In a number of studies,[129,137,138] the hypothesis was put forward that the changes in activity and selectivity following a change of carrier are associated with the presence of Ni^{n+} in Ni/Al_2O_3 and Ni/SiO_2 and its interaction with Ni^0. It has been suggested that the electron transfer from Ni^0 to Ni^{n+} increases the strength of the C–O bond in the adsorbed state, diminishing the probability of its dissociation. Thus the following series of specific activities (per m^2 Ni) in the CO + H_2 reaction on nickel in the "normal state", expressed in arbitrary units relative to Ni/SiO_2, has been explained[138] by precisely this factor: 14% Ni/TiO_2 (15) > 24% Ni/ZrO_2 (8) > 21% Ni/Al_2O_3 (2) > 24% Ni/SiO_2 (1); the same explanation was also used to account for the selectivity of the Ni/TiO_2 and Ni/ZrO_2 catalysts being higher by factors of 2 and 3 respectively compared with Ni/SiO_2. A decrease in the activity of nickel in the SIMC state has been noted for Ni/TiO_2 and Ni/ZrO_2. Treatment with O_2 and subsequent low-temperature reduction restore the initial activity to these catalysts.

Thus the question of the unique catalytic properties of metals deposited on TiO_2, Nb_2O_5, ZrO_2, and certain other carriers in the CO + H_2 reaction remains open and requires further studies.

Examples of other reactions in which the influence of the SIMC on the catalytic properties of deposited metals was investigated are fairly rarely encountered in the literature. These exist data on the catalytic activity of platinum deposited on TiO_2 doped with the Ta^{5+}, Sb^{5+}, and W^{6+} cations (to test the hypothesis concerning the nature of the SIMC involving electron transfer) in the CO + O_2 and CO + H_2O reactions.[139] Under these conditions, the activity of the doped catalysts in the first reaction is reduced by a factor of 3–5 and the activation energy is increased by 45%, while in the second reaction the activity falls by a factor of 80. An increase in the activity of the Rh/TiO_2 and Pt/TiO_2 catalysts in the SIMC state has been noted[140,141] in the CO + NO reaction. There are contradictory data for the acetone hydrogenation reaction as regards the SIMC effect. Thus a sharp decrease in the activity of the Rh/CeO_2 catalyst has been observed[142] after its reduction at 653 K, while the activity of Pt/TiO_2 in the SIMC state increased appreciably.[143] An elegant study of the catalytic properties of the Ir/Nb_2O_5 system reduced at 473 K ("normal" state) and at 773 K (SIMC state) in the acroleine hydrogenation and deuteriation reactions has been carried out by Japanese workers,[144] who established that mainly allyl alcohol is formed on the catalyst in the SIMC state at 353 K, and not propanol as on the catalyst reduced at 473 K. The activation energy for the formation of the main product falls from 12 kJ mol^{-1} (for the normal state) to 5 kJ mol^{-1}, while the activation energy for the formation of propanol increases from 12 to 35 kJ mol^{-1} respectively. Active centres of two types were identified with the aid of a kinetic study of the rate of formation of each product as a function of the catalyst reduction time in combination with the study of the distribution of the hydrogen isotopes in acroleine, allyl alcohol, and propanal. The formation of propanal, CH_2 = CDCHO, and of part of allyl alcohol and the dissociation of D_2 takes place on purely metallic centres, while CHD = CHCHO and the remainder of the allyl alcohol are formed on metallic centres adjoining the boundary of the NbO_x "islands", which appear on the catalysts reduced at 773 K.

IV. The apparent effects of the strong interaction of a metal with the carrier

It is frequently assumed nowadays that the change in the catalytic properties of deposited metals combined with the loss of ability to absorb H_2 and CO constitutes convincing evidence for the existence of the SIMC. It is therefore useful to examine certain effects erroneously interpreted as true manifestations of the SIMC.

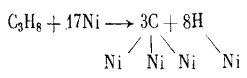
In the first place, the sintering of metallic particles at elevated reduction temperature lowers the activity of the metal surface and hence diminishes its chemisorption capacity and alters the activity and selectivity of the catalyst. It is therefore essential to monitor the metal particle size at different reduction temperatures. Furthermore, the active surface of the metal can decrease as a result of the migration of the metal into the carrier, as in the case of the Fe/TiO_2 system. In this instance, comparison of the specific activities per gramme of the metal with those of other catalysts yields undistorted information only when additional data are secured by adsorption, X-ray diffraction, X-ray photoelectron spectroscopy, analysis of the extended fine structure of the X-ray absorption spectra, etc.

One must not forget that the surface of the metal contaminated in some way (poisoned, for example, by sulphur or iron impurities which may be present in the carrier[145] or the Cl^- anions remaining after the preparation of the catalyst from metal chlorides[107]) is incapable of adsorbing H_2 and CO or can adsorb them to a much lesser extent than the clean surface, and has significantly different catalytic properties. When catalysts consisting of a metal deposited on SiO_2 and especially on Al_2O_3 are obtained by impregnation with acid solutions, a very small proportion of the carrier can dissolve and ultimately, after reduction at elevated temperatures, can form a film or "islands" of oxygen-deficient SiO_x and Al_2O_x on the surface of the metallic particles, as a result of which the properties of the catalyst change qualitatively, as in the metal–TiO_2 system in the SIMC state.[146,147] Thus, on raising the reduction temperature of the Pt/Al_2O_3 and Pd/Al_2O_3 catalysts from 523 to 773 K, their activity in the CO + H_2 reaction at 498 K increases by factors of 5.1 and 1.8 respectively.[146]

It is essential to recall that Group VIII metal cations exhibit a certain tendency to react with aluminium and silicon oxides to form aluminates and silicates, which are difficult to reduce, or solid solutions which are also not easy to reduce on heating.[137,148,149]

If the active specific surface of the metal and the degree of its reduction are known, this does not create serious difficulties in the study of the SIMC. However, account must be taken of the influence of the non-reduced cations on the behaviour of the reduced metal in view of the possible electron transfer.[138,150] There are data showing that certain carriers, especially alumina, can stabilise the metal in intermediate states such as Rh^+, Pt^{3+}, Re^{4+}, and Ni^+ and can thus inhibit their reduction.[151–153]

The energetic, electronic, and geometrical properties of deposited metallic particles can be simultaneously modified by the metal–carrier interactions and by changes in the properties of the metal—both bulk-phase and atomic. Both effects become very important when the size of the metallic particles is reduced and, as noted by Bond[4] and Ponec,[8] it is not always easy to separate the contributions of these two effects to the adsorption and catalytic properties of metals.



In the analysis of the dependence of the catalytic properties of deposited metallic crystals on their structure, it has been suggested[154] that three cases of structure-sensitive reactions be distinguished: (a) structural sensitivity for which the rate of reaction depends on the dispersity of the crystals which influences the number of specific centres in them (for example B_5 centres) is referred to as the primary structural sensitivity; (b) cases where the rate of reaction is independent of dispersity when the reaction is carried out under "clean" conditions but becomes structure-sensitive on partial poisoning of the surface of the catalyst (as already mentioned above) constitute a group of phenomena which are referred to as secondary structural sensitivity: (c) finally the third type of structural sensitivity may be due to the change in the electronic properties of crystals when their size is altered.

We shall now quote several examples. A study has been made[155] of the influence of the nickel particle size in the range 22–100 Å on selectivity of the propanol hydrogenation reaction at 473 K in the presence of Ni/SiO_2 catalyst. A sharp increase in selectivity with respect to propanol for a nickel particle size less than 50 Å was established. Taking into account the increase in the fraction of apical and edge atoms relative to the total number of surface atoms with decrease in crystal size, the authors concluded that the aldehyde is hydrogenated on edge and apical nickel atoms, while decomposition takes place on the planar surface of the crystal.

Apart from the number of edge and apical atoms and specific centres whose concentration is determined by the dispersity of the crystal, the ratio of different faces, whose activities in relation to the given reaction sometimes differ greatly, may vary on the surface of the crystal.[156] Thus, in order to account for the change in selectivity in the reaction of neopentane on platinum, it has been suggested[157] that neopentane isomerises via its three-point adsorption on atomic triplets located in the (111) plane and that the contribution of the isomerisation reaction increases with increase in the concentration of these faces on the surface. This result was confirmed in other studies.[158,159]

The Ni/SiO_2 catalyst containing nickel crystals oriented along the (111) plane and non-oriented crystals[160] exhibited different catalytic properties in the benzene hydrogenation and cyclohexene disproportionation reactions.[161] Whereas the rates of the first reaction were virtually the same on both catalysts, the second reaction was faster on the oriented crystals.

Analysis of the mechanism of the structure-sensitive and insensitive reaction involves directly the elucidation of the structure of the catalytically active centre, which may consist of a group of several atoms. Thus the hydrogenolysis of C_3H_8 can proceed on an assembly of 17 nickel atoms in accordance with the scheme[162]

A decrease in the rate of reaction is then observed for small nickel particles as their size diminishes further.

The influence of dispersity on the catalytic properties is manifested not only by a change in the rate and selectivity of the reaction but also by a change in the nature of the chemisorption bond in the adsorption stage as a function of the size of the crystals. For example, in a study of the adsorption of H_2 on nickel microcrystals deposited on SiO_2,[163] it was shown that the fraction of the irreversibly chemisorbed H_2 is related to the fraction of surface nickel atoms located on the edges and on the apices of the crystals. The different coordinative states of the surface metal atoms, which depend on the dispersity, influence significantly the form of the adsorption of CO, which was demonstrated[164] in relation to the Ni/SiO_2 and Ni/Al_2O_3 catalysts over a wide range of nickel crystal sizes and in another study[165] of the interaction of CO and H_2 on Ni/SiO_2 catalysts. It has been noted[166] that the form of the platinum particles themselves can change in the course of the adsorption of H_2 and CO on Pt/SiO_2 catalysts and hence their catalytic properties are also altered.

