[142]
Fibrinogen R (GP-IIb/IIIa-like R) from human endothelial cell lines, 150+(110–125)+95 kD AC → WL → (Ab to GP-IIIa)	WL (9b 100%)	[143]
Laminin R (200/120 kD-integrin) of B50 neuroblastoma cells (integrin $\alpha\beta_1$) WL → Laminin	WL (b)	[144]
Adhesin R of endothelial cells of bovine embryo aorta and human umbilical vein (not a member of the cadherin family), 130 kD WL→Ab	WL (b)	[145]
Adhesin R of neural cells from C2 muscle cells	AL (b)	[146]
Adhesin R of substrate from mouse OTT6050 teratocarcinoma cells, 125 kD	CL-1 (b)	[147]
GP-Ib of human platelets/Willebrand factor R, 165 kD (SU 143+22)	WL (removal of actin and GP-IX)	[148]
GP-Ib of human platelets/adhesion R to vessel subendothelium WL → DEAE	WL (b)	[149]
GP-IIb/IIIa of human platelets Con A → Heparin → GF → WL	Con A (b GP-IIb/IIIa+thrombospondin+fibrinogen), WL (removal of fibrinogen)	[150]
GP-IV of human platelets LL → WL	LL (removal of GP-IIb/IIIa by binding), WL (b GP-IV, Ib)	[151]
GP-IV of human platelets (CD 36-like), 88 kD WL → WL → GF; DEAE → WL → GF	WL (b)	[152]
GP-V of human platelets Superose 12 → Mono Q → WL	WL (66%; 7 times)*	[153]
GP-IX of human platelets, 17 kD WL → (Ab to GP-Ib) → GF (HPLC)	WL (b)	[154]
Thromboxane A-2 R/prostaglandin H-2 R from human platelets GF → WL → Red agarose → GF (HPLC)	GF → WL (22%; 1620 times)*	[155]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
Glycocalicin of human platelets WL → Mono Q	WL, Con A, CL–1**, E-FGA	[156, 157]
Bean lectin R from porcine spleen lymphocytes	FGA (b)	[158]
Peanut lectin R from mouse immature thymocytes, 170–180 kD	AL (b)	[159]
GP Thy-1 (antigen) of mouse thymocytes Con A → (Ab to Con A) → GF	Con A (83%; 19 times)	[160]
Antigen Thy-1 of mouse thymocytes, less than 27 kD + 28 kD	Thorn apple lectin (<27 kD not b 50%; retarded 25%; 28 kD b and desorbed 25%)**	[161]
Mammalian interleukin 3 R, 140 kD	WL (b)	[162]
Interleukin 4 R from gibbon MLA 144 line T-lymphocytes, 130 kD CM → WL → Interleukin 4	WL (35%; 4.5 times) CM (filtration) → WL (10–15 times)	[163]
CDw44 antigen from T-lymphocytes of patients with chronic leukemia, 85 kD F10-44-2 (MAb) → DEAE → WL → CM → GF	WL (b)	[164]
Leukosialin (sialoformin, CD 43) from human leucocytes (MOLT-4 cells), 95 kD	WL and CL-1 (b 100%), Con A and LL (partial b); desorption with detergent (except for WL)**	[165]
Leukosialin from human line HL-60 promyelocytes WL → Ab	WL (b)	[166]
Leukosialin from human K562 erythroleukemic leukocytes, 105 kD	WL better than other lectins	[167]
Lymphocytic antigen from membrane, 28 kD	LL (b)**	[168]
GP (H-antigen) containing fucose from human erythrocytes DEAE → (aleuria lectin)	Aleuria lectin (b)**	[169, 170]
GP containing A-antigen from human blood group A (+) erythrocytes, 500 kD (SU 42–55 kD)	Snail lectin (b)	[171]
GP containing Cad-antigen from human blood Cad-group erythrocytes	Dolichos L better than snail L, WL, E-FGA, Maclura L	[172]
Glycophorin M from human blood St^a-group erythrocytes	LL (removal of glycophorin N)	[173]
Glycoprotein precursors of blood group N antigen with Thomson–Friedenreich (T) antigen activity from patients with malignant carcinoma of the ovary (*Vicia unijuga* L)→AL	*Vicia unijuga* L (b), AL (b)	[174]
Glycophorins A, B, N from human blood Dantu-group erythrocytes	LL (no glycophorin N b)	[175]
Glycophorins A, B, C, E from human erythrocytes WL (HPLC) → Cu^{2+}-chelate	WL (separation of A+B+C and E–no b	[176]
Glycophorin A from human MM- and NN-erythrocytes	WL (b 100% for MM and 70% for NN), CL-1 (b of asialoglycophorin)	[177–179]
Gonococcus R from human erythrocytes (band-3), 186 kD (SU 93 kD)	Con A (b)	[180]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
GP of adipocyte ghosts from porcine great omentum, 47+79 kD PL → DEAE → GF	PL (b)	[181]
Lipoprotein R from insect fat body, 120 kD DEAE → HA → Con A → AC	Con A (b)*	[182]
R of cytolytic (antitumour) activity of mouse peritoneal macrophages, 153+140+90 kD	WL (b)	[183]
R for the activation of cytotoxic activity from mouse macrophages, 460 kD (110+170)	*Eristalis* L (b)	[184]
R for *Mycoplasma pneumoniae* microbe from human lung MRC-5 fibroblasts	WL (b)	[185]
GP of type II alveolar cells of rabbit and rat lung, 230 and 200 kD respectively	Maclura L (b)**	[186]
GP from human diploid fibroblasts PL (HPLC), Con A (HPLC)	PL (purification 58 times) Con A (purification 6 times)	[187]
GP induced by aldosterone from toad bladder epithelial cells, 65+70 kD	WL (purification 20 times)** Con A (b)	[188]
Epidermal factor R from A-431 cells, 170 kD	Con A and LL (b OS)**	[189]
Unique kidney antigen in human renal disease, 98+105 kD	Thorn appleperoxidase L (b) out of 5 L***	[190]
GP-II from chromaffin granules of bovine adrenals, SU 80–100 kD	WL (b)	[191]
GP-1 associated with ovocyte lysosomal membranes from the chinese hamster, SU 135+115 kD	Bovine heart Ln (b), Tomato Ln (b)	[192]
Transmembrane GP from frog olfactory neurones, 95 kD	WL (50 times)	[193]
Antigen 2B8 from rat olfactory neurones, 215 kD	WL, CL-1 (b asialoGP)	[194]
GP of oligodendroglial cultured cells, 99+77 kD IEC → WL	WL better than Con A, LL (no b with CL-1 LL SL, dolichos L)	[195]
GP from bovine brain oligodendroglia, 99+77 kD IEC → WL	WL (yield 70%)	[196]
GP from human brain myelin and oligodendrocytes, 120 kD AL → AL	AL (b)	[197]
Antigen of mouse cerebellum Purkinje cells, 400 kD GF → Con A → GF	Con A (b)	[198]
GC binding hyaluronic acid from 8-week mouse brain (GC is more than 50% proteoglycans) PL → GF → DEAE	WL (89–100%; 22 times)	[199]
R for α-latrotoxin (neurotoxin) from bovine brain cortex, 280–320 kD (200+160+79+43) DEAE → WL → Ab	WL (70%; 4 times), b α-SU of toxin (200+160)	[200, 201]
Complex of scorpion α-toxin with rat brain Na-channel	WL (b β-SU of Na-channel)	[202]
GP of cows milk lipid droplets GP-1, 2, 3, 4, 5, 6, 7	Con A, WL GP-1, 2, 6 b GP-3, 4 retarded GP-7 not b	[203]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
R for endogenous factor–cobalamin from porcine and human ileum, 75+65+43 kD	WL, LL and Con A (b 45–79%); WL (b 75 kD); LL and Con A (b 75+65+43 kD)	[204]
Histocompatibility antigens H-2^b from mouse RBL-5 tumour cells GF → WL → Ab	WL (80%; 8 times)	[205]
Other class II histocompatibility antigens	5 lectins***	[206–208]
GP of mouse small intestine and teratocarcinoma cells Dolichos L → dolichos L	Dolichos L	[209]
GP binding collagen from mouse MDAY-D2 lymphoreticular tumour cells (collagen type II R), 110+130 kD WL → L-FGA → GF	WL (b)	[210, 211]
GP from human embryonic PA-1 carcinoma cells, 80–120 kD	Thorn apple L (b)	[212]
R for type I fimbriae (lectin) of *E. coli* from guinea pig erythrocytes, 65 kD	Fimbriae type I, Con A (b)**	[213]
SialoGP of Morris hepatoma 7777 cells	WL (b)	[178]
Epitectin (Ca-antigen) of human pharyngeal carcinoma cells, 1–1.5 MD (390+350 kD) Ab → WL	WL (irreversible binding)	[214]
Preneoplastic antigen in liver carcinogenesis from malignant nodes of rat liver, 145 kD (2 SU) GF → Con A	Con A (73%; 6 times)	[215]
GP of human malignant melanoma SK-Mel-37 cells, 110 kD Con A → WL	Con A → WL (b)	[216]
GP of rat hepatoma cells, 130 kD Con A → GF → (Ab to alkaline phosphatase)	Con A (b)	[217]
GP of rat liver and Morris hepatoma 7777 cells, 60+80+100 kD Con A (HPLC), Con A	Con A (HPLC) (b)	[218]
Antigen from Walker 256 rat carcinoma cells, 57 kD CM → WL → Phe; Con A	WL (removal of 98% contaminating protein)	[219]
GP of human embryonic PA-1 carcinoma cells, 80–120 kD	Thorn apple L (b)	[166]
GP of HM-1 pluripotent embryonal carcinoma cells, more than 90 kD	*Phytolacca* L (b 48%) Thorn apple L and lotus L (17% b), PTL (no b)	[220]
Dystrophin complex from rabbit dystrophic skeletal muscle, 156+50+43+35 kD	WL (removal of myosin and ATPase)	[51, 221]
Tumour antigen associated with *Herpes simplex* virus from human liver carcinoma, 70 kD GF → DEAE → GF → Con A	Con A (b)	[222]
GP of BNK-21 cells infected with *Herpes simplex* virus	Con A (b)	[203]
Major GP induced by Epstein–Barr virus, 320 kD DEAE → CL-2	CL-2 (100%; 144 times)	[223]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, %; purity, times in parentheses, notes)	Refs.
Histocompatibility antigens HLA-DR and MB from human lymphoblastoid cells transformed by Epstein–Barr virus	CL-2 (b)	[224]
R for measles *virus* from *Vero* cells	LL (b) PL (b)	[225]
R for the minor group of rhinoviruses from human *HeLa* cells, 450 kD LL → GF → IEC	LL (yield 100%) CL-2 (yield 100%) Con A (yield 20%)	[226]
Transcript GP of nuclear pore membranes of monkey COS-1 cells, 62 kD	succWL (b)**	[227]
Glycoconjugates of inducers of human and animal diseases		
Recombinant GP-160 of HIV-1 from Vero cells infected with two vaccinia viruses LL → (Ab to GP-41) → mono Q → LL	LL (b)	[228]
Prion GP from brains of hamsters with virus-like infection, scrapie type of illness, 26+28 kD	LL, CL-1 (b asialoGP)** out of 6 lectins	[229]
Antigen of the pneumonia initiator, *Pneumocystis carinii* bacteria, from infected ferret lungs, 66–110 kD Superose-12 → Con A	Con A better than WL (SL and asparagus lectin no b)	[230]
Bacterial antigens (vaccines) of the *Bordetella* family	L (b)	[231]
GP from the coating of spores of *Bacillus sphaericus* 1593 (toxin for gnatworm) *Culex pipiens*	Con A (b)	[232]
GP of plasma membranes of *Spiroplasma citri*, 84 kD	Con A (b)	[233]
Antigens of promastigotes of 14 strains of *Leishmania*, 14–86 kD	Potential lectin sorbents (14 L)***	[234]
Surface antigens of protozoa *Trypanosoma brucei brucei* variant AnTat 1.1, 60+94 kD Con A → HPLC (RP)	Con A (separation of 94 and 60 kD)	[235]
Antigens of epimastigotes of protozoa *Trypanosoma cruzi* (72 kD) and specimens of the metacyclic phase (90+85+55 kD) CB → DEAE → WL → Con A → GF (72 kD) CB → DEAE → WL → HA → Con A (55 kD)	WL (different affinity for each antigen)	[236]
GP-85 of infectious tripomastigote form of *Trypanosoma cruzi*, including sialic acid and residues of fucose and α-1,3-galactose	WL → WL**	[237]
Protective Ag of ringed tick (vaccine), 86 kD WL → Con A → EP → WL → GF (HPLC)	WL and Con A (b)	[238]
Filarial surface antigens of adult nematode–parasites *Brugia malayi*, 29+(17–200) kD	Con A, WL, SL, lotus L	[239]
Tegumental glycoconjugate antigens of adult specimens of *Schistosoma mansoni*, 23–300 kD, 24 kD	Con A and LL** (out of 7 lectins)	[240–242]
GP of *Schistosoma mansoni* from infected mice, 170 kD	AL (b)	[243]
Virulence antigens of the 3rd stage of the nematode–parasite *Trichinella spiralis*	LL (b)	[244]

Table 1 (contd.).

Receptors, sources, schemes of purification (sorbents)	Result of using IL (yield, % purity, times in parentheses, notes)	Refs.
Glycoconjugates of microscopic fungi		
Adhesin R of cells of the slime fungus *Dictyostelium discoideum* at a late stage of development, 95+(40–50) kD	WL (b)	[245]
GP-34 specific for the 'stalk' stage of the slime fungus *Dictyostelium discoideum* NC4 (absent from spores)	WL (b)	[246]
Antigens of the mycelial fungi *Aspergillus fumigatus, Mucor pusillus, Petriellidium boydii, Trichophyton rubrum*	Con A (b)	[247]

*Lectin affinity chromatography was the most effective purification stage;
**Investigation of receptors in combination with their treatment with endo- and exoglycosidases;
***Affinity for labelled lectin.

Abbreviations used

Ab—antibody;
MAb—monoclonal antibody
AL—arachis lectin
Asn—asparagine
ATP—adenosine triphosphate
AC—affinity chromatography
b—binding
BSA—bovine serum albumin
CB—Cibacron Blue
cGMP—cyclic guanosine monophosphate
CL—castor oil plant lectin
CM—carboxymethyl
Con A—concanavalin A
DEAE—diethylaminoethyl
EP—electrophoresis
GF—gel filtration
GL—gorse lectin
GP—glycoprotein(s)
Gp—glycopeptides
GrL—griffonia lectin
HA—hydroxyapatite
HIV-1—human immunodeficiency virus type 1
HPLC (RF)—high performance liquid chromatography (reversed phase)
IEC—ion-exchange chromatography
L—lectin(s)
L-FGA, E-FGA—bean lectin (leuco and erythro forms)
LL—lentil lectin
OS—oligosaccharides
PL—pea lectin
PS—phosphocellulose
PTL—potato tuber lectin
SDS—sodium dodecyl sulphate
SL—soyabean lectin
SU—subunits
succWL—succinylated wheat-germ lectin
Receptor nomenclature from *Trends in Pharmacological Sciences*, 1991, Supplement, 35 pp

Purification of receptors or separation of their subpopulations is also possible by retardation of the glycoprotein during elution from the lectin sorbent without the use of desorbing carbohydrates (i.e. due to weak affinity interactions with the lectin).[161,203,284] Separation by retardation on elution has also been described for mixtures of glycopeptides when using immobilised bean or castor-oil plant (*Ricinus communis*) lectin which confirms the effect of glycans on elution behaviour.

The simplest procedures for purifying receptors comprise filtration through one lectin sorbent (absence of binding) and binding with another lectin sorbent (concentration of receptors) for example by the scheme: wheat-germ lectin (WL^-)→Con A^+ or Con A^-→WL^+, as in the case of trypanosome antigens or rat kidney ATPase.[236,301] Other purification schemes are also used, for example lentil (*Lens culinaris*) lectin (LL^+)→WL^+ (fibronectin receptor[134]), LL^+→Con A^+ (prothrombin precursor[317]), WL^+→LL^+→castor-oil plant lectin-1 ($CL\text{-}1^+$) (insulin receptor[89]), WL^+→bean leucoagglutinin ($L\text{-}FGA^+$).[210,211] The combination of Con A^+→WL^+ is used in the case of melanoma antigens, dipeptidase IV and Mg^{2+}-ATPase,[216,290,291,305] and WL^+→Con A^+ in the case of the protective antigens of arthropods.[238] The examples of combination chromatography on lectins indicated above enable the separation of multiple forms (subpopulations) of receptors and an increase in the overall yield of any receptor heterogeneous in the carbohydrate portion. An example of appreciably increasing yield is the purification of dipeptidyl-dipeptidase IV by affinity HPLC on paired columns of immobilised Con A and WL.[291] In several cases rechromatography of antigens and receptors on immobilised LL,[228] WL,[46,69] dolichos (*Dolichos biflorus*) lectin[209] or peanut (*Arachis*) lectin[197] is used.

As is evident from Tables 1 and 2 the maximum degree of purification of receptors when using a particular type of lectin is achieved in the majority of cases by varying the first stages of purification immediately after solubilisation of the receptors with detergent. However it must be remembered that chromatography of crude preparations may lead to irreversible contamination of the lectin sorbent and a reduction in its affinity capacity.[125,150,291] In addition preferential binding of some receptors at the expense of others to WL at the first stage of purification may be expected, for glycoproteins from thrombocytes for example.

Lectin affinity chromatography of receptors is frequently used in combination with other affinity sorbents. Paired columns of immobilised thyrotropin and griffonia (*Bandeiraea simplificifolia*) lectin-I (GrL-I) enable thyrotropin receptors to be purified 808-fold.[108] Immobilised heparin and WL are convenient, following

(Con A)-sorbent, for the removal of thrombospondin and fibrinogen from a preparation of thrombocyte glycoproteins IIb–IIIa.[150] Immobilised WL is convenient, following immobilised fibroblast growth factor (elution of heparin receptors), for the removal of heparin from the receptor preparation.[118] After chromatography of thymocyte Thy-1 antigen on (Con A)-sorbent immobilised antibody to Con A was used to remove lectin molecules partially washed out from the sorbent with desoxycholate.[160] When purifying carcinoma cell galactosyl transferase the filtrate from the (CL-1)-sorbent was applied to immobilised *N*-acetyl-D-glucosamine.[254]

Table 2. Purification of enzymes (receptors) bound to cell surfaces and organelles with immobilised lectins.

Enzymes, sources, purification schemes	Result of using IL (yield, %, purification, times, notes)	Refs.
Oxido-reductases		
L-Trp oxidase of field cabbage (peroxidase-like)	Con A (83%, 4 times)	[248]
Ribonucleotide reductase of rat liver, SU 89 kD	Con A (b)	[249]
Peroxidase from human placenta	Con A (90%, 20 times); removal of eosinophilic peroxidase, myeloperoxidase, catalase and cytochrome P-450	[250]
Dopamine-β-hydroxylase associated with the β-adrenergic R from bovine adrenal medulla Con A→DEAE→GF (HPLC)	Con A (66%; 120 times)*	[251]
Dopamine β-hydroxylase from rat adrenal, 300 kD (SU 75 kD) Con A → GF (HPLC) → IEC (HPLC)	Con A (removal of chromogranins)	[252]
Tyrosinase from hamster melanoma DEAE → GF → Con A	Con A (80%; 7 times)*	[253]
Transferases		
N-Acetylglucosaminide-β-1,4-galactosyl transferase of mouse F9 carcinoma cells IEC → XL–1 → Acetylglucosamine → α-Lactalbumin	CL-1 (no b)	[254]
Galactosyl transferase of the Golgi apparatus of the budding yeast *Schizosaccharomyces pombe*, 61 kD DEAE (HPLC) → UDP-hexanolamine → Con A → Mono Q	Con A (73%; times) GL-1 (b)	[255]
Tyr-protein sulphotransferase of the Golgi apparatus of bovine adrenal cells, 50–54 kD	WL (b 37%)**	[256]
N-Heparan-sulphate sulphotransferase of rat liver, 97 kD DEAE → Heparin → ADP → WL	WL (44%; 3 times)	[257]
Oligosaccharyl transferase, stabilised with phosphatidylcholine, of calf thyroid microsomes	Con A (b)	[258]
Tyr kinase of cat brain (R of colony stimulating factor type 1 or obtained from growth factor of thrombocytes), 145 kD	WL (b)**	[121, 259]
Tyr kinase of insulin R of rat brain and liver	WL (b)	[260, 261]
Protein kinase/interleukin-1 R from rat liver mesangial cells in culture (SU 48 kD)	WL (b)	[262]
Phospholamban kinase of mammalian heart sarcoplasmic reticulum cells, SU 56+53 kD	affinity for Con A	[263]
Arginine-specific ADP-ribosyl transferase of animal skeletal muscle microsomes, SU 39 kD DEAE→Con A→GF (HPLC)	Con A (88%; 50 times)* WL (no b)	[264]
Poly A polymerase of the nucelar membrane of rat liver cells, 64 kD	Con A (5 times)**	[265]
Esterases		
p-Nitrophenyl acetate esterase type A from rat liver microsomes, 61 kD Con A → GF → DEAE → HA	Con A (80%; 3 times)	[266]
Carboxy esterase E1 from rat liver microsomes, 175 kD (SU 59 kD)	Con A (b)**	[267]
Peptidase associated with acetylcholinesterase of the electric eel and ewe brain basal ganglia AC → GF → Con A	Con A (b)	[259]
Alkaline phosphatase of fly integument, 180 kD Con A → GF → GF	Con A (b)	[268]
Phospholipase A-1 of rat liver lysosomes Con A → Chromatofoc. → GF; (Orange + Red agarose) → Con A → Phe	Con A (156%; 165 times)*	[269, 270]
Acid phosphatase of promastigotes of Mexican and Brazilian Leishmanii (inhibited with citrate) GF → DEAE → Con A	Con A (72%; 14 times)*	[271]
3′-Nucleotidase/nuclease of promastigotes of *Leishmania donovani*, 43 kD	Contains Asn-OC, available for L**	[272]
5′-Nucleotidase of rat heart, 74 kD CM → Con A → DEAE → ADP	Con A (123%; 13 times)	[273]
5′-Nucleotidase of rat kidney, 69 kD Con A → ADP	Con A (94%; 17 times)	[274]
5′-Nucleotidase of bovine thyroid, 150 kD (2 SU) LL → AMP	LL (81%; 10 times)*	[275]
Cell wall ribonuclease of the fungus *Aspergillus oryzae*, similar to ribonuclease T-2-L in carbohydrate composition	Possible affinity for Con A	[276, 277]
Sphyngomyelinase of human placental lysosomes, 123 kD (SU 62 kD) Con A → Sphyngosylphosphorylcholine → Hexyl → IEC (HPLC)	Con A (100%; 21 times)	[278]
Nucleotide pyrophosphatase of human placenta CB → AMP → WL → ADP → GF → DEAE	WL (96%; 2 times)	[279]
Nucleoside diphosphatase type B from rat brain, 75 kD (thiamine pyrophosphatase associated with 1D4) DEAE → Con A → GF → CB → Cu^{2+} chelate → GF	Con A (48%; 6 times)*	[280]
Glycosidases		
α-Glucosidase of human placental lysosomes, 110 kD Con A → GF	Con A (99%; 12 times)	[281]
Glucosidase II-processing GP from cow mammary gland, 290 kD Con A → HA → DEAE	Con A (79%; 8 times)	[282]
Glucosidase II-processing GP from bean shoots and soya cell culture, 220 kD (2 SU) DEAE → HA → Con A → GF	Con A (73%; 10 times)	[283]

Table 2 (contd.).

Enzymes, sources, purification schemes	Result of using IL (yield, %, purification, times, notes)	Refs.
α-1,2-Mannosidase-processing GP from rabbit liver microsomes, 52 kD DEAE → Con A → GF → CB → GF	Con A (77%; 27 times)*	[284]
β-Fructofuranosidase from radish cell walls (similar to cytoplasmic)	4 L	[285]
Trehalase of the American cockroach, 110 kD Con A → GF	Con A (48%; 32 times)	[286]
Trehalase of the brush border of rabbit renal cortex Phe; Con A	Con A (b 20%)	[287]
Saccharase–isomaltase complex from a biopsy sample of human small intestine, 210+212+245 (SU 145+130 kD)	LL (all forms b), snail L (b 212 and 245 kD)	[288]
N-Acetylglucosaminidase from spermatozoids of the surface membrane of *Phallusia mammilata*, 158 kD (2 SU) DEAE → Phenyl → Con A → EP	Con A (69%; 2.5 times)	[289]
Proteases		
Dipeptidyl peptidase IV of rat liver Con A → WL → Arg; Con A (HPLC) → WL (HPLC)	Con A → WL (74%; 46 times), Con A (84%; 32 times)	[290, 291]
Carboxypeptidase N from human placenta, 280 kD HA → LL → Histargin	LL (27%; 2.5 times)	[292]
Carboxypeptidase M from human placenta, 62 kD	Con A (b)	[293]
Aminopeptidase N from rabbit intestine	WL (b)	[95]
Aminopeptidase N from porcine intestinal mucosa, 130 kD SU (Stilbenedisulphonate) → Con A	Con A (37% yield, removal of SU 90 kD)**; affinity for CL-1, WL, tomato L	[294]
Peptidase dependent on Ca^{2+} participating in the action of the pairing pheromone of yeast *Rhodosporidium toruloides* (type 'a' cells) DEAE → Con A	Con A (107%; 3.3 times)	[295]
Proteinase of the surface of promastigotes of various *Leishmanii* species, 63 kD SU	Con A and LL (b)	[296]
Trypsin-like proteinase/esterase specific for Arg from rat liver insulin R	Con A (b)	[297]
Cysteine proteinase/neutral gelatinase from human malignant LOX melanoma cells SU 170 kD Sephacryl → WL	WL (purification; 10 times; removal of metalloproteinase with SU 50 kD	[298]
Other hydrolases		
Lipoamidase of pig brain, 140 kD CM → DEAE → GF → WL	WL (purification 10 times)	[299]
Ampicillin acylase of bacteria *Pseudomonas melanogenum*, 146 kD (2 SU)	Contains 13% hexose with probable affinity for L	[300]
NAD-glycohydrolase of bovine thyroid (probable thyrotropin R) GF → LL	LL (b)	[301]
Na^+, K^+-ATPase of rat kidney cortex microsomes, 95+54 kD Con A → WL	Con A (no b), WL (b β-SU, 54 kD)	[302, 303]

Table 2 (contd.).

Enzymes, sources, purification schemes	Result of using IL (yield, %, purification, times, notes)	Refs.
β-SU, Na^+, K^+-ATPase of rat brain (adhesion molecule on brain glial cells) and porcine intestine, 60–80 kD	WL and CL-1**, better than Con A	[303–305]
Mg^+-ATPase of rabbit skeletal muscle, 107 kD Con A → WL → IEC (HPLC)	Con A, WL, LL (b)	[51, 306]
ATPase of dog kidney and human K562 cells (P-glycoprotein), 170 kD	WL, Con A and CL-1 (b), AL (no B)	[307–309]
ATPase 'P' type (forming phospho intermediate) from cholinergic synapses of cells of the electric organ of *Torpedo californica*, 110+104+98+60 kD HA → WL → GF (HPLC)	WL (71%; 2 times)	[309a]
GTPase of rat olfactory neurones, 55 kD	Con A-FITC (b)***	[310]
Lyases		
Carbonic anhydrase of ovine salivary gland, 540 kD (SU 45 kD) Sulphonamide → WL → GF	WL and Con A (b)**	[311]
Catalytic component of bovine brain adenylate cyclase sensitive to hormone, 120 kD	WL (30%; 2 times)	[312]
Catalytic component of the adenylate cyclase system of bovine brain cortex sensitive to calmodulin, 155 kD Calmodulin → WL	WL (52%; 12 times)	[313]
Atrial natriuretic factor R with and without cyclase activity (guanylate cyclase) from bovine adrenal glomerula cells GTP → WL	WL (55%; 1.3 times)	[314]
Particle-bound highly active guanylate cyclase of rat lung Con A → GTP	Con A (25%; 3–6 times)	[315]
Phosphorylated form of guanylate cyclase of sea urchin sperm, 160 kD GTP → DEAE → Con A	Con A (5 times)	[316]
Carboxylase from rat liver microsomes dependent on vitamin K	Con A (b 80%) LL (b 70%)	[317]

*Lectin affinity chromatography was the most efficient step in the enzyme purification

**investigation of the enzyme in conjunction with its treatment with endo- and exoglycosidases

***affinity for non-immobilised lectin

Abbreviations used (see also Table 1)

ADP—adenosine diphosphate
AMP—adenosine monophosphate
ATP—adenosine triphosphate
FITC—fluorescein isothiocyanate
GrL-I—griffonia lectin-I
GTP—guanosine triphosphate corr
RNA—ribonucleic acid
UDP—uridine diphosphate

Enzymes are named in accordance with the International Classification (Enzyme Nomenclature, Recommendations of the Nomenclature Committee of the International Union of Biochemistry, Orlando, Acad. Press, 1984, 646 pp).

Tandem chromatography has also been used in other combinations of a lectin sorbent with non-lectin sorbents. Paired columns with immobilised Con A and phenylalanine are effective in the purification of phospholipase A_1,[270] with Affigel S-145 and with immobilised WL in the case of the thromboxane A_2 receptor.[155] A technologically simple procedure is the filtration of partially purified receptors through carboxymethyl sorbents before and after immobilised WL for receptors of interleukin 4 and glycoprotein CDw 44.[163,164] The possibilities of tandem chromatography using a lectin sorbent are well illustrated for the thromboxane receptor which was purified 1620-fold on paired columns directly from the crude solubilised protein extract.[155] In addition paired combinations of lectin and non-lectin sorbents give an increase in the yield of receptors.[155]

The use of immobilised Con A, PL, WL and CL-1 in variants of affinity HPLC is promising for the purification of membrane-bound glycoproteins.[176,187,218,291]

2. Solubilisation of receptors and features of the lectin affinity chromatography of receptors

Many factors are important when carrying out lectin affinity chromatography. These are the solubilisation method to increase receptor solubility, buffer composition (detergent type, organic solvents, buffer types, pH, ionic strength, presence of metal cations or EDTA, the need to reduce disulphide bonds in proteins, protease inhibitors, phospholipids, etc.), method of application, washing and elution, times and temperatures. For each receptor purification it is necessary to select the optimum procedure for lectin affinity chromatography depending on the lectin sorbent chosen (lectin type, matrix, means of lectin immobilisation, capacity of sorbent for conjugated lectin or binding of model glycoconjugates, conditions for regeneration and storage for repeated use). The actual procedure for chromatography on a lectin sorbent under the conditions selected is a simple operation. The complexity of working with a lectin sorbent is seemingly determined by the presence in these proteins not only of carbohydrate-binding regions but also of regions of hydrophobic binding, binding of cations of divalent metals and by the presence of other domains.

Perhaps the most complex factor is the selection of the means of solubilising receptors (type of detergent or solubilisation by treatment with hydrolases).

Most frequently 0.5–1.0% Triton X-100 (TX-100) is used for the solubilisation and lectin affinity chromatography of receptors. TX-114 has also been used, for example in the case of glycoproteins of thrombocytes and kidney.[149,152,190] Carbohydrates are also used occasionally for solubilisation instead of TX.[202] Since high concentrations of TX-100 cause desorption (washing off) of lectin from the sorbent,[218] lectin affinity chromatography of receptors is carried out at concentrations of detergent lower than in the initial solubilisation in the crude extracts when using immobilised Con A,[218,255,259,286] WL [97,119,125,202,279] or dolichos lectin.[209] Extremely low TX-100 concentrations (0.01–0.02%) were effective in the purification of olfactory receptors.[107,309] The absence of TX-100 did not permit elution of receptors even at high carbohydrate concentrations (0.5–1.0 M) in the case of (Con A)-sorbent.[182,215,259] As a rule, it is important to control the ionic strength of the buffer when selecting the detergent concentration. The buffer ionic strength is usually increased during lectin affinity chromatography from 0.1–0.2 M to 0.4–0.5 and even to 1 M NaCl or KCl in the case of receptors of neurotoxin or bovine dopamine.[75,200] Chromatography of receptors on WL-sorbent is carried out as a rule in the presence of 5–10 mM Mg^{2+} ions[77,97,107,119,125,279] and/or 1–2 mM Ca^{2+} ions.[45,46,50,52,131,133,142–145,200] Ca^{2+} cations are also used in the chromatography of receptors on FGA- and (CL-2)-sorbents but in the case of Con A-, LL- and (pea lectin)-sorbents 0.5–1.0 mM manganese, potassium and magnesium chlorides are used together.

Various combinations of TX-100 and Na desoxycholate are also used,[34,210,211,239,289] although in some cases the preferential use of nonionic detergents (TX-100 and CHAPS) rather than cholate has been recorded, such as on solubilisation of the serotonin transporter, Na-channel, etc.[23,31,36] Cholate (0.5–1.5%) is used in the solubilisation of erythrocyte Cad-antigen, liver esterase, the antigens of nematode parasites and AIDS virus, 5′-nucleotidase and macrophage receptors.[172,184,239,266,275] During lectin affinity chromatography the cholate concentration may vary depending on the type of receptors being investigated. For Dopamine receptors 0.2–0.3% is used,[73–75] for tumour glycoproteins[210,211,216] and proteins of T-lymphocytes[160,164] and thrombocytes 0.4–0.5%,[154] for thyroid gland glycoproteins[275,289] 0.6% and for the L-Glu receptor 0.05%.[33a]

A 0.5–2% solution of 3-[3-(cholamidopropyl)dimethylammonium]-1-propanesulphonate (CHAPS) is widely used for the solubilisation of receptors.[57,77,94,111,112,248,265] It is seemingly promising to use fractionation of receptors with detergents. In the case of vasopressin receptors, contaminants are removed by a preliminary treatment with 0.5% CHAPS and the actual receptors are solubilised in high yield on subsequent treatment of the extract with 2% CHAPS.[94] When solubilising Ca-binding sarcolemma glycoproteins and receptors of corticotropin releasing factor 6–8 mM CHAPS is used.[42,115] The concentration of CHAPS varies in the following way during chromatography on WL-, Con A- or (CL-2)-sorbent: 20 mM for the glutamate receptor,[33] 0.1–0.8% for other transporter glycoproteins[28,41,52] and 1% for receptors of inositol triphosphate, the bacterial antigen of infected ferret lung cells and carboxypeptidase M.[55,230,293]

One more nonionic detergent, Nonidet P-40 (NP-40), is widely used for the solubilisation of receptors at concentrations of 0.5–2%.[72,129,143,159,161,212,224,283,295,303] Lower concentrations of NP-40 are used during chromatography on lectins, e.g. 0.1–0.2% for WL- and (Con A)-sorbents,[72,318] 0.4–0.5% for immobilised Con A,[258] LL,[168] WL,[100,145] AL [159] and thorn apple lectin.[212] The concentration of NP-40 was reduced from 0.4 to 0.07% at the stage of eluting receptors with carbohydrate.[258] The need to use 0.4% NP-40 for oligosaccharide transferase is explained by the fact that the glycans of this glycoprotein bound to asparagine are inverted inside the membrane vesicles and do not react with the lectin without previous treatment with a relatively high concentration of detergent.[258]

Digitonin (1–2%) is also used for the solubilisation of receptors.[45–47,50,51,53,54,59,61,64–66,68,76,79,80,93,98] Occasionally it is expedient to change the type of detergent. Thus, after solubilisation of receptor complexes with 1% digitonin (for example Ca channels) the components of the complexes may be separated successfully using 1% TX-100.[54,84] Digitonin (0.1%) is used in the chromatography of opioid receptors,[59,61,64] receptors of dopamine and cholecystokinin,[76,79,80,98] α_1-adrenergic receptors,[65,66] and receptors of dihydropyridine and Ca channels.[45–47,49–51,53] Chromatography is usually carried out in this way on WL-sorbent although there are also data for immobilised CL-2,[98] LL and Con A.[59,64,98,305]

n-Octyl-β-D-glucopyranoside (0.05–0.2 M) is also used for the solubilisation of receptors.[128,131,135,137,141,144,226] The octylglucoside (40–50 mM) is included at the stage of purification by gel filtration as in the case of β_1-integrin and sphingomyelin.[137,278] The octylglucoside (2 mM) is used during chromatography of glycoproteins of animal lung alveoli on immobilised *Maclura* lectin.[186] Yeast peptidase solubilised in NP-40 was chromatographed on (Con A)-sorbent in the presence of 0.3 mM octylglucoside.[295]

Sodium dodecyl sulphate (SDS: 2%) is also used for the solubilisation of receptors of slime mould antigen,[246] the cationic detergent DTAB for H^+,K^+-ATPase[303] and 8 M urea for the bacterial antigen of infected ferret cells.[230] Tween-20 or Tween-40, Renex-30 or Brij are used for lymphocyte receptors[130,160,164] Lubrol PX for adenylate cyclase and guanylate cyclase[312,313,315,316] and lysolecithin in combination with other detergents for Mg^{2+}-ATPase.[305] Replacement of Brij (0.5%) by cholate (0.5%) or Zwittergent (1%) is used in the purification of antigens on WL-sorbent.[164,238] Emulgen-109P (1%) is also used for the chromatography of fucosylated erythrocyte proteins on immobilised aleuria (*Aleuria aurantia*) lectin,[169] Zwittergent (0.5%) in place of TX-100 (0.5% for the chromatography of Purkinje cell antigen on (Con A)-sorbent,[198] Tween-60 (0.1%) in the purification of adenylate cyclase[312,313] and Lubrol (0.1–1%) in the purification of guanylate cyclase[315,316] on immobilised WL and Con A respectively.

Occasionally $C_{12}E_8$ [n-dodecylocta(ethyleneglycol) monoester] is used, 1% for solubilisation[307,309a] and 0.1% for lectin affinity chromatography.[294]

Traditionally SDS is used during lectin affinity chromatography, 0.01% at the stage of eluting with *N*-acetyl-D-glucosamine for WL-sorbent,[40,302] 0.1–0.5% for (Con A)-sorbent[203,235,318] or WL-sorbent,[246] 1% for the non-specific elution of receptors, particularly for immobilised SL, CL-1, Con A and LL.[165,195,318] The use of such a set of non-specific elutions will possibly be useful for regenerating lectin sorbents. However, it is necessary to keep in mind that SDS may be precipitated as a solid in the presence of metal cations,[203] and may wash out lectin from the sorbent and reduce the lectin capacity, as in the case of immobilised Con A.[235] In addition some proteins are able to form complexes (such as dimers) even in the presence of SDS as in the case of the opioid receptors.[62]

The multistage process of receptor chromatography on a lectin sorbent (application, different variants of washing the sorbent, elution of receptors) is characterised by a reduction in detergent concentration or by variation of combinations of different detergents and by the possible absence of detergent at the very last stage, viz. elution of receptors with carbohydrate. This is seen when purifying thrombocyte glycoprotein-Ib,[148] lymphocyte antigen CD 43,[165] dopamine receptors,[77] sarcolemma receptors,[42] yeast galactosyl transferase,[255] insulin receptors[92] and adrenal glycoproteins[191] using immobilised WL. The detergent itself (SDS) was ineffective even at high concentrations in comparison with *N*-acetyl-D-glucosamine in eluting the purified receptors from the WL-sorbent.[165] Desorption of receptors with carbohydate without a detergent (TX-100) did not occur for the (Con A)-sorbent (see above).

Treatment of extracts or purified membrane glycoproteins with a chloroform–methanol mixture was also carried out to solubilise phospholipid-containing glycoproteins (such as ligatin) or to remove lipid contaminants.[171,237,319] Treatment with organic solvent is seemingly also important when regenerating the lectin sorbents used in the first stages of purifying receptors because of the contamination of the sorbents with glycolipids.[291]

Apart from the means of solubilisation enumerated above there is undoubted interest in the data on the solubilisation of receptors with hydrolases since the soluble receptors obtained frequently do not even require the presence of detergents in the elutant during lectin affinity chromatography. Phospholipase C is used for the solubilisation of hepatoma glycoproteins,[217] trypsin for lysosomal enzymes,[280] trypsin in combination with TX-114 for CD 36 antigen,[152] Ca^{2+}- and thiol-dependent proteinase for thrombocyte glycoprotein-Ib,[148] papain for lymphocyte Fc-receptors solubilised with Tween and Renex and purified on a WL-sorbent[130] and lysozyme for the treatment of the high molecular form of fly integument alkaline phosphatase associated with chitin and purified on a (Con A)-sorbent.[268] Trypsin was also useful for the separation of the subunits of the saccharase–isomaltase complex from human intestinal membranes.[287]

Organic solvents are used together with detergents during receptor chromatography on immobilised lectins and improves the stabilisation of receptors while reducing hydrophobic interactions between receptor and lectin. Ethyleneglycol is used in chromatography on (Con A)-sorbent, 1 M for the purification of Thy-1 antigen,[160] 20% for phospholipase A_1 [269] and 10% (together with 25% glycerol) for guanylate cyclase.[316] The increase in concentration of ethyleneglycol used may be compensated by a reduction in the concentration of carbohydrate eluting the receptors,[160] which indicates the possibility of also using carbohydrate for reducing the hydrophobic binding of receptors with the lectin. Chromatography on immobilised GL-1 was carried out in the presence of glycerol (5%) but the concentration of glycerol was varied when using WL-sorbent from 10% [38,50,52,111,117,163] [for (Con A)-sorbent[310]], to 20% [155,246,257] [for (Con A)-sorbent[258]] or 30%.[107]

β-Mercaptoethanol (1 mM)[235,303] was used in the purification of the rat inositol triphosphate receptor and of trypanosome antigens on a (Con A)-sorbent and 10 mM β-mercaptoethanol in combination with 2% detergent in the isolation of the glycosylated subunits of ATPase on WL-sorbent.[56] Evidently other agents capable of reducing disulphide bonds in protein complexes may also be used.

Problems of eluting receptors, bound to lectin sorbents, with carbohydrates are important. Excess concentrations of carbohydrates are usually used (up to 0.5 M, more rarely 1 M monosaccharide) as in the following, α-methyl-D-mannopyranoside and α-methyl-D-glucopyranoside for Con A, LL- and PL-sorbents, *N*-acetyl-D-glucosamine for immobilised WL and thorn apple lectin, lactose or D-galactose for immobilised CL-1, CL-2, AL and SL, *N*-acetyl-D-galactosamine for SL and L-fucose for immobilised GL-1 and aleuria lectin. Occasionally stepwise elution with increasing concentrations of carbohydrate or a linear carbohydrate gradient is used, such as in the purification of membrane-bound oxidase[248] and histamine receptors[81] on (Con A)-sorbent or membrane-bound lipoamidase,[296] receptors of dihydropyridine and dopamine transporter[49,80] on WL-sorbent. Firstly this enables removal of contaminating glycoproteins with a lower affinity for the lectin, secondly, it permits separation of subpopulations of receptors close in physicochemical properties, thirdly, it enables removal from the sorbent of firmly bound glycoproteins with the aim of regenerating the immobilised lectin, fourthly, it affords a quantitative assessment of the strength of the binding of the purified receptors to the lectin in order that excessive concentrations of carbohydrate are not used for subsequent desorption. It was shown that lipoamidase was eluted at 60 mM *N*-acetyl-D-glucosamine,[296] dopamine transporter at 125 mM *N*-acetyl-D-glucosamine,[80] histamine

receptors at 80 mM α-methylmannoside,[81] but Trp oxidase was separated into forms eluted at 10, 20 and 50 mM α-methylglucoside respectively.[248] Before elution of receptors with a carbohydrate specific for the lectin it was useful to wash the lectin sorbent either with lower concentrations of the same carbohydrate (a variant of the stepwise elution with carbohydrate) as for LL- and (Con A)-sorbents[134,293,294] or with a carbohydrate non-specific for the lectin at a relatively high concentration (0.5 M) as for WL- and (griffonia lectin-I)-sorbents.[108,183,227] When working with immobilised bean lectin, the elution of lymphocyte receptors was carried out without using carbohydrate (monosaccharides were unsuitable for this lectin which is specific for oligosaccharides) by acidifying the elutant to pH 3 [158] as was used for the elution of eukaryote nuclear glycoproteins during chromatography on WL-sorbent.[227]

When working with immobilised WL, significantly more effective eluting agents are used in place of *N*-acetyl-D-glucosamine. These include chitotetraose,[192] 3–10 mM chitotriose[100,110–112,163] or 15 mM chitobiose (containing 10 wt.% chitotriose as contaminant) as for immobilised thorn apple lectin.[161] It is not excluded that contaminating chitotriose and chitobiose in commercial preparations of *N*-acetyl-D-glucosamine make an appreciable contribution to the specific desorption of the receptors indicated above.

Provision of a relatively long contact time for the immobilised lectin and the glucoconjugate solution (when applying it) and with the desorbing carbohydrate (when eluting glycoconjugates and regenerating the sorbent) is a feature of lectin affinity chromatography. The contact time depends on the temperature. For complete binding of receptors with a WL-sorbent incubation of the mixture was carried out for 16–70 h at 4 °C [93,107,154,155,239] or 1.5–3 h [53,110,111] under conditions of suspending the sorbent[53,107,110,154,239] or recycling application of the receptors onto the sorbent as a variant of the column chromatography.[79,91,92,111,155] Elution of receptors from WL-sorbent with carbohydrate was carried out overnight[93] or for 1.5–3 h at 4 °C,[53,75] 15–20 min at room temperature[194,342] or with a double treatment with carbohydrate for 30 min and longer.[92,107,163] Extended contact of receptors and sorbent was also used for immobilised thorn apple, lentil, soyabean and lotus lectins.[134,212,239] When working with (Con A)-sorbent, the application of receptors was carried out for 12–21 h at 4 °C [239,316] or for 4 h at room temperature.[265] Desorption was carried out with portions of carbohydrate after incubation for a period of several hours[47,92,269] and increasing the temperature to 37 °C with the aim of reducing the hydrophobic binding of receptors to the lectin.[25,280]

An important factor of lectin affinity chromatography is the affinity or sorption capacity of the lectin sorbent determined either by binding model standard glycoproteins or by the quantity of lectin immobilised in 1 ml gel (the companies manufacturing lectin sorbents usually indicate the capacity from the amount of lectin in 1 ml gel). Since the data shown in Tables 1 and 2 comprise lectins immobilised on agarose in an overwhelming majority, data on the capacity of agarose sorbents will be considered below. The commercial preparations of WL-agarose (Sepharose, Affigel) most frequently used have the following lectin capacities: 5 or 1–2 mg ml^{-1} gel (Pharmacia, Sweden[65,214]), 6–10 mg ml^{-1} (E.Y. Lab., USA[36]), sorbent manufactured by Miles–Yeda (Israel[320]), 1 mg ml^{-1} (Bio-Rad, USA[124]) etc. In some cases investigators have synthesised the sorbents themselves, for example WL-Sepharose 4B (6–20 mg ml^{-1} [35,48,117]), WL-Affigel-10 (5–10 mg ml^{-1} [83,196]) and WL-Reactigel-6X (5 mg ml^{-1} [109]). Comparison of the synthesised WL-Sepharose sorbents with various lectin capacities in the range 0.08–10 mg ml^{-1} showed that one glycoprotein (glycophorin A for example) was well bound on the low capacity sorbent (0.08 mg ml^{-1}), but for other glycoproteins (such as fetuin, ovomucoid and α_1-glycoprotein or orosomucoid) capacities of more than 3 mg lectin per ml gel were necessary.[176] Erythrocyte glycophorin receptors and receptors from hepatoma cell were successfully obtained from crude extracts in good yield and a high degree of purity by purification in one step on WL-Sepharose (0.08 mg ml^{-1}).[176] When purifying insulin receptors, it was shown that the maximum yield of receptors was achieved using Miles-Yeda WL-sorbent in comparison with similar sorbents from other companies.[320] WL-agarose with a capacity of 4 mg ml^{-1} or above is most frequently used for purifying receptors. Exceptions are hepatoma cell sialoglycoproteins[124,176] and α_1-adrenergic receptors.[320] It was noted that when applying an excess quantity of receptors to a WL-sorbent its sorption properties were increased and there was a corresponding increase in the yield of material bound.[83] The same effect may also be observed on increasing the contact time of receptor and lectin (see above).

In the majority of the cases shown in Tables 1 and 2 the WL-sorbents are used as sialo-specific reactants for binding sialoglycoproteins which may readily be checked by treating the receptors with sialidase.[256] Immobilised succinylated WL is used as a sorbent specific for *N*-acetyl-D-glycosamine, as in the purification of the nuclear pore protein of mammalian cells,[227] or unmodified WL-sorbent for the purification of oligodendroglial glycoproteins.[196] It is better to use immobilised slug (*Limax flavus*) lectin in place of WL-sorbent for the purification of glycoproteins (such as eel Na-channels) which contain polysialic acids [(NeuAc-α-2,8-)$_n$].[35] Among the other widely used lectinagarose sorbents those with relatively high capacities may be mentioned such as 10–16 mg ml^{-1} gel for Con A (Pharmacia, Sweden), 12 and 4 mg ml^{-1} gel for CL-1 and bean erythroagglutinin.[156] The capacity of LL-Sepharose is 2 mg ml^{-1} gel (Pharmacia, Sweden). (Con A)-Sepharose of low capacity (0.5 mg ml^{-1}) is used for the purification of yeast peptidase.[295]

The means of immobilising the lectin onto the agarose may influence the binding of receptors. A comparison of the various means of activating Sepharose for the subsequent immobilisation of Con A showed that the maximum capacity of the sorbent for lectin at minimum selectivity towards glycoproteins was achieved for activation with cyanogen bromide, a significant reduction in capacity at maximum selectivity was found for activation with divinyl sulphone and intermediate results were obtained with glutaraldehyde.[321] Lectin–agarose sorbents immobilised with a carbodiimide have also been used for the purification of receptors.[156] It was noted that irrespective of the means of activating agarose the selectivity of the lectin sorbent was increased when applying an excess amount of the glycoprotein being purified.[321] It is possible that the reason for the irreversible binding of part of the applied glycoprotein when using a lectin sorbent obtained from cyanogen bromide-activated Sepharose (such as LL-Sepharose) is the presence of unblocked residues of carbonate and imidocarbonate groups, which are eliminated by previous treatment of the activated agarose with 0.1 N HCl.[322] An additional treatment of the immobilised lectin with glutaraldehyde in the presence of the appropriate lectin carbohydrate is recommended for the stabilisation of lectin sorbents with the aim of preventing washing out of lectin and reducing the sorbent capacity particularly in the presence of detergent.[58,318]

III. Investigation of receptor glycans with lectin sorbents

A selection of lectins with a known oligosaccharide specificity may serve as an effective instrument for the structural analysis of receptor glycans (see reviews on the specificity of lectins towards glycans[323,324] or glycoconjugates[21]). Such an analysis frequently leads, with the aid of combined chromatography, to lectins of the desired glycoproteins or their glycopeptides and oligosaccharides (see examples in reviews[21,25,26]) sometimes combined with treatments of the glycoconjugates with glycosidases, with glycosoxidases, with chemical modification of the carbohydrate portion or with chemical deglycosylation. The choice of lectin may prove to be useful for the separation of the receptors obtained into sub-populations depending on their microheterogeneity in carbohydrate. For example, glycophorin A type N, in contrast to glycophorin A type M, does not have glycans bound to asparagine (Asn) which enables both types to be separated readily on immobilised LL [173,175] but not on a WL-sorbent.[177] Glycophorins A, B and C are readily removed from glycophorin E by their specific binding to immobilised WL.[176] The Thy-1 antigen does not have glycans bound to serine/threonine (Ser/Thr) and its separation into three sub-populations occurs due to the Asn-glycans 1) not reacting with the lectin fraction, 2) being retained (emerging in a large volume of eluent) and 3) bound (as a result of glycans of the polylactosamine type).[161] The neural cell adhesion molecules (N-CAM) of brain contain tissue-specific Ser/Thr-bound glycans with an affinity for immobilised AL,[146] and also polysialic acids possibly reacting with slug lectin.[35,325] The hexose transporter in defective cells has unmasked Asn-glycans of the oligomannose type but in normal cells these glycans are masked by Asn-glycans of complex type which reduces the affinity for Con A and increases binding with WL.[29] Tri- and tetra-antenna (poly-antenna) Asn-glycans of a complex type are detected in lactotransferrin and transferrin receptors and are particularly numerous in the transferrin receptor according to results from the interaction with L-FGA.[132,138,139] The varying ratio of Asn-bound glycans of various types is readily determined for various histocompatibility antigens and their α- and β-chains using combinations of lectin affinity chromatography of the oligosaccharides by the analysis of the three fractions from (Con A)-sorbent, the three fractions from (CL-1)-sorbent and the two fractions from LL-sorbent.[207,208]

The oligosaccharide structures of the erythrocyte β_1-adrenergic receptor and of β-fructofuranosidase[70,284] have been established with the aid of lectins, as has the common localisation in subunits of glycans of the oligomannoside and of complex types in dopamine receptors,[72] the distribution of poly-antenna sialylated oligomannoside glycans and of glycans with a branched residue of *N*-acetyl-D-glucosamine in the four non-identical sub-units of the acetylcholine receptor.[88] The presence has been revealed of glycans of the lactosamine type in the β-sub-unit of the thrombocyte Ib receptor and in the α_2-like component of the Ca-channel sensitive to dihydropyridine or in both sub-units of the intestinal peptide receptor,[54,96,149] and also in two sub-populations of the dopamine receptor, in the receptors of corticotropin releasing factor and in α_1-adrenergic receptors.[65,75,115] Differences between six of the seven glycoproteins of milk lipid droplet membranes were successfully detected with the aid of two immobilised lectins (Con A and WL) as a result of the retention of these glycoconjugates on elution.[203]

Chromatography on lectin is important not only for the assessment of glycan structure and correcting the carbohydrate microheterogeneity of receptors but also for obtaining functionally active sub-populations of receptors, such as in relation to the enzymic activity of receptors.[57,110,314] When purifying on lectins glycoprotein receptors with an established glycan structure it is possible to take the features of the interaction of a lectin with standard reagents into account for subsequent standardisation of the lectin specificity.

When studying receptors it is possible to use a set of lectins in combination with glycosidases and in combination with antibodies. In essence, the combined use of lectins and antibodies is foreseen in all antigen purification procedures since initially antigens are precipitated from extracts by immunoprecipitation (in Tables 1 and 2 several cases are shown of immunoaffinity chromatography jointly with a lectin sorbent). Since immunoprecipitates comprise a collection of polypeptides (such as sub-units) the localisation of glycans in antigen components by lectins enables one to speak of the intra-antigenic specificity of lectins. Often the carbohydrate structures in the glycoconjugates themselves emerge in the role of antigens important for biorecognition.[10,11,170,326] In addition carbohydrates may play an appreciable role in receptor function, as in the case of complement receptors, the transporter activity of Na^+/H^+-antiporter and of the glucose transporter.[44,129,327] In other cases glycans of a particular type are not important for receptor function, for example the receptor of lutropin or *E*-cadherin.[104,328] It is possible that glycans are important for the directed assembly of receptor components (see above) and also serve to anchor the lectins and lectin-like effectors. There is scope for the purification of antigens using lectins as is evidenced by the data on the antigenic specificity of lectins in relation to cells.[329–331]

IV. Interconnection between receptors, endogenous lectins and enzymes

The antigens of human leucocytes and their interaction with adhesion receptors and receptors of homing lymphocytes have attracted considerable interest from investigators.[4–9] As a rule the antigens of leucocytes are glycoproteins,[165] such as CD 36, CD 43, CD 44, CDw 44,[152,164,199,332,333] which react with immobilised lectins. In addition some antigens themselves display the properties of lectins (for example CD 14 binds lectin lipopolysaccharide[334]) or adhesins (such as antigens CD 8, CD 11, CD 19, etc.[335,336]). In addition antigens are frequently associated with enzymes. Leukemia antigen CD 13 is aminopeptidase N,[337] CD 45 is a protein-tyrosine-phosphatase,[338] C 73 is an exo-5′-nucleotidase[339] etc. Antigen 1D 4 from mammalian brain is not only associated with a type B nucleoside-diphosphatase but also reacts with lectins forming a triple complex.[340] Enzymes forming part of the so-called adhesin molecules on cell surfaces participate actively in the functioning of membrane channels (such as Na^+,K^+-ATPase of rat brain[304]) and serve as receptors of polydomain proteins of the extracellular matrix (for example, chicken muscle 5′-nucleotidase is a fibronectin receptor[341]). In addition a serine esterase is necessary for the development of monocyte adhesion due to IgG receptors (antigen CD 32) and carboxypeptidase N (kininase I) possibly functions with peptide hormone receptors (kinins).[292,342] An important role in cell metabolism is played by the membrane-bound enzymes of tyrosine metabolism, such as tyrosyl-protein sulphotransferase (which reacts with a sialo-specific lectin[256]), tyrosinase (which reacts with an

α-mannose-specific lectin[253]), tyrosine kinases in the composition of insulin receptors[260,343–345]), receptors of insulin-like growth factor type I,[120] receptors of type I colony stimulating factor or growth factor obtained from thrombocytes,[121,260] interleukin-3 receptors,[162] receptors of the Ca^{2+} antagonist or Ca-channel blockers,[52] and receptors of lysosomal enzymes.[346] Receptors with tyrosine kinase and other protein kinases react specifically with WL (see Tables 1 and 2) and the receptors of the lysosomal enzymes themselves display the properties of lectins specific for mannose-6-phosphate. It was also shown that the phosphorylation of proteins by kinases may be inhibited by initiation factor 2 reacting with a lectin specific for the *N*-acetylglucosamine residue,[347] although the activation of receptors containing kinases by binding with a sialospecific lectin is also possible.[91] The data presented indicate the close interaction of cellular antigens, enzymes and lectins forming a single complex functioning system. Other examples of modulation (inhibition or activation) of membrane enzymes by lectins have been shown previously.[25] The highly effective procedures listed in Tables 1 and 2 for the purification of receptors and membrane-bound enzymes of various classes of the International Classification (achieving a degree of purification of 50–440 times on a lectin sorbent) are additional proof of the possibly important role of the participation of endogenous lectins in the regulation of such receptor systems.

An important role in biorecognition is discharged by a receptor lectin[10,12,20,326,348] which has been well studied in the case of mammals and is a complicatedly organised oligomeric high molecular glycoprotein with a set of functionally different domains (collagen type, carbohydrate-binding portions, carbohydrate-containing portions as targets for other lectins, growth factors regulators of the complement system, etc.). Examples are the receptors of mammalian liver asialoglycoproteins,[16] receptors binding IgE or IgG (antigens CD 16, CD 32, CD 64),[336,342,349] homing receptors[350–356] and other adhesion proteins with lectin properties.[357,358] Each of the receptor proteins indicated may under definite conditions function according to one of the domains expressed, consequently it is occasionally difficult to determine whether the receptor is behaving as a lectin or as a donor of carbohydrates in a reaction with another glycoprotein. In such cases help is obtained from an analysis of the primary amino acid sequence or analysis of the nucleotide sequence with subsequent recognition of portions of homology with known lectins. Thus the similarity has been demonstrated for lectin domains of the Fc receptor for IgE and lectin-35, which contains RNA, and other soluble lectins,[349,359,360] IgE and IgG receptors,[349] a laminin-binding receptor of the non-integrin type and lectin-35,[361] ELAM-1 adhesion molecules and lectins,[358] insulin-like growth factor II and the mannose-6-phosphate receptor[362–364] and for elastin receptors and galactose-binding lectins.[365,366] A biochemical and immunological similarity has been shown for the type III complement receptor (antigens CD 11b and CD 18) with lectins and with conglutinin,[336,367] the β-glucan-specific receptor of monocytes (lectin) and the phagocytosis receptor of complement alternative route activators,[368] the receptor of circulating mannosyl glycoproteins from liver sinusoidal cells (lectin) and cerebellum lectin R1,[369] and also the erythrocyte lectin receptors, glucose transporters and band 3, 4 and 5 proteins,[370,371] carbohydrate transporter and nucleotide-binding protein.[372] Other receptors and antigens also participate in lectin–glycoconjugate interactions, such as the interaction of endogenous ceruloplasmin (ferroxidase) and human erythrocytes,[373,374] complex-formation between antigen CD 4 and the 160 kD coat glycoprotein of human immunodeficiency virus type 1,[375] antigens CD 4, CD 8, CD 2 and CD 3 and mitogenic exogenous (foreign) lectins of plants or microbial virulency factors.

Other examples of receptors similar to one another may be found in Table 1. In addition, a structural and functional similarity between the elastin and laminin receptors[380] and between the α_2-macroglobulin receptor and the low density lipoprotein receptor[381] has been shown.

Examples of receptor lectins and adhesins of various organisms (including microorganisms) may also be found in books.[26,376] Besides the lectins mentioned above with the usual (frequently met) specificity towards carbohydrates (mannose-, galactose- and fucose-specific) the specificity of new lectins as potential instruments for the analysis of glycoconjugates must be mentioned. Receptor ligatin is specific for mannose-6-phosphate in glycoprotein composition,[26,319] lectins of T-suppressors from fish roe are α-rhamnose-binding,[12,26] receptors of lymphocyte homing display sialospecificity and an affinity towards sulphated fucan,[353,354] the colonisation factors of bacteria possess an increased affinity towards sulphated glycolipid,[18] adhesive lectins of Protozoa (parasites, such as the stimulators of amoebic dysentry) are directed to a galactoso/*N*-acetylgalactosamine-specific protein,[377] receptor lectins of insect larvae (such as mosquitos) are *N*-acetylglucosamine-specific,[378] the sorption domains on polysaccharides of several microorganism glycosidases and receptors of macrophage phagocytosis are β-glucan-specific,[27,368] the core protein of cartilage proteoglycan behaves as if xylose-specific, type I fimbria of bacteria and lectins of several plant bulbs recognise glycans of the oligomannoside type[21] and the lectin receptors of hepatocytes are specific for the L-glycero-D-mannoheptose residue in lipopolysaccharides.[20,379] After solubilisation of such receptor lectins (with enzymes, low ionic strength, etc. see above) the preparations obtained may be used in a set with the other commercial lectins as described above.

V. Conclusion

Potential targets for lectins may be not only the glycoproteins listed above (see also Tables 1 and 2) but also proteoglycans bound to the cell surface (such as the hyaluronate-binding receptor or the high molecular form of insect alkaline phosphatase associated with chitin,[199,268] polysaccharides with various degrees of branching and bond type,[21,382] lipopolysaccharides,[20,21,379] lipophosphoglycans[298] and glycolipids[18,21]). Apart from the external and cell surface-bound glycoconjugates many intracellular glycoconjugates bound to organelles have been described, which react with a wide selection of lectins,[11] including poly A polymerase, ribonucleotide reductase and glycoprotein 62 of the nuclear membrane[227,249,265] galactosyl transferase of the Golgi apparatus,[255] phospholipase A_1, tyrosine kinase and lysosomal α-glucosidase,[269,280,346] eukaryotic ribosomal initiation factor-2,[347] glycosidases for processing glycoproteins of the endoplasmic reticulum[281–283] and others (see Tables 1 and 2). Procedures have been described for the purification and separation of proteoglycans, polysaccharides and unidentified glycoconjugates on lectin sorbents.[21,26,382,383] After solubilisation in 95% tetrahydrofuran in water glycolipids may be separated successfully on immobilised lectins, such as on (snail lectin)-sorbent.[384] Bacterial lipopolysaccharides may also in principle be separated by selective precipitation with lectins, particularly in the case of various Ra type lipopolysaccharides.

Different variants of qualitative and quantitative microanalysis using a set of lectins are used for the detection and identification of receptor glycoconjugates.[21,27] Lectin–peroxidase conjugates are widely applied in histochemistry particularly in cases of human cancer and other diseases.[385] Lectins labelled with peroxidase or biotin are most widely used in blotting variants of analysis, such as in the case of blood cell membrane glycoproteins,[387] histocompatibility antigens,[20] sarcolemma glycoproteins[42] and acetylcholine receptors.[88] Lectin conjugates of this same type are used with multiwell plates for immunoenzyme analysis in the study of receptors of native cells of proto- and eukaryotes,[388–390] plasma membrane receptors[391] or purified receptors, such as erythrocyte receptors for type I fimbriae of bacteria and the phosphomannosyl receptor.[213,392] In this way lectin analysis supplements the use of antibodies to a significant extent.[18,386,393]

Investigators have shown increased interest in receptors of microorganisms both in the composition of the cell surface of eukaryotes and the surface of protokaryotes (see Tables 1 and 2). This is linked with the recognition of types of lectin, i.e. glycoconjugates, in infection and immune processes,[13–15,376] with possible use of lectins in medical diagnostics,[394,395] and also when working with bacteria, yeasts and fungi (examples[393,395–401]).

Data on the interaction of lectins with glycans of soluble glycoproteins[24,26] may be used in the lectin analysis of forms of these glycoconjugates bound to cellular structures, since a significant affinity has been established for the carbohydrate portion of them as in the case of RNAase T_2-L of *Aspergillus oryzae*,[276] β-fructofuranosidase[284] and mammalian liver α-1,2-mannosidase,[283] and also of recombinant glycoprotein-160 of the AIDS virus.[228] Such affinity is explained by the general rules for the biosynthesis of glycoprotein glycans in the endoplasmic reticulum and Golgi apparatus of cells. In addition, in the process of glycoprotein secretion into the extracellular space, glycoproteins remain bound in several cases to the cell surface or are solubilised by endogenous hydrolases (see above on the solubilisation of receptors).

It must be noted that the possibilities of lectins (there is even a set of what would have seemed to be fairly well studied commercial lectins) are still far from being exhausted since our ideas on the specificity of lectins towards oligosaccharides, glycopeptides, neo-glycoproteins (more broadly neo-glycoconjugates) and natural glycoproteins with a known distribution of glycans on the protein surface are constantly being extended, particularly in recent times. The specificity of commercial lectins towards bacterial glycoprotein,[22] steroid glycoside[402] and carbohydrate-containing antibiotics, animal glycolipid and bacterial lipopolysaccharide[21] has not been investigated in practice. New types of carbohydrate–peptide bonds are being discovered, viz. Rha-Rha-Rha-Asn for bacilli, Gal-β-1,3-Ga1*N*Ac-Ser/Thr for fungi, Fuc-Ser/Thr,[403,404] Glc-α-1,6-Glc-β-1,6-Glc-α-1-Asn [405] and Glc*N*Ac-Ser/Thr [11] for mammals. The latter two structures react with immobilised Con A and WL respectively.[11,405]

The procedures for obtaining lectin preparations are therefore relatively simple,[382,385,406] and the list of highly purified lectins from microorganisms, invertebrates, plants and animals is growing rapidly.[26,376] The use of lectin sets in combination with glycosidases and antibodies as fine instruments for the analysis of glycoconjugates is extremely promising.

I. Introduction

In the present review the term secondary amino acid is taken to mean Pro and *N*-substituted amino acids in which the substituent is an alkyl radical (methyl in the majority of cases).†

Until recently the use of secondary amino acids in peptide chemistry has fluctuated and has been limited primarily to Pro, the amino group of which is the least hindered. However because of the spread of attention to this area of chemistry, other secondary amino acids have become involved in condensations and the experimental data presently available enable certain general conclusions to be drawn on the main features and peculiarities of the use of secondary amino acids in peptide synthesis.

When considering the features of condensation at a secondary amino acid residue it is necessary to consider separately the acylation of the secondary amino group of these amino acids and their derivatives since condensations in which secondary amino acids participate as the carboxy component are no different in practice from those of the usual amino acids. Only the most general features of the latter variant will therefore be given.

The presence of bulky side chains in amino acid carboxy components leads to a decrease in the rate of condensation.[2] An alkyl substituent on the nitrogen atom of a secondary amino acid generates additional steric hindrance to the formation of the peptide bond but this effect is less significant than the influence of the side chain. In the most common cases of activation the presence of a substituent on the nitrogen atom in *N*-methylamino acids and in Pro has practically no effect on the yield of product.[3]

The presence of any protecting group on the *N*-alkylamino group of a carboxyl component begins to show an appreciable influence on the reactivity of the carboxyl group only in cases of the sterically most hindered condensations and the best yields are achieved when using Z and Fmoc rather than a Boc protected amino group.[4]

II. Methods of acylating secondary amino acids and their derivatives

In spite of the increased nucleophilicity of a secondary amino group (the pK of which is 1–1.5 units higher than for an amino group[5]) which must aid acylation, the duration of condensations in these cases is sharply increased and yields of peptides are reduced. This is explained by the shielding of the nucleophilic centre which is displayed to the smallest extent by Pro and increases with the increase in size of the *N*-alkyl substituent. For example in the synthesis of tripeptide fragments of an enkephalin analogue yields are reduced from 70 to 40% on increasing the size of the radical R.[6,7]

$$\text{Boc—D-Ala—Gly} + \text{(N-R)Phe(4-F)—NH}_2 \xrightarrow{\text{DCC/OBT}} \rightarrow \text{Boc—D-Ala—Gly—(N—R)Phe(4-F)—NH}_2$$

R = Me, Et, cyclo-Pr.

The ability of secondary amino acids to be acylated is also reduced with an increase in the bulk of the side chain and by the presence of branching at the α- and β-carbon atoms.[5] Thus steric factors play the chief role in the acylation of secondary amino acid residues and this must be considered when choosing variants of the condensation reaction.

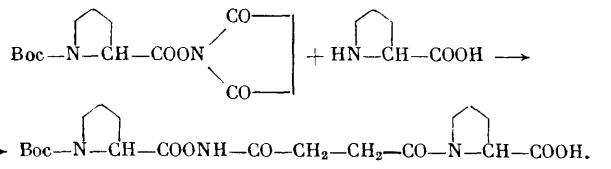
Until recently special methods had not been developed for acylating secondary amino acid residues and traditional acylating reagents were used for this, such as active esters and symmetrical or mixed anhydrides of amino acids. The carbodiimide method was also used for the activation of the carboxyl component.

† Abbreviations used are those recommended by the IUPAC–IUB Commission[1] and also the following: Abu—α-aminobutyric acid, Aib—α-aminoisobutyric acid, BOP—[(benzo-triazol-1-yl)oxy]-tris(dimethylamino)phosphonium hexafluorophosphate, BOP–Cl—bis(2-oxo-3-oxazolidinyl)phosphinic chloride, t-Bu—t-butyl, Lac—lactic acid, (*N*–Me)Bmt—(4*R*)-4[(*E*)-2-butenyl-4,*N*-dimethyl-*L*-threonine, HOBT—*N*-hydroxybenzotriazole, HOSu—*N*-hydroxy-succinimide, Piv–Cl—pivaloyl chloride, SPip—thiopipecolic acid, DKP—diketopiperazine, DCC—dicyclohexylcarbodiimide, THF—tetrahydrofuran.

1. Active ester method

To effect nucleophilic attack on the carbonyl carbon atom of a carboxyl component by a secondary amino acid the carboxyl group must be well activated.

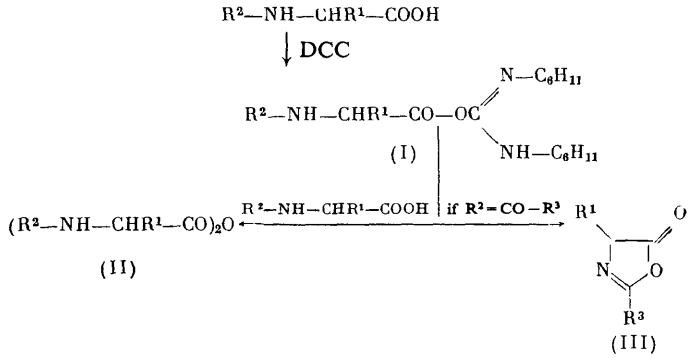
$$R^2{-}NH{-}CHR^1{-}COOX + R^3{-}NH{-}CHR^4{-}COOY \rightarrow$$
$$\rightarrow R^2{-}NH{-}CHR^1{-}CON(R^3){-}CHR^4{-}COOY,$$



where R^1 is the side chain of the carboxy component, Y and R^2 are protecting groups, R^3 is alkyl, R^4 is the side chain of the amino component and X is an electron-accepting group.

Pentafluorophenyl esters are used fairly successfully for the acylation of secondary amino acids, particularly Pro.[8,9] If the condensation is conducted with the least sterically hindered residues Pro or (*N*-Me)Ala then from 1 h to 1 d is required for complete reaction, although the reaction time is 5–30 min when condensing at a primary amino group by this method which is comparable with the time for acylation with anhydrides.

The electron-accepting properties of pentachloro- and pentafluorophenol are clearly linked with their pK values (5.2 and 5.5 respectively) and determine the reactivity of the corresponding activated esters. However, although pentachlorophenol is a stronger acid as a result of its weaker + *M* effect,[5] the ratio of the aminolysis rates for a primary amino group by pentachloro- and pentafluorophenyl esters is 1:40. This is linked with the steric hindrance of the electrophilic centre by the chlorine atoms in the *ortho* position, since fluorine atoms having a small atomic radius do not cause such hindrance.[5] Thus the application of pentachlorophenyl esters for the acylation of amino acids is of doubtful expedience.



2,4,5-Trichlorophenyl esters of amino acids acylate (*N*-Me)Ala and Pro residues satisfactorily on catalysis by HOBT.[9,10] It is not excluded that HOBT esters are the real acylating reagents in this case.

When using HOSu esters, which are insufficiently reactive, a side reaction of succinoylating secondary amino acid residues is observed.[11–13]

2. Carbodiimide method

DCC was introduced into peptide synthesis in the mid-fifties.[14] When reacting equimolar quantities of DCC and a urethane-protected amino acid a mixture is formed of an *O*-acylurea (I) and a symmetrical anhydride (II).

The anhydrides (II) acylate secondary amino acid residues fairly readily but the efficiency of an *O*-acylurea (I) as an acylating reagent for secondary amino acids has not been assessed. When urethane protection is present on the amino group of the carboxy component, racemisation is reduced to a minimum and the use of the DCC method usually leads to a good yield on extended (days or longer) reaction at temperatures from 0 to 20 °C.[3,15–18] Other conditions being equal, the activation of the carboxy component with DCC leads to a higher yield than on using 1-ethyl-3-(dimethylamino)-propylcarbodiimide.[19] When activating fragments not containing *C*-terminal Pro or *N*-acylaminoacids having no urethane protection by the DOC method, an oxazolone (III) may act as acylating agent and its efficiency in relation to secondary amino acids is also unclear.[11]

Recently activation of the carboxy component with DCC has frequently been carried out in the presence of HOBT or HOSu due to numerous side reactions and racemisation. This procedure suppresses the formation of *N*-acylureas and leads to minimum racemisation of the amino acid residue. The duration of acylation is unchanged by this.[20] Many examples of the use of the DCC/HOBT method have been described in the literature for the acylation of secondary amino acids in satisfactory and good yield.[6,7,9,13,21] However for the reaction of Piv–Pro with (*N*-Me)Phe–OMe and Boc-*D*-Ala–(*N*-Me)Leu–(*N*-Me)Leu with (*N*-Me)Val–OBzl the DCC/HOBT method does not lead to the formation of the required product and in the latter case the reaction does not go even in boiling THF.[2,22]

The DCC/HOSu method is not used as frequently as the DCC/HOBT method for the acylation of secondary amino acid residues but there are examples of its fairly successful use. Thus the yield was 96% in the reaction of Boc–Ala with (*N*-Me)Leu–OBzl when using DCC/HOSu and was 82% in the reaction of Z–Pro with Sar–(*N*-Me)Val–OBu^t.[3,23] On the other hand the yield was 10% on condensing Z–Val with (*N*-Me)Leu–OBu^t and 2% overall on using preformed Z–Val–OSu. Under analogous conditions the DCC/HOBT method gave 50% yield.[13] There are numerous data on the acylation of the sterically less hindered Pro residue by this method when yields were 60 to 80% at 20 °C with a reaction time of 20–48 h.[24–26] The use of the DCC/HOSu method turned out to be unsuccessful for the reaction of Z–Arg(Z_2)–Arg($Adoc_2$) with Pro–Pro–Lys(Boc)–Gly.[27] It has also been shown that the DCC/HOBT method gives fewer side products than the DCC/HOSu method.[21]

3. Symmetrical anhydride method

This method is a variant of the DCC method, a double excess of carboxy component being involved in reaction with DCC. The *O*-acylurea (I) formed first reacts with the excess of carboxy component and is converted into a symmetrical anhydride (II). At the present time the symmetrical anhydride method is used mostly in solid phase synthesis and frequently gives good results when making peptides containing secondary amino acids. Thus an analogue of substance P containing (*N*-Me)Phe and Sar was obtained in 60% yield.[28] However in this case a single acylation of the secondary amino acid residue requires no less than 16 h reaction time in place of the more usual 30 min to 1 h.[5,28] An increase in the reaction temperature gives an increase in the reaction rate and in the yield of the desired product. On heating Boc–Pro anhydride with *D*-(*N*-Me)Leu–OMe to 130 °C for 5 min the dipeptide was obtained in 97% yield. The product was contaminated by the epimer according to NMR spectroscopy.[19]

A serious limitation to the carbodiimide method is the impossibility of obtaining anhydrides from peptide fragments and from amino acids without urethane protection although they are formed from other *N*-acyl substituted derivatives of Pro and possibly of other secondary amino acids.[11] The symmetrical anhydride method also gives a whole range of side products linked with the use of DOC in peptide chemistry.

4. Mixed anhydrides with alkylcarbonic acids

The method of mixed anhydrides with alkylcarbonic acids is the most frequently used of the traditional methods of forming peptide bonds for acylating secondary amino acids.[20]

$$Z-NH-CHR^1-CO-O-COOR^2 + R^3-NH-CHR^4-COY \rightarrow$$
(IV) (V)

$$\rightarrow Z-NH-CHR^1-CON(R^3)-CHR^4-COY + R^2-OCON(R^3)-CHR^4-COY$$
(VI) (VII)

In spite of the high reactivity of the anhydrides (IV) the yield of peptide (VI) is frequently less than when the carbodiimide method is used. The main reason for this is the presence in the carboxy component (IV) of two reaction centres and the ambiguous nature of the reaction as a result. The preferred direction of attack depends on the nature of the substituents R^1, R^2 and R^3. The presence of groups R^1 and R^3 hinder the formation of peptide (VI) more strongly the greater their molar volume and degree of branching.[29,30] In some cases the mixed anhydride method is not generally suitable. For example in the reactions of Boc–*D*-Ala–(*N*-Me)Leu–(*N*-Me)Leu with (*N*-Me)Val–OBzl (–20 °C, 26 h),[22] Boc–Phe with a fragment containing *N*-terminal (*N*-Me)Ala [9] and Boc–Ile with Pro–Leu–Ser(Bzl)–Arg(NO_2)–Leu–Phe–OMe [31] it did not lead to the formation of the desired products.

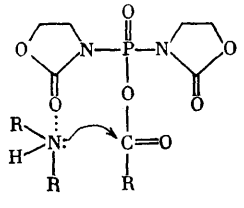
A branched group R^2 increases the electron density on the carbonyl carbon atom of the alkylcarbonic acid residue and hinders it to some extent which reduces the possibility of attack on the latter by the secondary amino group. The acylation of secondary amino acids using mixed anhydrides of isobutylcarbonic acid (IV, R^2 = iso-Bu) is preferred to the use of anhydrides of ethylcarbonic acid (IV, R^2 = Et).[20] Thus when acylating a tripeptide containing an *N*-terminal Pro residue with a mixed anhydride of ethylcarbonic acid the urethane EtOC(O)–Pro–Lys(For)–Asp was obtained in 61% yield.[32] The use of anhydrides of isobutylcarbonic acid is also accompanied by the formation of the urethanes (VII),[33–35] and their yield depends on the choice of solvent in which the condensation is carried out and on the types of base used. For the reaction of Z–Gly–Phe with Pro–OMe the yield of urethane increases from 13 to 33% along the series THF, chloroform, DMF.[36] A minimal quantity of urethane is formed when using *N*-methylmorpholine or *N*-Methylpiperidine on obtaining the anhydrides (IV).[37]

The molecular weight of both the secondary amino and the carboxy component have a significant influence on the yield of product.[20] For example the yields on fragment condensation of Boc–*D*-Ala–Gly and Boc–Tyr–*D*-Ala–Gly with (*N*-Me)Phe–Met-ol were 70 and 50 % respectively.[38]

In spite of the relative stability of pure mixed anhydrides (IV) at temperatures up to 25 °C, they disproportionate with the formation of symmetrical anhydrides in the presence of even traces of base, and the amino component itself may cause this.[22,39] To suppress this process the condensation is carried out at –20 to –15 °C, but to increase the yield it is desirable to carry out the reaction at a higher temperature.

Of all the above reactants the symmetrical anhydrides are the most acceptable for the acylation of secondary amino acids but for the most sterically hindered condensations of the type of Boc–(*N*-Me)Val with (*N*-Me)Val–OBu^t, even they are ineffective.[2]

5. Mixed anhydrides with pivalic acid and phosphorus acids



At the present time the mixed anhydrides obtained from Piv–Cl and BOP–Cl are the best known and most widely used reagents for acylating secondary amino acids. In particular they have been used successfully in the synthesis of the cyclic undecapeptide cyclosporin A and its analogues which contain seven secondary amino acids.[22,40–42]

Piv–Cl was first used in peptide chemistry in 1962.[43] However the mixed pivalic anhydride method has not been widespread in usual condensations seemingly due to the possibility of forming *N*-pivaloyl peptides.[20] For example in the reaction of the acetonide of (*N*-Me)Bmt with Abu–Sar–(*N*-Me)Leu–Val–(*N*-Me)Leu–Ala–OBzl a mixture was obtained of heptapeptide and *N*-pivaloyl hexapeptide in a 1 : 1 ratio.[42] It was later shown that the formation of *N*-pivaloyl peptides does not occur when acylating secondary amino acids with mixed pivalic anhydrides.[22] Other virtues of this method are the high acylating ability of the anhydride and its thermal stability up to 50 °C even in the presence of triethylamine and *N*-methylmorpholine which enables the most sterically hindered condensations to be effected.[2,22]

Some authors[2,44] regard the significant duration of the stage of forming the mixed pivalic anhydride in chloroform a disadvantage of this method. It is recorded that the yield of the desired peptide depends markedly on the duration of the activation. Thus for the reaction of Boc–*D*-Ala–(*N*-Me)Leu–(*N*-Me)Leu with (*N*-Me)Val–OBzl the yield of tetrapeptide is 60% when activating the carboxyl component with Piv–Cl for 2 h and 88% for 4 h.[22] However on carrying out the activation in THF the formation of the mixed pivalic anhydride is complete after 5–20 min at –20 °C.[13,45,46]

Activation of secondary amino acids with urethane protection with Piv–Cl is not accompanied by racemisation even at elevated temperature. Only in the case of the extremely sterically hindered condensation of Z–(*N*-Me)Val with (*N*-Me)Val–OBu^t for 24 h at 50 °C was 6% epimer detected in the dipeptide.[2] Fragment condensations using Piv–Cl are accompanied by racemisation, the extent of which depends on a large number of factors.[2,22,40]

In 1980 BOP–Cl was proposed as a reagent for the synthesis of esters and other derivatives of carboxylic acids.[47] Its high efficiency when forming peptide bonds at residues of secondary amino acids was shown for the first time in 1985.[4] A mechanism of electrophilic catalysis at the condensation stage has been proposed to explain this effect.[2]

It has been recorded that BOP–Cl is a more effective reagent than Piv–Cl for carrying out sterically very hindered condensations.[2,4] Thus in the reaction of the mixed anhydride of Z–(*N*-Me)Phe and pivalic acid with (*N*-Me)Val–OBu^t a positive result is achieved only at enhanced temperature while BOP–Cl

enabled preparation of the product in 92% yield after 48 h at 20 °C in this condensation.[2] The difference in yields of product when using BOP–Cl or Piv–Cl is reduced with a reduction in steric limitations. Thus in the reaction of Z–Pro–(*N*-Me)Phe with Ala–Bu^t both reagents lead to the formation of tripeptide in 85% yield but in this condensation racemisation was 38% with Piv–Cl and on using BOP–Cl it was 64%.[2] This ratio is less in other examples. Usually the use of BOP–Cl is accompanied by less racemisation than the use of Piv–Cl in fragment condensations.[2] This is possibly explained by the high reactivity of the mixed anhydride of the carboxyl component with the phosphoric diamide compared with its mixed pivalic anhydride, consequently the long condensation time in the second case leads to an increase in the extent of racemisation of the carboxy component.[48]

One further advantage of BOP–Cl is the possibility of using it as a condensing reagent in a one-pot synthesis without preactivating the carboxy component as a separate stage. The analogous method using Piv–Cl leads to the formation of up to 40% *N*-pivaloyl peptide,[22] which is explained by the lower reactivity of BOP–Cl towards an amino group compared with carboxylate anion.[49] However the best results of all were achieved by carrying out the preparation of the mixed anhydride of the carboxy component and the diamidophosphoric acid as a separate stage since otherwise some contamination by the BOP-amino component is formed.[2]

Carrying out sterically hindered condensations using BOP–Cl, as for Piv–Cl, may be accompanied by a little racemisation of the carboxy component even in the presence of urethane protection of its amino group. For example 4% epimer was obtained in the reaction of Z–(*N*-Me)Val with (*N*-Me)Val–OBu^t.[8] In this case it is possible to suppress the racemisation by the addition of HOBT but not HOSu.[2] However on adding HOBT the overall yield of dipeptide was sharply reduced (from 92 to 21%). This fact is readily explained by the formation of an HOBT ester of the carboxy component caused by steric factors. This ester is a weak acylating agent in such difficult condensations.

It is also interesting to record the BOP–Cl proved to be ineffective in condensations of *C*-α-methylamino acids. For example after carrying out the reaction of Boc–Aib with Aib–OBzl none of the desired product was detected.[4]

It is possible to regard the possibility of disproportionation of such mixed anhydrides as being a drawback of the use of BOP–Cl for the activation of both secondary and primary amino acids, particularly at long reaction times.[2,4] The relatively poor solubility of BOP–Cl in certain organic solvents, especially those used in peptide synthesis, should also be noted.[41]

It is also possible to use BOP–azide, which is a fairly stable compound, in place of BOP–Cl for the activation of the carboxy component. When carrying out preactivation with BOP–azide (10 min, 0 °C) in the condensations of Boc–Ala with (*N*-Me)Phe and Z–Phe with (*N*-Me)Ala–OMe the yield of dipeptide was 60% after 4 h.[50]

The use of diethyl phosphorocyanidate as an activating reagent has been described. In the condensation of Boc–Pro with *D*-(*N*-Me)Phe–*D*-Ala–Val–Ant–OMe (2 h, 0 °C, then 24 h, 20 °C) the pentapeptide was formed in 89% yield.[51]

Data have appeared recently on the use of diphenyl phosphinic chloride as a highly efficient activation reagent for the acylation of secondary amino acid residues.[13,52–55] The advantage of this reagent over BOP–Cl was shown in the activation of both primary and secondary amino acids in the synthesis of cyclosporin fragments.[54] The use of diphenyl phosphinic chloride for the activation of a carboxy component with a urethane protected amino group was not accompanied by racemisation of the latter but the process of forming the mixed anhydride was analogous to activation using Piv–Cl.[53,54] An advantage of diphenyl phosphinic chloride is the speed of formation and the stability towards disproportionation of mixed anhydrides made from it.[48,56]

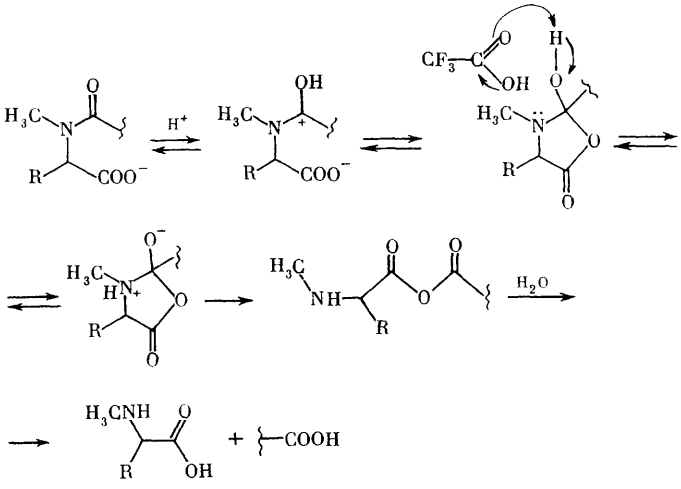
Of the new condensing reagents mention must be made of benzotriazolyloxy-tris(dimethylamino)phosphonium hexafluorophosphate with which a fragment condensation at an (*N*-Me)Bmt residue has been effected without racemisation of the carboxyl component.[40,57]

Other condensation methods have occasionally been used for secondary amino acid residues. Thus a new reagent was proposed recently, viz. 1,2-dihydro-4,6-dimethyl-2-thiooxo-3-pyridinecarbonitrile, and was used in the synthesis of a protected (8–11)cyclosporin fragment without racemisation and with yields at the condensation stages of 80–87%.[58] It is interesting that this reagent may be used for building up a chain both by traditional activation of a carboxyl group or by activation of the amino group of an amino component. To effect condensation in this case it is also necessary to have an equimolar quantity of triphenylphosphine present.[59]

Occasionally the azide method is used for fragment condensations at a Pro residue.[59] The *N*-carboxyanhydride method gives poor results for similar condensations.[60] Good results were recorded using Woodward's reagent K in solid phase synthesis for the acylation of secondary amino acids.[61]

III. Side reactions caused by the presence of secondary amino acids in peptides

In addition to the peculiarities described above, complications also arise when obtaining esters and amides of secondary amino acids and on removing protecting groups during peptide synthesis. All these processes proceed with significantly more difficulty or are accompanied by side reactions which are absent when working with unsubstituted amino acids.