In a study of the adsorption of H_2 and CO on highly dispersed iridium deposited on Al_2O_3, it was shown that the H/Ir and CO/Ir ratios approach two and that this is not associated with the spill-over effect.[167] It has been established that such a high H/M ratio is characteristic of adsorption on atomically dispersed iridium and not on corner and edge atoms of small crystals because the stoichiometric adsorption on iridium crystallites smaller than 6 Å is approximately unity.

We shall now turn our attention to the electronic properties of the metallic crystals and clusters themselves as a function of their size without taking into account with the influence of the carrier. The general postulates concerning this problem have been described in another review:[10]

1. Depending on the number of atoms (n) in the cluster, the latter can have different structures (linear, two-dimensional, three-dimensional) and for $n > 10$ the three-dimensional crystals are probably more stable than the linear and two-dimensional structures. According to the results of calculations, among three-dimensional structures there may be a tetrahedron, a square pyramid, a pentagonal pyramid, a trigonal bipyramid, a triangular prism, or an icosahedron, i.e. structures which are not characteristic of massive metals. The icosahedral structures of small palladium and nickel clusters are apparently more stable than the face-centred cubic structures, which are in their turn preferred for copper and silver clusters.

2. The bond energy in the cluster calculated per atom is smaller than in the crystal, but increases with increase in n. The average bond energy in cubic and octahedral crystals with $n > 50$ does not differ very greatly from the energy of macrocrystals. In many cases, the equilibrium distances between atoms in the cluster are greater than in the metal lattice.

3. The ionisation potential of the cluster is greater than the electronic work function of the metal and diminishes with increase in the size of the cluster, approaching the electronic work function of the massive metal. Thus the electronic work function depends on the dispersity of the metal.

4. In the copper, silver, gold, and nickel clusters, the population of the *d* atomic orbitals is increased by virtue of the *p* atomic orbital [sic] compared with the $d^8s^1p^2$ configuration (the Engel-Brewer rule), while for the palladium cluster the population of thd *d* atomic orbitals increases with increase in *n*, approaching the value for the massive metal, i.e. the *d* character depends on the dispersity of the metal. It has been shown that for nickel the average magnetic moment per atom diminishes with decrease in *n*, amounting to 0.46 μ_B for Ni_{13} and 0.25 μ_B for Ni_8 compared with 0.54 μ_B for crystalline nickel.

5. With increase in the size of the cluster, the levels of the individual atoms are grouped into bands and the width of the *d* band increases with increase in the size of the cluster. The width of the forbidden gap then diminishes. It is of interest to note that all the possible features of the bulk-phase band structure are observed for the cubooctahedral Ni_{13} and Pt_{13} clusters.

In conclusion of this chapter, one should also mention a series of important factors which complicate the study of the SIMC effect. These are the reversibility of the SIMC as a function of the reaction conditions,[168,169] its sensitivity to the presence of water[169,170] and its relation with the spill-over of hydrogen,[171–173] the dependence on the way in which the catalyst is obtained,[34,37,174] and the presence of strongly retained forms of hydrogen.[175]

* * *

Summarising briefly the data presented above, one may note that the attention devoted by many investigators to the experimental and theoretical study of the SIMC effect has led to a sharp increase in the number of studies designed to elucidate the physicochemical and catalytic properties of deposited metallic catalysts. This fact is itself important because the above group of catalysts is of significant interest for industry. However, here one should note that the SIMC effect is frequently used to explain changes in adsorption and catalytic properties induced by completely different causes, for example by a change in the dispersity of the deposited metallic particles as a function of the nature of the carrier and the amount of the deposited metal, the complete encapsulation of the metal particles in the bulk of the carrier on sintering, the spill-over phenomena, etc.

Such a broad treatment of the phenomenon hinders to some extent its objective study and analysis and it is therefore useful, in our view, to restrict the consideration of the SIMC effect to the following phenomena, which influence the adsorption and catalytic properties: (a) the change in the electronic structure of the metal atoms or clusters located on the carrier and also in the electronic structure of the atoms at the metallic crystal–carrier interface; (b) the formation, as a consequence of the reduction of the carrier, of metal atoms doping the deposited crystals of the catalytically active metal; (c) partial shielding of the surface of the deposited crystals by a creeping film of the carrier accompanied by a change in the energetic, structural, and electronic properties of the surface.

Naturally, it is sometimes difficult to isolate these phenomena in a pure form and the application of a set of modern physicochemical methods and a wide variation of the procedures used to prepare the given deposited metallic catalysts are essential conditions for the understanding of the mechanism of the SIMC effect and for the synthesis of new effective catalytic systems.

Inhibition and synergism in phase transfer catalysis

F S Sirovskii, V N Mochalov, M V Panova
State Research and Design Institute of the Chlorine Industry, Moscow

ABSTRACT. Questions concerning inhibition and synergism in phase transfer catalytic reactions in various systems are examined. Effects induced by the decomposition of the catalyst during the reaction and also by the introduction of various reagents and additives are analysed. Factors giving rise to synergistic and inhibition phenomena are considered.

I. Introduction

The phenomenon of the synergism and inhibition of catalysts is well known in homogeneous and heterogeneous catalysis. In some cases, the mechanism of the action of promoting agents and catalytic poisons has been investigated and catalytic systems ensuring a high selectivity of reactions have been created. There are numerous patents devoted to the use of the synergistic effect in industrial processes.

The same effects involving the synergism and inhibition of catalysts have been observed also in phase transfer catalytic reactions. However, in this field synergism has been studied to an extremely slight extent. Whereas inhibition, albeit induced by different causes, is encountered fairly frequently, synergism is manifested much more rarely and to date it is generally considered to be a kind of exotic phenomenon. It is therefore useful to consider initially inhibition, since this effect has been better investigated and is more common.

The inhibition of a phase transfer catalytic reaction, understood in a broad sense, can be induced by a whole series of factors which will be considered below.

For the benefit of readers who are not familiar with the details of the problem, it is useful to explain briefly the essential features of phase transfer catalysis itself before considering specific effects. It consists in the fact that contact between two reactants in immiscible phases (a liquid–liquid or a liquid–solid system) is possible by virtue of the presence of a transferring substance — the phase transfer catalyst. Such transferring agents are as a rule quaternary onium salts. These substances effect either the transfer of a reactant into one of the phases (for reactions in a liquid–liquid system with a neutral aqueous phase) or the removal of the product from the reaction zone (for reactions involving concentrated solutions of alkalis). It is hardly possible within the framework of a single review to consider in detail the principles of phase transfer catalysis.

A number of designations have been adopted in the literature on phase transfer catalysis. The quaternary onium salt is usually designated by QX or Q^+X^-, where $Q(Q^+)$ is the quaternary onium cation and $X(X^-)$ is the anion (usually inorganic) or by the term "quat" from the word "quaternary". The subscripts "wph" and "oph" or "w" and "org" refer to the reagents and the catalyst in the aqueous and organic phases respectively. The symbol $MY(M^+Y^-)$ is understood as the inorganic reagent, where M is the metal cation and Y the anion. Subsequently this notation will be used without further explanation.

II. Inhibition in a liquid–liquid system

1. Inhibition as a result of the poisoning of the catalyst by extraneous anions

This type of effect was first observed by Starks and Owens.[1] It was noted that the interphase reaction of alkyl iodides with sodium cyanide, i.e.

$$RI + NaCN \xrightarrow{quat} RCN + NaI,$$

ceases after the attainment of 15–25% conversion.[1] It is usual to explain this by differences between the mutual extractabilities of the reactant ion (Y^-) and the departing ion (X^-) or the catalyst counterion (Z^-).

Such a difference in the reaction of the type

$$RX + M^+Y^- \xrightarrow{quat} RY + M^+X^- \qquad (1)$$

can be described with the aid of the ion-selective equilibrium constant $K^{sel}_{Y/X}$ (Gordon and Kutina[2]):

$$K^{sel}_{Y/X} = (C^{X^-}_{wph} \cdot C^{QY}_{oph})/(C^{Y^-}_{wph} \cdot C^{QX}_{oph}),$$

where $C^{Y^-}_{wph}$ and $C^{X^-}_{wph}$ are the concentrations of the reactant anion and the leaving anion respectively and C^{QY}_{oph} and C^{QX}_{oph} are the concentrations of different forms of the catalyst. The above constant determines the effectiveness of the catalyst in reaction (1).

$K^{sel}_{Y/X} < 0.1$ corresponds to the "poisoning" of the catalyst. Reaction profiles corresponding to different values of $K^{sel}_{Y/X}$, which makes it possible to select approximately a catalyst effective in the given system, have been published.[2] However, the special case where the catalysts 'own' counterion Z^- differs from both the reactant ion (Y^-) and the ion of the leaving group (X^-), i.e. in the system where there are three different anions, was not considered in the above studies. Theoretical examination of this version[3] showed that, even for $K^{sel}_{Z/X} \leqslant 10$, the "poisoning" effect can be avoided by taking a

tenfold excess of the inorganic reagent (M^+Y^-) relative to the substrate (RX). If $K^{sel}_{Z/X} \leqslant 1$, there is no poisoning even for a stoichiometric ratio of the reactant and the substrate. Hence it was concluded that the catalyst should be introduced into the reaction in the form Q^+X^-, i.e. when its counterion is identical with the leaving group. For $K^{sel}_{Z/Y} < 1$, the initial rate is higher if the catalyst is added in the form Q^+Z^- and not Q^+Y^-. The opposite effect is manifested for $K^{sel}_{Z/Y} > 1$.