For example Sar–OMe is obtained in only low yield when using a solution of thionyl chloride in methanol while both Gly and many other amino acids give good yields of methyl esters under these conditions.[62] The t-butyl ester of Val is obtained in quantitative yield after 4 h at 20 °C when using isobutene in the presence of sulphuric acid. Under the same conditions the reaction of (*N*-Me)Val is incomplete even after 96 h.[41]

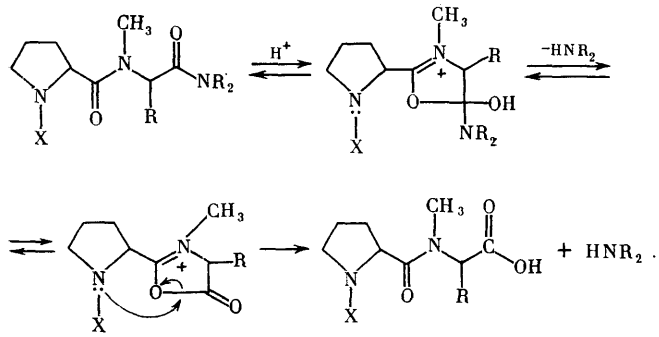
The saponification of alkyl esters of secondary amino acids proceeds with significantly more difficulty than in the case of the corresponding derivatives of unsubstituted amino acids. For example under identical conditions the rate of saponification of Sar–OMe is five times slower than for Gly–OMe,[62] and the hydrolysis of Lac–Pro-*D*-(*N*-Me)–Leu–OMe even with a three-fold excess of sodium hydroxide proceeds only to 90% after 2 h.[19] It has been reported that it is impossible to obtain the hydrazide of Bz–(*N*-Me)Val from its methyl ester by reaction with hydrazine hydrate.[21] Similarly the aminolysis of alkyl esters of secondary amino acids is difficult, consequently their amides are obtained by treating an activated ester or mixed anhydride of the protected secondary amino acid with an amine.[6,7,63] Occasionally the roundabout method of obtaining the amide of an amino acid with subsequent alkylation of its amino group is used.[6,7] A similar approach is applied to the synthesis of fragments consisting only of

secondary amino acids. For example on treating the tripeptide Boc–Leu–Leu–Val–OBzl with methyl iodide in the presence of silver oxide, methylation of the nitrogen atoms of all three amino acid residues occurs.[44] Milder conditions are used to prevent methylation of the urethane nitrogen atom (CH_3I, K_2CO_3, 18-crown-6, DMF, 20 °C).[64] Such a method of synthesis of tripeptide sequences of secondary amino acids enables prevention of the formation of cyclic dipeptides (DKP) in a 1 + 2 cocondensation.[44]

Data have recently appeared on the ready fission of the peptide bond on acid treatment of peptides containing sequences of two or more secondary amino acids.[65,66] Two mechanisms have been proposed by which such fission may occur. The first of these, in which the hydrolysis process does not depend on acid strength in the medium in which it occurs, has acquired the name exopeptolysis. The second, which depends on acid strength, is called endopeptolysis. Both mechanisms assume a ready transition of the peptide bond into the *cis* form and the spatial approach of the appropriate portions of the molecule.

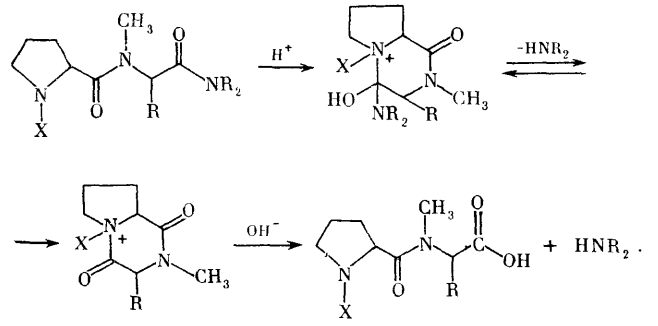
Exopeptolysis may be illustrated by the example of the dipeptide Tfa–(*N*-Me)Phe–(*N*-Me)Ala which is split 29% at the peptide bond in a medium of formic acid after 120 h at 20 °C and 21% in trifluoroacetic acid under the same conditions.[65] At the same time the alkyl esters of this dipeptide are stable in trifluoroacetic acid.[65,66] The following mechanism has been proposed for exopeptolysis.[65]

Endopeptolysis is characteristic of tripeptides made up of secondary amino acids through the *N*-terminal position may be occupied by a Gly residue. The peptide bond between the second and third secondary amino acids is readily split in acid medium in such tripeptides, particularly in cases when the *N*-terminal secondary amino acid is Pro.[66] The rate of hydrolysis of such tripeptides depends sharply on the strength of the acid in which the reaction is effected, i.e. trifluoroacetic ≫ formic ≫ acetic acid. The sensitivity of tripeptides towards acidic fission is proportional to the steric strain about the amide bond between the second and third secondary amino acids, with the exception of the case when the first two positions of the triad are occupied by Pro residues.[66]



Z–Pro–(N-Me)Phe–SPip > Z–Pro–(N-Me)Phe–(N-Me)Ala,
Z–Pro–(N-Me)Phe–(N-Me)Ala–OMe > Z–Val–(N-Me)Phe–(N-Me)Ala–OMe, Z–Val–(N-Me)Phe–(N-Me)Ala,
Z–Pro–(N-Me)Phe–Ala–OMe ≫ Pro–(N-Me)Phe–NR_2 > > Pro–Pro–Pro, Pro–Pro–SPip, Pro–Phe–NR_2.

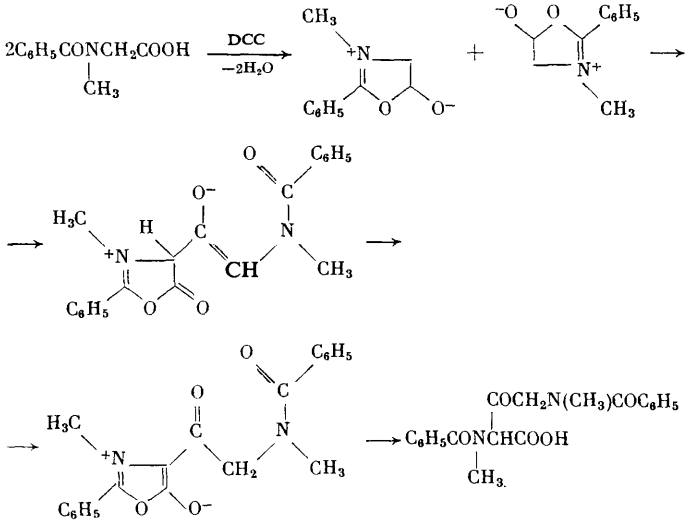
In certain cases the hydrolysis goes so easily that when deblocking the tripeptide Z–Abu–Pro–(*N*-Me)Phe–SPip–OBu^t fission of the *C*-terminal secondary amino acid is effected more rapidly than removal of the t-butyl protection. Endopeptolysis is difficult if the *N*-terminus in the triad is an unsubstituted secndary amino acid or the dipeptide Pro–Pro. If the sequence consists of alternating *L* and *D* isomers of secondary amino acids (*L*, *D*, *L*) then the rate of endopeptolysis is two orders of magnitude lower than for sequences containing only *L* isomers. Thus the tripeptide Z–Pro–*D*-(*N*-Me)Phe–(*N*–Me)Ala–OBu^t does not decompose in the presence of trifluoroacetic acid for several days but its *L*–(*N*-Me)Phe analogue is completely decomposed under the same conditions in 15 min.[2] The dipeptide Z–Pro–*D*-(*N*-Me)Phe–NMe_2 remains unchanged in trifluoroacetic acid for days while its *L* analogue loses the NMe_2 group completely under the same conditions after 14 h.[66] This may be explained by the fact that the energy barrier for the transition of a *trans* amide bond into the *cis* configuration for an *L*-, *D*-pair of amino acids in the triad is greater than for an *L*-, *L*-pair. It may therefore by considered quite definite that conformational factors plays a most important role in the stability of the peptide bond between secondary amino acids.



Two possible mechanisms have been proposed for the endopeptolysis reaction (the second is preferred) (see Scheme).[66]

Scheme

Oxazolonium



Diketopiperazine

Similar processes were observed in the synthesis of cyclosporin when for example the deblocking of the undecapeptide Boc–*D*-Ala–(*N*-Me)Leu–(*N*-Me)Leu–(*N*-Me)Val–(*N*-Me)Bmt–Abu–Sar–(*N*-Me)Leu–Val–(*N*-Me)Leu–Ala with a solution of trifluoroacetic acid in chloroform at 0 °C with subsequent neutralisation of the excess of acid led to a complex mixture of products among which were peptides of shortened sequence. The

avoidance of side reactions in this case was successful if the deblocking temperature was reduced to −20 °C.[40,42]

The side reaction of *C*-α-acylation of the Sar residue, observed on using the carbodiimide method, is also effected by an oxazolonium mechanism.[67]

The ease of forming DKPs from certain peptide derivatives is an extremely pressing problem when using secondary amino acids in peptide synthesis. This concerns primarily condensation reactions where a dipeptide ester containing a *C*-terminal secondary amino acid acts as the amino component. In this case the energies of the *cis* and *trans* configurations of the peptide bond are close and for the formation of DKPs it is necessary to overcome a significantly lower energy barrier for the *trans*−*cis* transition (since DKPs exist only as the *cis,cis* isomers) than in the case of a dipeptide containing no secondary amino acids.[3,5,20,68] The formation of DKPs in the case under consideration is most frequently catalysed by bases, especially by an excess of tertiary amine, frequently present in the reaction medium.[5,68,69] The rate of formation of a DKP depends on several factors except in the presence of a catalyst. The presence of side chains and radicals on the nitrogen atom of the secondary amino acids forming part of the dipeptide gives an energy advantage to the formation of the six-membered DKP ring due to the entropy factor. Steric hindrance has great importance in the nucleophilic attack on the carbonyl carbon atom by the amino group, and arises particularly in the presence of a side chain on the *N*-terminal amino acid.[68,69]

The rate of cyclisation of dipeptide esters consisting of two secondary amino acids is fairly high seemingly due to the enhanced nucleophilicity of the secondary amino group.[11] Thus the formation of DKP from the dipeptide (*N*-Me)Leu−(*N*-Me)Val−OBzl was the main obstacle in the synthesis of the (7−11) cyclosporin fragment when extending the peptide chain from the *C*-terminus.[22] The process of forming DKPs may not only compete with peptide synthesis but may completely exclude it when using a dipeptide ester as the amino component. This process is obviously particularly dangerous when using esters of dipeptides consisting of two secondary amino acids as the amino component since in this case the condensation time grows and there is a fairly high rate of DKP formation.

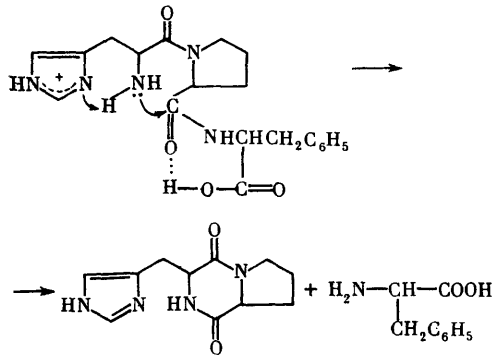
The presence of a side chain on the *C*-terminal secondary amino acid seemingly does not have an appreciable effect on the rate of DKP formation while the nature of the tertiary amine and the solvent in which the condensation is carried out influence it appreciably.[68,69]

The problem of DKP formation from dipeptide esters with a *C*-terminal secondary amino acid is a characteristic not only of synthesis in solution but also for the solid phase method of peptide synthesis based on chloromethylated resin. In the case of such a polymeric support DKPs are readily formed from the protected dipeptide benzyl esters at the stage of neutralising the dipeptidylpolymers with tertiary amine after deblocking.[70] In a similar situation, when using Sephadex LH-20 as the polymeric support, formation was also recorded.[71]

Furthermore it was observed that on using the DCC condensation method in solid phase synthesis on chloromethylated resin, DKPs were also formed at the stage of equilibrating the dipeptidylpolymer with a solution of the next amino acid.[72] In this case acid catalysis of DKP formation occurs and has been confirmed on numerous occasions in the classical synthesis of peptides. DKPs are formed most frequently when removing protecting groups from dipeptide esters with acids having pK_a 3−5. This effect is observed in the removal of a Z group by hydrogenation in solutions containing acetic acid or, for example, on removing 2-(4-biphenylyl)propyl-2-hydroxycarbonyl protection with formic acid.[18,73] The mechanism of such catalysis is obviously similar to the general acid catalysis mechanism.

It must also be noted that there is a danger of forming DKPs from dipeptide esters with a *C*-terminal secondary amino acid when removing Fmoc protection by the action of such strong organic bases as piperidine or diethylamine.[74,75] When using 4-(aminomethyl)piperidine in this situation 10−20% DKP is formed even from benzyl esters of dipeptides containing no secondary amino acid.[74]

If a phenacyl ester of a dipeptide is introduced into the condensation reaction instead of an alkyl or benzyl ester then the probability of DKP formation is increased.[5] Consequently to prevent this process it is recommended to use tertiary butyl esters of dipeptides.[3,22]



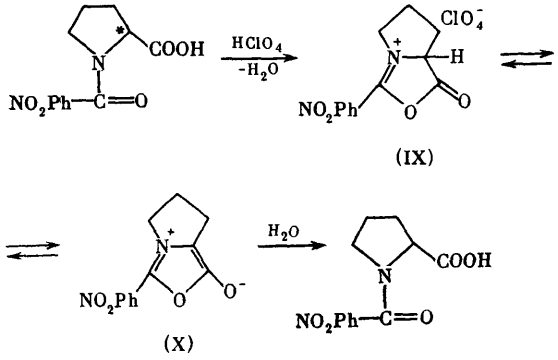
In certain cases cyclisation to a DKP may occur even with *N*-protected peptides. For example the 4-nitrophenyl ester of the dipeptide Z−Gly−Pro forms an (*N*−Z)-substituted DKP and in the course of condensing Z−(*N*-Me)Val with (*N*-Me)Val−OBu^t when using BOP−Cl, and particularly when using Piv−Cl at increased temperature, up to 10% of the corresponding DKP was obtained the mechanism of forming which is unclear.[2,75]

The DKP cyclo[(*N*-Me)Phe−(*N*-Me)Ala] is formed from the tripeptide cinnamyloxycarbonyl−Pro−(*N*-Me)Phe−(*N*-Me)Ala−OMe during column chromatography on silicagel and substituted Pro is split off.[76]

Although it is considered that trifluoroacetates and especially hydrochlorides of dipeptide esters consisting of any amino acids are completely stable,[72] the trifluoroacetate of the dipeptide (*N*-Me)Phe−(*N*-Me)Ala−OMe is converted into the DKP on storage in chloroform solution.[76]

It is also known that amides of dipeptides containing a *C*-terminal secondary amino acid are inclined to DKP formation.[77,78] For example, the dipeptide Phe(4-NO_2)−Pro−NH_2 forms the DKP during recrystallisation.[78] Individual cases of similar transamidations have been recorded when obtaining certain tripeptides. When treating the tripeptide His−Pro−Phe with 50% acetic acid fission of Phe occurs and the DKP (VIII) is formed after 24 h at 20 °C. Under the same conditions the tripeptide

Trp–Pro–Phe is stable and no traces of decomposition were detected after 24 h. The methyl ester of the first tripeptide is between these compounds in stability. In the opinion of the authors[79] the instability of the tripeptide His–Pro–Phe is explained by a combination of conformational factors favouring DKP formation and a so-called intramolecular catalysis.[79]



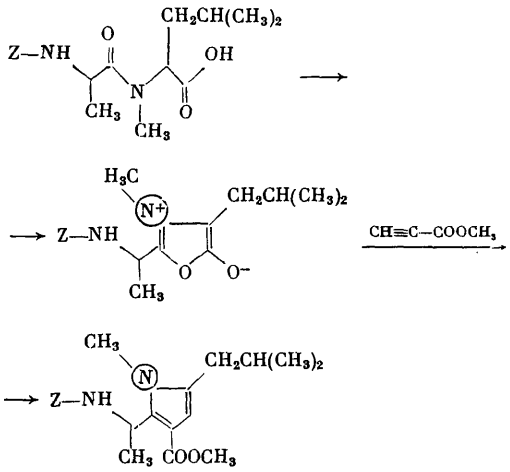
(VIII)

Intramolecular transamidation has also been described in the tripeptide *D*–Val–Pro–Sar which is 50% decomposed on storage for 3 weeks at 20 °C. It was reported that no sign of decomposition was detected for the hydrochloride of this peptide under the same conditions.[80]

The tripeptide Aib–Pro–Trp also shows an increased inclination towards intramolecular transamidation.[81]

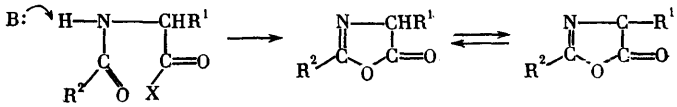
IV. Racemisation of secondary amino acids in peptide synthesis

Proline is a unique secondary amino acid, widely distributed in nature, and has been used in peptide synthesis for a long time. Equally with Gly, Pro plays an important role as a *C*-terminal residue in fragment condensations which is linked with its high stability towards racemisation in activation processes and removal of protecting groups.[3,82] This was explained previously by the impossibility of effecting an oxazolonium mechanism of racemisation for its *N*-acyl derivatives because of the absence of a hydrogen atom on the tertiary nitrogen atom. However it was found in 1972 that *N*-acyl substituted Pro and other secondary amino acids may give the stable oxazolonium salts (IX) on treatment with perchloric acid.[67,83]



(IX)

(X)



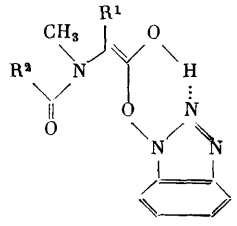
Complete racemisation of the Pro residue took place in 1 h at 20 °C on storing the salt (IX) in the presence of anhydrous perchloric acid. This process is connected with the equilibrium in the oxazolinium ion (IX)–mesoionic oxazolone (X) system, since it was shown that on precipitating salt (IX) from the reaction medium with dry ether no racemisation occurred on storing it in the dry state.[67] These facts serve to confirm the possibility of racemising *N*-acyl-Pro according to the oxazolonium mechanism but the formation from it of the mesoionic oxazolone (X) is difficult due to conformational restrictions and occurs only in the presence of strongly acidic reagents (perchloric acid). The extent of the structural limitations for other secondary amino acids is far lower than for Pro and the formation of the mesoionic oxazolone and consequent isomerisation is observed under the mild conditions of peptide synthesis. In addition their susceptibility towards racemisation according to the oxazolonium mechanism is extremely high.

The formation of the mesoionic oxazolone (X) is accompanied by the appearance of a rapidly disappearing bright yellow colouration of the reaction mixture (absorption λ_{max} = 400 nm). Subsequently its formation was successfully confirmed by reaction with the 1,3-dipolarophile acetylenecarboxylic acid.[3]

In 1981 NMR signals for the mesoionic oxazolone (X) were recorded on reacting Z–(*N*-Me)Val and Z–(*N*-Me)Ala with DCC and it was established that this ion is stable in deuterochloroform at −20 to −5 °C for 3 h.[21]

The formation of 5(4H)-oxazolones on activation of *N*-acylamino acids is explained by base catalysis but in the case of *N*-acyl secondary amino acids acid catalysis of the formation of the mesoionic oxazolone (X) takes place.[65,67,83] Consequently the presence of salts of strong acids and tertiary amines, normally accompanying almost any peptide condensation, is undesirable in the reaction mixture.[3,28] An excess of tertiary amine reduces the racemisation of secondary amino acid residues when using DCC and isobutyl chloroformate as condensing reagents.[3] A stronger base such as triethylamine is more effective than *N*-methylmorpholine.

On treating derivatives of *N*-acyl secondary amino acids with strong acids, such as when decarbobenzoxylating the dipeptide Z–Ala–(*N*-Me)Leu with a solution of 5.6 N hydrobromic acid in acetic acid, significant racemisation takes place and was linked with



acid catalysed enolisation.[82] However the fact that the addition of water in this case sharply reduced the extent of racemisation indicates that in the above case a mesoionic oxazolone was formed in the anhydrous medium and no acid-catalysed enolisation took place.

Racemisation of secondary amino acid derivatives by enolisation may be catalysed both by alkali and by acid and its mechanism is evidently the same as for derivatives of the usual amino acids.[20,83]

It must be noted that the racemisation of derivatives of secondary amino acids rarely proceeds according to one mechanism. Frequently, depending on many factors, it is possible that either the oxazolonium or the enolisation mechanism may predominate.

The factors affecting the mechanism of racemisation include the method of activation, the nature of the substituents in the secondary amino acid residue, the polarity of the solvent used for the condensation, the pH of the medium, etc. Definite rules for this problem have now become apparent.

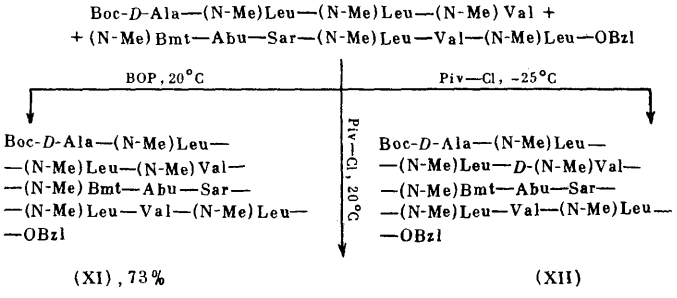
In particular the use of such well known antiracemisation additives as HOBT or HOSu in the activation of *N*-acyl secondary amino acids with DCC suppresses their racemisation by the oxazolonium mechanism.[3,21] HOSu proved to be more effective than HOBT which, while suppressing the formation of the oxazolonium ion, aids racemisation by the enolisation mechanism by being a stabiliser of the enolised form of *N*-alkylamino acid HOBT esters.[21]

In the condensation of Boc–Abu–Sar with (*N*-Me)Leu–Val–(*N*-Me)Leu–Val–(*N*-Me)Leu–Ala–OBzl by the mixed pivalic anhydride method no *C*-α-acylation side reaction, which proceeds through the formation of a mesoionic oxazolone [of the type of (X), see previous section], was observed.[40] The racemisation process in this case, as for DCC activation, is suppressed by an excess of triethylamine more efficiently than by *N*-methylmorpholine. This may serve as indirect confirmation of the fact that the racemisation of secondary amino acids when activated by Piv–Cl is explained by acid catalysed enolisation and not by the formation of an oxazolonium ion.[40]

It has been established that racemisation when using BOP, BOP–Cl and diphenylphosphinic chloride as activating reagents for *N*-acyl secondary amino acids is chiefly explained by the formation of an oxazolonium ion.[2,40]

The addition of HOBT or HOSu when using BOP–Cl has little effect.[84] According to other data HOBT has a weak influence on the suppression of racemisation but HOSu has no effect at all.[2,85] It has been recorded that on cyclising a hexapeptide by activation of an (*N*-Me)Phe residue with BOP–Cl the addition of HOBT increased the racemisation by even twofold.[86]

As in the case of the usual amino acids, urethane protection of an *N*-alkylamino group reliably prevents racemisation of a secondary amino acid.[3,21,22,40] For example, on carrying out the reaction of Boc–(*N*-Me)Leu with (*N*-Me)Val–OBzl using Piv–Cl the product contained no diastereomeric contamination even at 50 °C.[22] Only in cases of the most sterically hindered condensations when the reaction time was huge was a small degree of racemisation observed for a secondary amino acid with urethane protection. For example, the epimerisation of the (*N*-Me)Val residue activated by BOP–Cl in the reaction of Z–(*N*-Me)Val with (*N*-Me)–OBu^t was 4% after 2 d at 20 °C but less than 1% after 4 d at 0 °C.[2]



It was considered previously that the presence of urethane protection prevents racemisation of amino acids by the oxazolone mechanism.[20] It was established more recently that urethane protection may not be a reliable barrier to the formation of 5(4H)-oxazolones. Under certain conditions, for example with an excess of DCC in the reaction mixture, oxazolones are also formed from such amino acids, but they are extremely stable towards the tautomeric conversion which causes the racemisation.[11,87] However the presence of an excess of tertiary amine may in this case lead to marked racemisation.[11]

Racemisation proves to be extremely significant when activating *N*-acyl secondary amino acids by the DCC method if acetyl or benzoyl is used as the acyl group. If the same acyl groups are used on amino acids then racemisation is displayed to a lesser degree.[21]

Among the factors affecting the racemisation of amino acids the so-called asymmetric induction, which has been little considered until recently, may be mentioned.[88,89] This phenomenon explains the high extent of racemisation of *C*-terminal amino acid residues on activation or deblocking when a thermodynamically more favoured epimer is formed in the racemisation process.[22] This process may lead to the preferential formation of a product with reversed configuration, consequently the term 'racemisation' is unsuitable in this case and one should speak of a high degree of epimerisation.

On the other hand asymmetric induction may be caused by the different reactivites of *L* and *D* activated amino acids towards the asymmetric amino component. Thus an *L* isomer is activated, but the *D* isomer reacts more readily, then as a result of epimerisation occurring in parallel with the condensation it is possible to obtain a product containing residues chiefly of the *D* amino acid.[11,89] Occasionally this process leads to the complete inversion of the configuration of the amino acid being introduced.[40]

In certain cases the phenomenon of asymmetric induction may be a very valuable method of synthesis for individual epimers which are difficult to obtain by classical means. Thus when making a protected undecapeptide intermediate in the synthesis of cyclosporin by a 4 + 7 fragment condensation from identical amino and carboxy components, two different pure epimers are obtained depending on the reaction conditions.[40]

Mixture of (XI) and (XII) in a 4:1 ratio

When activating the tetrapeptide fragment with Piv–Cl racemisation of the (*N*-Me)Val residue occurs through the enol and because of the absence of steric constraints for this process the thermodynamically more favoured sequence of *L* and *D* amino acids

is formed. When activating the same tetrapeptide with BOP on oxazolonium ion is formed which due to steric constraints may react only in the *L* form.[40]

The increased tendency of derivatives of secondary amino acids apart from Pro to racemise on alkaline or acid treatment was explained previously by the ease of enolisation of these compounds under the conditions indicated.[82] Facilitated enolisation is linked with the absence of a hydrogen atom on the nitrogen atom or tertiary amides which *N*-acyl secondary amino acids are.

The hydrogen atom of *N*-acyl amino acids is significantly more mobile than a hydrogen atom of a carbon atom. By ionising first, the amide hydrogen atom prevents deprotonation of the hydrocarbon and provides the higher stability of an amino acid towards racemisation compared with secondary amino acids.

Experimental confirmation of the above is provided by the fact that treatment of (*N*-Me)Ile–OMe with alkali gives 1% epimer while Z–(*N*-Me)Ile–OMe having no hydrogen on the nitrogen atom gives 9% epimer under the same conditions. Analogously under alkaline conditions the ionisation of the carboxyl group prevents enol formation, and consequently racemisation, of Z–(*N*-Me)Ile.[82]

It is also reported that the electron-donating effect of the *N*-alkyl group is an additional factor facilitating the enolisation of secondary amino acids. However the enolisation mechanism presented may not explain the high stability towards racemisation of the Pro residue in the dipeptide Boc–Ala–Pro–OMe [less than 0.1% epimer in 1 N sodium hydroxide after 3 h).[82]

There are hints after the enhanced tendency towards racemisation of derivatives of secondary amino acids is impossible to explain fully by the absence of a hydrogen atom on a completely protected nitrogen atom preventing enolisation.[20] In order that this mechanism can be sufficiently justified it would be necessary for more than 90% of the amide groups in a peptide consisting of the usual amino acids to be converted under saponification conditions into the conjugate bases, which is improbable since the p*K* for monosubstituted amides lies in the 14–15 range. Furthermore these mechanisms do not explain the increased racemisation linked with the formation of a mesoionic oxazolone. Since disubstituted amides, which *N*-acyl secondary amino acids are, exist as *cis* and *trans* conformers which are close in energy, and monosubstituted amides have predominantly a *trans* conformation of the amide bond, it has been suggested that the *cis*-conformation existing more readily in *N*-acyl secondary amino acids facilitates the racemisation process.[20] Indirect confirmation of this hypothesis is the known ease of racemisation of residues of secondary amino acids in cyclic dipeptides on treatment with alkali. Both amide bonds in DKP has only the *cis* configuration.[90] It is evident that steric factors make a decisive contribution to the easing of racemisation of derivatives of secondary amino acids.

* *
*

It may be concluded from the material considered above that no single traditional condensation method is able to guarantee success when acylating residues of secondary amino acids with the exception of the easiest cases. Such reagents as diphenyl phosphine chloride, BOP–Cl and Piv–Cl are capable of effecting the most sterically hindered condensations. Recently BOP–Cl has been used most widely for these purposes. In the synthesis of peptides containing secondary amino acids and especially for sequences of several secondary amino acids the risk of obtaining unstable compounds, which may decompose according to a different scheme, is sharply increased. The danger of decomposing such peptides is particularly high in the acidolysis process when removing protecting groups.

The side reaction of DKP formation is extremely acute and in certain cases requires a change in the synthesis strategy for peptides containing secondary amino acids.

The prevention or reduction of the extent of racemisation of secondary amino acid residues during peptide synthesis may be achieved mainly by known methods such as urethane protection or by adding agents to prevent racemisation. However the efficiency of these methods depends strongly on the carboxy and amino components reacting and on the condensing agent used. When using BOP and BOP–Cl the racemisation of secondary amino acid residues is caused mainly by the formation of the oxazolonium ion and when using Piv–Cl by acid catalysed enolisation.

Problems of the chemical physics of heterogeneous catalysis

O V Krylov
Semenov Institute of Chemical Physics, USSR Academy of Sciences

ABSTRACT. A series of fundamental problems of the chemical physics of heterogeneous catalysis are considered: new methods for investigating the mechanism of heterogeneous catalysis making it possible to study the reaction *in situ* with a high degree of time resolution; the dynamics of the elementary step, including energy and electron exchange processes in catalysis; macrodynamics of heterogeneous catalysis, including the formation of dissipative structure; chain mechanisms; heterogeneous-homogeneous catalysis and the role of a multiphase structure in heterogeneous catalysis.

The bibliography includes 245 references.

IV. Macrodynamics of the catalytic process 943

I. Introduction

The advances in the theory of heterogeneous catalysis during the last decade are associated both with the rapid development of new physical research methods and the development of computational-theoretical methods, including quantum chemistry, the qualitative theory of differential equations, etc. The theory of the elementary step, the dynamics of the catalytic process, the organisation and self-organisation of complex catalytic processes, the structure of catalysts, and the structure of active centres can be included among the problems of the chemical physics of heterogeneous catalysis.

The present review deals with the dynamics of heterogeneous catalysis and the methods of study associated with it, i.e. the physical methods which make it possible to determine the rates of various processes directly under catalytic conditions. Problems concerning the structure of catalysts and the structure of active centres, which require special analysis, are not discussed.

The present development of the dynamics of catalysis is characterised by two tendencies.

The first (microscopic) tendency is associated with the transition of studies to the atomic-molecular and further the subatomic level, with the use of the advances in quantum chemistry and in surface science for the elucidation of the mechanism of the elementary step in adsorption and in catalysis, and with account being taken of the electron and energy transfer processes in the elementary step and of the role of individual energy levels in the molecule and in the catalyst in effecting the elementary catalytic step.

The second (macroscopic) tendency presupposes the establishment of the features of a complex catalytic process based on the knowledge of the rates of its constituent elementary reactions, the organisation and self-organisation of catalysis, and the construction of a complex catalyst based on the set of data concerning the optimum catalyst for accelerating a particular stage.

The study of the kinetics and mechansm of a catalytic reaction at a microlevel and a macrolevel makes it possible to solve the problem of choosing an active and selective catalyst for a specified reaction. For this purpose, it is necessary to elucidate the structure of the intermediate surface compound in catalysis and to demonstrate the dependence of the rates of reactions on the rates of formation and consumption of such compounds, to establish the relation between the rate of reaction and the structure and chemical composition of the catalyst and the electronic structure of its constituent atoms, and to investigate the changes in the structure of the catalyst under catalytic conditions and the electron and energy transfer processes. In order to meet these requirements, it is essential to apply on a broad front modern physical methods (X-ray diffraction analysis, electron diffraction, various forms of optical and electronic spectroscopy, and laser beam methods) directly under catalytic conditions (*in situ*).

II. Methods of study

The rapid development of the theory of catalysis is impossible without the development of new methods of study, especially *in situ* (under reaction conditions). Optical (IR, UV) and microwave spectroscopic (EPR) methods for the study of the surfaces of catalysts were applied in the 1950's–1960's. X-Ray and photoelectron spectroscopic methods, low energy electron diffraction, secondary ion mass spectrometry, the method based on the fine structure of X-ray absorption (EXAFS), and a number of other methods were applied in the 1970's–1980's. Automatic apparatus for the testing of catalysts and computer techniques have been rapidly improved. New methods are appearing annually.

Unfortunately in the majority of studies the new research methods are used to compare different properties of the catalyst before or after the reaction—at best under catalytic conditions but in a stationary state. Nevertheless, in order to construct a theory of catalysis, it is essential to perform direct measurements of the duration of the dynamic processes on the surfaces. This can be done with the aid of non-stationary methods: the use of the so-called transient regimes, pulsed influences, abrupt changes in the temperature and pressure of the gas, abrupt alteration of the ratio of the components of the catalytic reaction, etc. It is essential to be able to measure both the rate of the catalytic reaction under non-stationary conditions and the rate of change of the concentrations of the absorbed substances and in the structure and various properties of the catalyst itself under the reaction conditions. These processes have to be investigated over all time scales.

Budar[1] drew attention to the fact that the turnover number of the reaction $n = r/N$ (r is the rate of reaction referred to the number N of active centres on the surface) is in the range from 10^{-2} to 10^{2} s^{-1} for many heterogeneous-catalytic reactions. The characteristic reaction times $\tau = 1/n$ are correspondingly between 10^{2} and 10^{-2} s. For such reaction times and turnover numbers, the reaction products are in fact formed in amounts which can be measured analytically in the usual catalytic experiments. In the analysis of the times taken to achieve various elementary stages of the process, it is therefore necessary to examine in the first place whether they fall within the range from 10^{-2} to 10^{2} s, i.e. whether they can influence significantly the rate of catalysis.

We examined[2] the characteristic times of heterogeneous processes occurring in catalysis. Many elementary processes fall within the time range indicated: adsorption and desorption, the majority of chemical stages on the surface, surface diffusion, phase transitions, and electron capture by the so called slow states. The bulk-phase diffusion in the solid catalyst is in most cases a slower process and its rate influences not so much the rate of the catalytic reaction as a whole as the change in the activity of the solid. On the other hand, the exchange of the energy of atoms and molecules with the surface (translational, vibrational, and rotational relaxation, spontaneous phase transition, and electron capture by the so called fast states on the surface) are as a rule faster processes with characteristic times of $10^{-12}-10^{-6}$ s. The electronic excitations can relax even faster, over a period of $10^{-15}-10^{-13}$ s. However, these short characteristic times must also be known in order to construct a complete dynamic picture of the catalytic process.

The methods for the measurement of the characteristic times of all heterogenous processes important for catalysis, both rapid and slow, have therefore assumed major importance. Naturally, the measurement of short times is a more difficult task.

It is necessary to investigate the dynamics of the changes in both the composition of the gas phase and in the concentration of the surface compounds and in the catalyst structure *in situ*. The jump methods are commonest. For example, after the attainment of a stationary state in a flow system, the pressure of one of the components is diminished abruptly and the variation of the pressures of the reactants and reaction products is investigated. In certain cases, it is possible to reject a particular proposed reaction mechanism. The interaction of an alcohol with an aldehyde on MgO,[3] the oxidation of CO on MnO_2 and Cr_2O_3,[4] and the decomposition of HCOOH on ZnO and metals[5] have been studied by this method. The characteristic times amounted to minutes and tens of minutes in the above investigations.

The minimum characteristic times which can be measured using the kinetic flow regime combined with chromatographic analysis are $10-10^{3}$ s. Using cold traps, it is possible to shorten this range somewhat. The pulse type of kinetic study using a katharometer for gas analysis makes it possible to measure times in the range $1-0.1$ s, while without the resolution of peaks in experiments using a katharometer or a flame-ionisation detector it is possible to attain also 10^{-2} s. Mass spectrometric analysis permits the measurement of even shorter times ($0.1-1$ s) in the flow regime at atmospheric pressure and $10^{-3}-10^{-4}$ s in the flow vacuum version.

Further shortening of the measurable characteristic times is limited by the distance from the surface of the catalyst to the sampling site. Unique procedures have been developed for the removal of samples at short distances from the catalyst (less than 1 mm).[6] It has been possible to improve the time resolution to $<10^{-3}$ s. Gleaves et al.[6] called their method the time analysis of products (TAP). The rates of adsorption, desorption, and intracrystal diffusion of acrolein during the oxidation of C_3H_6 on bismuth molybdate and the mechanism of the activation of the reactants in the oxidation of ethylene on silver, in the oxidation of butane on $(VO)_2P_2O_7$, and in the oxidative ammonolysis of methanol on $Mn_2P_2O_7$ were investigated by the TAP method.

In order to understand the mechanism, it is essential to determine simultaneously the composition of the gas phase and the spectroscopic characteristics under the conditions of non-stationary catalysis. Tamaru[7] was one of the first to investigate the rates of reaction of surface compounds on oxide catalysts by IR spectroscopy. Together with the investigation of the dependence of the rate of reaction under stationary conditions on the concentration of a particular surface form, the response of the system to rapid changes in the reaction conditions, for example, the alteration of the isotopic composition of one of the reactants or a change in temperature or pressure, was analysed. Investigators have called this procedure the dynamic approach to the study of chemisorption states.

A set of physical methods for the study of catalysis *in situ* has been developed at the Institute of Chemical Physics of the USSR Academy of Sciences.[8] Catalytic reactors which serve simultaneously as cells for IR, UV, and Raman spectroscopy, as cameras for the study of the X-ray structure, as tubes for EPR measurements, and as cells for the Mössbauer spectrometer were devised. The mechanisms of the interaction of NO with CO on metals,[9] of the oxidation of NH_3 on metals and oxides,[10] and of the partial oxidation of isobutene on complex oxides[11] were investigated with the aid of IR spectroscopy. Raman spectroscopy was applied *in situ* to the study of the high-temperature oxidative condensation of methane on alkaline earth and lanthanide oxides.[12] A new method, namely the spectroscopy of surface electromagnetic waves,[13] has been used to study the oxidation of methane on the same catalysts at a lower temperature. The changes in phase composition in the catalyst on partial oxidation of propene on the Bi–Co–Fe–Mo–O catalyst and in the Fischer–Tropsch synthesis on iron catalysts were studied by X-ray phase analysis and by Mössbauer spectroscopy *in situ*.[14,15] The oxidation of allyl alcohol to acrolein on the V–Mo–O_3 catalyst was investigated by EPR.[16]

In all the studies listed above, the process kinetics were analysed from the change in the intensity of one line in the spectrum (or on the X-ray diffraction pattern). The kinetics of the change in the composition of the gas phase were investigated simultaneously by gas chromatography. This did not ensure satisfactory time resolutions, the measured characteristic times amounting to several seconds and more. The application of mass spectrometric analysis of the gas phase helped to shorten the measured characteristic times.

In the study of reactions of surface compounds alone without the analysis of the gas phase, it is possible to measure also shorter times. The commonest method for the study of surface compounds is IR spectroscopy. It ensures a high resolution with respect to energy and can be used at any pressure of the gas phase. However, the existing versions of IR spectroscopy do not permit the attainment of a time resolution better than to within 1 min.[17] For example, when the FTIR method (Fourier transform IR spectroscopy) was used to study surface compounds in the autooscillatory process involving the oxidation of CO on platinum, the resolution was to within 1 min.

New versions of IR spectroscopy ensure a higher sensitivity, a better time resolution, and in many instances also a better spectroscopic resolution. For example, using the IRAR method (infrared absorption reflection) and sensitive detectors, it has been

possible to increase the sensitivity of the measurement to within 10^{13} cm^{-2} or 0.01 of a monolayer of adsorbed molecules on the face of a single crystal.[19] The method of emission IR spectroscopy permits the investigation with a high sensitivity of catalytic reactions at a high temperature,[10] while diffuse reflectance IR spectroscopy increases significantly the possibility of detecting surface compounds in the spectral range 2000–4000 cm^{-1}.[20] The spectra obtained by the method of surface electromagnetic waves (SEW) exhibit an unusually high spectra resolution especially if one uses powerful light sources such as lasers.[13] According to Shafranovskii, et al.,[21] the SEW method is at least four times more sensitive than the IRAR method.

A disadvantage of the electronic and photoelectron spectroscopic methods, whose sensitivity is extremely high and which give rise to an extremely good time resolution, is the impossibility of using them at high pressures. The kinetics of reactions on the faces of single crystals were investigated by X-ray photoelectron spectroscopy (XPES) and measurements were made of the changes in the concentrations of surface compounds. The kinetics of the oxidation of NH_3 on platinum were investigated[22] on the basis of the Auger spectra of the adsorbed oxygen. The oxidation of hydrogen on platinum has also been studied by Auger spectroscopy. It proceeds via the formation of surface OH groups.[23] The measured characteristic times of surface processes in the above studies exceeded 1 s.

The application of vibrational LEES (low energy electron scattering) spectroscopy, which is highly sensitive, ensures a satisfactory time resolution and the possibility of measuring the vibrational spectra of isotopically-substituted molecules, to the study of surface reactions is developing rapidly. The disadvantages of the method are a low spectra resolution (compared with IR spectroscopy), a non-linear dependence of the line intensities on concentration, and, what is most important, the necessity to carry out measurements under vacuum conditions. The kinetics of the $C_6H_6 + D_2$ deuterium exchange on Pt(111) were investigated by this method.[24] At 314–346 K, the characteristic process time was 30–120 min and the resolution was to within ~5 min.

The application of multichannel detectors appreciably increases the sensitivity of the LEES method and hence the time resolution. In the study of the decomposition of N_2O on Si(110) by the LEES method, a time resolution of 5 ms was attained.[25] Similar resolutions were achieved in the study of the adsorption and desorption of CO on Ni(110), Rh(100), and Cu(100), the dissociation of NO on Rh(100), the decomposition of CH_3OH on Ni(100) and Fe(100), and the oxidation of hydrogen on Rh(100).[17] In the adsorption of CO on Ni(111), the resolution was improved as far as 20 μs.[26] The use of electron pulses makes it possible to reduce the resolution time to 1 μs. Owing to the disadvantages of the LEES method mentioned above, there has been a marked diminution of its application in very recent times in the study of the kinetics of reactions of surface compounds, the procedure being replaced by optical methods.

The measurement of even shorter times involves the use of laser techniques. By virtue of the high monochromaticity and high power of the laser radiation one can (1) ensure the independent excitation of various vibrations of the reactant molecules in order to drive the reaction in the required direction, (2) one can detect with a high degree of sensitivity and indentify the reaction intermediates and the energy state of the molecule in the gas phase can be determined with respect to all degrees of freedom—translational, rotational, and vibrational, and (3) the lifetime of the excited states on the surface can be determined.[27]

The laser spectroscopy of species in the gas phase, which has been rapidly developing in recent years, has been used in particular for the determination of the degree of excitation to various energy levels of the desorbed molecules.[28–30] For this purpose, the laser beam is passed in the immediate vicinity of the catalyst. Among the methods employed, we may mention the intracavity laser spectroscopy (ICLS),[31] which is characterised by a sensitivity of 10^8-10^{10} cm^{-3} and a time resolution of 10^{-6} s, laser magnetic resonance (LMR)[32] with a sensitivity of 10^8-10^{10} cm^{-3} and a time resolution of $10^{-2}-10^{-1}$ s, and laser-induced fluorescence (LIF)[33] with a sensitivity of 10^6-10^{10} cm^{-3} and a time resolution of $10^{-8}-10^{-9}$ s. The multiphoton ionisation (MPI) method exhibits the greatest sensitivity (10^3 cm^{-3}) and is most general.[34] Its time resolution is $10^{-8}-10^{-9}$ s and its spectra resolution is 10^{-3} cm^{-1}. The MPI method has been used successfuly to investigate the quantum state of the desorbed molecules.[35,36]

Other laser techniques—coherent anti-Stokes Raman spectroscopy (CARS),[37] opto-acoustic spectroscopy,[31] multiphoton excitation,[38] and high-resolution sub-Doppler laser spectroscopy[39]—still await their application in the study of the quantum kinetics in gas–solid systems. The electron beam-induced fluorescence (EBIF) method, which provides information about electronically excited states, has been used to investigate the desorption of the N_2 molecule.[40] The IR luminescence method involving the application of a Fourier spectrometer, i.e. the emission of radiation characteristic of excited states, has been employed[41] to identify the vibrational and rotational states of CO_2 as the product of the oxidation of CO on platinum. The time resolution of the method is 10^{-6} s.

Laser methods have been used more rarely for the determination of the kinetic constants of surface processes. The laser-stimulated desorption (LSD) method[42] made it possible to determine the constants for a series of catalytic reactions which are difficult to determine by other procedures. In principle it is possible to attain a picosecond (10^{-12} s) time resolution with the aid of the LSD method.[17]

In order to determine the true lifetime of the ultrashort-lived excited state on the surface, the pulsed picosecond laser technique has begun to be used recently. The specimen is usually irradiated by a laser pulse (for example, a pulse from the neodymium laser) lasting several picoseconds and is probed by the laser before, during, and after the laser flash. The lifetimes of the vibrationally excited states of the OH groups on a series of adsorbents[43,44] and of the CO group in the adsorption of CO on metals and complexes[45] have been measured by this (direct) method. It proved to be $10^{-10}-10^{-11}$ s.

The lifetimes of the electronically-excited states on the surface, measured with the aid of laser picosecond photoelectron spectroscopy (LPS),[46] are about 70 ps. There are as yet very few data on the lifetimes of the electronically excited states and they all lie within a very broad range—from 10^{-5} to 10^{-15} s.[28]

A new method for the study of surfaces has appeared recently—the spectroscopy of second harmonic generation of laser radiation (SGSLR).[47–50] When the pulse technique and a photon counter were employed, unique time resolution, amounting to 100 femtoseconds (10^{-13} s), was achieved, i.e. a time of the order of magnitude of the period of a single vibration. The exceptional sensitivity of the SGSLR method is due to the fact that it makes it possible to measure forbidden transitions in a centrosymmetrical system. Within the bulk of a solid, such symmetry predominates, whilst on the surface it is usually disturbed and the restrictions on

the manifestation of the signal are eased. The kinetics of the adsorption of O_2 on Rh(111)[51] and on Si(111),[52] the kinetics of the dehydrogenation of benzene,[53] etc. have been investigated by the SSGLR method. In the study of two-dimensional phase transitions on the Si(111) face, it was found that, as a result of the exposure of the Si(111) surface to laser radiation, the (7 × 7) structure disappears over a period shorter than 150 fs. During this period, the evaporation of atoms cannot take place: it is easy to calculate that the Si atom ejected at a thermal velocity travels only 0.1 nm during this period. The authors[54] justifiably assume that during such a short period only electronic excitation takes place in the forbidden gap of silicon and that Si atoms move slightly away from the ordered positions. In 1989 yet another short wave femtosecond range began to be used in spectroscopy and a resolution as far as 10^{-14} s was achieved. This makes it possible to investigate the properties of the transition state (activated complex) not by calculation but by means of direct measurements. It is difficult to overestimate the importance of transition state spectroscopy for chemical kinetics and catalysis. Although very simple reactions of the type[55]

$$IHg+I^{\bullet}\rightarrow I+HgI^{\bullet},$$

were investigated in the first studies, there are no fundamental obstacles to extention of this method also to complex, including heterogeneous-catalytic, processes.

The rate of transport of current carriers in a semiconductor has been investigated with the aid of laser pulses lasting 6 fs.[56] Laser pulses having an energy of 2 eV and a duration of 200 fs have been used to desorb NO from the Pd(111) face. Translationally and vibrationally excited NO molecules are desorbed. On the other hand, on exposure to nanosecond pulses, unexcited NO molecules are desorbed.[57]

The rates of phase transformations on the surface and in the bulk phase during adsorption and catalysis can be investigated by dynamic structural methods *in situ*. Numerous studies on the structures of two-dimensional phases of adsorbates and adsorbent surfaces have been performed by the slow electron diffraction (SED) method. This method was also used for kinetic purposes[58] and it is then referred to as dynamic SED or video-SED. In the study of the oxidation of CO on Pt(100) by the video-SED method, the movement of diffraction waves on the surface for a constant interconversion of the Co(1 × 1) and CO(*hex*) structures and diffusion of CO between the phases was observed. The time resolution of video-SED method is about 1 s.

Approximately the same time resolution is attained also when scanning tunnel microscopy (STM) is employed.[59–67] This new very highly sensitive method makes it possible to obtain a direct image of the surface atoms with a spatial resolution less than 0.1 nm, i.e. not only at the atomic but also at a subatomic level. The STM method provides a very detailed photographic picture of chemisorption. The high degree of localisation of the method is to some extent a disadvantage, since the minute details of the region investigated thus revealed are difficult to relate to real atoms and surface orbitals.[66] There are no fundamental reasons to prevent the application of electron microscopy *in situ* to investigate catalysts under a controlled atmosphere.[66] The adsorption of H_2 on Si, of S on Re(001),[62] of O_2 on GaAs,[63] and of NH_3 on Si(111)[65] were investigated by the STM method.

In the method based on the extended fine structure of X-ray absorption (EXAFS), a powerful source of X-rays, usually a synchrotron source, with an energy of 1–25 keV is used. With the aid of these X-rays, the fluorescence or emission of Auger electrons is excited, this being accompanied by the formation of holes in deep levels. The EXAFS method reflects fairly accurately the local structure of the surface and makes it possible to measure the distances between the atoms of the adsorbate and the surface or between the surface atoms. The usual time resolution in the EXAFS method is 10^{-6} s. New highly intense sources of soft X-rays (0.1–3 keV) make it possible to obtain nanosecond (10^{-9} s) pulses. Numerous studies on catalysts and their genesis have been carried out with the aid fo the EXAFS method.[68] The application of the method to the study of the real dynamics of a catalytic process is so far in its initial stage[69] and will undoubtedly expand. In one of the latest studies,[70] the spectra of the Pt/Al_2O_3 catalyst were investigated under the conditions of the reforming of hydrocarbons at 20 atm and 400 °C.

Various physical methods have been applied to investigate the changes in the bulk-phase structure of the catalyst during the catalytic process. We have already mentioned the use of the Mössbauer effect for the analysis of the phase composition of the catalyst *in situ*. In the instruments used hitherto,[14] the power of the γ-radiation sources was low and the measurement of a satisfactory spectrum required a long time, which was necessary to accumulate data. For this reason, only very long characteristic times, of the order of minutes and tens of minutes, can be measured by this method.

In many cases the phase transformations of the catalyst take place relatively slowly and determine not so much the rate of the catalytic step proper as the rate of deactivation or activation, i.e. processes involving the formation and ageing of the catalyst. The diffusion of oxygen from the surface into the bulk of the oxide catalyst and back again can be the rate-determining stage of the catalysis proper in oxidation-reduction reactions. This has been demonstrated by the EPR method *in situ* in relation to oxidation reactions on $V-MoO_3$ catalysts.[16] The measured characteristic times are in the range 1–10 s.

The first studies on the application of NMR spectroscopy *in situ* to the investigation of the structure of a catalyst and its changes have been published.[71,72]

Spontaneous phase transitions can occur as a result of the shift of the lattice by fractions of interatomic distances, in which the diffusion of species in the solid plays a subsidiary role. The formation of nuclei and growth of crystals do not take place. A method of measurement of the highest rates of phase transitions has been developed.[73] Using a pulse source of X-rays with a current of tens of kiloamperes, the authors investigated the structural transformations occurring under the influence of a shock wave. In each experiment, the apparatus was completely disrupted. The minimum measurement time was 10^{-8} s and the transformation was completed over a period shorter than 1 μs. The conversion of α-cobalt into another modification was achieved over a period of 2×10^{-8} s. Thus in spontaneous transformations the rearrangement of the entire lattice can be completed over an unusually short time. For this reason, the further development of the X-ray phase analysis (XPA) method requires the development of powerful sources of X-rays and sensitive detectors. The use of synchroton radiation ("X-ray cinema") is promising.

The molecular beam method occupies a special place in studies of the dynamics of the interaction of molecules with surfaces and of the exchange of energy between the molecules and the surface in order to elucidate the elementary stages in chemisorption and catalysis.[28,74,75] A stream of reactant molecules emitted from a high-pressure

chamber via a small aperture into a vacuum chamber strikes a target (the catalyst). In the beam, the collisions of molecules with one another or with the wall are impossible. Diffusional limitations are also excluded. With the aid of the molecular beam method, it is possible to determine (1) the minimum lifetime of the reactant molecule on the surface required for the occurrence of the reaction, (2) the probability of the reaction in a single collision with the surface, (3) the dependence of the rate of reaction on the energy of the molecules in the beam and on the surface temperature, (4) the distribution of the energy (translational, vibrational, and rotational) between the surface, reactant, and the reaction products, (5) the dependence of the rate of reaction on the surface coverage by measured amounts of the adsorbent, (6) the probability of the deactivation of the excited molecules, and (7) the angular distribution of the desorbed and scattered molecules.

The energy of the molecules in the beam is determined by the design of the source. In thermal Knudsen sources, the gas is maintained at a temperature between 77 and 3000 K. These sources yield beams having an atomic flux density of $(2-4) \times 10^{14}$ s^{-1} cm^{-2} and energies from 0.008 to 0.32 eV. The temperature of the beam is frequently also referred to. However, the estimation of the energy of the molecules in the beam in degrees Kelvin is useful only in the case of a Maxwell–Boltzmann distribution.

The application of an ultrasonic beam makes it possible to narrow the distribution with respect to velocity by a factor of 100 compared with the Maxwell distribution in thermal sources. Despite the high density, the molecules in the ultrasonic beam travel parallel to one another and do not collide. By applying a high pressure (>0.1 MPa), it is possible to attain flux densities of $10^{16}-10^{18}$ s^{-1} cm^{-2} for energies of 1–2 eV. By diluting heavy gases with light ones, which move rapidly, for example, helium, it is possible to raise the kinetic energy to 10 eV. By combining the heating of the molecules in the source with ultrasonic flow, it is possible to obtain molecular beams with equal translational and vibrational energies. If a low pressure of a neutral gas is established in the space between the source and the target, it is possible to preserve the vibrational excitation in the molecules having quenched the translational excitation.

The method of modulated molecular beams for the relaxation spectroscopy of molecular beams (RSMB) is used to investigate the kinetics of heterogeneous-catalytic reactions. The interruption of the beam and the application of pulses of the reactants to the target-catalyst greatly increases the signal/noise ratio. The method makes it possible to measure characteristic times up to 10^{-4} s.

The method of molecular beams has found an interesting application in the investigation of real catalytic reactions at a high pressure.[76] The reaction is studied on the face of a single crystal cleaned in an ultrahigh vacuum. After the reaction, the pressure is rapidly reduced and the face of the single crystal is exposed to the molecular beam. Attempts have also been made to obtain high-density molecular beams simulating a high pressure.

Together with the molecular beam method, the method of ion beams has also been developing.[27,77] The theory shows that ion beams are rapidly neutralised on interaction with the surfaces of metals, forming neutral molecules in a vibrationally or electronically excited state. Thus experiments with ion beams can yield information about the interaction with the surfaces of solids of neutral molecules in the ground or weakly excited states, which corresponds approximately to the information obtained by the method of molecular beams. One of the simple ways of studying the interaction of atomic and molecular ions with the surface involves the acceleration of the ions by means of ionic cyclotron resonance.[78]

In our analysis of the research methods listed above, we drew attention mainly to their dynamic and kinetic applications and their time resolution. However, many of the methods being developed are designed primarily for the determination of the structures of catalysts, the structures of the surface and the active centres, and their energy levels.

III. Dynamics of the elementary step in catalysis

Over a long period, the rates of the elementary processes on the surface have come to be estimated from the standpoint of the transition state theory proposed in the 1930's. In this theory, the real dynamics of the motion of nuclei is not considered and account is taken only of the fundamental characteristics of the potential energy surface for the system and of the thermodynamic equilibrium between the reactants and the transition state (activated complex) at the apex of the potential barrier. The ranges of values of the pre-exponential factor k_0 in the Arrhenius equation for different surface processes have been calculated.[79–81]

Very fine experiments are needed for the determination of the exact values of k_0 and clearly there are not enough such experiments. Furthermore, it has been stated recently in a number of instances that transition state theory is inadequate and is subject to limitations when applied to the processes on surfaces: the tunnelling of nuclei at low temperatures, the possibility of a non-adiabatic course of the reaction, and the need to introduce corrections associated with non-equilibrium effects.[81] For example, in adsorption kinetics the factor k_0 is only partly determined by the laws of equilibrium thermodynamics; its other component (the sticking coefficient) is determined by local non-equilibrium effects.[66] The sticking coefficient is usually much smaller than unity.

The non-equilibrium effects in adsorption and catalysis have been examined in a monograph.[28] Several questions have been posed.

1. Are excited molecules formed in exothermic processes on the surface?
2. What is the lifetime of excited molecules on the surface?
3. What is their reactivity?
4. Is the concentration of the active centres related to the characteristics of the mechanism of catalytic reaction?
5. What is the lifetime of the excited states of the solid catalyst?

An accurate answer to the majority of the questions formulated requires a detailed knowledge of the dynamics of the elementary step. In particular, it is necessary to have detailed information about the potential energy surface. Calculations on the dynamics of the interaction have encountered considerable difficulties and can be performed only in the simplest cases. For example, a simplified trajectory method has been used[82] to describe the interaction of NO with the Pt(111) surface. The calculation, in which account was taken of 19 surface platinum atoms, made it possible to find the dependence of the rotational excitation of the desorbed NO molecules on the initial velocity of the molecules incident on the platinum surface. The majority of the answers to the questions posed above have been obtained experimentally.

The most important result of experiments carried out by the molecular beam method is the frequently observed extremely narrow angular distribution of the scattered molecules. The same thing frequently happens in the desorption of the molecules formed in the catalytic reaction. Thus analysis of the angular distribution of the

CO_2 molecules formed in the reaction of the adsorbed CO and O molecules on platinum showed that the intensity varies in accordance with the $\cos^n\varphi$ law, where $n = 6-40$.[83] The very narrow distribution of the desorbed or scattered molecules indicates their translational excitation.

Three reactions have been investigated on platinum by the thermal desorption method:[84,85]

$$N_2O+CO\rightarrow N_2+CO_2,$$
$$2NO\rightarrow N_2+O_2,$$
$$C_{ads}+O_{ads}\rightarrow CO_g.$$

In all three cases, a narrow angular distribution of the reaction products was observed, i.e. they were translationally excited. It is of interest to note that, after the adsorption of the CO molecules on platinum and the subsequent desorption, the angular distribution obeyed the $\cos\varphi$ law, which corresponds to complete thermal accommodation. Evidently the CO molecules desorbed after the equilibrium adsorption and those formed in the C + O reaction on the surface have different structures. In the second case, the CO molecule is not at the bottom of the potential well before escaping into the gas phase. This suggests the need to revise a series of mechanisms of heterogeneous catalysis according to which the reaction proceeds via adsorption interaction on the surface and desorption. Cases in which the reaction of a molecule continues also after its escape from the surface into the gas phase are apparently possible in catalysis.

The application of modern detection methods has made it possible to record the variation of the vibrational and rotational energies of the scattered and desorbed molecules. It was found that in many exothermic catalytic reactions vibrationally excited molecules are formed on the surface. Such reactions include the recombination of H atoms on copper,[86] the oxidation of CO on platinum and palladium,[87,88] the oxidation of carbon on copper,[89] the oxidation of H_2 on platinum,[90] etc. This indicates the energy of the catalytic reaction can be utilised for its possible acceleration.

The formation of vibrationally excited species in the endothermic NH_3 decomposition reaction on platinum has been observed.[91] On excitation of certain N_2 molecules, the 9th vibrational level proved to be occupied (energy of 2.4 eV). When the mechanism of this reaction was considered, only one exothermic stage was discovered:

$$NH_{ads}+NH_{ads}\rightarrow N_2^*+2H_{ads}+2.4\text{ eV}.$$

This may excite the molecule to the 9th vibrational level.

The phenomena involving the "cooling" of the molecule after catalytic reaction were also observed. The formation of translationally cold molecules with a temperature below the surface temperature after the $D_2 + O_2$ reaction on platinum was explained by the fact that the rate of desorption exceeds the rate of the thermal excitation of the reaction product (D_2O) adsorbed on the surface.[92] "Rotational cooling", i.e. a decrease in the "rotational temperature" of the molecules compared with the surface temperature, is frequently observed in the adsorption and desorption of NO on platinum,[93] nickel,[94] and palladium[95] and in the oxidation of NH_3 to NO on germanium.[96] The "rotational cooling" can be explained by the transfer of the energy of the rotation of the NO molecule before desorption to the translational energy on desorption. The interesting phenomenon of the different probabilities of the adsorption of NO from molecular beams oriented with the N or O atoms pointing towards the surface has been investigated.[97]

The explanation of the observed relations is in its initial stage. With the aid of trajectory calculations, attempts have been made[98] to relate the excitation of the molecules on desorption to the characteristics of the potential energy surface. In the thermal desorption of H_2 from Ni(111), one of the observed peaks corresponds to the predominantly vibrational excitation of the desorbed molecule, while the other corresponds to the predominantly translational excitation. In the former case (surface coverage $\theta > 0.5$), the desorption process is limited by the passage of the molecules through the "inlet" potential barrier, while in the latter case ($\theta < 0.5$) it is limited by their passage through the "outlet" potential barrier. Calculations of a similar kind have shown which part of the energy of adsorption and catalysis is transmitted to the surface and consumed on heating the latter and which is distributed in the form of the translational, vibrational, and rotational energies of the reaction product.[99]

On recombination of the N atoms on metals, electronically excited nitrogen molecules were detected.[100,101] The formation of singlet oxygen O_2 ($^1\Delta_g$) was observed in the oxidative dehydrogenation of butane on the Li–Sn–P oxide catalyst.[102]

Thus the formation of excited molecules in catalysis is an established experimental fact. The task for the immediate future is to find the general rules governing this phenomenon and to discover the relation between the formation of excited molecules and the characteristic features of the mechanism of the elementary step.

If during catalysis and desorption excited molecules are formed in conformity with the detailed equilibrium principle, it is to be expected that the excitation of the molecules reacting on the surface will also influence their reactivity. This phenomenon has been investigated in a number of studies on molecular beams.

In a large number of investigations of the interaction of molecular beams having different energies with the surface, a change in the probability of adsorption was observed as a function of the kinetic energy of the molecules in the beam (see, for example, the studies on the adsorption of H_2 on palladium[103] and nickel,[104] of N_2 on tungsten,[105] of O_2 on platinum,[106] etc.). The sticking coefficient s_0 usually increased with increase of the kinetic energy E_i of the molecules in the beam (the usual range is $E_i \simeq 0.5-10$ eV). The sharp changes in this relation for certain values of E_i are usually explained by the existence of an activation barrier to adsorption, while smoother relations are accounted for by the non-uniformity of the surface, i.e. the distribution of the activation barrier with respect to energy.

However, for very low energies of the beam, for example in the adsorption of O_2 on W(100) for $E_i < 0.03$ eV,[106] s_0 diminishes and does not increase with increasing energy. In this case the dependence of s_0 on the surface temperature T_s is much more marked than the dependence of s_0 on T_i. This can be explained by the occurrence not of direct adsorption but of adsorption via a precursor—a presorption state. Before passing to the chemisorbed state, the molecule can exist for a certain time in a weakly bound presorption state and can migrate in this state along the surface. The concept of a precursor and of its role in chemisorption was first put forward by Langmuir and its role in catalysis was examined in detail as early as the 1930's by Roginskii and Zel'dovich.[107] Prolonged debates concerning the question whether the presorption state is a "myth or reality"[106] were terminated, as a result of experiments with molecular beams, by an unambiguous answer: the precursor is real. Controversy continues concerning the nature of the presorption state: some workers believe that it is a physically

adsorbed molecule while others postulate that it is a short-lived excited state. It may be that both cases occur.

Whereas experiments with beams having differing energies have demonstrated incontrovertibly the influence of the translational energy on activated chemisorption, the available data on the translational excitation are fairly contradictory and do not permit a final conclusion. The appreciable increase in the probability of the dissociative adsorption of CO_2 ($\rightarrow CO + O$) on Ni(100) when CO_2 molecules are heated in a source of an ultrasonic beam has been attributed[108] to the involvement of the vibrationally excited molecules in the adsorption process. According to the authors,[108] distorted (bent) CO_2 molecules participate in the dissociation $CO_2 \rightarrow CO + O$.

Controversy concerning the mechanism of the activation of methane and other paraffins in their interaction with metals has continued for a long time. The large isotope effect, observed in the dissociative adsorption of CH_4 and CD_4 on rhodium, has been explained by the translational excitation of these molecules on passing from the presorption state to the chemisorbed state.[109] The subsequent data were fairly contradictory. Lo and Ehrlich,[110] who investigated the adsorption of CH_4 on W(211), adhere to their previous standpoint,[109] i.e. they explain the activation of CH_4 by vibrational excitation. On the other hand, it is believed that the activation of CH_4 on W(110) is caused by translational excitation with subsequent tunnelling of the H atom on chemisorption.[111] The dependence of the sticking coefficients s_0 of methane, ethane, propane, and butane on Ir(110) on the molecular beam energy has been attributed to the direct translational activation of the molecules colliding with the surface.[112] A deficiency of the above studies has been the lack of accurate data concerning the distribution of energy between different levels in the initial molecules.

Direct selective excitation of one of the bonds in the molecule by a laser makes it possible, in principle, to obtain molecules in a definite vibrational state and thus to achieve selective catalysis. The number of studies in this field is extremely large (see the relevant reviews[113–115]), but the results are not so far convincing. Most experiments have been carried out using irradiation by the IR CO_2 laser of various adsorbed compounds with light corresponding to an absorption band of the OH vibrations. The observed desorption was explained by the selective excitation of the bonds in the adsorbed molecule. However, as noted by Chuang,[116] in reality this explanation is doubtful, since there is no clear-cut dependence of the yield on the vibration frequency. The "translational temperature" of the desorbed molecules is usually low and close to T_s. These phenomena have been explained by "indirect" or "resonance" heating.[117] Phonons are emitted from the intermediate vibrational excitation levels, which leads to the heating of the specimen.

These considerations apply also to various data concerning the effect of the laser on catalytic reactions. The reported[118] acceleration of the oxidation of NH_3 on platinum following exposure to the light from a laser at a frequency of 933 cm^{-1} (vibrations of the N–H bond) was not confirmed in a subsequent test.[28]

More definite positive results have been obtained in the study of the electronic excitation of a solid and of adsorbed molecules by laser radiation in the visible and UV ranges. Thus the desorption of oxygen in the form of O_2 and O from the ZnO surface has been observed on exposure to laser light at the frequency corresponding to the forbidden gap in ZnO (λ = 354 nm).[119]

The use of short ($< 10^{-8}$ s) low-power laser pulses and the study of the process at a low temperature are most promising. By applying very short nanosecond (5 ns) laser pulses with a very low power (0.1–1 mW cm^{-2}), with an energy of 4.6–5.3 eV, Natzle, et al.[120] observed the selective desorption of NO from the Ag(111) surface at a low temperature (25–50 K).

The problem of direct detection of vibrationally excited molecules on the surface in chemisorption and catalysis has not so far been solved. Infrared adsorboluminescence might be used as a direct method for their detection. However, experiments and calculations have shown that, during the period taken by adsorption, the molecules have sufficient time to be virtually completely thermalised and the observed glow is simply a result of the heating of the specimen due to the heat of adsorption.[28] An IR laser has been used[121] for the vibrational excitation of physically adsorbed layers of CO on NaCl(100) at 22 K. The infrared adsorboluminescence observed subsequently was characterised by lifetimes of 2–12 μs.

The lifetimes of excited chemisorbed species on the surface have been measured directly in only one group of studies.[43,44] The lifetimes were calculated from the fluorescence decay time by means of the pulse excitation with a laser of the local vibration of the adsorbed molecule. In a number of studies, the lifetime of the vibrationally excited molecules on the surface was also determined by an indirect procedure—from the width of the lines in the IR spectra. For example, the experimental width of the absorption band of CO on Ni(100) and Ni(111), namely $\Delta\nu$ = 10 cm^{-1}, corresponds to the two-phonon breakdown of the C–O vibrations predicted by the theory.[122] The determination of the vibrational relaxation times from SEW spectra has been examined.[123]

Although the measured lifetimes of the vibrationally excited states are fairly short ($\sim 10^{-10}$ s), the excited species presumably participate in catalytic processes.

As regards the stages of the chemical interaction proper in a catalytic reaction, it is usual to distinguish two extreme cases; the Langmuir–Hinshelwood (OH) or surface interaction mechanism and the Eley–Rideal (ER) or impact mechanism. In the former case, the reaction proceeds between the species of two chemisorbed substances, while in the latter it occurs between a chemisorbed species and a species from the gas phase. The oxidation of CO on platinum and palladium has been investigated in greatest detail.[81,124] If the LH mechanism is valid, the elementary stage is the reaction

$$CO_{ads} + O_{ads} \rightarrow CO_2$$

while in the case where the impact (ER) mechanism operates the elementary stage is the reaction

$$O_{ads} + CO_g \rightarrow CO_2$$

or

$$CO_{ads} + O_{2g} \rightarrow CO_2 + O_{ads}.$$

Strictly speaking, both names are incorrect. In reality both the impact and surface mechanisms had been proposed by Langmuir.

The study of the oxidation of CO on Pt(111) by the relaxation spectroscopy of molecular beams[125] showed that the LH mechanism is valid. When CO molecules were admitted onto the Pt(111) surface coated by adsorbed oxygen, an arrest in the release of CO molecules was observed ($< 6 \times 10^{-4}$ s). The lifetime τ of CO molecules on the surface depends not only on the rate of the surface reaction but also on the rate of desorption of CO. On the other hand, when the ER mechanism operates, there should be no arrest and $\tau = 0$. In certain cases, the ER mechanism apparently also operates in a pure

form. Examples of the translational activation of molecules in dissociative reactions following direct impact against the surface (in the presence of the necessary activation energy) were quoted above. Catalytic reactions involving methane proceed as a result of the direct activation of the CH_4 on impact against the surface:[126]

$$CH_4 \rightarrow CH_3 + H_{ads}$$

In reality the LH and ER mechanisms represent certain limiting cases. In the intermediate (and probably the common) version, chemisorbed molecules and mobile weakly adsorbed species in the presorption state (see above) participate in the reaction.

In the oxidation of H_2 on metal single crystals,[127,128] several surface stages were observed:

$$O_{ads} + H_{ads} \rightarrow OH_{ads},$$

$$OH_{ads} + H_{ads} \rightarrow H_2O.$$

The rate of reaction depends on the surface coverage. The repulsive interaction between neighbouring like species exerts the greatest influence. Such interaction has been examined from the standpoint of the lattice gas theory.[81]

Yet another type of elementary process on the surface has been examined.[129,130] In the dehydrogenation of cyclohexane on platinum,[131] the adsorbed labelled benzene readily exchanges with cyclohexane in the gas phase so that labelled benzene is evolved into the gas phase:

$$Pt \cdot {}^{14}C_6H_6 + C_6H_{12} = Pt{:}C_6H_{12} + {}^{14}C_6H_6.$$

A similar exchange of an alcohol with the Al_2O_3 surface hydroxyl has been observed for the dehydration of the alcohol on Al_2O_3:[129]

$$(OH)_{surf} + ROH \rightleftarrows (OHROH)_{surf} \rightleftarrows (OR)_{surf} + H_2O.$$

Thus the dehydration of the alcohol involves adsorption substitution. According to an estimate,[129] the rate of the associative desorption exceeds by many orders of magnitude the rate of the direct desorption (for example, the evolution of water on dehydration of a surface OH group).

An associative complex has been detected by the direct IR spectroscopic method *in situ* in a study of the selective oxidation of isobutene to methylacrolein on a complex oxide catalyst.[11] It has been demonstrated[132] that associative substitution processes and, in a more general form, reactions involving strongly chemisorbed species occur widely. In the reactions mentioned above,[129–131] the activated complex included one strongly and one weakly chemisorbed species. Subsequently this phenomenon was "rediscovered" and was called "adsorption-induced desorption"[133] without referring to earlier investigations.[129,130]

Processes involving the migration of the reactants on the surface (surface diffusion), where one of the reactants diffuses towards the other which is adsorbed more strongly, or towards an active centre at which it reacts also occur extensively in catalytic surface reactions.

It is noteworthy that the surface migration process proceeds as a significantly activated process, its activation energy being appreciably smaller than the activation energy for desorption. Since the species on the surface are far from free in their migrations, in many cases the local concentrations can be replaced by average concentrations when surface diffusion is considered.[28,134]

There exist many examples of the experimental determination of the surface diffusion coefficients by the method of electronic[135,136] and ionic[137] projectors. However, the choice of objects is small and is determined by the possibility of obtaining an image of a section of the surface of the metal in an electronic projector or of individual species in an ionic projector. The diffusion of metal[137] and oxygen[135] atoms and CO molecules[136] on the surfaces of metals has been investigated by this procedure. A method for the determination of the surface diffusion coefficients by studying the desorption induced by the rapid heating of a section of the catalyst has been developed at the Institute of Chemical Physics.[138] Measurements have shown that the activation energy for surface migration is 0.1–0.3 of the activation energy for desorption or 20–60 kJ mol^{-1}, while the pre-exponential factor is between 10^{-2} and 10^{-4} cm^2 s^{-1}.

A model of surface diffusion as a process involving the migration of species both via jumps between centres and in the energy space as a result of the absorption and emission of phonons has been investigated in detail.[134] The possibility of the migration of species over large distances in a single jump has been demonstrated. Allowance for such a jump, which covers many lattice periods, leads to the appearance of characteristic relations in the kinetics of surface reactions, in particular, in the time variation of the rate constant.

The number of measured rate constants for surface diffusion is still very small. It is also essential to know the rate constants for the diffusion of the reaction components into the bulk of the catalyst or into its micropores. In oxidative catalysis, the elementary stage of the process may be the diffusion of oxygen atoms (ions) into the bulk of the oxide catalyst. In selective oxidation catalysts such as bismuth molybdates, the diffusion coefficients of oxygen at the catalytic temperatures can reach $10^{-4}-10^{-6}$ cm^2 s^{-1}. The usual mechanisms of the diffusion of atoms in a solid via vacancies or interstices do not explain such high diffusion coefficients.[139] In order to obtain an explanation of this kind, it is essential to consider cooperative mechanisms (see the next section).

Despite the enormous practical importance of real studies on diffusion in ultraporous catalysts of the type of zeolites, they were begun only recently. At the temperatures of catalytic cracking, the diffusion coefficients of ethane and heptane in the HT-zeolite are respectively $10^{-11}-10^{-12}$ and $10^{-13}-10^{-15}$ cm^2 s^{-1}.[140] MAS–NMR (NMR with magic angle spinning) methods are used to investigate the diffusion in zeolites.[141] Trajectory calculations of the diffusion coefficients of molecules in zeolite pores using data for the real geometry and for the movements of the atoms constituting the zeolites are extremely interesting.[142]

There also exist a further two types of elementary processes in catalysis; electron transfer and proton transfer between two reactants or between reactants and the catalyst.

There have been an enormous number of studies in which the rates of transfer of an electron between the surface and the bulk of a solid were considered, in particular between the adsorbed molecules and a solid. These investigations are in the main associated with the development of microelectronics.[143] "Fast" surface states with capture cross-sections $\sigma \simeq 10^{-13}-10^{-15}$ cm^2 (the corresponding electron or hole capture times are $10^{-8}-10^{-10}$ s) and "slow" surface states with $\sigma \simeq 10^{-18}-10^{-21}$ cm^2 (capture times $10^{-4}-10^{-1}$ s) have been observed. "Ultraslow" traps, characterised by capture cross-sections of $10^{-20}-10^{-30}$ cm^2, which are apparently associated with adsorbed states have also been noted. These ultraslow slow stages in fact determine in many instances the charge and potential of the

surface. The capture times vary in this instance within the range $10^{-1}-10^{3}$ s at low temperatures, i.e. they are equal to or exceed the characteristic times of the catalytic reaction.

It has also been demonstrated[143] that the so called electronic theory of catalysis on semiconductors,[144] in which considerable importance is attributed to the equilibrium Fermi level in the semiconductor as a criterion of its adsorption and catalytic activity, is inconsistent with the experimental data. Owing to the relatively low rate of transport of species on the surface and in the surface layer of the adsorbent and the catalyst, non-equilibrium processes occur.

It has been shown in a number of studies[145,146] that, under the conditions of adsorption and catalysis, the electron and hole transport to adsorbed molecules is effected over large distances from the bulk of the solid. Adsorption requires the obligatory direct overlap of the orbitals of the molecule being adsorbed and the surface atom—active centre. Pure charge transfer is overtaken by the subsequent movement of atomic species, for example, the diffusion of oxygen in the oxide, which frequently limits the rate of the catalytic oxidation.

For example, in the oxidation of allyl alcohol on V/MoO_3, investigated by the EPR method *in situ*,[146] the alcohol molecule initially interacts with the surface oxygen ions O_s^{2-}:

$$CH_2{=}CHCH_2OH+O_s^{2-}\rightarrow CH_2{=}CHCHO+H_2O+\square_s^{2-}.$$

After this, the electron rapidly passes from the surface into the bulk phase, which leads to the reduction of the vanadium ion which is observed by EPR:

$$\square_s^{2-}+V_v^{5+}\cdots O^{-}\rightarrow \square_s^{-}+V^{4+}\cdots O^{-}.$$

Next follows a slow stage—the diffusion of oxygen to the surface (or the reverse diffusion of a vacancy into the bulk of the catalyst):

$$\square_s^{-}+V^{4+}\cdots O^{-}\rightarrow V^{4+}\square_v+O_s^{-}.$$

Under the conditions of stationary catalysis, the movement of electrons into the bulk of the catalyst and from the bulk to the surface and the corresponding movement of oxygen ions reach equilibrium and a surface layer only a few angstroms thick actually "works".

At low temperatures, the electron moves over distances up to 1–2 nm via a tunnel mechanism. The reaction has a low activation energy. At a higher temperature, charge is transferred via the polaron or band mechanism. At still higher temperatures, the main catalyst lattice is oxidised and reduced.

In acid–base catalysis, the most probable elementary stage is proton transfer to the adsorbed molecule with formation of a positive ion (a carbonium ion in the case of hydrocarbons: $C_nH_m + H^+\rightarrow C_nH_{m+1}^+$) or a proton is split off with formation of a negative ion (a carbanion in the case of hydrocarbons: $C_nH_m\rightarrow C_nH_{m-1}^- + H^+$). The carbonium and carbanion mechanims of catalysis have been recognised by most investigators who have studied the reactions of hydrocarbons on oxide catalysts.[147] However, in reality there are very few examples of the spectroscopic detection of carbonium ions on the surface and under catalytic conditions there have been almost none.

Attempts have been made to use the NMR method for this purpose. For example, the kinetics of the conversion of methanol into hydrocarbons on the H-ZSM-5 zeolite were investigated on the basis of the MAS–NMR spectra *in situ*.[141] The formation of protonated methyl ether $(CH_3)_2OH^+$ is apparently an intermediate stage. In the latest study,[148] it was possible to determine the mobility of the protons of the hydroxy-groups of oxides from the width of the NMR line. It was found that the range corresponding to a sharp increase in the mobility of protons on catalysts such as γ-Al_2O_3, Al_2O_3.HF, and others coincides with the region corresponding to the rapid increase in catalytic activity in the dehydration of alcohols. The average residence time of the protons in the equilibrium state is of the order of 10^{-6} s. The authors[148] concluded that the transport of protons ensures more effective interaction with the adsorbed molecules than the transport of the molecules themselves to the hydroxy-groups (under these conditions, we have $\sim 10^{-4}$ s).

The dynamics of proton transfer in the adsorption of molecules with participation of the hydroxy-groups of the surfaces of the oxides has been examined.[149] By analysing the changes in the IR spectra (specially overtones of the OH vibrations) during adsorption, the author[149] concluded that the potential barrier to proton transfer may be lowered.

In subsequent studies, it was shown that proton transfer processes in cyclic complexes of the reactants with the catalyst occur widely in heterogeneous catalysis.[150] The transfer of a proton (or protons) in a single cyclic complex appreciably reduces the activation energy. Such cyclic complexes were first proposed to account for the catalysis of acid reacitons on Al_2O_3 as early as 1938 in studies by Shilov.[151] It remained only to demonstrate their involvement in catalysis by direct spectroscopic measurements.

IV. Macrodynamics of the catalytic process

Together with the concept of chemical kinetics as the science of the rate and mechanisms of chemical reactions, the term "dynamics" of chemical reactions has been increasingly applied in recent times. The term dynamics is applied to the theory of the general evolution of chemical systems on the basis of kinetic equations and dynamic equations of mathematical physics.[152,153] The methods developed by mathematicians for the study of dynamic systems have been vigorously applied in recent years to heterogeneous catalysis.

The kinetic description of heterogeneous-catalytic processes is based on the ideal adsorbed layer model developed by Langmuir.[154] According to this model, all the sections on the surface are uniform and on each of them equilibrium adsorption is observed. The catalytic reaction takes place on interaction of the reversibly adsorbed species. Further development of the formal kinetics of catalytic processes showed that fractional orders, which do not arise from the simple Langmuir kinetics, are frequently encountered in the kinetic equations.

The concept of the kinetics of catalytic processes on non-uniform surfaces was therefore developed in the studied of Roginskii, Zel'dovich, and Temkin.[155] According to this concept, the existence of biographic or induced non-uniformities is postulated and either a distribution function for the centres with respect to heats of adsorption or the law governing the interaction of the species on adsorption is introduced. The idea of a non-uniform surface or of the interaction of the adsorbed species made it possible to explain numerous kinetic relations observed in the study of adsorption and catalytic processes.

Studies in the recent decades have shown that the real picture is still more complex. It has been observed with the aid of physical methods that even on ideal atomically clean single crystal surfaces the kinetics of adsorption and of the reaction are not described by simple Langmuir equations.[156] We may also note the problem of the so called "pressure gap" in studies on catalysis, which are usually carried out at a pressure of 1 atm, and in studies on the physics of surfaces where the kinetics of the elementary heterogeneous processes are investigated under high vacuum conditions ($10^{-6}-10^{-2}$ Pa). In some investigations, attempts have been made to fill this gap. For example, the oxidation of CO on Pd/Al_2O_3 has been investigated[157] in the pressure range from 10^{-4} to 10^{4} Pa. The difference between the turnover numbers at low and high pressures of almost an order of magnitude indicates the operation of different mechanisms of the reaction under these conditions.

Numerous studies have shown that deviations from the Langmuir kinetics may be induced not only by the non-uniformity of the surface on interaction between the molecules but also by entirely trivial causes; mass and heat transfer and non-isothermal conditions in the catalyst bed. Among the non-trivial causes associated with the dynamics of the catalytic process itself we may note the following:

(1) phase and structural rearrangement of the catalyst;

(2) phase transformations of the two-dimensional adsorbed layer;

(3) diffusion of the reactants and intermediates between the active centres (kinetics with a precursor);

(4) diffusion of the reactants and intermediates between the different phases in a complex catalyst (spill-over);

(5) exchange of material between the surface and the bulk of the catalyst under the conditions of the catalytic reaction mixture;

(6) the possibility of the extension of the reaction to the gas phase (heterogeneous-homogeneous processes);

(7) the non-equilibrium nature of the process and the influence of the energy exchange on the reaction kinetics;

(8) radical-chain processes on the catalyst surface;

(9) complex autocatalytic and coupled reactions.

For a complete kinetic and dynamic description of the catalytic reaction, it is essential to divide all the relaxation processes into rapid and slow, to elucidate the question of the existence and of the number of stationary states, to carry out studies under conditions remote from equilibrium, and to construct phase portraits of the system (in terms of the "concentration–concentration" or "concentration–temperature" variables).[152] Kinetic models have been devised with three, four, and more independent variables in which account is taken of the catalytic stage proper and the interactions, listed above, which complicate the process dynamics. Even the superposition of two processes with similar characteristics can give rise to a fairly complex overall picture of the dynamic behaviour of the system.[124] The non-linearity arising under these conditions greatly hinder the description of the catalytic reaction.

Theories in which account is taken of the lateral interaction of the nearest molecules on the surface are used for the description of the kinetics of adsorption, desorption, and the reaction on the catalyst surface. These are the Ising[157] and lattice gas[81] models.

The CO oxidation reaction on metals has been subjected to the most comprehensive and detailed investigation. Most workers tend to the view that the main reaction proceeds via the Langmuir–Hinshelwood mechanism. The "non-linearity" of the kinetic equations, caused by the interaction between the adsorbed susbtances, leads to a series of unusual features in the dynamic behaviour of the system.[124,158] Critical phenomena, a multiplicity of stationary states, and autooscillations arise. It has been shown[124] that the slow relaxation, observed in the oxidation of CO on metals, i.e. the anomalously long period of the transition from the initial to the stationary state, can be induced by purely kinetic causes arising from the Langmuir–Hinshelwood mechanism. It had been believed previously that such phenomena are caused by extraneous factors, for example by the slow diffusion of substances on the surface or in the bulk of the catalyst.

At the microscopic level, new approaches to the description of the dynamics of catalytic processes with allowance for the interaction between the reaction medium and the catalyst have been developing on a wide scale. Such processes are considered from the standpoint of the thermodynamics of irreversible processes[159] and synergistic effects.[160]

The application of the concept of reaction affinity, introduced by De Done and borrowed from the thermodynamics of irreversible processes, made it possible to determine the directions of the transformations in a system of complex consecutive reactions.[161] For the occurrence of the reaction, it is essential that the affinities of all the stages in the chain of consecutive reactions are positive. Hence it was concluded that thermodynamic coupling (i.e. the occurrence of a thermodynamically unfavourable reaction after another more favourable one) is impossible. However, in chain or catalytic reactions there is a possibility of kinetic coupling: this requires that the concentration of the intermediate should be higher than the "equilibrium" concentration, if the concentrations refer to the number of reactants (i.e. the species on the left-hand side of the chemical equation of the given stage), or is below the "equilibrium" concentration if the concentrations refer to the number of reaction products (the species on the right-hand side of the equation). At high concentrations of the intermediate, there is a possibility of highly endothermic stages, for example, the desorption stage, which is almost always thermodynamically unfavourable. For example, in the decomposition of NH_3 on tungsten and molybdenum film, the stationary surface coverage by nitrogen atoms under catalytic conditions is much higher than the equilibrium concentration (i.e. the concentration in the absence of catalysis involving the reaction $N_2 \rightleftarrows 2N_{ads}$). The high concentration of nitrogen atoms ensures the occurrence of both the endothermic desorption of N_2 and of the catalytic reaction as a whole.[162]

Thus the widely used concept of the decrease in activation energy on catalysis compared with the non-catalytic reaction as the main cause of catalysis is incorrect or at any rate inadequate. Catalysis is also characterised by the formation of superequilibrium concentrations of intermediates, which is necessary to overcome the endothermicity of the unfavourable stages.

Whereas for small deviations from equilibrium it is possible to make do with linear mechanisms, for large deviations the breakdown of linearity cannot be disregarded. New stationary states arise and are stabilised as a result of energy exchange with the medium. They are organised in both space and time. Prigogine[159] called such structures dissipative. Dissipative structures are formed in open systems under the conditions of exchange of material or energy with the medium and for the cooperative occurrence of microscopic processes.

Four types of dissipative structures have been observed;[163] (1) spatially non-uniform; (2) periodic in time (autooscillations); (3) spatial-temporal (autowaves); (4) bistable or polystable (of the "trigger" type). An increasing number of observations of dissipative structures accumulate in heterogeneous catalysis every year, which

suggests that the observed phenomena are general in character. This applies particularly to complex catalytic systems.

Among spatially non-uniform structures—dissipative structures of the first type, two-dimensional phases have been investigated in greatest detail. In the study of low-temperature adsorption in single crystals of metals and oxides, an enormous number of two-dimensional phases have been discovered.[164,165] Their role in catalysis was also studied, in particular the possibility of a reaction between two adsorbed susbtances forming different phases has been examined. The oxidation of CO on single crystals of platinum group metals has been studied in greatest detail (and continues to be studied). The phases of the adsorbed CO and O on the Pd(111) face and the possible mechanisms of the interaction between them have been investigated by the video-SED method.[165,166] At low coverages, isolated portions of the two-dimensional O_{ads} and CO_{ads} phases are observed and reaction between them is possible as a result of surface diffusion. At moderate coverages, the phases come into contact and the reaction can proceed at the interface. Finally, at coverages close to one monolayer, mixed two-dimensional phases are formed in which each adsorbed CO molecule has a neighbouring O atom and can react with it.

In our studies,[167] the topochemical model of the formation and growth of nuclei was used to describe the kinetics of two-dimensional phase transformations. This model made it possible to explain a series of anomalous phenomena in the kinetics of heterogeneous catalytic reactions. The initial nuclei are formed more readily on dislocations, edges, and other defects. There are also data showing that the reactions of two-dimensional phases can proceed via a cooperative pathway as a result of shifts in linear series. For example, the conversion of the (1 × 1) structure into the hexagonal structure (*hex*) on Pt(100) is a result of the shift of atomic layers through a disordered state.[168]

The so called kinetic phase transitions[169] and their role in heterogeneous catalysis are widely investigated. The ZGB (Ziff, Gulari, and Barshad) model[170] has been used in very numerous investigations. The authors[170] examined similar kinetic transitions in relation to the oxidation of CO on a square uniform lattice. The probability of adsorption in each collision of the molecule with an active centre was assumed to be unity and the probability of reaction in each entry of a CO molecule and an O atom into neighbouring centres was also assumed to be unity. The very fact that the CO molecule occupies one centre on the surface while the O_2 molecule occupies two centres leads to sharp breaks on the curve describing the dependence of the surface coverage on the composition of the gas mixture and to corresponding changes in the reaction rates. Conditions were found under which periodic interaction of the metal alternately with CO and O_2 ensures a higher yield of the product than the interaction with a CO + O_2 mixture. Such sharp breaks were called kinetic first- and second-order phase transitions.

In subsequent studies,[171–174] the ZGB model was developed further: other types of lattices were examined, for example, the hexagonal lattice, and account was taken of the influence of the rates of desorption and diffusion and of the finite probability of reaction (< 1). In all cases, stationary oxidation of CO is possible only in the middle range of coverages θ_{CO} (in the simplest case from 0.33 to 0.52). At the edges of this range, the catalytic activity changes abruptly and a "kinetic phase transition" takes place. Much importance has been attributed to the formation of clusters under the conditions of low coverages θ_{CO} and θ_O and to subsequent percolation in the same CO oxidation reaction on platinum.[175]

The study of the role of two-dimensional and adsorption phases in catalysis is in its initial stages. The application of the video-SED method in catalysis suffers from an evident disadvantage; with its aid, it is possible to determine the structure of the surface only in a high vacuum. Furthermore, the majority of studies have been carried out with an abrupt transformation of the equilibrium phase into a non-equilibrium one by the rapid increase or decrease in temperature, which hinders the study of the initial stage of phase formation. The rapid development of tunnelling electron microscopy, which can be used at a high pressure and even in a liquid, will make it possible to carry out investigations during catalysis *in situ*.

The question of three-dimensional phase transformations and of their role in catalysis has been elucidated to the greatest extent. This problem has been examined in greatest detail in connection with oxidation-reduction reactions of oxidation catalysts. For example, the stability of the catalytic oxidation reactions involving the formation and decomposition of the oxidised and reduced phases has been discussed:

$$M+{}^1/_2O_2=MO, \quad MO+R=RO+M,$$

where M is the metallic phase, MO the oxide phase, and R the oxidised substance. On the basis of the phase rule, some workers[176,177] suggested that under stationary conditions the catalyst should consist of only one phase, M or MO, and that phase transformations cannot serve as stages in a catalytic reaction occurring under stationary conditions.

Further investigations demonstrated that these considerations are erroneous. In reality, during the reaction the catalyst exists in a non-equilibrium state. After oxidation and reduction under catalytic conditions, several phases usually coexist. In particular, it was shown that in the stationary state the oxidised and reduced phases can coexist in the catalyst.[178] On the other hand, under certain external conditions none of these phases can exist.

The existence of non-equilibrium phases in a series of catalytic reactions has been observed at the Institute of Chemical Physics by X-ray phase analysis *in situ*. Thus, in the selective oxidation of propene on the complex Bi–Mo–Co–Fe oxide catalyst, a non-equilibrium iron molybdate phase is formed in which there is a high concentration of vacancies and there iron exists in a state intermediate between Fe^{2+} and Fe^{3+}.[179] After extensive oxidation of methane on Pt/V_2O_5, the formation of a phase having the stoichiometric composition V_2O_4 was observed but with a crystal structure corresponding to that of the initial V_2O_5, i.e. having an enormous number of vacancies.[180] The non-equilibrium phases observed in the above investigations[179,180] facilitate the transport of oxygen via the lattice, which in the given instance is a stage of the overall catalytic process. Under the conditions of the Fischer–Tropsch synthesis on an iron oxide catalyst, a layered structure consisting of alternating fairly thin (20–30 Å) layers of iron oxide and carbide, is formed.[181]

The question of the catalytic transformations occurring in the vicinity of the phase transition point is also of interest. It has been shown that the ferroelectric $BaCO_3$ phase, which is inactive in the oxidation of CO, is converted at the Curie point (403 K) into a catalytically active paraelectric phase.[182] The Curie point of barium titanate shifts by several degrees following the adsorption of various gases; electron acceptors (NO and oxygen) increase it, whilst the electron donor CO and propene reduce it. Hence it follows that not only the phase transition but also, conversely, adsorption and catalysis influence the phase transition point.

Dissipative structures of the second type consist of auto-oscillations. In the 1970's–1980's studies on autooscillations in heterogeneous catalysis developed in an avalanche-like fashion mainly in relation to catalytic oxidation. We may note for example, studies on the autooscillations in the oxidation of cyclohexane on the NaY[183] and KY[184] zeolites, the oxidation of propene on $Co_xMg_{1-x}O$,[185] and the oxidation of CO on palladium-containing zeolites.[186]

Autooscillations are a striking manifestation of the self-organisation and non-equilibrium phenomena in catalysis. In order to account for autooscillations, various kinetic models are used, including negative feedback, non-linearity, and the presence of buffer stages (see the relevant reviews[187,188]). Common explanations include the change in the activation energy for the reaction with surface coverage (for example, as a result of the charging of the surface and the formation of an oxide layer on metals[186]), the thermokinetic mechanism which presupposes the heating and cooling of the system (provided that its heat capacity is high), a heterogeneous-homogeneous mechanism,[189] the existence of two and more surface forms, and the existence of two different phases (for example, oxidised and reduced).

A series of studies in which two-centre and two-phase models of autooscillations in heterogeneous catalysis were confirmed have been published recently. Thus it has been shown that the autooscillations in the H_2 oxidation reaction on different catalysts can be explained by the existence on the surface of Z and Z* centres having different activities and by the transfer of adsorbed species on the surface from one set of centres to another.[190] The autooscillations in the CO oxidation reaction on Pt(100), investigated by means of direct observations of the surface structure using the video-SED method[191] and scanning photoemission spectroscopy,[192] are induced by the coexistence of two structures—a square (1 × 1) structure and a hexagonal (*hex*) structure—of two-dimensional phases. For a coverage $\theta_{CO} < 0.5$, the *hex* structure is stable, whilst for higher values of θ_{CO} the (1 × 1) phase induce a decrease in θ_{CO}, as a result of which the phase transition takes place again and the oscillatory cycle is repeated. The mechanism of this phase transition was investigated with the aid of scanning tunnelling microscopy. It involves the formation of isolated groups (nuclei) comprising adsorbed CO and the subsequent diffusion of the CO species into the layer over the isolated groups.[193] Such isolated groups are much larger than atomic groups but smaller than the area of the single crystal face (90 μm^2).[194]

On Pt(110), autooscillations are observed in the oxidation of CO over a narrower temperature range and are sensitive to small oscillations in pressure. Here too, as on Pt(100), the autooscillations are induced by the presence of two surface phases, but, in contrast to the process on Pt(100), synchronisation is acheived not as a result of the propagation of surface waves of phase transformations but apparently occurs via the gas phase.[195] The synchronisation of autooscillations on the (110) faces of two separate small palladium crystals is achieved very rapidly, over a period of several seconds.[196] On the other hand, on the Pd(111) and Pd(100) faces of the single crystal such synchronisation has not been observed.[197]

The very important problem of the synchronisation of autooscillations in catalysis is still far from being solved. Rigorously periodic autooscillations are frequently observed not only on single crystals but also on powders containing a large number of grains and microcrystals. An attempt has been made[198] to explain the synchronisation of the autooscillations in the oxidation of CO on a palladium-containing zeolite by phase transitions accompanying the oxidation of palladium in combination with thermal effects. The strong heating occurring in the exothermic reaction

$$O_{ads} + CO_{ads} \rightarrow CO_2$$

leads to the diffusion of oxygen and further to the Pd→PdO phase transition. It has been shown[198] that, for small sizes of the palladium crystals, all the oscillations are averaged out and the reaction proceeds in a stationary regime. An increase in the size of the small crystals facilitates the diffusion of O_2 between them and increases the thermal conductivity, which in fact leads to the synchronisation of the autooscillations.[199]

Among other oscillatory regimes in liquid-phase reactions, apparent non-periodic oscillations or chaos have been observed.[200] Deterministic chaos is described in terms of the so called strange attractor in which all the trajectories are attached to a definite region in the three-dimensional phase space. The transition from regular autooscillations to chaotic ones and back again has been observed in the oxidation of CO on Pt(110).[201] The transition to deterministic chaos took place via a stage involving the doubling of the period of the oscillations.

Autooscillations have been observed also in non-oxidative heterogeneous-catalytic reactions: in the interaction of NO with CO on Pt(100),[202] in the decomposition of CH_3NH_2 on platinum,[203] and in the hydrogenation of nitrobenzene on deposited copper and nickel catalysts.[204]

Dissipative structures of the third type—spatial-temporal periodic structures or autowaves—are observed on smooth catalyst surfaces in the same cases as autooscillations.

Travelling waves have been observed in the oxidation of NH_3 on a platinum filament.[205] After brief heating of a small section of the filamental catalyst and after the transition of the reaction on this section from the initial kinetic regime (from a state with a low catalyst activity) to the diffusional regime (to a highly active state), it is possible to obtain a travelling wave in which sections having a high activity alternate with those having a low activity. The travelling wave can be obtained also by the converse procedure involving the rapid cooling of one of the surface sections.

The autowaves arising in the oxidation of CO on the Pt(100) face have been investigated by the video-SED method with scanning of the surface.[206] Autowaves are generated by the alternation of the (1 × 1) and *hex* structures with diffusion of the CO between the phases. Irradiation of a small spot on the Pt(100) surface with laser light induces the desorption of CO in the spot and the propagation of chemical waves at a rate of 2 mm min^{-1} at 480 K.[207]

The problem of the existence of stationary periodic structures or Turing structures in heterogeneous catalysis is separate. In liquid-phase reactions, such structures arise for certain ratios of the rates of reaction and diffusion. They can be observed when the autooscillatory Belousov–Zhabotinskii reaction is carried out in a layer of chromatographic gel.[208]

Dissipative structures of the fourth type, which arise when there are two and more stationary regimes corresponding to the same parameters and with an abrupt transition between them, have long been known in heterogeneous catalysis. The critical phenomena observed in the oxidation of CO and hydrocarbons on metals[209] have been sometimes explained by the self-heating of the catalyst with transfer of the reaction to the diffusional region. Further investigations demonstrated, however, a non-thermal cause of the observed phenomena. The existence of two stationary regimes in the oxidation of CO on platinum—one at high CO concentrations and

the other at high O_2 concentrations—can be explained by the competition between the adsorption and impact mechanisms.[124,153] The ZGB model mentioned above, according to which the critical phenomena in catalysis are caused by kinetic two-dimensional phase transitions, was later used[210] to explain such bistability.

Critical phenomena of this kind have been observed in the study of the oxidation of ammonia on fine platinum filaments.[205,211] The thermographic method developed by Berelko, et al.[205] made it possible to achieve the compensation of the heat evolution in the reaction over a very short period of 10^{-4} s. This procedure made it possible to demonstrate that the rapid transition from the low-temperature stationary regime to the high-temperature regime is induced by kinetic causes and not by a "thermal explosion". Critical phenomena have been observed also in a calorimetric study of the oxidation of propene on the deposited catalyst MoO_3/MgO.[212] The sharp increase in the rate of reaction after the attainment of a certain degree of surface coverage by oxygen was explained by the formation of a more active surface phase.

Hysteresis phenomena have been observed in many critical reactions. These involve the occurrence of the reaction via different stationary states depending on whether the reaction takes place with rising or falling tempertures or depending on the direction in which the reactant concentration varies. Hysteresis has been observed in the oxidation of methane on Pt/V_2O_5 [180] and of NH_3 on platinum.[211] This phenomenon has been usually explained by phase transformations and by changes in the structure of the catalyst on the surface.

In the extensive oxidation of propene on the $CuO/Cu_2O/Cu$ or NiO/Ni catalyst, the hysteresis loop was observed under conditions where the temperature of the O_2 pressure was varied in the forward or reverse directions.[213] These phenomena were attributed to catalyst oxidation and reduction processes. According to Greger, et al.,[213] the removal of oxygen from the catalyst and the absorption of O_2 are independent processes which are influenced by the particle size, the morphology of the particles, and the presence of impurities. Over a wide range of external parameters, two catalyst phases coexist: oxidised and reduced.

The critical phenomena in catalysis have also been attributed to the appearance of a branched chain reaction involving the formation of active centres.[211] An attempt to explain the "catalytic explosion" observed in the decomposition of HCOOH on Pt(110) by the occurrence of a branched chain reaction has in fact been made.[214] However, all the attempts to accelerate the decomposition by introducing the possible intermediate active species formed in the decomposition of HCOOH (hydrogen atoms, CO, and others) yielded a negative result.

There are general relations between catalysis and chain reactions.[215] In heterogeneous catalysis, there is a possibility of the formation of active species: free atoms and radicals escaping from the surface of the gas phase, quasi-free species propagating the chain reaction in the adsorbed layer, and also excited molecules. The commonest case is, however, the formation of non-equilibrium centres of the catalyst itself, similar to the species involved in a gas-phase chain reaction. Examination of the simplest kinetic schemes for A→B catalytic reactions showed that the catalyst activation stage

$$A+Z\rightarrow A+Z^*,$$

where Z is an active centre, is analogous to the chain reaction initiation stage, the catalytic stage proper

$$A+Z^*\rightarrow B+Z$$

is analogous to the propagation of a chain reaction, while the catalyst deactivation stage $Z^*\rightarrow Z$ is analogous to linear chain termination. The possible mechanisms of the formation of new active centres in catalysis, analogous to the occurrence of a branched chain reaction, have also been examined.

The kinetic differences between catalysis and a chain reaction are apparently not very significant. However, there are so far few chain mechanisms in catalysis whose reality has been demonstrated. There have been studies indicating a chain mechanism of the oxidation of CO on V_2O_5/SiO_2,[216] of the isomerisation of olefins on MoO_3,[217] of the Fischer–Tropsch synthesis on iron catalysts,[218] and of the synthesis of hydrocarbons from methanol on zeolites.[219] Further development of physical methods will make it possible to detect more reliably the intermediate species characteristic of chain mechanisms in catalysis.

Here we should like to draw attention to a number of features characteristic of a chain reaction which are frequently observed in catalysis: (a) the alternation of the formation and destruction of active centres (the occupation and liberation of the centres on the surface); (b) the attainment of superequilibrium concentrations of intermediates helping to overcome the endothermicity of unfavourable stages; (c) the attainment of the maximum rate of the reaction after some time has elapsed from its start.

The occurrence of heterogeneous-homogeneous catalysis, where the active species are desorbed from the surface and propagate the chain reaction in space, also constitutes indirect evidence in support of a chain mechanism. The phenomenon of heterogeneous-homogeneous catalysis was discovered in the 1930's and was investigated mainly by the method involving separate calorimetric measurements on the catalyst and the gas phase, which served as the principal means of detecting the homogeneous chain propagation of the heterogeneous-catalytic reaction.[220]

A series of data showing that not only free radicals but also excited molecules can escape from the surface in exothermic catalytic reactions have appeared recently. We have already quoted a number of examples of the narrow angular distribution of the desorbed molecules, indicating their translational excitation. For example, in the decomposition of hydrazine, i.e.

$$N_2H_4\rightarrow N_2+2H_2$$

on Ir(110) the entire evolved nitrogen is distributed within the limits of 7° around the normal to the surface and is translationally hot.[221] In an earlier study[222] of the catalytic decomposition of N_2H_4 by the method of separate calorimetric measurements, the heating of the gas phase relative to the catalyst was explained by the radical-chain propagation in the gas phase of the reaction initiated on the surface. In the light of new data,[221] this result can be explained also by the escape from the catalyst of excited molecules, which are subsequently deactivated in the gas phase with evolution of heat.

In the course of the oxidative dehydrogenation of butene on the Li–Sn–P oxide catalyst, the formation of an electronically excited molecule—singlet oxygen $O_2(^1\Delta_g)$—was observed.[223] It may be that the flow of the gas phase observed in certain catalytic oxidation reactions at 400–500 °C is caused by the formation of electronically excited molecules.

The heterogeneous-homogeneous mechanism of catalysis is apparently the principal mechanism of catalysis at high temperatures. Depending on the nature of the molecules and catalysts, ionic mechanisms of the electrophilic or nucleophilic substitution type, common in liquid-phase organic processes, predominate at low

temperatures (200–500 °C) and acid–base interaction plays an important role. Homolytic mechanisms involving the formation of free radicals and excited molecules predominate at a high temperature.

The transition from the measurement of macrocharacteristics (separate calorimetric measurements, increase in the free volume of the gas over the catalyst) to the direct detection of intermediate species became a new stage in the study of the mechanism of heterogeneous-homogeneous catalysis. The method involving the freezing out of radicals in a matrix beyond the layer of catalyst with their subsequent detection by EPR, which was devised at the Institute of Chemical Physics in Erevan[224] and subsequently developed further,[225] played a major role. The direct detection of free radicals in the gas phase beyond the catalyst without freezing out, for example, by laser magnetic resonance[226] and multiphoton ionisation[227] methods, has given rise to some prospects.

The oxidative condensation of methane on various oxide catalysts has been studied in particularly great detail in recent years:[225,228]

$$2CH_4+O_2=C_2H_4+2H_2O.$$

In this reaction, free radicals are formed on interaction of a methane molecule with the surface oxygen O_s:

$$O_s+CH_4\rightarrow CH_3^{\bullet}+OH_s.$$

The recombination of the radical from the gas phase, i.e.

$$2CH_3^{\bullet}\rightarrow C_2H_6$$

leads to the formation of an ethane molecule (and subsequently, on oxidative dehydrogenation, of ethylene). Although the reactivity is determined by the properties of the catalyst, the selectivity depends on the equilibrium in the gas phase:

$$CH_3^{\bullet}+O_2\rightleftarrows CH_3O_2^{\bullet}.$$

At a low temperature, the $CH_3O_2^{\bullet}$ radical undergoes further extensive oxidation to CO_2 and H_2O, while at temperatures above 600 °C the equilibrium is displaced towards methyl radicals and the selectivity in the formation of their C_2 product increases as the temperature rises. If the activation energy E for the interaction of methane with the catalyst, i.e.

$$CH_4+Cat\rightarrow CH_3^{\bullet}+Cat-H$$

is plotted against the energy Q of the bond between hydrogen and the catalyst Cat–H, then the points corresponding to the case where the acceptor (Acc) is the catalyst lie on a single straight line with the corresponding points for a homogeneous radical reaction:

$$CH_4+Acc\rightarrow CH_3^{\bullet}+Acc-H.$$

The Polanyi–Semenov relation holds:[228]

$$E=E_0-\alpha Q.$$

Heterogeneous-homogeneous radical processes also probably play a definite role in other high-temperature catalytic reactions (vapour phase conversion of methane, oxidation of ammonia, the synthesis of HCN). These should in fact be sought. The study of high-temperature catalysis is in the initial stage and the discovery of new reactions may be expected.

When the macrodynamics of catalytic reactions is examined, it is desirable to pay special attention to the organisation of the process on multicomponent and especially multiphase catalysts. The high reactivity and selectivity of such catalysts is attained as a result of the separation of the process in space: each stage of the catalytic reaction proceeds on a separate phase.

The principle of the separation of a complex reaction into stages each of which is accelerated by its own catalysts was proposed by Lebedev already about 60 years ago;[229] thus a selective catalyst was chosen for the synthesis of butadiene from alcohol:

$$2C_2H_5OH\rightarrow C_4H_6+2H_2O+H_2.$$

Dehydration, dehydrogenation, and condensation stages were isolated in this reaction and for each its own catalyst was selected. Subsequently a complex catalyst consisting of oxide phases accelerating the above stages was devised.

One of the advantages of multiphase catalysis is the possibility of displacing an unfavourable equilibrium as a result of the removal of an intermediate from one phase to another. Weisz,[230] who investigated in detail the conversion of hydrocarbons on the so called bifunctional catalysts, was one of the first to understand this. It was shown that in the reforming reaction on Pt/Al_2O_3 dehydrogenation of n-paraffins (A) is effected on platinum while the subsequent skeletal isomerisation of the n-olefin (B) to the iso-olefin (C) takes place on Al_2O_3 or aluminosilicate: $A\rightleftarrows B\rightarrow C$. By selecting a catalyst, it is possible to accelerate the removal of the substance B from one phase to another and to displace the equilibrium $A\rightleftarrows B$. An increase in the diffusion coefficient and a decrease in the distances between the species promoted the shift of the reaction towards complete conversion. In particular this can be achieved by the mechanical displacement of phases.

The shift of an unfavourable equilibrium can be achieved also in a simple catalytic reaction $A\rightleftarrows B + C$ without intermediates.[231] For this purpose, it is necessary to remove the reaction products constantly to other surface centres, which adsorb it more strongly. The occurrence of the reaction in the so called chromatographic regime was discovered in relation to the dehydrogenation of cyclohexane to benzene. The thermodynamically unfavourable reaction (at a low temperature)

$$C_6H_{12}\rightleftarrows C_6H_6+3H_2$$

can be effected by carrying it out under pulsed conditions with constant removal of products.

In such cases, a multiphase structure is always useful. The activity and selectivity in certain reactions can be increased by using special adsorbents for the reaction products. Thus, zeolites have been used for the removal of water in certain condensation reactions and for the removal of lower alcohols in the exchange of alcohols with esters.[232] Under real conditions of stationary heterogeneous catalysis, not only the concentration gradients of the intermediate compounds diffusing in the pores between the particles of different catalyst phases but also stationary gradients of the catalyst composition within each phase can be established.

The principle of the constant removal of the product from the reaction zone in order to increase the selectivity of the catalysis has been used in metallic membrane catalysts. The application of

palladium alloys in the form of membranes increases their selectivity in the dehydrogenation of butane to butadiene as a result of the removal of hydrogen to the other side of the membrane.[233,234] The involvement of hydrogen in another catalytic reaction (hydrogenation, oxidation) on the other side of the membrane increases the yield of butadiene still further.

The role of the multiphase structure of the partial oxidation catalyst was examined in detail in our investigations[14,235] based on the study of their structure by X-ray phase analysis and Mössbauer spectroscopy *in situ*. It was found that under the reaction conditions the complex Bi–Co–Fe–Mo–O catalyst consists of five main phases: (1) the β-$FeMoO_4$ phase necessary for the adsorption of oxygen; (2) the β-$CoMoO_4$ phase stabilising the β-$FeMeO_4$ phase by virtue of the coherence of the lattices; (3) the non-equilibrium partially reduced $Fe_2(MoO_4)_3$ phase through which oxygen atoms are transported from the oxygen adsorption centres to propene adsorption centres; (4) the $Bi_2(MoO_4)_3$ phase necessary for the adsorption and activation of propene; (5) the MoO_3 phase ensuring the maintenance of stoichiometric relations in the reduction of iron molybdate. The active centres are located near the interface. Non-equilibrium concentrations of vacancies and stationary hydrogen concentration gradients are created in the catalyst.

In oxidative catalysis there is a possibility also of separation in space of centres within a single phase.[236] The study of the oxidation of allyl alcohol to acrolein[16] on the MoO_3 catalyst with added vanadium by EPR *in situ* showed that organic molecules are adsorbed on the outer surface of the catalyst. On the other hand, oxidation and reduction processes occur on the V^{4+}/V^{5+} active centres within the bulk of the catalyst. Constant exchange of oxygen and electrons takes place between the surface and the bulk phase.

The separation of the active centres in space is apparently a general rule for complex catalytic processes. The theory of these processes has been inadequately developed. It must take into account the shifts of the equilibrium, the coupling of stages, and the transport processes between the centres, phases, or particles.

The role of surface and bulk-phase diffusion in heterogeneous catalysis is apparently much greater than has been thought hitherto. The phenomenon of the interphase diffusion of adsorbed species has been called spill-over. The spill-over of hydrogen, first observed in the adsorption of hydrogen on Pt/WO_3,[237] ensures the transfer of hydrogen atoms from the metal to the oxide. In the absence of the metal, there is no adsorption of hydrogen on the oxide. The spill-over phenomenon must play a major role in reactions involving hydrogen, displacing the equilibrium by virtue of the removal of hydrogen atoms.

The mechanism of spill-over is different in different systems. The exchange of D_2 with the hydrogen of the OH groups on Pt/SiO_2 has been investigated[238] by IR spectroscopy with Fourier analysis *in situ*. It was found that deuterium diffuses from the metal to the carrier in a weakly bound state on top of strongly bound OH groups on SiO_2 and exchanges with them. The driving force of spill-over is the concentration gradient between different states of deuterium. The spill-over of hydrogen atoms across an oxide film has been observed.[239] Platinum deposited on silicon and fully coated by a layer of the inert SiO_2 exhibits activity in the dehydrogenation of cyclohexane. The activity of the catalyst decreases exponentially with increase in the thickness of the film from zero to 30 nm and becomes constant for thicknesses in the range 30–2200 nm. The spill-over of hydrogen in the H_2-D_2 exchange and C_2H_4 hydrogenation reactions has been observed without direct contact between the oxide (SiO_2, Al_2O_3) and the metal (Pt/SiO_2, Pt/Al_2O_3), i.e. through the gas phase.[240] According to different data,[241] atomic and ionic species can participate in spill-over. The diffusion coefficients of the H and D atoms in the Pt/SiO_2 and Pt/Al_2O_3 systems proved to be unexpectedly very high: $10^{-3}-10^{-6}$ cm^2 s^{-1}.

The "spill-over of oxygen"—the diffusion of oxygen atoms across an oxide lattice from one active centre to others—was already mentioned above. The phenomenon of the spill-over of the NCO species from the surface of a metal (Pt, Rh) on to a carrier (γ-Al_2O_3) and conversely under the conditions of the reaction of NO with CO has been observed.[242] It has been shown by IR spectroscopy *in situ* that the NCO species participate in the reaction as intermediates.

Synergistic phenomena—the superadditive increase in the activity of the catalyst on mechanical mixing of the components—can be explained by the transfer of material between phases, diffusion, and spill-over. The conversion of propene in its oxidation on the mixed catalyst $CoMoO_4$ + MoO_3 or $CoMoO_4$ + $Bi_2(MoO_4)_3$ was found to be higher than the sum of the conversions on each component separately.[243] This can be explained by the fact that on one or both phases intermediates of possibly free-radical character are formed and after being released into space are adsorbed on another phase and undergo further reaction.

Numerous instances of synergism in partial oxidation reactions have been listed in a review.[244] A new term has been proposed for the designation of the synergistic intensification of catalysis in mixtures—remote control.[245] Synergistic effects have been noted in the hydrogenolysis of thiophene on (MoS_2 + CoS)/γ-Al_2O_3, in the oxidation of isobutene to methylacrolein on SnO_2 + Sb_2O_4, and in the dehydration of *N*-methylformamide on MoO_3 + Sb_2O_4; the influence of platinum on the reduction of Ni is associated with these effects.[245] The operation of the remote control mechanism makes it useful to introduce the catalyst in the form of several layers consisting of different materials.

The overall organisation of the process via parallel or consecutive mechanisms is very important in the dynamics of complex catalytic reactions. This determines, in particular, the selectivity of the catalyst—its ability to accelerate only one of several reactions occurring simultaneously. The principal factors influencing selectivity, namely the bond energy, the ligand effect, the ensemble effect, steric effects, and multiphase structure were examined in the present author's previous review.[235]

Thermochemistry of the dissolution and characteristics of the solvation of cellulose, polysaccharides, and their derivatives

V V Myasoedova, S A Pokrovskii, N A Zav'yalov, G A Krestov
Institute of the Chemistry of Non-Aqueous Solutions, Ivanovo

ABSTRACT. The results of thermochemical studies on solutions of cellulose, its derivatives, and other polysaccharides are surveyed and treated systematically. The existing ideas about the energy effects due to the amorphous-crystalline structure of polysaccharides, including cellulose, are analysed. It is shown that the enthalpies of solution under the conditions of thermodynamic equilibrium are thermodynamically most preferred. Attention is concentrated on the establishment of a relation between the heats of solution and the electron-donating capacities of the solvent and the polymer. New approaches to the quantitative estimation of the thermochemical parameters of solvation processes in solutions of cellulose and its ethers and esters, based on multiparameter correlations of the enthalpies of solution and transfer with the physicochemical properties of the solvents, are described.

I. Introduction

By virtue of their universality, thermochemical methods are widely used in the study of the solvation, dissolution, and interactions of cellulose and its derivatives in solutions.[1–5] The concept of electron donor–acceptor (EDA) complex formation is nowadays of fundamental significance, explaining the nature of the interaction of various organic solvent systems with polysaccharides.[6–8] According to this concept, the energy relations of the EDA interaction in the solution are determined by the electron-donating and electron-accepting capacities of the corresponding centres of the polymer and solvent molecules. The calorimetric method for the study of the specific solvation of cellulose and its derivatives in solutions therefore helps in the development of criteria for the solvent power of non-aqueous solvents on the basis of correlations between the enthalpies of solution and the EDA properties of the liquids.

There exist numerous data for the heats of wetting, swelling, and interaction of cellulose with various liquids, but the question of the elucidation of the relation between the enthalpies of reaction and the EDA capacities of the solvents were considered in only a few studies.[9–11] In our view, no account was taken of the following factors in these investigations.

The data on the heats of reaction of cellulose and its derivatives with solvents refer to non-equilibrium processes occurring in a heterogeneous medium.[1,42] The interpretation of such experimental data is difficult as a consequence of their thermodynamic indefiniteness. Enthalpy of solution data characterising the energy relations of the dissolution process at the molecular level, are best.

In the discussion of experimental results, use was made in the above investigations[9,10] of ether the electron-donating or the electron-accepting capacities of the solvents. The amphoteric nature of the functional groups of cellulose and its derivatives needs to be taken into account when the electron-donating and the electron-accepting properties of liquids are considered jointly.

There are few literature data on the heats of solution of polysaccharides, so that further investigations in the field of the calorimetry of solution of cellulose and its derivatives are essential.

II. Thermochemistry of the wetting, swelling, and interaction of cellulose with individual solvents, electrolyte solutions, and ionic complexes

Numerous studies have been devoted to the thermochemistry of the interaction of cellulose with liquids and solutions of electrolytes and complexes.[9–11,13–41] A considerable proportion of these studies dealt with the investigation of the heats of wetting, swelling, sorption, and interaction of cellulose with water.[12,13–28]

As a hydrophilic polymer, cellulose exhibits an enhanced affinity for water. However, water molecules are sorbed only by amorphous regions without the disruption of the crystalline regions of cellulose.[9,13] Consequently the enthalpies of reaction with water to a certain extent characterise the ratio of the crystalline and amorphous regions of cellulose, which depend on the previous history of the specimen and the methods of processing and preparation. The integral heats of reaction of the amorphous regions of cellulose with water have been calculated from the ethalpies of reaction of celluloses having different degrees of crystallinity with water.[14,15]

The second decisive factor is the moisture content of the initial specimen. The heats of reaction approach zero for a water content in the specimen corresponding to $P/P_0 \simeq 0.65$. To illustrate this, Fig. 1 presents the variation of the integral enthalpies of reaction with water of specimens of cotton (*1*), wood (*2*), mercerised cotton (*3*), and regenerated (*4*) cellulose and its amorphous regions (*5*) with different moisture contents,[14] the different degrees of crystallinity X of which are respectively 0.70, 0.65, 0.54, and 0.40.

Thermodynamic analysis[14] has shown that, with decrease in the moisture content, the compatibility between the amorphous regions of cellulose and water is determined by the changes in both the enthalpy and entropy of the system. With increase in the water content, the contribution of the enthalpy to the free energy of formation of the system becomes dominant. The appreciable exothermicity of the process is due to the specific interaction between the components with formation of hydrogen bonds.

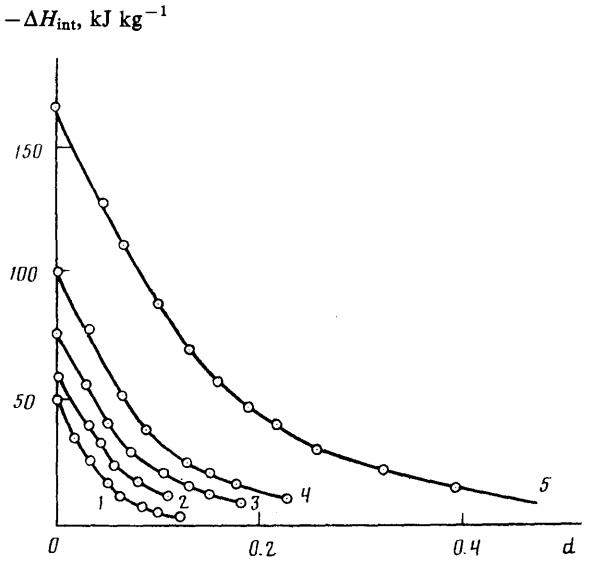

Figure 1. Dependence of the integral enthalpies of reaction with water on the water content in the initial specimens: (*1*)–(*5*) see text.

Among the communications devoted to the study of the cellulose–water system, mention should be made of an investigation[21] in which it was assumed that the thermal effects due to three processes contribute to the enthalpy of interaction (ΔH_{int}): the exothermic effect of the solvation of cellulose by water; the endothermic effect of the rupture of the intramolecular and intermolecular hydrogen bonds of cellulose on sorption of water; the exothermic effect of the solvation by water of the free hydroxy-groups formed on dissociation of the hydrogen bonds of cellulose.

The enthalpies of reaction of cellulose with solvents are determined by the nature of the EDA interaction in the systems.[9,10,29–32] As a rule, solvents with inadequate EDA interaction (water, alcohols, nitriles, ethers, and ketones, etc.) mix only with the amorphous component of cellulose. In our view, a general criterion of the solvating capacities of solvents was not put forward in the studies mentioned above.[9,10] Bearing in mind the polyfunctionality of polysaccharides, it is necessary to use jointly the parameters of the electron-donating and electron-accepting properties of the liquids for this purpose. The enthalpies of reaction of wood cellulose with individual liquids are listed in Table 1. The sharp increase in the absolute values of ΔH_{int} for certain primary amines and strong acids indicates the disruption of the crystalline regions of cellulose and of the specific solvation in the system. However, analysis of the data in Table 1 shows that there is no correlation between the absolute values of ΔH_{int} and the electron-donating properties of amines. Despite the high electron-donating capacity characteristic of bases such as piperidine (DN = 60.9), diethylamine (DN = 56.1), and triethylamine (DN = 60.1), they are characterised by low enthalpies of reaction with cellulose.

Table 1. Enthalpies of the interaction ($-\Delta H_{int}$) of wood cellulose with solvents and empirical parameters of the solvent polarities.

Solvent	$-\Delta H_{int}$, kJ mol^{-1}		DN	AN	$\frac{DN+AN}{2}$
	1 : 25	1 : 10			
Water	9.6	9.2	18.0	54.8	36.4

Nitric acid	–	82.8	–	–	

Note. The enthalpies of reaction are listed for 1:25 and 1:10 component ratios (by weight).
*Calculation based on the data of Makitra et al.;[33] in the remaining cases, the data quoted by Burger[68] were used.

It has been suggested[34] that, for effective interaction with cellulose, organic solvents should possess a favourable set of polar, basic, and steric properties. Since the available ΔH_{int} data refer to non-equilibrium conditions, the establishment of a relation between the heat effects and EDA properties of solvents constitutes an insoluble problem. The enthalpy of solution (ΔH_{soln}) data, characterising the specific solvation process at a molecular level, i.e. under conditions ensuring the complete utilisation of the EDA properties of the solvents, are in this sense preferable for the description of the influence of the solvent on the thermal effects.

Calorimetric data for the interaction of cellulose with aqueous solutions of bases, acids, and salts have been published.[10,11,35–39] The EDA capacity of aqueous electrolyte solutions increases with increase in their concentration. At a certain electrolyte concentration, the exothermicity of the interaction increases owing to the disruption of the crystalline regions of the polymer and the solvation of the macromolecules (Figs. 2 and 3).

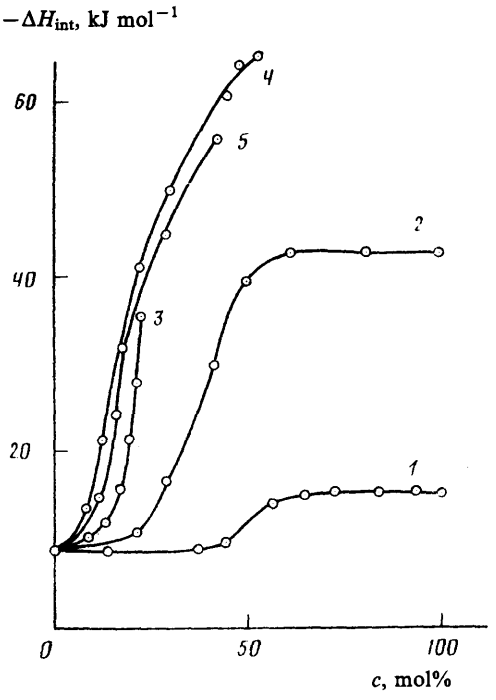

Figure 2. Dependence of the enthalpies of reaction of cellulose with aqueous solutions of monoethanolamine (curve *1*), ethylenediamine (curve *2*), and zinc chloride (curve *3*) at 298 K and with sodium hydroxide solutions at 333 K (curve *4*) and 298 K (curve *5*) on the concentrations of the bases and salts.

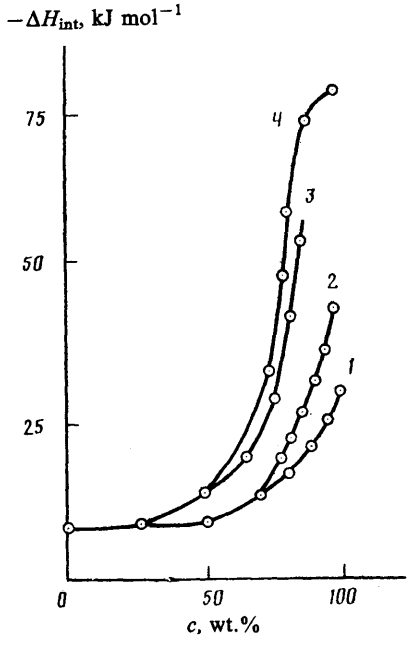

Figure 3. Dependence of the enthalpies of reaction of wood cellulose with aqueous solutions of trifluoroacetic (curve *1*), phosphoric (curve 2), sulphuric (curve *3*), and nitric (curve *4*) acids at 298 K on the acid concentration.

We may note that the interaction of cellulose with reactive compounds in solutions leads to the formation of cellulose derivatives. The thermochemical properties of concentrated solutions of metal hydroxides were attributed[11] to the formation of cellulose alkoxides, whilst in other studies[35] they were attributed to inclusion compounds. The interaction of cellulose with strong acid solutions is as a rule accompanied by the formation of the corresponding esters.[40,41] The enthalpies of reaction include additional contributions due to the exchange of the hyroxy-groups for ester groups, the dissolution of the water formed under these conditions in the solution, and the solvation of the product in the solution.

It follows from the data presented that, in a thermochemical study of the swelling, interaction, and dissolution of polysaccharides, it is essential to take into account the additional energy effect associated with the phase state of different regions of the polysaccharides, it is essential to take into account the additional energy effect associated with the phase state of different regions of the polymer.[4,9–11,17,42] The dissolution of polysaccharides having an amorphous-crystalline structure has been represented[42] in the form of three stages. The first involves the transition of the solid polymer to a hypothetical liquid amorphous state, the second is associated with the dissolution and solvation of macromolecules, and the third involves the mixing of the solvated polymer molecules with the solvent to give an infinitely dilute solution. The integral enthalpy of solution ΔH_{soln} is then regarded as the sum of contributions:

$$\Delta H_{soln} = \Delta H_m + \Delta H_g + \Delta H_{int} + \Delta H_{mix}. \quad (1)$$

The first stage characterises the enthalpy of fusion of crystalline regions (ΔH_m) and the enthalpy of the transition of the amorphous component from the vitreous to the highly elastic (ΔH_g) state. The second entails the interaction (ΔH_{int}) between the polymer and solvent molecules as a consequence of the solvation of the components. The third stage combines all the thermochemical effects of the mixing process (ΔH_{mix}) which occur on dilution (for example, the heats of conformational changes).

Analogous expressions have been proposed[9,10] for the enthalpies of the reactions of cellulose with solvents:

for systems in which the crystalline regions are not disrupted:

$$\Delta H_{int} = \Delta H_g N_a + \Delta H_{mix} N_a; \quad (2)$$

for systems in which the crystalline regions are disrupted:

$$\Delta H_{int} = \Delta H_m N_c + \Delta H_{mix}, \quad (3)$$

where N_c and N_a are the contents of the crystalline and amorphous (vitreous) cellulose (in mole fractions).

The quantities ΔH_g, characterising the transition of the vitreous component of the polysaccharide to the highly elastic state under the influence of the solvent, are particularly large for natural polar polymers with a high glass point T_g (T_g = 493 K for cellulose[13]). Thus, according to Tsvetkov et al.,[10] $\Delta H_g = -12.6 \pm 8$ kJ mol^{-1} unit^{-1} or -77.5 J g^{-1} for the fully amorphous vitreous cellulose.

The enthalpy of fusion of the crystalline regions of cellulose can be estimated in different ways. It has been suggested[10] that ΔH_m be estimated from the enthalpies of solution of laevoglucosan (a compound modelling cellulose) over a wide concentration range. It is assumed that the enthalpy of fusion of crystalline regions of

cellulose is equal to the hypothetical enthalpy of fusion of laevoglucosan and amounts to 14.2 kJ mol^{-1} or 87.3 J g^{-1}.

We believe that the most reliable values of ΔH_m have been obtained from measurements of the enthalpies of solution of cellulose specimens in different solvents.[43,44] The following relation has been used[43] in the determination of the degree of crystallinity:

$$\Delta H_{soln} = -X(\Delta H_c) + + \Delta H_a, \quad (4)$$

where X is the fraction of the crystalline phase in the specimen, ΔH_c the enthalpy of crystallisation, and ΔH_a the enthalpy of solution of the amorphous cellulose. In the calculation of ΔH_c, the degrees of crystallinity obtained by X-ray diffraction were used. ΔH_c is -15.6 kJ mol^{-1} (-96 J g^{-1}) for cellulose (I) and -19.2 kJ mol^{-1} (-118 J g^{-1}) for cellulose (II).

The enthalpy of fusion ΔH_m for cellulose crystallites has been calculated[44] from the equation

$$\Delta H_m = \Delta H_{inta}(\Delta H_{soln1} - \Delta H_{soln2})/(\Delta H_{int2} - \Delta H_{int1}), \quad (5)$$

where $\Delta H_{int\,a}$ is the enthalpy of reaction with water of the amorphous regions of cellulose, amounting to -168 J/g of cellulose at 298 K,[15] $\Delta H_{soln\,1}$ and $\Delta H_{soln\,2}$ are the enthalpies of solution of two cellulose specimens comprising the same crystalline modification, and $\Delta H_{int\,1}$ and $\Delta H_{int\,2}$ are the enthalpies of reaction with water of the same specimens. The quantity ΔH_m was found to be 36.4 kJ mol^{-1} (224 J g^{-1}) for cellulose (I) crystallites and 45.0 kJ mol^{-1} (277 J g^{-1}) for cellulose (II) crystallites. These results indicate a greater energetic stability of the cellulose (II) crystallites compared with cellulose (I) crystallites.

Various approaches have been used[10,43,44] for the estimation of the enthalpies of fusion of the crystalline regions of cellulose. However, it is noteworthy that the absence of systematic studies and the necessity to take into account the type of crystalline modification of the polymer preclude at the present time an unambiguous solution of the problem of the reliability of the available literature values of ΔH_m.

We therefore believe that it is essential to pose the problem of the determination of a common standard state in comparing thermodynamic data for processes involving the dissolution and solvation of cellulose and its derivatives. Since the polysaccharides are involatile, the use of an ideal gas as the standard state is excluded. The pure polymers, having an amorphous-crystalline structure, are also unsuitable for this purpose, because it has been shown that the phase state of the polymer plays an important role in the dissolution process. The lack of reliable thermodynamic data for the devitrification and fusion of the polysaccharides precludes an unambiguous solution of this problem. However, bearing in mind that the contributions of ΔH_g and ΔH_m have different signs in the range of degrees of crystallinity 0.5–0.7, cancelling out to an appreciable extent, the enthalpies of solution of such specimens of cellulose and its derivatives characterise mainly the specific solvation of the polymer.

The results of the estimation of the enthalpies of reaction from experimental enthalpies of solution of model oxygen- and hydroxyl-containing cellulose compounds in different solvents are of definite interest.[9,10,45–50]

Table 2 shows that the interaction of the model compounds in electron-donating solvents (ethylenediamine, aqueous NaOH solution) takes place preferentially via hydroxy-groups, while in electron-accepting solvents (acids) it involves mainly ester groups.

It has been established from thermochemical data for solutions of cellulose in the ferric sodium tartrate complex (FeTNa),[43,45,47,51] cadoxen,[46,50] and the copper–ammonia complex[52] that the interaction proceeds via two secondary hydroxy-groups. It is noteworthy that the enthalpies of reaction of cellulose and other hydroxylated compounds with FeTNa and cadoxen calculated per hydroxy-group, are close, amounting to 10.9–12.1 kJ/mol of OH groups.[47,50]

Table 2. Enthalpies of the interaction ($-\Delta H_{int}$) of cellulose and model compounds with solvents at 298 K (kJ mol^{-1}) (1:40 ratio by weight).[9]

Compound	NaOH (20 wt.%) (ref. 10)	Ethylene-diamine (ref. 10)	MMO*·H_2O (ref. 9)	FeTNa (ref. 45)	H_3PO_4 (83 wt.%) (ref. 10, 48)	CF_3COOH (ref. 48)

*Methylmorpholine *N*-oxide monohydrate (353 K).

To a first approximation, the enthalpies of mixing of the highly elastic amorphous cellulose with solvents can be estimated as the sum of the enthalpies of reaction via three hydroxy-groups and two oxygen atoms of cellulose. A common approach to the estimation of the values of ΔH_{mix} from ΔH_{soln} for model compounds is based on the hypothesis of the additivity of the intermolecular interactions of the functional groups which do not interact strongly with one another. In the case of cellulose, the mutual influence of the functional groups and the steric features of the macromolecular chain alter appreciably the EDA properties of the acetal oxygen atoms and hydroxy-groups.

It has been suggested that[9] the following assumptions be made in the calculation of ΔH_{mix}. The electron-donating capacity of the oxygen atoms of cellulose is equivalent to that of one oxygen atom of the cellulose ether group in model compounds, while the electron-accepting capacity of the hydroxy-groups of the glucopyranose cellulose unit is equivalent to that of four groups of low-molecular-weight alcohols, for example glycerol and ethanol. The enthalpies of reaction of wood cellulose (degree of crystallinity 0.7) with solutions of sodium hydroxide, EDTA, methylmorpholine *N*-oxide, and phosphoric and trifluoroacetic acids calculated on the basis of such a scheme (-23.5, -33.3, -24.6, -31.6, and -51.0 kJ mol^{-1} respectively) are close in order of magnitude to the values calculated by Eqn. (3) (-19.9, -36.2, -18.5, -13.6, and -31.2 kJ mol^{-1} respectively). For acids, the values of ΔH_{int} exceed significantly the experimental values in terms of absolute magnitude. Evidently the approach examined is promising for the qualitative estimation of the enthalpies of reaction of cellulose in solvents of different chemical types. However, more rigorous quantitative calculations require the

development of fundamentally new approaches taking into account all the characteristic features of the intermolecular interactions of both model compounds and of the functional groups in polysaccharide molecules.

When the interaction is of the electron donor–acceptor type, it is essential to take into account the EDA properties of all the system components.[12] Thus the influence of the EDA capacity of the functional groups of the polysaccharide molecules on the solvating capacity of the polymer can be followed by comparing the enthalpies of reaction of cellulose, chitin, and chitosan[53] with organic solvents. The replacement of hydroxy-groups by electron-donating groups (the acetamide group in chitin and the amino-group in chitosan) diminishes the aboslute values of ΔH_{int} in solutions of bases and increases them in solutions of acids. It has been established on the basis of thermochemical data[9] that the electron-donating capacity of the functional groups of cellulose derivatives in solutions diminishes in the sequence chitosan > chitin > cellulose diacetate > nitrocellulose > monocarboxycellulose.

Thus the following conclusions can be drawn from the analysis of thermochemical data for the enthalpies of reaction (wetting, swelling). In the interpretation of the values of ΔH_{int}, it is essential to take into account the structural features of various regions of the polymer, the previous history of the specimen, and the presence of impurities. The absolute values of ΔH_{int} for cellulose and its derivatives in solutions are determined by the EDA capacity of the functional groups of the polymer and the solvent. However, the establishment of a relationship between ΔH_{int} and the EDA properties of solvents is possible only at a qualitative level. For a successful solution of this problem on a quantitative basis, it is necessry to accumulate systematic data for the enthalpies of solution of cellulose and other polysaccharides in non-aqueous solvents.

III. Thermochemistry of the dissolution and characteristic features of the solvation of cellulose, other polysaccharides, and their derivatives in solutions

The experimental data available at present for the thermochemical properties of solutions of polysaccharides refer mainly to the enthalpies of solution of dextrans,[42,54,55] certain cellulose derivatives (nitrocellulose, cellulose acetates),[56–58] cellulose in solutions of ionic ferric sodium tartrate and cadmium-ethylenediamine (cadoxen) complexes, etc.[43–46,50,51]

Depending on the conditions of their preparation, dextrans undergo structural changes. The experimental densities and heats of solution of dextrans in water and 10% aqueous NaOH solution[54] indicate the polymorphism of polysaccharides.

As in the case of ΔH_{int} for cellulose materials,[15] a decrease in the absolute magnitude of the enthalpies of solution of dextrans with increase in the degree of crystallinity is observed.

One of the important problems in the thermochemistry of the dissolution of polymers is that of the influence of the molecular weight on the heat change. The enthalpies of solution and dilution of certain low-molecular-weight carbohydrates (saccharides) and dextrans with different molecular weights in water and dimethyl sulphoxide (DMSO) have been determined.[42] The values of ΔH_{soln} increased with the increase in the molecular weight (M) to 1000, while for the fraction with M > 1000 they remained almost unchanged on further increase in M. The enthalpies of dilution had the opposite character. The independence of the enthalpies of dilution of the molecular weight for M > 2000 demonstrates very small changes in the helical conformation of dextran and the absence of association in dilute and moderately concentrated solutions.

Table 3. The densities and enthalpies of solution of various modifications of dextran.[54]

Modification	Density of preparation		$-\Delta H_{soln}$, kJ mol^{-1}		Degree of crystallinity, %
	unground	ground	in 10% NaOH	in H_2O	
Current state of dextran —amorphous					
–	1.304	1.303	44.9	29.5	–
Current state of dextran —crystalline					
I	1.372	–	37.5	27.2	15.0
I	1.536	1.341	34.5	9.76	28.6
II	1.473	1.360	39.6	–	23.2

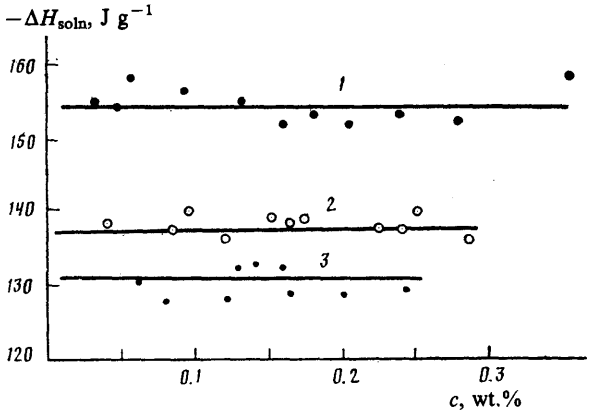

Figure 4. Dependence of the enthalpies of solution of dextran with M = 110000 in DMSO (*1*), water (*2*), and formamide (*3*) on the dextran concentration at 298.15 K.

We measured experimentally the integral enthalpies of solution of dextrans with $M = 2 \times 10^4$, 4×10^4, 7×10^4, and 11×10^4 in water, formamide (FA), DMSO, and their mixtures at 298.15 K.

It was found that an increase in the degree of polymerisation (DP) of dextrans from 100 to 680 does not lead to a significant alteration of ΔH_{soln}. This agrees with the theoretical idea that the degree of polymerisation (for specimens with DP > 10) has an insignificant influence on ΔH_{soln} for flexible-chain amorphous polymers.

Fig. 4 presents the variation of ΔH_{soln} for dextran with M = 110000 in individual solvents.[55]

At least three processes can contribute to the enthalpy of solution of fully amorphous dextran in a liquid:

$$\Delta H_{soln} = \Delta H_g + \Delta H_{conf} + \Delta H_{soln}. \quad (6)$$

The first (ΔH_g) is the transition of the amorphous polymer from the vitreous to the highly elastic state in solution. ΔH_g for amorphous dextran is 11.7 kJ mol^{-1} or 72.1 J g^{-1}.[10] The second (ΔH_{conf}) involves conformational transformations of the polysaccharide molecules in solution. Since the conformers of dextran in solutions have the same energies,[59] the quantity ΔH_{conf} can be assumed equal to zero. The third (ΔH_{solv}) is the solvation of a hypothetical liquid dextran by the solvent and is determined by the intermolecular interactions between the solution components. The presence of a multiplicity of hydroxy-groups in the dextran molecule leads to the formation of a stable solvation shell via polymer–solvent hydrogen bonds. The specific features of the solvation are responsible for the large negative values of ΔH_{solv} (from −54.8 J g^{-1} in formamide to −82.1 J g^{-1} in DMSO).

The exothermicity of the solvation of dextran increases in the sequence formamide ⩽ water < dimethyl sulphoxide. The values of ΔH_{solv} in formamide and water are close in absolute magnitude, which is apparently due to the characteristics of the individual solvents. The need to take into account both electron-donating and electron-accepting properties of the liquids in the solvation of a polysaccharide arises from the bifunctional nature of the hydroxy-groups of dextran. It has been suggested[60] that half the sum of their *DN* and *AN* numbers be used as a criterion of the donor–acceptor capacity of the solvent. Formamide and water are characterised by similar values of (*DN* + *AN*)/2—31.9 and 36.4 respectively. Furthermore, formamide and water are highly associated liquids with similar FA–FA, water–water, and FA–water hydrogen bond energies (~15.5 kJ mol^{-1}).[61]

The greater exothermicity of the solvation of dextran in DMSO compared with water and formamide is due to the complex influence of a set of factors. Thus the Flory parameter of the dextran–DMSO interaction is an order of magnitude higher than for the dextran–water interaction,[42] while according to ^{13}C NMR data[62] the conformational mobility of dextran micromolecules in water is greater than in DMSO. The endothermic contribution to ΔH_{solv} associated with the rupture of the solvent–solvent bonds is smallest in DMSO among all the liquids investigated.

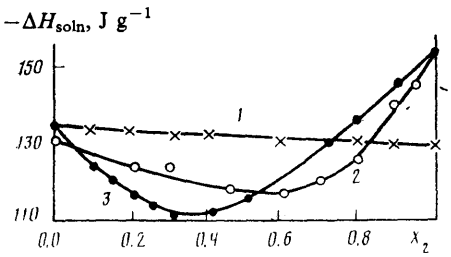

Figure 5. Enthalpies of solution of dextran with M = 110000 in water–formamide (curve *1*), formamide–DMSO (curve *2*), and water–DMSO (curve 3) mixtures at 298.15 K (X_2 = mole fraction of the second mixture component).

Fig. 5 presents the dependence of the integral enthalpies of solution of dextran with M = 110000 in water–formamide, water–DMSO, and formamide–DMSO mixtures on the composition of the mixed solvent at 298.15 K. The nature of the dependences of ΔH°_{soln} on the mixed solvent composition is various. The dependence of ΔH°_{soln} for dextran on the composition of the water–formamide mixture is linear. The water–DMSO and formamide–DMSO systems are characterised by an extremum in the $\Delta H^\circ_{soln} = f(X)$ relation. The nature of the observed dependences of ΔH°_{soln} for the polysaccharide on the solvent composition is associated with the characteristic features of the donor–acceptor interaction between the mixture components. In the range of compositions where an exothermic minimum is observed in ΔH°_{soln}, the molecular interaction of the solvent components is strongest. This confirms the similarity of the variations of the enthalpies of solution of dextran in solvent mixtures and of the enthalpies of mixing of the components of the binary solvent.[61] The formation of mixed associated species comprising the molecules of low-molecular-weight substances over the entire range of compositions weakens the solvation of dextrans and hence diminishes the exothermicity of the dissolution process.

Fig. 6 presents the dependences of the enthalpies of transfer of dextran from DMSO in water–DMSO and formamide–DMSO mixtures on the DMSO mole fraction, which characterise the enthalpy component of the solvation of dextran in the systems investigated. The figure shows that the dependence of ΔH°_{trans} for the water–DMSO system is characterised by a concavity on the descending section of the extremum for X_{DMSO} > 0.5 (mole fraction). The similar form of the relations for solutions of low-molecular-weight saccharides and polyhydric alcohols indicates the occurrence of selective solvation.[63] In the present instance, this implies that the hydroxy-groups of dextran are selectively solvated by water in the water–DMSO mixture. This conclusion agrees with those of an investigation[64] whose authors demonstrated the occurrence of the selective solvation of dextrans in a water–DMSO mixed solvent by gel-permeation chromatography.

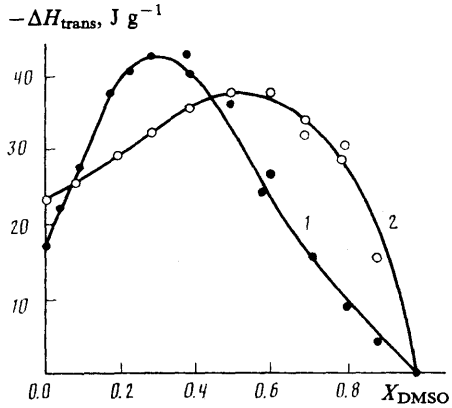

Figure 6. Enthalpies of transfer of dextran from DMSO in water–DMSO (curve *1*) and formamide–DMSO (curve *2*) mixtures at 298.15 K.

Comparison of the $\Delta H^\circ_{trans} = f(X)$ relations shows that, in contrast to the water–DMSO system, in the non-aqueous formamide–DMSO mixed solvent there is no selective solvation of the macromolecules. This is due to the difference between the

mechanisms of the formation of hydrogen bonds in the aqueous organic and composite non-aqueous solvents with dextran macromolecules.

Fig. 7 presents the dependences of the enthalpies of solution of cellulose (C), cellulose acetate (CA), cellulose diacetate (CDA), and cellulose triacetate (CTA) on the degree of substitution γ of the hydroxy-groups by acetate groups in non-aqueous individual and mixed solvents at 298.15 K. Evidently, for all the solvents investigated, there is a linear relation between the enthalpies of solution and the amount of bound acetic acid in cellulose acetates. The increase in the exothermicity of the dissolution of cellulose acetates in non-aqueous solvents with decrease in the degree of substitution is caused by the increased EDA capacity of the polymers.

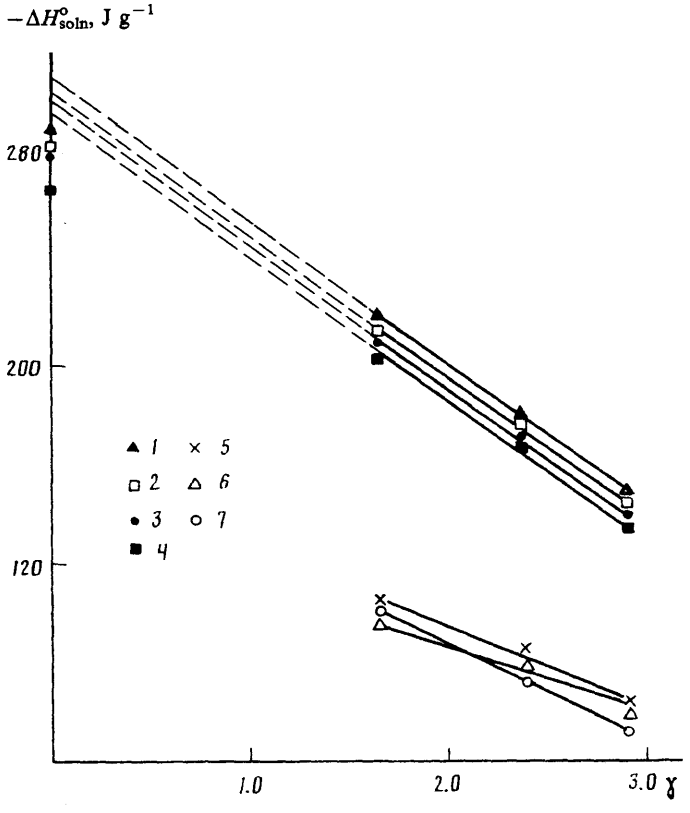

Figure 7. Dependence of the integral enthalpies of solution of cellulose, cellulose acetate, cellulose diacetate, and cellulose triacetate on the degree of substitution of hydroxy-groups by acetate groups in different solvents at 298.15 K: *1*, $CF_3COOH + C_2H_4Cl_2$; *2*, $CF_3COOH + CH_2Cl_2$; *3*, $CF_3COOH + CHCl_3$; *4*, CF_3COOH; *5*, DMSO; *6*, DMF; *7*, DMA.

In a thermochemical study of the dissolution of cellulose and its derivatives, it is essential to take into account the energy contributions associated with the fusion of the crystalline regions of the polymers (ΔH_m) and the transition of their vitreous regions to the highly elastic state under the influence of solvents (ΔH_g). The quantities ΔH_m and ΔH_g for cellulose are respectively 13.4 and 12.6 kJ mol^{-1} unit^{-1},[10] i.e. in the case of specimens with a degree of crystallinity of 0.59 the contributions of ΔH_m and ΔH_g to a large extent cancel out. In our view, the foregoing consideration can be applied also to cellulose acetate specimens. Thus the values of ΔH°_{soln} characterise mainly the specific solvation of the polymers and their absolute values are determined by the donor–acceptor properties of the solution components.

The results of the thermochemical measurements agree with data for the rotational mobility of molecular NMR-relaxation probes.[65] 1,4-Diazabicyclo[2.2.2]octane (DABO) was used in the present study as an active probe capable of competing with the solvent for the formation of hydrogen bonds with the molecules of cellulose acetates. A linear increase in the rate of spin–lattice relaxation W accompanied by a decrease in the degree of substitution γ has been found for DABO, indicating the restriction of its rotational mobility as a consequence of the formation of hydrogen bonds with the unsubstituted OH groups of cellulose acetates. Like the $\Delta H^{\circ}_{soln} = f(\gamma)$ relation, the $W = f(\gamma)$ relation constitutes proof of the formation of hydrogen-bonded complexes and of the intensification of the specific intermolecular interactions of the polymer with the solvent as the degree of substitution diminishes. The relation between the thermochemical and microdynamic properties of solutions of cellulose acetates in DMSO is illustrated by the linear correlation between ΔH°_{soln} and W (Fig. 8). On extrapolation of the linear relations between ΔH°_{soln} and the degree of substitution to zero values of the latter for solutions of cellulose acetates in trifluoroacetic acid and its mixtures with chlorinated hydrocarbons, the hypothetical enthalpies of solution of cellulose in these solvents were obtained (Fig. 7). The extrapolated and experimental values of ΔH°_{soln} are close in absolute magnitude (the difference is not more than 15 J g^{-1}). This is due to the differences between the degrees of crystallinity of specimens of wood cellulose and cellulose acetates.

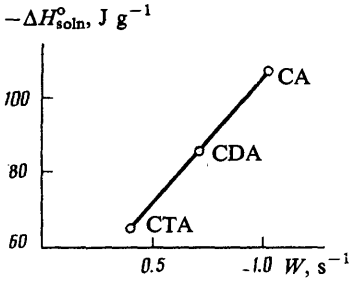

Figure 8. Dependence of the integral enthalpies of solution of cellulose acetates with different degrees of substitution on the rate of the spin–lattice relaxation of the ^{13}C nuclei in low-molecular-weight probes.

Using the literature values of the heats of fusion of cellulose[10] and the difference between the degrees of crystallinity, we estimated the endothermic contribution to ΔH°_{soln} associated with the fusion of additional regions of cellulose. It proved to be 15 J g^{-1}. Thus the validity of the linear extrapolation to the zero degree of substitution

was confirmed and the retention of this type of dependence of ΔH°_{soln} on the latter factor was demonstrated.

The amount of acetic acid bound in cellulose acetates can be determined calorimetrically on the basis of the observed dependence of the heats of solution of cellulose and its acetates in various solvents on the degree of substitution. The experimental data permit a comparative analysis of the influences of the nature and composition of the solvents on ΔH°_{soln} for cellulose acetates with a definite degree of substitution.

The addition of chlorinated hydrocarbons $C_xH_yCl_z$ to trifluoroacetic acid increases the solvent power of the mixtures in relation to cellulose and its acetates,[66] which is accompanied by an increase in the absolute values of ΔH°_{soln} in the sequence $CF_3COOH < CF_3COOH + CHCl_3 < CF_3COOH + CH_2Cl_2 < CF_3COOH + C_2H_4Cl_2$. This fact can be explained by the influence of chlorinated hydrocarbons on the self-association of the acid[67] and the formation of reactive acid monomers, which increases, in turn, the electron-accepting properties of the CF_3COOH-based mixtures in relation to the polymers.

In the series of individual solvents, an increase in the exothermicity for cellulose acetates is observed: dimethylacetamide (DMA) < dimethylformaide (DMF) < DMSO < trifluoroacetic acid. On solvation of cellulose and its derivatives, it is essential to take into account the mixed donor–acceptor capacity of the solvents.

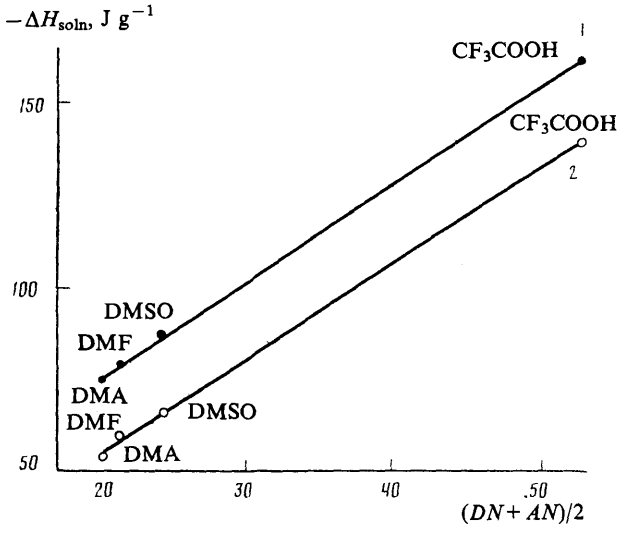

Figure 9. Dependence of the integral enthalpies of solution of cellulose diacetate (line *1*) and cellulose triacetate (line *2*) on half the sum of the donor and acceptor numbers of the individual solvents at 298.15 K.

The decisive role of specific solvation in the dissolution of the acetates is confirmed by the linear relation between ΔH°_{soln} for cellulose diacetate and triacetate and half the sum of the donor and acceptor numbers $(DN + AN)/2$ for the solvents investigated (Fig. 9). Such linear correlation makes it possible to combine the result of the determination of ΔH°_{soln} for cellulose acetates in solvents of different nature, differing significantly in their electron-donating and electron-accepting properties—ranging from the proton donating CF_3COOH to the dipolar aprotic solvents DMA, DMF, and DMSO.

We have thus shown that in dilute solutions of cellulose and its derivatives, the donor–acceptor interaction between the components is decisive. On the other hand, one can postulate that in the case of concentrated solutions of the polysaccharides it is not legitimate to relate the thermodynamic characteristics of the dissolution process to any one physicochemical parameter of the solvent. The limitations of simple correlations necessitate the application of more complex models.[68] The choice of a multiparameter model is determined by the type of the process in which particular physicochemical properties of the solvents predominate. Analysis of the available information about the structural-thermodynamic characteristics of solutions of cellulose and its derivatives[3] leads to the conclusion that the enthalpy contribution predominates over the entropy contribution. Processes of this kind are described satisfactorily by the Gutmann–Mayer and Krigovskii–Fossett models.[68] We confirmed the fruitfulness of this approach in a study of concentrated solutions of hydroxypropylcellulose in different solvents.

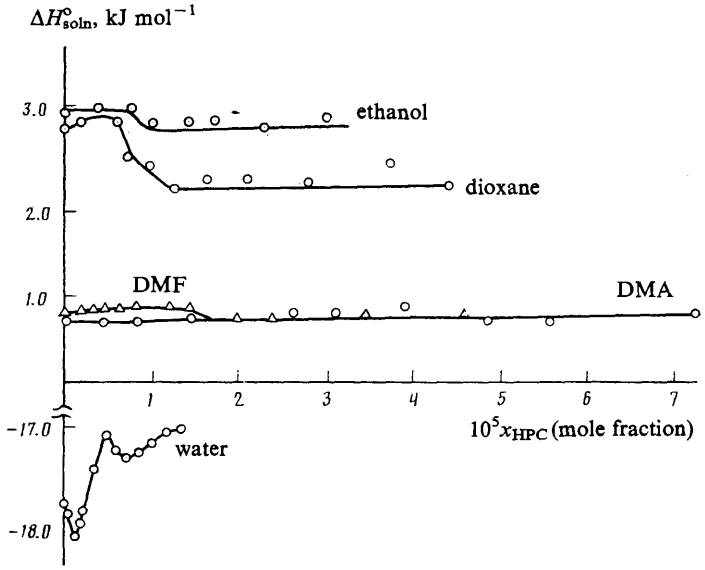

Figure 10. Dependence of the integral enthalpies of solution of DMSO in solutions of hydroxypropylcellulose on the mole fraction of hydroxypropylcellulose.

The experimental determination of the enthalpies of solution of cellulose ethers is difficult in view of the long time required for the attainment of equilibrium in dissolution processes. In order to find the thermochemical parameters of the solvation of hydroxypropylcellulose (HPC) and other cellulose ethers, it appears useful to introduce into the binary polymer–solvent system a third component—a liquid non-electrolyte—as a "probe" for solvation processes. Such a methodological procedure is extremely fruitful in the study of solvation processes in liquids.

We determined the enthalpies of solution of DMSO in solutions of hydroxypropylcellulose in water, ethanol, DMA, DMF, and dioxane (DO). The results of the thermochemical studies are presented in Fig. 10. Evidently the concentration of hydroxypropylcellulose does not exert a significant influence on ΔH°_{soln} for DMSO in the HPC–DMA and HPC–DMF systems. On the other hand, the influence of the hydroxypropylcellulose concentration on the enthalpy of solution of DMSO in water and certain non-aqueous solvents (dioxane and ethanol) is clearly manifested. Furthermore, the increase in ΔH°_{soln} for DMSO can be seen in the series of solvents water < DMA < DMF < DO < ethanol.

The enthalpies of solution of DMSO in ethanol, DMA, and DMF were determined for the first time. The enthalpies ΔH°_{soln} for DMSO in water and dioxane agree well with the literature values.[61,69]

The enthalpies of solution of DMSO in aqueous solutions of hydroxypropylcellulose are exothermic, while in non-aqueous solutions they are endothermic. These results can be explained from the standpoint of the donor–acceptor properties of the solvents.

It is known that the mixing of two electron-donating liquids is accompanied by an endothermic effect.[70] A similar effect occurs on mixing DMSO with ethanol. This phenomenon can be accounted for by a change in the electron-donating capacity of ethanol in the associated state, which is indicated by the donor numbers: DN_{SbCl_5} = 18.5,[68] DN_{bulk} = 27.8 according to Marcus,[71] and DN_{bulk} = 32 according to Gutmann.[71]

The first stage in the study of the characteristic features of solvation in the solvent (I)–solvent (II)–polymer systems was the determination of ΔH°_{soln} for DMSO (solvent I) in the individual solvents II. On passing from DMSO–solvent II mixtures to the hydroxypropylcellulose–solvent II systems, the values of ΔH°_{soln} for DMSO change owing to polymer solvation processes in the solution. It is known that,[57] when the concentrations of cellulose and its ethers are greater than 1 wt.%, the polymer molecules interact with formation of a fluctuating network of hydrogen bonds. In our case, this is manifested in the range of hydroxypropylcellulose concentrations in the solutions $X_{HPC} > 125 \times 10^{-7}$ (mole fraction), while the enthalpy of solution of DMSO does not change with increase in the polymer concentration.

The extremum in the $\Delta H^{\circ}_{soln} = f(X_{HPC})$ relation is probably associated with the change in the structure of the solutions. The increase in the exothermicity of the dissolution of DMSO in an aqueous HPC solution for a mole fraction of 7.5×10^{-7} is a result of the disruptive effect of polymer molecules on the water structure. A further increase in the hydroxypropylcellulose concentration leads to the stabilisation of the aqueous solutions.[72] In the region of the concentrations corresponding to the second minimum, several factors are superimposed: the simultaneous strengthening of the intermolecular hydrogen bonds between the molecules of the dissolved polymer and the transolvation of the dissolved hyroxypropylcellulose molecules by water molecules induced by this factor. The general trend towards a decrease in the exothermicity of the interaction with DMSO with increase in the hydroxypropylcellulose concentration in the aqueous solution is probably associated with the stabilisation of the structure of the solution as a result of the formation of cooperative HPC–HPC and HPC–water hydrogen bonds.

In non-aqueous solutions for X_{HPC} up to a mole fraction of 125×10^{-7}, ΔH°_{soln} for DMSO remains constant within the limits of experimental error. Bearing in mind that ethanol, dioxane, DMF, and DMA are associated liquids, one can postulate the retention of the primary structure of the solvent after the introduction of small amounts of added polymer.

The enthalpies of the transfer of the test substance from one solvent to another can be conveniently used as a thermochemical characteristic of the solvation of atomic-molecular species in a series of individual solvents. We used the enthalpies of transfer (ΔH°_{trans}) of DMSO from an individual solvent to a concentrated polymer solution as thermochemical characteristics sensitive to solvation processes. Fig. 11 presents the dependence of ΔH°_{trans} on the ratio of the donor and acceptor numbers of the solvents. The relation is non-linear with a minimum in the exothermicity of the enthalpies of transfer of DMSO corresponding to the region of equal donor and acceptor numbers (DN/AN = 1).

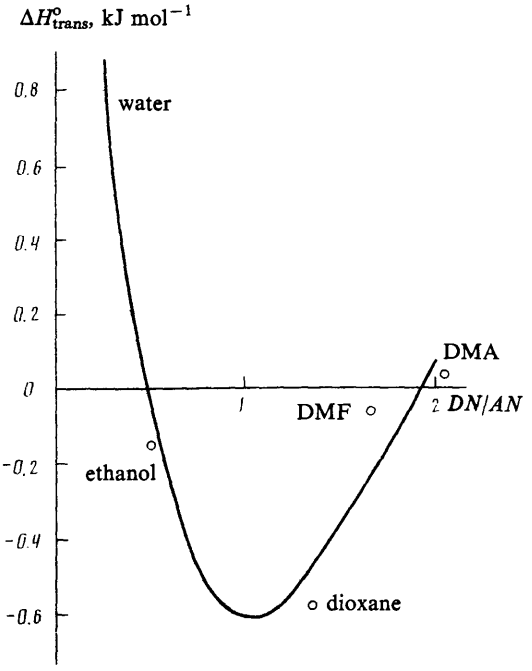

Figure 11. Dependence of the enthalpies of transfer of DMSO from the individual solvents to concentrated solutions of hydroxypropylcellulose on the ratio of the donor and acceptor numbers of the solvents.

In order to establish the relation between the phyisochemical properties of the solvents and the experimental thermochemical parameters [ΔH°_{soln} for DMSO, and the enthalpy of the transfer of the latter (ΔH°_{trans}) from the solvent to hydroxypropylcellulose solutions], methods of mathematical statistics were employed. The calculations were performed on an EC 1060 computer. The parameters of the solvents for such analysis are presented in Table 4. Pair and multiple regression analyses of ΔH°_{trans}, $\Delta H^{\circ}_{trans}/\Delta^{\circ}_{soln}$, and the physicochemical properties of the solvents were carried out.

The results of the calculation of the coefficients of the pair correlation of ΔH°_{trans} and $\Delta H^{\circ}_{trans}/\Delta H^{\circ}_{soln}$, on the one hand, and the properties of the solvents, on the other, are presented in Table 5.

Table 4. Physicochemical parameters of the solvents.

Parameter	Water	Ethanol	DMA	DMF	1,4-Dioxane	References

Note. The following parameters of the solvents are listed: the polarisability $(n^2 - 1)/(n^2 + 2)$, the polarity $(\varepsilon - 1)/(2\varepsilon + 1)$, the basicity B, the Richardt–Dimroth electrophilicity parameter E_T, the Kosower electrophilicity parameter Z, the Kamlet–Taft dipolarity parameter π^*, the dielectric constant ε, the dipole moment μ, the molar volume $\overline{V}$, the density ρ, the three-dimensional solubility parameter δ, and the Hildenbrandt parameter.

Table 5. Coefficients of the pair correlations of ΔH°_{trans} and $\Delta H^\circ_{trans}/\Delta H^\circ_{soln}$ with the physicochemical properties of the solvents.

Solvent parameter	$r\Delta H^\circ_{trans}$	$r\Delta H^\circ_{trans}/\Delta H^\circ_{soln}$
$(DN+AN)/2$	0.70	0.61
δ	0.74	0.53
$\overline{V}$	−0.63	−0.46
μ	0.32	0.47
ε	0.90	0.66
π^*	0.65	0.59
Z	0.68	0.52
E_T	0.71	0.59

Comparison of the correlations of ΔH°_{trans} and $\Delta H^\circ_{trans}/\Delta H^\circ_{soln}$ makes evident the advantages of using absolute rather than relative heats of transfer for the estimation of the influence of the solvent. The most significant parameters influencing ΔH°_{trans} are the dielectric constant, the Hildebrandt parameters, the Richardt–Dimroth electrophilicity parameter, and the sum of the donor and acceptor numbers of the solvents. The regression coefficients decrease in the above series from 0.9 to 0.7. Since there is a high degree of correlation between ΔH°_{trans} and ε, it is useful to employ a linear regression model of the type

$$\Delta H^\circ_{trans} = A + B\varepsilon, \qquad (7)$$

The coefficients of this model are presented in Table 6.

Table 6. Experimental and calculated heats of transfer of DMSO from the solvent to the hydroxypropylcellulose solution (kJ mol^{-1}) obtained with the aid of the linear model (7) and by fitting the multiple agreesion equation (8).

Solvent	ΔH°_{trans} (experiment)	ΔH°_{trans} [calc. by Eqn. (7)]	ΔH°_{trans} (expt)−ΔH°_{trans} [calc. by Eqn. (7)]	ΔH°_{trans} [calc. by Eqn. (8)]	ΔH°_{trans} (expt)−ΔH°_{trans} [calc. by Eqn. (8)]
Water	0.870	0.825	0.045	0.874	−0.004
Ethanol	−0.164	−0.196	0.032	−0.168	0.004
DMA	0.021	0.046	−0.025	−0.003	0.024
DMF	−0.069	0.025	−0.094	−0.050	−0.019
1,4-Dioxane	−0.596	−0.638	0.042	−0.591	−0.005

Note. The following parameters were adopted in the calculation by Eqn. (7): $A = -0.6809 \pm 0.0669$ and $R = 0.01924 \pm 0.00153$; the following parameters were adopted in the calculation by Eqn. (8): $A_0 = 0.1953 \pm 0.0396$, $A_1 = 0.6517 \pm 0.0446$, $A_2 = 0.7687 \pm 0.2491$, and $A_3 = -0.6753 \pm 0.2517$.

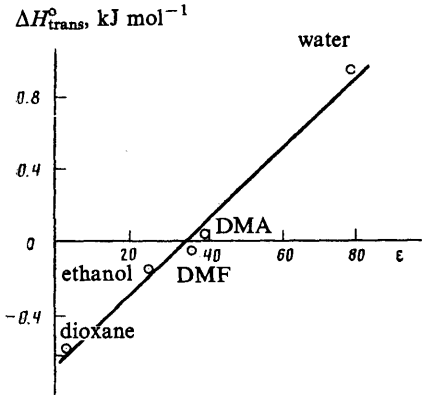

Figure 12. Dependence of ΔH°_{trans} on the dielectric constants of the solvents.

Comparison of the results of the calculation with experimental data shows that the absolute error in the fitting of Eqn. (7) is not more than 0.094 kJ mol^{-1}. The criterion of the linear fit F, defined as the ratio of the variance of the average value of ΔH°_{trans} to the variance of the calculated values, is 39.9. It characterises the quality of the proposed model (Fig. 12). Since a decrease in the pair correlation coefficients is observed for other physicochemical parameters (Table 5), they cannot be used to construct a one-parameter linear model similar to that defined by Eqn. (7). In constructing models with the aid of multiple regression, singular analysis of an undefined system of equations,[77] and computer methods, the following best fit was obtained:

$$\Delta H^\circ_{trans} = A_0 + A_1X_1 + A_2X_2 + A_3X_3,$$
$$X_1 = \frac{\varepsilon-40}{38}, \quad X_2 = \frac{E_T-50}{74}, \quad X_3 = \frac{(DN+AN)/2-24}{12}. \qquad (8)$$

The coefficients of this equation, the results of the calculation, and the experimental data are presented in Table 6. The criterion F is 292 and the error of the calculation does not exceed 0.024, which indicates a high accuracy of the multiparameter fit. All the coefficients of Eqn. (8) are significant at a level of fiducial probability exceeding 95% (Fig. 13).

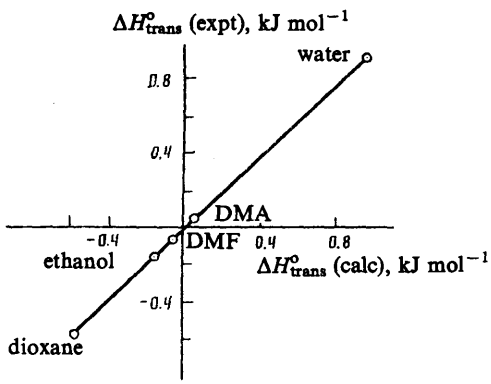

Figure 13. Experimental and calculated [by Eqn. (8)] enthalpies of transfer of DMSO from the solvent to the hydroxy propylcellulose solution.

The model developed is analogous to the Krigovskii–Fossett model,[68] which is applicable to the description of the influence of the solvent on the thermodynamics of solvation processes characterised by a significant contribution of the enthalpy factor.

Analysis of the significance of the coefficients of Eqn. (8) shows that the most significant contribution to the enthalpy characteristic of the solvation of DMSO in the hydroxypropylcellulose–solvent I–solvent II system is determined by the dielectric properties of the non-aqueous solvents. This agrees with the data of Solomonov et al.,[78] indicating a significant contribution of non-specific solvation to the enthalpies of solvation of organic non-electrolytes.

The characteristic features of the proposed model are determined by the necessity to take into account the combination of the donor and acceptor numbers of the non-aqueous solvents under the conditions of the specific solvation of the hydroxy-groups in the cellulose macromolecules (which have both electron-donating and electron-accepting properties).