The study of the "poisoning" of the catalyst by extraneous anions in processes occurring in the presence of alkalis, which is associated with the presence of an admixture of chlorates in technical alkali,[4] is very important. The quantity $\lg K^{sel}_{ClO_3/OH}$ is approximately 2. This means that chlorate is a powerful catalytic poison in reactions involving the hydroxide ion. Other lipophilic anions are inhibitors in reactions of this kind. For example, in the alkylation of acetone by alkyl halides in an alkali–organic phase system (catalyst—quaternary ammonium salt), the addition of sodium tetraphenylborate to the system stopped the process as a result of the removal of the catalyst from the reaction zone.[5]

The study of the inhibiting effect of extraneous anions by chemical kinetic methods[6] in relation to alkaline dehydrochlorination of 3,4-dichlorobut-1-ene made it possible to determine the corresponding inhibition constants. For this purpose, a series of inorganic salts were added to the reaction system. The familiar reversible inhibition model was used for the description of the results.[7] The dependence of the rate of reaction on the substrate concentration was expressed in a linear form in terms of double reciprocal variables (the Lineweaver–Burke plot), the effective rate constant was then determined. The following series based on the decrease in the inhibiting capacity of the anions was obtained: ClO_3^- (1) > NO_3^- (0.6) ≃ Cl^- (0.64) ⩾ SO_4^{2-} (0.24), where the inhibition constants are given in brackets. This sequence agrees quite well with the available data[8] for the relative lipophilicities of these anions.

Table 1. The influence of the catalyst counterion on the rate constant k_{obs} in the isomerisation of allylbenzene.[9]

Catalyst	$10^3 k_{obs}$, s^{-1}	Induction period, min	e_{QZ}*
MBu_4HSO_4	114	<0.1	$5.75 \cdot 10^{-2}$
NBu_4Cl	24	1.3	0.35
NBu_4Br	2.4	10	17

Note. Reaction conditions: 40% NaOH, catalyst—5 mol%, temperature 75 °C.
* The Brandstrom extraction constants e_{QZ} were taken from Ref. 11 for the water–methylene chloride system.

The influence of the catalyst's "own" counterion on the rates of different reactions occurring in the presence of alkalis has been examined.[9,10] In the study of the isomerisation of allylbenzene under the influence of an aqueous NaOH solution to a mixture of (*Z*)- and (*E*)-β-methylstyrenes,[9] the dependence of the rate constant and the induction period of this reaction on the catalyst counterion was found (Table 1). In this case, there is no departing group, i.e. the system contains only the Y^- (in the given instance OH^-) and Z^- anions. The dependence of $\lg k_{obs}$ on $\lg e_{QZ}$ (where e_{QZ} is the Brandstrom extraction constant[11]) is linear with a correlation coefficient of 0.995. However, since these data were obtained for only three catalyst, it is difficult to make any broad generalisations.

A similar influence of the catalyst counterion on the rates of dehydrochlorination of *m*-bis(α, β-dichloromethyl)benzene and *m*-bis-(α-chlorovinyl)benzene in the presence of tetrabutylammonium salts has been noted.[10] The usual extraction system was used to describe the reaction kinetics. The catalysts were the following tetrabutylammonium salts: the bromide, chloride, sulphate, and hydroxide. The activities of the sulphate and the hydroxide were virtually identical while on passing to the chloride and even more so to the bromide the rate of reaction fell appreciably, particularly in the initial period. Thus the lipophilic properties of the leaving anion and the catalyst counterion play a significant role in reactions involving not only neutral salts but also alkalis. However, the data obtained recently show that not everything proceeds quite so simply and smoothly. If in the estimation of the influence of the anions one is guided solely by the lipophilicity, one may conclude that quaternary ammonium iodides are in general ineffective in any phase transfer catalytic reactions. This has indeed been confirmed in a number of studies[1,11] and has led to the creation of the fairly well established view that these salts have no potential as catalysts.

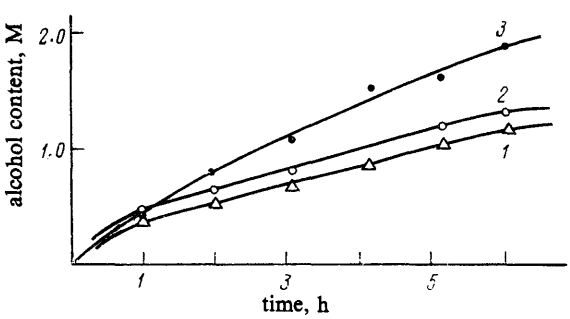

Figure 1. Hydrolysis of 2,3-dichloropropene using different phase transfer catalysts;[13] *1*, catamine; *2*, NBu_4Nr; *3*, NBu_4I. The amount of catalyst used was 10 mol% relative to the initial compound.

However the thesis that the activity of quaternary ammonium iodide is low in any phase transfer catalytic reactions is disproved both by data[12] on the alkylation of 2-methylacetoacetic ester (MAAE) and by the results of a study of the hydrolysis of 2,3-dichloroprop-1-ene to β-chloroallyl alcohol.[13] In the latter case, quaternary ammonium iodides proved to be appreciably more active as catalysis of the hydrolysis than the chlorides (Fig. 1). It was suggested[13] that the reaction proceeds via the mechanism

$$CH_2{=}CHCl{-}CH_2Cl + Q^+I^- \rightarrow [CH_2{=}CHCl{-}CH_2I],$$

$$CH_2{=}CHCl{-}CH_2I + NaOH \rightarrow CH_2{=}CHCl{-}CH_2OH,$$

which includes the intermediate formation of 2-chloro-3-iodoprop-1-ene, which should be hydrolysed much more readily than the initial compound (although the results of chromatographic analysis of the reaction mixture did not provide grounds for hypotheses of this kind). However, bearing in mind the fact that in the alkylation of MAAE by prenyl chloride in the presence of KF the exchange of chlorine for iodine does not occur when quaternary ammonium iodides are used as catalysts[12] and their increased catalytic activity is caused by the nucleophilic catalysis by the iodide anion, one may confidently postulate that the role of the iodide anion is similar also in the hydrolysis of 2,3-dichloropropene.

Table 2. The half-lives of quaternary ammonium salts in the chlorobenzene–50% NaOH two-phase system in the presence (A) and absence (B) of a molar excess of the salt NaY with a like counterion.

* The quantity ΔE_{act} was estimated approximately on the basis of two temperatures.

** The reaction takes place in the solid NaOH–PhCl system.

*** The reaction takes place in the CH_2Cl_2–50% NaOH two-phase system.

In all probability, the directly opposed effects induced by the presence in the system of highly lipophilic anions such as the bromide and the iodide, i.e., on the one hand, the inhibition of the reaction, observed in a number of studies,[1,5,9,11] and, on the other hand, the acceleration of the reaction under the influence of the same iodide anion, established in other investigations,[12,13] are induced by the difference between the mechanisms of the reactions investigated.

The dehydrochlorination of chlorohydrocarbons and the isomerisation of allylbenzene take place in liquid–liquid systems and have a common rate-limiting stage—the deprotonation of the substrate by QOH at the interface between the phases or in the bulk of the organic phase. Naturally, anions more lipophilic than OH^- effectively inhibit this process. The hydrolysis of 2,3-dichloropropene is a substitution reaction of the S_N2 type and I^-, which is more nucleophilic than OH^-, catalyses it. The somewhat greater effectiveness of iodides in the alkylation of MAAE on solid KF, where deprotonation takes place on a solid surface, is believed[12] to be caused by the smaller Q^+-X^- bond energy.

These results show that, in estimating the influence of the counterion, one cannot use as a basis solely its lipophilicity without taking into account the mechanism of the main reaction.

A phenomenon of a similar nature—nucleophilic catalysis by an extraneous ion—has been observed in the alkaline hydrolysis of n-BuBr and benzoyl chloride.[14] In the presence of 60% NaOH solution, aliquat 336, NBu_4HSO_4 (or NBu_4Br), both hydrolysis and the formation of an ether are very slow: the degree of conversion of benzyl chloride into dibenzyl ether after 24 h at 100 °C is 71%. The addition of 10 mol% of sodium acetate to the solution leads to the full termination of the reaction after 3 h. In contrast to the alkylation of MAAE,[12] where there was no exchange of the halogen between the alkyl halide and the extraneous anion (I^-), the intermediate formation of acetates, which undergo alkaline hydrolysis to a much greater extent, was noted in the given instance. The alcohol formed as the alkoxide is transferred by the quaternary salt to the organic phase where an ether is formed. The ratio of the products obtained on hydrolysis makes it possible to establish the sequence based on the relative extractabilities of the ions: $OR^- > AcO^- > OH^-$.

2. Inhibition as a consequence of the decomposition of the catalyst

This version of the inhibition occurs in catalysis by the ammonium salts of reactions which take place in the presence of alkalis at a high temperature. The quaternary ammonium base decomposes via the Hofmann reaction or the Menshutkin retroreaction or via both processes simultaneously. Thus, benzoyl alcohol, dibenzyl ether, hexadecane, dimethylhexadecylamine, and dimethylbenzylamine were detected among the decomposition products of the catalyst $[C_6H_5CH_2N(CH_3)_2C_{16}H_{33}]^+Cl^-$ used to generate dichlorocarbene.[15] The decomposition products of triethylbenzylammonium chloride (TEBA) under the conditions of the acetone alkylation reaction were benzyl chloride, benzyl alcohol, and dibenzyl ether,[5] i.e. the catalyst decomposed via the Menshutkin retroreaction. The decomposition of a whole series of quaternary ammonium and phosphonium salts has been investigated semiquantitatively[16] in the chlorobenzene–50% NaOH two-phase system and the stability of the salts was estimated from the half-life.