With the aim of further development of the proposed approach to the study of concentrated solutions of cellulose derivatives, we measured the enthalpies of solution of poly(ethylene glycol) (a high-molecular-weight probe) with $M = 400 \pm 20$ in solutions of cellulose acetates with different degrees of substitution in DMSO. The results of the thermochemical measurements are presented in Fig. 14. The dissolution of poly(ethylene glycol) in the test systems is characterised by negative values of ΔH°_{soln}. Analysis of the observed concentration variations of the enthalpies of solution reveals their varied character. For solutions of cellulose acetates with $\gamma = 0.63$, there is virtually no dependence of ΔH°_{soln} for poly(ethylene glycol) on the cellulose acetate concentration in solution. In the case of individual cellulose acetates, the exothermicity of the dissolution of poly(ethylene glycol) increases in the range of concentrations from 1 to 2 wt.%, which indicates the occurrence of the poly(ethylene glycol)–cellulose acetate interaction.

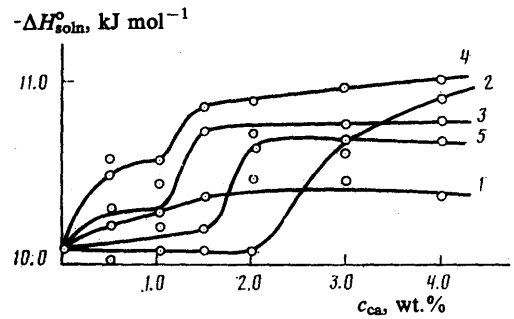

Figure 14. Dependence of the enthalpies of solution of poly(ethylene glycol) in solutions of cellulose acetate with different degrees of substitution γ in DMSO on the polymer concentration (c_{CA}, wt.%): *1*, 0.63; *2*, 0.96; *3*, 1.55; *4*, 2.43; *5*, 2.90.

Fig. 15 illustrates the dependence of the initial concentration at which the absolute values of ΔH°_{soln} for poly(ethylene glycol) increase in solutions of cellulose acetate on the degree of substitution γ. This dependence clearly illustrates the tendency towards a decrease in c_{init} with increase in γ for cellulose acetate, which is apparently due to the formation of a fluctuation network of intramolecular and intermolecular bonds in cellulose acetate.[3]

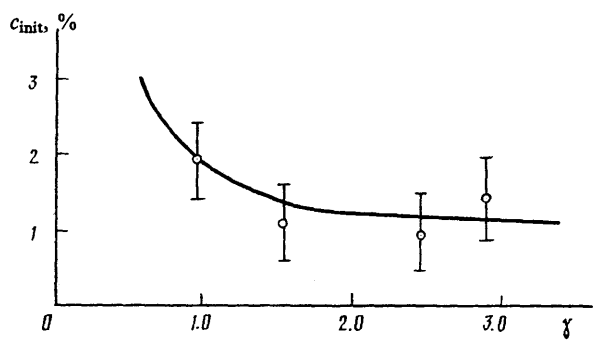

Figure 15. Dependence of the initial concentration corresponding to the onset of the change in ΔH°_{soln} for poly(ethylene glycol) in solutions of cellulose acetates on the degree of substitution.

Fig. 16 presents the dependence of the enthalpies of transfer of poly(ethylene glycol) from DMSO to a cellulose acetate solution at the initial concentration c_{init} on the degree of substitution γ. In the range $0.6 < \gamma < 1.0$, an abrupt increase in the exothermicity of the

transfer process is observed, which is associated with the intensification of the poly(ethylene glycol)–cellulose acetate intermolecular interactions. For $\gamma \geqslant 1.0$, the absolute values of ΔH°_{trans} for poly(ethylene glycol) hardly depend on the degree of substitution. The similarity of the values of ΔH°_{trans} for poly(ethylene glycol) in terms of absolute magnitude in solutions of cellulose acetate indicates the insignificant influence of the degree of substitution of the hydroxy-groups of cellulose by acetate groups on the poly(ethylene glycol)–cellulose ether interaction. For cellulose acetate with $\gamma \geqslant 0.63$, the poly(ethylene glycol)–cellulose acetate interaction is hindered. One of the possible causes of this is, in our view, the enhancement of the solvation of the cellulose acetate macromolecules with increase in the number of unsubstituted OH groups in the polymer.

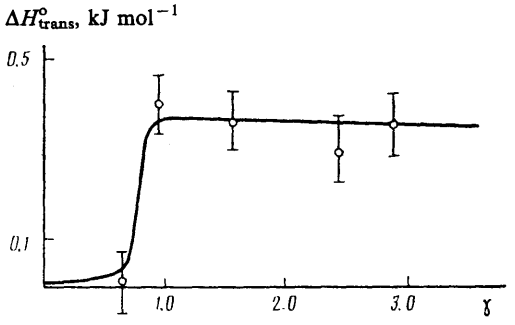

Figure 16. Dependence of the enthalpy of transfer of poly(ethylene glycol) from DMSO to a solution of cellulose acetates at the initial concentration c_{init} on the degree of substitution γ.

Thus the experimental enthalpy of solution data presented make it possible to consider the thermochemical characteristics of non-aqueous solutions of cellulose and its derivatives from a single standpoint based on the allowance for the EDA capacity of the polymer and the solvent and also to discover the principal characteristics of the influence of the physicochemical properties of the solvents on the enthalpies of transfer of the probes in concentrated solutions of cellulose ethers.

The chemistry of processes which create dielectric layers with functional group substituents on semiconductors by impurity thermo-oxidation

I Ya Mittova, V R Pshestanchik
The University, Voronezh

ABSTRACT. Processes are examined which involve the growth of film layers with dielectric properties on the surfaces of semiconductors during thermo-oxidation in the presence of impurity compounds specially introduced into the system. It is shown in relation to the thermo-oxidation of silicon and gallium arsenide that impurities influence significantly the kinetics and mechanism of the formation of dielectric oxide layers, accelerating the process, lowering the duration of the high-temperature treatment, and altering within wide limits the composition and properties of the resulting films. The rules governing processes involving the impurity thermo-oxidation of semiconductors, determined by the class of impurity compounds introduced, were discovered. The principal criteria governing the selection of the impurities influencing specifically the oxidation process are discussed, the methods for their introduction into the system are examined, and the experimental results concerning the kinetics and mechanisms of such processes are analysed.

The bibliography includes 90 references.

I. Introduction

Thin films are used in various branches of modern technology: microelectronics, optoelectronics, laser techniques, etc. This has given rise to a new flow of information about various aspects of the creation of thin-film materials, their structure and properties, the conditions governing their preparation, and the possibility of their practical application. The development of such research has been assisted to a considerable degree by the creation of modern powerful physical instrumental methods such as electronic Auger spectroscopy (EAS), X-ray electron spectroscopy (XES) and mass spectrometric analytical methods (MSAM), including local X-ray spectroscopic micro-analysis (LXSMA), infrared spectroscopy (IRS), secondary ion mass spectrometry (SIMS), X-ray spectroscopic analysis (XSA), and other electronic-probe and optical methods. The development of studies in the field of thin films has appreciably stimulated the development of new accurate physical methods for the monitoring of the composition, structures, and properties of materials. The study of processes leading to the formation of thin films with a wide variety of properties on the surfaces of solids has greatly promoted the development of ideas about the kinetics and mechanisms of heterogeneous reactions of the solid–gas and solid–solid types.

In the investigation of the kinetics and mechanism of the formation of thin oxide films on the surfaces of solids, it was established that phenomena involving the mass transfer (diffusion and electromigration) of species through a growing film play an appreciable role in these processes. In this connection, "physical" models of the growth of films appeared, in which stress is laid on the elucidation of the nature of the diffusing species and the determination of the rate and mechanism of the mass transfer. However, the chemical aspect of the problem—the role of the chemical interaction of the components in the formation and growth of thin films—has been to some extent neglected in such research. Nevertheless, on the basis of one of the key ideas in modern chemistry, namely the dependence of the composition and properties of substances on the conditions governing their preparation and the nature of the chemical bond in them, one can solve the main problem in this science, i.e. that of the creation of new materials with specified properties.

The establishment of correlations (and ultimately of causal links) between the preparation conditions (the process conditions and process kinetics and mechanism) and the composition and properties of thin films and heterogeneous thin film structures makes it possible not only to expand the ideas concerning the chemistry of the processes but also to obtain materials with a wide range of properties. In the creation of dielectric films on the surfaces of semiconductors during their thermo-oxidation, one of the methods for the solution of this problem involves the introduction into the oxidation atmosphere or onto the surface of the support of specific specially selected impurities which, by exerting a radical influence on the kinetics and mechanism of the film growth process, can ultimately alter the composition and properties of the films in the required direction. This method can be referred to as the impurity thermo-oxidation of semiconductors. It was found that the role of the impurities introduced is unusual and that it is extremely important for it is determined not only (and not largely) by their concentration but also by their nature, i.e. one can speak of a specific effect of various impurities. This effect consists primarily in the alteration of the nature of the chemical reactions responsible for film growth, but the incorporation of impurities in the layer formed naturally influences also the kinetics of the mass transfer of the oxidant in it. Certain general rules governing the impurity thermo-oxidation processes, which were found to be universal and permitted the use of a simple approach to the creation of dielectric layers and

various semiconducting materials, were discovered and formulated in the course of the study.

Investigation of the impurity thermo-oxidation processes is based on the combination of formal kinetic studies and modern instrumental physical and physicochemical methods, which permit an unambiguous establishment of the composition of the reaction products formed, of the distribution of the components within the thickness of the layer, and of the change in the composition and structure of the layers and supports, and hence one can obtain comprehensive information about the dependence of the film composition on the formation conditions and the process kinetics and mechanisms. The application of chemical etching methods and the study of voltage–capacitance and dynamic voltage–current characteristics make it possible to establish the relation between the metal/dielectric surface structures (MDS) based on them (electrical strength, mobility of charge carriers, density of surface states, effective surface and space charges, etc.).

II. Oxidation of silicon under the influence of impurity compounds

Silicon is so far the main material in the technology of semiconductor devices and integrated circuits (IS), while SiO_2 possesses a unique combination of physicochemical and dielectric properties which gives rise to its wide scale application in microelectronics as a universal multifunctional dielectric. The formation of heterogeneous Si/SiO_2 structures can serve as a model process in the chemistry of heterogeneous reactions by virtue of the following factors:

1. The highly symmetrical structure of silicon permitting a comparatively simple modelling of the oxidation process at the atomic level.

2. The high degree of stoichiometry of SiO_2 and hence its satisfactory reproducibility with different conditions in its preparation.

3. The tendency of SiO_2 to form glasses, which rules out side effects such as the diffusion of the oxidant via intercrystallite boundaries, the segregation of impurities, etc.

4. The absence of a flux of atoms from the support to the film; as a result the oxidation proper takes place only on the moving internal interface and the silicon atoms not linked to oxygen (sometimes detected in the film).[1] This arises owing to its rapid movement and "toppling" within the support. On the other hand, when layers are deposited, the increment in thickness is ensured by the movement of exclusively the outer interface, while the support influences only the initial stages of the process (adsorption and nucleus formation). In subsequent stages, its nature does not have an effect, which permits the construction of universal models.

5. A fairly high degree of ideality of the silicon/dielectric interface and the small thickness of the transition layer. These make possible the application of the "sharp transition" model to the Si/SiO_2 heterostructure.[2]

6. The thermal silicon oxide on silicon, grown under "clean" conditions, is a kind of reference standard against which the oxide layers obtained by any other method are compared.

The thermo-oxidation of silicon itself is described by the fairly simple model of Deal and Grove[3] and also by revised models,[4–13] which yield similar kinetic equations. According to general ideas, at high temperatures film growth on a surface coated by a natural oxide ($\sim$3 nm) initially obeys a linear law where the rate-limiting stage is assumed to be the chemical reaction at the Si/SiO_2 interface. Consequently the layer of natural oxides hardly constitutes a barrier to the diffusion of oxidant species. With increase in the thickness of the natural oxide film, its barrier functions become more marked and the rates of reaction and diffusion become comparable, which corresponds to a linear-parabolic oxidation regime. Subsequently diffusion becomes the limiting factor and parabolic oxidation takes place.

However, purely mathematical difficulties, associated with the determination of the contribution of the surface reaction and diffusion to the overall process, arise even in such description. As a result of this, the effective activation energy (EAE) is assumed to be an integral characteristic of the entire process. On the other hand, the hypothesis of an abrupt change to diffusional control of the reaction is a fairly rough approximation, because under real conditions the transition from one type of control to another takes place continuously and gradually. A formal model, reflecting this gradual transition and making it possible to determine the range of temperatures and times corresponding to the change in the controlling stage and the contribution of each component within the limits of these ranges, has been proposed.[14]

Yet another problem is to incorporate as completely as possible the factors influencing the above process components. These are the nature of the diffusing species, the field and deformation stresses near the interface and in the bulk of the oxide, the generation of defects in the course of the oxidation, the influence of the degree of doping of the support, etc. Such factors have been taken into account most fully in Tiller's studies.[10–13] The establishment of the types of all the diffusing species responsible for the growth of the thickness of the layer is important.

Since fluxes of both neutral and charged oxidant species occur in the film,[8,15] it is legitimate to consider a general case—mixed diffusion and electromigration. However, such study sometimes leads to cumbersome expressions even for the oxidation of silicon itself,[16] which are relatively unsuitable for more complex processes. Despite the allowance for varying numbers of factors in different studies, the final equations describe in the general case the linear-parabolic oxidation and differ only in their coefficients.

The opposite approach proved to be extremely productive: it involves the formal kinetic description of the process on the basis of a formalised kinetic equation generalised to the maximum extent:

$$d=k^n\tau^n, \qquad (1)$$

where d is the thickness of the layer, τ the duration of its formation process, and k the integral process rate constant.

This equation does not take into account the specific mechanisms of the individual stages and characterises the process as a whole. For the oxidation of silicon itself, the exponent n varies in the range 1–0.5, reflecting the gradual transition to the diffusional control of the reaction. This relation makes it possible to describe any new layer formation processes on any supports and to carry out a comparative formal kinetic analysis.

The need to search for new dielectric layer formation processes on silicon is not at first sight dictated by practical requirements, since silicon oxide itself in general satisfies the requirements of the technology of semiconductor devices and integrated circuits. However, on passing to a flexible technology, it becomes evident that, instead of a universal multipurpose dielectric, it is in many cases useful to employ layers with properties modified for a particular purpose. The problem of reducing the duration of the

high-temperature treatment of supports and heterostructures, which makes it possible to reduce the diffusional "spreading" of the elements of the integrated circuit, remains no less timely.

The first studies on the oxidation of highly doped silicon[17,18] already demonstrated the dependence of the kinetics of the growth of films on the level of doping. Naturally, the process mechanism and hence also the properties of the films change under these conditions. Systematic study of the oxidation of diffusionally and ionically doped supports[19–29] led to the discovery of the influence of impurities in an elemental state on the kinetics and mechanism of the oxidation process and the properties and composition of the oxide layers.

Overall, the kinetic relations for the thermo-oxidation of both diffusionally and ionically doped supports are similar to the familiar relations for the weakly doped reference silicon. In all cases, the oxidation proceeds either in the linear-parabolic or the parabolic regime but its rate changes consistently: $v_{ref} < v_d < v_i$ (the subscripts ref, d, and i refer respectively to the reference process and to diffusionally and ionically doped layers of silicon). The acceleration of the process in the last two cases (by a factor of 1.5–3) promotes also the more rapid transition from the linear-parabolic to parabolic oxidation, compared with the reference standard.

The change in mechanism is manifested particularly distinctly in the oxidation in the H_2O (vapour) + O_2 mixture, where regular layers are formed in very short time intervals. Compared with ion implantation, diffusional doping does not induce appreciable disturbances in the structure of the support and one can therefore assume that the acceleration of the process is caused in this case mainly by the influence of the impurities, while in the case of ionic doping it is caused by the combined influence of the impurity and radiation defects. However, it has been established[25] that the nature of the impurity itself exerts the main influence on the rate of the process and that radiation defects are an accelerating factor only in the initial instant of the oxidation. The implantation in silicon of a chemically neutral impurity (Ar^+) hardly alters the rate of its oxidation compared with the reference standard as a consequence of the rapid annealing of the radiation defects. Furthermore, on double implantation ($Ar^+ + As^+$ or $Ar^+ + Sb^+$) the overall concentration of radiation defects is higher than in ionic doping by only one active impurity, but the rate of the process is a maximum for singly implantation.

In the cases considered, the role of the impurity reduces to the transfer of oxygen from its oxidised forms to silicon and the process is faster than the direct oxidation of the support. Interactions of the type

$$2E_xO_y + ySi = ySiO_2 + 2xE \qquad (2)$$

have been called transit interactions.[30,31] In the oxidation of doped silicon, they are most significant at low temperatures and for short process times, where the contribution of the reaction component is high and the surface concentration of the impurity is a maximum.

The similarity of the kinetics of the above processes and of the reference process is confirmed by the similarity of the exponents in the kinetic equation (1) and of the effective activation energies. There is an analogy in the process mechanisms; the increase in the complexity of the mechanism on passing from reference supports to doped and implanted supports consist only in the appearance of the parallel transit oxidation with participation of the impurity. The flux of oxidant species diffusing across the film on the inner interface (or in its vicinity) is "divided" into two: the first interacts directly with the support, whilst the second interacts via the initial oxidation of the impurity with subsequent transfer of oxygen to silicon.

The similarity of the kinetics and mechanisms of the oxidation of doped and reference supports leads to a similarity of the compositions and properties of the films obtained. They consist of virtually pure SiO_2 slightly doped by the corresponding impurity (~1–3 at.%; XSA, EAS), whose physical characteristics are also similar to those of the reference standard.

The characteristic features of the growth of films in these processes are associated with the physicochemical nature of the impurity. Thus the influence of the electron-donating and electron-accepting impurities implanted in silicon on the nature of the time variation of the process is different. Electron-donating impurities (phosphorus, arsenic, antimony) accelerate the growth of films predominantly in the initial stage, i.e. they influence mainly the reaction component. An electron-accepting impurity (boron) gives rise to a relative stability of the acceleration of the process and of the effective activation energies, which can be explained by the value of the partition coefficient of boron between silicon and SiO_2 [9] and by the possibility of not only the reaction component but also the diffusion component of the process being acted upon. This also accounts for the continuous variation of the parabolic oxidation rate constant (calculated on the basis of the model of Deal and Grove[3]) with temperature, the linear dependence of the oxidation rate on the concentration of the incorporated impurity at all stages of the process, and the difference between the kinetics of etching of the grown oxide layers compared with those for the reference standard.

The observed acceleration of the process cannot be attributed to the catalytic effect, because the latter presupposes a decrease in activation energy together with an increase in the rate. On the other hand, in the cases considered an appreciable decrease in the activation energy was not observed.

Thus the chemical effect of the impurity (the transfer of oxygen to silicon as a result of the transit interaction) plays a decisive role in the acceleration of the thermal oxidation of silicon. The impurity was introduced in the elemental form, which in fact made it possible to discover the influence of a specific element on the kinetics and mechanism of the oxidation reaction. One of the criteria governing the selection of the accelerating impurity element is the possibility of the spontaneous occurrence of the transit interaction (2), which can be assessed thermodynamically.[32] At the same time, it is necessary to take into account also the probability of other reactions competing with the transit interaction. For example, thermodynamic calculation has shown[30] that the oxides of a series of transition metals are capable of transferring oxygen to silicon. However, the metal segregated under these conditions forms silicides with the support as a result of which the reoxidation of the metal with renewal of transit is impossible. On the other hand, the introduction of the same metal directly into the support immediately leads to the formation of silicide phases. It is for this very reason that, despite the fact that the typical oxidation catalysts are in fact certain transition metals and their oxides, in the given instance it is hardly possible to identify the catalytic effect. For this reason, the results of a number of studies[33,34] in which a strong catalytic action of transition metals (Pt, Pd, etc.) was allegedly noted, are susceptible also to another interpretation: the formation of silicide phases and the breakdown of the laminarity of the flow when silicon is in close contact with the metallic needle.

The use of impurities in the form of binary compounds is more fruitful, because we then have the possibility of the action of both components of the impurity—the cation- and anion-forming agents—on the kinetics and mehanism of the process, and their effects can be not only independent but also cooperative. By selecting different classes of compounds with the same cation-forming agent (or anion-forming agent), it is possible to discover the general features characteristic of the given class as well as the characteristic features determined by each component of the impurity separately, which permits the modification of the properties of SiO_2 in several ways at once. Oxides participate in the transit interaction and when they are used as impurities it is possible to obtain a kind of reference standard for the elucidation of the role of the anion. Furthermore, the oxygen anion is one of the few species whereby the impurity can be introduced into the system in two ways: via the gas phase (unlimited source of impurity) and by deposition on the oxidisable surface of a layer whose thickness can be regulated (limited source). This is necessary to elucidate the influence of the method of introduction of the impurity into the system on the kinetics and mechanism of the growth of layers.

It has been established that, when oxides are introduced into the system, the transit interaction in a pure form determines the acceleration of the process only in those cases where the impurity oxide is indifferent with respect to the growing SiO_2 layer. Thus oxidation in the presence of Ga_2O_3 and In_2O_3 [35] is characterised by virtually the same kinetic parameters as the processes on the reference silicon or slightly doped silicon ($n = 0.5-1$, similar effective activation energies and similar acceleration of the process compared with the reference standards). The composition of the layer approaches that of SiO_2 (IRS, XSA), but the inclusion of a certain amount of gallium (indium) in the films has a positive effect on their electrophysical characteristics.[36]

If the impurity oxide is miscible and is capable of forming vitreous layers, i. e.

$$mE_xO_y + nSiO_2 = mE_xO_y \cdot nSiO_2, \quad (3)$$

then the kinetics differ sharply from those for the reference standard and for the purely transition processes. Thus, when the oxides B_2O_3, PbO, Sb_2O_3, and Bi_2O_3 are introduced into the gas phase,[37–40] the acceleration is by a factor of 50–600. As a rule, the effective activation energies are high (reaching 950 kJ mol^{-1}) and the values of n can be both smaller than 0.5 (0.3) and greater than 1 (up to 2.16). The latter is due to reactions which lead to an increase in the thickness of the layer both on the inner and outer interfaces. The layers obtained are silicate glasses of different elements (IRS, XSA, LXSMA). In the vicinity of the inner interface, impurities (B, Pb, Sb, Bi) were detected, which confirms the occurrence of the transit reaction (2).

Thus two parallel processes—transit and vitrification—contribute to the accelerated increase in the thickness of the film. Whereas in the reference oxidation or oxidation of highly doped specimens, it was possible in the first instance to identify a sequence of stages and in the second to ignore the oxidation itself, considering only the accelerating factor (diffusion of the oxidant–transit–oxidation of the impurity element–renewal of transit), in the presence of two parallel accelerating processes, each of which proceeds via a series of consecutive stages, it is necessary to introduce the concept of the determining process.[41] This is the fastest of the parallel processes which makes the greatest contribution to the increment in the thickness of the layer. The latter addition is significant, since the fastest of the parallel processes may have no bearing on the increment in the thickness and as regards kinetics it will not be determining [for example, the diffusion of the element produced by reaction (2) into the support or the film]. Since the determining process is a multistage one, it is useful to identify the rate-limiting stage in it as the slowest in this sequence.

Clearly the determining process in oxidation with participation of impurities is either the transit reaction (oxidation of highly doped silicon; after the introduction of Ga_2O_3 and In_2O_3) or vitrification (in the presence of B_2O_3, PbO, Sb_2O_3, Bi_2O_3). The transit reaction is always limited by the diffusion of the oxidant [either O_2, or H_2O (vapour), or E_xO_y] to the inner interface via a film whose properties are similar to those of SiO_2. In the determining vitrification process, the rate-limiting stage is also the mass transfer of E_xO_y. However, here this proceeds not via SiO_2 but via a silicate glass of the given element having a less ordered and looser structure, which greatly accelerates the rate of transfer. Furthermore, in the experimental temperature range certain impurity oxides (PbO, Bi_2O_3) may be in the fused state, which also facilitates the mass transfer of E_xO_y.

The method used to introduce the oxide into the system without affecting significantly the process mechanism (the number of stages, their nature, and their sequence) greatly influences the rate of increase in the thickness of the layer (and hence also the kinetic characteristics). Evidently, in the oxidation of Si/E_xO_y structures with a layer of oxide deposited on the surface both the determining process and its rate-limiting stage are the same as in the previous case. The characteristic features of the procedure are as follows: (1) the transit interaction develops already in the initial instant at a high surface concentration of the impurity at the silicon/oxide interface generated; (2) the latter factor ensures an intense transit reaction with overlap of the local superheating fields;[42] (3) the mutual diffusion of the components in the vitrification process through the dense impurity oxide layer formed beforehand is hindered compared with mass transfer through the loose silicate film of the given element formed during the introduction of the impurity through the gas phase; (4) apart from the parallel consecutive process considered, which ultimately promotes an increase in the thickness of the resulting film, it is essential to take into account the competing process involving the evaporation of the deposited impurity film and leading to a decrease in its thickness. As a consequence of these causes, exponents $n < 0.5$ as well as somewhat reduced effective activation energies are characteristic of oxidation reactions of the Si/E_xO_y heterostructures.

Thus, when the reaction leading to the mutual dissolution of the oxides (vitrification) is possible, it in fact ensures the main increment in the mass of the film and is the determining process on which depends also the composition of the resulting layers. The possibility or impossibility of the transit reaction and of vitrification are determined primarily by the nature of the cation-forming element.

The method of introduction of the impurity into the system is as a rule dictated by the type of the anion-forming impurity element. The sulphides of Group IIIA–VA elements can be usefully deposited directly on the oxidisable silicon surface, because the evaporation of these compounds at the high temperatures (and in an oxygen medium) used in the growing of the films, is impossible without decomposition and chemical reaction. In other words, it is useful to create a limited source of the impurity.

The rate of increase in the thickness of the layers in the thermo-oxidation of Si/E_xS_y is the same as for Si/E_xO_y; the exponents n are less than 0.5 (0.12–0.40) and as a rule decrease in the course of time (to 0.05); the effective activation energies are 140–540

kJ mol^{-1} depending on the nature of the cation-forming impurity element and the process stage.[36] The Si/E_xS_y heterostructures are oxidised in two or three stages. In the first stage, the deposited sulphide layer is transformed in accordance with the sulphide–sulphate–oxide sulphate–oxide scheme (IRS, XSA, LXSMA). Bearing in mind the high temperatures of the thermo-oxidation of these heterostructures, it must be emphasised that, since this stage is limited by the diffusion of oxygen through a very loose sulphate–oxide–sulphate layer, it is completed very rapidly and it is as a rule possible to record the increment in the thickness of the layer starting from the second stage. By this instant, the front of the migration of the impurity oxide (as the final sulphide oxidation product) reaches the support and ensures the transit reaction.

We may note that oxides forming part of the composition of the oxide sulphate phases are also capable of entering into similar reactions. The transit reaction is the determining process in the oxidation of the Si/E_xS_y heterostructures for which the sulphide oxidation products do not form vitreous layers with SiO_2. The growth of the film is then limited by the given stage, for example, as in the Si/In_2O_3 heterostructures with $n_{av} = 0.13$.[43] Here the rate-limiting stage is the mass transfer of the impurity oxide, bound in the film (limited impurity source) to the internal interface; in the absence of vitrification, it is hindered and the process acceleration rapidly decays with time. The resulting layer consists of the impurity oxide and the concentration of SiO_2 increases only in the vicinity of the inner interface (XSA, IRS, MSMA). Some migration of SiO_2 from the inner interface to the outer one has apparently a favourable effect on the formation of bridge bonds and the "healing" of defects. The resulting layer therefore consists of a dielectric film, although In_2S_3 is in fact a semiconductor.

If vitrification is possible, then it is added to the above sequence, i.e. it follows the transit reaction. In this instance, the above process is in fact determining and leads to the formation of the silicate layer of the given element (IRS, XSA, MSMA, LXSMA). It is limited by the mass transfer of the impurity oxide, forming part of the composition of the deposited film, to the inner interface, which is faster than the analogous process in the absence of vitrification. This stage is in fact the first of those recorded (after the rapid oxidation of the deposited sulphide layer) for the Si/GeS_2, Si/PbS, Si/Sb_2S_3, and Si/Bi_2S_3 heterostructures.[44–47] Here the values of n are 0.22–0.40 and the effective activation energies are 180–240 kJ mol^{-1}.

The process does not terminate in the formation of a silicate framework of the given element because the impurity oxide incorporated in it is capable of mass transfer (rate-limiting stage) and a further transit reaction (determining process), which ultimately leads to the formation of a silicon oxide framework (IRS, XSA). The transfer of the impurity component, bound up in the network of the silicate glass of the given element, is more strongly inhibited than in the previous stage, although most of it is present in the form of the oxide. The formation of the silicate framework of the element is therefore rapid and that of the silicon oxide framework is much lower. Very low values of n (0.18–0.05) correspond to this stage and the effective activation energies are 240–540 kJ mol^{-1}.

The characteristic features of the processes considered depend also on the type of the cation-forming element. If the vitrification is limited, then the mass transfer of the impurity is strongly inhibited and the transition from the silicate framework of the element to the silicon oxide framework is difficult, so that the latter can hardly ever be detected in a pure form in the temperature and time range investigated. This is the situation in the oxidation of the Si/GeS_2 heterostructure, where the solubility is limited in the $SiO_2–GeO_2$ system.[44] On the other hand, antimony forms the most thermally unstable sulphide in the series considered and hence in the oxidation of the Si/Sb_2S_3 heterostructures the competing process involving the evaporation of the deposited sulphide is most marked, appreciably reducing the thickness of the deposited impurity layer in the initial instant of the oxidation.[46]

The stability of bismuth oxide sulphates gives rise to a definite arrest in the process in the sulphide layer oxidation stage.[47] On the other hand, the fastest conversion of the sulphide into the oxide takes place in the case of lead. This factor, together with the vigorous occurrence of reactions (2) and (3) as well as the facilitated mass transfer of the impurity oxide in the loose network of the lead silicate glass lead to the virtually instantaneous formation of the lead silicate framework and to the rapid replacement in the latter of the lead oxide component by the silicon oxide component.[45]

Thus the thermo-oxidation of the Si/E_xS_y structures makes it possible to obtain dielectric layers with a high rate of growth (acceleration by a factor from 5 to 60). The anion-forming agent (sulphur) ensures the gradual development of the process and the formation of the resulting layers under milder conditions than those established in the oxidation of Si/E_xS_y structures and also in the presence of oxides in the gas phase. On the other hand, sulphur is absent from the final product, evaporating predominantly in the form of SO_2 during the conversion of the sulphate into the oxide. On vitrification in the system, the oxide is fully consumed in the transit reaction; part of the impurity element produced in reaction (2) diffuses to the support, while another part diffuses into the film and then evaporates. In the impurity process considered, one can therefore obtain relatively pure silicon oxide layers with a satisfactory quality[36] and over a short period.

The idea of introducing anions into the film, where they are retained and ensure a change in its properties in the required direction, is undoubtedly fruitful. Here preference should be given to chlorine. A number of studies have been published[48–52] in which the influence of chlorine on the properties of silicon/oxide layers and heterostructures was demonstrated. It involves a decrease in the instability of the MOS† structures [metal oxide structures?], an increase in the lifetime of the minority carriers in the silicon support and in the electrical strength of the films, a decrease in the density of surface states at the Si/SiO_2 interface, and the suppression of the generation of packing defects and their "healing".

Taking into account the foregoing factors, it is useful to introduce chlorine together with the cation, i.e. to employ oxidation with participation of impurity chlorides. Here too the type of the anion-forming element determines the method used to introduce the impurity into the system—evaporation from the gas phase. The chlorides of the Group IIIA–VA elements employed are comparatively volatile and can be readily introduced into the gas phase, while it is almost impossible to use the method involving their deposition on a support because of their high chemical reactivity and tendency to hydrolyse.

Despite the fact that at high temperatures the impurity chlorides employed undergo pyrolysis and pyrohydrolysis to different extents in an oxidising medium (which contains in addition an undetermined amount of water vapour), the difference between the kinetics of the oxidation reactions of silicon on evaporation from the gas phase

† MOP in Russian (Ed. of Translation).

[sic!] [into the gas phase?] of impurities with the same cation-forming agent (oxides and chlorides) makes it possible to regard the involvement of the latter in "chloride" transit

$$2ECl_x + O_2 + Si = SiO_2 + 2E + xCl_2, \quad (4)$$

$$(4/x)ECl_x + 2H_2O + Si = SiO_2 + (4/x)E + 4HCl. \quad (5)$$

The thermodynamic feasibility of these reactions is one of the criteria governing the choice of the impurity chlorides and at the same time the choice of the oxidising medium. Thus reaction (4) is thermodynamically impossible for $GaCl_3$ and $InCl_3$ and the oxidation of silicon in the presence of these oxides therefore takes place in a H_2O (vapour) + O_2 mixture. On the other hand, if both reactions are impossible, then the chloride can be used in the form of an impurity merely for the introduction into the gas phase of a volatile compound of the given impurity (provided that the vapour pressure, for example, of the chloride, is much higher than that of the corresponding oxide), subject to the condition that the pyrolysis and pyrohydrolysis of the chloride take place preferentially in the system, while the oxide transit reaction (2) is thermodynamically feasible.

The thermo-oxidation of silicon in the presence of chlorides ($GaCl_3$, $InCl_3$, $SbCl_3$, $BiCl_3$, $PbCl_2$, $GeCl_4$, and PCl_3) [53-59] takes place in a linear-parabolic regime. For $GaCl_3$, $InCl_3$, $SbCl_3$, and $BiCl_3$, the determining process is reaction (4) or (5) whose rates are limited by the mass transfer of the chloride fragment across the growing layer. Under these conditions, there are countercurrents of chlorine or hydrogen chloride formed at the inner interface in the course of these reactions and responsible for the breaks observed in the growing films.[36] The latter facilitate to a certain extent the transfer of the impurity to the reaction surface. The grown films consist mainly of SiO_2 slightly doped with chlorine and (to different extents) with the impurity cation-forming agent (IRS, XSA, XES, EAS, LXSMA). The presence of chlorine in the vicinity of the inner interface (XES, SIMS, LXSMA) demonstrates the occurrence of the chloride transit reactions (4) and (5). If reaction (2) plays a decisive role in the growth of the films, then the film will probably have been partly etched by chlorine and hydrogen chloride—the reaction products derived from the chlorides—in the vicinity of the outer interface.

The degree of doping of the films by the cation-forming agent and the acceleration of their growth compared with the reference standard (process characteristics) are determined in this instance also by the nature of the cation-forming element. The acceleration is $\sim$1.5 for $GaCl_3$ and $InCl_3$ and $\sim$2 for $SbCl_3$ and $BiCl_3$. This is caused by the possibility of reaction (3) for $SbCl_3$ and $BiCl_3$. The tendency towards vitrification is most marked for bismuth and the level of doping of the films with bismuth is highest (XSA, LXSMA). However, the concentration in the given processes of impurity oxides as secondary oxidation products of the elements produced by reactions (4) and (5) is low. Thus the physicochemical characteristics of the cation-forming elements (Ga, In, Sb, Bi) are responsible for the nature of the determining process and hence of its controlling stage.

In the range of comparatively low oxidation temperature (750–950 °C), the principal accelerating agent in the growing of films in the presence of lead chloride[57] is the impurity introduced initially. It has been established that at these temperatures most of the $PbCl_2$ passes to the specimen being oxidised in a chemically unaltered state. For the given process, it is possible to identify the following sequence: (1) mass transfer of the impurity chloride to the inner interface; (2) transit interaction of type (4) with participation of $PbCl_2$; (3) oxidation of the lead generated in the transit reaction; (4) type (3) vitrification. Since the resulting film consists of a lead silicate glass (IRS, LXSMA), the determining process in this stage is the mutual dissolution of the oxides [reaction (3)], which, however, is limited by the mediating effect of the mass transfer of $PbCl_2$ from the outer to the inner interface. In the loose film of the lead silicate glass, this process is not greatly hindered, as is indicated by the value of the exponent n close to unity (n_{as} = 0.84).

The oxide forms of lead, which are the products of the interaction of $PbCl_2$ in the gas phase, exert the main influence on the kinetics and mechanism of the oxidation reaction in the range of high temperatures (1100–1200 °C). The nature of the determining process (vitrification) is retained in this stage and the rate-limiting stage is the mass transfer of PbO to the inner interface. At moderate temperatures (1000 and 1050 °C), the reactive reactants are simultaneously lead chloride and lead oxide.[57] $PbCl_2$ creates the most favourable conditions in the given process for the rapid formation of films. The acceleration of film growth is a maximum (by a factor of 22) in the range 750–950 °C and a minimum (by a factor of 3–5) in the range 1100–1200 °C, whilst in the range 1000–1050 °C the acceleration has intermediate values (by a factor of 6–12). Chlorine has been detected (LXSMA) in the films corresponding to the low-temperature stage, which, together with presence of lead in the support (XSA, LXSMA), constitutes proof of the occurrence of the chloride transit reaction (4).

The nature of the cation-forming elements determines the relative stabilities of the chlorides over the entire experimental temperature range ($GaCl_3$, $InCl_3$, $SbCl_3$, $BiCl_3$) or in a particular portion of it ($PbCl_2$) and hence are responsible for the definite influence of the impurity introduced initially on the characteristics of the growth of films and their properties.

On the other hand, $GeCl_4$ and PCl_3 [55,56,58] undergo virtually complete pyrohydrolysis already in the gas phase and are converted into the corresponding oxides. The latter give rise to a flux of the impurity in the film, the mass transfer of the $Ge(P)_xO_y$ fragments limiting its growth as a whole. At advanced stages of the process, vitrification is the determining reaction (IRS, XSA); on the other hand, at the beginning there is a possibility of an "induction" period where the film growth (process with $GeCl_4$) is determined by the finite rates of pyrohydrolysis of the chloride and of the deposition of the corresponding oxide on the support and also by the limited miscibility in the E_xO_y–SiO_2 system. These features of the processes arise from the properties of the cation-forming impurity elements, which exhibit the most marked non-metallic properties in the series of chlorides considered and hence form unstable chlorides.

The change in the mechanism of the thermo-oxidation of silicon after the introduction of impurity chlorides into the gas phase compared with the reference oxidation[3,18,36] and thermo-oxidation in the presence of the halogens and hydrogen halides,[48] on the one hand, and the growing of films in the presence of oxides, on the other, leads to an appreciable difference between the properties of the films. Thus, in the "chlorine" and "hydrogen chloride" oxidation, chlorine is known to be concentrated in the vicinity of the inner interface,[60] while in the cases examined above films comparatively uniformly doped with impurity cation and chlorine were obtained (XES). Under these conditions, there is a change in the kinetics of the etching. For example, the magnitude of the mobile charge changes by an order of magnitude (for $SbCl_3$ and $BiCl_3$; there is no charge on $GeCl_4$, $PbCl_2$, and PCl_3) and there is

also some decrease in the surface charge and in the density of the surface states. However, the last two characteristics are poorer for the chloride processes examined than for the "chlorine" and "hydrogen halide" processes, because the inner interfaces are disturbed and there is an increase in the degree of defectiveness of the films caused by the reactions (4) and (5), the evolution of gaseous products, and breaks in the direction of the outer interface.

III. Impurity thermo-oxidation of gallium arsenide

The foregoing ideas concerning the involvement of impurities in the formation of oxide layers on silicon can be largely extended to other semiconducting materials, in particular, to compounds of the type $A^{III}B^{V}$. The main principle of the selection of the impurity from the standpoint of its ability or the ability of its derivatives to participate in the transit transfer of oxygen is applicable also in this instance. On the other hand, determining processes of the second type (vitrification) do not play a significant role here, because such a process is retarded at the low oxidation temperatures characteristic of the compounds $A^{III}B^{V}$. Nevertheless, the mutual dissolution in the oxide systems $A_2^{III}O_3-B_m^{V}O_n$, $A_2^{III}O_3-E_xO_y$, and $B_m^{V}O_n-E_xO_y$, which is appreciable in many instances, can promote the improvement of the properties of dielectric layers, diminishing their defectiveness.

Compared with silicon, the oxidation of gallium arsenide, the most important of the compounds of the type $A^{III}B^{V}$, has a number of characteristic features which hinder the formation of high quality dielectric layers. Firstly, it is impossible to identify the sequence of processes, because the diffusion of oxygen to the support is always accompanied by the diffusion of gallium and arsenic into the film. Thus, there are always countercurrents of the components in the film. Under these conditions, the reactions ensuring the increment in the mass of the layer are possible not only on the inner interface but also on the outer one, as well as in the bulk of the film. Secondly, the evaporation of the volatile component of the support (arsenic) is responsible both for the imperfection of the semiconductor/dielectric interface and for the increased defectiveness of the growing film. The degradation of the support necessitates in its turn the application of comparatively low temperatures in the oxidation of GaAs at which the transport processes investigated are greatly retarded. Thirdly, thermodynamic calculation has shown,[64] that the thermo-oxidation of GaAs proper is itself a transit process because, on being oxidised, arsenic subsequently transfers oxygen to gallium:

$$As_2O_3+2GaAs=Ga_2O_3+4As, \quad (6)$$

$$3As_xO_y+2yGa=yGa_2O_3+3xAs. \quad (7)$$

Hence the thermodynamically stable pairs are Ga_2O_3-GaAs and Ga_2O_3-As.[62] The arsenic reduced in the course of the transit reactions (6) and (7) proper is concentrated on the inner interface and exerts a negative influence on the properties of the metal/dielectric surface structures (MDS structures) obtained subsequently.[63] The above features are responsible for the complexity of the composition of the layers obtained and also for its marked dependence on the process parameters. In the general case, the film grown on GaAs during its thermo-oxidation consists of Ga_2O_3, As, As_2O_3, and $GaAsO_4$,[62,64,65] the first of the above components predominating in layers obtained under not unduly severe conditions.

Thus impurity transit is essential for the acceleration of the oxidation of both the gallium and arsenic components of the support in order to increase the rate of formation of the layer consisting predominantly of Ga_2O_3 and to increase the efficiency of the oxidation of arsenic, promoting thereby its segregation in the film in an oxidised and not elemental state. The latter factor ensures the "healing" of defects and the improvement of the properties of the films and the MDS structures.[66]

The postulate of the transit interaction, put forward above, involving the oxide forms of the impurity as the main factor accelerating the oxidation of the supports in which impurity ions have been implanted was confirmed also for gallium arsenide. It was established that antimony implanted in GaAs accelerates the oxidation of the latter, that boron does not increase the rate of growth of films, and that phosphorus retards it.[67] These features are correlated with the results of thermodynamic calculations for the corresponding transit processes and the available information about the physicochemical properties of impurity oxides.[68] As for silicon, it has been found that the kinetics of the thermo-oxidation reactions of gallium arsenide doped with antimony ions and of the reference process are similar. However, for the Si/SiO_2 heterostructure the partition coefficient of antimony is such that it is mainly concentrated at the inner interface, while in the corresponding gallium arsenide/oxide heterostructures antimony is segregated in the film (EAS, SIMS, MSMA), which has a favourable influence on the electrical strength of the latter. This is apparently caused by the interaction of the oxide forms of antimony with Ga_2O_3 and As_2O_3 (IRS).

The thermo-oxidation of GaAs when the gas phase contains impurity oxides (GeO_2, SnO, PbO, Sb_2O_3, Bi_2O_3, V_2O_5) capable of the transit interaction

$$(3/y)E_xO_y+2GaAs=Ga_2O_3+(3x/y)E+2As, \quad (8)$$

$$(3/y)E_xO_y+2Ga=Ga_2O_3+(3x/y)E, \quad (9)$$

also ensures the acceleration of the formation of the films.[69-71] The acceleration is by a factor of between 2 and 26 depending on the type of the cation-forming impurity element. The resulting films contain mainly Ga_2O_3 and are weakly doped with arsenic and impurity oxides (XSA, MSMA, IRS, SIMS).

The influence of the oxides GeO_2 and SnO on the kinetics of the thermo-oxidation of GaAs is similar. This is caused by the characteristic features of the evaporation of the above impurity compounds. The rate of oxidation in the linear regime is smaller for both processes compared with the parabolic regime (n = 0.28 and 0.40). According to Tananaev and Shpirt,[72] the evaporation of GeO_2 entails the formation reactions of GeO, Ge_nO_n, and Ge (the products of the disproportionation of GeO), which reduce the surface concentration of the impurity in the initial instant of the oxidation reaction. In the process with participation of SnO, the main influence is apparently exerted by the polymeric Sn_2O_2, Sn_3O_3, and Sn_4O_4 molecules, which make an appreciable contribution to the overall pressure of the impurity vapour; however, they are formed as a result of a complex series of reactions,[73] which is in fact the reason for the induction period.

The films obtained are weakly doped with the impurity component, in contrast to the layers grown in the presence of PbO, Sb_2O_3, and Bi_2O_3 (XSA, EAS, IRS). Lead, antimony, and bismuth are incorporated to the greatest extent in the growing layer, but, compared with the element silicate glasses obtained in the

corresponding processes on silicon, their concentration is low (from 1 to 6 at.%; XSA, MSMA, EAS), which confirms the retardation of the mutual dissolution of the intrinsic and impurity oxides caused by the nature of GaAs and the corresponding oxides. The appreciable accelerations obtained (by a factor of up to 26) indicate the decisive role of the transit interactions (8) and (9) in the film formation processes involving all the oxides investigated. The transit reaction can proceed preferentially at the inner (Sb_2O_3, n = 0.77) and outer interfaces and also in the bulk of the films (PbO, n = 1.4; advanced stages of the processes with GeO_2, SnO, Bi_2O_3, n = 1.10–2.17). Since the main component of the layers obtained is Ga_2O_3, the rate-limiting stage is apparently in all cases the diffusion from the support into the gallium film, such a film being essential for the formation of films both by the impurity-transit mechanism and in the course of the parallel process of the oxidation of the support itself.

The creation of a restricted source of the impurity by depositing the corresponding oxides on the oxidisable GaAs surface leads, as for silicon, to values $n < 0.5$ (for the GaAs/PbO, GaAs/Sb_2O_4, GaAs/Bi_2O_3, and GaAs/V_2O_5 heterostructures, n = 0.01 to 0.42 [74,75]),which corresponds to the interactions in the solid phase. At the inner interface, the impurity oxide transfers oxygen to the gallium of the support already in the initial instant. The impurity element produced thereby diffuses both to the support and to the film and undergoes further oxidation. There is also simultaneous diffusion of gallium into the deposited E_xO_y layer, which is responsible for the transit reaction both at the outer interface and in the bulk of the layer. The rate-limiting stage is the diffusion of gallium. The resulting layers consist mainly of the impurity oxide containing Ga_2O_3, arsenic, and its oxides (IRS, EAS, XSA).

Thus, while the determining process and the rate-limiting stage are apparently identical for the unrestricted and restricted impurity sources, there is also a fundamental difference. In the former case, gallium diffuses in a layer whose composition is similar to that of its own oxide, while in the latter it diffuses into the pure impurity oxide. The formation of Ga_2O_3 in the oxidation of the GaAs/PbO heterostructures in argon,[74] the presence of the impurity element in the support, and the steady increase in the Ga_2O_3 content on moving from the outer to the inner interface (XSA, EAS) demonstrate the occurrence of the transit interactions. Again the retardation of the transport processes and the extremely low oxidation temperatures employed preclude, as in the case of silicon, the transition from the impurity oxide layer to a weakly doped intrinsic oxide.

It is quite important that an accelerated formation of films can be achieved on gallium arsenide in the presence of transition metal oxides, in particular V_2O_5. In the oxidation of the GaAs/V_2O_5 heterostructures, not only the acceleration of the increase in the thickness of the layers (by a factor of $\sim$6) but also an appreciable decrease in the effective activation energy compared with the value for the reference process has been observed, which makes it possible to interpret the process mechanism as catalytic. In this case, the method of introduction of the impurity into the system is evidently also extremely important. Thus, when V_2O_5 is introduced into the gas phase (an unrestricted source of impurity), there is no decrease in the effective activation energy and the determining process is the transit reaction, as for other impurity oxides. Only for a restricted impurity source are there possibilities for the development of the process via a heterogeneous-catalytic mechanism (contact between two solid phases along the entire surface, creating a high concentration of surface-active centres and possibly ensuring the coverage of the local superheating fields).

A similar retarded growth of films compared with the parabolic regime (n = 0.075–0.43) has been observed also for the thermo-oxidation reactions of the gallium arsenide/sulphide heterostructures.[76–80] Here the anion-forming impurity element determines, as already mentioned, the main features of the process and the method of introduction of the impurity into the system. Because of this, a similarity is manifested between the processes considered and the oxidation of the analogous silicon structures. The intensity of the chemical interactions in the heterostructure being oxidised depends on the nature of the semiconductor matrix. Thus the main bulk of the layer grown by the thermo-oxidation of the GaAs/In_2S_3 heterostructure consists of In_2O_3.[76] Here the transit reaction is fairly feeble because of the similarity of the chemical properties of Ga_2O_3 and In_2O_3 and also because of the low process temperatures. For the same reason, the content of antimony in the films grown by the thermo-oxidation of the GaAs/In_2S_3 heterostructures (as well as heterostructures with other deposited sulphides) is higher than in the analogous layers grown on silicon (XSA, SIMS, EAS, LXSMA). The increase in the gallium content in the vicinity of the inner interface (in the oxidised form) as the process develops (XSA, EAS) reflects the increase in the contribution of the transit interaction to the overall process. It is of interest to note that, compared with the relatively pure reference oxides, these films are enriched in silicon, which indicates a higher miscibility in the As_2O_3–In_2O_3 systems compared with As_2O_3–Ga_2O_3.[68]

In the layers obtained by the oxidation of the GaAs/E_xS_y heterostructures at comparatively low temperatures, it is possible to detect simultaneously all the products of the oxidation of the sulphide (XES). Here the determining process is the transit interaction of these products (the oxide and oxide sulphate forms) with the gallium of the support, which is limited as a rule by the diffusion of this component. Thus the films grown by oxidising the GaAs/GeS_2 heterostructures[77] contain GeO_2 and $Ge(SO_4)_2$ as well as Ga and As. As the process develops near the inner face, there is a steady increase in the Ga_2O_3 content and a decrease in that of GeO_2, which demonstrates the occurrence of the transit reaction. If the decrease in the concentration of the impurity oxide component were caused by the competing evaporation process, the ratio of its concentrations in the outer and inner layers would have been the reverse of that observed.

The layers obtained by the thermo-oxidation of the GaAs/PbS heterostrucures[78] contain lead in the form of $PbSO_3$ (XES). Apparently it is in this instance a secondary product of the interaction of PbO (formed on oxidation of the sulphide) with the SO_2 evolved. The presence of PbO in the system and the occurrence of the transit reaction are indicated by the presence of elemental lead in the support (XSA). The oxidation sequence of the deposited sulphide layer is clearly manifested for the GaAs/Sb_2S_3 heterostructure.[79] Antimony oxide as well as antimony sulphite are present at the outer interface; deeper layers contain the impurity sulphate and the incompletely oxidised impurity sulphide (XES). $Bi_2(SO_4)_3$, Bi_2O_3, and gallium and arsenic oxides have been detected in films grown by the thermo-oxidation of the GaAs/Bi_2S_3 structures (IRS, XSA).[80] In all the layers obtained in the presence of the sulphides of Group IV and V elements on the surface of gallium arsenide, the concentration of gallium is higher compared with the analogous films obtained by the oxidation of GaAs/In_2S_3, which indicates a greater contribution of the transit reaction and its decisive role.

Indeed, as already emphasised, the transit reaction in the $GaAs/In_2S_3$ heterostructure is relatively ineffective and hence the increment in the thickness of the layer (n = 0.075) is correspondingly very small; for $GaAs/GeS_2$, its probability is higher and n is now 0.21. The highest values of n occur for the GaAs/PbS (0.42), $GaAs/Sb_2S_3$ (0.43), and $GaAs/Bi_2S_3$ (0.35) heterostructures, in which there are conditions for an extremely vigorous transit reaction and in addition mutual dissolution is observed (IRS) in the $Ga_2O_3-E_xO_y$ systems. Together with the presence of large impurity ions (especially of lead and bismuth) in the bulk phase, this factor facilitates the mass transfer in the film. This feature and also the vigorous transit reaction actually explain the increased content of gallium in the given layers compared with the layers grown by the oxidation of the $GaAs/In_2S_3$ heterostructures.

The formation of arsenic sulphides at the inner interface, observed in the thermo-oxidation of the GaAs/PbS and $GaAs/Sb_2S_3$ heterostructures (XES), is especially important. This suggests that not only the oxygen transit reactions examined but also direct anionic transit takes place. Such transfer of sulphur from one component to another promotes the binding of arsenic and prevents the evaporation of arsenic, the degradation of the inner interface, and the penetration of arsenic into the resulting layer in a free state. For this reason, the electrical strength of the layers increases by a factor of 5–10 compared with the reference oxide, while the density of the surface states decreases severalfold.

Thus the same main kinetic features are manifested in the oxidation of the $GaAs/E_xS_y$ heterostructures as in the processes on the corresponding silicon structures: low values of n, the gradual occurrence of the interaction of oxygen with the sulphide film, and the occurrence of a competing evaporation process from the outer interface.

A common feature of the $GaAs/E_xS_y$ oxidation processes is the decisive role of the impurity oxide transit limited by the diffusion of gallium, which is indicated by the extremely high effective activation energies for the process, close in order of magnitude to the reference values. Naturally, the composition of the resulting layers is determined in many respects by the characteristics of the semiconductor matrix, which determines the oxidation regime. In the case of gallium arsenide, the successive conversion of the deposited sulphide into the oxide with subsequent transit interaction is retarded. This makes it possible to detect in the film various sulphide reaction stages but does not enable one to achieve a transition of the sulphide film–film oxidation products type and the interaction with the intrinsic oxide phases—the intrinsic oxide weakly doped with the impurity.

The features of each process examined above are determined by the nature of the cation-forming impurity. In particular, for the $GaAs/Sb_2S_3$ heterostructures the deposited layer, transformed during the oxidation process, hinders the diffusion of gallium to the least extent and the concentration of the latter near the outer interface is highest (XSA). Since the oxidation of the sulphide begins at precisely this boundary, the concentration of the oxide forms of the impurity is a maximum in this region and best conditions are created for the transit interaction. Furthermore, the similarity of the properties of the oxide in the $As_xO_y-Sb_xO_y$ system ensures to a certain extent their miscibility, while gallium antimonates are apparently formed in the $Ga_2O_3-Sb_xO_y$ system (by analogy with arsenates). This is in fact the reason why the acceleration of the oxidation of these heterostructures is greatest (by a factor of $\sim$20).

The influence of the cation-forming impurity element is revealed most strikingly in the thermo-oxidation of gallium arsenide in the presence of chlorides, whose introduction into the gas phase is actually determined by the nature of the anion-forming element. It was already emphasised above that $PbCl_2$, $SbCl_3$, and $BiCl_3$ are stable in an oxidising medium even at the high temperatures used to grow the films on silicon.[81,82] These compounds actually ensure a flux of the impurity to the support in the oxidation of gallium arsenide when they participate and enter into the chloride transit reaction:

$$2ECl_n + 4Ga + 3O_2 = 2Ga_2O_3 + 2E + nCl_2. \quad (10)$$

As in all the previous cases, there is simultaneous oxidation proper of the support by oxygen. The chloride transit reaction is determining, because, on the one hand, the process is accelerated relative to the reference process (by a factor up to 230) and, on the other, the process kinetics differ appreciably from those of the process in the presence of the oxides of the same elements where the oxide transit reaction is determining. The determining process is in the general case limited by the diffusion of gallium atoms bound initially in the support. The process thus controls the reaction on the outer interface to an even greater extent, because of the source of the impurity is unrestricted and the mass transfer of ECl_n in the gas phase takes place at a high rate.

The characteristics of the processes depend on the nature of the cation-forming agents. Thus the oxidation in the presence of $PbCl_2$ and $BiCl_3$ proceeds in the linear regime owing to the loosening of the resulting layer and the facilitation of the mass transfer in the latter.[81,82] This fact is not only responsible for the acceleration of the diffusion of gallium and of the impurity chloride fragments but also promotes the rapid outflow of arsenic from the inner interface, which also limits the hindrance to the transfer of gallium. Antimony, on the other hand, enters the layer in such small amounts apparently owing to the rapid diffusion in the film and evaporation in the form of the oxide produced in the transit of the element from the outer interface. On the other hand, the inclusion of a certain amount of antimony in the film does not promote its loosening and does not create conditions which prevent the accumulation of arsenic at the inner interface. These factors retard the diffusion of gallium and the film grows the linear-parabolic regime.[82]

Depending on the process characteristics, the composition of the layers also varies (IRS, XSA). The films grown in the presence of $PbCl_2$ are doped with the impurity to the greatest extent; they constitute complex formations which are the products of the interaction of Ga_2O_3, PbO, and As_2O_3 and contain also oxide chloride fragments. The layers grown in a medium with $BiCl_3$ are fairly weakly doped with bismuth, but their arsenic content is increased apparently as a result of the miscibility in the $As_2O_3-Bi_2O_3$ system. Oxidation in the presence of $SbCl_3$ results in the formation of Ga_2O_3 films weakly doped with antimony and chlorine.

The characteristics of the cation-forming elements are responsible for the instability of the chlorides $GaCl_3$ and $InCl_3$. After the introduction of $GaCl_3$, n = 1.63 and the effective activation energy is only 6 kJ mol^{-1} for the oxidation process.[83] This is a virtually non-activated process and such parameters indicate the occurrence of physical adsorption.[84] Thus in the given instance the determining process is the deposition on the support of a layer of Ga_2O_3 formed during the reactions

$$ECl_3 + H_2O = EOCl + 2HCl, \quad (11)$$

$$EOCl + 2H_2O = E(OH)_3 + HCl, \quad (12)$$

$$2E(OH)_3 = E_2O_3 + 3H_2O. \quad (13)$$

In this instance the growth of the oxide film is virtually unlimited, since the mass transfer in the gas phase is rapid. Naturally the resulting layer consists of Ga_2O_3, which, however, is strongly doped with arsenic (IRS, XSA). The competing arsenic evaporation process is suppressed, because the rate of growth of the layer is so high that it inhibits kinetically the diffusion of arsenic to the outer interface and hence its evaporation in the form of oxides.

On introduction of $InCl_3$, the deposited In_2O_3 layer, formed by reactions (11)–(13), is capable of entering into a transit interaction with the gallium of the support. This process is determining,[85] since, for the high value of the exponent n at an advanced stage of the process (n = 1.57), the effective activation energy is likewise high (110 kJ mol^{-1}) and is close to the corresponding reference value. This means that the rate-limiting stage is the diffusion of gallium. Here film growth takes place on two interfaces ($n > 1$) and on the outer one the pyrohydrolysis of the chloride makes an appreciable contribution to the increment in film thickness. The resulting layer consists mainly of In_2O_3 containing chlorine and also of gallium and arsenic oxides (XSA, MSMA, SIMS). The vigorous interaction in the $In_2O_3-As_2O_3$ oxide system ensures the "healing" of the defects in the In_2O_3 semiconductor and sharply increases the electrical strength of the layers (by more than two orders of magnitude) compared with the films grown on GaAs under relatively clean conditions.

Thus, taking into account the characteristic features of the cation-forming elements under the conditions employed, the chlorides examined can be divided into two groups—stable and unstable. Within the framework of each group, the similarity of the cation-forming elements leads to the similarity in the behaviour of their chlorides in the oxidising medium. However, the fact that gallium is one of the components of the support whilst the derivatives of indium interact both with the components of the support and with their oxide forms is responsible for the difference between the mechanisms of the formation of the layers and hence of their properties.

IV. Characteristic features of the effect of impurity compounds on the thermo-oxidation of indium phosphide

The following conditions must be maintained for the formation of impurity oxide layers with a satisfactory quality on semiconductors: (1) the impurity introduced initially or its oxidation products must ensure the acceleration of the formation of layers via the transit or catalytic mechanism; (2) the mutual dissolution of the intrinsic and impurity oxides, possibly with formation of compounds (silicates, arsenates, etc.) is desirable; (3) in the presence of the quantities of the cation-forming agent listed above, the anion-forming agent should improve the properties of the layers ("healing" the defects, neutralising the charge in the film, etc.); (4) in the oxidation of semiconducting compounds with a volatile component, it is desirable to create a restricted source of impurity in the form of a deposited film; (5) the optimum chemical binding of the volatile component of the support by the anion-forming impurity element (and not the cation-forming element, since in this case the "metallic" nature of the inner interface is more marked).

These general conditions are applicable also to semiconducting compounds such as InP. Its main feature is that, among all the compounds of the type $A^{III}B^{V}$, the enthalpy of formation of $B^{V}_{m}O_{n}$ (P_2O_5) is greater than that of $A^{III}_{2}O_3$ (In_2O_3) only for InP. Therefore, according to the results of thermodynamic analysis,[86] phosphorus should remove oxygen from indium, i.e. its transit reactions

$$0.3P_4O_{10}+2InP \rightleftharpoons In_2O_3+3.2P, \quad (14)$$

$$0.3P_4O_{10}+2In \rightleftharpoons In_2O_3+1.2P \quad (15)$$

will occur in the reverse direction—"reverse" transit.

However, it is believed[87] that the $InPO_4-P$, $In(PO_3)_3P$ pairs should be thermodynamically stable under equilibrium conditions in the In–P–O system. Thus in the above system the growing of regular films is possible only over an extremely long period as a result of the secondary interaction of the indium and phosphorus oxides with formation of $InPO_4$. Indeed, according to the literature data,[88,89] the composition of the intrinsic oxide layers on InP approaches that of $InPO_4$. Furthermore, in contrast to, for example, GaAs, non-oxidised indium has been detected in the intrinsic oxide films grown on InP.[90]

The thermo-oxidation of InP itself in the temperature range 575–675 °C is a two-stage process. The first stage ($n \simeq 0.5$) corresponds to diffusional control and the rate-limiting stage is apparently the diffusion of indium from the support. The second stage with n = 0.13 corresponds to the type of process in which the interaction in the solid phase, namely the formation of $InPO_4$, is determining. The process is limited by the mutual diffusion of the oxides. There is a high content of indium in the resulting layers (EAS, IRS), which indicates its presence in a free state. This may be a consequence of the degradation of the support[88] or, what is more likely, may be a result of reactions (14) and (15), which are apparently determining in the first stage. The $INPO_4$ content in the layers on the whole increases with increase in the process parameters, but the concentration of free indium also increases in the same direction (XSA, EAS). The latter is responsible for the very low resistivity of the films ($< 10^6$ Ω cm).

Thus the very mechanism of the formation of intrinsic dielectric layers on InP is responsible for their unsatisfactory properties and it is essential to introduce an impurity, in the first place with the aim of increasing the efficiency of the oxidation of indium both directly (with indium as the transit impurity) and indirectly by enhancing the oxidation of phosphorus (with phosphorus as the transit impurity) and of weakening its effects on In_2O_3 via reactions (14) and (15). Furthermore, in contrast to $Ga_2O_3-As_2O_5$ system, in the analogous $In_2O_3-P_2O_5$ system better possibilities arise for interactions, since indium possesses metallic properties to a greater extent than gallium, while phosphorus possesses non-metallic properties to a greater extent than arsenic. The correct choice of the impurity can therefore intensify the process, for example, by increasing the mutual diffusion on loosening.

The introduction of impurity compounds into the gas phase, capable of undergoing both the transit reactions indicated above and reactions responsible for the increase in the rate of diffusion ($PbCl_2$) or a possible catalytic effect (V_2O_5), does indeed increase the rate of formation of oxide layers on indium phosphide. Acceleration by a factor of 2–3 has been achieved as regards thickness and by a factor of 8–11 as regards time using $PbCl_2$; for V_2O_5, the above factors are 8–9 and 40–60 respectively. In both cases, the kinetics change compared with the impurity-free reference process. The introduction of $PbCl_2$ ensures a more favourable kinetic regime for film growth by increasing the amount of oxygen capable of being

"retained" in indium (EAS) and also by loosening the resulting layer by incorporating lead atoms in it. The films consist mainly of $InPO_4$; their composition also includes impurity components: lead and chlorine (XSA, EAS, IRS). Vanadium oxide is believed tentatively to accelerate the formation of films via a catalytic mechanism, but it is incorporated in the growing layer (IRS, XSA, EAS). The fraction of oxidised indium in these impurity layers is greater than in the reference layers, but the content of unoxidised indium is still appreciable and the dielectric characteristics are therefore unsatisfactory.

Good results are obtained by the preliminary deposition of a PbS layer on the InP surface to be oxidised. As in the oxidation of similar heterostructures based on silicon and gallium arsenide, in this case the process begins with the formation of a sulphate framework. Indium phosphate is then formed and adds to the framework. It may be that $PbSO_4$ phases interact with one another (IRS). In the vicinity of the outer interface of the heterostructure, mainly $PbSO_4$ is concentrated, the $InPO_4$ content increasing on moving towards the inner interface (IRS, EAS, XSA). Indium sulphides are formed at the inner interface (EAS), which diminishes sharply the concentration of indium in the films and frees them from the unoxidised indium. Therefore, in the oxidation of the InP/PbS structures, not only is the formation of the layers accelerated (by a factor of 4–6) but an appreciable increase in their electrical strength (approximately by an order of magnitude) compared with the reference standard is ensured.

Thus analysis of the surveyed data concerning the thermo-oxidation reactions of silicon and gallium arsenide in the presence of impurities shows that on silicon the greatest acceleration of the process is attained after the introduction of lead compounds, i.e. this element is optimal as a cation-forming agent. As mentioned above, among the anion-forming agents chlorine exerts the most favourable modifying effect on the properties of the layers, whilst oxygen compounds as a rule react too vigorously with the oxidisable surface.

The best cation-forming agent for gallium arsenide is antimony, which has the same valence as arsenic. Its compounds ensure an appreciable acceleration of the process. In addition, as already emphasised, here there is the greatest probability of the mutual dissolution of the intrinsic and impurity oxides, which promotes the healing of defects and the improvement of the properties of the resulting layers. Among anion-forming agents, sulphur is best. It binds the volatile components of the support and diminishes thereby the degradation of the inner interface, improving its properties. For compounds of the type $A^{III}B^{V}$ with a volatile component (B^{V}), the method of introduction of the impurity into the system which depends on the nature of the anion-forming element, i.e. the creation of a restricted impurity source, is convenient. Under these conditions, the deposited impurity layer not only interacts chemically with the support but also serves as a mechanical barrier to the evaporation of the volatile component.

In the thermo-oxidation of InP/PbS structures, the component A^{III} is bound chemically by sulphur on the inner interface which, together with the greater effectiveness of its oxidation as a result of the transit reaction, minimises the probability of the appearance of free indium in the resulting layers. In contrast to the corresponding structures based on gallium arsenide, the deposited impurity layer fulfills various functions in relation to the components of the support (A^{III} and B^{V}): it binds chemically the former, preventing its rapid diffusion into the film, and prevents the evaporation of the latter. The general criteria governing the selection of the impurity formulated above retain their validity also for a material such as indium phosphide which is not simple as regards the growing of dielectric layers.

Asymmetric hydrogenation on metals

E I Klabunovskii
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences

ABSTRACT. The most recent findings in the field of asymmetric hydrogenation of prochiral compounds with C=C and C=O bonds on dissymmetric catalysts—bimetals and hydrides of intermetallic compounds modified with (*RR*)-(+)-tartaric acid and (*S*)-α-amino acids—are reviewed.

The bibliography includes 121 references.

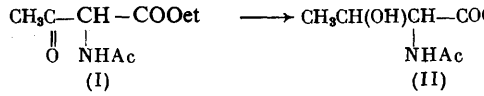
I. Introduction

Despite the well recorded progress made in recent years in carrying out asymmetric reactions with the use of chiral metal-complex catalysts, and primarily in the asymmetric hydrogenation of dehydroamino acids on rhodium phosphine complexes, there is continued interest in studies on dissymmetric metal hydrogenation catalysts modified with chiral ligands. This is mainly due to the ease in preparing them and the technological effectiveness of their application. Amongst the disadvantages of dissymmetric heterogeneous catalysts should be included the relatively narrow spectrum of their action; effective systems have so far only been found for the hydrogenation of the carbonyl bond in ketoesters and diketones. Attempts to extend the range of such reactions and substrates have so far not produced the required results, although there are individual reports of the successful asymmetric hydrogenation of prochiral compounds with C=C and C=N bonds.

A significant proportion of current research has been directed at improving dissymmetric metallic catalysts and the preparation of novel, including polymetallic, catalysts that are active in the asymmetric hydrogenation of the C=O bond, an elucidation of their structure, action mechanism, and the general characteristics that make it possible to predict their catalytic and enantioselective properties. In this review† the results of studies carried out over the last years are examined. Previous studies have been reviewed by Klabunovskii and Vedenyapin.[1]



†In this review the following notation is used: Ni–TA is a catalyst modified with (*RR*)-(+)-tartaric acid; Ni-AA is a catalyst modified with an amino acid (Ala—alanine, Val—valine, Glu—glutamic acid, Phe—phenylalanine, Pro—proline, Ile—isoleucine); MAA is methyl acetoacetate; EAA is ethyl acetoacetate; MHB is methyl β-hydroxybutyrate, EHB is ethyl β-hydroxybutyrate, PEA is (*S*)-phenylethylamine.

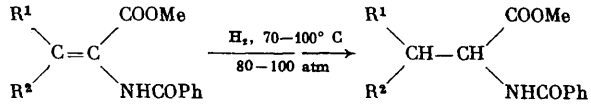
II. Skeletal nickel catalysts

The skeletal catalysts also known as Raney catalysts have been extensively used in organic synthesis in the hydrogenation of unsaturated organic compounds because of the ease in preparing them and their high activity. Skeletal Ni catalysts exhibit high enantioselectivity in the hydrogenation of prochiral carbonyl compounds.

Skeletal Ni catalysts are obtained by leaching a Ni–Al alloy usually containing up to 50% Ni with a solution of NaOH on heating to 80–100 °C and washing the resulting Ni powder with water. The catalyst is then modified with optically active compounds. The modification process involves bringing into contact a previously reduced catalyst at a given temperature and pH with a solution of the modifying agent—an optically active hydroxyacid or amino acid.

In general, modification of catalysts with chiral compounds can help to increase the selectivity of hydrogenation. Thus ketoacid (I)—a precursor of threonine—can be hydrogenated on Ni–TA with 100% selectivity and with an overall yield of 82% on the *allo*-threonine derivative (II),[2] while hydrogenation of (I) on a skeletal Pd–Cu–TA catalyst containing 15.1% Pd at 75 °C and 50–100 atm results in the yield of *allo*-threonine increasing to 90% while the *threo* isomer is completely absent[3,4]

In the diastereoselective hydrogenation of *D*-fructose to a mixture of sorbitol and mannitol, a catalyst such as the hydride of the intermetallic compound $LaNi_3Co_2$ proved effective only after it was modified with (*RR*)-(+)-tartaric acid.[5]



Attempts have been made to use modified Ni catalysts for the synthesis of optically active compounds of practical importance. Thus, for example, optically pure (3*S*,5*S*)-2,6-dimethylheptane-3,5-diol[6] and (*R*)-(−)-3-hydroxytetradecanoic acid (an endotoxin component) were obtained on Ni modified with (*RR*)-(+)-tartaric acid.[7] Modified catalysts were also studied in the synthesis of α-amino acids of practical importance. One of the methods used to synthesise them is hydrogenation of C=C or C=N bonds to the corresponding precursor compounds. However, enantioselective hydrogenation of the C=N bond was ineffective. For example the optical yield‡ of the product derived from hydrogenation of

‡The optical yield (*p*, %) that characterises the enantioselectivity of the reaction is determined from the following equations:

$$p = \frac{([R] - [S])}{([R] + [S])} \times 100 = \frac{[\alpha]^t_{exp}}{[\alpha]^t_{lit}} \times 100\%.$$

acetophenoxime to PEA is only 3.5%,[8] whereas diastereoselective hydrogenation of azomethines is very successful.[9]

A more promising method is the enantioselective hydrogenation of the C=C bond in the (*E*) and (*Z*)-methyl esters of *N*-benzoylaminoacrylic acids in methanol of Ni–(*S*)-AA.[10,11]

(III, a): R^1 = Me, R^2 = Et; (III, b): R^1 = Et, R^2 = Me.

On a Ni–(*S*)-Phe catalyst, Ile containing 70% as the *erythro* form and 30% as the *threo* form is obtained from (*Z*)-(III, a), while Ile containing 60% as the *erythro* isomer and 40% as the *threo* isomer is obtained from (*E*)-(III, b). In the latter case p = 15%.[12] Replacement of Ni–(*S*)-Phe by a Ni–(*S*)-Pro catalyst resulted in an optical purity of p = 8%, while when a Ni–(*R*)-Pro catalyst was used the value of p was only 1.5%. Other amino acids such as Ala, Val, GluOme proved ineffective as modifying agents.

It was recently reported[13] that enantioselective hydrogenation of the C=C bond in (*E*)-PhCH=C(Ph)COONa (30 °C, 1 atm., absolute ethanol) can be carried out on Ni–TA with p = 17.03%. Hydrogenation of the (*Z*)-isomer is less effective.

The poor efficiency of modified Ni–Ta catalysts in a number of cases has been attributed by Harada et al.[14] to the residual content of Al in the skeletal catalysts impairing their enantioselective properties as a result of the formation of considerable quantities of Al_2O_3 or bayerite after leaching of the metal–aluminium alloy. Thus, metals deposited on Al_2O_3, such as Ru/Al_2O_3 modified with (+)-TA did not exhibit enantioselectivity in the hydrogenation of EAA[15] most likely because the formation of highly dispersed X-ray-amorphous metal on the surface of the catalyst.

Studies by Nitta et al.[16] carried out recently showed that only when there is a sufficiently high nickel content (50% or more) deposited on Al_2O_3 can the catalyst be effective in enantioselective hydrogenation.

It was shown by Zubareva et al.[17] that in a 2% Ni/Al_2O_3 catalyst the metal phase cannot be detected by X-ray phase analysis (XPA) because of the formation of an X-ray-amorphous phase. An increase in the content of metal deposited on the surface helps to increase the size of crystallites, and starting with 8% Ni on Al_2O_3 the catalyst modified with TA by now has the ability to cause asymmetric hydrogenation of ethyl acetoacetate (EAA) to ethyl β-hydroxybutyrate (EHB) with p = 3%.

$$\underset{\text{(EAA)}}{CH_3COCH_2COOEt} \xrightarrow{\text{Ni.(+)-TA}} \underset{\text{(}R\text{(−)-EHB)}}{CH_3CH(OH)CH_2COOEt}$$

On increasing the percentage of Ni on Al_2O_3 to 50% (reduction temperature 500 °C, current of $H_2:N_2$ = 1:1, modified with tartaric acid at pH 4.7) the optical yield of (*R*)-(−)-EHB increased to 19.5%.[17] On changing the conditions for preparing the Ni/Al_2O_3 catalyst (reduction temperature 400 °C, current of H_2, modification with TA at 83 °C, pH 4.2) and the hydrogenation (135 °C, 100 atm., ethyl acetate as solvent, EAA:catalyst = 8:1) the composition of the catalyst was found to be 20% Ni/Al_2O_3, and by using it the value of p could be increased to 66–76% with, however, a low degree of conversion (~10%). On increasing the degree of conversion (y) of EAA to 98%, the value of p decreased to 50%.[17]

It was to be expected that the powdered catalysts that are obtained by decomposition of metal salts by the Sabatier method would prove effective in asymmetric hydrogenation processes. Thus, highly effective Ni–TA is obtained by decomposition of Ni nitrate in a current of He with subsequent decomposition of the resulting Ni oxides in a current of H_2 + He (1:10) at 280 °C and modification at 50 °C in a 0.5 solution of TA at pH 5.1.[18] It was not necessary in this case to introduce also into solution NaBr, which is known[19] to increase the enantioselectivity of hydrogenation. Hydrogenation of EAA at 100 °C and 100 atm takes place at a high rate on this catalyst, the rate of formation of excess (*R*)-(−)-EHB (w) being 20.5 mmol (g Ni)$^{-1}$ h^{-1} ($w = pv$). It should be noted that, according to Smith and Misoiu,[20] the optical yield in the hydrogenation of EAA is usually lower than in the hydrogenation of methyl acetoacetate (MAA) under the same conditions, so the optical yield of p = 63–71% obtained on this catalyst may be regarded as quite high.

It was found by XPA of samples of skeletal Ni–(+)-TA catalysts which actively hydrogenate EAA,[21,22] obtained from Ni–Al alloys containing 50.0, 45.2, and 38.3% Ni, that with an increase in the fraction of Ni in the alloy the content of the $NiAl_3$ phase increases, assisting a more effective removal in the leaching of Ni–Al alloys and an increase in the optical purity of EHB. During the reaction the value of p passes through a maximum, which occurs at a degree of conversion of the initial EAA of y = 30–60%. In a number of cases of asymmetric hydrogenation, in particular on Ni catalysts, an antibatic variation of p and y occurred, i.e., the enantioselectivity of reaction decreased as the overall rate of hydrogenation increased.[1] Often during the reaction the initially constant value of p starts to decrease after significant degrees of conversion are reached.[23] This is possibly due to the adsorption inhibition of reaction by both the initial substrate (a fall in p in the hydrogenation of EAA on Ni–TA when the initial concentrations of EAA are increased has been recorded by Lipgart et al.[24]) and the reaction product. In the latter case it is to be expected that this inhibition will differ according to whether a racemic or optically active reaction product interacts with the chiral centre of the catalyst.

For a quantitative determination of this interaction, Chernysheva et al.[25] studied the degree of inhibition of the asymmetric hydrogenation of EAA by the reaction product EHB on a Ni–TA catalyst, and the relative adsorption coefficients were determined by the method of Balandin,[26] according to the equation

$$\frac{1}{v} = \frac{b_2/b_1}{k}\frac{C_2}{C_1} + \frac{1}{k},$$

where k is the rate constant of the reaction, b_1 and b_2 are the adsorption coefficients of the initial EAA and reaction product EHB (or inhibitor) C_1 and C_2 are their concentrations.

It was found that the hydrogenation of EAA is markedly inhibited when even small quantities of EHB are added to the initial EAA. Moreover, some variation in the rates of hydrogenation also occurs when the (−)-enantiometer of EHB instead of racemic EHB is added to the initial mixture. Inhibition by the raction product does not have a significant effect on the ratio of the adsorption coefficients—b_{EHB}/b_{EAA} is usually 0.2–0.3. However, when other compounds, such as thiophene or pyridine, which strongly inhibit the catalyst are added to the initial EAA, b_{EHB}/b_{EAA} varies considerably—from 15 to 25. This ratio increases even more (up to 1400) if the catalyst is first treated with thiophene and then modified with TA. At the initial stages of the reaction when the degrees of

conversion of EAA are no greater than 10%, the introduction of pyridine has a favourable effect on the optical yield of yield—the value of p increases from 2.35 to 13.5%. This suggests that introduction of strongly absorbing compounds which poison the most active unmodified catalyst sites (at small degrees of conversion) increases the proportion of modified sites and thus increases the optical yield.

Similar results were obtained by Yasumori[27] in the hydrogenation of MAA on Ni–TA in the presence of pyridine and also NH_3, Et_3N, $BuNH_2$, whereby with an increase in the amounts of poison the rate of hydrogenation decreased by a factor of 2–3 while the optical yield increased from 11% (without introduction of poison) to 17, 33, 39, and 50% respectively.

According to the results given by Klabunovskii and Vedenyapin,[1] an optically active site must contain an array consisting of regularly ordered metal atoms and molecules of modifying agent and substrate. Hence an enantioselective reaction, according to Budar, is classed as a structurally sensitive reaction and the enantioselectivity should vary in relation to the surface structure. In fact, as was first found for Ru–TA–SiO_2 catalysts,[1] the value of p in the hydrogenation of EAA increased to a given limit with the increase in size of crystallites of Ru (up to 4.5 μm). This observation was subsequently confirmed for Ni–TA/SiO_2 and Pt–quinine/Al_2O_3 catalysts.[28]

The idea[1] that two types of site—optically selective and non-selective—exist on the surface of dissymmetric catalysts was applied in an electrochemical study of the mechanism of the modification of skeletal Ni catalysts with (+)-tartaric acid.[29] The assumption that a selective site is a ternary heteroligand complex of the type metal–modifying agent–substrate, which was first stated by Petrov et al.[30] was subsequently supported in two studies.[29,31]

It was found[32] that modification of Ni catalysts with solutions of chelates such as Ni[(*S*)-Ala]$_2$ and Ni[(*S*)-Glu]$_2$ in the hydrogenation of MAA gives the product MHB with p = 3.7 and 17.4% respectively [these values of p are similar to those obtained on Ni–Ala and Ni–Glu catalysts (p = 4.7 and 15.1%)].

Correlation of the rates of hydrogenation of acetylacetone (AA) and EAA with the hydrogenation of their chelates with Cu, Ni, Co, and Zn on skeletal Ni and Ni–TA showed[33] that both at atmospheric pressure and at 100 atm the rate of hydrogenation of the chelates is lower than the rate of hydrogenation of pure AA and EAA, but the composition of the products is the same, with the rate of hydrogenation decreasing in the series of chelates Cu–Ni–Zn–Co in accordance with the values of the stability constants of the acetylacetonate complexes of these metals. Hydrogenation of Co, Zn, Cu, and Ni acetylacetonates on a Ni–TA catalyst gives an optically active pentanediol with similar values of p, equal to 9.6, 11.1, 10.6, and 12.4% respectively. The difference between the rates of hydrogenation of EAA and Ni(EAA)$_2$ is not so large as for AA and Ni(AA)$_2$, which is due to the lower stability of the Ni(EAA)$_2$ complex compared to Ni(AA)$_2$.

The formation of a ternary complex on the surface of the catalyst was studied by means of IR spectroscopy of the adsorbed molecules.[34–36] It was found that (+)-TA, AA, and Ni^{2+} in solution form a ternary complex in which, according to the IR spectra, the AA molecule experiences an effect from (+)-TA. Comparison of the absorption bands for AA in this complex with the absorption bands for AA adsorbed on the surface of Ni–TA/SiO_2 showed that an AA molecule forming part of an adsorbed complex assumes a shape which is different to that of the pure heteroligand complex in solution. There is an increase in the asymmetry of the substrate molecule as a result of a surface effect, i.e., in this case an achiral factor assists a chiral process.

The steric model of the surface complex proposed previously[1] is supported by IR spectroscopic data on the adsorption of CO on a Ni–TA/SiO_2 catalyst, which show that TA adsorbed on the faces of a Ni crystal inhibits the adsorption of CO. This conclusion is based on the absence of an absorption band at 1940 cm^{-1} that characterises the bridged form of CO adsorption and on the decrease in intensity of the absorption band in the region of 2050 cm^{-1}.[36]

The high enantioselectivity of powdered Ni–TA catalysts in the hydrogenation of EAA is not corroborated during electrocatalysis.[37] Electroreduction of EAA in a monolayer, carried out on Ni–TA deposited on a Pt electrode, took place with 100% conversion but with a low optical yield (p = 8–12%). According to the charge curves, modification of the Ni catalyst reduces the surface area by a factor of 10 (from 4 to 0.4 m^2). In the region of the hydrogen overvoltage the conversion of EAA was 10–25% and p = 8–10%. During electrocatalysis, those sections of the surface (edges and apexes of the crystals) where the intensity of the electrical field is highest would appear to be the most active; however, these sections are least suitable for enantioselective hydrogenation because of the steric hindrance towards orientation of chiral clusters, which require quite an extensive area.[1]

At the same time, in the electroreduction of phenylglyoxylic acid in the presence of strychnine,[38] for example, it would appear that in a double electrical layer asymmetric synthesis occurs with considerable efficiency ($p \sim 20\%$).

III. Dissymmetric bimetallic catalysts

Dissymmetric bimetallic catalysts are of considerable interest both from the practical viewpoint (the possibility of synergism occurring for catalytic and enantioselective properties) and from the theoretical point of view, since the possibility arises for studying the influence of their phase state, cluster, and ligand effects on the catalytic and dissymmetric properties of these catalysts.

Bimetallic and modified dissymmetric catalysts were first studied in the case of Cu–Ru catalysts.[1] Systems based on Ni were subsequently developed.[39]

Dissymmetric Ni–Cu powdered catalysts without a support, modified with TA, displayed high enantioselectivity in the asymmetric hydrogenation of EAA. Their efficiency depends to a significant extent on their genesis and the reaction conditions.

Zubareva et al.[39–42] studied the hydrogenation of EAA in the presence of powdered Ni–Cu–TA catalysts which were prepared by reduction of mixtures of Ni and Cu oxides (nickel–copper catalyst, NCC-1), hydroxides (NCC-2), or carbonates (NCC-3) in hydrogen or a mixture of H_2 + N_2. It was established that varying the nature of the initial salts leads to a change in the phase and surface composition of the catalysts obtained, and the ratio of reduced to non-reduced forms of the phases of Ni compounds in an NCC is a factor that affects the magnitude of the optical yield. As is shown in Table 1, the NCC-1 catalyst consists of phases of solid Ni–Cu solutions enriched with Ni or Cu and a small quantity of NiO (~5%). In precipitated NCC-2 and NCC-3 catalysts, Cu and Ni form separate phases, as a result of which there is a sharp increase in the total hydrogenating activity of these catalysts. For catalyst samples that were reduced in a current of pure H_2, in which Ni, according to the XPA data, occurred in a reduced state, the value of p did not exceed 20–24% and did not depend on the

nature of the initial compounds used to prepare the catalysts. With reduction in a current of $H_2 + N_2$ the optical yield for NCC-1, NCC-2, and NCC-3 was 50.0, 14.4 and 8.4% respectively. The fact that a small quantity of NiO is contained on the surface of NCC-1 [up to 10% according to the results of X-ray photoelectron spectroscopy (XPES)] evidently assists complexation with TA. However, the presence of fairly large quantities of NiO in NCC-2 and NCC-3 leads to a reduction in p.

Table 1. Effect of conditions of formation on the catalytic and enantioselective properties and phase composition of nickel–copper catalysts (NCC) modified with (*RR*)-(+)-tartaric acid in the hydrogenation of EAA.[41]

Catalyst*	H_2/N_2**	S_{sp}, $m^2 g^{-1}$	$A \times 10^2$, (mmol m^{-2} min^{-1})	p, %	Composition of NCC from X-ray phase analysis, wt. %							
					Phase 1		Phase 2		Cu	Ni	NiO	CuO + Cu_2O
					Cu	Ni	Cu	Ni	the rest consists of phases 1 and 2			
NCC-1	0.1	9.3	0.6	50.0	23.3	76.7	79.4	20.6			5.1	–

* Catalysts NCC-1, NCC-2, and NCC-3 were obtained by reduction of Ni and Cu oxides, hydroxides, and carbonates respectively.

** Composition of gas flow during reduction of catalysts.

According to the XPES data[41] (in the region of Ni3*p* and Cu3*p*) the ratio of surface concentrations of Ni/Cu is close to 1.5 in the initial NCC-1 (Fig. 1*a*, curve *2*). In NCC-2 the surface layer is enriched with copper in the form of Cu^0 (curve *2*). After modification of both catalysts their surface is enriched with nickel—for NCC-1 the ratio of Ni/Cu is 1.3 while for NCC-2 the ratio of Ni/Cu is equal to 2. From the spectra in the region of Ni2*p* and Cu2*p* (Fig. 1*b* and 1*c*) it follows that the Cu and Ni atoms in NCC-1 are in a reduced state (with a small quantity of NiO). Moreover, it follows from the shift in Ni2*p* lines (Fig. 1*b*, curve *3*) that a certain proportion of Ni in modified NCC-2 changes to the Ni^{2+} oxidation state, which is consistent, according to the results of Balandin,[26] with the spectrum of nickel oxide NiO modified with TA. Thus, on the surface of NCC-1, which displays the highest enantioselectivity, Ni^0, Cu^0, and Ni^{2+} sites occur.[42] This conclusion is consistent with the results obtained by Zubareva et al.[42] for Ni–TA/SiO_2 catalysts, for which the presence of Ni^0 and Ni^{2+} sites on the surface of the catalyst has been demonstrated.[43]

The effect of the conditions for reducing Cu and Ni oxides obtained by decomposition of the nitrates on the enantioselectivity of these mixed catalysts modified with (+)-TA in the hydrogenation of EAA (100 °C, 100 atm) was studied by Klabunovskii et al.[44] According to differential thermal analysis data, the reduction of NiO and CuO occurs at the same time in the mixture, despite the difference in reduction temperatures of the individual oxides (320 and 270 °C respectively). It was established that the value of p does not depend on the time of reduction of the catalyst if modification is carried out at 50 °C and pH 5.0 but it increases slightly with an increase in time of reduction from 51 to 65% when modification is conducted at pH 10.0. Reduction at higher temperatures results in more complete alloying and homogenisation of the alloy.[45] However, the maximum value of p is reached when the oxides are reduced at 220 °C. It was established[46] that Ni–Cu catalysts contain two phases—a Cu phase and a Ni–Cu alloy phase. With an increase in the Cu content in the catalyst, the Ni–Cu alloy phase is enriched with nickel in bulk and with copper on the surface. According to the results of Klabunovskii et al.,[47] the hydrogenating activity of (70% Ni–30% Cu) catalysts is 5 times higher than that of a pure nickel catalyst, while the activity of the latter is 5 times higher than the activity of a Cu catalyst. However, the enantioselectivity of a (70% Ni–30% Cu) catalyst proved to be lower than that of Cu–TA (p = 50%) and Ni–TA (p = 33%) catalysts. Thus, in bimetallic Ni–Cu catalysts synergism occurs in the total catalytic activity but not in the enantioselectivity.

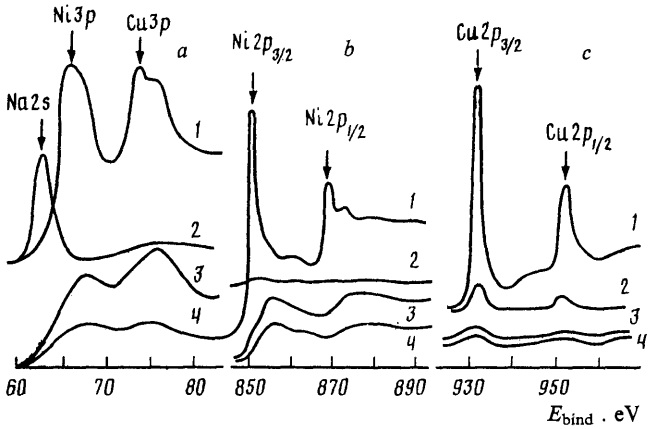

Figure 1. X-Ray photoelectron spectra of nickel–copper catalysts[41] in the region of Ni3*p* and Cu3*p* (*a*), Ni2*p* (*b*), and Cu2*p* (*c*). *1*, Initial NCC-1; *2*, initial NCC-2; *3*, NCC-1 modified with (*RR*)-(+)-tartaric acid; *4*, NCC-2 modified with (*RR*)-(+)-tartaric acid.

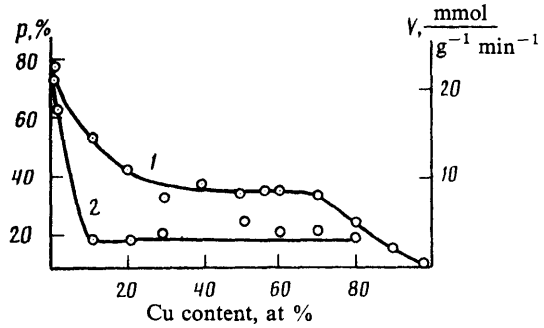

Figure 2. Dependence of the rate of hydrogenation of EAA (curve *1*) and optical yield (curve *2*) on the composition of dissymmetric Ni–Cu catalysts modified with (*RR*)-(+)-tartaric acid.[44]

Increasing the Cu content in a mixed Ni–Cu catalyst deactivates the catalyst, since Cu as an inactive component dilutes the Ni sites[44] that are responsible for the enantioselectivity of reaction. If the specific activity is attributed solely to the Cu–Ni alloy phase over the range 20–80% Cu (Fig. 2), the value of p and the specific rate remain constant, which is an indication of the constant magnitude of the surface concentration of the active component in a Ni–Cu catalyst. The value of p is little affected by both the phase state and the total hydrogenating capacity of Ni–Cu catalysts, in contrast to pure Ni catalysts, in which the enantioselectivity is strongly dependent on these factors.

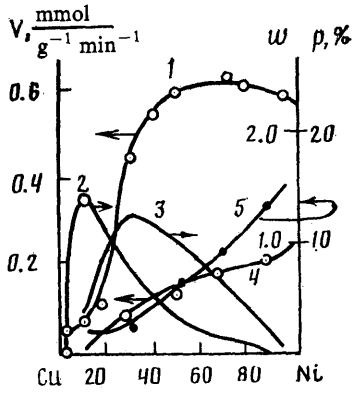

Figure 3. Dependence of the rate of hydrogenation v (curves *1* and *4*), the optical yield p (curves *2* and *5*), and rate of formation w of excess (–)-enantiomer (curve *3*) on the composition of Ni–Cu catalysts modified with (*S*)-phenylalanine (curves *1*, *2*, and *3*) and (*RR*)-(+)-tartaric acid (curves *4* and *5*) in the hydrogenation of EAA.[48]

The fact that on increasing the proportion of Ni in a Ni–Cu catalyst the latter segregates on the surface is apparently supported by data[48] on the hydrogenation of EAA on a Ni–Cu catalyst modified with (*S*)-phenylalanine (Fig. 3, curves *1–3*). In fact, whereas (*S*)-(+)-EHB is formed on Cu–(*S*)-Phe, the other enantiomer, (*R*)-(–)-EHB, is formed on Ni–Cu–(*S*)-Phe even with a Ni content of 10–15%, as on a Ni–(*S*)-Phe catalyst. The conclusion that Ni segregates on the surface of a Ni–Cu catalyst is also supported by the correspondence of the maxima on the curves plotting the change in w and the content of surface H_2 in Cu–Ni catalysts, which according to Takai[49] have a Ni content in the Ni–Cu catalysts ranging from 20 to 40%. The effect of the pH of the modifying solution of TA on the value of p for Ni and Ni–Cu catalysts for all compositions[44,50] is evident in the appearance of two maxima for p at pH 6 and 10.5.[50] For a pure Ni–TA catalyst p is equal to 57% (pH 5) and 71% (pH 10), while for a Ni–Cu–TA catalyst p = 20% (pH 5) and p = 22% (pH 10) (Fig. 4). This type of dependence of p on the pH of the modifying solution is substantially different from that reported previously for Ni,[1,48] when only a single maximum for p was found.

The introduction of just 10–15% Cu into Ni–TA sharply reduces the values of y and p. This demonstrates that Cu cannot be regarded as simply an inert component of the catalyst. It would appear that when there is a large content of Cu, it breaks up the dissymetric clusters[50,51] that are responsible for asymmetric hydrogenation and which consist of several surface atoms of Ni in a different valence state.

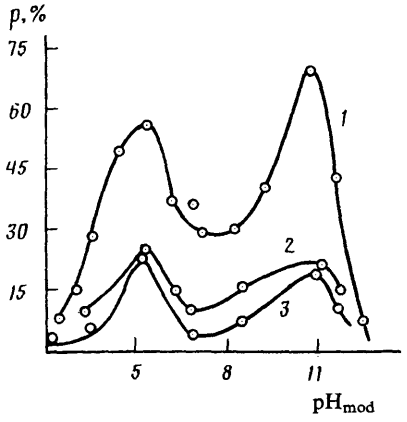

Figure 4. Dependence of the optical yield of (–)-EHB on the pH of the modifying solution of (*RR*)-(+)-tartaric acid.[44] Catalysts: *1*, Ni; *2*, Cu(50%)–Ni(50%); *3*, Cu(20%)–Ni(80%).

It was shown by Vedenyapin et al.[36] that tartaric acid forms complexes on the surface of Ni/SiO_2 and Cu/SiO_2 catalysts, and the value of ν_{COO^-} in the region of ν_{as} at 1600 cm^{-1} and ν_s at 1400 cm^{-1} for Ni/SiO_2 and Cu/SiO_2 catalysts modified with TA at pH 5 and 10 does not differ by more than 10 cm^{-1}, which suggests that there is a similar type of coordination of the COO^- group in TA. This is supported by the fact that for Ni/SiO_2 catalysts modification at pH 5 and 10 leads to the highest and approximately equal values of p. It should be noted that a change in the temperature of modification and concentration of TA solution has no effect on the type of adsorption of TA on Ni and Cu.[36] The same type of effect of the pH of the modifying solution of TA on p for Ni and Cu–Ni catalysts supports the assumption that the structure of the dissymmetric sites remains unchanged on introduction of different quantities of Cu to the composition of the catalyst. When both acidic and alkaline modifying solutions are used, two types of dissymmetric clusters having similar enantioselective properties are formed on the surface of the catalyst. It can be assumed from this that copper does not exhibit a ligand effect in Cu–Ni catalysts and the properties of the dissymmetric clusters do not change; its introduction only changes the number of such clusters.

According to Klabunovskii and Vedenyapin,[1] a dissymmetric cluster is located on specific sites of the surface, which makes it possible for contacts to occur between the metal, modifying agent, and substrate with the minimum steric hindrance. These sites can be steps on the crystallographic faces of the metal, which accounts for the high sensitivity of asymmetric hydrogenation to the structure of the active surface of the catalyst and in particular the size of the metal crystallites. This is supported by the dependence of p on

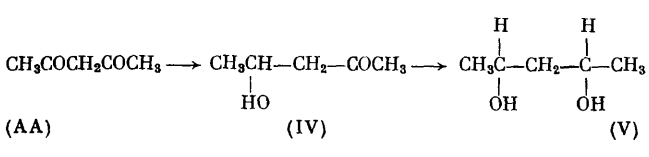
reaction temperature and on the concentration of hydrogen in the reducing atmosphere in the reduction of oxides (a decrease in the ratio of H_2:He increases p from 11 to 19%), since these factors affect the rate of formation of a Ni–Cu metal catalyst, its phase composition, the structure of the surface, the size of the metal particles, and hence the steric hindrance and magnitude of the optical yield.

It follows from the dependence of p, v, and w on the composition of Ni–Cu catalysts that the sites of enantioselective hydrogenation contain 4 times more active formations (atoms, clusters) than sites of non-selective hydrogenation.[52] It is assumed in this case that only one enantiomer is formed on the enantioselective sites.

Dissymmetric Ni–Co catalysts have been investigated in a number of studies.[53,54] On a skeletal Co catalyst modified with TA, the optical yield in the hydrogenation of EAA did not exceed 5–8%.[1] At the same time, it was found that intermetallic compounds (IMC) (for example, $LnNi_5$) modified with TA display considerable enantioselectivity in this reaction only after the introduction of cobalt into their composition (in this case the value of p reaches 52% or more).[55] It was to be expected that the introduction of Co would assist the segregation of Ni on the surface of the IMC, thus increasing the enantioselectivity of the catalyst. Therefore it was of interest to study the effect of genesis of Ni–Co–TA catalysts of different compositions on their enantioselective properties in the hydrogenation of EAA. In order to do this, a study was made of powdered Ni–Co catalysts obtained by decomposition of Ni and Co acetates or nitrates at 450 °C and by reduction of the resulting mixed oxides at 350 °C in a current of H_2 or H_2 + He for 1.5 h. Modification was carried out with a 5% solution of TA at pH 4.5–5.0.[56,57] Hydrogenation of EAA was carried out at 20–80 °C and 25–100 atm in a solution of ethyl acetate with added acetic acid.[56] Under these conditions a Co–TA catalyst did not exhibit enantioselectivity, but when 20% Ni was introduced into the catalyst the optical yield reached 3.6%, introduction of 50% Ni gave p = 6.3%,[53] and introduction of 80% Ni gave p = 9–15%.[57] A variation in the conditions for preparing the catalysts did not result in any improvement in their enantioselective properties whereas a change in the pH of modification and the nature of the solvent used in hydrogenation had a considerable effect on the values of p and y.

The conditions were found (120 °C, 110 atm) at which an increase in the content of Ni in Ni–Co catalysts to 50% increased the optical yield to 46–50% [58] (for Ni–TA catalysts under these conditions p = 65%, with a conversion of EAA close to 100%). This shows that, as in the case of Ni–Cu catalysts, the Ni component of the catalyst is mainly responsible for asymmetric hydrogenation, so that even a small increase in its content in Ni–Co catalysts markedly increases their enantioselectivity.

Thus, a Ni–Co system is considerably different in terms of its enantioselective action to the corresponding IMCs based on La, Ni, and Co, in which, on the other hand, an increase in the content of Co rather than Ni [for example, in the series $LaNi_3Co_2$–$LaNi_2Co_3$, which correspond to the systems 67% (60% Ni–40% Co)/La and 67% (40% Ni–60% Co)/La]§ results in an increase in optical yield in the hydrogenation of EAA.



Ni–Co catalysts were tested in the practically significant reaction involving hydrogenation of an equilibrium mixture of menthone–isomenthone (70:30) to isomeric menthols. On unmodified Ni, Co, and Ni–Co catalysts the reactions occur most effectively in an aqueous medium, the conversion reaching 99%.[59] The maximum yield of racemic menthol (40–44%) was obtained on Ni and Ni–Co catalysts in an alkaline medium. Modification of these catalysts with a solution of TA reduced the rate and selectivity of the reaction, although in the hydrogenation of EAA the samples of modified catalysts exhibited high enantioselectivity—p = 65% on Ni–TA and p = 54% on (90% Ni–10% Co)–TA.[60]

In the hydrogenation of the same mixture on a Co–TA catalyst it was possible to obtain up to 80% of neoisomenthol,[61] which is difficult to prepare, whereas on Ni, Pd, Rh, and copper chromite catalysts, neoisomenthol was not formed during hydrogenation in the gaseous and liquid phases.[62]

Supported dissymmetric catalysts based on Ni are of definite interest since they make it possible to study the asymmetric adsorption of the modifying agent and substrate on the surface of the catalyst by means of IR spectroscopy of the adsorbed molecules and to elucidate a number of questions concerning the theory of a strong interaction between metal and support. As has been demonstrated above, supported dissymmetric catalysts are less effective than skeletal ones,[1] especially when Al_2O_3 is the support, and only by increasing the content of metal on the support (up to 50% for Ni)[16,63] or by selecting special conditions of preparation (see below) is it possible to obtain an enantioselective catalyst.[17]

This may be due, as in the case of bulk catalysts, to the effect of an increase in the size of the crystallites[63] or to the diffusion of TA into the pores during modification of the catalyst.[64] For a clear demonstration of the effect of crystallite size on the enantioselectivity it is necessary to vary the size of the crystallites when there is a constant degree of covering the surface of the support with metal. In addition, it is known that, apart from the average dimensions of the crystallites, their distribution in size plays an important part, since crystallites of a smaller size are responsible for a greater activity but a lower enantioselectivity.

A bimetallic Ni–Cu–TA catalyst deposited on an Aerosil support that was active in the asymmetric hydrogenation of acetylacetone (AA) was first reported by Klabunovskii.[65] The conditions were found at which hydrogenation occurred selectively with the formation of only the (*R*)-(−)-ketol (IV) with p = 9.1% without the presence of diol (V).[65]

(AA) (IV) (V)

(Ni–Cu–TA)/Aerosil and Ni–TA/Aerosil catalysts were also studied in the hydrogenation of EAA.[65] It was found that with an increase in Ni content on the support the optical yield and rate of formation (w) of excess (−)-EHB increased, while the rate of formation of EHB racemate v_r ($v_r = v - w$) passed through a maximum (Fig. 5). This occurs because the increase in Ni content on the support is accompanied by an increase in the total surface of the unmodified part of the metal phase. On increasing the Ni content, the surface area starts to diminish as a result of the enlargement of Ni particles from small crystallites of Ni that are inactive in asymmetric hydrogenation. This was demonstrated for both Ni[66] and Ru–TA catalysts.[1] Thus, the optical yield (small in the case of dilute catalysts) increases with an increase in metal content on the surface of the support.[43] This may account for the

§ This representation of the catalyst composition denotes a 67% metal content (60% Ni and 40% Co) on the surface of La.

high efficiency of catalysts with a large content of metal on the support.[16] The nature of the support also has a considerable effect on the enantioselective action of the catalyst. Thus, it was found for Ni/support (1 : 1) catalysts that were active in the enantioselective hydrogenation of MAA that there was a decrease in optical yield in the following series of supports (p in brackets, %): no support (57) > SiO_2 (56.2) > zeolite Y (45.6) > Al_2O_3 (43.7) > kieselguhr (29.1) > MgO (6.1) > TiO_2 (3.1). In the same series the degree of interaction between Ni and the support increases, which during reduction of the catalyst inhibits the growth of the large crystallites which increase the enantioselectivity of the process.[43]

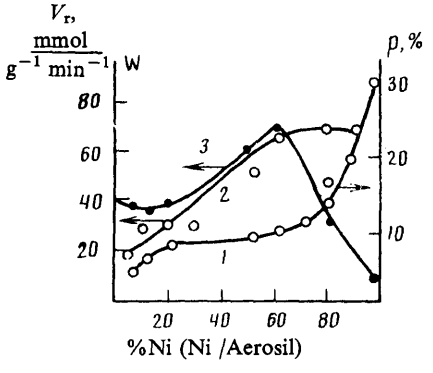


Figure 5. Dependence of the optical yield p (*1*), the rate of formation w of excess (−)-EHB (*2*), and the rate of formation v_r of the racemate of EHB (*3*) on the content of Ni in Ni−TA/Aerosil catalysts during the hydrogenation of EAA.[65]

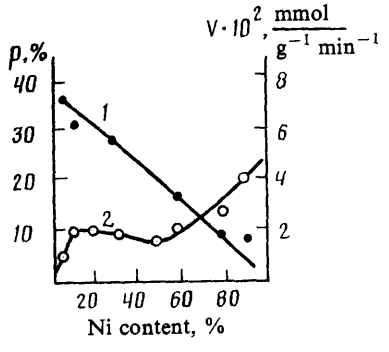

Figure 6. Dependence of the rate of hydrogenation (curve *1*) and optical yield (curve *2*) on content of Ni on the support in the hydrogenation of EAA on a Ni−TA/Aerosil catalyst.[67]

Vedenyapin et al.[67] studied catalysts obtained by impregnating supports [silica gel, Aerosil (120 m^2 g^{-1}), and kieselguhr (7.8 m^2 g^{-1})] with a solution of salts and then reduced in a current of H_2 at 380 °C. It was established that the enantioselectivity of these catalysts depend on the nature of the support, decreasing from 9% to zero in the following series: Aerosil > kieselguhr > silica gel. The average diameter of the particles ($\overline{D}$) decreases in the same series: 22, 17, and 12 nm respectively. Introduction of only 5% Cu into a 5% Ni/Aerosil catalyst leads to a decrease in $\overline{D}$ to 2−3 nm, which causes a reduction in p from 4.1 to 3.3%.

On increasing the Ni content on the support from 10 to 60% the value of $\overline{D}$ increases from 8−11 to 120 nm. This increase in $\overline{D}$ has hardly any effect on p, but with a further increase in Ni content, p increases while the rate of hydrogenation falls (Fig. 6). The fact that powdered Ni metal catalysts under these conditions give EHB with p = 50−60% demonstrates the complex nature of the dependence of p, whose increase cannot be solely related to the growth of the Ni crystallites. The depositing of Ni on a support results in an increase in the degree of dispersion of the metal phase and a reduction in p. This "inhibiting" effect of the support (Aerosil) occurs with a Ni content of up to 80%.

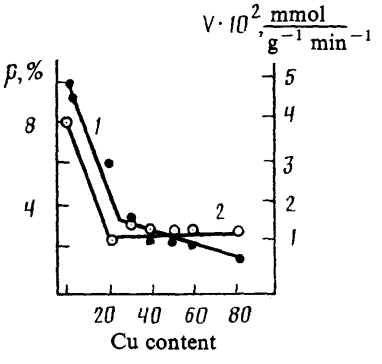

Figure 7. Dependence of the total rate of hydrogenation (curve *1*) and the optical yield (curve *2*) in the hydrogenation of EAA on Ni−Cu−TA/Aerosil catalysts on their Cu content.[67]

For Ni−Cu/Aerosil catalysts (Fig. 7) the values of p and v fall sharply when even small quantities of Cu are introduced. This effect had been observed previously[68] for bulk (powdered Ni−Cu−TA catalysts. This may occur because Cu under these conditions is inactive in the hydrogenation of EAA, but assists an increase in the degree of dispersion of the metal phase. From IR spectroscopic studies of supported Ni−Cu−TA catalysts it was possible to obtain information about the coordinate interaction between the metal phase and the molecule of modifying agent. IR spectra of adsorbed TA and AA on 20% (Ni−Cu)/Aerosil catalysts with a varying composition of Ni−Cu showed that in the interaction between TA and the Ni−Cu phase adsorption of both COOH groups of tartaric acid occurs, but to an unequal degree. This follows from the dependence of the spectroscopic characteristics of the Ni−Cu catalysts on their composition, and the bond between TA and metal which has the least covalent character occurs for Ni−Cu catalysts of composition 1 : 1.[36,69,70] The proximity of the COO^- vibration frequencies in the regions of 1600 and 1400 cm^{-1} for catalysts that are modified at pH 5 and 10 indicates the similar nature of the coordination of COO^- with the metal phase in both cases, which also results in similar values of p (in the hydrogenation of EAA, for example).[68] Substantial differences in the spectra of TA adsorbed on

Ni (1751 and 1275 cm^{-1}) occur if the surface of Ni is treated with TA in the presence of NaBr, in the latter case TA is adsorbed in the form of carboxylate ions (1416 and 1257 cm^{-1}).[71]

Supported dissymmetric bimetallic catalysts based on ruthenium have been the subject of a number of studies.[72-77] It was in the case of skeletal Cu–Ru catalysts modified with TA that the possibility of using bimetallic dissymmetric catalysts in enantioselective hydrogenation was first demonstrated.[72]

Since Cu does not adsorb hydrogen, the magnitude of the surface area of Ru in these catalysts could be determined electrochemically from the charge curves for H_2 adsorption by galvanostatic and potentiodynamic methods in KOH and H_2SO_4.[73]

Hydrogenation of EAA in the liquid phase on Cu–Ru–TA occurs enantioselectively, but p falls from 17–20% for pure Cu to 0.6% when even 0.5% Ru is introduced into the catalyst and then increases to 2.5% on a Ru–TA catalyst (with an increase in H_2 pressure the value of p increases slightly).[74] As the Ru content increases, the size of the crystallites first increases then diminishes, the specific surface increasing at the same time.[75] The effect of the size of crystallites of a metal catalyst on enantioselectivity was first demonstrated by these experiments,[1] and this was confirmed subsequently in a number of studies.[28,66]

A study of supported 10% (Cu–Ru)/Aerosil catalysts with a variable ratio of Cu:Ru in the liquid-phase hydrogenation of EAA (90 °C, 100 atm) showed that an antibatic relationship occurs between v and p, whereby when Ru:Cu = 4:6 falls from 4% to almost zero, while at the same time v increases linearly.[76,77] Under these conditions a Cu–TA/Aerosil catalyst does not hydrogenate EAA asymmetrically [whereas a skeletal Cu–TA catalyst gives (–)-EHB with p = 17%] [78] and only Cu–Ru–TA catalysts with Ru:Cu = 4:6 exhibit enantioselectivity, which suggests that there is synergism in the enantioselective action of Ru–Cu catalysts as a result of the activation of Cu in a mixed catalyst over a given Cu–Ru composition range.

This assumption about the enantioselective activity of just the Cu atoms in Cu–Ru/Aerosil catalysts is consistent with a dependence of p on pH of the modifying solution that is typical for a skeletal Cu–TA catalyst. Optically active (*R*)-(–)-EHB with p = 12% is obtained in the modification of a Cu catalyst only in the region of pH 3–7 with a maximum value of p at pH 5.[68]

A characteristic feature of Cu–Ru catalysts is that the value of p, as in the case of Ni–TA catalysts, depends on the total metal content on the support (with a constant Ru:Cu ratio, equal to 2:8). An increase in metal content from 5% (Cu+Ru) to 15% reduces p from 25 to 4%, and with a further increase in metal content p falls to zero, while retaining, however, quite a high overall rate of hydrogenation. The results obtained can be regarded as an indication that there are two types of sites on the surface of a bimetallic catalyst—inactive but stereospecific Cu sites and highly active but non-stereospecific Ru sites. Despite the lack of mutual solubility between these two metals, Cu and Ru are in close contact in supported catalysts, according to Sachtler,[79] possibly in the form of bimetallic clusters.

In skeletal Cu–Ru–TA catalysts Cu has an effect on Ru but the reverse action of Ru on Cu does not occur, which is attributed to the difference in the structures of supported and skeletal catalysts. In the latter a structure is formed that assumes the covering of the Cu phase by the Ru phase. Correlation of data obtained for Ru/SiO_2 and Ru/Al_2O_3 catalysts indicates the effect of supports on the activity of catalysts and their adsorbing capacity relative to hydrogen.

In a study of skeletal Ru that contained a small quantity of bayerite [$Al(OH)_3$] after leaching of a Ru–Al alloy, it was established that metallic Ru interacts with hydrated Al_2O_3, the Ru atoms being located close to the OH groups of bayerite, thus achieving a high degree of dispersion of Ru and the possibility of chiral modification of the catalyst when it is treated with TA,[80] whereas Ru/Al_2O_3 undergoes virtually no chiral modification.[1] These conclusions were based on a study of the spill-over of hydrogen on these catalysts. In skeletal ruthenium catalysts a more uniform distribution of metal particles and OH groups is achieved, and their interaction is more intimate than with supported catalysts. The possibility of chiral modification of the former has been attributed to this.[80]

Because of the small asymmetrising activity detected in bimetallic catalysts based on ruthenium, it was of interest to study other bimetallic systems containing Group VIII metals, in particular, palladium.

Skeletal Cu–Pd catalysts of different compositions were obtained and studied in the hydrogenation of EAA. The catalysts were obtained by leaching of a Cu–Pd–Al alloy (70% Al), and they contained Cu and Pd phases, their solid solution, and bayerite (about 40–58%). An increase in Pd content from 5 to 100% additively increase the rate of hydrogenation of EAA (100 °C, 100 atm).[81] A more complex relationship between activity and enantioselectivity occurs when there are small quantities of Pd present (up to 5% Pd). In the region of 1–5% Pd the values of w and p pass through a maximum.[82] From an electrochemical study of the catalysts using charge curves and $i\varphi$ curves it was possible to determine the quantity of hydrogen adsorbed on the catalyst. The curve showing the dependence of the ratio of H:(Pd + Cu) on the content of Pd (%) for catalysts with a Pd content of less than 10% deviates from linearity, displaying a decrease in adsorption of hydrogen on catalysts with this composition. This is attributed[81] to a screening of the Pd phase (or Cu–Pd alloy) by the Cu phase, which is supported by the results of enantioselective hydrogenation. Only catalysts containing less than 5% Pd exhibit enantioselectivity in the hydrogenation of EAA, and when the content of Pd is increased from 1 to 5 at.%, p decreases from 9 to 1%.

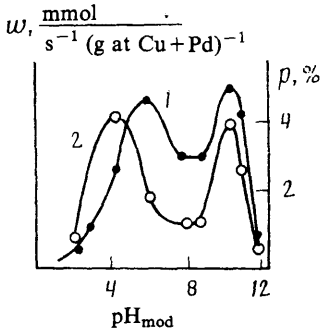

Figure 8. Dependence of the rate of formation of excess (*R*)-(–)-EHB (curve *1*) and optical yield (curve *2*) on the pH of a solution of (+)-tartaric acid during modification of a Pd(2.7%)–Cu(97.3%).

Two optimum regions of pH of the modifying solution were established by Vedenyapin et al.[82] At pH 5 and 10 the values of p were 4.1 and 4.6 % respectively in the hydrogenation of EAA on a Cu–Pd–TA catalyst containing 2.7% Pd (Fig. 8).

By carrying out the hydrogenation of EAA in ethanol solution it is possible to increase p slightly, as occurred for Co–TA catalysts.[83] However, this solvent effect proved insignificant for Cu–Pd–TA catalysts—p remained at a level of 2–3% and only the total rate of hydrogenation increased. It should be noted that, despite the results of Sachtler,[64] the rates of hydrogenation of pure EAA on modified and unmodified Cu–Pd catalysts proved to be similar, whereas the rate of hydrogenation of EAA in ethanol on a modified catalyst is higher than its rate of hydrogenation on an unmodified catalyst.

On changing the Pd content in Cu–Pd–TA catalysts, the values of p and w pass through a maximum at a level of 2% Pd (Fig. 9), while on changing from skeletal Cu–TA to Cu–Pd–TA p falls from 15 to 4–5%.

Thus, as in the case of Cu–Ru catalysts, a deviation from additivity occurs when small quantities of Pd are introduced into a Cu catalyst. With a Pd content of about 5% the specific rate, relative to 1 m^2 of surface of the Pd phase, increases by a factor of about 150 compared to the rate of hydrogenation on pure Pd. This may be regarded as evidence that in a bimetallic catalyst the properties of copper vary markedly when it is promoted by palladium, and it acquires a capacity to hydrogenate EAA and make a contribution to both the total rate and the rate of enantioselective hydrogenation.

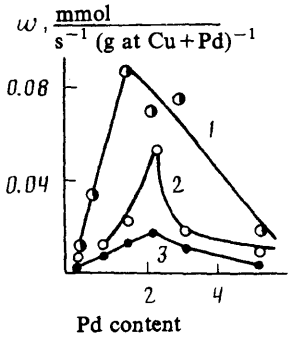

Figure 9. Dependence of the rate of formation of excess (*R*)-(−)-EHB on the composition of Pd–Cu catalysts in ethanol (curve *1*) and without a solvent (curves *2* and *3*) at pH_{mod} 4.5 (curves *1* and *2*) and pH_{mod} 10.5 (curve *3*) during hydrogenation of EAA.[82]

A comparison of different dissymmetric catalysts containing copper, such as Cu–Pd and Cu–Ru, reveals considerable differences between them. While the presence of only 0.1–0.5% Ru in the case of Cu–Tu–TA causes almost complete suppression of enantioselectivity, this suppression in Cu–Pd–TA catalysts only occurs when more than 5 at.% Pd is added. The total activity of Cu–Ru catalysts increases with an increase in Ru content, whereas on Cu–Pd synergism of catalytic action occurs, which may be due to a difference in structure of the active phase and dependent on a ligand effect.[81,82] A similar effect was detected for skeletal Cu–Ru–TA catalysts. Comparison of Cu–Pd and Cu–Ru catalysts by an electrochemical study of the adsorption of H_2 on them showed that with an increase in Cu content in the catalysts the strength of the Ru–H and Pd–H bonds decreases. The maximum on the $i\varphi$ curves is shifted to lower potential when copper is introduced into a Ru or Pd catalyst, which suggests that they interact electronically, i.e., there is a ligand effect.[84]

In contrast to the phase composition of Cu–Ru catalysts, for which a sandwich structure has been accepted (the surface is mainly covered with Ru atoms), the surface of Cu–Pd, according to electrochemical data,[82] is enriched with copper when Pd < 5%, which assists the formation of Cu–Pd clusters that provide synergism of catalytic action of such a catalyst through the ligand effect. This leads to a change in state of the Cu atoms, resulting in not only their high catalytic activity but also the distinctive dependence of p on the pH of modification.

Kuznetsova et al.[85] studied copper–palladium (CPC) and nickel– palladium (NPC) catalysts deposited on A-300 Aerosil and on γ-Al_2O_3. The catalysts were obtained by impregnation of the support with solutions of Cu^{2+} and Pd^{2+} or Ni^{2+} and Pd^{2+} salts, reduction in a current of H_2/He (1 : 10) at 360 °C, followed by modification at pH 5 and 50 °C with a solution of TA (method A) or by modification of reduced Cu/SiO_2 and Ni/SiO_2 catalysts with a solution of $PdCl_2$ + TA (method B).

Table 2. Activity and enantioselectivity of supported catalysts modified with TA in the hydrogenation of EAA.[85]

Catalyst	Optical Yield, p, %	Activity $A \times 10^2$ mmol (g cat)$^{-1}$ min^{-1}
10% Pd/SiO_2	0	18
10% Ni/SiO_2	7.1	9
(2% Pd–8% Cu)/SiO_2	0	5
(1% Pd–10% Cu)/SiO_2	1.6	5
(1% Pd–9% Ni)/SiO_2	7.0	8
(1% Pd–10% Ni)/SiO_2	4.6	11

It was established that asymmetric hydrogenation with p = 1.6% only occurred on the CPC obtained by method B and not by method A, which is apparently due to the presence of Pd^{2+} ions on the surface of the catalyst that can form a complex with TA. In the case of the NPC, regardless of the method of preparation (A or B), an enantioselective reaction occurred with p = 7 and 4.6% respectively. It should be noted that under these conditions a nickel catalyst—(10% Ni–TA)/SiO_2—also exhibited low enantioselectivity (Table 2), while in all cases replacement of SiO_2 by Al_2O_3 led to complete inhibition of the asymmetric activity of the catalyst.

IV. Dissymmetric intermetallic catalysts

Multicomponent hydrogenating metal catalysts—intermetallic compounds (IMCs) of rare earth elements (REEs) with Ni, Co, Cu, and other *d*-metals and their hydrides—are of interest for

asymmetric catalysis as cluster models, in a similar manner to bimetallic systems.

A study was made of two structural types of IMC enriched with nickel—LnM_3 and LnM_5.[65] Comparison of $LnNi_5$ catalysts (Ln = La, Sm, Gd, Ce, Pr, Nd) with Ni catalysts deposited on the oxides of the same REE demonstrated the high activity of IMCs and their hydrides in the hydrogenation of propylene, the greatest activity (1 atm, 100 °C) being exhibited by $LaNi_5$ [86] and the least activity by $CeNi_5$.[87] The specific activity of the hydrides of IMCs such as $LaNi_5$ and $LaCo_5$ is ten times higher than that of a supported 5% Ni/CeO_2 catalyst.[88] In this case the catalytic activity is higher the lower the equilibrium pressure of hydrogen in the system $IMC-H_2$, i.e., the more stable the hydride,[89] which was demonstrated for a $LnNi_5$ series of IMCs (Ln = La, Ce, Pr, Nd, Sm) and for $La_{1-x}Pr_xNi_5$.[89–91]

According to XPES data and magnetic measurements, segregation of Ni and its enrichment of the surface occurs on the IMC hydrides during the reaction, with the Ni:La ratio increasing from 5 to 6. However, conventional metal catalysts such as Ni/CeO_2, Ni metal, and skeletal Ni—have low activity under these conditions. This suggests that IMC hydrides may be regarded as a new class of hydrogenation catalysts with high activity, despite their small specific area.[87,92,93] The high activity of intermetallic REE compounds may be related to their ability to form hydrides with a high IMC—carbon bond energy that significantly exceeds the metal—C bond energy for Ni, Pt, and Pd catalysts. Calculated values of the bond energies of $(LnH_3)-C$ (for Ln = La, Pr, Gd, and Lu) according to the multiplet theory of catalysis[26] were 56.7, 34.3, 34.8, and 50.3 kcal mol^{-1} respectively.[94]

Replacement of a proportion of the Ni atoms by Co gives more stable hydrides with higher IMC—H bond energies, and the highest activity in the hydrogenation of propylene is exhibited by $LaNi_{5-x}Co_x$—hydride when $x = 2$. For this system the greatest density of hydrogen occurs in the $LaNi_3Co_2-H_4$ lattice. A similar pattern occurs for $LaNi_{5-x}Cu_x-H_4$, for which, according to the multiplet theory of catalysis,[26] the highest catalytic activity corresponds to the maximum hydride stability. The strength of the $IMC-H_x$ bond increases with an increase in x, and the free energy of the system ΔG decreases from 1.46 ($x = 1$) to −0.63 ($x = 3$); a further reduction in ΔG leads to a decrease in catalytic activity.[96] Other systems of $LaNi_{5-x}M_x$ and their hydrides, where Ln = La, Sm, Gd, and M = Al, Ti, V, Cr, Mn, are also active in the hydrogenation of propylene.[57]

It was found for the first time by Konenko et al.[97] that IMC hydrides such as $LaNi_5-H_6$ and $La_{1/2}$, $Pr_{1/2}Ni_5-H_5$ treated with a solution of (+)-tartaric acid at pH 4.8 exhibit enantioselectivity in the hydrogenation of EAA at 80 °C and 100 atm to (*R*)-(−)-EHB, with $p = 9.8$ and 5.7% respectively. However, a similar asymmetric effect ($p = 5.7\%$) was found for a 5% Ni/CeO_2 catalyst that was modified under the same conditions. This could suggest that the Ni which enriches the surface of the IMC as a result of segregation and forms dissymmetric clusters during modification with tartaric acid is responsible for the enantioselective properties of the catalyst. However, the fact that enrichment of an IMC with lanthanum, as in the case of La_3Ni, will hinder the segregation of Ni and affect the catalytic properties does not support this theory (partial replacement of La by Pr generally results in catalyst deactivation).[98] It is found that the initial La_3Ni, being modified with TA, achieves the asymmetric hydrogenation of EAA with $p = 11.9\%$, whereas a ferromagnetic sample with a specific magnetisation of saturation $\delta = 0.6-0.75$, in which considerable segregation of Ni has occurred as a result of the initial treatment of the sample, is inactive in enantioselective hydrogenation.[99]

Replacement of a proportion of the Ni atoms in $LaNi_5$ by other metals results in the formation of paramagnetic IMCs and their stabilisation. Thus, $LaNi_5$ forms the least stable hydride while an IMC of the type $LaNi_{5-x}Cu_x$ forms the most stable hydride.[99,100] According to the multiplet theory of heterogeneous catalysis, the catalytic system with the optimum energy values of the bonds between the catalyst and the atoms of the substrate molecule will have the highest catalytic activity. In fact, the highest catalytic and enantioselective activity in a series of $LaNi_{5-x}Cu_x$ IMCs was exhibited by $LaNi_3Cu_2-H_{3.7}$ ($p = 15.6\%$), which in terms of stability occupies a position between $LaNi_5$ and $LaNiCu_4$.[100] Thus, the isostructural replacement of one or two Ni atoms by Cu in $LaNi_5$ leads to more efficient dissymmetric catalysts. Similarly, in Ni—Cu catalysts modified with TA,[102] an increase in Cu content to 30 at.% gives a maximum value of p (in $LaNi_3Cu_2$ the Cu content is 28.7% and p reaches 17%).[100] This shows that it is the IMC hydrides as a whole, rather than the individual phase of Ni that separates out during segregation, which exhibit catalytic and enantioselective activity.[101]

The effect of pH of the modifying solution of TA on the value of p also confirms the participation of the whole IMC cluster, i.e., all of its components, in the formation of a complex with TA. Thus, for IMCs of the type $LaNi_4Cu$ the optimum value of pH is 5, whereas for $SmNi_4Cu$ and $GdNi_4Cu$ the optimum is pH 9. Modification of an IMC of composition $LnNi_3Cu_2$, where Ln = La, $La_{0.5}Sm_{0.5}$, and $Sm_{0.5}Gd_{0.5}$, at pH 9 leads, in line with the stability constants of Ln—TA complexes, to an increase in optical yield p from 4.4 to 6.1 and 9.9% respectively. The hydrogen pressure and reaction temperature also affect p. On the most active IMC of composition $LaNi_4Cu-H_{6.3}$, values of $p = 11.5\%$ at 80 °C and 40 atm, $p = 17\%$ at 80 °C and 80 atm, and $p = 9.7\%$ at 40 °C and 80 atm were obtained.[101]

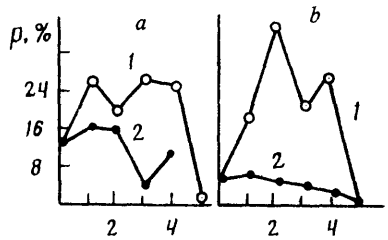

Figure 10. Dependence of the optical yield (*a*) and degree of conversion (*b*) in the hydrogenation of EAA on the number of atoms of M in the lattice of intermetallide $LaNi_{5-x}M_x$ [M = Co (*1*) and Cu (*2*), $pH_{mod} = 4.5$, hydrogenation conditions: 80 °C, 80 atm, 7 h].[103]

Thus, the dissymmetric properties of intermetallic catalysts are governed by both the ratio of Ni/Cu in the crystal lattice and the nature of the cluster that incorporates REE atoms of different types. The most effective catalysts were obtained[95,103] when cobalt was

introduced into the matrix of $LaNi_5$ hydride. These catalysts exhibit higher enantioselectivity and catalytic activity than that of $LaNi_{5-x}Cu_x$ catalysts. For the hydride $LaNi_4Co-H_{3.3}$ the value of p (26.6%) is more than twice that of $LaNi_5$ (p = 12%) and that of IMCs containing Cu.

The dependence of p on the number of Co atoms in an IMC of the type $LaNi_{5-x}Co_x$ is shown in Fig. 10. The corresponding $LaNi_{5-x}Cu_x$ are given for comparison. It is clear that for both types of catalysts there is an extremal dependence of the optical yield and degree of conversion of EAA on the number of Co or Cu atoms replacing Ni in $LaNi_5$.[103] While the optical yield did not exceed 17% when Cu was introduced into $LaNi_5$, when Co was introduced it increased to 30%, and with modification of $LaNi_3Co_2$ with a solution of TA at pH 4.5 with added trimethylacetic acid it rose to 45%.[104,105] It should be noted that the introduction into the modifying solution of NaBr, which is very effective for skeletal Ni,[18] has almost no effect in the case of IMCs, which is an indication once again of the special properties of IMC catalysts.[104]

When instead of Co other metals such as Mn, Cr, Ti, V, or Al are introduced into $LaNi_5$, the stability of the corresponding hydrides increases but their enantioselectivity is reduced. Only when Mn and Cr are introduced ($LaNi_4Mn-H_3$ and $LaNi_4Cr-H_{2.5}$) is there any appreciable activity (p = 20 and 16%).[104]

Interesting results were obtained in the partial replacement of Co by Cu in $LaNi_{5-x}Co_x-H_n$.[106] In this case both the total catalytic activity and enantioselectivity of the catalyst were reduced, the latter being greatest in $LaNi_3Co_2-H$ (p = 52%).[55]

Hydride of intermetallide	y, %	p, %
$LaNi_3Co_2-H_{3.5}$	100	52
$LaNi_3CoCu-H_{5.7}$	96	9
$LaNi_3Co_2Cu-H$	20	27
$LaNi_2CoCu-H_{3.8}$	30	17
$LaNiCo_2Cu_2-H_{3.6}$	12	13

Intermetallic catalysts that do not contain Ni have low activity. The successive and complete replacement of Ni by Co leads to a sharp decrease in catalytic and asymmetric activity. The partial introduction of Cu atoms into $LaCo_5$ does not lead to an increase in activity.[106]

The highest value of p (about 60%) was found for a $LaNi_{5-x}M_xM_y$ system containing Co and Cu. This asymmetrising effect is attributed to the formation of heterometallic complexes $[LaM_xM_y-TA]$.[107]

This behavioural feature essentially distinguishes intermetallic catalysts from bimetallic Ni–Co catalysts that are modified under the same conditions as IMCs and for which the value of p steadily increases with an increase in Ni content.

According to Klabunovskii et al.,[108] asymmetric activity in the hydrogenation of EAA and AA decreases in the following series of metal catalysts modified by TA and amino acids: Ni > Cu > Co, the value of p not exceeding 5–8% for Co. It was therefore to be expected that IMCs containing Ni and Cu would be more enantioselective than those containing Ni and Co. However, the results obtained indicate that, on the contrary, Ni–Co IMCs are more active than Ni–Cu IMCs. This may occur because Ni and Co are not segregated to any significant degree on the surface of an IMC, otherwise the enantioselectivity of the catalyst would be governed by the nature of the metal segregated on the surface of the catalyst. The catalytic and enantioselective activity of IMCs are determined rather by the nature of the cluster which contains the atoms of three different metals—La, Ni, and Co (or Cu).

Intermetallic catalysts that are modified in the optimum pH region decompose to a lesser degree during catalysis, which is supported by a test for their ferromagnetic properties) (test carried out by the Faraday method). Hence, a higher value of p is characteristic of those hydrides that decompose to a lesser degree during modification and hydrogenation. Moreover, the catalytic properties also depend on the strength of the IMC–H bond. Introduction of Co into an IMC increases the strength of the IMC–H bond and improves the stability of the hydride. This relates in particular to $LaNi_3Co_2$, for which maximum values of the magnetic moment, a maximum density of the hydrogen atoms in the hydride lattice, and optimum values of the IMC–H bond energy have been found.[95]

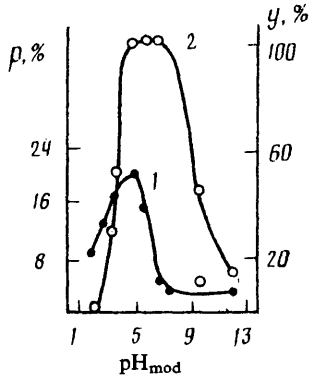

Figure 11. Dependence of the optical yield (*1*) and degree of conversion (*2*) on $LaNi_3Co_2-H_{3.5}$ on the pH of the modifying solution of (+)-tartaric acid.[103]

The dependence of p on the pH of the modifying solution of TA has the same extremal nature as the dependence for modified Cu and Co metal catalysts.[102,109] The dependence of p and y on the initial pH of the modifying solution of TA for $LnNi_3Co_2$ and $LaNi_4Cu$ catalysts is shown in Fig. 11.[103] This suggests the identity of the tartrate complexes of the metals contained in the dissymmetric site that are formed on the surface of the catalysts.[1]

The increase in pH of the solution of TA in the course of modification and the evolution of hydrogen during modification of the hydride also point to complexation on the surface of the IMCs during their modification, in addition to the asymmetric effect in hydrogenation. At the same time a proportion of components of a $LaNi_3CoCr-H_{4.2}$ catalyst passes into solution (especially La) and the surface of the IMC is enriched with Ni. Data on the

composition of the surface layer, obtained by using XPES,[13] are given below.

Hydride of intermetallide	La	Ni	Co	Cr
IMC (initial)	14.7	60.0	15.8	9.5
IMC hydride	17.5	64.6	7.9	10.0
IMC–$H_{4.2}$ after modification at pH 4.5	8.3	65.2	7.8	18.7
The same after modification at pH 7.0	22.3	44.5	12.2	21.2
Bulk composition of the initial hydride $LaNi_3CoCr-H_{4.2}$	32.3	40.9	13.7	12.1

Replacement of La in $LaNi_3CoCr-H_{4.2}$ by Sm or Gd results in a sharp fall in catalytic and enantioselective activity of the catalyst, which is an indication of the inclusion of REE atoms in addition to *d*-metals in the dissymmetric cluster.

The decrease in *p* may be related to the increase in strength of the tartrate complexes of IMCs containing Sm and Gd in comparison to IMCs based on La.[101] Replacement of La in $LaNi_5-H_4$ by other rare earth elements (Pr, Sm, Gd)[60] leads to a reduction in stability of the corresponding hydride, and this gives rise to the need for a considerable increase in the hydrogen pressure that is necessary for hydride formation in the preparation of an IMC hydride. On the other hand, replacement of Ni in $LaNi_5-H_4$ by atoms of other transition metals strengthens the IMC–H bond. Therefore, catalysts based on more stable hydrides, such as $LaNi_4M$ with M = Al, Ti, V, with a high overall catalytic activity exhibited low enantioselectivity.[110] Data on a number of polymetallic hydrides that have been studied are summarised in Table 3.[57,96,103,110–112]

Table 3. Dependence of the degree of conversion (*y*, %) and optical yield (*p*, %) in the hydrogenation of EAA on IMC catalysts (80 °C, 80 atm, 7 h) on the composition of IMC hydrides modified with (+)-tartaric acid (pH 4.5).[57,96,103,110–112]

Catalyst	*y*, %	*p*, %	Catalyst	*y*, %	*p*, %
$LaNi_5$-$H_{6.0}$	14.9	12.7	$LaNi_4Cu$-$H_{5.8}$	17.5	17.0
$LaNi_4Co$-$H_{4.8}$	48.8	26.6	$LaNi_3Cu_2$-$H_{3.7}$	13.0	15.6
$LaNi_3Co_2$-$H_{3.7}$	100	20.0	$LaNi_2Cu_3$-$H_{3.5}$	9.5	4.3
$LaNi_2Co_3$-$H_{3.9}$	52.9	28.0	$LaNi_3CoCr$-$H_{4.2}$	58.2	13.5
$LaNi_2Co_2Cu$-$H_{3.9}$	10.0	21.0	$LaNi_3CuCr$-$H_{3.9}$	64.7	16.0

20% Ni – 80% Co	22.0	11.0			
$LaNi_4Al$-$H_{4.0}$	60.9	6.3			
$LaNi_4Ti$-$H_{3.5}$	93.4	1.1			
$LaNi_4V$-$H_{3.5}$	95.4	5.2			
$LaNi_4Cr$-$H_{4.0}$	96.0	16.3			
$LaNi_4Mn$-$H_{5.0}$	40.7	23.4			

It is evident from Table 3 that the use of catalysts based on polymetallic IMCs, especially 5- and 6-component systems, in asymmetric hydrogenation does not have any advantages over IMCs of a simpler composition. In certain cases the polymetallic systems generally proved inactive. However, for an understanding of the mechanism of action of these catalysts, the important conclusion that a change in the nature of all the components of the IMC, including the REEs, has a considerable effect on the catalytic and enantioselective properties of the catalysts follows from the data given.

This again provides confirmation that during the modification of IMC hydrides, heterometallic tartrate complexes contained in a catalytic cluster of asymmetric hydrogenation are formed on the surface. This cluster is similar to that which has been proposed for dissymmetric monometallic hydrogenation catalysts.[1]

Dissymmetric intermetallic catalysts were studied in the practically significant diastereoselective hydrogenation of fructose to mannitol and sorbitol.[113,114] Previously[112] the hydrogenation of *D*-fructose to sorbitol and mannitol had been optimised with respect to sorbitol by means of mathematical planning of the experiment. Skeletal Ni modified with (+)-tartaric acid proved to be the best catalyst. Hydrogenation of an aqueous solution of *D*-fructose at 80 °C and a hydrogen pressure of 90 atm gave sorbitol in 65.7% yield (sorbitol : mannitol = 1.9 : 1).

A number of isostructural IMC hydrides — $LaNi_3Co_2$ and $LaNi_3Cu_2$ and also $LaNi_3M'M''$, where M'M'' = CuCo, CoCr, MnCr, $Co_{0.5}Cu_{0.5}Cr$, modified with (+)-tartaric acid — were studied[113,114] for the diastereomeric hydrogenation of *D*-fructose. The task involved finding catalysts and optimising the hydrogenation of fructose to mannitol — a product of practical importance. It was found that the pH of the modifying solution of TA is of crucial importance for preparing the optimum catalyst. The maximum values of the degree of conversion of fructose were achieved by pH 7–8 for $LaNi_5$, $LaNi_3Co_2$, and $LaNi_3Cu_2$ and at pH 4.5–5.5 for $LaNi_3CoCr$. By varying the reaction conditions it was found that the highest yield and maximum diastereoselectivity could be attained when $LaNi_3Cu_2$ was used. The optimum conditions were: 1.5 g of catalyst, a 15% solution of fructose, 80–90 °C, a hydrogen pressure of 50 atm. It should be noted that by introducing up to 50% sorbital into the reaction mixture it was possible to increase substantially the diastereoselectivity of the reaction with respect to the formation of mannitol. The excess of mannitol was 46% and the total yield was 73%. The $LaNi_3Co_2$ catalyst was more selective towards formation of sorbital (39% excess of diastereoisomer and 70% yield).

Comparison of the selectivity of action of the catalyst with the content of the stereoisomeric forms of *D*-fructose in the reaction system showed that the stereoisomers of α-*D*-fructopyranose and α-*D*-fructofuranose are mainly responsible for the formation of *D*-mannitol.[113]

---o0o---

The studies described above have not covered all aspects of research into asymmetric hydrogenation on metals. Questions relating to the reaction mechanism, which has recently been the subject of considerable attention in a number of studies, have remained untouched. Ideas have been developed concerning the decisive role in asymmetric hydrogenation of the coordination of metal ions on the surface of the catalyst with molecules of modifying agent — these are usually hydroxyacids or amino acids — and with

substrate ions—mainly readily complexing diketones and ketoesters. The previously advanced theories[1] about asymmetric hydrogenation occurring via the formation of an intermediate ternary complex of metal–modifying agent–substrate have received support in a number of studies.[26,31,64] The nature of the chirodiastaltic interaction between molecules of modifying agent and substrate (or semihydrogenated compound) in such complexes is evident in correlation[108] between the stability constants of complexes that simulate an intermediate complex on the surface of the catalyst and the enantioselectivity of the catalyst containing this complex.[65] By finding these correlations it is possible to predict the composition of effective dissymmetric catalysts and the nature of the modifying agent—in the metal series Ni–Cu–Co with (*S*)-α-amino acids as modifying agents. Additional correlations between the conformation of a ternary complex determined from circular dichroism spectra and the configuration of the hydrogenation product make it possible to establish the configuration of the product with sufficient reliability.[69,115]

The second aspect of asymmetric hydrogenation (which was only mentioned in two studies)[6,7] is the problem of the industrial development of asymmetric catalysis for the preparation of optically active compounds of practical importance. Considerable progress in the field of asymmetric metal-complex catalysis is known to have been achieved in this area. Chiral rhodium phosphine complexes proved very effective in the synthesis of a number of important optically active products, and only the complex nature of synthesising the ligands and the high cost of the processes have placed a restraint on their widespread application.[116,117] In certain cases these processes have had a practical application in the synthesis of high-cost products [for example, 3,4-dihydroxylphenylalanine (DOPA) for the treatment of Parkinson's disease, phenylalanine[117] for the production of the sweetener Aspartame, menthol[118] for the food and perfumery industries and medicine] on a large scale.

Modified heterogenous metal catalysts, because of the limited range of their action (on the whole it is only the C=O bond that is effectively hydrogenated), have so far found less applications, despite their evident technological advantages over metal-complex catalysts. However, there is an indication[119] that a Ni–TA catalyst has been used to obtain (2*R*,4*R*)- and (2*S*,4*S*)-pentanediol by hydrogenation of acetylacetone. (*S*)-Alkyl-β-hydroxybutyrates—important optically active synthons[120] that have already come on the market—have also been obtained in this manner. Thus, it is possible to look forward to a wider practical realisation of asymmetric hydrogenation on heterogeneous metal catalysts modified with optically active compounds.

Reactivity of transition metal solvates

B D Berezin
Institute of the Chemistry of Nonaqueous Solutions, USSR Academy of Sciences, Ivanovo

ABSTRACT. Reactivity data are generalised for one of the most important classes of complexes, solvates, which are quantitatively nearly unstudied. Various approaches to studying and describing the reactivity are compared with respect to solvation of the reagents and the transition state. The specifics and mechanism of ligand substitution in pure and mixed organic solvents are found. The reactivity of simple (homoleptic) and mixed solvates toward macrocycles is examined in detail using porphyrins as an example. The kinetic method of indicator reactions is applied to porphyrins in order to study the state of transition metal salts in organic solvents and the stability of the coordination spheres of acidosalts (MX_n^{n-2}), acidosolvates (MX_2S_{n-2}) and their transition states. The concentration dependence of the rate constant of an indicator reaction is demonstrated to be due to a change in the inner coordination sphere and a shift of equilibria between the various coordination complexes.

A bibliography with 38 citations is included.

I. General concepts of the reactivity of complexes

The reactivity of a compound refers to the rate at which the given compound reacts with others. The rate constant at 298 K, k_v^{298}, is used as a measure of the reactivity of a compound in a series of similar reactions.[1] The number of chemical reactions in which one compound or another participate can be practically infinite. However, the rates differ dramatically from reaction to reaction. Therefore, the reactivity of any compound refers to a specific reaction or at least a specific type of reaction (acid–base, complexation, redox, etc.). The rate constant is related to the free energy of activation

$$\Delta G^{\neq} = -RT \ln k_v - RT \ln \frac{kT}{h}, \quad (1)$$

which is determined by the energy and structural changes occurring during activation in the transition state (Fig. 1). Hence, the numerical values of k_v^{298} and ΔG^{298} are controlled by the mechanistic subtleties of the fundamental reaction step.

The free energy of activation contains two components. These involve energy (energy E or enthalpy of activation $\Delta H^{\neq}$) and structure (entropy of activation $\Delta S^{\neq}$)

$$\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}. \quad (2)$$

According to the basic equation of the theory of absolute reaction rates[2]

$$k_v^{298} = \varkappa \frac{\kappa T}{h} \exp(S_0/R) \exp(-\Delta H_0^{\neq}/RT). \quad (3)$$

For complicated reactions, which include ligand substitution in solvates, the coefficient representing surmounting of the potential barrier by the reagents, $\varkappa$ (transmisison coefficient), cannot be found. It is usually taken equal to unity. The enthalpy of activation is less frequently used in kinetic calculations than the activation energy, which is usually found graphically using the Arrhenius equation. The quantities $\Delta H^{\neq}$ and E are interrlated

$$\Delta H^{\neq} = E - RT. \quad (4)$$

At 298 K, the difference between $\Delta H^{\neq}$ and E is 2.5 kJ mol^{-1}. The enthalpy of activation for a complicated chemical reaction in solution is determined by the energy change resulting from the cleavage of some and the formation of other chemical bonds, the energy difference of electrostatic repulsion and attraction, and the energy changes due to loss or addition of solvent molecules in the transition state. The entropy of activation is related to the probability of forming the transition state, i.e. to the steric relationship of the reaction centres in the reacting reagents. If the solvent actively participates in the reaction (as a reagent and as a strongly solvating species), this is reflected in $\Delta S^{\neq}$. As a rule, desolvation favours conversion from the transition state to the final one and increases $\Delta S^{\neq}$. Conversely, additional solvation reduces the probability of generating the transition state and reduces $\Delta S^{\neq}$. Especially complicated situations are encountered in complexation involving macrocycles where the macrocyclic effect appears.[3] The quantities $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are interrelated for formation of complexes with porphyrins. Desolvation of the reagents in the transition state increases the energy requirements for their activation, i.e. the increase of $\Delta S^{\neq}$ causes $\Delta H^{\neq}$ to increase. Solvation in the transition state is energetically favourable but structurally unfavourable. Therefore, a decrease of $\Delta S^{\neq}$ decreases $\Delta H^{\neq}$. This is known as the kinetic compensation effect,[1] which is mathematically described by

$$\Delta H^{\neq} = a + b\Delta S^{\neq}, \quad (5)$$

where a and b are coefficients. The transition state serves as a manifestation of the chemical form of the mass action.[4] The complexity of this action is reflected in the activation mechanism of the fundamental chemical reaction.

The reactivity of complexes has been well studied and is well documented in a monograph.[5] This refers not to ligand substitution processes in complexes but to a change of the chemical nature of coordinated ligands under the influence of outer-sphere species. There are no broad systematic data for the reactivity of coordination (complex) compounds in substitution reactions of some ligands by

others, except for the case water ⇆ ligand. Existing books[6–8] contain only anecdotal kinetic data for these reactions. Ligand substitution in solvates apparently obeys the same rules as substitution of water molecules in aqua complexes. Their stoichiometric mechanisms[8] are apparently also similar.

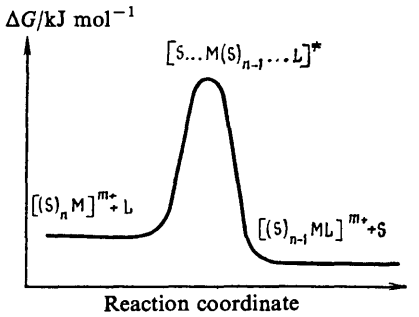

Figure 1. Coordinate and transition state of an $S_N2(I)$ solvate coordination reaction.

Let us examine in general the mechanisms of complexation in solution. The limiting steps of ligand substitution reactions are usually classified by their molecularity. Unimolecular, bimolecular and termolecular reactions differ in the number of species used in forming the transition state (and in activating the reagents). The duration of the fundamental step is $\sim 10^{-13}$ sec. The theory of termolecular reactions in solutions is complicated and not fully solved.[2] Bimolecular reactions are more numerous. Representing as a reagent the ligand (L or X^-) entering the coordination sphere of the complex, these reactions are denoted by the symbol S_N2 (according to Ingold–Hughes). This stands for substitution of a ligand by another nucleophilic ligand in the complex

$$[M\ (S)_n]^{m+} + L \rightleftharpoons [M(S)_{n-1}L] + S \ldots \quad . \tag{6}$$

In this instance, L should be an electron donor, i.e. have an O, N, S, Hal, etc. atom with a negative charge or an electron pair or both. Therefore, H_2O, NH_3, solvents derived from them, H_2S, all solvents with $-S-R$ bonds, $R-S-R$, $R_2S=O$, R_2SO_2, and certain others are nucleophiles. According to the Langford and Gray classification,[8] three types of bimolcular reaction mechanisms can be distinguished: *D*, dissociative; *A*, associative; and *I*, interchange. The *D*-mechanism of substitution includes two steps and presumes two possible routes for its occurrence. If the solvent loss step is fast and the second step of ligand L or X^- addition is slow

$$[M(S)_n]^{m+} \overset{-S}{\rightleftharpoons} [M(S)_{n-1}] \overset{+L}{\rightleftharpoons} [M(S)_{n-1}L], \tag{7}$$

then the $S_N2(D)$ mechanism is observed. If the first step is slow and the second fast, then the reaction wil be monomolecular (its rate does not depend on [L]). Such a mechanism is denoted $S_N1(D)$. Both *D* mechanisms are equally probable. Realisation of one or the other depends on the nature of the metal and solvent. In both instances, the intermediate formed is $M(S)_{n-1}$, a solvate with coordination number smaller than maximal by one unit.

The associative mechanism (*A*) is less probable for solvates since it is caused by deformation of the initial coordination sphere of $[M(S)_n]^{m+}$ by the substituting ligand L

$$M(S)_n]^{m+} + L \rightleftharpoons [M(S)_nL]^{m+} \rightleftharpoons S + [M(S)_{n-1}L]^{m+}. \tag{8}$$

If the coordination number *n* does not reach the maximal value in a given solution, then one stable form of the coordination sphere simply rearranges into another. The species $[M(S)_{n-1}L]$ becomes an intermediate and a stable solvate. On the other hand, the intermediate $[M(S)_nL]^{m+}$ with a strained coordination sphere converts to the stable solvate $[M(S)_{n-1}L]$. This is an example of the $S_N2(A)$ mechanism. Hence, intermediates of different stability with a coordination number greater than *n* of the initial solvate can form in the $S_N2(A)$ mechanism.

The interchange mechanism (*I*) is very common. In this mechanism, movement along the reaction coordinate causes the M–S bond to stretch and then cleave whereas the M–L bond forms and strengthens. Both processes occur simultaneously (Fig. 1). this is the $S_N2(I)$ mechanism

$$[M(S)_n]^{m+}L \rightleftharpoons [L \ldots M(S)_{n-1} \ldots S]^{*} \rightleftharpoons S + [M(S)_{n-1}L]^{m+}. \tag{9}$$

Reactions of this type are often encountered, even in organic chemistry. Their occurrence is due to the large deformation of the coordination sphere or organic radical at which substitution is occurring. Langford and Gray[8] assume incorrectly that an outer-sphere intermediate (for example, $[M(S)_n \ldots L]^{m+}$) is formed in $S_N2(I)$ reactions. An outer-sphere complex forces the reaction to take path *D* or *A* and not the interchange route.

The activation mechanisms of the reacting species or their separate fragments are very important. Langford and Gray[8] prefer to differentiate two activation mechanisms: associative activation (denoted '*a*') and dissociative activation ('*d*'). The symbols '*a*' and '*d*' coincide with (*A*) and (*D*). Obviously the entering group L contributes greatly to activation in stoichiometric *A* processes; the leaving group S, in *D*. Also, interchange mechanisms with associative I_a and dissociative activation I_d, where the principal contribution to the activation comes from the leaving group S, should be differentiated in $S_N2(I)$ processes.

We discovered and studied[9] a large group of $I_{a,d}$ reactions with associative–dissociative activation where the entering and leaving groups contribute equally to the activation. In order to find the stoichiometric mechanism of the reaction (S_N1, S_N2, S_E1, S_E2, *A*, *D*, *I*) It is necessary to study the substitution kinetics, find the kinetic equations and investigate the influence of the nature and concentration of entering and leaving groups on the type of kinetic equation. Fulfilment of a first-order kinetic equation

$$-\frac{dC_{solvate}}{dt} = k_v C_{solvate}, \tag{10}$$

suggests that the substitution reaction is unimolecular, dissociative, and $S_N1(D)$. If a second-order kinetic equation is obeyed

$$-\frac{dC_{solvate}}{dt} = k_v C_{solvate} C_L, \tag{11}$$

a bimolecular associative $S_N2(A)$ or interchange $S_N2(I)$ mechanism is expected.

The mechanistic subtleties, also called the intimate[8] or activational mechanism (this last term is more definitive) must be found by studying the temperature dependence in a series of substitution reactions involving various entering and leaving ligands. The presence or absence of a dependence of the enthalpy of activation

$(\Delta H)^{\neq}$ on the nature of L and S enables the activational mechanism (I_a, I_d or $I_{a,d}$) of the reactions to be defined as interchange substitution of ligands. Due to a lack of experimental data, the mechanism was not examined where activation involves accompanying ligands (X^-) in mixed and similar complexes $[MX_m(S)_{n-m}]$ in addition to inner-complex and macrocyclic compounds.[8] Complicated mechanisms with multi-centered interactions in the transition state are possible here.

Determination of the stoichiometric and activational contributions to the reaction mechanism still does not provide a comprehensive understanding. A model of the transition state must be constructed. The type of reaction centres and orbitals used in the chemical interaction in addition to the role of the solvent in forming the transition state (solvation of the transition state) can be determined by changing the structure of its component parts and the nature of the medium. Quantum-chemical calculations of the potential energy surface must be performed.

Therefore, the term 'reaction mechanism' represents a complicated and gradual transition of the starting reagents into the final products that is examined on a molecular and electronic level.

A large volume of experimental data exists on formation in aqueous solutions of complexes involving metal salts and ligands. Almost all monographs on coordination chemistry in aqueous solutions treat this topic.[6-8,10-15]

The stability of complexes is controlled by the dynamic equilibrium of two opposing processes: substitution of H_2O by ligands (direct process) and substitution of ligands by H_2O (reverse process). The stability constant of a complex K_s reveals which process predominates. If $K_s > 1$, the formtiton reaction predominates; if $K_s < 1$, dissociation prevails. If $K_s = 1$, $k_v^f = k_v^d$.[16] It is very important to obtain data on the mechanism and transition state of both complexation steps. Since complexation (if it is true complexation) is reversible, the reaction passes through the same transition state on moving forward or backward along the reaction coordinate.

Complexation in mixed solvents is more complicated. This can give rise to mixed solvate and ligand coordination spheres $[MX_mS_1S_2]$, $[MX_{m-p}L_pS_1S_2]^{m-p}$, $[ML_mS_1S_2]^{m+}$, $[MS_{1m}S_{2n-m}]$, $[M(S_1)_n]^{m+}$, $[M(S_2)_m]^{m+}$ and all intermediate forms. The quantity K_s in binary solvents (even more complicated in ternary systems) is determined by the simultaneous occurrence of very many reactions in equilibrium with each other. More often than not the dependence of K_s on solvent composition in these complicated systems provides no definitive information on the reaction. For this, the kinetics of all competing reactions must be studied. Such a fruitful approach has previously been used.[17]

Let us examine substitution of water in aqua complexes by other ligands. Analysis of the data in Table 1,[8] which contains experimental values of the rate constants (k_H^{298}, sec^{-1}) for substitution of H_2O in $[Pt(dien)OH]^{2+}$, indicates that the substitution accelerates where the chemical affinity of the ligand for Pt^{2+} increases.

The high rate of 'substitution' by OH^- is not due to the chemical affinity of hydroxide for Pt (it is not large compared with other ligands[11]) but to the extensive inner-sphere ionisation of H_2O. This is supported by the fact that the rate of exchange of Cl^-, Br^- and I^- by X^- is completely independent of the presence of OH^- in solution.[8]

Data for the influence of the nature of the solvent on the rate of substitution of $^{35}Cl^-$ by $^{36}Cl^-$ in *trans*-$[Pt(py)_2Cl_2]$ are presented in Table 2. The substitution includes a formation step of two solvates *trans*-$[Pt(py)_2S(Cl)_2] \rightleftharpoons [Pt(py)_2SCl]^+$ and conversion of the latter into $[Pt(py)_2Cl^{36}Cl]$. It is clear from Table 2 that formation of $[Pt(py)_2Cl_2S]$ or $[Pt(py)_2Cl_2S_2]$ and their conversion into $[Pt(py)_2SCl]^+$ strongly affects the reaction rate and changes its mechanism. The ligand exchange rate is especially high if such solvates are not formed (in C_6H_6 and CCl_4) or if the solvent can solvate the leaving ligand (DMSO, H_2O, CH_3NO_2, ROH). If the solvent can solvate Pt^{II} but not the leaving ligand [DMF, $(CH_3)_2CO$, $CH_3CO_2C_2H_5$], the ligand substitution rates are minimal.

Table 1. Rate of H_2O substitution by a ligand in $[Pt(dien)OH_2]^{2+}$ in aqueous solution at 298 K*.[8]
$[Pt(dien)OH_2]^{2+} + X^- \rightleftharpoons [Pt(dien)X]^+ + H_2O$.

Ligand	$10^2 k_H^{298}$, s^{-1}	Ligand	$10^2 k_H^{298}$, s^{-1}	Ligand	$10^2 k_H^{298}$, s^{-1}

n-C_3H_7OH	0.42	C_6H_6	10^2
trans-C_4H_9OH	0.10	CCl_4	10^4

The ligand substitution rate depends mainly on solvation of the leaving ligand X^- in complexes where the central atom is coordinatively saturated and is incapable of further solvation, for example, $[Co(en)_2X_2]^+$ (Table 3).

Before commenting on Table 3, attention should again be drawn to the very unfortunate terminology that for some unknown reason complicates the coordination chemistry of ligand substitution reactions.[6-8] This concerns solvolytic dissociation of acidocomplexes, for example:

$$[CoL_mX_{n-m}]^{z+} + S \rightleftharpoons [CoL_mX_{n-m-1}(S)]^{z+1} + X^-, \qquad (12)$$

in which the Co–X bond is completely broken by the solvent. If H_2O acts as S, then reaction (12) represents hydrolytic dissociation. Reactions of type (12) have incorrectly been called 'solvolysis' or 'hydrolysis'[6-8] since in general chemistry hydrolysis (solvolysis) means splitting of water (solvent) into ions with subsequent bonding

by a cation, anion or neutral molecule. Therefore, the term 'acid hydrolysis' in the sense used before[6,8] does not correspond to the actual process. The term 'base hydrolysis' is just as incorrect.[6,8]

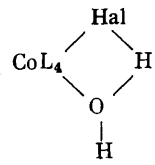

Table 3. Rate of hydrolytic dissociation of the Co–X bond at 298 K in Co^{III} complexes.[8]
$[CoL_mX_{n-m}]^{z+} + H_2O \rightleftharpoons CoL_mX_{n-m-1}(H_2O)]^{z+1} + X^-$.

Investigation of ligand (Cl^-, Br^-) substitution in Co^{III} complexes with a mixed coordination sphere containing covalently bound and difficultly exchangeable molecular ligands [NH_3, en = $NH_2(CH_2)_2NH_2$; 1,2-pn = $CH_3CH(NH_2)CH_2NH_2$; 2,3-bn = $CH_3CH(NH_2)CH(NH_2)CH_3$] and relatively readily substituted acidoligands enables some useful conclusions to be drawn (Table 3). Chelating ligands (diamines) hinder dissociation of the $Co^{III}-Hal$ bond (where Hal is a halogen) more than NH_3. However, adding methyls to the diamine increases the rate of dissociation by weakening the Co–Hal bond and creating steric hindrances that stabilise the $[CoL_2Hal]^{z+}$ species with coordination number 5. Therefore, the rate constant for removal of Cl^- from the tetramethylethylenediamine complex is three orders of magnitude greater than that for the ethylenediamine complex. Obviously the dissociation takes the same path, *D*, with preliminary loss of Cl (Br^-) due to solvation and substitution by H_2O. The *trans*- and *cis*-effects are evident in $[CoL_2X_2]^+$ and $[CoL_4X_2]^+$ in which L is a diamine or NH_3, respectively. The presence of NO_2^- or N_3^- *trans* to Cl^- accelerates dissociation of the Co–Cl bond by 4–8 times. An analogous effect of Br^- on a bond *trans* to Co–Br is seen. Susbtitution of NH_3 by Br^- in the position *trans* to Br^- in *trans*-$[Co(en)_2LX]^{2+}$ accelerate the reaction by almost two orders of magnitude.

In an analogous situation, Cl^- weakens the Co–Cl bond by almost 200 times. The *cis*-effect was unexpectedly large in Co^{III} complexes. The *cis*-effect in these Co^{III} complexes is apparently even stronger than the *trans*-effect. All of the changes in the dissociation rate are probably not assignable to only the electronic influence of the atom *trans* or *cis* to the Co–Hal bond. An analysis of Table 3 leaves no doubt that other factors, especially solvation, play a large role. For example, the *cis*-effect in Co^{III} complexes on dissociation in H_2O can be visualised as stabilisation of species

due to an intramolecular H-bond.

Data on the structural and energy activation parameters and systematic investigations of the kinetics in nonaqueous and mixed solvents are not available. Therefore, the role of solvation in solvolytic dissociation of Co^{III} complexes cannot be found.

The mechanism of substitution of an anion X^- by water or a molecule of another solvent is apparently very complicated.[6] The role of the H-bond $X^-...H_2O$, which should be large, is not overlooked. The rate of cleavage of Co–X in $[CoL_5X]^{2+}$ increases in the halide series from F^- to I^- (for F, Cl, Br and I, k_v is 8.6×10^{-4}, 1.7×10^{-2}, 6.3×10^{-2} and 8.3×10^{-2} sec^{-1}, respectively). The reduction of the Co–X bond strength in this order affects the dissociation kinetics. Other anions in aqueous solution fall into the following order of dissociation rate: NO_3^- (0.27) > SO_4^{2-} (0.012) > $H_2PO_4^-$ (2.6×10^{-3}) > $CH_3CO_2^-$ (1.2×10^{-3}) > N_3^- (2.1×10^{-5}) > SCN^- (5×10^{-6}). This also clearly demonstrates the role of strengthening the Co–X bond in the dissociative mechanism *D*. Apparently a drop in the rate generally corresponds to an increase in K_s of $[Co(NH_3)_5X]^{2+}$.[6]

The K_s of these complexes borrowed from previous work[6] are presented in Table 4. Comparison of k_v and K_s indicates that a known correlation exists between the ease of breaking the Co–X bond and the stability of $[Co(NH_3)_5X]^{2+}$.

However, the relative dissociation rates and K_s do not agree. It should be remembered that K_s is not a measure of the M–X bond strength since formation of the complex in solution is related to desolvation of the reagents. The results presented in Table 3 leave open the possibility that Co^{III} complexes and those of other M^{III} dissociate by an interchange mechanism $S_N2(I_{a,d})$. The dissociation rate constants of $[CoL_4Cl_2]^{2+}$ can be several hundreds of times greater than k_v^{298} of $[CoL_5Cl]^{2+}$ whereas the corresponding ones for Rh^{III} complexes are the same. This suggests a possible bimolecular *cis* attack of the reagent (including solvent molecules) on the central atom near the Co–X bond.[6] For strongly covalent Rh^{III} chloride complexes, the attacking molecules contribute insufficiently to activation of a system reacting by the S_N2 mechanism to cause it to occur.

Kinetic data for substitution reactions of water in octahedral Co^{III} complexes and in other M^{III} and M^{II} complexes are very interesting to the chemistry of solvates.

Table 4. Rate constants of $[Co(NH_3)_5X]^{2+}$ at 298 K in aqueous solution.[6]

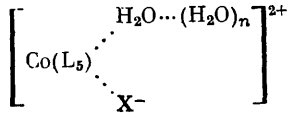
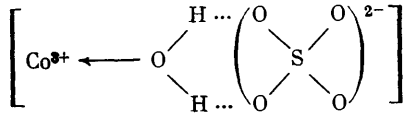
*Formation constant of the associate of the complex with X^-.
**Conversion with loss of H_2O.

Rate constants for H_2O substitution in $[Co(NH_3)_5H_2O]^{3+}$ are given in Table 5. The substitution rate of H_2O by the acidoligand in octahedral monosolvates within experimental and calculational uncertainty is independent of the nature of X^- and averages $k_v \approx 2 \times 10^{-6}$ $dm^3\ mol^{-1}\ sec^{-1}$. Such a small rate constant is indicative of a rather covalent $Co^{III}-H_2O$ bond. Even for NH_3 the rate constant of H_2O substitution has such a value. The rate of exchange of H_2O by SO_4^{2-} is slightly greater. There is no doubt that the substitution reaction of H_2O in octahedral Co^{III} complexes follows the dissociative mechanism S_n1 (or D)



$$[CoL_5H_2O]^{3+} \underset{fast}{\overset{slow}{\rightleftharpoons}} [CoL_5]^{3+} + H_2O, \quad (13)$$

$$[CoL_5]^{3+} + X^- \underset{slow}{\overset{fast}{\rightleftharpoons}} [CoL_5X]^{2+}. \quad (14)$$



Therefore, the mechanism here is different from that of $[ML_3H_2O]^{2+}$, where M = Pt^{II} and others.

It has been proposed[6] that reaction (13) passes through formation of an outer-sphere encounter complex and that anion X^- enters the inner sphere from the outer. However, this does not provide a very detailed mechanism since outer-sphere associates (complexes) occur in practically all solutions of complexes and participate in practically all reactions. The intermediate $[CoL_5]^{3+}$ apparently does not accumulate (the probability of its formation is very small) during reaction of $[CoL_5H_2O]^{3+} + X^-$. It is a highly reactive species and reacts immediately. The high charge of the central atom facilitates this. The water exchange rate, i.e. dissociation of the $M-OH_2$ bond, in $[M(H_2O)_6]^{2+}$ is very fast[17] (k, sec^{-1}: Cr^{2+}, 7×10^9; Mn^{2+}, 3×10^7; Fe^{2+}, 3×10^6; Co^{2+}, 10^6; Ni^{2+}, 3×10^4; Cu^{2+}, 8×10^9).

Owing to the low covalency of the $M^{II}-H_2O$ bond in octahedral complexes, the probability of removing a water molecule from the coordination sphere of $[M(H_2O)_6]^{2+}$ is very large. Therefore, intermediates $[M(H_2O)_5]^{2+}$ are formed in one concentration or another on coordination of aquasolvates with various ligands. A different situation ensues for M^{3+} solvates. The transition state arising through exchange of a solvent molecule for X^- in octahedral complexes sterically shielded by ligands can be represented as the system

with a Co...OH_2 bond. From this H_2O migrates into the bulk solvent (into a vacancy in the second corodination sphere). As a result, a very weak bond to X^- forms. The reaction occurring by this path is second-order. The constant k_v in this instance does not depend on the nature of X^- since the energy demands for activation with any X^- are determined by the same process, cleavage of the $Co^{III}-OH_2$ bond and removal of H_2O. Entry of SO_4^{2-} (Table 5) into the Co^{III} aquasolvate introduces substantial corrections into the process since removal of H_2O is enhanced by SO_4^{2-}. There is a probability of forming the associate

II. Kinetics of complexation in organic solvents

We will now examine the reactivity of complexes in nonaqueous solvents, without touching upon the broad range of aqueous–organic solutions where the composition of the solvates is, as a rule, unknown. It has been correctly noted[6] that ability to investigate the kinetics and mechanisms of a reaction involving complexes in nonaqueous media is limited by the very low solubility of many complexes.

A very important feature of complexation in organic solvents[16] is the weaker solvation of simple acidoligands and the strong solvation of complicated organic acidoligands, especially inner-sphere types. Water readily forms solvates of simple inorganic acidoligands (F^-, Cl^-, Br^-, I^-, NO_3^-, ClO_4^-, SO_4^{2-}, etc.) and enhances solvolytic dissociation of complexes with these ligands and formation of simple solvates. If the acidoligand contains a hydrocarbon residue, water does not solvate it. Such an anion is unstable in aqueous solution

and remains within the complex or in the solid as a salt. The opposite picture is seen in many organic solvents.

Transition metal cations can be solvated more strongly in nonaqueous solvents than in water [for example, DMSO, DMF, NH_3, amines, simple chain polyethers (glymes), crown ethers, their N and S derivatives, etc.[18]] and more weakly (alcohols, simple monoethers, ketones, carboxylic esters, alkylsuphides, alkylphosphines, etc.). Solvation can be practically absent (alkanes, cycloalkanes) or very weak (alkenes, arenes).

Hence, the contribution of partial or complete loss of the solvation sphere on complexation in organic media to the energy and entropy of activation can be greater or less than in aqueous medium.

It is usually weaker than in H_2O. The structuring of the organic solvents can have a substantial effect on the reactivity of solvates. The possibilities of outer-sphere complexation and substitution of X^- in octahedral complexes (Table 6) with release of them into the outer sphere drop sharply.

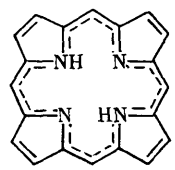
Table 6. Rate constants of Co—X bond dissociation in organic solvents (k_v, sec^{-1}) at 303 K.[6]

Solvent	Complex		
	trans-$[Co(En)_2Cl_2]^+$	*trans*-$[Co(En)_2NO_2(Cl)]^+$	*trans*-$[Co(En)_2NO_2(Br)]^+$
H_2O	$1.2\cdot10^{-4}$	$2.8\cdot10^{-3}$	$4.2\cdot10^{-3}$
DMSO	$3.7\cdot10^{-5}$	$1.4\cdot10^{-4}$	$8.0\cdot10^{-4}$
DMF	$5.8\cdot10^{-6}$	$5.4\cdot10^{-5}$	$6.9\cdot10^{-4}$
Methanol	$2.0\cdot10^{-5}$	$2.0\cdot10^{-4}$	–

The rate of solvolytic dissociation of the Co^{III}—Hal bond decreases in the order H_2O > DMSO, CH_3OH > DMF. This is probably a result of the decreased total chemical affinity of the solvent for Hal and Co^{III}.

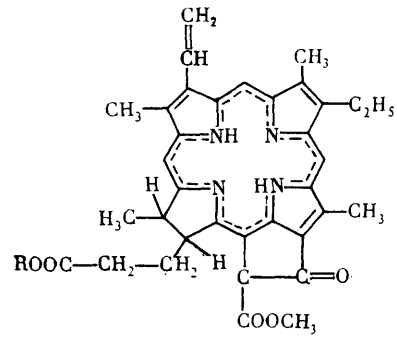
The ability of Co^{III} cationic complexes to form outer-sphere associates with X^- depends on the *cis*- or *trans*-configuration of $[CoL_4XY]^+$ and is determined by the size of the dipole moment of the complexes, the relative permittivity of the solvent and the degree of solvation of X^-.[6] Outer-sphere complexes (ion pairs) are formed more readily for *cis*-complexes than for *trans*-complexes.

A large amount of experimental data has been accumulated on reactions of *d*-metal solvates with porphyrins.[9,19] Porphyrins are far from the only ligands that can be used effectively to study the complex-forming reactivity of *d*-metal solvates.



The method developed has been called the kinetic method of porphyrin indicator reactions.

III. Indicator reactions and the stability of *d*-metal coordination spheres

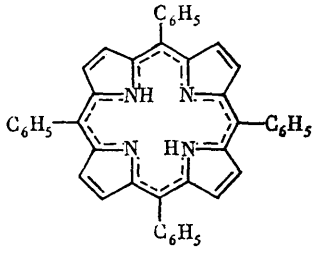


An indicator reaction between a solvate and a porphyrin (H_2P) (I) to form a porphyrin complex (MP)

$$[MX_mS_{n-m}] + H_2P \rightarrow MP + 2HX + (m-2)X^- + (n-m)S, \quad (15)$$

is a unique instrument for studying various solvate coordination spheres. Their composition in various salts, the relative stability of the M—S bond, and the variability as a function of solvent can all be found.[9,19,20]

(I)
Porphyrin nucleus

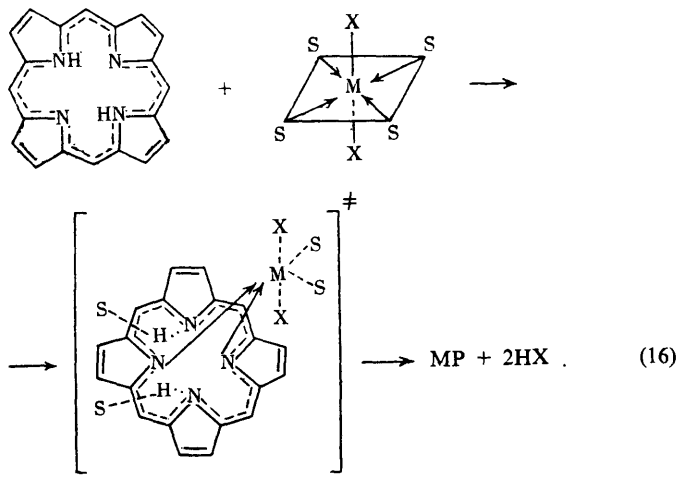


(II)
Chlorophyll ligand ($R = C_{20}H_{39}$)

A series of studies[21–28] has been carried out on the influence of the organic solvent and the structure of the transition-metal coordination sphere on the kinetics of complex formation with the most important natural porphyrin, the chlorophyll ligand (II). It was discovered that the inner coordination sphere of the metal determines the rate in addition to the energy and entropy of activation of the coordination. Therfore, coordination of H_2P by metal salts was called[20] the kinetic indicator reaction of porphyrins. The kinetic parameters of these reactions are very sensitive to the composition of the metal solvate coordination sphere, i.e. to the number and nature of ligands S and X^-.

Indicator reactions of porphyrins lie at the base of the kinetic method for studying the structure and properties of solvates. There apparently are few ligands that can be used successfully to study the change of composition, structure and properties of metal solvates as a function of concentration, solvent, temperature, the presence of force fields, etc., owing to the stringent requirements placed on kinetic indicator reactions.[20] The kinetic indicator reaction (15) should have a simple stoichiometry, i.e. its product should be the 1:1 complex (one metal per one ligand). Complexes with the indicator ligand should be kinetically and thermodynamically stable.[9] They should retain their composition and geometric configuration over the whole range of concentration changes of the coordinating solvent S and the acidoligands X^-. The reaction should proceed slowly enough to be easily controlled by ordinary chemical kinetics. One of the reagents should have a specific, accurately determined property, for example, a distinctive electronic absorption spectrum (EAS) with strong absorption bands. Porphyrins satisfy all these requirements. They form highly stable complexes MP of 1:1 composition. Their rate of formation is easily measured. Metalloporphyrins have distinctive EAS with very large molar absorption coefficients (ε) that reach 200 000. Therefore, formation of metal complexes with porphyrins is an ideal indicator reaction enabling a retention or change of the $[MX_m(S)_{n-m}]$ coordination sphere to be easily and quickly detected.