The ammonium salt decomposed in the general case in accordance with the equation

$$RN^+R_3'Y^- + NaOH \rightarrow R_3'N + R_2'NR + R''CH{=}CH_2 + \\ + R_2O + NaY + H_2O.$$

Symmetrical and asymmetric tetraalkyl derivatives decompose mainly via the Hofmann reaction while benzyl-substituted salts decompose via the Menshutkin retroreaction. Similar data have been obtained also by other workers.[5,15] Factors such as the nature of the heteroatom and the counterion, the structure of the alkyl chain, the reaction temperature, and the presence of a salt with a like counterion were investigated. The results are presented in Table 2.

Although it has been stated in the early and familiar monograph of Weber and Gokel[17] with a reference to Herriott and Picker[18] that phosphonium ions are more thermally stable than the corresponding ammonium catalysts, the results of Landini et al.[16] contradict this view which is in general widely held. It is essential to note that in the original study of Herriott and Picker[18] it is also claimed that, although phosphonium salts are more active than ammonium salts, they undergo thermal decomposition and side reactions to a much greater extent. Thus according to the data of Herriott and Picker[18] benzyltriphenylphosphonium chloride decomposes even under mild conditions 30 °C, 2 N NaOH). It is therefore incomprehensible whence arose the idea that quaternary phosphonium salts are more stable in the presence of alkalis. This has also been repeated in the monograph of Dehmlow and Dehmlow.[19] As can be seen from Table 2, all ammonium salts are appreciably more stable than the phosphonium salts. The high stability of the symmetrical tetraalkylammonium salts falls after the introduction of the benzyl substituent and increases in the sequence chlorides $\ll$ bromides $<$ iodides. Interpretation of data [16] on the influence of the concentration of alkali on the decomposition of a quaternary salt (Table 3) showed that the observed pseudo-first-order rate constant (determined as the reciprocal of the half-life $\tau_{1/2}$) is correlated fairly well with the activity and basicity of the alkali (r = 0.955, 0.968), at any rate in the case of tetrahexylammonium chloride.

Table 3. The influence of the NaOH concentration on the half-life of quaternary onium salts in the chlorobenzene–aqueous alkali two-phase system at 60 °C.[16]

The available literature data on the stability of phosphonium salts in the presence of alkali are fairly contradictory. Compared with ammonium salts, these compounds are stable on heating, decomposing at temperatures above 300 °C.[20] On the other hand, the rate constant for the reaction of tetrabenzylphosphonium iodide with NaOH at 39 °C is 2.72 litre mol^{-1} min^{-1},[21] which is greater by approximately three orders of magnitude than the decomposition constant of benzyltrihexylammonium chloride under analogous conditions (the above value was estimated from the data of Landini et al.[16]). In another place in the same monograph,[19] it is stated that benzyl-substituted phosphonium salt are less stable than their ammonium analogues in the presence of NaOH. The contradiction between these data is due to the different reaction conditions.

It is noteworthy that the inhibition due to the decomposition of the catalyst differs kinetically from that considered in the previous section. Whereas in the inhibition induced by the poisoning of the catalyst by extraneous anions a sharp fall of the reaction rate is observed after the attainment of a specific threshold degree of conversion, in the given instance the rate of reaction falls gradually. Formally this phenomenon is described as first-order irreversible inhibition of the catalyst.[7] The kinetics of the decomposition of the catalysts were investigated in relation to the dehydrochlorination of the α-isomer of hexachlorocyclohexane catalysed by katamin AB.[22] The rate of this reaction was described adequately by the equation

$$\ln\{[C_6H_6Cl_6]/[C_6H_6Cl_6]_0\} = k_1[NaOH]c_{cat}[1-\exp(-k_2\tau)]/k_2,$$

where k_1 and k_2 are the effective rate constants for the dehydrochlorination and decomposition of the catalysts respectively and τ is the reaction time. The activation energies for these two reactions are 54 and 68 kJ mol^{-1} respectively. Istomin's data for the decomposition of the tetrabutylammonium hydroxide catalyst, which occurred independently of the main reaction, have been published.[10] The decomposition was found to be a zero-order process with a rate of reaction (r_{decomp}) independent of the current concentration of the catalyst:

$$r_{decom} = k^{eff}_{decomp},$$

where k^{eff}_{decomp} is the pseudo-zero-order rate constant for the decomposition of the catalyst.

However, the rate of reaction is a function of the initial catalyst concentration:

$$k^{eff}_{decomp} = k^0_{decomp} + k^1_{decomp}c^0_{cat},$$

where k^0_{decomp} and k^1_{decomp} are the rate constants for the decomposition of the catalyst at the interface and in the bulk of the film containing the catalyst.

This type of dependence can be achieved by the fact that, in the presence of highly concentrated alkali, the main bulk of the catalyst is concentrated in the film at the interface.[8] The catalyst in this film supplies the organic phase and the observed rate of its decomposition therefore remains constant as a function of time. The rate of decomposition of the catalyst depended very greatly on the basicity function (H_-):

$$\lg k^{eff}_{decomp} = (-17\pm1)+(0.77\pm0.09)H_-(r=0.982).$$

The activation energy for the decomposition of the catalytst is approximately 110 kJ mol^{-1}, while the activation energy for the dehydrochlorination reaction is lower by a factor of two. Thus the data in Refs. 22 and 10 agree. From this it follows that, when the dehydrochlorination takes place at a high temperature, then a constant supply of the fresh catalyst to the reaction mass is necessary to maintain its concentration at the required level.

III. Inhibition in a solid–liquid system and inhibition by onium salts

The inhibition effects are also manifested in solid–liquid systems. This is associated, firstly, with the adsorption–desorption of the substrate and catalyst on the solid surface and, secondly with the enormous role of water in phase transfer catalysis. As noted in a familiar monograph,[17] this role is "like the weather, discussed a lot but little understood". Hitherto the influence of water has been studied somewhat more effectively, but the discrepancy beween the data quoted has diminished little. Different workers reach diametrically opposite conclusions, which is apparently caused both by experimental errors and by the not always correct interpretation of the results. Nevertheless, the popularity of solid–liquid systems has been increasing, since the reaction proceeds at a higher rate in the absence of water as a consequence of the increased nucleophilicity of the anions. Furthermore, in certain cases the Gibbs free energy of reaction (2) in "dry" systems is greater and hence the equilibrium degree of conversion in substitution reactions of the type

$$RX + Y^- \rightleftarrows RY + X^- \qquad (2)$$

is higher.

The role of water in the reactions with participation of alkali is also considerable, since it is known that the basicity of the hydroxide ion in the absence of water of hydration is appreciably greater.[23]

The influence of water in substitution reactions in a solid–liquid system has been investigated.[24] It was established that, for X = Cl^- or Br^- and Y = F^-, Br^-, Cl^-, $HCOO^-$, or $MeCOO^-$ (in the forms of salts with K^+ or Na^+) and R = C_6H_{13}, C_8H_{17}, $C_{10}H_{21}$, or $PhCH_2$, reactions (2) catalysed by quaternary ammonium salts do not occur when the reactants in the solvent are thoroughly dried. This agrees with the data of Starks and Owens[1] but not with those of Zwan and Hartner.[25] Zwan and Hartner[25] investigated the reactions of benzyl chloride and hexyl bromide with solid KF, KCN, AcOK, and the potassium salt of adenine in acetonitrile catalysed by aliquat 336, 18-crown-6, and tetramethylenediamine. Aliquat 336 proved to be the most active catalyst in virtually all cases apart from the reaction with KCN. All the reactants and solvents were carefully dried and the reaction was carried out in a sealed tube in the presence of 4 Å molecular sieves. Unfortunately, the authors[25] do not quote the water content, which hinders the comparison of the results. It is of interest to note that the quaternary salt was established in the above study.

The influence of water on the kinetics of the consecutive-parallel 1,4-dichlorobutane formylation reaction has been analysed:[24]

$$Cl(C_2H_4)Cl \xrightarrow[k_1]{HCOONa} Cl(C_2H_4)OCOH \xrightarrow[k_2]{HCOONa} HCOO(CH_2)_4OCOH.$$

The constants k_1 and k_2 were calculated directly from the kinetic curves. Fig. 2 shows how the presence of water influences k_1. As can be seen, in the fully dried system there is no reaction, after the addition of traces of water the rate increases sharply, while on further addition of water it falls. A similar effect had been observed earlier.[1] According to the authors,[24] the results show that the quaternary salt is incapable of abstracting a non-hydrated ion from the crystal lattice.

An interesting effect has been observed in the study of the interaction of solid potassium formate, containing 0.015 mol% of water, with chlorodecane.[26] The reaction was carried out for a reactant ratio of 1.5:1 in *o*-dichlorobenzene at 75 °C. In the absence of the catalyst, the reaction did not occur and after 3 h the water content in the formate fell by only 10%. On the other hand, after the addition of even 5.5 mol% of aliquat 336 a rapid reaction begins with a first-order rate constant of 2×10^{-3} min^{-1} and approximately 90% of the water present in the initial formate is transferred to the organic phase. This happens also in the presence of a larger water content in the formate. The data are summarised in Table 4.