Ethanol homosolvates of MCl_2 (M = Fe, Co, Cd, Hg and Pd), $M(NO_3)_2$ (M = Co, Ni, Cu, Zn, Cd and Ag), $M(CH_3CO_2)_2$ (M = Co, Ni, Cu and Zn), MI_2 (M = Cd and Hg),[21–26] homosolvates of $Cu(CH_3CO_2)_2$ with monohydric alcohols, acetone, ethylacetate, dioxane, CH_3CO_2H, DMF, py and XL,[27–29] binary heterosolvates of $Cu(CH_2CO_2)_2$ and $Zn(CH_3CO_2)_2$ in CH_3CO_2H—ROH (R = CH_3,



C_2H_5, C_5H_{11}), CH_3CO_2H–py, CH_3CO_2H–dioxane, CH_3CO_2H–acetone,[20,30] binary heterosolvates of Co^{II} and Zn^{II} acetates in CH_3CO_2H–ethylacetate, CH_3CO_2H–ethyleneglycol, CH_3CO_2H–monoethanolamine, CH_3CO_2H–CH_3OH, CH_3CO_2H–DMF, CH_3CO_2H–DMSO, CH_3CO_2H–py, CH_3CO_2H–H_2O, CH_3CO_2H–n-C_4H_9OH [31] and other solvates have been studied using indicator reaction (15) and II and tetraphenylporphine (III) as ligands. Systematic investigations carried out in our laboratory and those of others[9,20,31,32] demonstrated that the reaction of solvates of divalent 3*d*-metals with porphyrins in organic solvents follows very complicated kinetic laws.

(III)

The formation rate of MX_2 complexes with II, III and other porphyrins in addition to the energy and entropy of activation of reaction (15) are determined primarily by the steric relationship of both reagents, i.e. the macrocyclic effect;[3] the electronic structure of the porphyrin reaction centre (H_2N_4); the nature of the chemical bond M^{2+}←S, i.e. the nature of M and S; the presence of acidoligands X^- in the inner sphere and their number and nature; the compatibility of the various solvents S_1, S_2, etc., in the inner sphere of heterosolvates; the polarity and donor–acceptor nature of solvents S_1, S_2, etc. as media in which the reagents are activated, the solvation or desolvation of the transition state $[MX_2.H_2P]^{\neq}$; the removal of H^+ and X^- after overcoming the potential barrier; and the formation of metalloporphyrins MP or their solvates $(S)_iMP$.[33]

Compared with all other known complexation reactions, indicator reaction (15) proceeds extraordinarily slowly. Its rate typically is 10^6 times less than that of the other reactions. The bimolecular multicentered mechanism, denoted $S_{EN}2$ by the Ingold–Hughes classification or $I_{a,d}$ by Langford–Gray, is responsible for this. The transition state is formed by loss of two solvent molecules (S) from the inner sphere of the solvate, the weak coordinative interaction M←P, and lengthening of the two N–H...S bonds in the porphyrin:

$\longrightarrow$ MP + 2HX . (16)

The reaction with porphyrins of coordinatively saturated complexes, for example $HgCl_4^{2-}$ or HgI_4^{2-}, that do not contain solvent molecules also follows a bimolecular mechanism.[9] In this instance atoms are not lost from the coordination sphere as the transition state is approached. The coordination sphere of MX_4^{2-} in the transition state is probably only deformed. This produces instead of the tetrahedral configuration a distorted octahedron with two vacant coordination sites that are necessary for bonding to two tertiary N atoms of the porphyrin. The reaction mechanism is also denoted $S_{EN}2$. The octahedral acidocomplexes $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_5H_2O]^{2-}$ or the covalent molecular-ligand complexes $[Co(NH_3)_6]^{3+}$ and $[Co(NH_3)_5H_2O]^{3+}$ do not have the required number (two or more) of solvent molecules to experience compression of the coordination sphere. Therefore, the above salts cannot react with porphyrin even under forcing conditions.

Porphyrins are molecular ligands that lose two H^+ during complex formation. Therefore, complexation reaction (15) follows a $S_{EN}2$ mechanism. Hence, H_2P is simultaneously electrophilic and nucleophilic.

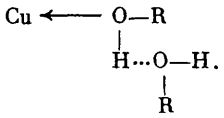


Table 7. Kinetics of formation of Cu(Chl) from $[CuAc_2(S)_4]$ and the chlorophyll ligand in organic solvents (S).[9]

S	k_7^{298}, $dm^3\ mol^{-1}\ sec^{-1}$	E, $kJ\ mol^{-1}$	$\Delta S^{\neq}$, $J\ mol^{-1}K^{-1}$	*DN* *

*Estimated *DN* are given in parentheses.

An examination of the indicator reaction mechanism would seem to indicate that its rate and activation parameters should depend on the structure and stability of the inner coordination sphere in general and on the structure and stability of the solvation sphere in particular. The rates of formation of complexes from homosolvates of $[CuAc_2(S)_4]$ in various solvents are listed in Table 7. The stability constants of the homosolvate salts have not been determined. The relative stability of the copper acetate solvation sphere can be judged from the donor numbers (*DN*). It is clear from Table 7 that the reaction rate tends to decrease at the same time as the activation energy increases and *DN* increases, i.e. as the strength of the Cu–S bond increases and the solvation sphere becomes stronger. However, there are several exceptions to this rule. Methanol forms a stronger solvate and reacts faster than ethanol and especially propanol. Attention should be drawn to the donor numbers in parentheses in Table 7. In alcoholic solutions $SbCl_5$ is extensively solvolysed. Therefore, it is difficult to determine the electron-donating ability of alcohols relative to $SbCl_5$.

In estimating the change of electron-donor properties of various alcohols relative to metal salts, their structure and known properties should be considered. Methanol should form stronger solvates than ethanol firstly because conditions are favourable for formation of a second solvation sphere in its solvates. This second sphere stabilises the first by forming H-bonds to coordinated CH_3OH. As the alkyl chain lengthens, steric hindrances to the interaction are created

This interaction facilitates formation of the second and successive alcohol solvate spheres. Secondly, the electron-donor ability of the electron pair of the alcohols depends little on the size of the alkyl group, i.e. on its inductive effect. Therefore, the electron- and proton-donor properties of uncoordinated CH_3OH and C_2H_5OH are almost identical. The higher $\Delta S^{\neq}$ and E for methanol are due to the presence of a second solvation sphere.

The rate of coordination of solvates by porphyrins is affected by the exchange conditions of coordinated solvent molecules with the medium. The rate of exchange substantially decreases and the conditions for it worsen for alcohols as the length of the alkyl chain and other large molecules increases. This feature of solvates formed by large molecules has been called steric hindrances of the solvation sphere.[9] They are created during attack of the solvation sphere of such a hugh reagent as a porphyrin. We are inclined to assign the increase in energy and entropy of activation and the decrease of reaction rate of $CuAs_2$ solvates with pentanol, dioxane, DMF, py and quinoline to steric hindrances of the solvation sphere. As we suppose, such hindrances lead not only to loss of two solvent molecules but also to deformation of the remaining sphere of ancillary ligands.[34] There is no doubt that steric hindrances created by a huge coordination sphere will affect the kinetics of reactions between many large ligands with a shielded reaction centre.

An important property of the indicator reaction (15) is the dependence of its rate on the concentration of a 3*d*-metal salt (the so-called 'concentration' dependence of the rate constant) and of a coordinating or uncoordinating salt background,[25,26,35] where the porphyrin does not change but the structure of the coordination sphere of the 3*d*-metal salt does. Results characterising the influence of concentration of 3*d*-metal salt on the formation rate of chlorophyll (Chl) analogues with Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+} and Cd^{2+} are presented in Table 8.

Evidently the coordination spheres of $[CuAc_2(C_2H_5OH)_4]$ are rather stable as the salt concentration changes from 2.5×10^{-4} to 25×10^{-4} mol dm^{-3} since the concentration dependence of k_v is very weak. The dependence of k_v on salt concentration increases in the order $CdAc_2 < Co(NO_3)_2 < Ni(NO_3)_2$. This order apparently corresponds to the ease with which the composition and structure of the coordination sphere changes and the number of solvate forms increases, i.e. the stability of the coordination sphere of $[MX_2(S)_4$ decreases.

Therefore, the kinetic method of porphyrin indicator reactions enables the uniqueness or variety of solvate coordination spheres to be judged. It follows from Table 8 that ethanol solvates of Ni^{2+} and especially Co^{2+}, compared with those of Cu^{2+} and Cd^{2+}, have a much lower ability to complex porphyrins. However, the reactivity of solvates can depend strongly on the nature of the porphyrin and solvent. It is important that not only k_v but also more frequently E and $\Delta S^{\neq}$ change on changing the composition of the solvate.[9,19,26,35]

The methanol solvate of $CoCl_2$ (Table 9) has many forms in solution. Therefore, the concentration dependence of k_v is very strong. Increasing the concentration of $CoCl_2$ in methanol shifts the equilibrium toward the stable forms of low reactivity. The situation is the same for $CoAc_2$ in methanol.

Table 8. Coordination-sphere stability of solvates and concentration dependence of formation rate constants (k_v) of metalloporphyrins, chlorophyll (MChl) analogues, in ethanol at 298 K.[9]
$MX_2 + H_2Chl \rightarrow MChl + 2\,HX$.

	25	1.60	44	−109

Table 9. Influence of a salt background on coordination-sphere stability of methanol solvates in Co(Chl) formation reactions.[20]
$H_2Chl + [CoX_m(S)_{n-m}] \rightarrow Co(Chl) + 2\,HX + (m-2)\,X^-$.

Reagent salt MX_2	Background salt MX	Concentration of reagent salt, $c\,10^3$ M	k_v^{298}, dm^3 mol^{-1} sec^{-1}	E, kJ mol^{-1}	$\Delta S^{\neq}$, J mol^{-1} K^{-1}
$Co(NO_3)_2$	–	2.5	$2.56 \cdot 10^{-3}$	43	−161
$Co(NO_3)_2$	3M $LiNO_3$	2.5	$2.40 \cdot 10^{-2}$	56	−87
$CoCl_2$	–	2.5	$1.78 \cdot 10^{-3}$	65	−93
$CoCl_2$	–	25	$3.10 \cdot 10^{-4}$	67	−87
$CoCl_2$	2M LiCl	2.5	$4.90 \cdot 10^{-3}$	52	−114
$CoCl_2$	2M LiCl	25	$1.89 \cdot 10^{-3}$	50	−128
$CoAc_2$	–	2.5	$1.32 \cdot 10^{-2}$	99	+52
$CoAc_2$	–	25	$3.40 \cdot 10^{-3}$	83	−15
$CoAc_2$	2M LiAc	2.5	$1.11 \cdot 10^{-3}$	–	–
$CoAc_2$	2M LiAc	25	$1.13 \cdot 10^{-3}$	86	−12

Addition of LiAc stabilises the form $[CoAc_4]^{2-}$. This causes the dependence of k_v on $CoAc_2$ concentration to vanish.

A detailed analysis of the kinetic data demonstrated that the dependence of k_v (and also E and $\Delta S^{\neq}$) on 3*d*-metal salt concentration is mainly determined by the change of properties of $MX_2(S)_{n-2}$. Similar changes of k_v in aqueous solutions have usually

been ascribed to a change of the salts activity coefficient. For the example involving 3*d*-metal salts in organic solvents that are incapable of solvolytic dissociation

$$MX_2(S)_{n-2} \overset{+S}{\rightleftharpoons} [MX(S)_{n-1}]^+ + X^- \quad (17)$$

$$[MX(S)_{n-1}]^+ \overset{+S}{\rightleftharpoons} [M(S)_n]^{2+} + X^- \quad (18)$$

the reaction proceeds without involving the ions, i.e. with a small change of salt activity coefficient as classically interpreted.

As the salt concentration increases, the geometry of the solvate can change owing to a shift of autocomplexation equilibria, the isomerisation *cis*-octahedron $\rightleftharpoons$ *trans*-octahedron, changes in the degree of solvation

$$MX_2(S)_4 \rightleftharpoons MX_2(S)_2 + 2S,$$

loss of the second solvation sphere, a reduction of the solvating ability of the solvent, salt dimerisation, etc.

In this instance, the lack of a concentration dependence of k_v (and also $\Delta S^{\neq}$ and E) is consistent with a stable salt coordination sphere within the given concentration range. On the other hand, the presence of such a dependence means that the initial coordination sphere is unstable and changes.

Kinetic data for the indicator reaction (15) occurring in the presence of a salt background (Table 9) suggest whether the complex coordination sphere is stable and if stabilising conditions can be found.

It follows from Table 9 that the inert (noncoordinating) background salt $LiNO_3$ has a different effect from that of a coordinating salt (LiCl, LiAc) which can provide inorganic ligands (Cl^-, Ac^-) for the Co^{II} solvate.

Lithium nitrate does not change the EAS of $Co(NO_3)_2$. It can be concluded on the basis of the EAS[35] that $Co(NO_3)_2$ in methanol exists as the octahedral complex $[Co(CH_3OH)_6]^{2+}$. In the presence of $LiNO_3$, ion pairs of the type shown below can form

$$Co^{2+} \longleftarrow \overset{CH_3}{\underset{|}{O}}—H\cdots NO_3^-$$

and partially $Co^{2+} \leftarrow NO_3^-$.

Therefore, NO_3^- ions reduce the stability of the solvate. The formation rate of Co(Chl) increases almost 10 times on adding $LiNO_3$. The energy and entropy also considerably increase. Free methanol molecules are practically nonexistent in 3 M $LiNO_3$. Therefore, the acceleration of the indicator reaction can be attributed to weakening of the bonds in the fragments

$$Co^{2+} \longleftarrow \overset{CH_3}{\underset{|}{O}}—H,$$

associated with NO_3^- in addition to a decrease of solvation in the transition state ($\Delta S^{\neq}$ increases by 74 J mol^{-1} K^{-1}; the activation energy, by 13 kJ mol^{-1}). The increased solvation in the transition state apparently destabilises the latter.

In the presence of a coordinating salt background, the Co(II) solvate is transformed into complex acidoligands $[CoCl_4]^{2-}$, $[CoCl_5]^{3-}$, etc. The promoting action of the salt background becomes weaker (LiCl) or changes into inhibiting action (LiAc) as a result of stabilisation of the solvate coordination spheres in $[CoX_n]^{2-n}$.

The existence of a concentration dependence in the system $H_2Chl + CoCl_2 + LiCl$ leaves no doubt that the series of acidocomplexes $[CoCl_3]^-$, $[CoCl_4]^{2-}$ and $[CoCl_5]^{3-}$ exists in the presence of LiCl in methanol. These differ little from each other in entropy and enthalpy of activation. Lithium acetate converts the $CoAc_2$ solvate into a single stable coordinated form $[CoAc_4]^{2-}$. This is kinetically 10 times less active in the indicator reaction where Co(Chl) is formed. The lack of a concentration dependence of k_v^{298} in methanolic LiAc is consistent with the lack of other coordinated forms of $CoAc_2$.

However, the effect of background salts on the stability of 3*d*-metal solvates depends strongly on the organic solvent. It has been found[25] that LiCl slows the coordination of the CoX_2 solvate with H_2Chl in *n*-pentanol, in contrast with methanol. However, LiAc accelerates it. This opens wide possibilities for using indicator reactions to study the influence of solvent containing salt on the solvates of a reagent. Even more promising is the use of this method to investigate mixed solvates of 3*d* -metals in binary organic solvents.

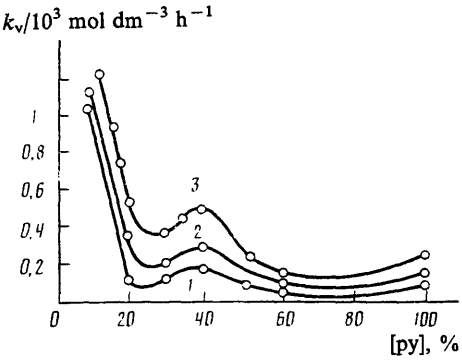

Figure 2. Dependence of formation rate constant of Cu(Chl) in CH_3CO_2H—py on medium composition at: 298 (*1*), 318 (*2*), 328 K (*3*).[30]

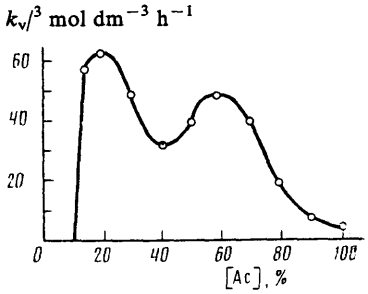

Figure 3. Dependence of formation rate constant of Cu(Chl) in CH_3CO_2H—CH_3COCH_3 on medium composition at 298 K.[30]

Formation of the analogues Cu(Chl) and Zn(Chl) in the systems CH_3CO_2H—coordinating solvent and py—coordinating solvent has been studied.[30] For concentrations of coordinating solvent in CH_3CO_2H from 0 to 100%, kinetic curves of composition *vs.* property were obtained. Lots of composition—rate of indicator reaction (Figs. 2 and 3), composition—activation energy (energy curves), and composition—entropy of activation (structure curves) (Fig. 4) all have peaks.

Concentration dependences of the formation rate of Cu(Chl) from $CuAc_2$ and H_2Chl in the systems CH_3CO_2H–py and CH_3CO_2H–acetone are plotted in Figs. 2 and 3, respectively. These data reflect the change of properties of the binary solvent (its solvating ability) and the change of stability of Cu^{II} solvates as a function of medium composition. Addition of a strongly coordinating component (py, ROH, acetone, dioxane, etc.) to CH_3CO_2H causes a gradual destruction of its dimeric structure $(HAc)_2$, accumulation of solvates $CH_3CO_2H...S$ and a subsequent transition to the structure of the solvent. As the medium composition changes, the mixed solvation sphere of $[MX_2(CH_3CO_2H)_4]$ converts successively to a mixed solvent sphere $[MX_2(CH_3CO_2H)_{4-m}S_m]$†, and then to $[MX_2(S)_{n-2}]$. Formation of $[MX(S)_{n-1}]^+$ and $[M(S)_n]^{2+}$ is also possible.

It is noteworthy that solvates of only divalent cations are examined here. Solvates of MX_3 and MX_4 do not react with porphyrins under ordinary conditions and cannot presently be investigated by porphyrin indicator reactions.

It has been demonstrated[36] that small additions of a second component to a pure solvent greatly changes the structure of the latter, causing either a loss of structure (destabilisation) or higher degree of structure (stabilisation). Destabilisation of the intrinsic solvent structure increases its solvating power whereas stabilisation reduces it.

In our opinion, the increased rate of reaction (15) observed in the majority of cases in CH_3CO_2H with small additions of a strongly coordinating solvent is due to destruction of $(CH_3CO_2H)_2$ dimers and an increased solvation of the transition state [cf. equation (16)] in addition to the destabilisation of the CH_3CO_2H–cation bond that favours reaction (16).

It can be stated that where two or more molecules of a weakly coordinating solvent enter the coordination sphere of *d*-metals they make a poor match. If a strongly coordinating solvent (S_c) enters the inner sphere of MX_2, the effective charge on the metal decreases, the initial M–S bonds are destabilised, and the ability to substitute S increases. In all probability, a similar type of competition for a coordination site arises between any pair of solvents differing in donor–acceptor numbers.

The change of kinetic parameters with large additions of a coordinating component,[20] as demonstrated previously,[31] is caused by substitution of HAc by S_c in the first solvation sphere. Thus, all mixed (HAc–py) $CuAc_2$ solvates are less active than the pure HAc ones. The maximal complexation rate is reached with 40% py. This can be attributed to the special properties of the CH_3CO_2H–py associate that dominates the solvent structure in this range. The second maximum on the curve corresponds to accumulation of the associate and produces a maximum in E and $\Delta S^{\neq}$ (Fig. 4). The first maximum at 20% py represents complete substitution of the very weak ligand CH_3CO_2H by the strongly coordinating py. In HAc and alcoholic solutions, $CuAc_2$ is known[31] to exist as a dimer. However, Cu_2Ac_4 has been found to be unreactive toward porphyrins.

Addition of a strongly coordinating solvent to an HAc solution shifts the equilibrium of the dimer

$$2[CuX_2(S)_{n-2}] \rightleftharpoons [Cu_2X_4(S)_4] + (n-6)S, \qquad (19)$$

where X^- is any carboxylate, toward the monosolvate. As the dimer breaks up, the monosolvate $[CuX_2(S_c)_{n-2-m}(HAc)_m]$ accumulates, i.e. HAC is lost from the inner sphere. This process occurs in parallel with the change in composition of the solvation sphere of the monosolvate, which is present in small quantities in HAc (about 0.1%) and alcoholic solution, and corresponds exactly to this change.

The dimers and their break-up by large amounts of S_c undoubtedly affect k_v. However, they do not change the nature of the dependence of k_v on solvent composition (Fig. 2) and even more the nature of the structure–kinetic curves (Fig. 3) since they do not affect the energy and entropy of activation.

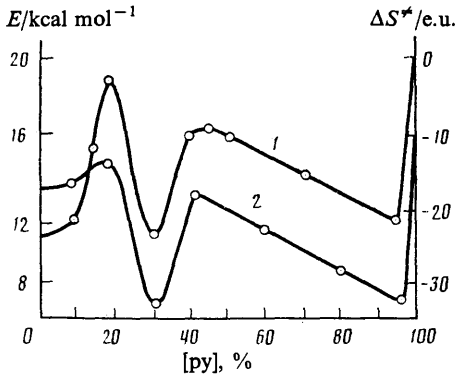

Figure 4. Dependence of energy (*1*) and entropy of activation (*2*) for Cu(Chl) formation in CH_3CO_2H–py on medium composition at 298 K.[20]

This conclusion is also supported by the fact that the curves shown in Figs. 2 and 3 are completely identical if the total concentration of $CuAc_2$ is changed by 10–100 times.

The kinetics of complexation in the mixed solvent HAc–acetone are especially interesting. The reaction sharply accelerates and the rate constant increases three times with even 1% acetone added. In view of the weak basicity and small size of $CO(CH_3)_2$, such an effect cannot be related to a change of properties of HAc as a solvent. The activity of the first mixed acetone–HAc solvate in reaction (15) is so high that even trace amounts cause a large effect. It can be assumed that acetone (ketones) is highly effectively coordinated to copper salts since π-backbonding is possible.

The path of the composition–rate curves suggests that all mixed acetone solvates of $CuAc_2$ are more highly reactive than HAc solvates, which are some of the most reactive solvates (Table 7). It is assumed that the first maximum on curve *1* (Fig. 2) corresponds to the first mixed solvate $[CuAc_2(C_2H_6CO)(HAc)_3]$; the minimum, to the second; and the third, to the third solvate $[CuAc_2.(C_2H_6CO)_3(HAc)]$. The solvate $[CuAc_2(C_2H_6CO)_4]$ is six times less active than $[CuAc_2(HAc)_4]$.

We are inclined to ascribe the elevated reactivity of mixed acetone solvates to the *trans*-effect of acetone in octahedral copper complexes and to its labilising action on bound HAc.[20] The catalytic action of acetone was also observed for Co^{II} salts. The *trans*-effect is proposed to occur in mixed HAc solvates of $CoAc_2$ with py, DMSO and DMF. It can stabilise the transition state of an indicator reaction.

The rate of complexation of tetraphenylporphine (H_2TPP) is slower for all mixed acetone–HAc solvates of $ZnAc_2$ than for the

†The inner coordination sphere is shown in square brackets; the outer sphere is not indicated.

pure HAc solvate. In these instances, there are no maxima on the composition–rate curves. The minima in the energy and entropy on the composition–energy (entropy) of activation curves correspond to the maximal accumulation of mixed acetone–HAc solvates of $CoAc_2$.

Individual rate constants for reactions involving mixed solvates of $ZnAc_2$ and $CoAc_2$ were first obtained by Golubchikov.[31] In these reactions one (k_1) or two (k_2) molecules of HAc in the inner sphere are replaced by a coordinating solvent. The data presented in Table 10 show that entry of one solvent molecule of any kind into the solvation sphere of $ZnAc_2$ instead of weakly bound HAc decreases the coordinating ability by about 2 times; two molecules, by 4–15 times. Under analogous conditions the reactivity of $CoAc_2$ in saturated solvents (excluding monoethanolamine) changes little. The strong catalytic effect in py, DMSO and DMF may be due to a *trans*-effect. Monoethanolamine forms a monosolvate $\{CoAc_2(HAc)_2[NH_2(CH_2)_2OH]\}$ in which the chelate is tightly bound to Co^{II} by the NH_2-group and weakly by the OH-group. In our opinion, the 10-fold increase of rate of coordination to monoethanolamine is explained by the interaction of the OH-group in the transition state with the leaving HAc ligand or an ancillary Ac^- ligand. This enhances the reaction.

Table 10. Individual rate constants of tetraphenylporphine coordination by $ZnAc_2$ and $CoAc_2$ solvates $MAc_2(HAc)_4$, $MAc_2(HAc)_3(S)$ and $MAc_2(HAc)_2(S)_2$ at 298 K.[31]

Reagent salt	Coordinating solvent (S_c)	Rate constants, $dm^3\ mol^{-1}\ sec^{-1}$		
		k_0	k_2	k_1
$ZnAc_2$	HAc	38.5	–	–
	Py	39.0	26.8	6.4
	DMSO	37.8	18.8	2.3
	DMF	39.5	14.1	–
	Butanol	39.0	19.1	8.2
	H_2O	18.7	10.9	5.0
$CoAc_2$	HAc	0.100	–	–
	Py	0.095	0.478	0.670
	DMSO	0.109	0.199	1.21
	DMF	0.079	0.71	–
	Butanol	0.105	0.111	–
	H_2O	0.083	0.064	0.043
	Methanol	0.096	0.096	0.096
	Ethanol	0.106	0.110	–
	Ethyleneglycol	0.105	0.090	0.037
	Monoethanolamine	0.100	0.97	–

A combination of porphyrin indicator reactions and thermodynamic methods is especially effective for investigating the reactivity of individual solvates by the kinetic method. This approach has been successfully used to investigate the state of Cu^{II} carboxylates, including dimers, in binary solvents (consisting of coordinating and weakly coordinating solvents[37,38]).

In conclusion, the special role of solvates in the coordination chemistry of solutions must be emphasised. The chemistry of complexes begins with just these complexes, which are formed during dissolution of metal salts in aqueous and nonaqueous solvents. Methods for preparing the complexes are based on substitution of solvent–ligands by ligands of any other type (molecular, acidoligands, inner-sphere, macrocyclic, etc.). The lack of sufficient data on the structure, stability and reactivity of solvates impedes development of many concepts of the theory of ligand substitution, the theory of their stability in solutions, and the optimal methods of synthesis. Taking into account the importance of solvates to electrochemistry, hydrometallurgy, analytical chemistry of nonaqueous solutions, homogeneous and heterogeneous catalysis, biochemistry and other practically important areas it becomes obvious that efforts need to be focussed on a systematic study of them.

Features of the complexation of trivalent rare earths

L I Martynenko
Lomonosov Moscow State University

ABSTRACT. Reasons why chelates of rare earths (RE) do not obey the tetrad 'doublet' effect are discussed. The examination is based on the concept of an ionic metal–ligand bond in RE complexes. The mutual influence of ligands in lower, higher, polynuclear and mixed complexes formed by ligands of low, medium and high denticity is discussed from this viewpoint. Intermolecular interactions in complexes of various structure are examined relative to variations in the volatility of chelates and their selectivity in sublimation and deposition. Structural rearrangement occurring at different points in the RE series for different ligands is proven to be the reason behind the irregular change of properties of RE complexes as a function of RE ionic radius.

A bibliography with 42 citations is given.

I. Introduction

The predominantly ionic nature of the RE^{III}–ligand bond has been cited as the main feature of RE (Sc, Y, La, Ce–Lu) complexes in previously published reviews.[1,2] The most important consequence of the ionic bonding is a high and variable coordination number (CN) for RE.[3] During the last decade, new evidence supporting such an approach for analysing the nature of the bonding in RE complexes has been gathered. The ionic bond, with a small covalent contribution, does occur. However, questions about the size of the covalent contribution to the metal–ligand bond in such compounds is still actively discussed. A consensus has not been reached. Therefore, in this review we direct special attention to this aspect of RE coordination chemistry.

Problems of RE^{III} complexation are discussed using complexes with organic ligands of various classes as examples (abbreviations for these ligands are given below):

a) Aminocarboxylic acids:

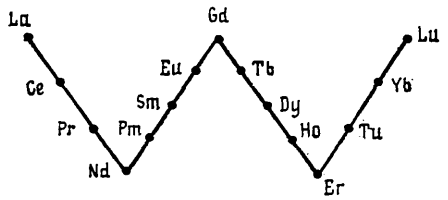
H_4EDTA—ethylenediaminetetraacetic acid
H_5DTPA—diethylenetriaminepentaacetic acid
H_2EDDA—ethylenediaminediacetic acid
H_3NTA—nitrilotriacetic acid
H_2IDA—iminodiacetic acid
Hal—α-alanine
Hgl—aminoacetic acid (glycine)

b) Carboxylic and hydroxycarboxylic acids:

HA—acetylacetone
HDPM—dipivaloylmethane
HPiv—pivalic acid

c) β-diketones:

HA—acetylacetone
HDPM—dipivaloylmethane
HPTFA—pivaloyltrifluoroacetone
HAcim—acetylacetoneimine



d) Neutral ligands with N and O donors:

phen—*o*-phenanthroline
bipy—α,α′-bipyridyl
py—pyridine
DMSO—dimethylsulphoxide
MESO—methylethylsulphoxide
DMF—dimethylformamide
THF—tetrahydrofuran
HMPA—hexamethylphosphortriamide
TPPO—triphenylphosphineoxide
TBP—tributylphosphate
3(4) – Pic—3(4)-picoline

II. The 'tetrad' effect and the nature of the chemical bond in RE coordination compounds

Let us recall that the tetrad effect consists of the periodic change of properties in the 15-membered RE series La, Ce–Lu.[4,5] This enables the series to be broken into four 'tetrads' corresponding to

the four straight lines in the letter 'W':

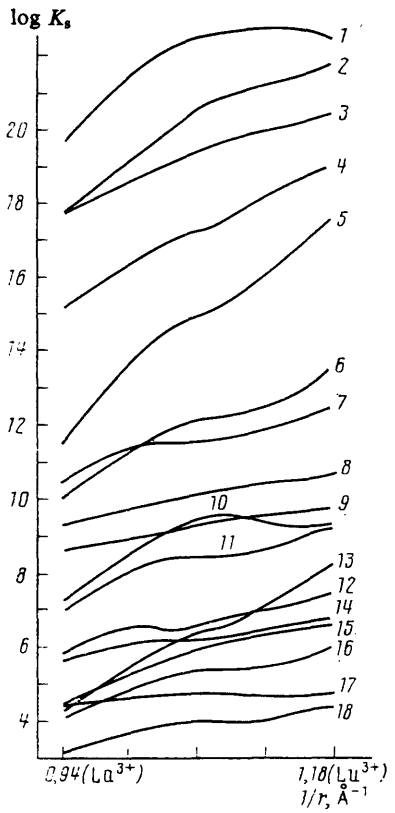


Figure 1. Dependence of lg K_s (K_1, K_2 or β_2) on RE^{III} ionic radius: M(DTPA)$^{2-}$(K_1) (*1*); M(NTA)$_2^{3-}$ (β_2) (*2*); M(DPM)$_2^{+}$(β_2) (*3*); M(EDTA)$^{-}$(K_1) (*4*); M(EDDA)$_2^{-}$ (β_2) (*5*); M(IDA)$_2^{-}$(β_2) (*6*); M(NTA)(K_1) (*7*); M(DPM)$^{2+}$(K_1) (*8*); M(DPM)$_2^{+}$(K_2)(*9*); M(NTA)$_2^{3-}$ (K_2) (*10*); M(EDDA)$^{+}$(K_1) (*11*); M(EDDA)$_2^{-}$ (K_2) (*12*); M(IDA)$^{+}$(K_1) (*13*); M(NTA)(OH)$^{-}$(K_2) (*14*); M(EDDA).(OH)(K_2) (*15*); M(IDA)$_2^{-}$(K_2) (*16*); M(al)$_2^{+}$(K_1) (*17*); M(gl)$_2^{+}$(K_1) (*18*)

Many articles published over the last few years on the chemistry of RE compounds, including complexes, have tried to prove that there is a tetrad effect [or double-u (W) or double–double effect]. It has been assumed that its detection is a direct indication of the reliability of new results obtained. However, such a position is incorrect since the change of properties in RE complexes, especially if their structure is complicated, frequently does not exhibit a W-shaped nature. We read, 'There are only a few ligands for which the rules are observed over the whole RE series and many for which such rules are observed for only a part of the series' (Ref. 6, p. 185).

It must also be noted that even if the dependence in coordinates of property–RE atomic number is W-shaped, in other coordinates, for example property–RE^{III} ionic radius, the dependence is not W-shaped but monotonic.

Let us examine as an example the dependence of lg K_s for RE complexes of polyaminocarboxylic acids on the inverse of the RE^{III} ionic radius. It is clear from Fig. 1 that the W-rule is not obeyed.[7,8] More often than not the curves are smooth and sometimes, for example for EDTA, the dependence of lg K_s on $1/r$ is practically a straight line.

In our opinion, the latter example is of prime importance. It indicates that the bonding in RE complexes is predominantly ionic since the coulombic force itself, which determines the strength of the complexes, is inversely proportional to the distance (its square) between the interacting centres of positive (RE cation) and negative (ligand) charge. This in turn depends on r.

The dependence of the properties of RE complexes not on $1/r$ but on atomic number is plotted in Fig. 2.[6] The similar W-shaped changes of average free energy of complexation ($\Delta\overline{G}$) and ionic radii are interesting. This indicates that the ionic radius itself is the principal factor determining the properties of RE compounds including $\Delta\overline{G}$ of complexation. Since both quantities exhibit a W-shaped change in the RE series, it is obvious that the dependence of $\Delta\overline{G}$ on r will not be W-shaped. In fact, this same conclusion was made before.[6] According to the previous report,[6] since all described properties reflect the lanthanoid† contraction, it follows that this contraction is not a smooth function of Z (atomic number).

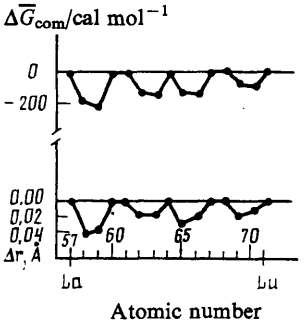

Figure 2. Dependence of average free energy of complexation $\Delta\overline{G}_{com} = \Delta G_{exp} - \Delta G_{int}$ (*a*) and RE ionic radii $\Delta r = r_{exp} - r_{int}$ (*b*) on atomic number.[6]

Therefore, the principal reason for the W-effect is taken to be the controlling influence of changes of radius (atomic, ionic) in the RE series on properties of the compounds. Consequently, the W-shaped dependence on atomic number is seen for those properties that depend on the RE^{III} ionic radius, i.e., have an ionic nature.

† Correctly stated 'lanthanide' and not 'lanthanoid' contraction (Ref. 9 p. 10) (author's note).

The W-shaped dependence can be converted into a smooth one (sometimes linear) by changing the 'atomic number' coordinates into 'ionic radius' (Fig. 1). This indicates that the ionic component predominates in the chemical bonding in RE complexes. Moreover, a deviation from linearity (ideality) in property–radius coordinates can be qualified as a result of the superposition of other factors, primarily, stereochemical hindrances, a covalent contribution and structural changes in the RE series.

In this sense, plotting graphs of any property of RE compounds in property–atomic number coordinates is uninformative since the dependence of the examined property on ionic radius taints all effects. If the plot is made in property–ionic radius coordinates, those factors that are specific for the given system and not for the RE series in general will be identified. Thus, the irregularities in the functions $\lg K_s = f(1/r)$ (Fig. 1) indicate[7,8] at what place in the RE series the structure of the RE complexes changes and how the covalent contribution influences the strength of the complexes if their structure is mainly determined by the ionic contribution.

The dependence of the properties of RE complexes, for example their stability, on ionic radius has a well interpreted physical meaning. It suggests that a decrease of metal ionic radius, makes the metal–ligand bond in the complex stronger. This follows from Fajans simple polarisation theory (for example, cf. Ref. 9, pp 25–40). According to this, the polarising effect exerted on the ligands by RE^{III} cations with a hard rare-gas outer electron shell ($5s^25p^6$) increases from La^{3+} to Lu^{3+} (and from La^{3+} to Sc^{3+}) owing to an increased positive charge density on these cations. As a result, the ligand unavoidably draws nearer to the metal. This increases the metal–ligand electrostatic interaction and simultaneously increases the covalent contribution to the chemical bond (especially if the ligand or its separate functional groups can be polarised).

It is noteworthy that RE^{III} ions, which have a rare-gas configuration, can present only energetically unfavourable vacant 5*d*-, 6*s*- and 6*p*-orbitals and unfilled 4*f*-orbitals, which are highly shielded by the $5s^25p^6$ electrons, to the ligands for formation of covalent donor–acceptor bonds. The small degree of participation of 4*f*-orbitals in complex formation is well documented. For example, the small shifts of absorption bands in RE electronic spectra even on formation of very strong complexes with polydentate ligands provide evidence for this (Ref. 8, pp 5–23, 65–76). This is also supported by the low stability of RE complexes with monodentate ligands (including strong-field ligands such as CN^-, CO, etc.). Only the chelate effect arising on formation of RE complexes with polydentate ligands substantially increases the stability of the RE^{III} complexes. For example, K_s of Nd^{III} complexes with $EDTA^{4-}$ and $DTPA^{5-}$ are 10^{16} and 10^{22}, respectively.

Furthermore, since the ratio between the ionic and covalent contribution to the RE^{III}–ligand bond is often poorly defined, the choice of coordinates for examining the dependence of properties on position of the metal in the RE series is made arbitrarily in many instances.

For example, we learn (Ref. 10, p. 205) that *'additional effects* of stabilisation resulting from the influence of the ligand field and spin–orbit coupling are determined by the number of *f*-electrons. Therefore, the correct correlation for revealing *all effects that determine the bond energy* is the dependence on the number of *f*-electrons, i.e., on the RE atomic number'. The question arises, 'If the 4*f*-electrons influence namely the *"additional"* effects of complex stabilisation (which can be agreed to), then why will it be correct to correlate the strength of *all chemical bonding* with the number of *f*-electrons and not the parameters determining the principal (ionic) contribution to the chemical bonding?' In our opinion, a mistake has been made here since the nature of the chemical bonding in RE complexes must be carefully discussed taking into account recently obtained data.

The semiquantitative nature of the simple polarisation approach based on Fajans rules (or the contemporary but also semiquantitative Pearson concept of hard and soft acids and bases[11]) usually yields the correct prediction of the principal tendencies in the change of properties of one or another series of chemical compounds, if the series is chosen legitimately. In our opinion, the RE series is an ideal subject for demonstrating the fruitfulness of such an approach. Therefore, the concept underlying further examination of the properties and structure of RE complexes can be formulated as follows:

1. Complexes of a given composition in the series La, Ce–Lu and La–Y–Sc are formed mainly by ionic interaction of the RE^{III} and ligands. The strength of the ionic bond increases in these series as the RE^{III} radius decreases.

2. The covalent contribution to the RE^{III}–ligand bond increases according to Fajans rules as the polarising action of the RE^{III} cations increases, i.e., from La^{3+} to Lu^{3+} and from La^{3+} to Sc^{3+}.

3. The presence of a W-effect in the dependence of any properties of RE compounds on atomic number is consistent with primarily ionic bonding in these compounds. The lack of a W-effect for the majority of RE^{III} complexes indicates the existence of effects that complicate the simple ionic model. These are a greater or lesser covalent contribution, a change of structure in one or another part of the RE series, the influence of steric hindrances that weaken the chemical bond, etc.

III. Evidence for a covalent contribution to the RE^{III}–ligand bond

The bonding in RE complexes is undoubtedly primarily ionic. However, it is important to estimate the amount of covalent interaction between the RE^{III} cation and the ligands. The simple polarisation model of Fajans predicts, as already indicated, an increase in the covalent (and ionic) contribution to the metal–ligand bond as the RE ionic radius decreases. However, compounds of the lighter lanthanides, i.e., RE with the maximal radius, are viewed as having the greatest covalent contribution in a number of reports.

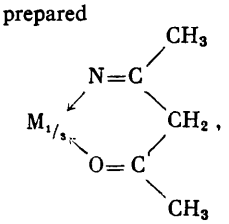
Thus, Tananaev et al. (Ref. 6, p. 186) report that 'the *f*-orbitals contract faster in the first half of the series and slower in the second owing to the decrease of exchange interactions (a decrease in the number of unpaired electrons) in the f^7–f^{14} series.' Hence the conclusion was drawn that the *f*-orbitals more actively participate in chemical bonding in the first half of the RE series than in the second half.

This conclusion is supported[6] by data for the faster decrease of average molar volumes of the unit cells in the first half of the RE series than in the second. In our opinion, this conclusion is inaccurate since it is obvious that the rapid contraction of the *f*-orbitals in the beginning of the RE series controls the rapid decrease of molar volumes. This occurs because the ionic radius decreases quickly whereas the covalent contribution takes a different path.

Kostromina has come to the same, in our opinion, inaccurate conclusion.[10] A comparison of the enthalpic and entropic contributions to the thermodynamic stability of *f*- and *d*-element complexes (Ref. 10, p. 195 ff.) suggested that the enthalpic contribution to the formation energy of *d*-element complexes is large

and the entropic contribution to that of the *f*-elements with about the same K_s is large. Then, the conclusion was reached that 'for elements of the Ce subgroup the covalent component provides a substantial contribution to the bond energy' by carrying out multistepped calculations using data from methods of varying accuracy such as electronic spectroscopy, thermochemistry and pH measurements (Ref. 10, p. 216). Such a calculation was not carried out for RE of the Y subgroup. However, the whole discussion by Kostromina[10] leads one to believe that the covalent contribution to the bonding of later RE with polydentate ligands is relatively small.

We have already noted that the simple polarisation approach predicts a rule opposite to that accepted previously[6,10] New experimental data, as will be demonstrated below, confirm the correctness of the polarisation prediction.



A large number of physical-chemical methods can detect the covalent contribution to the RE^{III}–ligand bond. We will discuss results obtained by photoelectron spectroscopy (PES), IR spectroscopy and kinetics studies.

1. Photoelectron spectroscopy

The principles of the PES method have been developed previously.[12,13] The study of RE β-diketonates by Vovna et al.[14] demonstrated a decrease of metal–ligand covalency as the metal radius increased in the following series of tris-acetylacetonates: ScA_3 > LuA_3 > YA_3. It was noted that an increase of the metal radius in tris-acetylacetonates of the iron subgroup (Fe^{III}–Ru^{III}–Os^{III}) caused the opposite effect, an increase of covalency. It is noteworthy that such a trend agrees completely with Fajans rules, according to which the polarising action of ions with a rare-gas electron configuration, for example RE^{III}, increases with decreasing radius. However, ions with an unfilled (as in the Fe subgroup) or completely filled 18-electron shell polarise (and are polarised) more strongly the greater their radius. Since the covalent bond can be viewed as a polarising perturbation of the ligands by the metal, the series cited above agree with predictions of simple polarisation theory.

The same result as for the RE^{III} tris-acetylacetonates was obtained by PES for RE^{III} tris-dipivaloylmethanates $M(DPM)_3$. The photoelectron spectra of $M(DPM)_3$ are consistent with a greater donor strength of DPM compared with acetylacetone. For $M(DPM)_3$, additional bonding molecular orbitals are detected in the valence band whereas the upper MOs are withdrawn from the valence band. Like for the RE^{III} tris-acetylacetonates, signals in the PES of the RE^{III} tris-dipivaloylmethanates shift by 0.2–0.3 eV to higher ionisation potentials owing to an increase of covalency and a change of $M(DPM)_3$ geometry as the RE^{III} ionic radius decreases (Ref. 14, p. 149). The smallest covalent contribution to the metal–ligand bond among the $RE(DPM)_3$ studied is found for $Pr(DPM)_3$. The MO in its spectrum is not split (splitting is a sign of covalency).

It is also very interesting to compare the PES of RE acetylacetonates and acetylacetoneiminates. As demonstrated previously,[15] where RE acetylacetoneiminates $M(Acim)_3$ with chelate rings were first prepared

substitution of one of the O atoms in the six-membered chelate rings in MA_3 by a N atom in $M(Acim)_3$ causes the PES to change. This is indicative of a relatively large covalent contribution to the M^{3+}–$Acim^-$ bond. It can be seen in Fig. 3 (Ref. 15, p. 87) that the splitting of PES signals of $Lu(Acim)_3$ is much greater than that of LuA_3.

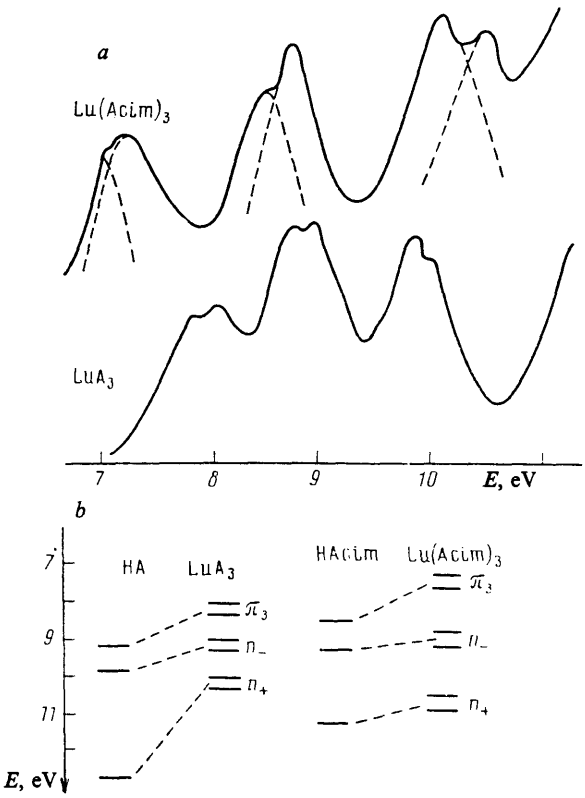


Figure 3. Photoelectron spectra of Lu acetylacetonate and acetylacetoneiminate (*a*); comparison of orbital energy of free ligands (HA, HAcim) and the same ligands in Lu complexes (PES data) (*b*).[15]

This fact agrees well with general concepts of polarisation theory, according to which the N atoms (one of the two donors in $Acim^-$) are more strongly polarising. Consequently, this forms a stronger covalent bond than the O atoms (in A^-) under otherwise equal conditions. However, it is noteworthy that the thermodynamic and, therefore, the chemical stability of $M(Acim)_3$ compounds is less than that of MA_3. Hence, $RE(A)_3$ are unstable in air, quickly hydrolyse, and lose volatility. However, $RE(Acim)_3$ of the Ce subgroup are difficult to isolate pure.[15] Apparently the large covalent contribution (due to substituting O by N) to the bonding in $M(Acim)_3$ is accompanied by a weakening of the metal–ligand coulombic interaction. As already stated, this is the principal component of the chemical bond in all RE^{III} compounds.

As is clear from the preceding, the PES method provides direct evidence for a covalent contribution to the bonding of RE^{III} to

ligands and also indicates that this contribution increases as the RE ionic radius decreases. In our opinion, these data are of prime significance in understanding the coordination chemistry of RE.

2. IR spectroscopy of RE complexes

The literature contains an enormous amount of information on the IR spectra of RE complexes. Unfortunately, the M–O and M–N stretching vibrations are located in the low-frequency IR region (<400 cm^{-1}). As a rule, they are insufficiently characterised due to the mixing of these vibrations with skeletal vibrations of the polydentate organic ligand. The broad contours of these bands make their assignment and analysis difficult. Therefore, the type of metal–ligand bond is usually evaluated by noting how coordination to M^{n+} affects the position of the absorption bands in the spectrum of the free ligand (Ref. 8, pp 76–102). Numerous investigations have demonstrated that the C–O stretches in spectra of RE^{III} complexes with O- and N-donor ligands, as a rule, do not shift compared with their position in the spectrum of the free ligand (for example, in the spectrum of the Na salts, which are usually taken as a model of the ligand with ionic bonds[8]). This is consistent with a RE^{III}–O ionic bond. On the other hand, absorption bands corresponding to the N–H and C–H bonds in the ligand shift in the spectra of chelates with a RE^{III}–N bond. This is consistent with a partially covalent M–N bond. Apparently the N atom is softer than the hard, strongly electronegative O donor and experiences a shift of electron density owing to polarisation by the RE^{III}. This shift extends to the ligand bonds conjugated with the RE^{III}–N bond. The importance of analysing the structure of complexes by IR spectroscopy is supported by the data in Table 1. It is clear that the ν(C–N) and ν(N–H) bands of a RE^{III} complex with IDA shift most in spectra of RE(IDA) compared with their position in ionic NaIDA, less in $RE(IDA)_2$ and least in $RE(IDA)_3$. In the last compounds, the polarising action of the RE^{III} is 'absorbed' by the three IDA ligands and, therefore, is weak.[16]

Hence, IR spectroscopy not only indicates partial covalency in the metal–ligand bond but also enables the relative strength of this bond in series of related compounds to be characterised.

Let us illustrate the capabilities of IR spectroscopy using RE^{III} β-diketonates as an example. As seen in Table 2, the shift of ν(C=O) to low frequencies in the spectra of RE^{III} tris-acetylacetonates is maximal for anhydrous MA_3.

The low-frequency position of the ν(C=O) band indicates that the C=O bond is weakened most where only acetylacetonates enter the RE^{III} coordination sphere. Introduction of additional neutral ligands such as H_2O, phen, DMSO, etc. into the inner sphere weakens the coordination of the principal ligand, acetylacetonate. This strengthens the C=O bond and increases ν(C=O). It is also shown in Table 2 that chelation of acetylacetoneiminate by RE^{III} greatly weakens the N–H bond in the ligand. The greatest weakening occurs in $M(Acim)_3$, the M^{3+} cations of which have the smallest ionic radius, i.e., are the strongest polarisers.

It is interesting that the sensitivity to the size of the RE^{III} polarising action in this instance also (like for RE complexes) is substantially greater for the M^{3+}–N bond than M^{3+}–O.

Structural data confirm the correctness of conclusions about RE chelate structures made on the basis of IR spectra. For example, the average Yb^{3+}–O distance in YbA_3,[17] for which ν(C=O) = 1585 cm^{-1}, is 2.211(8) Å, i.e., slightly less than in $Yb(Acim)_3$ (2.233 Å) and in $YbA_3 \cdot 3H_2O$ (2.23 Å).[19] This agrees with ν(C=O) = 1595 cm^{-1} (Table 2).

3. Kinetic studies

Systems of ionic compounds are known to be kinetically labile under appropriate conditions (solutions, melts, vapors). However, systems of covalent compounds (organic compounds, Pt complexes), as a rule, are kinetically slow. This can sometimes reach the point where equilibrium is not attained. For example, Pt complexes cannot be characterised by stability constants for this reason. Therefore, it can simply be said that rapid exchange reactions are a sign of ionic bonding whereas slow processes are typical of covalency.

Table 1. IR spectra of RE iminodiacetates[16].

Compound	ν(N–H), cm^{-1}	$\Delta\nu^*$(N–H), cm^{-1}	ν(N–C), cm^{-1}	$\Delta\nu^*$(N–C), cm^{-1}

(Pr–Yb)A_3·phen	1625	–

However, there usually is no simple and direct dependence between the kinetic parameters of exchange processes in systems with complexes and the type of metal–ligand bond that determines the

thermodynamic and structural characteristics. Comparison of kinetic, thermodynamic and structural parameters is most often complicated by the different mechanisms of the reactions being compared. However, if subjects with reactions described by identical kinetic equations can be found, such an examination can become valid.

We carried out a special investigation of the kinetic parameters of solutions of RE complexes and proved that the metal exchange in systems with light and heavy RE occurs by the same mechanism (identical kinetic equations) but with different rates. Such a conclusion suggests that the kinetic sluggishness typical of heavy RE complexes (RE of the Y subgroup) is due to a larger covalent contribution to the metal–ligand bond in these chelates compared with the same chelates of light RE (RE of the Ce subgroup).

Results of a study of the metal exchange in aqueous solutions containing RE^{III} and H_4EDTA are presented in Table 3.

Table 3. Metal exchange rate in aqueous solutions of EDTA complexes.[20]

M^{3+}_{leav}	M^{n+}_{ent}	$10^{-2}k'$, $dm^3 mol^{-1} sec^{-1}$	$10^{-2}k''$, $dm^3 mol^{-1} sec^{-1}$
Nd^{3+}	Yb^{3+}	4.67±0.33	18.0±0.20

Er^{3+}	Cu^{2+}	(5.5±0.1)·10^{-2}	0.83±0.03
Yb^{3+}	Cu^{2+}	(1.56±0.05)·10^{-2}	0.33±0.01

It was found[20] that the exchange

$$[M_{leav}(EDTA)]^- + M^{n+}_{ent} \rightleftharpoons [M_{ent}(EDTA)]^{4-n} + M^{3+}_{leav},$$

obeys the following kinetic equation:

$$V = V_I + V_{II} = k'[H^+][M_{leav}(EDTA)^-] + k''[M_{leav}(EDTA)^-][M^{n+}_{leav}],$$

where M^{3+}_{leav} and M^{n+}_{ent} are the leaving and entering cations, respectively, and k' and k'' are the exchange rate constants for the dissociative and associative mechanisms. The rate of the dissociative process (V_I), as previously demonstrated,[20] is limited by cleavage of the leaving cation–acetate ($EDTA^{4-}$) bond in the intermediate protonated complex whereas the rate of the associative process (V_{II}) is limited by cleavage of the leaving cation–N($EDTA^{4-}$) bond in the intermediate binuclear complex. Table 3 clearly shows that V_I does not depend on the nature of the entering RE^{III} cation but decreases as the leaving cation shifts towards the heavy RE. The rate V_{II} also is minimal in complexes of heavy RE, which have the minimal ionic radius and, therefore, provide the greatest chance for covalency owing to the large polarising effect.

Fig. 4 shows that the slope of the dependences of rate constants on ionic radius of leaving RE^{III} changes in the middle of the RE series. This can be related[20] to the change of inner-sphere hydration on going through the RE series. Whereas inner-sphere dihydrates $[M(H_2O)_2(EDTA)]^-$ are typical of heavy RE, formation of di- and trihydrates is equally probable for RE in the middle of the series. Thus, the following equilibrium was studied for the system with Eu^{III}

$$[Eu(H_2O)_2(EDTA)]^- \rightleftharpoons [Eu(H_2O)_3(EDTA)]^-,$$

and it was demonstrated[21] that the reactivity of the inner-sphere dihydrate is less than that of the trihydrate $[Eu(H_2O)_3(EDTA)]^-$. Structural data indicate that inner-sphere trihydrates are more characteristic of the light RE. This was found, in particular, for Nd and Eu complexes of EDTA. The structural data suggest (Ref. 8, p. 10) that the RE^{III} draw closer to the ligand if the number of inner-sphere waters of hydration decreases in the RE^{III} complexes of EDTA. In particular, the average RE^{III}–O ($EDTA^{4-}$) and RE^{III}–N ($EDTA^{4-}$) bond lengths in $[Er(H_2O)_2(EDTA)]^-$ are substantially less (2.27 and 2.56 Å) than in $[Nd(H_2O)_3(EDTA)]^-$ (2.53 and 2.83 Å).[22,23] Such a decrease of the bond lengths should certainly increase the polarisation of metal–ligand interactions. This increases the covalent contribution to the bond and affects the rate of electrophilic and nucleophilic substitution in addition to the size of the change of k' and k'' with decreasing RE^{III} ionic radius, as can be seen in Fig. 4.

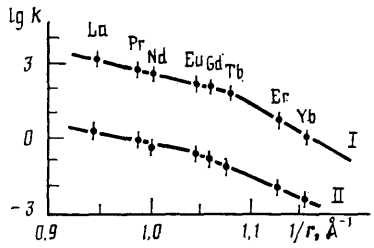

Figure 4. Change of metal-exchange rate constant in solution of RE^{III} EDTA complexes.[20] *I*, lg k'; *II*, lg k''.

Hence, the kinetic data and the PES and IR results confirm the correctness of the hypothesis ensuing from the simple polarisation model that the covalence in the metal–ligand bond increases as the RE^{III} radius decreases in the series La–Ce–Lu and La–Y–Sc.

IV. Mutual influence of ligands and metals in homoleptic and polynuclear RE^{III} complexes

If a complex contains several identical or different ligands in addition to several cations, all of these components of the coordination sphere affect each other. Obviously their mutual influence will be stronger the more labile their bonding in the complex. In our opinion, it is completely justified to assume that the mutual influence of coordination-sphere components is more easily transferred through an ionic metal–ligand bond than through a

covalent one. The reasons for this are the long range and sphericity of coulombic forces in contrast with the directionality and saturation (relatively short range) of covalent forces.

In our work[7,8] in addition to that of others,[6,10] it is possible to find numerous examples in support of the prediction just given, which invokes a strong and rapidly attained mutual influence of coordination-sphere components in RE^{III} complexes. In particular, the regular decrease of successive K_s for RE complexes formed by incorporation into the coordination sphere of one, two, three and more identical (cf. Table 1) or different ligands support the correctness of such an approach. The changes of successive K_s in the RE series of neutral mono-, bis- and tris-IDA complexes of RE [8,24] are plotted in Fig. 5 as an example. It can be seen that the first ligand (formation of the mono-complex) is bound most strongly in the coordination sphere (CS). The energy stored in one metal–ligand bond decreases smoothly on going to the bis- and tris-complexes. The anomalous path of $\lg K_3$ near the heavy RE is due to the generation of steric hindrances owing to the decrease of ionic radius and the approach of the cations and anions in the complex. In general, incorporation of each successive ligand decreases K_s by almost two orders of magnitude. This should be expected if the ionic model of the CS is accepted. According to this model, neutralisation of the positive charge of the RE^{III} cation by each negatively charged ligand should substantially weaken the metal–ligand bond in the CS.

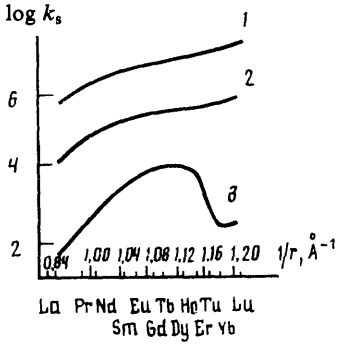

Figure 5. Change of stability of mono- (*1*), bis- (*2*), and tris-IDA complexes (*3*) of RE.[24]

The path shown in Fig. 5 for the successive K_s is normal for an ionic CS.[8] However, these data of themselves do not answer the question of whether the position of ligands in higher complexes is equivalent. For example, is each IDA ligand in bis- and tris-IDA complexes of RE bound with the same strength? In order to answer this question, data obtained by other methods can be used. For example, an IR study of solid RE complexes, as already mentioned above (cf. Table 1), indicates successive weakening of the RE^{III}–N bond on going from the mono- to bis- and tris-IDA complexes and equivalence for the two IDA residues in the bis-complex and three in the tris-complex. This conclusion agrees with PMR spectroscopic results.[11] However, this method detects equivalent ligands in higher RE complexes only for ligands of low denticity (in particular, including tridentate IDA). According to PMR, only one of the ligands remains highly dentate in complexes of ligands with high denticity for example, $[M(EDTA)_2]^{5-}$ with sexadentate H_4EDTA. The second only partially uses its donor atoms. This fact is explained in the monograph of Kostromina[11] by the large energy gained by retaining the configuration of the mono-complex $[M(EDTA)]^-$ in the bis-complex $\{[M(EDTA)](EDTA)\}^{5-}$ compared with the compound where some of the chelate rings of $[M(EDTA)]^-$ are broken and both $EDTA^{4-}$ residues are identically bound, i.e., exhibit decreased denticity of 4: $[(EDTA)\equiv M\equiv(EDTA)]^{5-}$. Apparently such a redistribution of donor atoms opens (breaks) the EDTA ring in the mono-complex. This sharply reduces the entropy of the system.

It is interesting that a similar nonequivalence of the structural components of the CS based on the polydentate complexants H_4EDTA and H_5DTPA is achieved not only in higher complexes (excess of ligand) but also in polynuclear complexes (excess of M^{3+}).

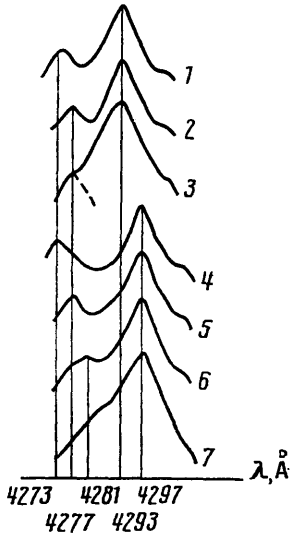

Figure 6. Electronic spectra of Nd complexes with $EDTA^{4-}$ (*1–3*) and $DTPA^{5-}$ (*4–7*).[25] Concentration, M: $[Nd_4(EDTA)_3]$ = 0.04 (*1*); 0.14 (*2*); $[Nd_5(DTPA)_3]$ = 0.02 (*4*); 0.15 (*5*); 0.40 (*6*). Solid complex (*3*, *7*).

As demonstrated in Fig. 6,[25] high-resolution electronic spectroscopy (Ref. 8, pp 65–76] detects nonequivalent positions for the two Nd atoms in the dinuclear complexes $[Nd_2(EDTA)]^{2+}$ and $[Nd_2(DTPA)]^+$. In dilute solutions, one of the two moles of Nd^{3+} used per one mole of complexant forms the mono-complex $[Nd(EDTA)]^-$ or $[Nd(DTPA)]^{2-}$ with absorption bands at 4292 and 4297 Å, respectively. The second mole of Nd^{3+} remains as the aqua-ion $[Nd:aq]^{3+}$ with an absorption band at 4273 Å. Polynuclear complexes form as these solutions are concentrated (Ref. 8, pp 15–18). This produces only a small shift to long wavelength of the absorption band of the aqua-ion (to 4277 and 4281 Å in the H_4EDTA and H_5DTPA systems, respectively). A shift

of this value corresponds to coordination of Nd^{3+} by only one or two of the acetato-groups of the ligand. Therefore, high-resolution spectrography reveals the nonequivalence of the two Nd^{3+} ions in dinuclear complexes. Consequently, here, like in the higher complexes, the ligands and RE ions remain different. Their positions are not averaged. The energy gain from this structure apparently determines the state of the system in polynuclear complexes based on $EDTA^{4-}$ and $DTPA^{5-}$. Such an unaveraged state for the metals and ligands does not contradict the postulated ionic bond in RE complexes. In fact, PMR [10] and kinetic studies[20] detect rapid exchange in such systems so that the discussion is not about the nonequivalence of polynuclear or polyligand CS that presumes metal–ligand covalency but about which arrangement of donors and RE ions is thermodynamically most favorable.

Results of mathematical modelling of equilibria in EDTA solutions of Nd^{III} and Yb^{III} using experimental pH measurements are presented in Tables 4 and 5.[26]

Table 4. Modelled pH-tritration of $2Nd^{3+}-EDTA^{4-}-KOH$ solutions.[26]

Model No.	Model	Sum of squares of experimental deviations
0	H^+; Nd^{3+}; $NdOH^{2+}$; $EDTA^{4-}$; $HEDTA^{3-}$; H_2EDTA^{2-}; H_4EDTA; H_3EDTA^+; $Nd(EDTA)^-$	2.07
1	{0}+HNd(EDTA)	0.12
2	{1}+$Nd_2(EDTA)^{2+}$	0.07

Table 5. Stability of Nd^{III} and Yb^{III} EDTA complexes by mathematical modelling[26].

Compound	ln β	log K_s	pK_a
$[Nd(TDTA)]^-$	36.02±0.08	15.66	–
$H[Nd(EDTA)]$	40.88±0.09	–	2.11
$[Nd_2(EDTA)]^{2+}$	38.46±0.16	1.06	–
$[Yb(EDTA)]^-$	43.01	18.70	–
$H[Yb(EDTA)]$	47.10±0.09	–	1.78
$[Yb_2(EDTA)]^{2+}$	44.04±0.52	0.45	–

Note. β is the overall formation constant. K_s is the step-wise stability constant. K_α is the acid dissociation constant.

The data suggest that the strength of the polynuclear complexes decreases from light RE (Nd) to heavy ones (Yb). The very large difference in successive K_s corresponding to binding of one or two RE^{III} by one $EDTA^{4-}$, respectively, is interesting. For Nd^{III} and Yb^{III} this difference is greater than 14 and 18 orders of magnitude, respectively. Therefore, the thermodynamic efficiency of removing part of the donors from the mono-complex to form the polynuclear compounds is small. The same can be said about the nonequivalence of identical ligands in a system with more EDTA ligands and other RE polyligand compounds based on high-denticity ligands.[7] However, the less stable the mono-complex is (achieved with a low-dentate complexant), the less the difference is in the state of the second and successive ligands in the RE CS and the greater their mutual influence.

V. Mutual influence of ligands in heteroleptic RE complexes

If the principal ligand, i.e., the ligand forming the stronger bond to the RE^{III} in a mixed coordination sphere has high denticity and high donor activity then, as a rule, additional weaker ligands enter the complex with a relatively small K_s. Let the additional ligand be citrate with a comparatively low denticity (equal to 4). Then, RE^{III} form heteroleptic complexes in addition to those with the principal ligand, for example, EDTA. However, these have low stability.[7,27] This agrees well with the low stability (consider the successive K_s) of higher homoleptic complexes of RE with H_4EDTA. However, if the principal and additional ligands are of comparable denticity and donor strength (for example, H_2IDA and H_3Cit), their state in the $RE^{III}CS$ is essentially the same and resembles the situation discussed above for formation of higher homoleptic IDA complexes (cf. Table 1 and Fig. 5).

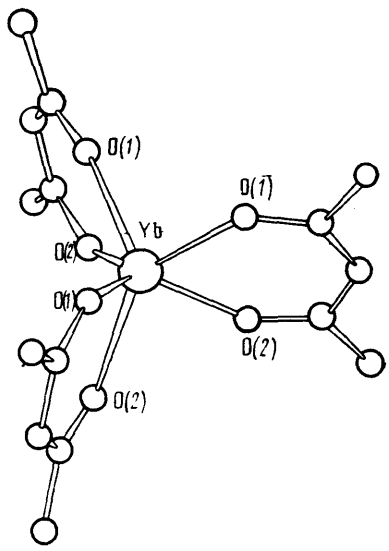

Figure 7. Crystal structure of anhydrous Yb tris-acetylacetonate.[28]

Mixed complexation in systems with principal and additional ligands of comparable strength have been studied by us in connection with adduct formation in RE^{III} tris-β-diketonates. Since RE^{III} characteristically have high and variable coordination number and the denticity of each β-diketonate is 2, only six donors surround the RE^{III} in monomeric tris-β-diketonates (Fig. 7).[28]

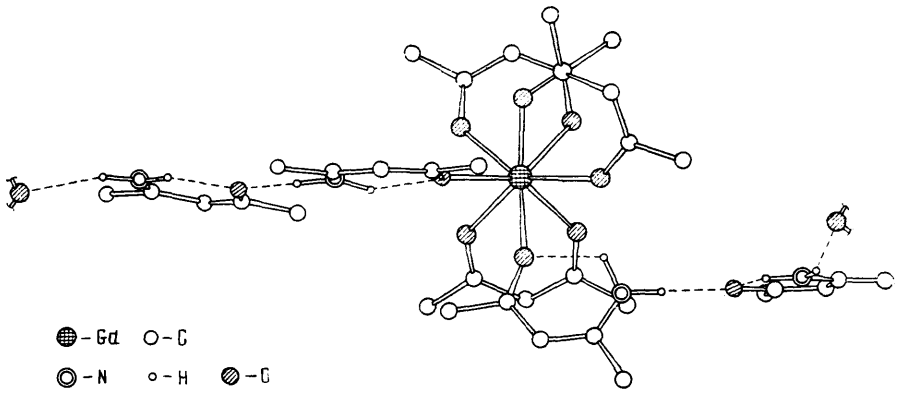

Figure 8. Structure of the adduct $GdA_3 \cdot 4HAcim$.[30]

In general this is clearly insufficient to saturate the $RE^{III}CS$. Therefore, tris-β-diketonates, including RE^{III} tris-acetylacetonates MA_3 and tris-dipivaloylmethanates $M(DPM)_3$, usually polymerise.[29] Polymerisation does not occur if an additional ligand capable of entering the inner CS of the RE^{III} tris-β-diketonate and increasing its CN to 7–9 is present. Mixed complexes based on tris-β-diketonates form. These are called adducts (i.e., addition products) although the additional ligands are inner-sphere and in this sense are equal to the principal ligands. The structure of the adduct of GdA_3 with HAcim of composition $GdA_3 \cdot 4Acim$ is shown in Fig. 8.[30] Of the four HAcim molecules, two are monodentate (through O) and increase the CN to 8. Two HAcim molecules are outer-sphere and bonded through H-bonds.

Incorporation of an additional neutral ligand into the CS of a RE tris-β-diketonate usually lengthens the $RE^{III}-O$ distance owing to partial neutralisation of the metal charge (ion–dipole interaction) and generation of steric hindrances. This can lead to competition with donor atoms of the principal ligand for the CS. This does not open the chelate rings formed by the principal ligand even if the additional neutral ligand is bidentate (bipy, phen, etc.). However, the $RE^{III}-O$ distance in adducts (including hydrates) is always slightly greater than in the monomeric tris-β-diketonates themselves (Table 6).

Apparently this difference in bond lengths would be much greater if data for the monomeric and not dimeric (as in Table 6) tris-β-diketonates were used for comparison in systems with $RE(DPM)_3$ of the Ce subgroup. Polymerisation has the same weakening effect on the $M^{3+}-O$ bond as adduct formation. However, data for the monomers exist only for RE of the Y subgroup where both polymerisation and adduct formation are sterically hindered. The influence of the additional ligand on the strength and length of the $M^{3+}-O$ bond is less than in these same systems with RE of the Ce subgroup. There are no structural data for anhydrous RE tris-β-diketonates (acetylacetonates) of the Ce subgroup. Even for the heavy RE only the one structure mentioned above, YbA_3, has been solved.[28]

Therefore, the mutual influence of identical and mixed ligands in the $RE^{III}CS$ is substantial. It is not determined by any one factor, for example, the nature of the metal, but by several parameters. First of all, a donor strength and steric characteristics must be assigned to the ligands interacting in the inner sphere of RE^{III} complexes.

Table 6. Influence of adduct formation on M–O bond length in chelate rings of RE^{III} tris-β-diketonates.[17,18]

tris-β-Diketonate	M–O bond length, Å	Adduct	M–O bond length, Å

$[NdA_3]_1$		$[NdA_3 \cdot 2H_2O] \cdot H_2O$	2.44
		$[NdA_3 \cdot H_2O \cdot DMSO] \cdot DMSO$	2.43
		$[PrA_3 \cdot 2H_2O] \cdot H_2O$	2.44
		$[EuA_3 \cdot phen]$	2.40
		$[GdA_3 \cdot 2HAcim] \cdot 2HAcim$	2.38
		$[YbA_3 \cdot H_2O]$	2.233
$[YbA_3]_1$	2.211	$[YbA_3 \cdot HAcim]$	2.23

Our attempt to determine the stability of $M(\beta\text{-diket})_3 \cdot xQ$ adducts by gas–liquid chromatography (GLC) demonstrates just how complicated it is to predict the result of the mutual influence of ligands in heteroleptic RE complexes, for example, in the CS based on β-diketones. It is clear from Table 7 that the stability of the adducts changes differently in the RE^{III} series depending on the nature of the principal ligand, i.e., the β-diketone. Since HDPM creates steric hindrances in the $M(DPM)_3CS$ owing to the two tert-butyl radicals in each molecule, the probability of incorporating an additional ligand in it decreases as the RE ionic radius decreases. The adducts have minimal stability for the small Lu^{3+} and maximal

Table 7. Effective formation constants (K_{eff}) of RE tris-β-diketonate adducts $ML_3 \cdot Q$[31].

ML_3	Additional ligand, Q	Determination method	K_{eff}

for the large Nd^{3+}. Conversely, $M(PTFA)_3$ are less sterically hindered (Table 7) and add an additional ligand more strongly the smaller the RE^{III} ionic radius. In this instance, the normal relation predicted by Fajans simple polarisation theory is seen.

Table 8. Temperature of maximal thermolysis (T_s) of RE tris-dipivaloylmethanate adducts $M(DPM)_3 \cdot Q \rightarrow M(DPM)_3 + Q$.[18]

The reversal in the dependence of effective formation constants of the RE^{III} tris-β-diketonate adducts due to steric parameters of the principal ligand (Table 7) is confirmed by chromatography of $RE(DPM)_3$ and $RE(PTFA)_3$ with and without additional ligands. As demonstrated previously,[31] the difference between the retention times (Δt_{ret}) of the tris-β-diketonates and their adducts is greatest for DPM complexes of the light RE. This is consistent with maximal stability of the adducts $M(DPM)_3 \cdot Q$ for the light RE. For $M(PTFA)_3$, the greatest difference in retention time of the tris-β-diketonates and their adducts is seen in the middle of the RE series. At this point, the steric hindrances to adduct formation are still small and the complexing power of the metal (Ho^{3+}) is still significant, in contrast with the light RE^{III}, owing to the 'average' size of M^{3+}.[31]

A study of the thermal stability of the RE tris-β-diketonate adducts also demonstrates the complexity of the competition between the different ligands in the $RE^{III}Cs$. It is evident from Table 8, in agreement with the GLC data (Table 7), that the thermal stability of $M(DPM)_3 \cdot Q$ for all additional ligands studied[18] decreases as the RE ionic radius decreases, i.e., the steric effect of the DPM, the principal ligand, is unfavourable and here has the definitive effect.

The thermal stability changes in the opposite direction for adducts of less sterically hindered RE acetylacetonates. Table 9 shows that the temperature of maximal thermolysis of the adducts does not decrease with decreasing RE^{III} ionic radius [as for $RE(DPM)_3$]. It increases somewhat (Q = phen) or changes little (Q = bipy). The simple explanation is that acetylacetone is not a sterically hindered ligand. Therefore, the normal relation resulting from Fajans polarisation laws is in effect during adduct formation.

Table 9. Temperature of maximal thermolysis of RE tris-acetylacetonate adducts $MA_3 \cdot Q$.[18]

It is interesting (Table 9) that the temperature dependence is much stronger for $MA_3 \cdot Q$ adducts with phen than bipy. This can be explained by the greater rigidity of phen compared with bipy. The latter can rotate fragments around the C–C bond and, therefore, more flexibly than phen fills the voids in the MA_3 structure. Hence, steric effects for systems with $RE(A)_3$ are determined mainly by the structure not of the principal but of the additional ligand.

It is noteworthy that Table 9 includes data for $RE(A)_3$ adducts $MA_3 \cdot Q$ only with bidentate additional ligands (phen, bipy) whereas Table 8 includes data for $RE(DPM)_3$ adducts with monodentate additional ligands. This is due to the fact that $RE(A)_3$ form not only mono- but also bis-adducts with monodentate ligands owing to the lack of steric hindrances on coordination of the principal ligand. As a rule, formation of $MA_3 \cdot 2Q$ is characteristic for light RE, which have a large ionic radius, whereas mono-adducts $MA_3 \cdot Q$ are typical of heavy RE, which have a small ionic radius. Solid $MA_3 \cdot 2Q$ and $MA_3 \cdot Q$ undergo thermolysis by different mechanisms. Therefore, the thermal stability of such adducts over the whole RE series cannot be compared, in contrast with $M(DPM)_3 \cdot Q$, where the RE adducts have a constant composition.

The change of composition of $RE(A)_3$ adducts is sometimes even more complicated. For example, adducts of MA_3 with monodentate (neutral) HAcim reportedly have the following composition:[17]

$$MA_3 \cdot 2HAcim \quad (M = La - Gd);$$
$$MA_3 \cdot 4HAcim \quad (M = Sm - Tu, Y);$$
$$MA_3 \cdot HAcim \quad (M = Tb - Lu).$$

Regions of stability of the different adducts in the RE series overlap. For example, Tb forms all three adducts: $TbA_3 \cdot HAcim$, $TbA_3 \cdot 2HAcim$ and $TbA_3 \cdot 4HAcim$. It is important to note that the mono-adduct is thermally more stable than the bis-adduct.[17]

$$TbA_3.HAcim \xrightarrow[-HAcim]{105\ ^\circ C} TbA_3(s.) + HAcim\uparrow \quad \xrightarrow[sublimation]{110\ ^\circ C} TbA_3(g.),$$

$$TbA_3.2HAcim \xrightarrow[-2HAcim]{95\ ^\circ C} TbA_3(s.) +$$

$$+2HAcim\uparrow \xrightarrow[melting]{105\ ^\circ C} TbA_3(l.) \xrightarrow{160\ ^\circ C} \text{thermolysis}.$$

Thermolysis of only the mono-adduct produces the monomeric sublimable TbA_3. Thermolysis of the bis-adduct leads to melting, polymerisation, and anhydrous $[TbA_3]_n$ that cannot be sublimed.

Therefore, practically each studied series of mixed RE complexes has its own specific type of complicated interaction of numerous factors that often have an equivalent influence on the properties of the complexes. However, it can be confirmed with certainty that such an array of structures and properties of RE^{III} complexes is a consequence of the predominantly ionic interaction in these compounds.

VI. Intermolecular interaction in RE complexes with polydentate organic ligands

The predominantly ionic metal–ligand bonding in RE^{III} complexes frequently leads to catenated structures where one polydentate ligand is shared between two or more RE^{III}. Such a structure is especially characteristic for compounds with a deficit of ligands (of moderate denticity). Therefore, it is very often found in 1:1 complexes. For example, monocitrates $[M(Cit)]_n$ monotartrates $[M_2(tart)_3]_m$ and mononitrilotriacetates $[M(NTA)]_p$ have extensively linked (by polymerisation) chain structures (Ref. 8, p. 11).

As a rule, such compounds are difficultly soluble. However, addition to the RE^{III} coordination sphere of another such ligand can form a monomeric structure with weak intermolecular contacts. This solubilises the initially poorly soluble 1:1 complex:

$$\underset{\text{ppt.}}{[M(Cit)]_n} + n Na_3Ci \rightarrow \underset{\text{solution}}{n Na_3[M(Cit)_2]};$$
$$\underset{\text{ppt.}}{[M(NTA)]_m} + m K_3(NTA) \rightarrow \underset{\text{solution}}{m K_3[M(NTA)_2]} \text{ etc.}$$

If the ligand forming the RE^{III} complex is highly dentate (denticity 6 and greater) and sufficiently flexible to surround the RE^{III} with a spherical (or hemispherical) shield that isolates it from other RE^{III}, the resultant structure is monomeric. As a rule, the intermolecular contacts in it are weak. Such a compound is very soluble in polar solvents, for example, water.[1,2,7,8]

Conversely, the number of donors in 1:1 complexes with ligands of low denticity (1, 2 and 3) is insufficient to saturate the inner CS of RE^{III} even if a bridging structure is formed. Therefore, other ligands must be added (or they are added during synthesis, for example, solvent) to the CS of such complexes to produce monomers. Such CS most often are mixed. Their properties and intermolecular contacts are determined by the stoichiometry of the complex and the relationship among properties of the system components. An example would be RE^{III} chloride–HAcim complexes synthesised and studied previously.[15] The properties of these $MCl_3 \cdot n$ HAcim are exceedingly varied:

$$MCl_3 \cdot 3{,}5HAcim \quad (M = Pr, Nd, Sm);$$
$$MCl_3 \cdot 3HAcim \quad (M = Gd - Yb);$$
$$MCl_3 \cdot 4HAcim \quad (M = Lu, Sc);$$
$$MCl_3 \cdot 6HAcim \quad (M = La, Pr, Nd, Sm, Gd - Er, Lu).$$

Among RE complexes with low-dentate ligands, the most completely studied are the β-diketonates. This is due to practical applications related to their ability to dissolve in low-polarity solvents and to sublime. Therefore, they are suitable for extraction, chromatography and sublimation.

We have already mentioned the coordinative saturation of RE^{III} tris-β-diketonates and their tendency to saturate the CS by adding ligands or by forming bridging O bonds. (This was first found structurally in $[Pr(DPM)_3]_2$.[32]) Intermolecular contacts in such compounds are controlled by the properties of the affected principal and additional ligands in addition to the degree of polymerisation (oligomerisation) of the tris-β-diketonates themselves. Somehow the majority of these compounds can be vaporised by heating under vacuum. They can be distilled or sublimed.

The discovery that RE^{III} complexes can be sublimed at first was surprising since it was generally accepted that ionic compounds were involatile. Attempts to find an appreciable covalent component in tris-β-diketonates and to explain their volatility by their covalent nature were unsuccessful.[33,34] However, it has now been established that the volatility and solubility of tris-β-diketonates in low-polarity solvents are due to their pseudoorganic properties. The hydrocarbon radicals of the β-diketonate ions form a hydrophobic sphere around the ionic core that has little tendency to form associates. This determines the behaviour of RE tris-β-diketonates, which is characteristic for ordinary molecules comprising the world of organic compounds.

The pseudoorganic nature of neutral RE tris-β-diketonates is responsible for the low selectivity in fractional sublimation, gas chromatography and extraction. However, the specific properties of different RE^{III}, no matter how subtle they may be, still cause substantial differences in the thermodynamic characteristics, for example, K_s (cf. Fig. 1). On the other hand, if the compounds do

not decompose or at least the RE CS does not open temporarily during sublimation and extraction, the selectivity leads to differences in the intermolecular interactions.[35] Therefore, fractional sublimation of tris-β-diketonates under ordinary conditions is suitable only for group separation of RE mixtures. For example, dimeric $[M(DPM)_3]_2$ of light RE can be separated by fractional sublimation from monomeric $[M(DPM)_3]$ of heavy RE,[33] whereas intragroup separation of RE^{III} without competing decomposition is ineffective.[35]

Intermolecular interaction of RE complexes explains the important loss of individual properties of complexes in the mixture to be separated. For RE β-diketonates, the mutual influence of individual RE complexes is accompanied by formation of heterometallic oligomers. Preliminary experiments demonstrated that these can be detected by mass spectrometry. However, reliable proof of their existence comes from preparative chemical studies. We will give some examples.

The pioneering work of Sievers and Eisentraut[36] demonstrated that group separation of RE^{III} mixtures by fractional sublimation of $RE(DPM)_3$ of the Ce and Yb subgroups was not complete. The separated components contained an approximately 3% impurity of the other RE subgroup elements even though an apparatus with a gradient heater was used. In our opinion, such a consistent mutual contamination that could not be eliminated by repeated sublimation is due to formation of oligomers that are stable in the vapour.

Another example. It has been found[17,18] that adducts of $RE(A)_3$ of the Ce subgroup with DMSO ($MA_3 \cdot 2DMSO \cdot H_2O$) and HAcim ($MA_3 \cdot 2HAcim$) do not give volatile products containing RE on heating in vacuum. Moreover, as we showed in collaboration with Dzyubenko and Kalinichenko,[37] these compounds in the presence of $RE(A)_3$ adducts of the Yb subgroup do appear in the sublimate. The percent transferred can be significant. Thus, heating in vacuum a 1 : 1 mixture of $[NdA_3 \cdot 2DMSO \cdot H_2O]$ and $[YA_3 \cdot DMSO]$ produced 40% of the starting Nd in the sublimate even though the starting complexes are involatile.

The amount of involatile $MA_3 \cdot nH_2O$ transferred to the vapour and then into the sublimate increases sharply if coordinatively saturated Zr^{IV} tetrakis-acetylacetonate is added to the starting compound, for example, $YA_3 \cdot 3H_2O$.[38]

In the preceding examples, the loss of identity of $RE(A)_3$ on mixing with each other can be linked to formation of oligomers that contain RE of different subgroups in one molecule. However, in our opinion, break-up of YA_3, which tends to oligomerise, by coordinatively saturated ZrA_4 is more probable in the example with ZrA_4. This prevents formation of $[YA_3]_x$ oligomers that are less volatile than YA_3.

Furthermore, the components in a subliming mixture of $RE(A)_3$ have practically no influence on each other if a stable adduct that does not decompose during sublimation is present. Since MA_3 adducts with strong donor ligands such as HMPA and TPPO only partially dissociate on heating in vacuum and partially lose the additional ligand (in contrast with adducts with weaker donors: H_2O, DMSO, HAcim), the coordinative saturation of the RE complexes is preserved during sublimation. This prevents oligomerisation of the individual chelates and interaction of the components with each other. In fact, as demonstrated in Table 10, the separation coefficients of RE mixtures determined experimentally and calculated from the sublimation parameters of the individual components are practically the same for such mixtures. Consequently, coordinatively saturated RE complexes exhibit independent behaviour, retain their integrity, and remain monomeric during separation.

It is noteworthy that multiple repetitions and intricate mathematical treatment of the experimental results is necessary to obtain reliable data for the fractional sublimation of partially dissociated adducts of RE β-diketonates. This happens since small changes in the experimental conditions have a large effect on the results.[39]

Table 10. Separation of RE mixtures by fractional sublimation of $MA_3 \cdot HMPA$.[37]

Sublimed mixture (M', M")A_3.HPMA	Separation coefficient $\alpha^{M'/M''}$	
	experimental data for the mixture	calculated data for individual adducts
(Nd, Pr)A_3.HMPA	1.2±0.1	1.2
(Gd, Nd)A_3.HMPA	6.0±0.1 *	1.2
(Er, Gd)A_3.HMPA	4.4±0.3	5.4
(Er, Nd)A_3.HMPA	35±5 *	6.5
(Er, Ho)A_3.HMPA	1.3±0.1	0.97

*Experimental $\alpha^{M'/M''}$ are greater than calculated since the mixture was separated in a gradient furnace.

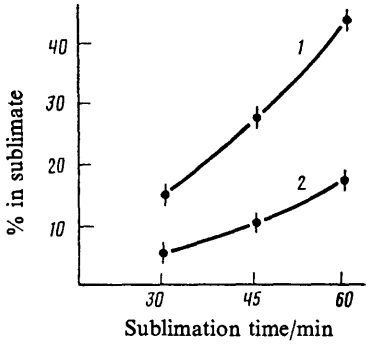

Figure 9. Sublimation of $Nd(Piv)_3 \cdot 3.5HPiv$ (*1*) and $Er(Piv)_3 \cdot 3HPiv$ (*2*) at 360 °C and 10^{-1} torr.

The RE carboxylate system is an example of a sublimation system where the mutual influence of the components is very strong.

The volatility of RE carboxylates was recently discovered by our co-workers at Moscow State University (Kuz'mina et al.[39,40]). Fig. 9 shows that RE pivalates $M(Piv)_3 \cdot nHPiv$ only partially vaporise. The individual RE^{III} pivalates of the Ce subgroup under our experimental conditions sublime more completely than those of the Yb subgroup. The separation coefficient for $Nd^{3+} - Er^{3+}$ from separate sublimation of Nd and Er pivalates is (heating at 360 °C and 10^{-1} torr for 75 min) $\alpha^{Er/Nd} = 68.7$. Such an α value promises

good group separation of RE mixtures. However, an experimental check of the separation gave $\alpha^{Er/Nd} \approx 1.0$, i.e., the sublimate had the composition of the starting mixture. The reason for the lack of separation was the loss of integrity of the components owing to polymerisation of the chelates during sublimation. It can be assumed that the carboxylates act as bridges to form strongly bonded oligomers that are stable in the vapour. Preliminary mass spectroscopic data[40,41] enabled detection of heterometallic RE oligomers that were stable even under the high vacuum of the mass spectrometer.

Instances where the properties of individual RE chelates are suppressed by another component of the mixture are quite common. However, let us recall that this is characteristic for systems in which the complex is not monomeric and oligomers and polymers form owing to coordinative unsaturation.

Such instances are characteristic not only for vapour processes but also for complexation in liquid solutions and solid-state mixtures of chelates. For example, it was found[17] that trihydrates of individual $RE(A)_3$ are isomorphous for the series Pr–Tm and Y whereas $YbA_3 \cdot 3H_2O$ has a different structure. However, coprecipitation from aqueous solutions of $MA_3 \cdot 3H_2O$ and the Yb^{III} complex causes the latter to lose its integrity and form the trihydrate $YbA_3 \cdot 3H_2O$, isomorphous with the other RE $MA_3 \cdot 3H_2O$. It is interesting that addition to the coordination sphere of $RE(A)_3$ of a ligand more bulky than H_2O, for example, HAcim,[17] leads to simultaneous precipitation of crystals of the separate noniso-morphous $NdA_3 \cdot 2HAcim$ and $YbA_3 \cdot HAcim$ with insignificant mutual contamination (2% Nd in $YbA_3 \cdot HAcim$ and 7% Yb in $NdA_3 \cdot 2HAcim$).

This fact suggests that $YbA_3.3H_2O$ in the presence of other RE $MA_3 \cdot 3H_2O$ loses its integrity owing to rather strong intermolecular interaction, possibly with conversion of monomeric structures into catenated ones. The greater bulk of the additional ligand in $MA_3 \cdot HAcim$ than in $MA_3 \cdot 3H_2O$ prevents such a process. The monomeric structure is preserved. The chelate does not lose its integrity.

The mutual influence of components in a precipitated mixture was detected by us[42] during attempted group separation of mixtures of protonated RE EDTA complexes. If $HM(EDTA) \cdot xH_2O$ are prepared separately for RE of the Ce and Yb subgroups, the solubility differs ($\alpha_{calc}^{M'/M''} = 10-1000$). However, coprecipitation under the same conditions gives separation coefficients close to unity. Such a result is consistent with coordinative unsaturation in the RE^{III} mono(EDTA) complexes and polymerisation of the CS.[8]

These data indicate that the behaviour in the presence of other RE can be changed by varying the composition of the complexes and thereby changing the stability of the CS and the degree of coordinative saturation in the RE^{III} chelates. An excess of ligands ensures coordinative saturation and prevents formation of polymers. On the other hand, a deficit of ligands generates polymers, i.e. strong intermolecular interaction.

However, this does not mean that preparation of coordinatively saturated RE chelates guarantees highly effective separation of RE mixtures. Results of sublimation of $RE(A)_3$ adducts with additional ligands of various donor strength are plotted in Fig. 10. It is quite clear that formation of the stable adducts $MA_3 \cdot phen$[18] completely averages the properties of the RE chelates. Conversely, thermolysis of the less thermodynamically and thermally stable chelates $MA_3 \cdot HMPA$ [39] and $MA_3 \cdot HAcim$ [17] reveals certain differences in the sublimation behaviour of RE chelates. Therefore, stable coordinatively saturated compounds are suitable for practical use where the composition of the RE mixture must be preserved without change.[29] Less stable compounds that partially dissociate are promising in separation and purification processes of RE mixtures.

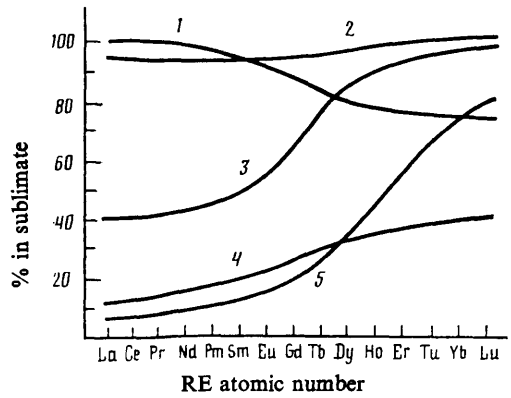

Figure 10. Sublimation of RE^{III} pivalates (*1*) and acetylacetonate adducts (*2–5*) (optimal temperature, 10^{-1} torr): $M(Piv)_3$ (*1*); $MA_3 \cdot phen$ (*2*); $MA_3 \cdot HMPA$ (*3*); $MA_3 \cdot 3H_2O$ (*4*); $MA_3 \cdot n HAcim$ (*5*).

VII. Reasons behind the variation in RE-chelate property changes across the series

One of the most interesting problems in RE chemistry is the variable nature of the change in structural and thermodynamic characteristics of their complexes with ligands of different structure and properties (for example, cf. Fig. 1). This has often been discussed in the literature.[1,2,7,8,10] At the start of this article we prove that the irregularity in the change of RE-chelate properties does not produce a W-effect. We confirm that the principal role in this is played by a ligand of one or another structure that can react flexibly as the ionic radius changes across the RE series. Owing to different flexibilities, each of the ligands has its own limit on permitted interatomic distances and angles for a given structure around the metal.

The greater the ligand geometry deviates from the optimal one in a given RE chelate, the less stable is the structure. In our opinion, it is obvious that the strain that accumulates in the chelate structure surfaces in the details of isostructural complexes across the RE series. When the flexibility of the complex reaches its limit as the RE^{III} radius changes, the chelate rearranges its structure. However, it would be incorrect to assume that the point where the slope changes on the curve of one or another property vs. RE ionic radius (cf. Figs. 1 and 5) corresponds to the place at which the 'old' structure can no longer exist and a new CS structure is formed. Numerous investigations carried out in our laboratory[8,9] and those of others[6,10] of the structure and properties of RE chelates confirm that the old, no longer stable structure continues to exist at one or another break in the RE series, although conditions are favourable for generation of a new structure.

Let us return to Fig. 1 and recall that the slower increase of K_s for RE complexes as the ionic radius decreases usually occurs due to

generation of steric hindrances that prevent a regular approach of the metal and ligand on moving across the RE series. That point for DTPA complexes occurs (cf. Fig. 1) near Sm. Apparently the RE^{III} and ligand in general do not come closer after the octadentate $DTPA^{5-}$ ligand forms a closed sphere around the RE^{III}. Therefore, the strength of the coulombic interaction between the RE^{III} and $DTPA^{5-}$ is practically constant in the series from Sm to Lu and K_s does not change. Ligands of lower denticity change their structural role several times in the RE series. This is reflected in the plots of the dependence of the Cs properties on RE^{III} ionic radius.

Unfortunately, data for isostructural chelates of the whole RE series or several of its members are usually lacking. These could indicate how the ligand strain in a chelate ring increases in an isostructural series and eventually leads to a CS structural change. Therefore, in our opinion, the data on polymorphic transformations in a series of anhydrous $RE(A)_3$ obtained by Trembovetskii[17] in our laboratory are interesting. It was found that anhydrous $RE(A)_3$ (volatile species[29]) synthesised by the reaction

$$MA_3 \cdot HAcim \xrightarrow{T^\circ C} MA_3 + HAcim$$

can exist in four modifications:

I. ScA_3—monomer, octahedron (X-ray structure).[17]

II. ErA_3, TmA_3—unknown structure.

III. YbA_3, LuA_3—monomer, trigonal prism (X-ray structure).[28]

IV. (Y, Tb, Dy, Ho, Er, Tm, Yb)A_3, oligomeric structure (NMR and IR spectroscopy).[17]

Only TmA_3 and YbA_3 are obtained simultaneously in two modifications by sublimation (metastable species are marked with an asterisk): TmA_3^{II}, TmA_3^{IV*}, YbA_3^{III}, YbA_3^{IV*}, respectively. On prolonged heating in vacuum, the following monotropic transitions occur: $TmA_3^{IV} \rightarrow TmA_3^{II}$, $YbA_3^{IV} \rightarrow YbA_3^{III}$. The species ErA_3^{IV} was also metastable. However, it is more stable than TmA_3^{IV*} and TbA_3^{IV*}. Only extended heating (for 23 h) produces the rearrangement $ErA_3^{IV} \rightarrow ErA_3^{II}$. Therefore, the type IV MA_3 structure is metastable for RE^{III} with a small radius. Apparently[17] this is due to steric hindrances to forming the oligomeric species $[MA_3]_n^{IV}$ that are generated by the shielding of the small ions of heavy RE^{III} by the chelate rings.

The metastability of ErA_3^{IV}, TmA_3^{IV} and YbA_3^{IV} is evident in the higher vapour pressure compared with the corresponding type II and III, which condense in the hotter zone of the sublimator. Direct proof of the metastability of (Er, Tm, Yb)A_3^{IV} was obtained by differential scanning calorimetry (DSC). It was demonstrated[17] that the monotropic transition $MA_3^{IV} \rightarrow MA_3^{II,III}$ is an exothermic process. It is clear from Fig. 11 that only the melting endotherm of the chelates is detected on heating all stable MA_3 from 80 to 200 °C. Metastable MA_3^* exhibit also a premelting endotherm and then an exotherm for the monotropic rearrangement (Ref. 17, pp. 99–105). Obviously the MA_3 molecules acquire the mobility (premelting) necessary to rearrange into the stable TmA_3^{II} and YbA_3^{III} near the melting points of the metastable modifications TmA_3^{IV} and YbA_3^{IV}.

The existence of metastable MA_3 for the heavy RE^{III} and their ability on heating to transform into more stable structures support the hypothesis that a new structure gradually replaces an old one on moving across the RE series. Therefore, it is as a rule impossible to find a single point in the RE series where one structure transforms into another. The regions of existence of two or more structures usually overlap.

We have already presented examples of the coexistence under actual experimental conditions of different compounds {for example, $TbA_3 \cdot HAcim$, $TbA_3 \cdot 2HAcim$ and $TbA_3 \cdot 4HAcim$[17] or $[Eu(H_2O)_3(EDTA)]^-$ and $[Eu(H_2O)_2(EDTA)]^-$ (Ref. 11, 26]}. This also supports the presence of a certain range in the RE series where the complex is changing from one structure to another.

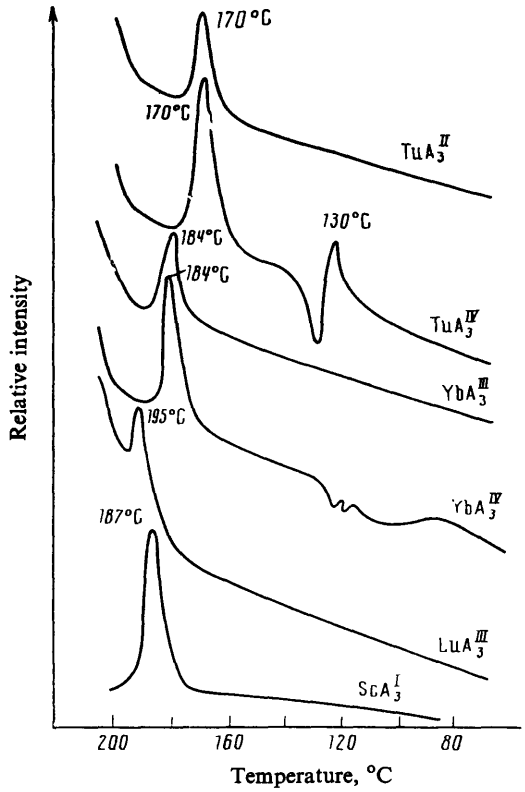

Figure 11. Scanning calorimetry of MA_3.[17]

VIII. Conclusion

The data presented demonstrate the complexity of RE^{III} complexes with organic polydentate ligands and reveal the unwarranted simplicity of the concept of a W-effect. Numerous facts indicate that the crystallographic instability of RE chelates due to small differences in ionic radii of neighbouring RE does not appear in any individual RE but in a more or less broad range of the RE series. Moreover, these ranges can considerably shift in the presence of several RE toward the light or heavy RE. This must be considered in developing industrial separations, purifications and applications of RE compounds since the RE^{III} characteristically lose their integrity in mixtures of coordinatively saturated and unsaturated compounds.

Mechanism of heterogeneous oxidation of acrolein to acrylic acid

T V Andrushkevich, G Ya Popova
Institute of Catalysis, Siberian Division of the Academy of Sciences of the USSR

ABSTRACT. A summary and analysis is given of results in the literature, and of our own results, of investigations into the mechanism of the heterogeneous oxidation of acrolein on oxide catalysts. The mechanism by which acrylic acid and oxides of carbon are formed from acrolein and oxygen is discussed. General principles for the interaction of acrolein with oxide catalysts are considered, and special attention is given to the nature of adsorption centres and the role of surface compounds of acrolein and acrylic acid, in the course of acrolein oxidation. On the basis of a proposed mechanism, some principles are formulated for the specific selection of catalysts for the selective oxidation of acrolein to acrylic acid.

The bibliography contains 74 references.

I. Introduction

The selective oxidation of organic compounds constitutes a large area of heterogeneous catalysis. In a series of monographs and reviews, dedicated to the problem of selective oxidation of hydrocarbons,[1–7] consideration is given to the mechanism of reaction, the nature of catalytic action, and the chemical composition of catalysts. Special attention is given to activation of the oxidised substances and oxygen, the stages of reaction, and the state of the active surface. However, the question of the mechanism of selective conversion of unsaturated aldehydes, in particular acrolein, has received insufficient attention.

Heterogeneous catalytic oxidation of acrolein to acrylic acid is carried out abroad on the industrial scale—it is the second stage in the process for the synthesis of acrylic acid from propylene.[8–12] The practical value of this reaction has stimulated, especially in recent years, a large number of scientific investigations into the mechanism and kinetics of the conversion, and also the selection of catalysts. In the present work we have attempted to summarise the literature data, and also our own data, on the mechanism of the heterogeneous oxidation of acrolein and to reveal some principles for the course of this reaction.

For the oxidation of acrolein to acrylic acid, multi-component oxide catalysts are used. The reaction proceeds by a consecutive-parallel scheme:

The principal products are acrylic acid and the oxides of carbon but, with some catalysts, acetic acid is also obtained. The small number of products and the difference in their acid-base properties from those of the starting material, make this reaction a convenient model for application of the ideas of Boreskov, on the intermediate chemical interaction of the catalyst with components of the reaction mixture, to the selection of catalysts. According to these ideas,[1] the direction of conversion of the intermediate surface compounds (SC), which are formed by interaction of the catalyst with the reaction mixture, is determined by the structure and bond energy of the SC.

Investigation of the reaction mechanism, i.e. defining the forms and energetic characteristics of the SC, the elucidation of their chemical bonding with the catalyst, and their directions of conversion into reaction products, is the most reliable route to an understanding of the nature of the catalytic action and to elaboration of the principles of catalyst selection. It is from precisely these points of view that we consider the available data for acrolein oxidation in the present work.

II. Mechanism by which oxygen takes part in the formation of acrylic acid and products of more deep-seated oxidation

Two mechanisms can be distinguished for the introduction of oxygen into the molecule which is undergoing oxidation: a step-wise mechanism, involving alternating oxidation and reduction of the catalyst by oxygen and the substances undergoing oxidation (the so-called oxidation-reduction mechanism) and a unified (associative) mechanism, with oxygen taking part in the gas phase.[13–16]

At the present time, for many selective conversion reactions of hydrocarbons, the oxidation-reduction mechanism for the participation of oxygen is well established.[17–20]

The question of whether one or other mechanism is in operation is determined by a direct comparison of the independently measured rates of catalysis and of catalyst reduction (or reoxidation), which are found in the stationary state. Equality of these rates indicates

the step-wise oxidation-reduction mechanism, but if the rate of catalysis exceeds the rate of reduction, participation by oxygen in the gas phase is indicated. It should be particularly emphasised that it is important to maintain the stationary state of the catalyst during the process of measurement, since it differs considerably from the initial state and depends on the composition of the reaction mixture.[21] With movement towards the stationary state, there are changes in the oxygen content and in the energy of its bonds with the catalyst, the oxidation state of the cations, and the concentration of the strongly-sorbed form of the substance being oxidised, all of which control change in the rates of the particular reactions and accordingly their selectivity. Hence, it follows that the extent of reduction should not change significantly during measurement of the rate of reduction for the stationary catalyst. If these conditions are not observed the rate of catalysis may exceed the rate of reduction, to an extent that increases as the heterogeneity of oxygen in the catalyst increases.

The overall situation is illustrated graphically in Fig. 1,[22,23] from which it can be seen that the stationary state (the plateau on all curves, Fig. 1*a*), differs considerably from the initial state with respect both to activity and selectivity. Comparison of Fig. 1, which shows movement of the catalyst towards the stationary state in the reaction mixture (0.2% C_3H_4O, 0.4% O_2, the remainder He), with Fig. 1*b*, which shows the changes observed in the reducing mixture (0.2%, 99.8% He), leads to the conclusion that the catalyst is reduced by the reaction mixture with the formation of strongly-bonded surface compounds. The latter follows from the absence of a carbon balance for the first pulses. Fig. 1*b* also indicates that even a few percent increase or decrease in the extent of reduction of the surface of the catalyst causes a sharp change in the rate of formation of acrylic acid and oxides of carbon. This picture is typical of catalysts for the oxidation of acrolein.[21] It is therefore necessary to maintain a constant surface composition of the catalyst during measurement of the rates of catalysis and reduction.

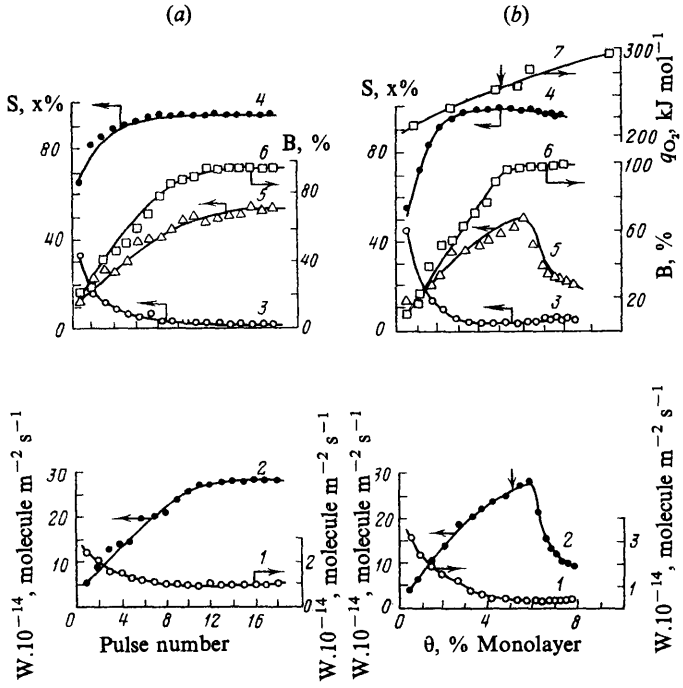

Figure 1. Dependence of the rate of formation of products of deep-seated oxidation (*1*), rate of formation of acrylic acid (*2*), selectivity for CO + CO_2 (*3*) and for $C_3H_4O_2$ (*4*), the extent of conversion of acrolein (*5*) and the carbon balance (*6*) on the impulse number of the reaction mixture (*a*) and on the extent of reduction of the surface (*b*); *7*, heat of adsorption of oxygen. Catalyst $V_2O_5.MoO_3/SiO_2$, T_r = 260 °C. Vertical arrows on Fig. 1*b* indicate the stationary state of reduction.

*Methods and conditions for the preparation of catalysts and their physico-chemical characteristics are described in Ref. 21.
**Samples obtained by different methods and differing in disperison.

Table 1 gives the rates of formation of acrylic acid and products of more deep-seated oxidation on vanadium- and cobalt-molybdenum catalysts.[21–24] As can be seen from Table 1, the rates of formation of acrylic acid for catalysis and reduction are close, indicating the oxidation-reduction mechanism for its formation. In the formation of products of more deep-seated oxidation, oxygen of the catalyst also participates; there is, however, a definite contribution by oxygen in the gas phase, as indicated in some cases by an appreciably higher rate of catalysis than the rate of reduction and the formation in the oxidising pulses of CO and CO_2. An analogous correlation of the rates of catalysis and reduction is also observed at other temperatures.

Table 2. Catalytic properties of tin–molybdenum catalysts for the oxidation of acrolein under conditions of catalysis and reduction.[27]

The oxidation-reduction mechanism for the formation of acrylic acid on a vanadium–molybdenum catalyst has also been confirmed by the relaxation method.[25] The oxidation-reduction mechanism for the formation of acrylic acid and the associative mechanism for the formation of CO and CO_2, were shown to occur on vanadium–molybdenum oxide catalysts, promoted by Na, Mn, Zn, and Cu.[26] This conclusion was drawn on the basis of kinetic data, which indicated that oxygen has different effects on the mild and deep-seated oxidation of acrolein and on the basis of the change in catalytic properties of samples by treatment of them with reaction mixtures with different oxygen contents.

An analogous conclusion that acrylic acid is formed exclusively by the oxidation-reduction mechanism, and that CO and CO_2 are formed primarily by the oxidation-reduction mechanism, follows from a comparison of conversion and selectivity under the conditions of catalysis and reduction, on promoted tin–molybdenum catalysts (Table 2).[27]

In the opinion of Yakubovich,[28] a step-wise oxidation-reduction mechanism is involved in the formation of acrylic acid and products of deep-seated oxidation, on molybdates of Cr, Cd, Ni, Ba, Co, Mn, Mg, Cu, Zn, Fe, and Ca.

The step-wise oxidation-reduction mechanism can therefore be considered to be established for the preparation of acrylic acid on catalysts of various composition. Products of deep-seated oxidation may be formed by the oxidation-reduction mechanism, with varying contributions from the associative mechanism.

The oxidation-reduction mechanism assumes that oxygen of the latice, generally considered[29–32] to be in the charged state, O^{2-}, takes part in the catalysis. Participation of lattice oxygen in the formation of acrylic acid and the oxides of carbon was demonstrated by isotopic labelling with ^{18}O in reduction experiments with acrolein and phosphomolybdic heteropoly acid.[33] The same is shown by other data.[34] On exposure of $K_3PMo_{12}O_{40}$ to acrolein vapour at catalyst temperatures of 150–300 °C, an ESR signal was observed, as a result of reduction to give an oxygen-deficient Keggin unit, with the gain of two electrons. From the IR spectrum it was established that the oxygen lost was a bridging oxygen atom (Mo–O–Mo). The same view that bridging oxygen participates in the formation of acrylic acid from acrolein, is held by other authors.[33]

It should be noted that the role of bridging or doubly bonded oxygen in the oxidative conversion of acrolein is scarcely discussed in the literature. But in the series of molybdates of elements of group II and period 4, it is those which contain molybdenyl bonds that are chosen.[28,35] The lowest selectivity for acrylic acid is observed for the molybdates of Ba, Ca, and Cd, which are exactly those for which molybdenyl doubly bonded oxygen (Mo=O) is absent.

In connection with the course of reaction by the oxidation-reduction mechanism and the participation of oxygen in the stage at which acrylic acid and products of deep-seated oxidation are formed, a question arises concerning the effect of the bond energy of oxygen to the catalyst on the direction of acrolein conversion and the rates of particular reactions.

For reaction by the two-stage oxidation-reduction scheme, a plot of the dependence of rate on the oxygen-catalyst bond energy shows a maximum, corresponding to optimum bond energy.[36] The ascending part of the curve corresponds to the case when reaction is limited to oxidation on the surface, and the descending part when its rate is determined by the loss of oxygen. A quantitative dependence of activity on bond energy has been found for a series of oxide catalysts in the oxidation of hydrogen, nitrous oxide, and ammonia, and also for the deep-seated oxidation of some hydrocarbons.[37] For all these reactions, the dependence of rate on the bond energy of oxygen with the catalyst follows a descending curve, i.e. the activity of the catalyst is lower, the higher the energy of its bonds with oxygen.

For complex reactions which include a series of parallel and consecutive stages, for each of which there is an optimum strength for the metal–oxygen bond (M–O), its influence on the activity of the catalyst, and especially on its selectivity, is not obvious.

Boreskov[38] has formulated the general requirements for catalyst selectivity: "The energy of the bond between oxygen and the surface of the catalyst must be sufficiently low to provide the required rate of oxidation of the starting material, but at the same time be sufficiently high to ensure that further oxidation of the useful products of incomplete oxidation does not occur".

This position is convincingly confirmed by the way in which selectivity depends on the extent of reduction of the surface, as found for many oxide catalysts in partial oxidation reactions of hydrocarbons.[21,39] Thus, for each catalyst, the selectivity for mild oxidation products invariably increases with the extent of oxygen removal but for products of deep-seated oxidation the selectivity falls. Also, since oxygen as a rule is not homogeneous on the catalysts investigated and its bond energy with the surface increases as a result of reduction, it is generally recognised at the present time that the absence of weakly-bonded oxygen is a requirement for

selectivity. In the oxidation of acrolein, the dependence of selectivity on the extent of reduction for each catalyst is analogous to that described for hydrocarbons and the same rule is applicable, requiring the absence of weakly-bonded oxygen for the course of reaction to be selective. However, the search for a correlation of selectivity and activity, with the bond energy of oxygen in a series of oxide catalysts, has led to complex and even contradictory results. Thus for simple oxides, the rate of formation of acrylic acid and products of deep-seated oxidation was seen to depend on the bond energy with oxygen (Fig. 2), but selectivity was not dependent on this parameter.[40] In contrast, it is established[28,35] that the energy of the M–O bond in a series of molybdates of Mg, Ni, Zn, Mn, Fe, Cr, Cu determines the selectivity precisely and does not influence activity. It should be noted that in the latter case the bond energy of oxygen was determined from the initial rate of reduction by samples of hydrogen. This rate undoubtedly characterises the initial state of the catalyst but since, as shown above, this differs considerably from the stationary state, it is doubtful whether the conclusions of the authors[28,35] can be considered to be sound.

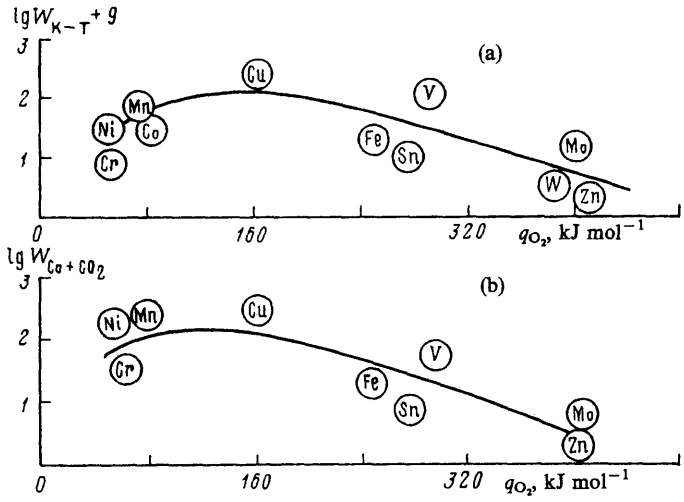

Figure 2. Dependence of the rate of oxidation of acrolein to the acid (*a*) and to Co + CO_2 (*b*) at 300 °C, on the bond energy of oxygen with the surface of oxide catalysts.[40]

An attempt has been made[28,35,40] to find a dependence of catalytic properties on the electronegativities of the cations, which determine the acidity of the catalyst. In the case of molybdates, the acidity of the catalyst does not influence selectivity but it affects the activation energy of the reaction.[28,35] For simple oxides, on the other hand, the selectivity depends on electronegativity.[40]

It is also very difficult to find any correlation of activity and selectivity with the bond energy of oxygen in the cases of V–Mo- and Co–Mo-catalysts. For these examples, as a measure of the bond energy, the heats of the adsorption (q) on the catalysts were determined in the stationary state, either by adsorption of oxygen on the previously reduced surface,[23,24,41] or *in situ*.[42]

As seen from Table 1, for the series of binary and promoted V–Mo-catalysts, only a fall in the rate of acrylic acid formation can be seen to occur with increase in the oxygen bond energy, whereas for the α- and β-modifications of $CoMoO_4$, which have identical values for the oxygen bond energy, the rates differ considerably. All catalysts in the stationary state are characterised by the presence of strongly-bonded oxygen (q_{O_2} = 225–335 kJ mol^{-1}) and with the exception of α-$CoMoO_4$ show high selectivity, but no quantitative correlation of selectivity with q_{O_2} is found.

The oxygen bond energy thus plays an important role in the oxidation of acrolein to acrylic acid but it is not possible to show a dependence of catalytic properties on q_{O_2} as the only parameter. In the oxidation of acrolein, and with the aim of selective oxidation,[36,38,43] it is therefore necessary to take account of other important factors, i.e. specific interaction of the substance being oxidised and the product of reaction with the catalyst surface.

III. Surface complexes of acrolein and acrylic acid and their role in the formation of reaction products

At the present time, basic information on the structure of surface compounds (SC) is obtained by the method of IR spectroscopy. Thermal desorption measurement has previously been widely used to provide evidence of the involvement of SC in the formation of reaction products but in recent years the use of spectroscopic methods *in situ*[44] has also made it possible to study the kinetics of conversion of the SC, and to measure the rate of the catalytic reaction simultaneously.

In Table 3, a summary is given of literature data on the structures of surface compounds of acrolein. Table 4 contains information on the catalysts on which these SC have been observed, together with their catalytic properties in the reaction of acrolein oxidation.

We have attempted on the basis of the literature data to reveal some general principles for the interaction of acrolein with oxide catalysts, giving special attention to the nature of the centre of adsorption and the role of surface complexes in the oxidation of acrolein. We do not dwell on the spectroscopic identification of SC, since this question is considered in detail elsewhere.[58,59]

Centres of adsorption on the surface of oxide catalysts may be protons, H^+ (Brønsted acid centres, BAC), coordinatively-unsaturated cations of transition metals (Lewis acid centres, LAC), and oxygen. These probably give rise to the diversity of the adsorbed forms of acrolein on the surface of oxide catalysts.

The presence of BAC on the catalyst surface, in the form of OH groups or delocalised protons, H^+, leads to the formation of a H-bonded complex with acrolein [SC (I), Table 3]. As a rule, this complex is weakly bonded with the surface and easily decomposes at room temperature as a result of brief pumping, or purging with helium, with the release of acrolein into the gas phase. It is therefore thought that hydrogen-bonded acrolein is not an intermediate in the process by which oxidation products are formed. However, in the presence of strong BAC, more strongly bonded SC (I) may be formed, which are able to participate in the reaction, and this also possibly occurs in the case of heteropoly acids (HPA) and heteropoly salts (HPS).[53]

The interaction of acrolein with aprotic centres (LAC) is accompanied by the formation of a coordinatively-bonded π-complex of acrolein (II), a surface acrylate (IV) and a carbonato-carboxylate complex (V). A number of workers have also observed the

formation of a σ-complex of acrolein (VI) at aprotic centres.[51,55] Surface ions of oxygen, O^{2-}, may also act as centres of adsorption, at which carbonyl-bonded acrolein (III) is stablised (Table 3).

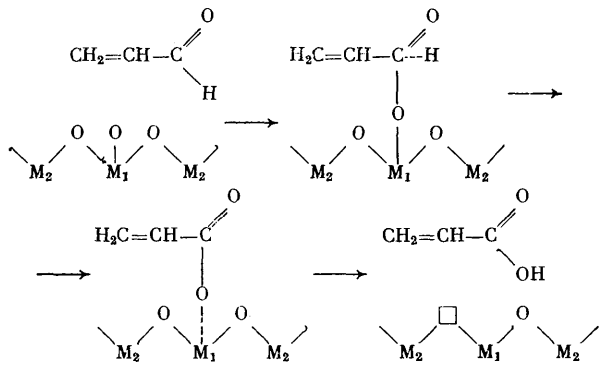
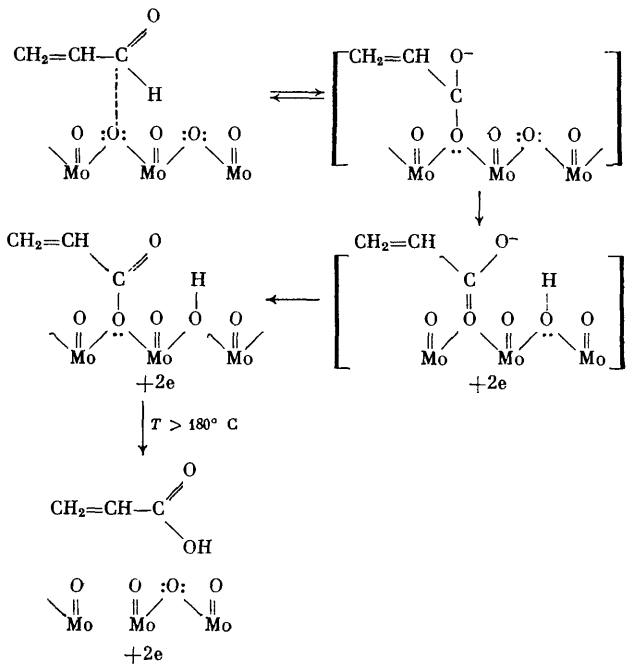
*For name of the corresponding SC see Table 3.

As seen from Table 4, it is very difficult to link any form of surface complex directly with the defined chemical composition of the catalyst and with its catalytic properties: one and the same SC, for example coordinatively-bonded acrolein or acrylate, may be observed on a catalyst for the selective, deep-seated, or destructive oxidation of acrolein. Furthermore, on some catalysts, in spite of the rather diverse composition of the products of oxidation, only one surface complex was identified.



There are various opinions on the role of SC in the course of reaction. Thus, it is assumed that coordinatively-bonded acrolein is an intermediate in the formation of acrylic acid and also of products of deep-seated and destructive oxidation:[50]

where $M_1 = Mo^{6+}(T_d)$, $Mo^{5+}(T_d)$; $M_2 = Mo^{6+}(O_h)$, $Co^{2+}(O_h)$. The initial interaction presumably occurs with Mo^{6+} in either tetrahedral (T_d) or octahedral (O_h) coordination, or with Mo^{5+}.



Coordinatively-bonded acrolein, for which the centres of adsorption on Co–Mo–V-oxide catalysts are Co^{2+} or Co^{3+} ions, in octahedral coordination, is thought[50] to be an intermediate in the formation of products of destructive oxidation. Certain authors believe[48–50] that surface acrylates [SC (IV)] are blind-alley forms for the adsorption of acrolein on Mo-containing oxide catalysts, whereas others[54] recognise acrylates as intermediate compounds both in the partial and the deep-seated oxidation of acrolein. The literature data allow a more definite judgement to be made on the direction of conversion for carbonyl-bonded acrolein (III) and surface carboxylates (V): almost all authors hold the opinion that (III) is an intermediate SC in the formation of acrylic acid, but (V) in the formation of deep-seated oxidation products.

The mechanism for the formation of acrylic acid through carbonyl-bonded acrolein is presented in the following scheme:[50]

$M_1=V^{5+}$, Mo^{6+} (*Oh*); $M_2=V^{4+}$

An analogous mechanism is also proposed for the oxidation of acrolein on phosphomolybdic heteropoly acids (HPA):[53]

This mechanism is confirmed by the results of an investigation into the adsorption of acrolein on $K_3PMo_{12}O_{40}$ by the methods of IR spectroscopy and ESR *in situ*.[53]

Another mechanism has been proposed[33] for the oxidation of acrolein and methacrolein on HPA, similar to the mechanism for the oxidation of aldehydes by chromic acid or permangante in solution.

The scatter of opinions on the mechanism of acrylic acid formation is due, first of all, to the use in most cases of insufficiently selective catalysts, with the result that several reaction products are obtained. Furthermore, the forms of adsorption were investigated under the conditions of pre-catalysis, when it is impossible to make a direct comparison between the rate for decomposition of the SC and the formation of reaction products. Such a comparison provides the most convincing evidence of the participation of one or other SC in the formation of reaction products.[60]

These conditions were observed in a study of the mechanism of acrolein oxidation by the method of IR spectroscopy *in situ* on a V–Mo–Si-oxide catalyst.[61,62] This catalyst possesses high selectivity: for acrolein conversions of less than 20%, acrylic acid is virtually the only reaction product, and with high conversions, further oxidation is also insignificant. Furthermore, good IR transmission of the sample made it possible to investigate the decomposition of surface compounds in the temperature range 25–350 °C, under the conditions of catalysis. Adsorption of acrolein on this catalyst led to the identification of a hydrogen-bonded SC (I), coordinatively-bonded SC(II), carbonyl-bonded SC (III), acrolein, and acrylate SC (IV).[58]

The hydrogen-bonded complex does not take part in the reaction; it is weakly bonded with the surface and is removed after brief pumping at room temperature. Prolonged standing at 25 °C, or increase of the temperature to 100 °C, converts the surface complex (II) into SC (III), an unsymmetrical acrylate which is converted into the symmetrical acrylate SC (IV) with further increase in temperature.

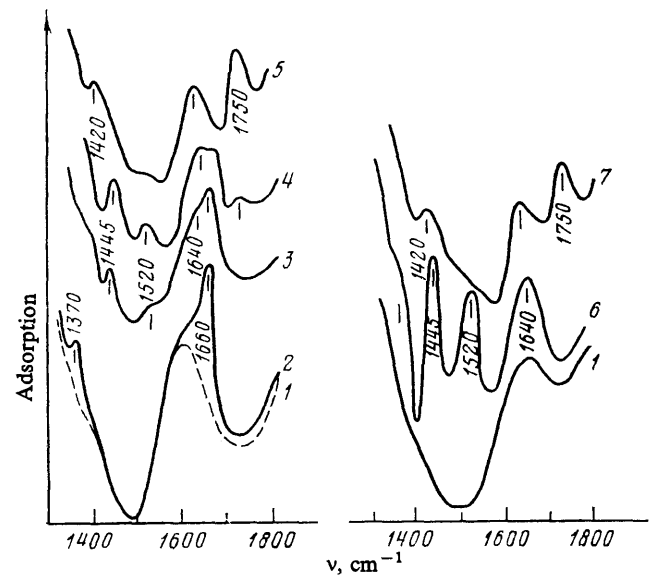


Figure 3. IR spectra of the initial V–Mo–Si–O-catalyst (*1*) and with passage of the reaction mixture containing 0.2 vol.% C_3H_4O; 0.4 vol.% O_2; 99.4 vol.% He at 25 (*2*), 125 (*3*), 160 (*4*), and 280°C (*5*) and after adsorption of acrylic acid at 80 °C (*6*) and 280 °C (*7*).[62]

Under the conditions of the catalytic reaction, with partial oxidation on a V–Mo–O-catalyst, in the temperature range 75–300 °C, the method of high-temperature IR spectroscopy *in situ* identified three surface complexes: coordinatively bonded acrolein (II), acrylate IV) and a molecular form of the adsorbed reaction product, acrylic acid (VII).[61,62]

Because of the high rate on conversion of SC (III) into (IV) under the conditions of reaction it is not possible to observe the change in concentration of SC (III).

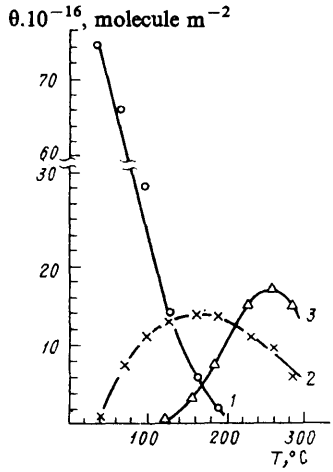

Figure 4. Dependence of the stationary concentrations of SC (II) (curve *1*), (IV) (*2*), and (VII) (*3*), on reaction temperature.[62]

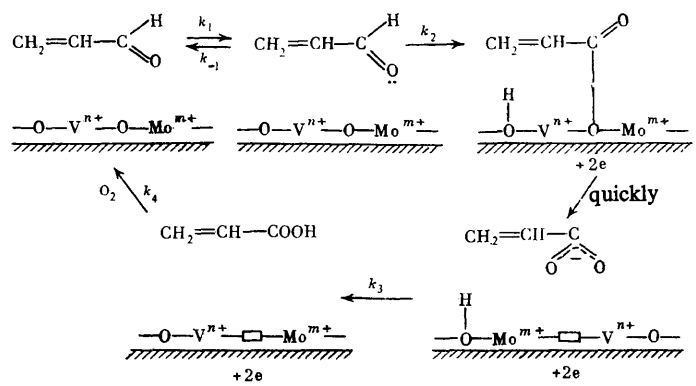
Fig. 3 presents the IR spectra which are obtained by passing the reaction mixture, containing acrolein, through a reaction cell with the V–Mo–Si–O-catalyst, and after the adsorption of acrylic acid. In the temperature range up to 100 °C, only the σ-complex of acrolein [SC (II)] is formed on the surface: $\nu_{C=O}$ = 1660, $\nu_{C=C}$ = 1620, δ_{C-H} = 1370 cm^{-1} (Fig. 3, spectrum *2*). With increase of the temperature to 160 °C, the intensities of the absorption bands at 1370 and 1660 cm^{-1} decrease and absorption bands appear, related to acrylate [SC (IV)]: $\nu_{C=C}$ = 1640, $\nu_{as\,COO^-}$ = 1520, $\nu_{s\,COO^-}$ = 1445 cm^{-1} (Fig. 3, spectra *3* and *4*). Further increase in temperature to 250 °C leads to a decrease in intensity of the absorption bands characteristic of acrylate, and to the appearance of absorption bands at 1420 and 1750 cm^{-1} (Fig. 3, spectrum *5*), which are caused, in our opinion, by re-adsorption on the SiO_2 carrier of acrylic acid, formed at the stage of disintegration of the acrylate. This was confirmed by the formation of SC (VII), by the adsorption of acrylic acid (Fig. 3, spectrum *7*). Acrylate is another surface compound, formed by the adsorption of acrylic acid on the V–Mo–Si–O-catalyst (Fig. 3, spectrum *6*).

The dependence of the stationary concentrations of surface complexes of acrolein on reaction temperature is given in Fig. 4.



In order to resolve the question of the participation of the observed SC in the course of reaction, a comparsion was made of the rates of formation of reaction products and the rates of destruction of the SC (Table 5). On the basis of such a comparison, it was concluded that acrylic acid is formed by decomposition of the surface acrylate. In the temperature range for which the re-adsorption of acrylic acid on SiO_2 [SC (VII)] is observed, the rate of formation of acrylic acid is close to the sum of the rates of decomposition of SC (IV) and SC (VII).

The active component of the investigated V–Mo–Si–O-catalyst is the chemical compound VMo_3O_{11}, in which vanadium is found in the V^{4+} state and the charge on Mo is close to 6+.[63] It has been shown[58] that the centres of stabilisation for SC (II) on this catalyst are the molybdenum ions, but the centres of stabilisation for acrylate are V^{4+} ions.

Table 5. Comparison of the rates of formation of products of desorption and decomposition of surface compounds.

285	–	5.0	14.0	–	0.5	5.2	7.2	0.30

The stated mechanism for the formation of acrylic acid on a V–Mo–Si–O-oxide catalyst can be presented as follows:

A study[62] has been made of the kinetics of conversion for the SC of acrolein, and a non-stationary kinetic model was proposed for the oxidation of acrolein to acrylic acid on a V–Mo–Si–O-catalyst, describing the change in concentration of the SC and the gaseous components of the reaction mixture with time in the temperature range 25–300 °C.

Values of rate constants for the separate stages are given below:

$$k_1 = 23\ atm^{-1}\cdot s^{-1};\ k_{-1} = 1.0\cdot 10^2 \exp\left(-\frac{10\,000}{RT}\right) s^{-1};$$

$$k_2 = 4.5\cdot 10^6 \exp\left(-\frac{19\,000}{RT}\right) s^{-1};$$

$$k_3 = 2.1\cdot 10^3 \exp\left(-\frac{13\,000}{RT}\right) s^{-1};$$

$$k_4 = 1.8\cdot 10^{-14} \exp\left(-\frac{8000}{RT}\right) m^2.molecule.atm^{-1}s^{-1}.$$

Thus, the first stage of reaction in the oxidation of acrolein on a V–Mo–Si–O-catalyst is a donor-acceptor type interaction, with transfer of an electron pair to a vacant orbital of the highly charged and electronegative Mo^{n+} cation. The formation of the σ-complex (II) is accompanied by activation of the C–H bond which undergoes heterolytic fission in the presence, on the surface, of nucleophilic oxygen, with formation of a fragment $(CH_2=CH-C=O)^-$ possessing a formal charge $Q = -1$. This fragment is a good electron donor and restores the catalyst by sharing the electrons of the carbonyl group, with consequent formation of an electrophilic species $(CH_2=CH-C=O)^+$. Calculation shows that the positive charge is almost totally localised on the carbon of the carbonyl group ($Q = 0.8$),[58] so that the species is highly reactive to nucleophilic attack by oxygen of the catalyst, leading to the formation of SC (III). The change from SC (III) to (IV), a symmetrical acrylate with equivalent oxygen atoms, does not apparently present energetic difficulties and occurs rapidly. Decomposition of the surface acrylate (IV), resulting in the formation of acrylic acid, is the slowest step. This mechanism is also confirmed by experimental data, obtained for the stationary state in the course of the reaction. The corresponding kinetic equation:[64]

$$W_{aa} = k_1 C_{acr}/(1 + k_2 C_{acr} + k_3 C_{acr}/C_{O_2}) ,$$

where C_{acr} and C_{O_2} are the concentrations of acrolein and oxygen respectively, describe the experimental data well over a wide range of temperatures and concentrations.

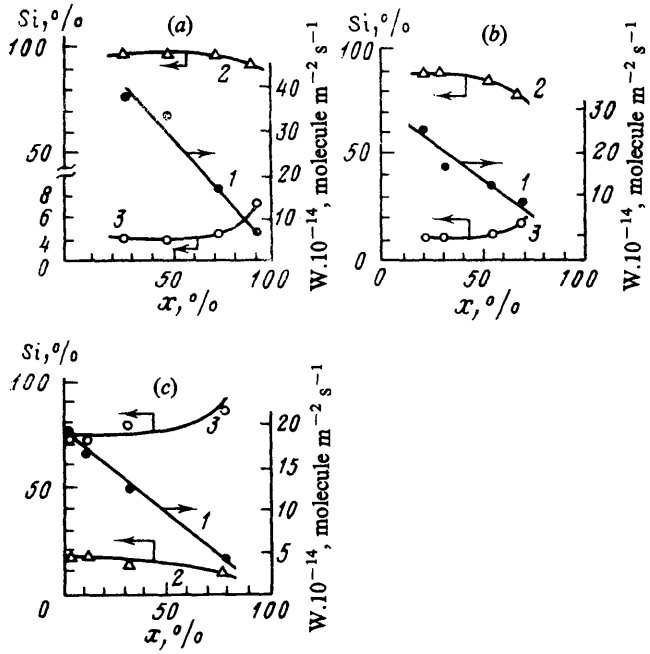

Figure 5. Dependence of catalyst activity (*1*), and its selectivity for C_3H_4O (*2*) and CO + CO_2 (*3*), on the extent of conversion of acrolein at 260 °C, on: *a*, $V_2O_5.3MoO_3/SiO_2$; *b*, β-$CoMoO_4$; *c*, α-$CoMoO_4$.[24] Composition of the reaction mixture: 0.2 vol.% C_3H_4O; 0.4 vol.% O_2; 99.4 vol.% He.

IV. Bond energies of intermediate compounds and the direction of acrolein conversion

The formation of coordinatively-bonded acrolein [SC (II)], appears to be the general form of its interaction with oxide catalysts, on the surface of which there are aprotic centres. It is probably the precursor of the other oxidised SC, namely SC (III), (IV), and (V). However, for selective oxidation of acrolein to acrylic acid, it is insufficient that a σ-complex of acrolein should be formed, followed by its oxidation to a surface acrylate by oxygen of the catalyst. As seen in Table 4, surface compounds of types (II), (III), and (IV) may be formed on inactive and unselective catalysts. The direction of conversion of the surface compounds is influenced more decisively by the strengths of their bonds with the centres of stabilisation and the reactivity of oxygen of the catalyst.

The influence of the bond strengths of the surface complexes of acrolein and its oxidation product, acrylic acid, on the direction of the reaction is confirmed graphically, by comparison of the catalytic properties of vanadium– and cobalt–molybdenum catalysts, and also by their thermal desorption data.[58]

Fig. 5 shows the dependence of the selectivity of these catalysts for acrylic acid and products of deep-seated oxidation, on the conversion of acrolein. The reactions in all cases are described by the consecutive-parallel scheme (Scheme 1) and by first order equations, so that it is possible to express the initial selectivity (S^0) and the constant of (further) oxidation (*b*) as follows:

$$S^0_{aa} = \frac{k_1}{k_2 + k_1} , \quad S^0_{CO+CO_2} = \frac{k_2}{k_1 + k_2} , \quad b = \frac{k_3}{k_1 + k_2}$$

Table 6. Catalytic properties of various catalysts for the oxidation of acrolein (composition of the reaction mixture, vol.%: C_3H_4O—0.2%, O_2—0.4%, He—99.4%, reaction temperature—260 °C.

*Acetic acid present in the reaction products.
**Reaction temperature 300 °C.

In Table 6, the values of S^0_{aa} and *b* are given for the catalysts under investigation. In Fig. 6, the results of chromatographic analysis are shown for the products of thermal desorption for acrolein (Fig. 6*a*) and acrylic acid (Fig. 6*b*) on the V–Mo–Si–O-catalyst.[24] In both cases, in the temperature range 70–350 °C, the

desorption of acrolein and acrylic acid is not accompanied by destruction of the carbon skeleton. In the 350–500 °C region the products of thermal desorption are CO and CO_2. On α- and β-$CoMoO_4$, the thermal desorption curves have a similar appearance, yet acetaldehyde and acetic acid are also present among the products of decomposition.[24]

In Fig. 7*a*, the initial selectivities for acrylic acid and for products of deep-seated oxidation are compared with the relative amounts of the weakly sorbed (T_{des} = 70–350 °C) and strongly sorbed (T_{des} = 350–500 °C) acrolein (θ^{acr}_{weakly} and $\theta^{acr}_{strongly}$ respectively), and Fig. 7*b* shows the dependence of the further oxidation constant (*b*) on the relative amount of strongly sorbed (T_{des} = 350–500 °C) acrylic acid. The correlation of these values clearly indicates the participation of a weakly bonded form of acrolein in the formation of acrylic acid, but strongly bonded forms of acrolein and acrylic acid in the formation of products of destructive oxidation by parallel and consecutive pathways. The proportions of these forms also determine the selectivity. It should be noted that revelation of such a clear correlation was favoured by the purely fortuitous closeness of the bond energies for oxygen on these catalysts (see Table 1).

From Figs. 4 and 6*a*, it follows that the weakly bonded forms of acrolein are coordinatively-bonded acrolein [SC (II)] and acrylate [SC (IV)]. The structure of strongly bonded acrolein on the V–Mo–Si–O-catalyst could not be identified by IR spectroscopy, the amount being very small because of the high selectivity of the catalyst.

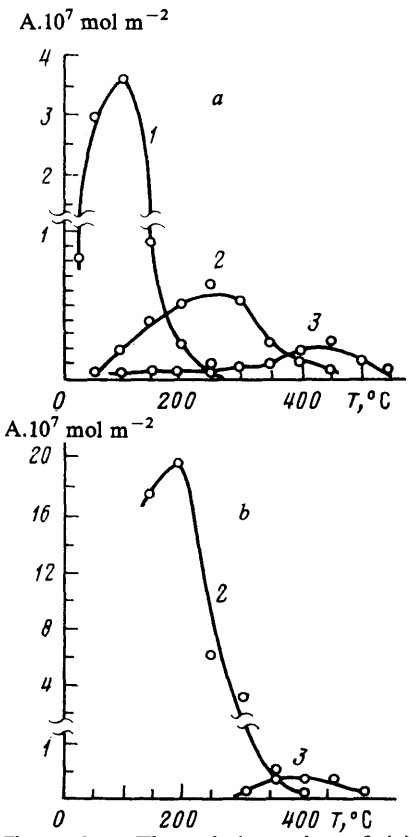

Figure 6. Thermal desorption of (*a*) acrolein and (*b*) acrylic acid with V–Mo–Si–O-catalyst.[24] *1*, acrolein; *2*, acrylic acid; *3*, CO + CO_2.[24]

Surface compounds of the acrylate type are formed by the adsorption of acrylic acid on both selective and non-selective catalysts for the oxidation of acrolein (see Table 4). It has been shown[65] that the properties of the surface acrylates, in particular the strength of the bond with the surface, can be judged by the temperature of decomposition by thermal desorption, and that the composition of the products of desorption on various catalysts differ considerably. Weakly bonded arylates that are formed for example, by the adsorption of acrylic acid on the V–Mo–O-catalyst and on MoO_3, are decomposed by an increase in temperature to 200 °C, with release of acrylic acid into the gas phase. Acrylate, formed on MgO, is strongly bonded with the surface and undergoes practically no change up to 400 °C. Further increase in the temperature leads to its destructive oxidation to give surface carboxylate, containing no C=C bond [SC (V)], and further decomposition occurs above 500 °C with release into the gas phase of acetic acid, acetaldehyde, and oxides of carbon. On CuO, a typical catalyst for deep-seated oxidation, further oxidation of the surface acrylates occurs at only 200 °C to give carbonato-carboxylate complexes, which decompose at 250 °C with the release into the gas phase of oxides of carbon. The low temperature at which further oxidation of SC (IV) occurs in this case is due, apparently, to the presence of weakly bonded oxygen in CuO.

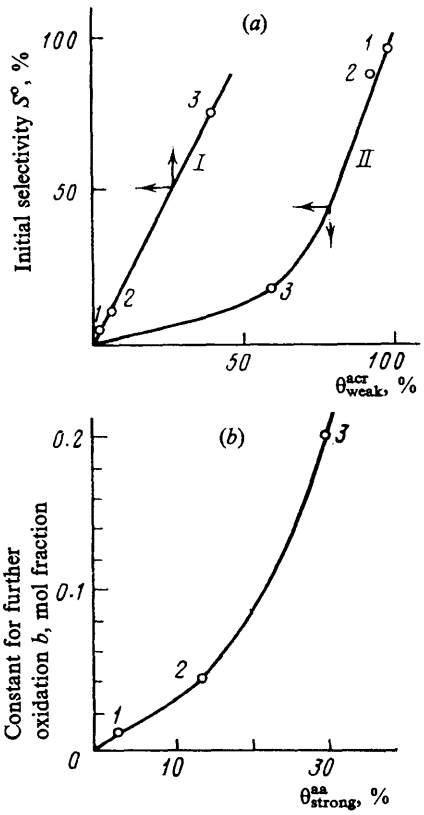

Figure 7. Dependence of initial selectivities for strongly adsorbed acrolein (curve *1*), and for acrylic acid (curve *2a*) in relation to weakly adsorbed acrolein; and the dependence of the constant for further oxidation on the relative quantity of strongly adsorbed acrylic acid (*b*). Catalysts used: *1*, $V_2O_5.9MoO_3/SiO_2$; *2*, β-$CoMoO_4$; *3*, α-$CoMoO_4$.

Thus, from all accounts, it follows that the bond strength of the intermediate surface compounds determines the direction of conversion of acrolein, but the simultaneous requirement of high activity and selectivity dictates that the SC should have an optimum bond energy. Evidently, the higher the bond energy of oxygen and the lower the bond strength of the SC of the adsorbed acrolein, the more selective the catalyst but the lower is its activity.

In Table 7 the heats of adsorption are given for acrolein and acrylic acid on promoted V–Mo–O-catalysts, measured *in situ* by a calorimetric method[66] together with the heats of adsorption for oxygen.[42]

Table 7. Catalytic properties of modified V–Mo-oxide samples, supported on SiO_2 (70 mass% SiO_2).

Composition of active material	$W.10^5$, mol m^2 h^{-1} for $x=70\%$	S^o_{aa}, %	Further oxidation constant, b mol fraction	Heat of adsorption, q kJ mol^{-1}		
				C_3H_4O [66]	$C_3H_4O_2$ [66]	O_2 [42]
$V_2O_4 \cdot 9MoO_3$	10.6	96.5	0.011	84	75	255
$V_2O_4 \cdot 9MoO_3 \cdot 1CuO$	12.3	98.3	0.005	84	75	226
$V_2O_4 \cdot 9MoO_3 \cdot 0.2Cs_2O$	0.3	97.5	0.058	84	96	326
$V_2O_4 \cdot 9MoO_3 \cdot 0.06P_2O_5$	6.3	88.0	0.014	117	75	335
$0.5 \cdot V_2O_4 \cdot 9MoO_3 \cdot 0.5SiO_2$	10.6	97.0	0.007	–	75	274

As seen from Table 7, the most active and selective catalysts (the binary and copper-promoted V–Mo–O-catalyst) are characterised by heats of adsorption $q_{O_2} = 230-250$, $q_{acr} = 75$, and $q_{acr} = 84$ kJ mol^{-1}. These values are apparently close to the optimum.

The influence of the energetic characteristics of the intermediate compounds on the rate of formation of acrylic acid on V–Mo-catalysts can be seen from Fig. 8. The slow stage of the oxidation reaction of acrolein is desorption of acrylic acid.[62,64] In accordance with the Brønsted–Polanyi equation, the rate of formation of acrylic acid is described by the following expression:

$$W_{aa} = A \exp \frac{-\alpha q_{aa} - \beta q_{O_2}}{RT} [V^{4+}],$$

where $A = k_0 \exp(-E_0/RT)$. The applicability of this equation is confirmed by Fig. 8. A coincidence is observed between the experimentally found number of V^{4+} centres for the stabilisation of acrylate and that calculated from the given equation, with $\beta = 0.07$ and $\alpha = 0.4$. These values for the coefficients α and β correspond to the limiting stage of the reaction; they allow a judgement to be made about the relationship of oxidation-reduction (β) and acid-base (α) properties of the catalyst.

From the mechanism of reaction we turn to a consideration of the principles underlying the choice of catalyst for the oxidation of acrolein to acrylic acid. The basic factor which determines the direction of reaction is the energy of the bond with the SC. Acrolein and the product of its oxidation, acrylic acid, differ in acidic properties and it is therefore possible to influence the strengths of the bonds of the intermediate compounds by regulation of the acid-base properties of the catalyst. For a selective course of reaction, optimum acidity is required: on the one hand, it is necessary to ensure the possible adsorption of acrolein as an organic base with a high velocity of conversion but on the other, to prevent the re-adsorption of acrylic acid to avoid further oxidation. Increase in the acidity above the optimum, gives rise to the formation of a strongly bonded SC of acrolein and leads to an increase in the proportion of products of deep-seated oxidation which are formed by a parallel route, lowering the initial selectivity for acrylic acid. A multistage mechanism for the formation of acrylic acid assumes the existence, in selective catalysts, of a number of centres, differing in their donor–acceptor properties and in their ability to form weakly bonded σ-complexes of acrolein (II) and acrylate (IV).

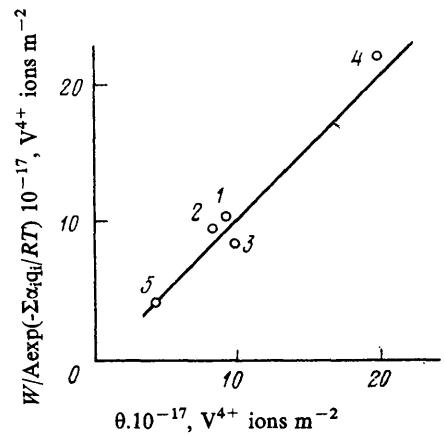

Figure 8. Comparison of the calculated and experimental numbers of V^{4+} centres. Catalysts used: *1*, $V_2O_4.9MoO_3/SiO_2$; *2*, $V_2O_4.9MoO_3.1CuO/SiO_2$; *3*, $0.5V_2O_4.9MoO_3.0.5TiO_2/SiO_2$; *4*, $V_2O_4.9MoO_3.0.06P_2O_5/SiO_2$; *5*, $V_2O_4.9MoO_3.0.2Cs_2O/SiO_2$.

Since acrylate, i.e. the surface complex from which acrylic acid is formed spontaneously, is a salt-like compound, the optimum composition of the catalyst must include elements such as V^{4+}, Mo^{4+}, or Ti^{4+}, which possess amphoteric properties in the oxidation state that is realised under reaction conditions. At the same time, the first stage, the formation of a σ-complex of acrolein, [SC (II)], requires the catalyst to contain highly electronegative ions of the Mo^{6+} type. Nevertheless, an important requirement for catalyst selectivity is the presence of oxygen with a sufficiently high energy bond. Although oxygen participates in all stages of conversion of the surface compounds, its energetic characteristics in the first place affect the stage at which the σ-complex undergoes conversion, since it is precisely on this that the subsequent structure of the SC depends: oxygen, possessing high reactivity, forms surface complexes with high oxygen content, thus promoting the destruction of adsorbed molecules and, consequently, their non-selective conversion. The sum total of these conditions also determines the influence of the acid-base and oxidation-reduction properties. The catalyst which best satisfies these requirements is the V–Mo–O-catalyst, which has energetic characteristics (q_{O_2}, q_{aa}, q_{acr}) that are apparently near to the optimum.

Knowledge of the detailed reaction mechanism allows the catalytic properties of the sample to be changed by the introduction of appropriate additives. Thus, the V–Mo–O-catalyst, on which the limiting stage of reaction is the conversion of the surface acrylate, can be improved by the introduction of a weakly basic additive such as Cu.[67] The introduction of strongly basic additives (Cs, Na, K) or an acidic additive, P, causes a sharp deterioration in the properties.[68] On the contrary, for the V–Sb–O-catalyst, the surface of which does not contain highly electronegative ions, the limiting stage is the formation of coordinatively-bonded acrolein [SC (II)].[69] This catalyst is improved significantly by the introduction of acidic additives, for example phosphorus:[70] its activity is increased and its selectivity is also increased, on account of the suppression of further oxidation of the acrylic acid.

The optimum combination of acid-base and oxidation-reduction properties may only be achieved by the use of a multi-component catalyst. This is confirmed by the low efficiency of individual oxides for the formation of acrylic acid.[40] Molybdates of group II metals of the periodic system[28] are also far from being optimum catalysts: with the reaction proceeding by the mechanism described above, acrylate must be stabilised on these compounds at highly basic ions, i.e. it must be strongly bonded with the surface; this, however, favours an increase in the temperature of the catalyst and destruction of the acrylate, as observed experimentally.

It should be noted that the views described here indicate only the general direction of the search for the chemical composition of a catalyst. In each particular case it is necessary to take account of the structure, coordination sphere, valency state, and proportions of the chemical elements in the catalyst, since these are all reflected in the oxidation-reduction and acid-base properties which determine the structure and strength of the various surface compounds. The examples of α- and β-$CoMoO_4$ are object lessons in this respect. These two polymorphous modifications, differing in the coordination of the Mo, and in the presence of Co^{3+} ions in α-$CoMoO_4$ but not in β-$CoMoO_4$, possess different catalytic properties in the reaction of acrolein oxidation:[24] α-$CoMoO_4$ in practice is a catalyst for the deep-seated oxidation of acrolein, but β-$CoMoO_4$ is a selective catalyst.

In conclusion, it should be noted that the oxidation of acrolein to acrylic acid is not an exception in the large number of reactions of partial oxidation. The role of the acid-base and oxidation-reduction properties of the catalyst in such reactions was shown for the first time in an earlier publication[71] and later by other workers.[72,73] At the present time, it is suggested that reactions and catalysts should be classified by their type of acid-base and oxidation-reduction activity.[74]

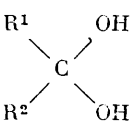
gem-Polyols — a unique class of compound

Yu M Shapiro
The Polytechnic Institute, Krasnodar

ABSTRACT. The formation and conversions of *gem*-polyols have been examined together with their chemical and physical properties.



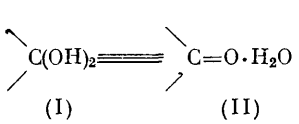
The bibliography contains 123 references.

Contents

I. Introduction 1035
II. The reality of 'hypothetical' compounds 1036
III. *gem*-Polyols as members of the *gem*-polyhydroxide family 1046

I. Introduction

Polyalcohols with a geminal structure (I), i.e. *gem*-polyols, are an ill-defined class of organic compound.



(I)

where R^1 and R^2 = OH or another group of atoms or a specific atom.

In his time, A M Butlerov was puzzled by the fact that "...methyl[ene] glycol was not only unknown but that its existence seemed unlikely: it was not obtained in reactions where its formation might have been anticipated. At present, theory cannot adequately explain this phenomenon..."[1] Although, today, a large number of stable compounds with structure (I) are known, including methylene glycol as the primary form of formaldehyde in aqueous solution,[2] *gem*-polyols more usually play a secondary, incidental role in chemistry as the hydrated form of carbonyl compounds. In the *Universal Decimal Classification* of recent years,[3] it is stated under the entry 547.421.2 that structure (I) represents 'Hypothetical geminal glycols'. In a standard text-book,[4] it is said that on formation of *gem*-diols they are immediately converted into the corresponding aldehyde or ketone.

The fact that the *gem*-polyol structure (I) has not been recognised is evident in nomenclature and formulae which chemists have adopted. Even specialists in this field have referred to such as hydrated carbonyl compounds with structure (II), which clearly is far from a true representation.

(I) (II)

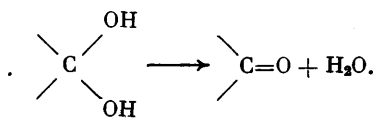
Thus, doubt on the authenticity of (I) has existed since the early days of organic chemistry and remains today. This is, in part, because of their unique properties, which are quite different from those of simple alcohols, and, in part, because little research has been carried out in this field. The chemistry of their formation and subsequent conversions cannot be generalised. Rather, it is dependent on the particular structure of the molecule, the medium, and other factors. Specific information on the nature of *gem*-polyols is still needed in all areas.

In spite of the fact that new data on the properties of (I) are currently being reported in the literature, reviews on this subject are sparse. From the period 1966 to date, the key cited reference is still that on the reversible hydration of aliphatic aldehydes[5] (Russian version see Ref. 6). Monographs have been devoted to the important analytical reagent, ninhydrin, and its analogues, which are stable *gem*-diols.[7,8] Furans with a *gem*-polyol group, and related compounds, have been discussed as part of a review.[9]

Derivatives of (I), especially acetals[10] and orthoesters,[11,12] have been reviewed much more. However, such compounds, which today are readily available, are not normally prepared from *gem*-polyols and therefore have no direct bearing on the theme of the present review.

The study of the chemistry of *gem*-polyols is important for the understanding of a whole range of reactions, certain of which pertain to quite unrelated aspects of organic and inorganic chemistry. These include the hydration of carbonyl-containing compounds and oxides, the interconversion of pyro-, meta- and ortho-acids, the hydrolysis of esters, the condensation of carbonyl-containing compounds, catalysis and isotopic exchange, hydride transfer and other redox conversions of polyhydroxides, etc. Significantly, *gem*-polyols or their derivatives are invariably cited as intermediates in any mechanistic analysis of the above reactions.[13–20] However, in most instances, the representation of *gem*-polyol intermediates is purely symbolic and does not imply the existence of molecules of structure (I) as real compounds.

The present review is devoted strictly to *gem*-polyols and reactions which are specific to them. From the accumulated experimental data, it has been possible to distinguish and consider (I) as a distinct class quite apart from carbonyl-containing compounds.



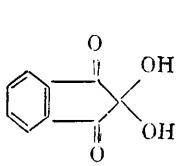
For convenience, *gem*-polyols can be subdivided into three groups: 1) stable, normally crystalline compounds; 2) less stable compounds which exist only in solution; and 3) very unstable intermediates. The first two groups refer essentially to *gem*-diols as a distinct class, while the third embraces all forms of *gem*-polyol. In certain instances, the salt form is more stable than the neutral molecule.

A whole range of modern techniques has been utilised for structural analysis of (I) and for the elucidation of the nature of the species in solution. A number of these have been discussed before.[5,6] They include UV-, IR-, and NMR-spectroscopy, circular dichroism,

polarograph, isotopic exchange, and chemical analysis. Each of these methods has its limitations, so that alternative analyses are always required. Thus, polarographic data on the hydration of aldehydes has, in certain instances, been disputed because of the inherent speed of the methodology, while others argue the obvious benefits of being able to regulate the pH and voltage accurately.[21]

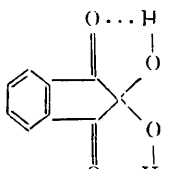
II. The reality of 'hypothetical' compounds

Doubt on the authenticity of geminal polyols is basically groundless. In reality, these compounds are in equilibrium with the corresponding carbonyl compounds and water:



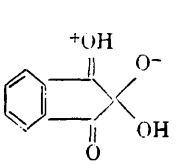
Normally, dehydration is facile, although in certain instances difficulty has been encountered. References in the literature to stable *gem*-diols first appeared in 1910 with reports on the synthesis of ninhydrin,[7] in which one of its three keto groups is hydrated with ease. Today, the list of such compounds is significant, and many authors have studied the factors which control the equilibrium between the *gem*-polyol (*gem*-diol in most instances) and carbonyl form. One elementary fact has been established: electron-accepting groups adjacent to the *gem*-diol group tend to stabilise, and electron-donating groups destabilise, the function. However, this is a complex issue since many other factors have to be considered. The requirements of listing all known *gem*-polyols (I) is clear, as also is the examination of their behaviour in different media and the results of structural analyses, etc.

1. Crystalline *gem*-diols



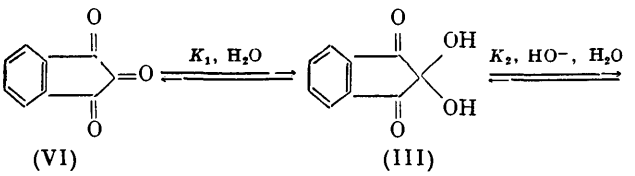
For convenience, these compounds have been subdivided into the following categories: 1) products obtained by hydration of aliphatic α-halogeno-ketones and -aldehydes, 2) aldehydo- or keto-hydrates of a number of α-aldehydo- and α-keto-acids, polyketones and α-keto-aldehydes, 3) hydrates of pyridylcarbonyl compounds, 4) conjugated cyclic ketone hydrates, and 5) *gem*-diols stabilised by intramolecular hydrogen bonds. The latter is evidently a factor to consider with all *gem*-diols.

a) Carbonyl-containing dihydroxymethylenes

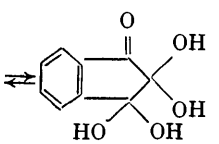


Ninhydrin is a well-known reagent for detection of amino groups (especially amino-acids). It exists in the very stable *gem*-diol form (III), both in the crystalline state and in solution.[7,8] Rukhman[7] was first to study the stability of (III), and proposed that either hydrogen bonding, as in (IV), was responsible or that stabilisation was gained by the formation of a zwitter ion (V).

(III)

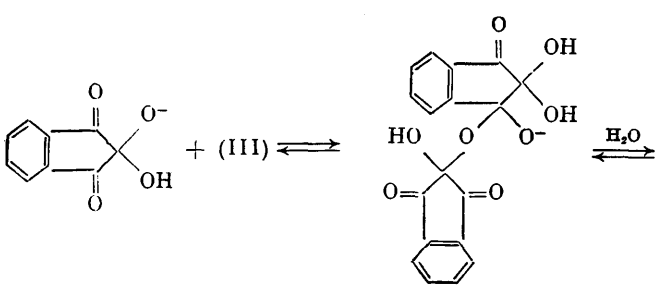


(IV)



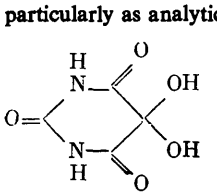
(V)

The formation of (III) proceeds readily even on dissolving 1,2,3-indantrione (VI) in water. A second carbonyl group is hydrated under base catalysis.[22] It is proposed that the anionic form (VIII) of ninhydrin is involved in the formation of the dihydration (VII). The relative amounts of the three forms (III, VI and VII) have been calculated as follows:

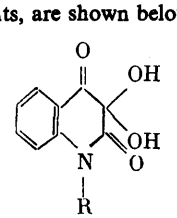


$$K_1 = \frac{[III]}{[VI]} = 2.9 \cdot 10^3; \quad K_2 = \frac{[VII]}{[III]} = 0{,}31 \pm 0.04;$$

(VI) (III)

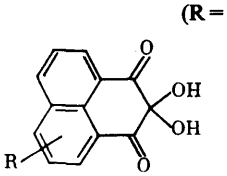


(VII)



(VIII)

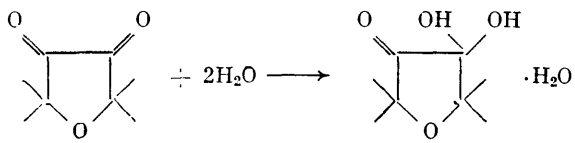
(VII) + (VIII).



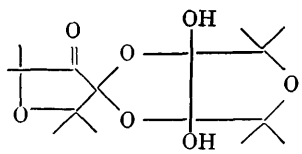
The 'ninhydrin phenomenon' pioneered research into the synthesis of other cyclic polyketones capable of forming *gem*-diols on hydration.[8] Certain of these compounds which have proved useful, particularly as analytical reagents, are shown below.

Alloxan

Quinisatin and its derivatives (R = H, CH_3, Ph)



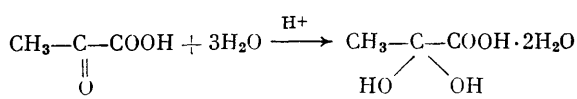
Perinaphthindantrione hydrate and its nitro derivative (R = H, NO_2)



Multi-step syntheses of oxirene [sic (Ed. of Translation)] and phenalene *gem*-diols have been reported.[23] The hydration of cyclic 1,2,3-tricarbonyl compounds has also been studied[24,25] and reviewed over a long period of time in monographs.[7,8]

Dehydration normally requires harsh conditions: distillation *in vacuo* or heating in oleum in methylene chloride.[25] For reactions proceeding via dehydration of *gem*-diols, syntheses have also been carried out in concentrated sulphuric acid.

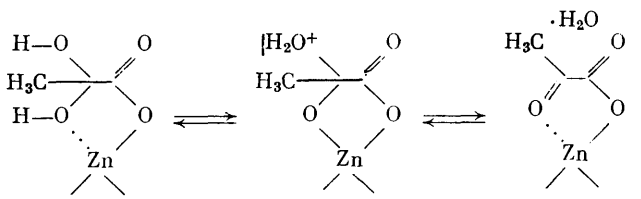
Studies of the hydrated forms of 2,2,5,5-tetramethylfuran-3(2*H*)-4(5*H*)-dione have shown that two structures exist in the crystalline state.[26,27] One incorporates 2 molecules of water for each molecule of the diketone and the other 0.5 molecules of water. In the 'dihydrate' structure, one of the two molecules of water is involved with *gem*-diol formation while the other is associated as a crystal hydrate:



The authors propose a hydrated dimeric structure for the other crystalline form:

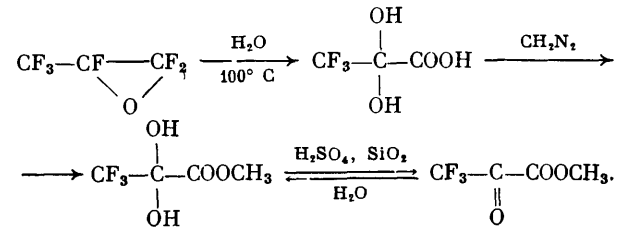
Significantly, the non-hydrated form of this diketone is coloured, while the hydrate is colourless. This is unusual and thought to be a consequence of strain in the non-hydrated furan skeleton and the presence of hyperconjugation with the keto-groups. Neither is possible in the *gem*-diol form.

There is reference to a large number of acyclic analogues, formed by hydration of ketones or aldehydes functionalised in the α-position by the carbonyl group of another aldehyde or ketone function or of a carboxyl function or derivatives thereof (e. g. an ester group).



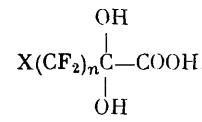
Much research has been devoted to pyruvic acid since this is important biologically. It has been shown that in the crystalline form the hydrate incorporates three molecules, only one being involved with *gem*-diol formation.[28] This hydration is catalysed by protic acids:

For the hydration of pyruvic acid by metalloenzyme complexes [sic (Ed. of Translation)],[29] the order of catalytic activity is as follows:

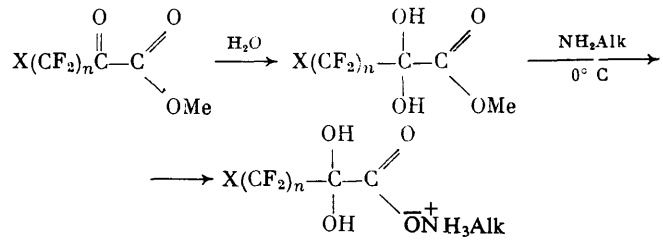


$$Cu^{2+}>Zn^{2+}>Ni^{2+}>Co^{2+}>Cd^{2+}>Mn^{2+}\ .$$

This order is in keeping with the ability of the metal to form a chelate complex with pyruvic acid. For the zinc-catalysed hydration in the presence of carbonic anhydrase, the following scheme has been proposed:



The hydration of pyruvic acid esters has also been reported.[30]



Hydration of halogenated pyruvic acids to the corresponding *gem*-diols is noticeably enhanced. Thus, hydrolysis of perfluoropropylene oxide affords directly trifluoropyruvic acid in the hydrate form (m.p. 124–126 °C; b.p. 156–158 °C).[31] Subsequent treatment with diazomethane gives the corresponding methyl ester. The resulting *gem*-diol dehydrates on heating in sulphuric acid containing silica gel to give methyl trifluoropyruvate, which readily reverts to the *gem*-diol on addition of water.

This research has been extended to the preparation of related fluorinated α,α-dihydroxycarboxylic acids,[32,33] their esters and various alkylamine salts.[34]

X = H, F, n = 1–4.

Structural analyses have been carried out by IR-spectroscopy (ν_{OH} = 3300–3370 cm^{-1}) and NMR-spectroscopy (^1H and ^{19}F).

b) Halogenated dihydroxymethylenes

In a review of their own work on polarographic and spectroscopic (UV) studies,[35] the authors pointed out the correlation between the stability of α-halogenated aldehyde hydrates and the number of halogen atoms. It was also noted that chlorinated hydrates are more stable than bromo derivatives. On the other hand, the stability of the hydrates decreases with increase in length of the alkyl chain. Many systematic analyses published in recent years[5,6] have shown that the stability of halogenated *gem*-diols obtained by hydration of aliphatic fluoro-, chloro- and bromo-aldehydes and -ketones decreases in the order F > Cl > Br. Trihalogeno derivatives are crystalline compounds while most other halogenated *gem*-diols exist only in solution. Chloral hydrate, which has a large number of practical applications, is clearly the best known of these halogenated *gem*-diols. NMR-spectroscopy and circular dichroism both confirm its structure as $CCl_3CH(OH)_2$ rather than the free hydrate, $CCl_3CH{=}O.H_2O$.[6]

It is interesting here to note one of the methods of preparing chloral from chloral hydrate.[36] Commercial 'chloral hydrate', comprising 73.5% chloral hydrate, 6.2% chloral and a mixture of acetals and hemiacetals, is heated for 20 min at 110–120 °C at 1.5–2 atm under nitrogen. The upper layer of the resulting product mixture contains 99% chloral.

Studies have shown that, even with polyhalogenated derivatives, the equilibrium between *gem*-diol and carbonyl form is markedly dependent on the medium.[37,38] ^1H NMR spectroscopy has indicated

that chloral hydrate and related compounds spontaneously dehydrate in non-polar media (Table 1). An increase in the polarity, which has been equated with the basicity (B),[38] leads to a shift in the equilibrium in favour of the *gem*-diol form:

$$\underset{\text{(A)}}{CCl_3-CH(OH)_2} \rightleftharpoons \underset{\text{(B)}}{CCl_3-CH=O} + H_2O.$$

From the data in Table 1, the stability constants (K) for the *gem*-diols in nitromethane have been calculated from the proportion of carbonyl form in the mixture.

$$K = A/B.$$

Thus, for chloral hydrate, bromal hydrate and α,α-dichlorobutyral hydrate, K = 4.9, 0.45 and 0.89, respectively.

Table 1. The proportion of the aldehyde form (%) of α-halogenoaldehydes in different solvents.[37]

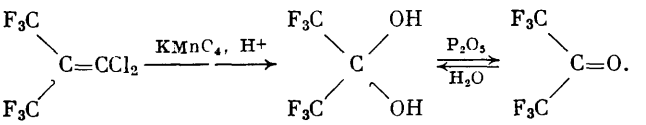
Solvent	Compound			B*
	$CCl_3CH=O$	$CBr_3CH=O$	$C_3H_7CCl_2CH=O$	
CCl_4	82	100	100	0
$CHCl_3$	60	67	88	4
CH_2Cl_2	35	69	100	23
$ClCH_2-CH_2Cl$	34	66	79	40
C_6H_6	60	100	100	48
CH_3-NO_2	17	69	53	63
CH_3-CN	0	20	41	160
D_2O	0	0	0	156
CD_3OD	0	0	0	218
$(CD_3)_2C=O$	0	12	29	224
$(CD_3)_2S=O$	0	2	7	312

* B — the relative value of solvent basicity.

A kinetic study of the hydration of trichloroacetaldehyde in aqueous dioxane[39] has shown that four molecules of water may be associated with the aldehyde in the form of a cyclic complex. IR-spectroscopy and circular dichroism spectroscopy indicate that the hydrates of hexachloroacetone, other halogenated acetones, and chloral form adducts with dioxane, cyclohexanone, cyclopentanone, dimethyl sulphoxide, and other bases.[40] The hydrate of hexachloroacetone also incorporates four molecules of water.

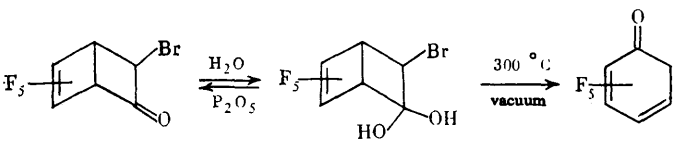
There is a reference[41] to the preparation of chloral hydrate by chlorination of ethanol in water under irradiation:

$$CH_3CH_2OH + 4Cl_2 + H_2O \rightarrow CCl_3CH(OH)_2 + 5HCl.$$



The product, in hydrate form, is distilled from the reaction mixture (b.p. 97.5 °C, m.p. 53 °C) and dehydrated by heating with concentrated sulphuric acid.

Aldehydes with a trifluoromethyl group in any location other than the α-position do not form crystalline hydrates.[42] They may be prepared by routine oxidation of the corresponding primary alcohols.

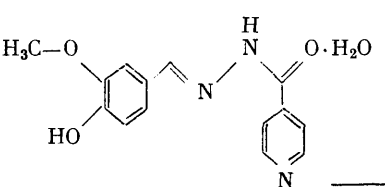


$$CF_3CH_2CH_2OH \xrightarrow{K_2Cr_2O_7,\ H_2SO_4} CF_3CH_2CH=O.$$

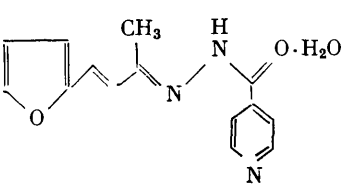
Trifluoroacetaldehyde cannot be prepared by this route. However, there is an indirect synthesis based on the conversion of trifluoroacetamide to the corresponding nitrile, followed by treatment with ethereal $LiAlH_4$ and concentrated HCl. The crystal hydrate of fluoral is dehydrated over P_2O_5.

Hexafluoroacetone was prepared for the first time in 1941 by direct fluorination of acetone in the gas phase over a copper gauze (m.p. −129 °C, b.p. −28 °C).[43] A more convenient method[44] involves oxidation of 1,1-dichloro-2,2-bis(trifluoromethyl)ethene in aqueous media, followed by cautious addition of the resulting hydrate (b.p. 57 °C at 93 mmHg) to P_2O_5:

The involvement of a hydrate form in the chemical conversion of a complex fluorinated ketone has also been reported:[45]

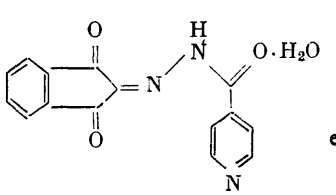


ν_{OH} 3440 см$^{-1}$
m.p. 55–57 °C



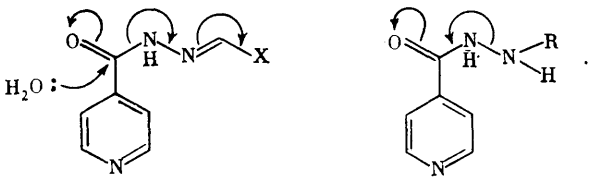
c) Pyridyl-substituted dihydroxymethylene compounds

Pyridinecarboxaldehydes, in particular 2-pyridyl and 4-pyridyl derivatives, are readily converted to crystalline hydrates.[46–49] Thus, 4-pyridinecarboxaldehyde hydrate is obtained by mixing the aldehyde itself with a 15-fold excess of water at 10–15 °C.[46] The resulting hydrate is a white, crystalline powder, m.p. 64–68.5 °C. Quinoline analogues have similar properties.[49] On the other hand, benzaldehydes and other compounds[50] are only hydrated in solution, provided that there is an electron-accepting substituent in the molecule.

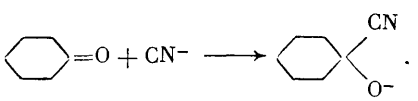


According to one reference book,[51] and elsewhere,[52] it is also reported that tuberculostatic isonicotinoylhydrazones also form crystal hydrates:

Ftivaside

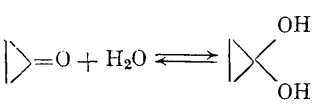


Larusan

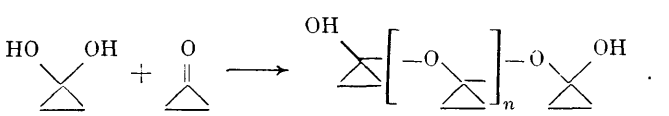


etc.

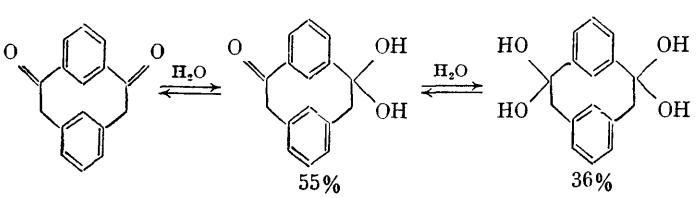
The precise nature of the hydrate form has not yet been established.[52] Significantly, isonicotinic acid hydrazides do not form hydrates. Thus, it can be assumed that hydration is primarily determined by the electron-accepting effect of the hydrazone residue on the carbon atom of the carbonyl group. Such stabilisation is absent in the free hydrazide:



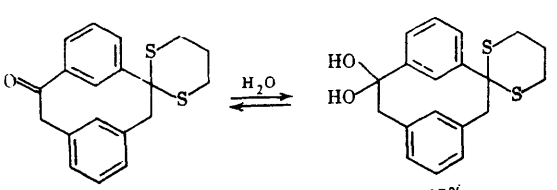
d) Dihydroxymethylene derivatives of strained ring systems



For cyclic systems, the interconversion between planar (sp^2) carbonyl structure and tetrahedral (sp^3) *gem*-diol form is associated with a structural modification of the whole molecule. In such compounds, neither form is especially favoured by neighbouring substituents. Strain in the ring system essentially determines the course of such (de)hydration, as well as other related reactions. Thus, while cyclohexanone interacts smoothly with cyanide ion (see below) and semicarbazide, there is no such reaction with cyclopentanone and cyclobutanone.[53]



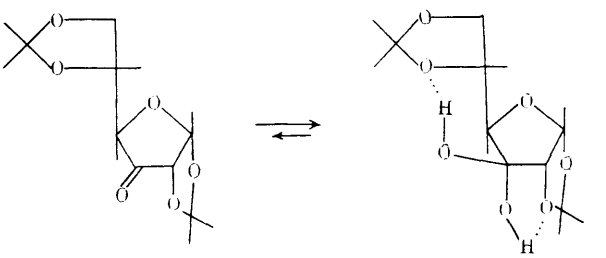
Cyclopropanone is readily hydrated to give the stable 1,1-dihydroxycyclopropane[53–56] (m. p. 82–84 °C).