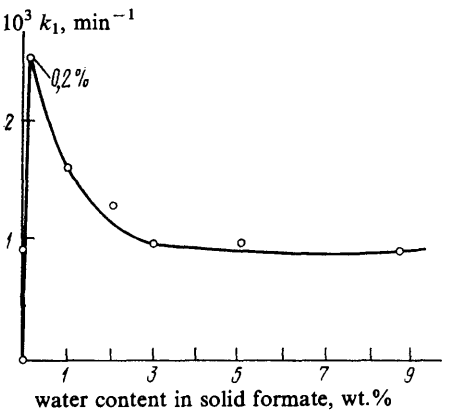

Figure 2. The influence of the water content in solid potassium formate on the observed rate constant for the formylation of dichlorobutane.[24]

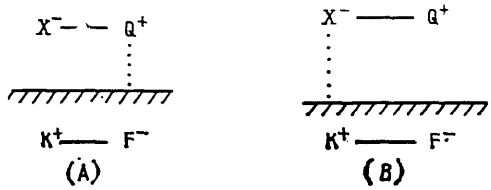
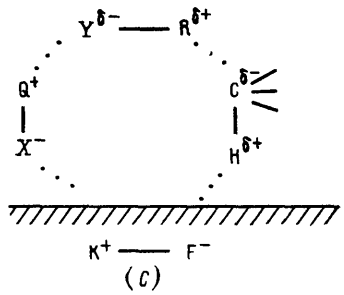
Table 4. The influence of the quaternary salt on the dehydration of solid HCOOK in the alkylation of 1-chlorodecane in *o*-dichlorobenzene (T = 348 K, catalyst—aliquat 336).[26]



Water content in solid formate, mol%	Salt concentration*, mol%	Degree of transfer of water to organic phase, % of initial amount	k, min^{-1}
0.015	0.0	10	no reaction
0.015	5.56	88	$2 \cdot 10^{-3}$
1	5.56	51	
2	5.56	30	
0.015	19.44		$1 \cdot 10^{-3}$
0.015	39–56		$< 1 \cdot 10^{-3}$

* Relative to 1-chlorodecane.

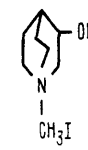


With increase in the concentration of the quaternary salt, the observed rate constant falls appreciably. This has been attributed[26] to the dehydration of the formate by the quaternary salt. The data obtained led to the conclusion that the observed effect is common to reactions in a solid–liquid system. However, it has been suggested[12] that a similar dependence, with an extremum in the dependence of the rate of reaction on the quaternary salt

concentration, is a result of effects associated with the adsorption of the catalyst on the solid surface. In the alkylation of MAAE by prenyl chloride in acetonitrile in the presence of solid KF, the dependence of the specific rate of reaction on the catalyst concentration also passed through an extremum. It was established that there is no ion exchange between QX and KF.

In earlier studies[27–29] of the reactions involving solid inorganic salts, it has been demonstrated that there are two types of adsorption of the catalyst on the surface of the solid reactant. The formation of two types of surface complexes of QX on KF was also postulated in the study described above:[12]

The MAAE adsorbed on the solid surface via the binding of the F^- ion to the CH group of MAAE is deprotonated. Complex (A) is thus of the "blind end" type since F^- is blocked. The adsorption of QX via Scheme (B) and the participation of the adsorbed complex in the alkylation process are confirmed, according to the author,[12] by data on the influence of the nature of Q^+ and X^- on the rate of alkylation (Table 5). These data agree to some extent with the nucleophilicity series quoted by Gordon.[30] Since prenyl iodide is not formed during the reaction, it was suggested that the alkylation proceeds on the surface of solid KF [Scheme (C)]:



Alkylation via this scheme should lead to variable orders with respect to the component. The author[12] suggests that, if the QX concentration is higher than the MAAE concentration, the contribution of the "blind end" complex (A) increases, which explains the decrease in the rate of reaction with increase in the catalyst concentration. However, in our view, this does not agree fully with the kinetic scheme proposed by the author.

Table 5 also shows that the influence of the catalyst counterion is by no means always wholly determined by its lipophilic properties. This postulate has been confirmed by the results of Ali Abbas et al.[13]

Another interpretation of the dependence of the initial rates of reaction on the concentration of the solid reactant with an extremum has been proposed in studies[31,32] where the reaction of 1,2,4-trichlorobenzene with solid potassium phenoxide was investigated in the presence of copper and 18-crown-6. The authors explain this dependence in terms of the influence on the rate of reaction by the degree of surface coverage of the solid reactant by the catalyst (18-crown-6) and use the Langmuir equation in the description of the adsorption-desorption process involving the crown-ether–potassium phenoxide complex on the surface of the phenoxide, i.e. they used the mathematical procedures for heterogeneous catalysis in phase transfer catalysis. A synergistic effect was also noted in the above studies when two catalysts, such as metallic copper and 18-crown-6, were used.

Table 5. The influence of the nature of the phase transfer catalyst on the observed alkylation rate constant.[12]

Catalyst	$10^2 k_{obs}$, litre mol^{-1} min^{-1}	Catalyst	$10^2 k_{obs}$, litre mol^{-1} min^{-1}

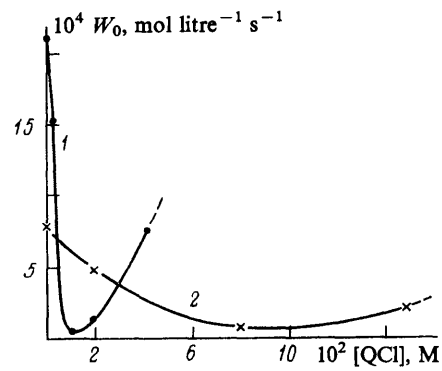
Note. Reaction conditions: solvent—CH_3CN, T = 293–295 K, [PC] = [MAAE] = 0.2 M, KF/MAAE = 2, [QX] = 0.05 M.



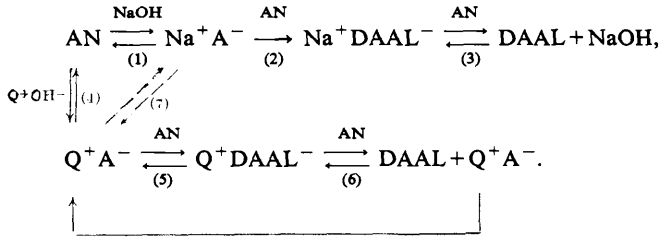


Figure 3. The influence of the new concentration of triethylbenzylammonium chloride on the initial rate of formation of diacetone alcohol at 40 °C in benzene solution in the presence of 50% aqueous NaOH at different initial molar acetone concentrations: *1*, 12; *2*, 8.[33]

Inhibition of the process by a quaternary ammonium salt has been observed not only in a solid–liquid system but also in a liquid–liquid system. Thus a study of the kinetics of the aldol condensation of acetone (AN) in the presence of 50% aqueous NaOH solution[33,34] established that, as a result of the addition of catalytic amounts of TEBA, the order of the reaction with respect to acetone changes and the initial rate of reaction falls appreciably (Fig. 3). This also entails the alteration of the composition of the

reaction products: considerable amounts of mesityl oxide (MO) and phorone (PHO) appear, while the amount of diacetone alcohol (DA) diminishes. The observed nature of the dependence of the initial rate of reaction on the Q^+Cl^- concentration persisted also on reducing the acetone concentration. The authors[33,34] explain the observed behaviour by a change in the reaction mechanism in the presence of the quaternary salt and propose the following process mechanism:

The reaction proceeds via the pathway (1)→(2)→(3) in the absence of Q^+Cl^- in the heterogeneous phase at the interface. Two molecules of acetone and water participate in it. After the introduction of the catalyst, the reaction can proceed via two pathways: (4)→(5)→(6) and (1)→(7)→(5)→(6). The heterogeneous pathway (1)→(2)→(3) is then blocked, as shown by the third order with respect to acetone of the reaction occurring in the presence of the catalyst.

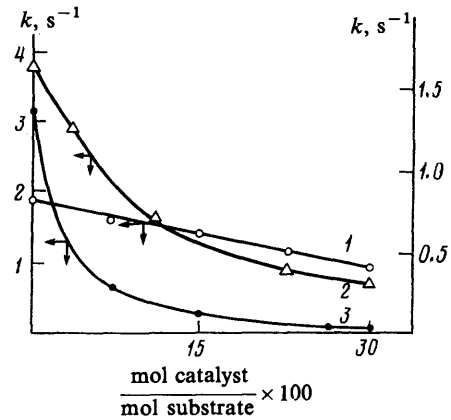

Figure 4. Dependence of the rate constant for the two-phase reaction on the catalyst concentration in the 1:1 benzene–water system at 25 °C:[35] *1*, 10^6k, t-BuCl + KNCS, $(n\text{-Bu})_4NBr$; *2*, 10^5k, hydrolysis of t-BuCl, $(n\text{-Bu})_4NBr$; *3*, 10^3k, hydrolysis of trityl chloride, $(n\text{-Bu})_4NCl$.

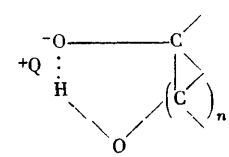

Inhibition of the reaction in a liquid–liquid system after the introduction of the phase transfer catalyst has also been observed in a study[35] of the substitution of tertiary alkyl chlorides by the thiocyanate ion (Fig. 4). Whereas in the reaction involving primary alkyl chlorides the introduction of the phase transfer catalyst accelerates the substitution, in the case of tertiary alkyl chlorides the introduction of a quaternary ammonium salt induces a marked inhibition. In the given instance, this is also a consequence of a change in the reaction mechanism, although it is not induced by the presence of the catalyst but is caused by a change in the structure of the substrate. On passing from a primary to a tertiary alkyl chloride, the S_N2 reaction mechanism changes to S_N1. This is confirmed by the fact that the hydrolysis of triphenylmethyl chloride (trityl chloride) is also inhibited sharply by tetrabutylammonium chloride.[35] Evidently, despite the fact that the quaternary salt transfers thiocyanate ions to the organic phase, the polarity of this layer is insufficient for the operation of the S_N1 mechanism. The reaction therefore takes place either in the aqueous layer or at the interface. The observed inhibition effect is induced by the removal of the thiocyanate ion from the reaction zone as a result of its extraction by the quaternary salt into the organic phase.

The inhibition of a number of other two-phase reactions by a phase transfer catalyst has been observed recently.[36] Thus the reaction of *p*-bromonitrobenzoylmethane with urotropine is inhibited by TEBA added in catalytic amounts. According to the author, this is induced by the transalkylation of TEBA with *p*-bromonitrobenzoylmethane. It was noted in the same study that, in the presence of TEBA, the acetylation of $p\text{-}O_2NC_6H_4C(O)CH_2NH_2$ by acetic anhydride in the presence of aqueous sodium carbonate proceeds with a lower yield as a consequence of the acceleration of the side reaction involving the cyclisation of the amino-derivative. However, the acetylation of 9,13-dimethyl-7-(1,1,5-trimethylcyclohex-5-enyl)nona-8,11,13-triene-10,15-diol by acetic anhydride in the presence of a phase transfer catalyst proceeds smoothly and with a satisfactory yield.[37]

All these features demonstrate that phase transfer catalysts are not a universal means of accelerating any heterophase process. In each specific case, the reaction mechanism plays the decisive role and not the presence in the system of two and more immiscible phases.

IV. Synergism and inhibition in multicomponent catalytic systems

This section is devoted to what is in our view the most interesting effect in phase transfer catalysis—the cocatalytic or, on the contrary, the inhibiting effect of compounds of substances added to the reaction system and capable of forming complexes with its components or a base of nucleophile stronger than the compounds present initially. Systems with alkalis have been most thoroughly investigated. At an early stage, in the study of the Williamson reaction under phase transfer conditions, it was observed that in the presence of alcohol an appreciably greater amount of the base passes to the organic phase than under the usual conditions.[18] The extracted alkoxide anion is a very powerful base. Thus the basicity of a 0.001 M solution of benzyltrimethylammonium t-butoxide in t-butyl alcohol is 1000 times higher than the basicity of a similar potassium t-butoxide solution.[38] It has been shown[39] that the most effective additive to quaternary ammonium salts, ensuring the maximum extraction of the base into the organic phase, is pinacol—2,3-dimethylbutane-2,3-diol. It was suggested that this is induced by the formation of a stable ion pair having the structure

It is essential to note that, in the absence of a quaternary salt, even the most effective diols increase the basicity of the organic phase extremely insignificantly, in contrast to polyglycols. This served as a basis for the application of a system comprising a quaternary ammonium salt and a diol in the synthesis of alkynes from 1,2-dihalo-derivatives,[40] because it had been shown earlier that 1,2-dibromoalkanes are readily dehydrobrominated by solid KOH in the presence of tetraoctylammonium bromide.[41] The following products are formed on elimination of 1,2-dihaloalkanes (Table 6):

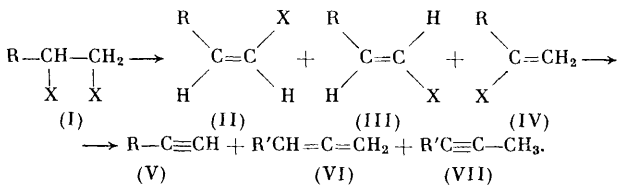

Table 6. Dehydrohalogenation of 1,2-dibromooctane by 50% KOH.[40]

Catalyst	Cocatalyst	Yield of products, %		(I)
		(V)	(II)–(IV)	
Oct_4NCl	Нет	0	70	30
	EtOH	0	88	12
	$C_5H_{11}OH$	10	90	0
	$C_7H_{15}OH$	8	92	0
	$HO(CH_2)_6OH$	48	52	0
	$HO(CH_2)_8OH$	50	50	0
	Hexane-2,5-diol	50	50	0
	2-Methylpentane-2,4-diol	44	56	0
	2,3-Dimethylbutane-2,3-diol	39	61	0
	2,5-Dimethylhexane-2,5-diol	39	61	0
	PEG 200	2	98	0
	PEG 1000	31	69	0

Note. Reaction conditions: amount of dihalo-derivative 5.36 mmol; amount of KOH 500 mmol, amount of catalyst 10^{-4} mol, amount of cocatalyst 2 × 10^{-4} mmol, amount of petroleum ether 5 ml, temperature 75 °C, time 2.5 h.

It has been established,[40] that apart from tertiary diols, primary diols in which the OH groups are separated by 6–8 carbon atoms are also extremely effective.

Fig. 5 shows how the yield of the elimination products varies in the presence of the cocatalyst (in the given instance pinacol) and in its absence.[40] The effect is most marked in the case of the least reactive chloro-derivative. It is extremely striking that the quaternary ammonium salt (QAS)–diol catalytic system does not ensure, in contrast to poly(ethylene glycols), the isomerisation of an alk-1-yne to an allene and an alk-2-yne. In all probability, this is induced by the completely different structure of the catalytic complexes involved in the reaction, because, as mentioned previously, we find, firstly, that, in contrast to polyglycols, diols do not increase the basicity of the organic phase in the absence of a QAS and, secondly, that the addition of a QAS to polyglycols also does not induce an increase in the basicity of the organic phase.[39] It is also noteworthy that, like other primary alcohols, ethanol is a fairly weak cocatalyst. Nevertheless, QAS–alcohol systems have been used widely by many investigators in elimination and alkylation reactions.[42] The study of the kinetics of the dehydrochlorination of 1,2-dichloroethane, catalysed by the TEBA–benzyl alcohol mixture,[43] showed that the dependence of the initial rate of reaction on the benzyl alcohol concentration passes through an extremum. The formal order of the reaction with respect to the concentration of alkali was ~2.5. In order to account for this, an extremely complex kinetic scheme was postulated. However, our calculations showed that the substitution of the activity of NaOH for its concentration leads to the first order of the reaction with respect to the above reactant, which renders the authors' entire reasoning[43] concerning the proposed mechanism extremely ill-founded. It is also essential to note that the intermediate complex, whose formation has been postulated,[43] cannot be produced for physical reasons.

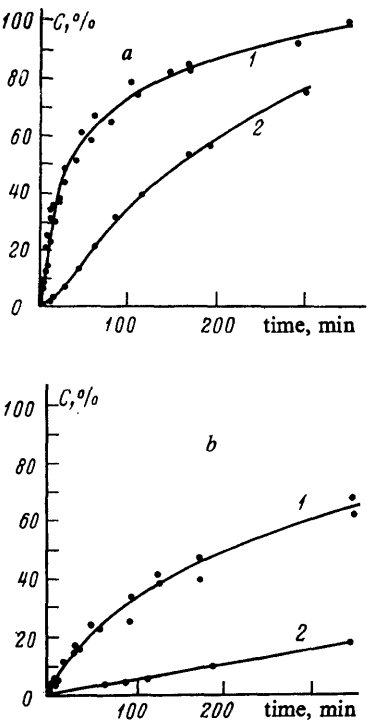

Figure 5. Elimination of 1,2-dibromooctane (*a*) and 1,2-dichlorooctane (*b*) by solid KOH in the presence of $(C_8H_{17})_4NBr$ with (curves *1*) and without (curves *2*) the addition of pinacol.[40]

The influence of a large number of different added proton-donating compounds on the katamin-catalysed dehydrochlorination of the α-isomer of hexachlorocyclohexane has been investigated.[22] Fig. 6 illustrates the dependence of the initial rate of reaction on the concentration of the additive. The dashed line represents the initial rate of reaction in the absence of the additive. Whereas the addition of a carboxylic acid inhibits the reaction, as might have been

expected, while that of benzyl alcohol accelerates it (the acceleration is directly proportional to the alcohol concentration), the addition of phenol and pentachlorophenol leads to complex relations. In our view, this is associated with the formation of complexes of the above compounds with the substrate, because according to Brandston's data,[11] phenols and other weak acids can be extracted in the presence of alkali by quaternary salts not only in the form of anions but also in the unionised form as a complex with the QAS. In particular, it has been shown that, after the addition of a base and a QAS to a phenol or carboxylic acid solution in methylene chloride or a similar solvent, the RO^-Q^+, $RO^-Q^+(ROH)$, $RO^-Q^+(ROH)_2$, etc. species are formed in the organic phase. Species of this kind can interact, in their turn, with the substrate. The formation of substrate–QAS–additive ternary complexes has been demonstrated by spectroscopic methods. The degree of association of the complex $CHCl_3/NEt_3$/TEBA calculated from IR spectroscopic data is 0.13.[44]

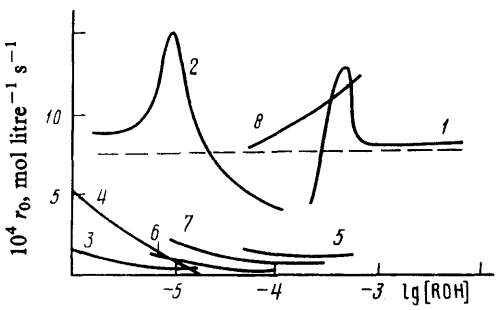

Figure 6. The influence of added proton-donating compounds on the rate of alkaline dehydrochlorination of the α-isomer of hexachlorocyclohexane in catalysis by katamin AB;[22] Additives: *1*, phenol; *2*, C_6Cl_5OH; *3*, $C_5H_{11}COOH$; *4*, picric acid; *5*, L-histidine; *6*, VIK-1 (mixture of α-methyl-substituted carboxylic acids, C_7-C_9 fraction); *7*, *o*-$HOC_6H_4SO_3H$; *8*, $C_6H_5CH_2OH$.