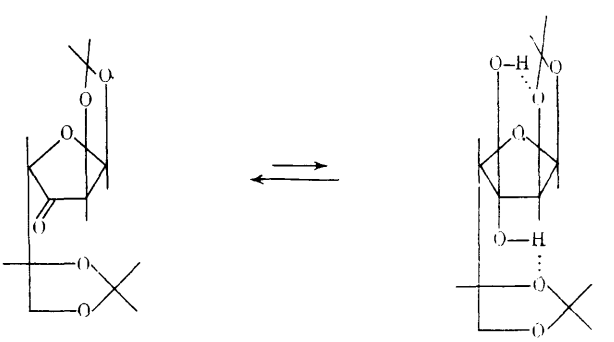
Ring strain also activates the hydroxyl groups of the *gem*-diol, leading to the formation of polymers:

Ketone derivatives of [2,2]metacyclophane are also readily hydrated to give crystalline *gem*-diols:[57]

55% 36%



45%



The fact that ring strain may be responsible for the readiness to form hydrates, as in the cyclic compounds shown above, may in part explain why aromatic compounds, such as benzaldehyde and acetophenone, do not exist in the hydrate form.[9]

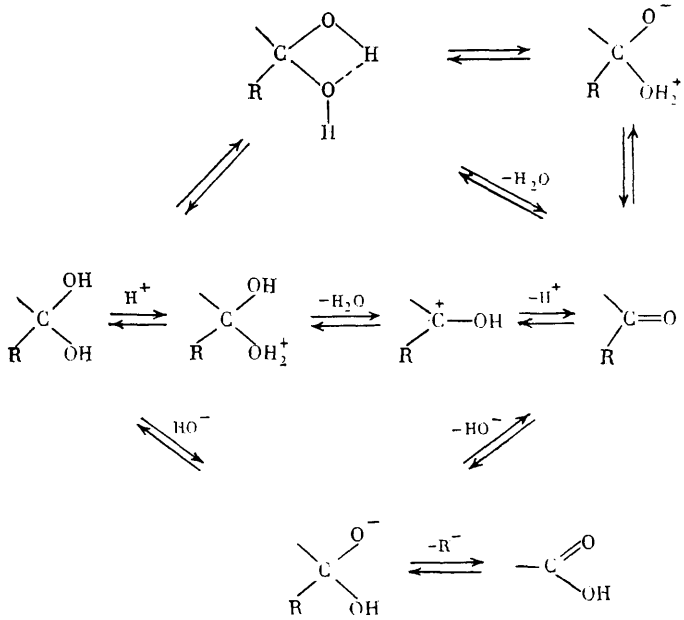
Ring strain and the influence of electro-accepting groups within the same molecule may contribute together in stabilising the *gem*-diol form. This clearly explains the high stability of ninhydrin[7,8] as well as the facile hydration of tetrahydrofuran-3,4-diones[26,27] and fluorinated bicyclo[2.2.0]hexenones,[45] which change colour on hydrate formation.

There is also the possibility of stabilisation of the *gem*-diol structure in a tetrahydrofuran system by both ring strain and hydrogen bonding with adjacent groups. This is evident in isomeric 1,2:5,6-di-*O*-isopropylidene-*D*-hexafuranoses having a keto group in the 3-position.[58–60]

m.p. 109–111 °C

Studies have shown that *gem*-diol intermediates play an important role in the interconversion of these isomers, as well as in various syntheses based on these compounds.

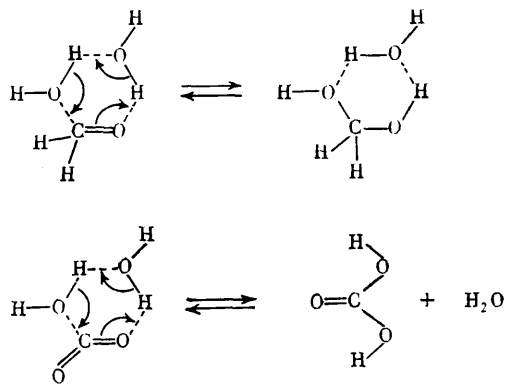
The data presented in this section support the view that *gem*-diols are a genuine class of compound, contrary to established belief. However, the list of known *gem*-diols is not great, so that it is not yet possible to make theoretical generalisations. The number of less stable *gem*-polyols is significantly greater, but, in contrast to those mentioned above, they exist only in solution.



2. *gem*-Polyols in solution

The formation of *gem*-diols (I) can take place in water, or media containing water, by a number of routes: by hydrolysis of halogenoalkanes, hydration of carbonyl compounds, carboxamides, etc., and by exchange of various functions by hydroxyl groups. *gem*-Diols may also be converted into other functional groups in such aqueous media. Studies of the products formed by certain reactions of carbonyl and other compounds[13–20] often indicate that *gem*-diols are short-lived intermediates. However, it may not always be possible to trap them by established techniques.

a) Stability and acid-base properties of *gem*-diols

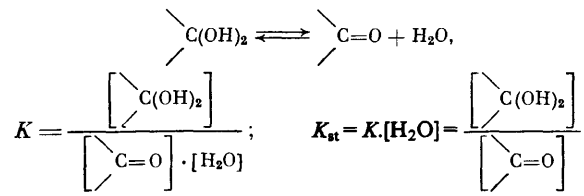


The recognition[5,6] that *gem*-diols are formed reversibly on hydration of aldehydes and ketones has had a profound effect on subsequent studies in this area and has been generally accepted by those who have undertaken theoretical analyses of the chemistry of carbonyl compounds.[13–20,47] Scheme 1 outlines the three possible routes for the formation and cleavage of *gem*-diols: in neutral media and under basic or acidic catalysis. However, conditions may be such that a clear distinction between these pathways cannot always be made.

Scheme 1

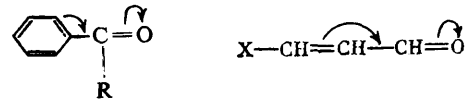
R = H, Alk, Ar, OH, NH_2 etc.

By considering the carbonyl form as starting material, only one process is involved: nucleophilic addition of oxygen at the carbon atom of the carbonyl group. Acid catalysis increases the developing positive charge at this carbon atom, thereby facilitating nucleophilic attack, in the same manner as a Lewis acid. Under basic catalysis, nucleophilic attack proceeds with direct participation of an alkoxide anion. It has been shown[61,62] that in neutral media, molecules of water are associated in a cyclic complex, thereby polarising the carbonyl group in the same manner as an acid catalyst.



The above-described mechanism of carbonyl group hydration is essentially the same for aldehydes and ketones of various type as well as for carbon dioxide. All the possible catalytic pathways for hydration of the latter have been discussed in a review article.[63]

The pathways outlined in Scheme 1 have also been examined from the side of the *gem*-diol. In this case, the catalytic and 'non-catalytic' routes are more distinct. The instability of *gem*-diols in water at pH 7 is thought to arise by self-protonation.[64] Acid catalysis is effectively the same since the initially formed species is an unstable hydroxonium salt. Under basic catalysis *gem*-diols may often become more stabilised in such a way that subsequent conversions may be determined by secondary reactions, for example by transfer of hydride ion[18] or heterolytic cleavage of a carbon–carbon bond.[19]



It is clear from the above discussion that the aspect of *gem*-diol stability is a very complex one. In aqueous media, *gem*-diols may be highly stable but impossible to isolate as such. On the other hand crystalline compounds may undergo a variety of conversions on dissolution. *gem*-Diols may not always be cleaved on acid catalysis. In studying the conditions for hydration of pyruvic acid it has been found that the rate of hydration increases in the presence of an excess of propionic acid.[65] The latter thus serves as a mild acid catalyst for the conversion of carbonyl compounds to *gem*-diols.

In order to compare the stability of *gem*-diols, the stability constants, K_{ST} where $K_{ST} = 1/K_d$), for a number of compounds have been listed in Table 2.

The data presented in Table 2, selected from known sources, have in the main been evaluated from the constants K_d (or K_h) or determined from the reported concentrations of the carbonyl and *gem*-diol forms. The value of K_{ST} in these examples is a more meaningful indication of the stability of the *gem*-diol, while K_d (K_h) has been used for an indication of the relative amount of the carbonyl (non-hydrated) form.

For aliphatic compounds it has recently been established that aldehydes are hydrated more easily than ketones. The stability of *gem*-diols increases as electron-accepting groups are introduced into the molecule and decreases on introducing electron-donating substituents. The ready hydration of α-ketocarboxylic acids and their salts is an obvious example to support this point. For aromatic and α,β-unsaturated aldehydes and ketones, there is less likelihood of forming *gem*-diols, even in neutral aqueous media, since the electron deficit of the carbonyl carbon is effectively neutralised by conjugation with the π-electron system.[5,6]

At the same time, dihydroxymethylene derivatives of [2,2]metacyclophane in aqueous solution have quite a high stability, although they can be regarded as analogues of hydrated aromatic ketones.[57] Acetone hydrate and other aliphatic ketone hydrates are

the least stable ketone hydrates. Carbonic acid is somewhat of an anomaly: it has a very unusual dihydroxymethylene structure and a low stability constant, K_{ST}.

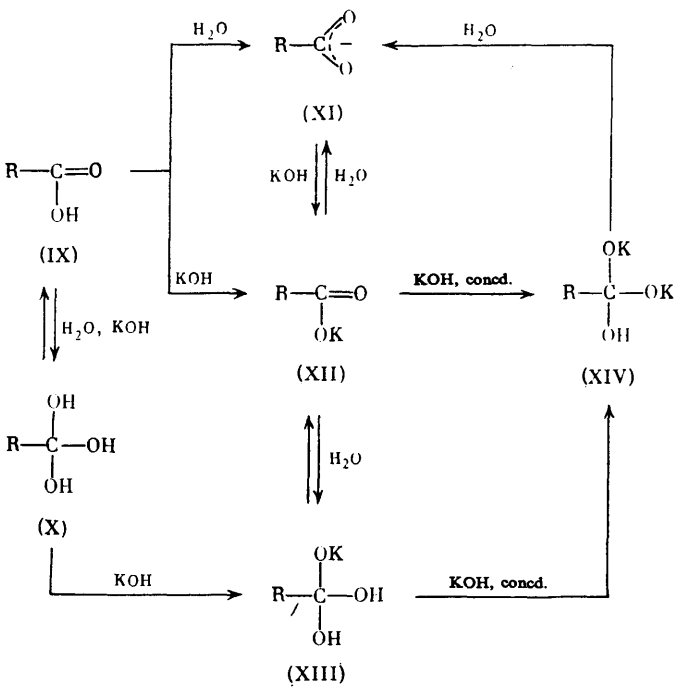
Note. a, UV- and IR-spectroscopy; b, polarography; c, NMR spectroscopy; d, electrical conductance.

There is no reference in the literature to the hydration of carboxyl groups to give 1,1,1-triols, sometimes referred to as orthocarboxylic acids. Derivatives of the latter, however, are well defined.[11] Indirectly, the formation and cleavage of 1,1,1-triols from carboxylic acids in water can be inferred by studying isotopic exchange of oxygen with the solvent; this has also been applied to other carbonyl-containing compounds.[69–73]

This mechanism is supported by the fact that no such oxygen exchange takes place with aliphatic alcohols or with phenols which display no tendency to undergo keto-enol tautomerism. With glucose only the carbonyl group is exchanged. The rate of oxygen exchange in acetone is very low compared with that of acetaldehyde. However, in the presence of aluminium oxide or silicon dioxide, the rate of oxygen exchange in acetone is enhanced due to the participation of the oxygen atoms of the catalyst.[74] Carboxylic acids exchange oxygen with the solvent more slowly than aldehydes. The rate of oxygen exchange of various carbonyl compounds decreases in the following sequence:[73]

For a given class of carbonyl compound, the rate depends to a large extent on the nature of the substituents. Thus, for substituted acetic

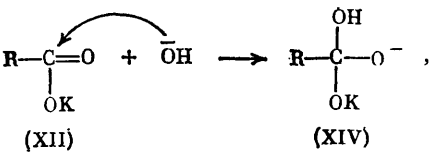
acids, the rate of exchange, as determined by IR-spectroscopy, is in the order:[75]



$$CF_3{-}COOH > CCl_3{-}COOH > CH_3{-}COOH > C(CH_3)_3{-}COOH$$

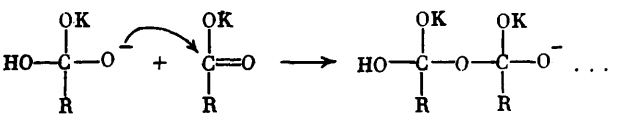
Benzaldehydes also readily undergo isotopic exchange by oxygen.[72] Electron-accepting substituents enhance the process while electron-donating groups have the opposite effect. Such evidence confirms that aromatic aldehyde hydrates have low stability: a fact that may not be apparent by other analytical techniques.

Thus, isotopic oxygen exchange, which has been studied with both carbonyl-containing compounds and inorganic oxide analogues.[70,71] can demonstrate the formation of all theoretically possible *gem*-polyol structures in solution. A dynamic equilibrium is set up, the position of which depends on many internal and external factors. In this context, it is interesting to study the reality of orthocarboxylic acids.



During the last few years a number of acid salts of orthocarboxylic acids (XIV) have been prepared by treatment of aqueous solutions of the corresponding carboxylic acid with concentrated base (>5 *N*). Such derivatives of benzoic furoic, sorbic, methacrylic acid, and others, have been prepared by this route.[9,76–78]

Scheme 2



It is possible that what chemists have assumed to be simple potassium carboxylates (XII), formed in routine syntheses, are in fact orthocarboxylic acid salts (XIV). With either salt, routine hydrolysis with mineral acid would give the corresponding carboxylic acid (IX). Salts (XIV) are colourless compounds which are not readily soluble in >5 *N* base. In water, such orthocarboxylic acid salts are converted into the carboxyl forms (XI) and (XII).

Scheme 2 illustrates the various pathways leading to the formation of orthocarboxylic acids and their salts. While the dissociated acid and its salts are converted in water to the carboxyl anion (XI), which is normally unaffected by base, treatment with highly concentrated base provides suitable conditions for the formation of the undissociated salt (XII) as well as the corresponding orthocarboxylic acids (X) and orthocarboxylic acid salts (XIII) as a result of catalytic hydration. The formation of orthocarboxylic acid salts (XIV) may proceed either by nucleophilic addition of hydroxide ion to the carbonyl carbon of the carboxylate salt form (XII),

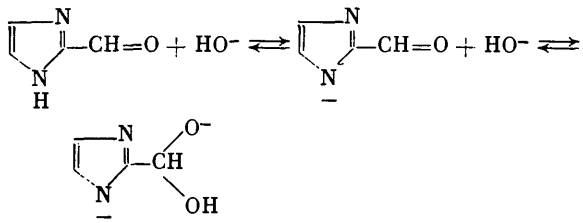
or by acid-base interaction of the monopotassium salt (XIII) with base in a second deprotonation. It is not possible to form the corresponding tripotassium orthocarboxylates under these conditions, presumably because of the weak acidity of the third hydroxy group. The structures of salts (XIV) have been confirmed by elemental analysis, IR spectroscopy (the absorption corresponding to $\nu_{C=O}$ being absent and that corresponding to ν_{OH} being present), and by potentiometric titration of the mixture of carboxylic acid salts and base obtained after cleavage of (XIV) in water. By the latter technique, it has been possible to determine the molecular weight and the proportion of inorganic anion and base in adduct (XIV). Thus, for salts of unsaturated carboxylic acids (cinnamic, acrylic, sorbic acids) it has been found that the adduct has a more complex structure in which one molecule of base is shared by 2–3 molecules of anion as a result of polymerisation.

Thus, although orthocarboxylic acids have not been demonstrated as stable species, their existence and properties have been inferred through the acid-base conversions of carboxylic acid salts in basic media.

Bases, as either reagents or catalysts, markedly accelerate hydration of carbonyl compounds relative to hydration in neutral media. A relationship has been established between the equilibrium constant for hydration (K_{H_2O}), the constant K_{OH}, for the adduct formation from aromatic aldehydes and hydroxide ion, and the acid dissociation constant, K_a, for the corresponding *gem*-diols (K_w being the dissociation constant for water).[79]

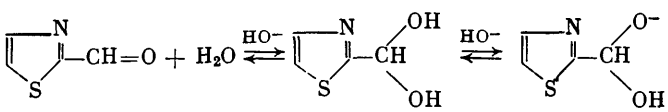
The final product of the reaction is the acid salt of the corresponding metacarboxylic acid (XVI), the formation of which may arise by interaction of base with the metacarboxylic acid itself

or its anhydride, i.e. the aldehyde form. Much work, principally undertaken by Zuman et al., has been devoted to a study of this equilibrium and its mechanism.[80–85]



$$ArCH{=}O + HO^- \overset{K_{OH}}{\rightleftharpoons} ArCH(OH)O^-$$
(XVI)

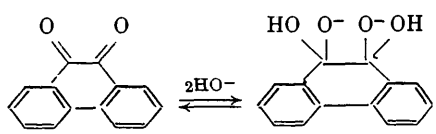
$$H^+ \updownarrow K_w \qquad K_a \updownarrow H^+$$



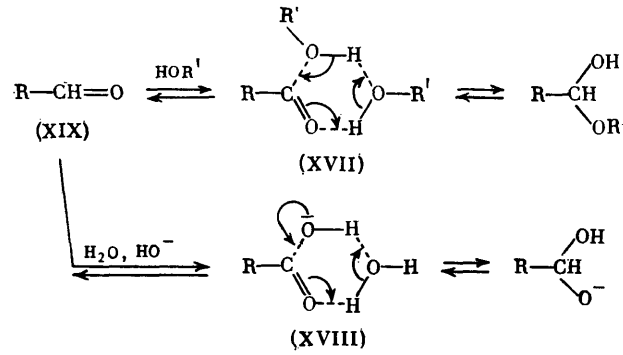
$$ArCH{=}O + H_2O \overset{K_{H_2O}}{\rightleftharpoons} ArCH(OH)_2$$
(XV)

$$K_a = K_{OH}\frac{K_w}{K_{H_2O}}$$

The reactions of a number of aromatic and heteroaromatic aldehydes with base have been reported.[80,81] Benzaldehyde and its derivatives, as well as furan-, thiophene- and *N*-methylpyrrole-carboxaldehydes, add hydroxide ion directly in one step to give the corresponding salt (XVI). Pyrrole- and pyrazole-carboxaldehydes react with base in two steps, the initial step being *N*-deprotonation.



Thiazole-2-carboxaldehyde is initially hydrated, and then reacts with base as follows:



Evidently pyridinecarboxaldehydes also interact with base according to this scheme since a polarographic study in media containing a high concentration of base has established that three forms exist: a carbonyl, a *gem*-diol and an anionic form (XVI).[83]

While hydration of α-polyketones usually involves only one carbonyl group, addition of water or hydroxide ion to a second keto group may take place in the presence of base. This is evident with ninhydrin[22] (see above). It has also been shown that 9,10-phenanthrenequinone forms a stable dianion:[84]

The pK_a values for a number of structurally varied *gem*-diols, given in Table 3, confirm the weakly acidic nature of these compounds. From these values for benzaldehyde derivatives, the corresponding values, J_-, J_{m-} and H_-, H_{m-}, have been calculated.[81,82,85] These denote, respectively, the readiness of the OH and OR group to add to the carbonyl group, (C=O), and the interaction of these with protic solvents.

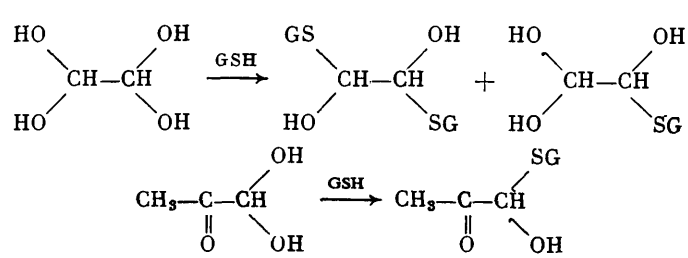
All of the examples studied are characterised by a final step involving the formation of the corresponding *gem*-polyol and its salt form. However, as has already been noted in review articles,[61,62] the formation of complex cyclic solvates or transition states precedes this stage. By studying the UV spectra of aromatic and heteroaromatic aldehydes in polar and non-polar solvents, an attempt has been made to analyse the spectra of solvate complexes, (XVII) and (XVIII), and calculate their stability constants.[89,90]

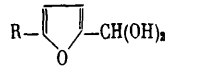
As solvation is reversible in polar media, aldehydes may exist in at least two forms—an unassociated carbonyl form (XIX) and a solvated form (XVII or XVIII)—as is the case with many other compounds which are solvated. This mixture of the two forms has been studied by measuring their light absorption properties. In particular, it has been established that benzaldehyde, as a dilute solution in water, is solvated to the extent of 70%, while the figure in ethanol is 54%. The corresponding values for *p*-nitrobenzaldehyde are 61 and 45%. Solvate complexes have well-defined UV-spectra so that the proportion of free and solvated forms in the mixture can be determined quantitatively. It cannot for certain be inferred that solvate complexes are necessarily converted into *gem*-diols or their derivatives, but their formation does represent an integral stage in the overall process.

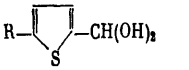
b) Characteristic reactions of *gem*-polyols

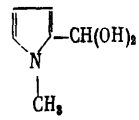
Differences in the reactivity of hydrated and non-hydrated carbonyl complexes have, up to now, not been considered. It has been thought that these reactions are one and the same, except in certain instances. It is now clear, from the evidence presented, that carbonyl compounds and *gem*-diols are distinct functional groups, and that the latter, just as acetals, may in part fulfil the role of a masking group for the former. However, apart from their masking, accelerating and inhibiting properties towards the carbonyl function, *gem*-polyols do undergo reactions which are uniquely their own.

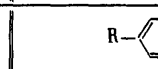
It has been argued that the degree of hydration of the carbonyl group may be an indication of its reactivity.[91] Thus, glutathione (GSH) only forms hemimercaptals with readily hydrated aldehydes and ketones. Glyoxal, which exists as a dihydrate in aqueous solution, affords two types of hemimercaptal, while methylglyoxal monohydrate forms only a ketohemimercaptal:

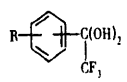












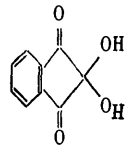


Table 3. Values of the first dissociation constant (pK_a) for *gem*-diols.

Compound	pK_a	Refs.

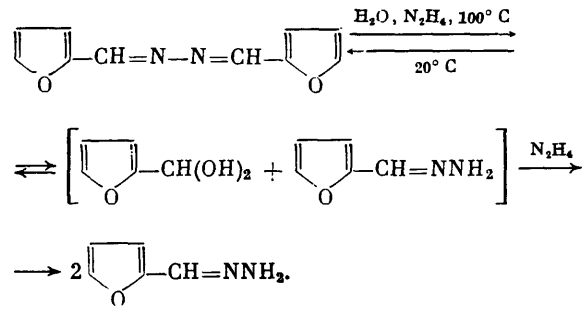
m-NO_2	9.18	[86]
	8.6	[8]
$O{=}C(OH)_2$	3.7	[88]

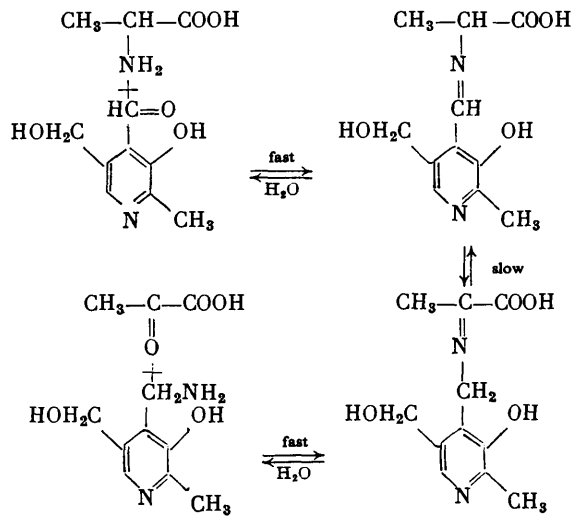
It has also been established that the formation of pyrazines by condensation of *o*-phenylenediamine with trifluoromethylglyoxal proceeds with participation of a hydrated carbonyl group.[92] X-Ray structural analysis and NMR spectroscopy indicates that, of the three possible hydrated forms of the ketoaldehyde, the ketone hydrate (XX) is directly involved.



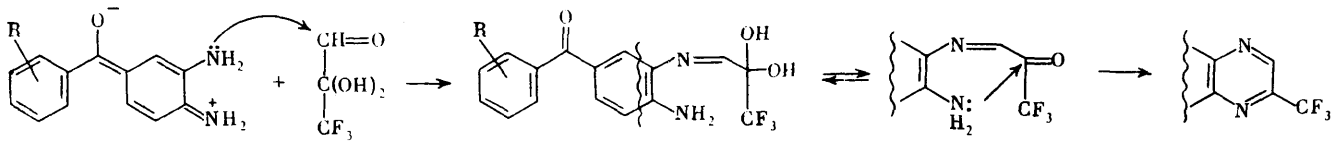
$$F_3C{-}C(=O){-}CH(=O) \overset{H_2O}{\rightleftharpoons} F_3C{-}C(OH)_2{-}CH(=O) \overset{H_2O}{\rightleftharpoons} F_3C{-}C(OH)_2{-}CH(OH)_2$$

(XX)

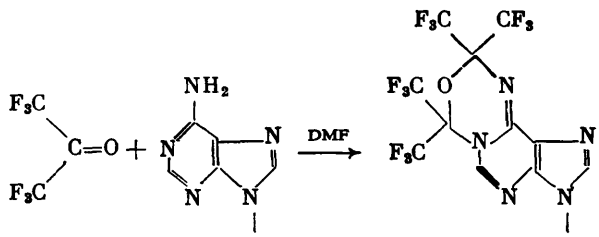
Initially, condensation takes place with the free aldehyde group; the hydrated keto group is then slowly dehydrated over 18 h at 23 °C prior to ring closure.



While in the above reaction it is apparent that the hydrated form hinders condensation, in other instances quite the reverse occurs, i.e. hydration facilitates condensation with amino groups. This is well illustrated in the review articles devoted to the chemistry of ninhydrin and analogues.[7,8] 4-Pyridinecarboxaldehyde hydrate has been recommended as a highly sensitive analytical reagent for phenylhydrazine and other unsymmetrically substituted hydrazines.[46] Interestingly, the analysis is not complicated by the presence of such reactive compounds as ammonia, hydroxylamines, aliphatic amines and aldehydes, acetone, etc.

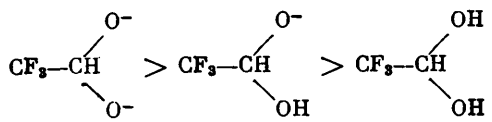


Evidently, the fact that aldehydes are not readily hydrated is reflected in the hydrolytic cleavage of the azomethine group. Thus, furfural hydrazone is obtained by heating the corresponding azine in aqueous hydrazine:[93]

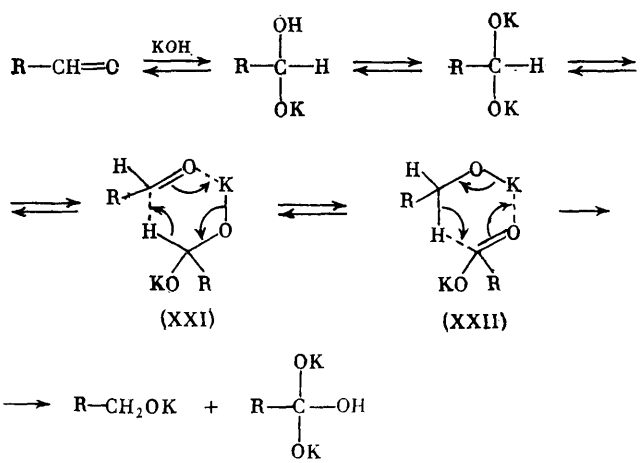


At 20 °C the equilibrium is shifted towards the azine.

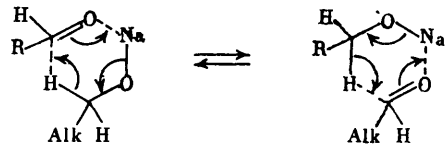
Such conversions have a direct bearing on biological processes, as has been demonstrated.[94,95] Thus, in model studies of transferase-catalysed transamination,[94] the authors have discovered a reversible isomerisation of Schiff bases which, on hydrolysis, are converted [in the example below] to pyruvic acid or a substituted pyridine-4-carboxaldehyde. Both products are readily hydrated carbonyl compounds (a fact which the authors did not heed).



Hexafluoroacetone, which is also readily hydrated,[31,42–44] interacts with adenine and its derivatives to give a product derived by condensation with both the amino group and an endocyclic nitrogen atom.[95]



In heterogeneous redox reactions, carbonyl compounds and *gem*-diols perform opposing roles: the former as an oxidant and the latter as a reductant (i. e. as a typical alcohol). In the case of fluoral hydrate, it has been shown that the reducing power increases as the concentration of base increases since the anionic form of the diol is a better oxidant than the neutral molecule:[88]

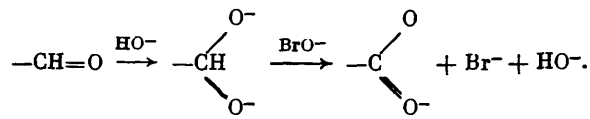


Oxidation of *gem*-polyols is accompanied either by loss of hydride ion[18,96] or, under more forcing conditions, by heterolytic cleavage of a carbon–carbon bond.[19]

For the disproportionation of furancarboxaldehydes on the surface of base granules under an inert atmosphere (in toluene, benzene or diethyl ether [not absolute]), it has been suggested that reaction proceeds via a cyclic complex (XXI) formed from one molecule of aldehyde and one of the corresponding *gem*-dialkoxide. This is converted to (XXII) by hydride transfer, in much the same way as a tautomeric rearrangement. It is an established fact that aromatic alcohols are formed from various aromatic aldehydes in the presence of formaldehydes.[2,18,96] The latter, functioning as a stable *gem*-diol, serves as a reductant, being oxidised by the same type of bond reorganisation depicted in complex (XXI).

(XXI) (XXII)

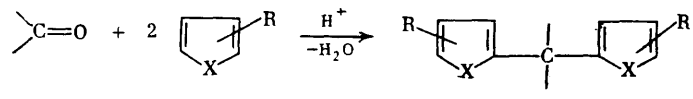
Simple aliphatic alcohols may perform the same function. Thus, a similar redox interaction has been proposed for the reaction of furfural with simple alkoxides:[97]



The familiar Meerwein–Pondorff–Verley–Oppenauer conversion with aluminium alkoxides[99] can thus be effectively performed with sodium alkoxides. The resulting aliphatic aldehyde may take part in a subsequent aldol condensation in the presence of an excess of aromatic or heteroaromatic aldehyde.[100]

Evidently, many established routes to carboxylic acids by oxidation of aromatic or heterocyclic aldehydes in basic media (notably Ref. 101) proceed via oxidation of a *gem*-dialkoxide. This has been confirmed for the hypohalite-mediated oxidation of furfural and its 5-methyl derivative.[102,103] A previously reported oxidation of furfural with sodium hypobromite[104] proved unsuccessful with 5-methylfurfural. However, 5-methyl-2-furoic acid was obtained in up to 95% yield by significantly increasing the amount of base (> 1 molar equivalent).

$$Br_2+2NaOH\rightarrow NaOBr+NaBr+H_2O,$$

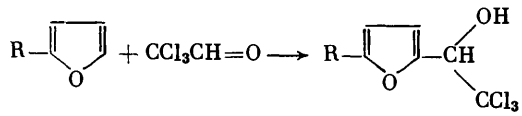


$$-CH=O+NaOBr+NaOH\rightarrow -COONa+NaBr+H_2O.$$

This would suggest that oxidation by hypobromite ion proceeds via the *gem*-dialkoxide rather than directly on the aldehyde:

Excess of base enhances hydration of the carbonyl group, especially in 5-methylfurfural, where the methyl group reduces the polarisation of the carbonyl function.

Under acidic catalysis, all forms of the carbonyl compound (hydrated or non-hydrated ketones and aldehydes) condense with aromatic systems to give polyaryl- or polyheteroaryl-alkanes:[105–107]

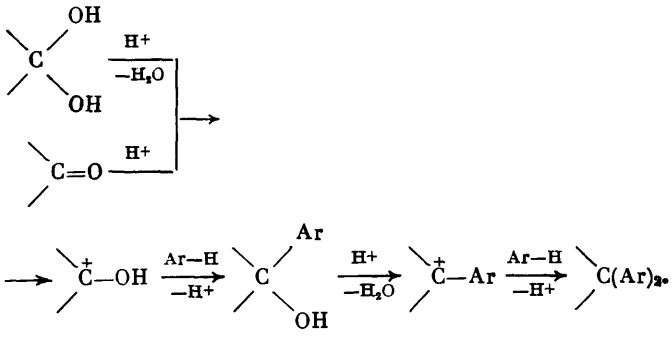


(XXIII)

X = CH = CH, O, S etc. R = H, Alk, OH, OAlk, Hal etc.

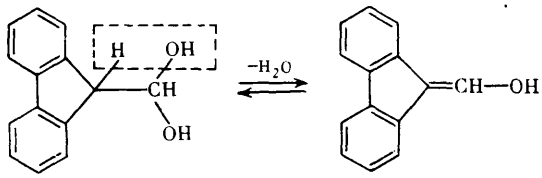
Reaction proceeds in two stages with the intermediate formation of secondary or tertiary alcohols (as is the case with alkylation). Termination of the reaction at this intermediate stage is relatively easy for carbonyl compounds which are readily hydrated, while reaction goes to completion in all other cases. In the case of chloral, condensation with various arenes affords the insecticide DDT and its analogues (XXIII, where X = CH = CH),[107] i. e. reaction goes to completion; however, the reaction of anhydrous chloral with furan

derivatives in the presence of $AlCl_3$ yields the corresponding secondary alcohol in up to 75% yield:[108]



R = H, CH_3, COOAlk.

The same product is obtained from chloral hydrate in sulphuric acid.

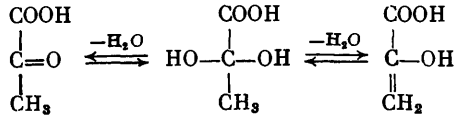


Trifluoropyruvic acid[109] and hexafluoroacetone,[110] which are even more readily hydrated, react in the same way with furan, thiophene, and *N*-methylpyrrole, even in the absence of catalyst.

It is known that electron-accepting (polyhalogeno) groups not only stabilise *gem*-diols but also inhibit the subsequent condensation of the intermediate secondary or tertiary alcohols with a second arene molecule. In the absence of such groups, the process continues (stage B), in the same way as aromatic alkylation with alcohols.

(A) (Б)

The formation of enols from *gem*-diols is interesting. Thus, 9-formylfluorene hydrate, having a labile α-hydrogen at C_9, dehydrates to give the corresponding enol.[111,112] In aqueous solution the *gem*-diol : enol ratio is 1 : 3.



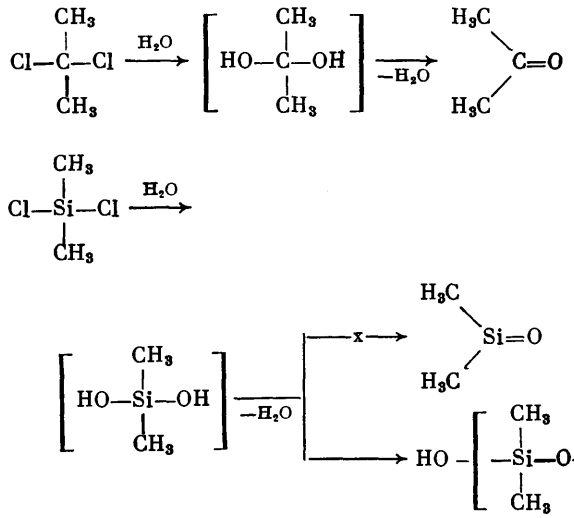
The enol group may be hydrated to reverse the reaction. Hydroxide ion accelerates the process. By comparison with simple alkenes, hydration of enols is four times faster.

$$(CH_3)_2C{=}CH{-}OH + H_2O \overset{K_1}{\rightleftarrows} (CH_3)_2CH{-}CH(OH)_2,$$

$$(CH_3)_2C{=}CH_2 + H_2O \overset{K_2}{\rightleftarrows} (CH_3)_2CH{-}CH_2{-}OH,$$

$$\lg(K_1/K_2) = 3.9.$$

Aqueous solutions of pyruvic acid contain three forms: a carbonyl, an enol and a *gem*-diol.[87] The *gem*-diol is considered to be an intermediate structure.



That *gem*-diols may be implicated in enolisation has been noted, especially by Toullec.[113]

III. *gem*-Polyols as members of the *gem*-polyhydroxide family

The reversible hydration of carbonyl groups is in many respects identical with the interconversion of oxides and hydroxides, and effectively is a special case of the latter. The stability and reactivity of *gem*-polyols can be examined in a whole series of related structures by taking into account the characteristics of each system as determined by the central atom. Such comparative studies, however, have rarely been reported. In recent years, quantum mechanics has shed light on the configuration, energy, bond lengths and other parameters pertaining to polyhydroxides of general structure $T(OH)_n$, where T = C, Si, B, Al, Sn and others; $n = 2-4$.[114,-117]

Of group IV elements, only carbon is reluctant to form polyhydroxides. Thus, hydrolysis of 2,2-dichloropropane affords acetone, while dichlorodimethylsilane gives a polysiloxane.[118]

In aqueous ammonia, stannic chloride is hydrolysed to $Sn(OH)_4$ — stannic acid.[119] However, hydrolysis of carbon tetrachloride, like the hydration of carbon dioxide,[63,120] affords dihydroxycarbon monoxide, i.e. carbonic acid

$$O{=}C{=}O + H_2O \rightleftharpoons O{=}C(OH)_2.$$

At the same time, the possibility of forming tetrahydroxycarbon (tetraol) in solution has been indicated by studies of isotopic oxygen exchange.[70,71] These have revealed that the rate of oxygen exchange increases with the atomic number of the central atom, which coincides with an increase in the stability of the polyhydroxide.

The fact that carbon dioxide is only partially hydrated, and anomalies in the hydration of carbonyl compounds, can be viewed with the properties of a large number of polyoxides, which also interact with water to give a variety of hydrated compounds, notably polybasic inorganic acids. The possible factors responsible for the formation of such compounds have been examined earlier.[120,121] The stability of polyhydroxides increases with the atomic number of the central atom and with the Periodic Group number. This is determined by the strength of the T—O bond. Thus, for the halogens in the maximum oxidation state, chlorine forms a monohydroxide, i.e. perchloric acid [$HOCl(=O)_3$], whereas iodine forms $(HO)_3I(=O)_2$. For sulphur, the dihydroxide is known (H_2SO_4), but for tellurium the analogue is $Te(OH)_6$. For nitrogen,

the monohydroxide (HNO_3) is known, but phosphorus forms both meta- and ortho-acids [$HOP(=O)_2$, $(HO)_3P=O$, and others] as the corresponding anhydride, P_2O_6, can be hydrated to various degrees. The stability of these polyhydroxides is determined by many factors inherent in the structure of the central atom. In this respect, a key role is played by vacant orbitals,[122] which give rise to partial double character as a result of a shift of a lone pair of electrons from oxygen:

For carbon compounds which lack vacant orbitals, such stabilisation can be achieved by neighbouring electron-accepting groups which lower the electron density at the carbon atom. Other factors, such as the anomeric effect[123] also have a stabilising effect. The fact that many *gem*-diols are stable only in solution, and are formed as reaction intermediates, would also argue in favour of another stabilising factor: the formation of complex solvates. The full analysis of this aspect would require a separate review.

Fluorine-containing aromatic aminoacids

V P Kukhar, Yu T Yagupol'skii, I I Gerus, M T Kolycheva
The Institute of Bioorganic Chemistry and Petrochemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. **Methods of preparing the following fluorine-containing aromatic aminoacids are reviewed: racemic and optically active phenylalanine and tyrosine derivatives with fluorine atoms or fluoroalkyl groups in the benzene ring or in the side chain. Possible bio-medical applications of these compounds are examined.**

The bibliography contains 100 references.

Contents

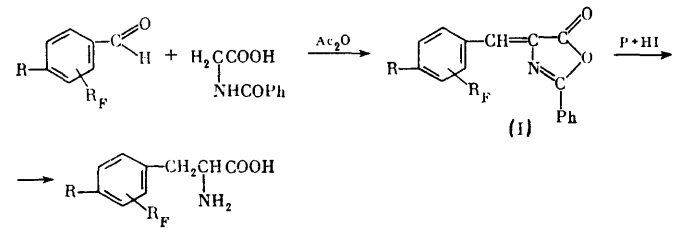
I. Introduction 1050
II. Synthesis of racemic fluorine-containing aromatic aminoacids 1050
III. Synthesis of optically active fluorine-containing aromatic aminoacids 1053
IV. Possible fields of application 1056

I. Introduction

The aromatic aminoacids—phenylalanine and tyrosine—are members of the essential aminoacids. They are constituents of important biologically active peptides, such as oxytocin, enkephalins, and kinins. The products obtained by metabolism of these aminoacids play a key role in processes which take place in the central nervous system and elsewhere in the living organism.

By replacement of atoms of hydrogen by fluorine in aminoacids, one can prepare compounds which are structurally very similar to the corresponding natural aminoacids since the size of the fluorine atom does not differ greatly from that of hydrogen. However, as the energy of the C–F bond is greater than that of the C–H bond, there is a significant change in the metabolism of derivatives containing fluorine. Furthermore, as a consequence of the electronegativity of the fluorine atom, there is a marked shift in electron density which has an affect on the physical chemical properties. With the development of organofluorine chemistry, new methods of selective fluorination have been designed and new fluorinating agents, as well as simple reactive fluorine-containing synthons, have become available. These have been usefully applied to the preparation of fluorine-containing aromatic aminoacids having atoms of fluorine or fluoroalkyl groups in various positions of the molecule. Interest in fluorine-containing phenylalanine and tyrosine is evident from the volume of publications in this area and from the applications of fluorine-containing aminoacids in biochemical studies and in medicine.

In 1970 a review was published on the synthesis of fluorine-containing aminoacids, including phenylalanine and tyrosine derivatives.[1] However, there is little mention of the biological activity of these compounds. A recent review covers the synthesis of aminoacids having a fluorine atom in the β-position of the hydrocarbon chain, including α-polyfluoromethyl derivatives.[2]

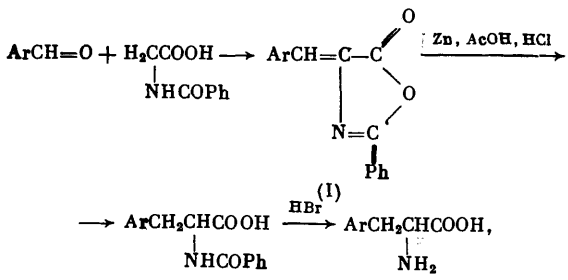


In the present literature survey, a systematic study has been made of synthetic routes to fluorine-containing derivatives of phenylalanine and tyrosine in both racemic and optically active form. The effect of fluorine substitution on biological activity has also been examined, and potential applications of these compounds in biochemical and medical research have been highlighted.

II. Synthesis of racemic fluorine-containing aromatic aminoacids

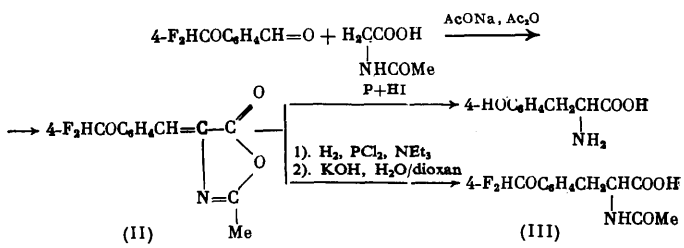
Various methods are available for preparing aromatic aminoacids with fluorine or fluoroalkyl substituents. These are based on either direct introduction of fluorine into the aminoacid molecule or syntheses from fluorine-containing residues and synthons. The latter methodology has been applied to the preparation of racemic fluorine-containing phenylalanine and tyrosine derivatives, which may be resolved into their enantiomeric forms by a variety of methods.

1. Methods based on the condensation of carbonyl compounds



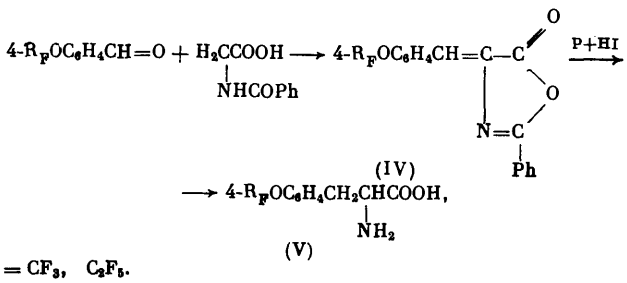
Phenylalanine and tyrosine derivatives with up to five fluorine atoms or trifluoromethyl groups in the benzene ring are usually prepared by the classical route from the corresponding fluorinated benzaldehydes and *N*-acetylglycine.[1] Normally, an oxazolone intermediate (I) is formed in high yield irrespective of the number of fluorine atoms in the aromatic nucleus. Subsequent reduction and hydrolysis (notably with a mixture of red phosphorus and HI) affords the desired fluorine-containing aromatic aminoacids.[1]

R = H, F, CF_3, MeO, OH; $R_F = F_n$, CF_3; $n = 1-5$



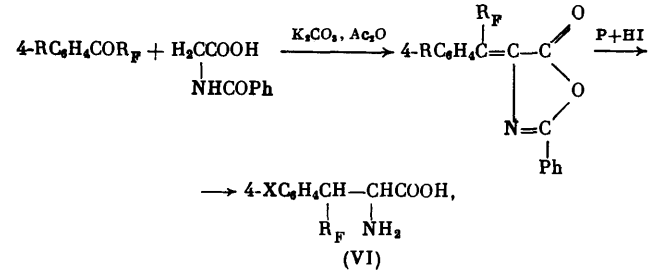
Fluorinated phenylalanine derivatives containing two, three or four atoms of fluorine at various positions of the benzene ring have also been prepared from the corresponding benzaldehydes via reduction of the intermediate oxazolones (I) under mild conditions (with Zn/AcOH). After acidic hydrolysis, ion-exchange resins have

been used to isolate the free aminoacids in higher yield and purity without contamination by inorganic salts.[3]

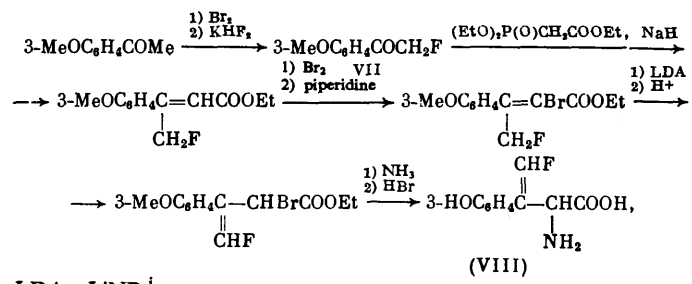


Ar = 2,4-$F_2C_6H_3$; 3,4-$F_2C_6H_3$; 3,5-$F_2C_6H_3$; 2,5-$F_2C_6H_3$; 2,6-$F_2C_6H_3$; 2,3,5,6-F_4C_6H; 2,3,4,6-F_4C_6H; 2,4,6-$F_3C_6H_2$; 3,5-Cl_2-2,4,6-F_3C_6.

4-Difluoromethoxybenzaldehyde, readily obtainable by treatment of 4-hydroxybenzaldehyde with chlorodifluoromethane, reacts with aceturic acid under the conditions of the Erlenmeyer azlactone synthesis to give the corresponding fluorine-containing unsaturated oxazolone (II). However, reduction of the latter with HI/P proceeds by cleavage of the difluoromethyl group to give tyrosine as the only isolable product. On the other hand, hydrogenation in the presence of Pd and NEt_3 affords methyl *N*-acetyl-4-difluoromethoxyphenylalanate which is converted to the *N*-acetyl derivative (III) on basic hydrolysis.[4]



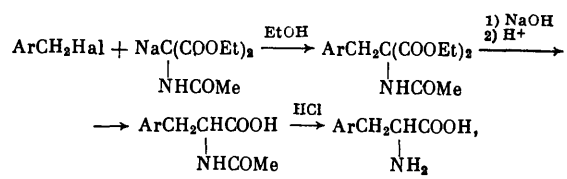
Benzaldehydes substituted by trifluoromethoxy and pentafluoroethoxy groups reacts with hippuric acid to give the corresponding fluorine-containing oxazolones (IV) which, in contrast to azalactone (II), is reduced by HI/P to the corresponding fluorine-containing aminoacids (V). Thus, perfluoroalkoxy groups remain intact under these conditions.[4]



R_F = CF_3, C_2F_5.

The Erlenmeyer condensation of ω-polyfluoroacetophenones with hippuric acid affords the corresponding β-(polyfluoromethyl)-phenylalanines and -tyrosines. It should be pointed out that oxazolones are not formed under these conditions from acetophenone itself or from ω-monofluoroacetophenone.[5] Amino-acids (VI) have two chiral centres and are formed as a mixture of diastereoisomers.

R = H, OCH_3; X = H, OH; R_F = CHF_2, CF_3.

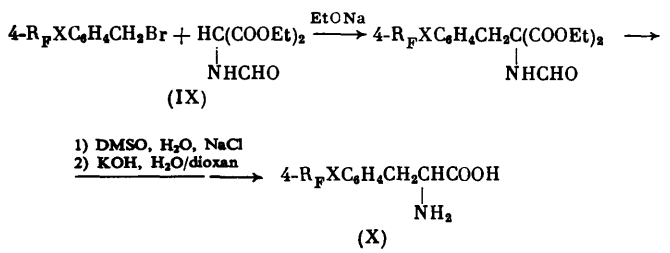


ω-Monofluoro-3-methoxyactophenone (VII) has been used as the key starting material for the synthesis of β-fluoromethylene-*m*-tryosine (VIII). Thus, Horner reaction with (VII) provides the corresponding substituted cinnamic acid ester which is converted by the route shown below to the *m*-tryosine (VIII)—an effective irreversible inhibitor of monoamineoxidase—in an overall yield of 32%.[6]

LDA – $LiNPr^i_2$.

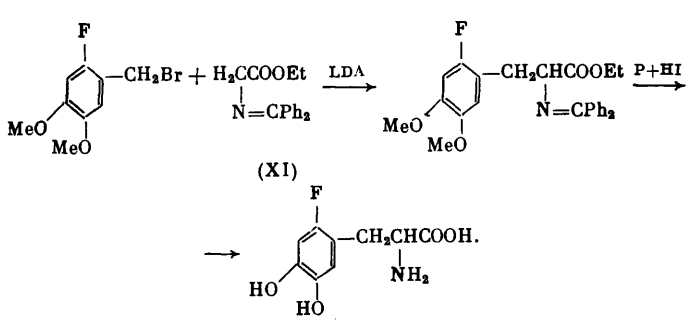
2. Methods based on alkylation

The reaction of benzyl halides with *N*-acylaminomalonic acid esters has been generally applied to the synthesis of fluorine-containing aromatic aminoacids. Aminoacids may be obtained in high yield by this route. However, the sensitivity of the condensation to traces of moisture is a limitation which has a significant effect on the overall yield. In an earlier review,[1] there is reference to the synthesis of fluorine-containing phenylalanines and tryosines by reaction of the sodio-derivative of diethyl acetylaminomalonate with fluorine-containing benzyl halides.



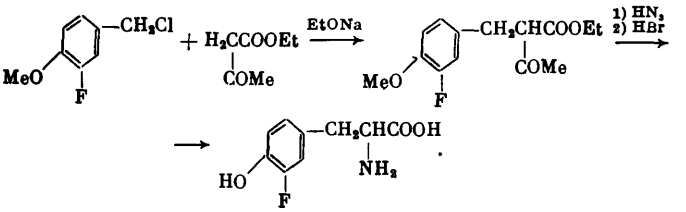
Hal = Cl, Br; Ar = 2-, 3- and 4-FC_6H_4, C_6H_4, C_6F_5, 4-HOC_6H_4, 3-$CF_3C_6H_4$.

As hydrolysis takes place in two steps, it is possible to isolate both the free aminoacid and its *N*-acetyl derivative. By alkylation with variously substituted fluoro- or trifluoromethyl-benzaldehydes,

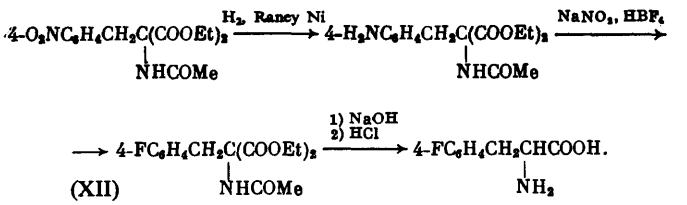


the following fluorine-containing aromatic aminoacids have been prepared: phenylalanine derivatives, $ArCH_2CH(NH_2)COOH$, where Ar = 2-FC_6H_4, 3-FC_6H_4, 4-FC_6H_4, 2,5-$F_2C_6H_3$, 3-$CF_3C_6H_4$, 2-Cl-5-$CF_3C_6H_3$, 4-Cl-3-$CF_3C_6H_3$;[7–9] tryosine analogues, where Ar = 2-F-4-$MeOC_6H_3$, 2-F-4-HOC_6H_3, 2,6-F_2-4-HOC_6H_2;[10–11] and the dihydroxyphenylalanine (DOPA) analogue where Ar = 2-F-3,4-$(HO)_2$-C_6H_2.[12]

Normally this route is based on diethyl acetylaminomalonate. However, it is possible to use other *N*-substituted malonates. Thus, condensation of 4-fluorobenzyl chloride with the corresponding phalimidomalonate, followed by hydrolysis in 5 *N* HCl at 100 °C affords 4-fluorophenylalanine in 50% yield (based on the starting benzyl halide).[13] By using the formamidomalonate (IX), removal of the protective group can be achieved under mild conditions so that fluorine-containing aromatic aminoacids with acid-labile substituents (e.g. R_FX = F_2HCO) may be prepared. Thus, treatment of fluorine-containing benzyl bromides with the sodio-derivative of (IX), followed by decarboxylation in aqueous DMSO with NaCl and basic hydrolysis, affords the corresponding polyfluoroalkoxy- and polyfluoromethylthio-phenylalanines (X) in 20–50% yield (based on the benzyl bromide).[4]

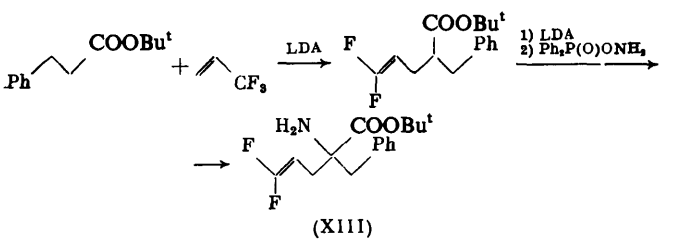


$R_FX = CHF_2O$, CHF_2S, CF_3S, CF_3CH_2O.

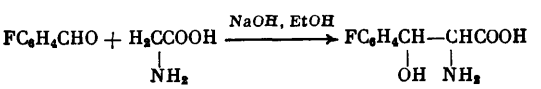


For the synthesis of fluorine-containing aminoacids from the corresponding benzyl halides, it is also possible to use other CH-acidic compounds, such as *n*-acylaminocyanoacetic acid esters,[1] in place of the acylaminomalonates. Thus, 6-fluoro-3,4-dihydroxyphenylalanine has been prepared from the glycinate Schiff base (XI), obtained from ethyl glycinate and benzophenone.[14] Generation of the carbanion in the initial deprotonation requires a strong base, e.g. LDA.

3-Fluorotryosine has been prepared by condensation of 3-fluoro-4-methoxybenzyl chloride with ethyl acetoacetate, followed by replacement of the acetyl group by an amino function with hydrazoic acid. A 63% yield has been recorded for this reaction.[15,16]

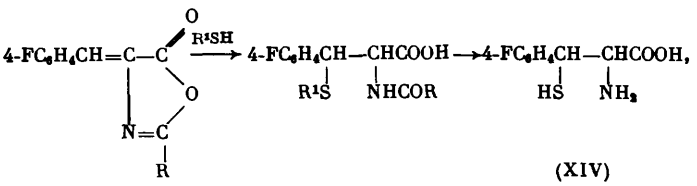


Introduction of the fluorine atom can take place during the course of the malonate-based route. Thus, after condensation of 4-nitrobenzyl chloride with the acetylaminomalonate, the nitro group may be reduced with H_2 over Raney nickel and fluorine introduced by the Schiemann reaction to give (XII).[17]



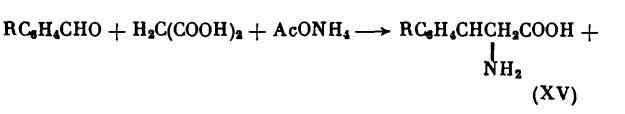
This method of introducing the fluorine atom *en route* is particularly useful for preparing phenylalanine labelled with the short-lived isotope ^{18}F ($\tau_{1/2}$ = 109 min).[18–20]

3. Other methods



Recently, the phenylalanine derivative (XIII), having a γ,γ-difluoroallyl group in the α-position, was prepared from 3,3,3-trifluoropropylene, as shown below. *O*-Diphenylphosphinylhydroxylamine was used in the last step to introduce the amino group into the α-position relative to the carbonyl group.[21]

Treatment of 2- and 4-fluorobenzaldehyde with glycine in the presence of base affords the corresponding fluorine-containing β-phenylserine.[22,23]

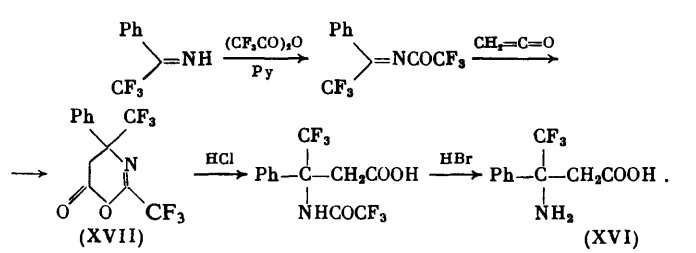


Fluorine-containing β-phenylthioserines have been prepared in the presence of base by reaction of mercaptans with the oxazolones obtained from α-acylamino-4-fluorocinnamic acids.[23] The free aminoacid (XIV) was formed on removal of the protecting groups.

(XIV)

R^1 = Et, $PhCH_2$.

A series of fluorine-containing aromatic aminoacids with an amino group in the β-position was prepared by the Rodionov reaction from benzaldehydes and malonic acid in the presence of ammonia. Thus, 4-fluorobenzaldehyde affords β-(4-fluorophenyl)-β-alanine in high yield.[23,24] Similarly, reaction with 3-fluoro-4-methoxybenzaldehyde, followed by treatment with HBr, affords β-(4-hydroxy-3-fluorophenyl)-β-alanaine.[24] β-[2- and 4-(Difluoromethoxy)phenyl]-β-alanines (XV) have also been prepared from the corresponding difluoromethoxybenzaldehydes.[25] The Rodionov reaction is accompanied by the formation of fluorine-containing cinnamic acids as by-product which may be removed by crystallisation.



(XV)

R = 4-F, 4-$OCHF_2$, 2-$OCHF_2$.

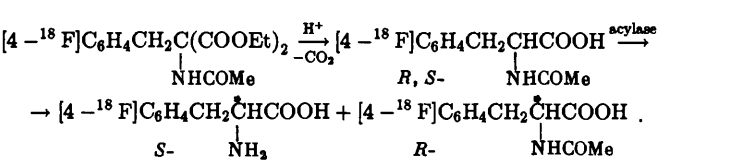
The Rodionov reaction with ω,ω,ω-trifluoroacetophenone gives 4,4,4-trifluoro-3-phenyl-3-hydroxybutyric acid, rather than the expected β-trifluoromethyl-β-phenyl-β-alanine (XVI).[25] The latter has been obtained, however, by cyclisation of ω,ω,ω-trifluoroacetophenone *N*-trifluoroacetylimine with ketene, followed by hydrolysis of the resulting oxazinone (XVII).[26]

(XVII) (XVI)

Fluorine-containing aminoacids have also been prepared by direct fluorination of the parent aminoacids. A variety of reagents has been used for introducing a fluorine atom into the benzene ring of phenylalanine and tryosine. This route has also been applied to the preparation of homochiral fluorine-containing aminoacids, reaction proceeding as a rule with retention of chirality. The direct fluorination of (*S*)-phenylalanine and (*S*)-tyrosine will be discussed in the next section devoted to the synthesis of optically active aminoacids.

III. Synthesis of optically-active fluorine-containing aromatic aminoacids

Three routes are available for the preparation of optically-active aminoacids substituted by fluorine atoms or fluoroalkyl groups: resolution of racemic compounds into their enantiomers, for which various methods are reported; asymmetric synthesis; and fluorination of homochiral aminoacids with retention of chirality.



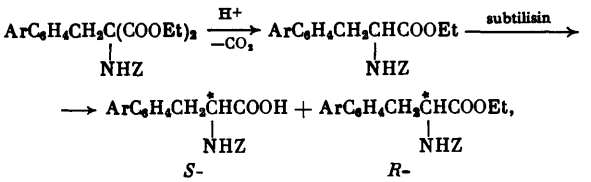
1. Optical resolution of fluorine-containing aromatic aminoacids

(*S*)- and (*R*)-Pentafluorophenylalanine have been isolated via recrystallisation of the diastereoisomeric salts formed on mixing *N*-benzoyl-(*R,S*)-pentafluorophenylalanine with brucine.[27] This method has been applied generally for the resolution of non-fluorinated aminoacids. However, it is laborious and low-yielding.

Chromatographic resolution of racemic aminoacids on chiral stationary phases is of much greater potential in this respect. This is exemplified by the optical resolution of 4-fluorophenylalanine.[28,29]

Enzyme-catalysed resolutions have been generally applied to the preparation of homochiral fluorine-containing derivatives of phenylalanine and tryosine. This route is based on the preferential enzyme-catalysed reaction of the *L*-enantiomer of a racemic mixture of a suitable aminoacid derivative. Thus, as long ago as 1946, the (*R*)- and (*S*)-enantiomers of 3-fluorotyrosine were isolated by papain-catalysed cleavage of racemic 3-fluorotyrosine anilide.[30] Similarly, papain-catalysed cleavage of racemic *N*-acetyl-(2-,3- and 4-fluorophenyl)alanine in the presence of phenylhydrazine afforded the (*S*)- and (*R*)-enantiomers of 2-, 3- and 4-fluorophenylalanine, respectively.[31] Mechanistically, the enzyme catalyses the formation of the corresponding *N*-acetyl-(*S*) fluorophenylalanine phenylhydrazide which is readily separated from the corresponding *N*-acetyl-(*R*)-fluorophenylalanine. The optically pure free aminoacids are obtained by subsequent hydrolysis of the resulting (*R*)- and (*S*)-fluorophenylalanine derivatives.

(*S*)-[4-^{18}F]-Fluorophenylalanine has been obtained by treatment of the racemic *N*-acetyl derivative with aminoacylase.[20] The use of aminoacylase is also recommended for the synthesis of homochiral aminoacids by the malonic ester synthesis, the enzyme substrates (*N*-acetyl derivatives) being formed without the additional requirement of an *N*-acylation step.

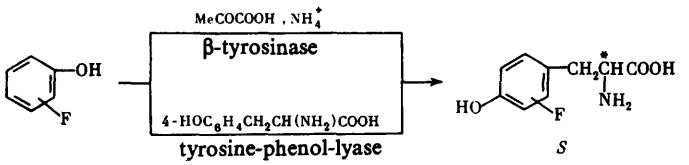


The enantiomers of pentafluorophenylalanine have been isolated via treatment of *N*-trifluoroacetyl-(*R,S*)-pentafluorophenylalanine with an acylase.[32]

α-Chymotrypsin has also been used for the enzymatic resolution of 4-fluorophenylalanine.[33] Thus, racemic 4-fluorophenylalanine is converted to the ethyl ester, which, on incubation with α-chymotrypsin affords (*S*)-4-fluorophenylalanine. The latter is

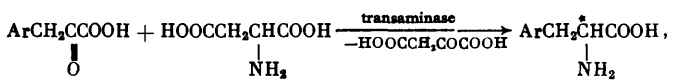
readily separated from the unreactive ethyl (*R*)-4-fluorophenylalanate. The same enzyme has been used for the resolution of methyl *N*-acetylpentafluorophenylalaninate.[34]

Subtilisin has been used[35] for the resolution of ethyl *N*-benzyloxycarbonyl-(*R,S*)-fluorophenylalaninates, obtained by the malonate route:



Ar = 3-FC_6H_4, 4-FC_6H_4, C_6F_5; Z = $COOCH_2C_6H_5$.

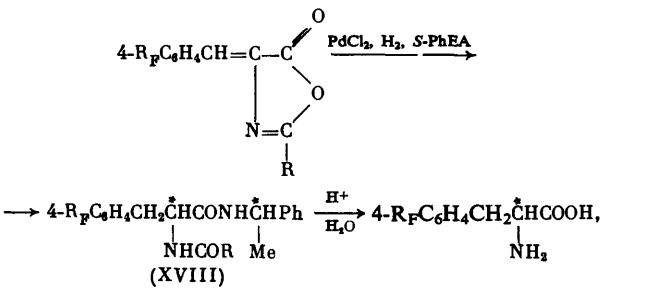
α-Chymotrypsin has also been used for the resolution of each of the three positional (*o*, *m*- and *p*-) isomers of methyl *N*-acetylfluorophenylalaninate and of *N*-acetyl-4-trifluoromethylphenylalaninate.[36] Carboxypeptidase A, however, is the preferred enzyme for the resolution of the *N*-trifluoroacetyl derivatives of these aminoacids.[36] All three positional isomers of *N*-benzyloxycarbonyl-(*S*)-fluorophenylalanine have been isolated with an enantiomeric excess (e.e.) of 90–97% by treatment of the appropriate racemic trifluoroethyl *N*-benzyloxycarbonylfluorophenylalanates with pig liver lipase.[37]



(*R*)-4-Fluorophenylalanine has been isolated by enzymatic resolution of *N*-benzoyl-(*R,S*)-4-fluorophenylalanine with an *Escherichia coli* culture.[38] All three of the positional isomers of fluorophenyl-alanine were resolved with lyophilised yeast, the (*R*)-enantiomers being isolated in 76–86% yield.[39]

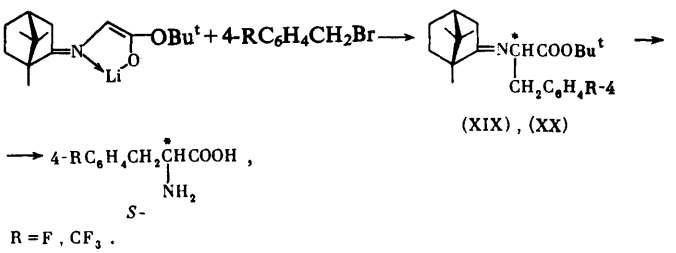
2. Asymmetric synthesis

As well as being used for the optical resolution of racemic compounds, enzymes have also been applied to the synthesis of optically active fluorine-containing aminoacids. Thus, 2- and 3-fluoro-(*S*)-tyrosine have been prepared by treatment of the corresponding 3- and 2-fluorophenols with tyrosine-phenol lyase.[40,41]



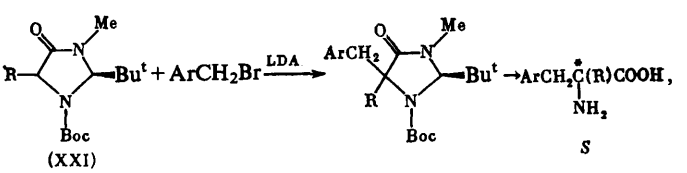
Fluorine-containing (*S*)-phenylalanines have also been synthesised. Thus, trifluoromethyl-, monofluoro-, and pentafluoro-(*S*)-phenylalanines have been prepared by action of transaminase on a mixture of aspartic acid and the appropriate fluorine-containing phenylpyruvic acid.[42]

Ar = FC_6H_4, $CF_3C_6H_4$, C_6F_5.



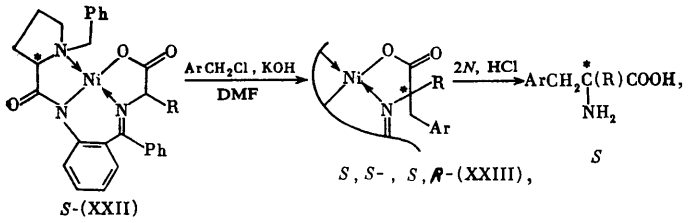
Reductive aminolysis has been used in the preparation of optically active *p*-fluoro- and *p*-difluoromethoxyphenylalanine.[43,44] Thus, reductive aminolysis of fluorine-containing oxazolones by hydrogenation over $PdCl_2$ in a variety of solvents containing (*S*)-(−)-α-phenylethylamine (PhEA) affords the corresponding *N*-acyl-(4-fluoro- or 4-difluoromethoxy-phenyl)alanine α-phenylethylamide (XVIII), predominantly in the (*S,S*)-configuration, with a diastereoisomeric excess (d.e.) up to 47%.

R_F = F, $OCHF_2$; R = Me, Ph.



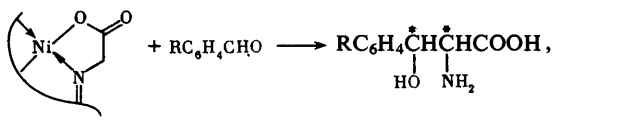
Crystallisation of the *p*-fluorophenylalanine amides affords the optically pure (*S,S*)-diastereoisomers, hydrolysis of which in 6 *N* HCl yields enantiomerically pure 4-fluoro-(*S*)-phenylalanine.[43] Attempts to cleave the amide bond in *p*-difluoromethoxyphenylalanine analogues leads to removal of the difluoromethyl group to give (*S*)-tyrosine.[44]

Fluorine-containing aromatic aminoacids have also been synthesised via alkylation with asymmetric induction. This is exemplified by the alkylation of the Schiff base derived from *tert*-butyl glycinate enolate and (1*R*)-(+)-camphor with fluorine-subtituted benzyl bromides.[45] Reaction proceeds with asymmetric induction to give the corresponding 4-fluoro- and 4-trifluoromethyl-phenylalanate Schiff bases (XIX and XX) with a d.e. of 98 and 76%, respectively. Hydrolysis of (XIX) and (XX) affords the corresponding (*S*)-aminoacid.



R = F, CF_3.

Stereoselective alkylation of chiral 4-imidazolidones (XXI) with pentafluorobenzyl or *p*-fluorobenzyl bromide also provides fluorine-containing aromatic aminoacids.[46,47] Thus, optically active α-methyl-4-fluorophenylalanine is obtained by alkylation of the diastereoisomeric alanine derivative (XXI), R = Me, with 4-fluoro-benzyl chloride, followed by hydrolysis.[48]

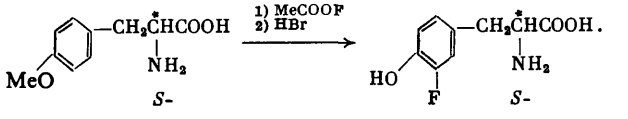


R = H, Me; Ar = 4-FC_6H_4, C_6F_5; Boc = $COOCMe_3$.

Asymmetric synthesis of (*S*)-fluorophenylalanines has been achieved from a homochiral nickel Schiff base complex prepared from (*S*)-2-[*N*-(*N'*-benzylprolyl)-amino]benzophenone and glycine.[49] Thus, complex (XXII) is alkylated with fluorobenzyl chlorides in DMF containing KOH to give a 95:5 mixture of the diastereoisomeric complexes, (*S,S*)- and (*S,R*)-(XXIII). The major isomer, (*S,S*)-(XXIII), may be isolated in optically pure form, and converted to the corresponding (*S*)-fluorophenylalanine (optical purity >99%) by treatment with HCl. The chiral prolyl ligand is also liberated and may be re-used.

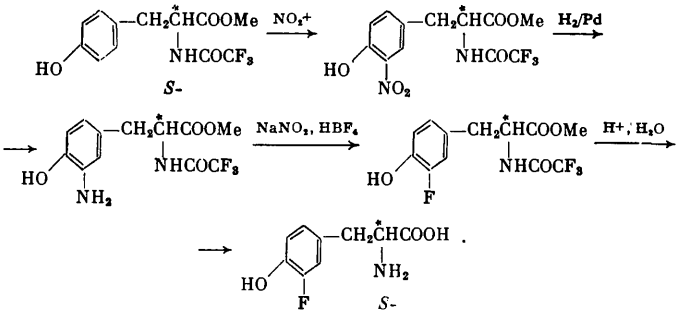
R = H, Me; Ar = 2-FC_6H_4, 3-FC_6H_4, 4-FC_6H_4.

A number of diastereoisomeric β-phenylserines may also be prepared by reaction of the chiral complex, (*S*)-(XXII), with fluorine-substituted benzaldehydes.[50]



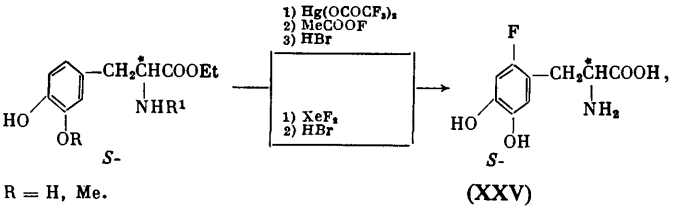
R = 2-F, 4-F 2-$OCHF_2$, 4-$OCHF_2$, 4-OCF_3, 3-CF_3.

3. Direct fluorination of enantiomeric aminoacids



One of the most viable routes to enantiomeric fluorine-containing aminoacids involves introduction of the fluorine atom into the aminoacid molecule with retention of optical activity. Such methodology avoids multistep sequences and is particularly useful for preparing [^{18}F]-fluorinated aminoacids. Elemental fluorine can be the fluorinating agent as well as such auxiliaries as acetyl hypofluorite and XeF_2.

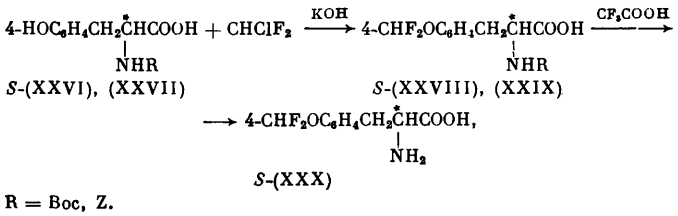
Thus, (*S*)-3-fluorotyrosine has been prepared via fluorination of *O*-methyl-(*S*)-tyrosine with acetyl hypofluorite.[51]



Enantiomeric (*S*)-monofluorophenylalanine and (*S*)-[3-^{18}F]-fluorotyrosine labelled with ^{18}F have also been obtained by this route.[52] Elemental fluorine has also been used for the ring-fluorination of aromatic aminoacids. Thus, treatment of a solution of tyrosine in hydrofluoric acid with N_2-diluted gaseous fluorine affords 3-fluorotyrosine in 46% yield, while fluorination of *O,N*-diacetyltyrosine in trifluoroacetic acid gives a 2:1 mixture of 2- and 3-fluorotyrosine.[53] (*S*)-Fluorophenylalanines with an ^{18}F label in the benzene ring were also prepared by this route;[54] the resulting mixture of labelled (*S*)-2-, (*S*)-3- and (*S*)-4-fluorophenylalanaine was separated by HPLC.

In order to avoid the formation of isomeric fluorine-containing aminoacids, methods have been devised for the regioselective introduction of fluorine atoms into the aromatic nucleus. This is exemplified by the synthesis of 3-fluoro- and 3,5-difluoro-(*S*)-tyrosine.[55]

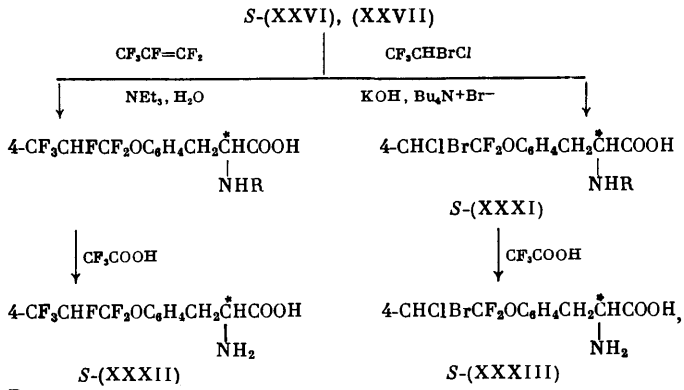
It is based on the nitration of a protected (*S*)-tyrosine derivative, followed by reduction of the nitro group and introduction of the fluorine atom by the Schiemann reaction. Reaction proceeds with retention of chirality at all stages of the conversion, and provides (*S*)-3-fluorotyrosine in 21% yield.



A procedure for introducing a fluorine atom regiospecifically at the 6 position of 3,4-dihydroxyphenylalanine has also been reported.[56] Thus, treatment of protected (*S*)- or (*R*)-3,4-dihydroxyphenylalanine derivatives with mercuric trifluoroacetate affords exclusively the corresponding 6-mercuri-derivatives, which are converted to the respective homochiral 6-fluoro-3,4-dihydroxyphenylalanines (XXV) in 20% yield via fluorination with acetyl hypofluorite. Homochiral (XXV) was also obtained via direct fluorination of a 3-methoxy-4-hydroxyphenylalanine derivative with xenon difluoride;[57] the yield of product after removal of the protective groups, was 25% (based on XeF_2). Both reactions proceed with retention of chirality.

R = H, Me. (XXV)

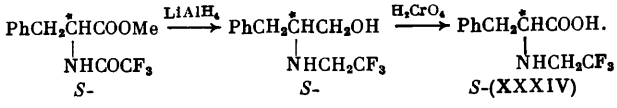
The procedure for polyfluoroalkylation of phenols[58] has recently been applied to the synthesis of polyfluoroalkylated (*S*)-tyrosine derivatives.[58] Thus, treatment of *N*-Boc-(*S*)-tyrosine (XXVI) or *N*-*Z*-(*S*)-tyrosine (XXVII) with chlorodifluoromethane in the presence of base affords the corresponding optically active *N*-protected *O*-difluoromethyltyrosine derivatives (XXVIII and



XXIX), which may be used in peptide synthesis as the carboxyl component.

R = Boc, Z.

The free aminoacid (XXX) was isolated by action of trifluoroacetic acid on the Boc-derivative (XXVIII). With the aid of ligand-exchange HPLC on a chiral stationary phase it was shown that the difluoromethylation proceeds without racemisation, and that the optical purity of (*S*)-(XXX) was >99.5%.



In a similar way,[58] *bis*(difluoromethylation) of *N*-Boc-(*R,S*)-3,4-dihydroxyphenylalanine affords 3,4-*bis*(difluoromethoxy)-(*R,S*)-phenylalanine in 14% yield. The interaction of (*S*)-tyrosine derivatives, (XXVI and XXVII), with hexafluoropropylene in aqueous triethylamine at 70 °C provides the corresponding 1,1,2,3,3,3-hexafluoropropoxy-(*S*)-aminoacids. On the other hand, the 4-polyhalogenoethoxy derivative of *N*-Boc-(*S*)-phenylalanine (XXXI) has been prepared by treatment of *N*-Boc-(*S*)-tyrosine (XXVI) with fluorothane, $CF_3CHBrCl$ (a commercially available inhalant-type anaesthetic), in 50% aqueous KOH containing $Bu_4N^+Br^-$ as phase transfer catalyst.

R = Boc, Z.

The corresponding unprotected polyfluoroalkoxy derivatives of (*S*)-phenylalanine (XXXII and XXXIII) were obtained by cleavage of the *tert*-butoxycarbonyl group in trifluoroacetic acid at 20 °C. The e.e. exceeded 95%, as was demonstrated by ^1H NMR spectroscopy with the aid of the chiral lanthanide shift reagent, Eu(hfc)$_3$. Thus, it has been confirmed that *O*-polyfluoroalkylation of *N*-protected (*S*)-tyrosine derivatives proceeds without racemisation.

Optically active methyl *N*-trifluoroacetyl-(*S*)-phenyalanate has been converted to *N*-trifluoroethyl-(*S*)-phenylalanine (XXXIV) by reduction with $LiAlH_4$, followed by oxidation of the resulting optically active aminoalcohol with Jones' reagent.[59]

IV. Possible fields of application

The replacement of hydrogen by fluorine in the aminoacid molecule does not introduce any steric hindrance since the van der Waal's radius of the atom fluorine is approximately the same as that of hydrogen. As a consequence, living organisms cannot normally distinguish fluorinated aminoacids from natural ones so that the former may be readily incorporated. This phenomenon is called the "masking effect", and is the rationale for using fluorinated aminoacids in biochemical and medical research into the study of metabolic pathways and the mechanism of action of various enzyme systems. In this respect, ^{19}F NMR spectrosocpic analyses and radioactive labelling (notably with the short-lived ^{18}F isotope) have been fruitfully applied in this field of research.

In studying the activity of phenylalanine-ammonia-lyase, it has been shown that deamination of (*S*)-4-fluorophenylalanine proceeds at half the rate of the same reaction with (*S*)-phenylalanine.[60] The substrate specifically of such enzymes as phenylalanine-*t*-RNA-ligase,[61] aspartate-transaminase,[62] chorismate-mutase,[63] lacto-peroxidase,[64] and tyrosine-phenol-lyase[65] has been studied by using 2-fluoro-, 4-fluoro- and 3,4-difluoro-phenylalanine as well as 3-fluorotyrosine. A study has also been made of the effect of molecular geometry and electronic charge distribution on the interaction of aminoacid oxidases with substrates and inhibitors;[6] a determination has been made of the correlation between the rate of degradation of aromatic aminoacids and the Hammett constant for substituents in the aromatic ring. 3-Fluoro- and 4-fluoro-phenylalanine were substrates for this study.

A study of the deactivation of leucocytic elastase by aromatic aminoacid derivatives has shown that deactivation is enhanced if there is a trifluoromethyl group in the *m*-position of the aromatic ring of phenylalanine. This is a consequence of an increase in the hydrophobicity of the molecule.[67]

By applying reverse-phase HPLC, a quantitative assessment has been made of the lipophilicity of phenylalanines containing fluoro-groups in the *p*-position. The change in free energy of sorption was measured as a function of the number of fluorine atoms in the molecule. The increase in hydrophobicity (π_x) for a series of fluorine-containing groups follows the order shown below.[58]

R_F	F	$OCHF_2$	$OCF_2CHClBr$	OCH_2CF_3	$SCHF_2$	OCF_3	SCF_3	OC_2F_5	OCF_2CHFCF_3
π_x	0.14	0.57	0.69	0.93	0.95	1.06	1.43	1.80	1.90

The initial study of 4-fluorophenylalanine metabolism showed that it was converted to tyrosine.[68] However, more recent research has revealed that the formation of tyrosine from 4-fluorophenylalanine proceeds six times more slowly than from phenylalanine.[69] This is explained by the higher C–F bond energy (116 Kcal/mol) relative to the C–H bond (99 Kcal/mol).

4-Fluorophenylalanine is a competitive antagonist of phenyl-alanine.[70] It also possesses fungicidal properties towards a number of pathogenic fungi which infect cucumbers and potatoes.[71]

A study of the physiological activity of 3-fluorotyrosine in mice has shown that this amino-acid, which participates in the normal metabolism of tyrosine, is converted to monofluoroacetic acid. The latter blocks the Krebs cycle, thereby inducing convulsions and death.[72]

A series of fluorinated derivatives of phenylalanine and tyrosine have been found to inhibit the growth of *Neurospora crassa*. 3-Fluorotyrosine is the most active inhibitor in this respect.[73] 2-Flurotyrosine also inhibits the growth of *Escherichia coli*,

Streptococcus faecalis, and other bacteria,[74] while 4-fluorophenylalanine inhibits the development of malignant tumours.[75–78]

In studying the substrate specificity of monoamine oxidase (MAO B)—an enzyme which plays a key role in the formation of neurotransmitters in the central nervous system (CNS)—it has been shown that β-fluoromethylene-*m*-tyrosine (VIII) is an effective irreversible inhibitor of MAO B in the presence of aromatic aminoacid decarboxylase.[79–81] β-Polyfluoromethyl-substituted phenylalanines and tyrosines (VI), which are structurally similar to aminoacid (VIII), have a sedative effect on the CNS.[5]

In studying the effect of introducing fluorine and trifluoromethyl groups at various positions of the phenylalanine and tyrosine ring on the opioid activity of enkephalin, it was demonstrated that substitution of phenylalanine by 4-fluorophenylalanine leads to a significant increase in enkephalin activity; however, introduction of a trifluoromethyl group at the *para*-position of phenylalanine, or substitution of tyrosine by 4-fluorophenylalanine, reduces the activity of the peptide.[82]

The decapeptide, P-Glu-*D*-*p*-F-Phe-Trp-Ser-Tyr-*D*-Ala-Leu-Arg-Pro-Gly-NH_2, having a (*R*)-4-fluorophenylalanine residue in the 2 position displays anti-ovulating activity in mammals,[83] while tripepetides with a (*S*)-4-fluorophenylalanine residue show analgesic activity.[84] Peptides containing fluorinated aromatic aminoacids, especially fluorophenylalanine, possess anti-tumour activity,[85] and have been used as medicaments.[86]

A large number of bradykinin and oxytocin analogues have been synthesised for studies of structure-activity relationships and the mechanism of action of these two peptides. Particular emphasis has been placed on susbtituting phenylalanine by 4-fluorophenylalanine (in oxytocin)[87] and by 3-trifluoromethylphenylalanine (in bradykinin).[88]

As fluorophenylalanine and fluorotyrosine derivatives participate in metabolic processes, they may be incorporated in proteins.[89,90] Thus, on administration of 4-fluorophenylalanine to rabbits, it was shown that this aminoacid is incorporated in the protein of muscles, the liver, and the blood (by replacing phenylalanine). Being incorporated in enzymes, 4-fluorophenylalanine may influence their activity, or have no effect at all, depending on the level of 4-fluorophenylalanine incorporation.[91]

[^{18}F] containing aromatic aminoacids are used for studying the metabolism of fluorinated aminoacids and enzymatic reactions.[92] On studying the distribution of 4-fluorophenylalanine-^{18}F in pig organs, it has been shown that most of the labelled aminoacid is incorporated in the pancreas.[93] Clincially, 4-fluorophenylalanine-^{18}F may be used for scanning this organ.[94,95]

A study of the metabolism of (*S*)-6-[^{18}F]-3,4-dihydroxyphenylalanine has shown that this compound is metabolised more quickly than ^{14}C-labelled 3,4-dihydroxyphenylalanine, which has shed light on the pathways by which this aminoacid is metabolised.[96]

^{19}F NMR spectroscopy has found widespread application in biological studies.[97] This is exemplified by a study of bacteriorodopsin containing 3-fluorotyrosine,[98] of the mechanism of transamination with 4-fluorophenylalanine in the presence of pyridoxal phosphate-dependent enzymes,[99] and of the enzymatic hydrolysis of 3-fluorotyrosine phosphate.[100]

---o0o---

From this analysis of published data, it is clear that fluorine-containing aromatic aminoacids have a valuable application in the following areas: specific modification of physiologically active peptides; the study of the structure and mechanism of action of complex biologically active molecules with the aid of ^{19}F NMR; and the preparation of effective regulators of bio-systems. Thus, the development of new methods of synthesis of fluorine-containing aromatic aminoacids, especially optically active derivatives, is both timely and potentially fruitful.