The available data[45] suggest that the following processes take place in the system:

$$ROH + NaOH \rightleftarrows NaOR + H_2O,$$
$$NaOR_w + QCl_w \rightleftarrows QOR_w + NaCl_w,$$
$$QOR \rightleftarrows QOR_{org},$$
$$QOR_w + nROH_w \rightleftarrows (QOR.nROH)_w,$$
$$(QOR.nROH)_w \rightleftarrows (QOR.nROH)_{org},$$
$$NaOH_w + QCl_w \rightleftarrows QOH_w + NaCl_w,$$
$$QOH_w + nROH_w \rightleftarrows (QOH.nROH)_w,$$
$$(QOH.nROH)_w \rightleftarrows (QOH.nROH)_{org}.$$

The role of the base can be assumed in the given instance by both $(QOH.nROH)_{org}$ and NaOH (through the interface). The QOR and $(QOR.nROH)_{org}$ species are most probably not reactive in the given process, which explains the extremum in the dependence of the initial rate of dehydrochlorination on the phenol concentration. The acceleration of the alkali elimination reaction after the addition of phenol to the QAS was observed also in the synthesis of phenylacetylene.[46] Unfortunately, detailed data are not available. The results of Sirovskii et al.[22] show that the effect of the additive depends on its acidity. Compounds with $pK_a < 5$ cause inhibition, those with $5 < pK_a < 10$ give rise to both synergism and inhibition, and those with $pK_a \geqslant 10$ give rise to synergism alone. On the other hand, according to another study,[47] the addition to the system of compounds more acid than water, particularly phenol, inhibits the substitution of hexyl chloride by sodium formate. The authors[47] believe that the presence in the system of compounds promoting extraction as a result of the formation of hydrogen bonds via the scheme

$$QX_{org} + HZ_w \rightleftarrows QX\ldots(HZ)_{n(org)}\ [\text{or } Q^+(HXZ)^-\ldots(HZ)_{n-1(org)}],$$

inhibits the process in all cases. In the light of the data presented below, this conclusion appears to be not entirely justified.

The synergistic effect of a mixture of two types of phase transfer catalysts has been observed in the alkylation of malonic ester by alkyl halides.[48] When a mixture of aliquat with crown-ethers was used, the initial rate of alkylation and sometimes the yield of the product were higher than would be expected from the simple summation of the catalytic effects. However, the mechanism of the cocatalytic action is not entirely clear in this instance.

It is of interest to note that the addition of an acid to the QAS increases the yield of the product in the bromination of cyclopentadiene by sodium hypobromite:[49]

$$C_5H_6 + NaOBr \xrightarrow{QX+RCOOH} C_5Br_6.$$

The corresponding data are presented in Table 7. The addition of the carboxylate anion probably promotes the extraction of the OBr^- into the organic phase.

Table 7. The influence of the catalyst on the yield of hexabromocyclopentadiene.

Concentration of $[(C_{7-9}H_{15-19})_3NMe]_2SO_4$, mM	Concentration of VIK-1*, mM	Yield of hexabromocyclopentadiene, %
0	0	56.3
7.75	0	28.0
0.775	3.05	65.4
1.55	6.1	78.1
3.10	12.2	50.0
7.75	30.5	48.4

Note. Reaction conditions: temperature from 0 to 5 °C, $V_{org}/V_w = 0.11$
*VIK-1 is a mixture of α-methyl-substituted aliphatic carboxylic acids (C_5-C_7 fraction).

In studies[44,50,51] devoted to the synthesis of cyclopropyl ethers by the addition of dichlorocarbene to olefins, the synergism, observed for the first time by the authors, occurring when mixtures of TEBA with a series of complex-forming agents are used, was investigated. Fig. 7 presents an example of the synergistic effect of TEBA and

triethylamine in the formation of 7,7-dichloronorcarane from cyclohexene and $CHCl_3$ on treatment with solid KOH. For a quantitative description of the effects of additives, the synergistic coefficient was used: $K_s = \eta_3/(\eta_1 + \eta_2)$, where η_1 and η_2 are the yields of the products when the phase transfer catalyst and the additive respectively are used separately and η_3 is the yield for the mixture comprising equimolar amounts of the catalyst and the additive. Depending on the mixture composition, an acceleration (synergism of the catalysts) or inhibition (antagonism of the catalysts) were observed (Table 8).

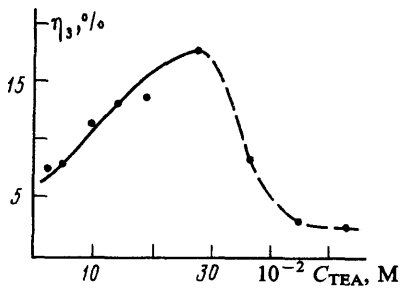

Figure 7. Dependence of the yield of 7,7-dichloronorcarane on the content of the triethylamine (TEA) in the reaction mixture (20 °C, 5 min, molar ratios cyclohexene: chloroform: solid NaOH: TEBA = 1:5:9.04:0.02; when TEBA at a concentration of 0.5 mM is used without added triethylamine, η_1 = 4.8%, while in the presence of triethylamine at a concentration of 0.5 mM without added TEBA, η_2 = 2.3%).[44]

The use of certain additives (for example, NEt_3, activated charcoal) in non-catalytic amounts leads to a complex variation of K_S (an initial increase followed by a sharp decrease). A similar picture has been observed also after the introduction into the catalytic mixture of a third component (for example, ethanol) capable of forming a complex both with the phase transfer catalyst or the additive and with $CHCl_3$. K_S depends also on the ratio of the components and the reaction temperature and is determined by the nature and content of alkali in the reaction mixture. A decrease in the amount of alkali introduced into the reaction lowers the observed synergistic effect as far as antagonism ($K_S < 1$).

In all probability the reaction is accelerated in the $CHCl_3$ deprotonation stage. Homoassociated species, in which the proton of one molecule is located between the two C–Cl bonds of a neighbouring molecule as a result of the formation of hydrogen bonds, are known to be formed in liquid $CHCl_3$.[52] Under the reaction conditions, the presence of such associated species can give rise to steric hindrance to the attack by the hydroxide ion on the C–H bond in $CHCl_3$, which leads to the formation of the anion CCl_3^-. Tertiary amines and quaternary ammonium salts exist in $CHCl_3$ as complexes with chloroform of types (VIII) and (IX):[52,53]

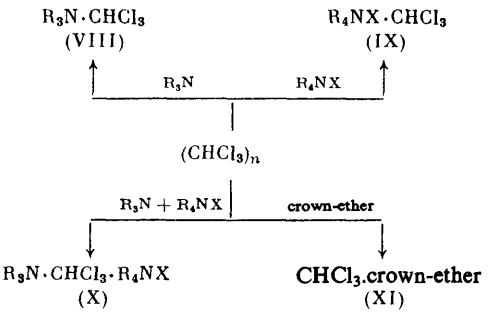

Table 8. The yields of 7,7-dichloronorcarane in the presence of various catalysts and their mixtures.[51]

Components of catalytic mixture [a]	Yields, %			K_S
	η_1	η_2	η_3

Note. Reaction conditions: T = 283 K, 2 mol% of catalyst, SKT charcoal.

*The ARA-5p anion-exchange resin contains the $[C_6H_5CH_2N^+.(CH_3)_3]Cl^-$ exchange groups.

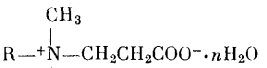
**Sintanol is the monoalkyl ether of poly(ethylene glycol) $C_{10}H_{21}O.(C_2H_4O)_{10}H$.

In complexes of this kind, the C–H bond in $CHCl_3$ should be more polar than in the homoassociated species. After the simultaneous introduction into $CHCl_3$ of a phase transfer catalysis and an additive, one may expect the formation, together with complexes (VIII) and (IX), of mixed complexes (X) in which the polarisation of $CHCl_3$ is more pronounced than in two-component complexes, as shown by IR and ^1H NMR spectroscopic data.

Thus the $CHCl_3$ molecule removed from the homoassociated species as a result of binding into complexes (VIII)–(IX) is activated as a consequence of the polarising action of the catalyst, which facilitates the heterolysis of the C–H bond and the formation of CCl_3^-. In binary mixtures of catalysts, deprotonation should take place more readily, since the phase transfer catalyst and the additive exert a concerted polarising action on different centres in the $CHCl_3$

molecule [complex (X)]. Since all the catalysts and additives listed in Table 8 are capable of forming complexes of different nature with $CHCl_3$ [including complex (XI)], it becomes understandable why the independent use of compounds which are not traditional phase transfer catalysts but exhibit donor–acceptor properties leads to the formation of dichloronorcarane (η_3 = 0.8–2.8%) and why their use in a mixture with the phase transfer catalyst gives rise in most cases to a synergistic effect ($K_S > 1$). The postulate that the acceleration of the addition of dichlorocarbene takes place in the deprotonation stage is supported by the analogous influence of additives also in reactions of other CH acids when the reaction takes place under the conditions of phase transfer catalysis and involves the stage indicated: in the intramolecular cyclisation of γ-chloropropyl mesityl sulphone in the presence of dimethyl sulphoxide (DMSO) and in deuterium exchange involving DMSO.[44] Overall, the nature of the activity of the above phase transfer catalysts and catalytic mixtures in these reactions is the same as in the dichlorocarbene addition reactions.

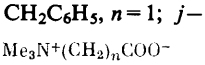
Cases of the inhibition of the reaction (Table 8) can be best explained by steric hindrance to attack on the C–H bond of the chloroform by the hydroxide ion OH^- in the pre-reaction three-component complex. This explanation is confirmed by the finding that, when a series of $Alk_4NX/NAlk'_4$ pairs (Alk = C_1–C_4; Alk′ = C_1–C_{20}) are used, the synergistic coefficient changes from $K_S > 1$ to $K_S < 1$ with increase in the length of the Alk or Alk′ carbon chain. However, one cannot rule out additional causes of the non-additive changes in the reaction rate such as the formation of complexes between the catalyst and the additive,[54] the modification of the catalyst by the additive,[41] or the participation of the catalyst and the additive in different stages of the process.



In some cases inhibition is induced by the solvent (benzene or toluene).[55] In reactions involving the alkylation of acetone by prenyl chloride, inhibition was observed after the replacement of part of the acetone by toluene despite the zero order of the reaction with respect to acetone.[55] The authors explained this effect by the "inhibiting" influence of toluene. The Lineweaver–Burk plots of the observed dependence of the rate constant on the catalyst concentration at different benzene concentrations consists of a set of straight lines intersecting in one point, which indicates inhibition of a mixed type. According to the authors,[55] in the given instance the solvent forms solvate complexes with QX and QA. Here A^- is acetone enolate, whose concentration is defined by the equation $[A^-] = K_e[AN]a_{OH^-}a_{H_2O}$, where K_e is the equilibrium constant for the deprotonation of the acid HA by OH^-, a_{OH^-} the activity of the hydroxide ion, a_{H_2O} the activity of water, and [AN] the concentration of acetone in aqueous alkali. The authors estimate the constant K_e as the ratio $K_{HA}/K_{H_2O} = 10^{-20}/10^{-16}$. According to their data,[55] 30% of acetone dissolved in 50% NaOH is enolised. Calculation of kinetic data showed that QX is bound by toluene approximately 6 times more effectively than QA. This is induced by the more pronounced lipophilicity of QA and by the fact that Cl^- is more effective solvated by toluene than A^-.[55]

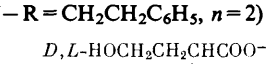
Consideration of the above instances of synergism and inhibition permits the conclusion that complex formation processes in fact determine the mode of the action of the additive—synergistic or inhibiting. As a rule, synergistic action is manifested on formation of ternary complexes incorporating the phase transfer catalyst, the substrate, and the additive. The binding of the additive in a complex with only one of the components leads to inhibition.

V. Catalysis by betaines

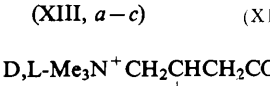


At first sight the topic of this section does not fit within the general framework of the review. However, we believe that the transition from the use of two-component catalytic systems to the construction of bifunctional catalysts is an entirely logical stage and that the use of betaines as such catalysts is one of the first steps in this direction.

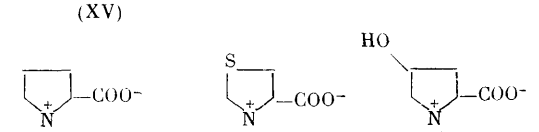
It has been stated in a monograph[56] that, in the presence of the betaine $(C_{12}H_{25})_3N^+CH_2COO^-$, the interaction of alkyl halides with aqueous alkali is 10–50 times faster than in the presence of the usual onium salts. The application of betaines of the type $R_3N^+(CH_2)_nCOO^-$ and $C_{12}H_{25}N^+R_2(CH_2)_nSO_3^-$ as promoting agents for the alkaline dehydrochlorination reactions of chlorobutanes and chlorobutenes was described as early as 1973.[57] A wide scale study of betaines as phase transfer catalysts has been undertaken recently.[58,59] Gol'dberg et al.[68] synthesised a series of betaines having the following structure:



(XII, *a*–*j*)

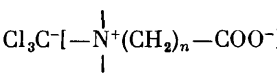


(*a*–R = CH_3, *n* = 2; *b*–R = C_2H_5, *n* = 1; *c*–R = n-C_3H_7, *n* = 0; *d*–R = iso-C_3H_7, *n* = 2; *e*–R = n-C_6H_{13}, *n* = 1; *f*–R = n-$C_{10}H_{21}$, *n* = 1; *g*–R = n-$C_{12}H_{25}$, *n* = 1; *h*–R = n-$C_{16}H_{33}$, *n* = 0; *i*–R = $CH_2C_6H_5$, *n* = 1; *j*–R = $CH_2CH_2C_6H_5$, *n* = 2)

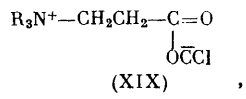


(XIII, *a*–*c*)

(XIV)



(XV)



L-(XVI) L-(XVII) L-(XVIII)

The betaines (XIII)–(XVIII) were tested as catalysts of two-phase reactions involving dichlorocarbene: the conversion of styrene into dichlorocyclopropane, dehydration of benzamine, and *N*-formylation of pyrrolidine. The betaine based on *b*-alanine (XIII*b*), homoserine (XIV), proline (XVI), and carnitine (XV), in the presence of which the yields of products attained were close to those obtained with the aid of the usual phase transfer catalyst, proved to be the most effective.[58] The betaines (XII*a*–*j*) have also been used in the conversion of styrene into dichlorocyclopropane and in the dehydration of benzamine and their activity proved to be close to that of TEBA. The use of these betaines in the Williamson reaction was found to be less effective; the yield of benzyl propyl ether in the reaction of propanol with benzyl chloride was lower by a factor of approximately 3 than in the case where NBu_4HSO_4 was used.[59]

It has been suggested[58,59] that the mechanism of the catalysis by betaines differs from that proposed for the usual onium salts, because betaines are incapable of solubilising the CCl_3^- anion in the form of an ion pair. On formation of a bis-ion pair of the type

the catalytic activity should have increased with increase in the length of the chain connecting the carboxy-group to the onium centre. However, the opposite behaviour is observed: the catalytic activity falls in the sequence (XIII*a*)–(XIII*b*)–(XIII*c*). The authors[58,59] believe it to be more likely that the electrophilic dichlorocarbene interacts with the carboxylate anion to form the betaine (XIX)

(XIX) ,

which is capable of migrating into the bulk of the organic phase and acting similarly to the ylide formed when trialkylamines are used as catalysts. This mechanism is confirmed by the absence of a relation between the lipophilicity of the onium component of the catalyst and its catalytic activity (Table 9).[59]

Table 9. The reaction of styrene with dichlorocarbene in the presence of the betains (XII).[59]

Catalyst (XII)	Reaction time, h	Yield of product, % of theoretical	Catalyst (XII)	Reaction time, h	Yield of product, % of theoretical
Without catalyst	4.5	4	*f*	0.5	98
TEBA*	0.5	71	*g*	0.5	81
a	2.5	59	*h*	0.5	80
b	0.5	64	*h**	0.5	79
c	0.5	75	*i*	2.5	70
d	0.5	58	*j*	2.5	31
e	0.5	100			

Note. Reaction conditions: 1.7 mmol of styrene, 2.5 ml of $CHCl_3$, 1.5 ml of 50% aqueous NaOH, 1 mol% of catalyst, temperature 25 °C.
* 0.5 mol% of catalyst.

The high catalytic activity of betaines, comparable to the activity of the usual onium salts, leads to the possibility of "constructing" new catalytic salts, leads to the possibility of "constructing" new catalytic systems containing in one molecule both a catalyst and a promoting agent fragment. The carboxylate group need not necessarily be used as the promoting agent. There are data showing that the introduction of the OH^- or NH_2 group into the quaternary salt molecule in the β-position relative to the onium centre also increases the catalytic activity.[60] It is also known that the activity of chiral catalysts increases after the introduction of the OH group in the β-position relative to the nitrogen atom. All these features provide extensive opportunities for investigators who have a lively imagination and are skilled in the art of organic synthesis.

Skeletal rearrangements of cage compounds with medium rings

B M Lerman
Institute of Chemistry, Bashkir Scientific Centre, Urals Division of the Academy of Sciences of the USSR, Ufa

ABSTRACT. Data on skeletal rearrangements in the chemistry of cage compounds are reviewed. The main principles of thermodynamically controlled isomerisation of cage hydrocarbons and syntheses of mono- and polycage structures are considered. Data on skeletal reconstruction accompanying functionally substituted carbo- and thia-containing cage-type polycyclanes are systematised. The rules for skeletal interconversions of isomeric tricyclic structures are considered.

The bibliography contains 99 references.

I. Introduction

The chemistry of cage compounds, first arising with and receiving significant development from adamantane, now includes its structural isomers, homologues and heteroanalogues, polyadamantanes, and also carbo- and heterocage compounds of many other types. The method of synthesis by skeletal rearrangement occupies a conspicuous place in this region of chemistry, which is distinguished by structural diversity. The various skeletal reorganisations of non-cage polycyclanes into cage systems, skeletal transformations of cage compounds themselves into compounds with more stable isomeric structures and also the interconversions of cage structures, characteristic of individual groups, are widely represented.

Skeletal rearrangements form the basis of important routes for the synthesis of both cage hydrocarbons and of functional derivatives of cage polycyclanes. The synthesis of adamantane and its alkyl homologues from non-cage precursors (adamantisation) and the synthetic approaches to mono- and polycage hydrocarbons based on available precursors of other cage structures are based on isomerisation under the action of strong Lewis acids. The conversions of functionally substituted cage polycyclanes by addition, elimination and substitution reactions accompanied by skeletal rearrangements open a route to cage compounds of various classes. The skeletal transformations indicated are represented mainly by adamantisation in the monograph[1] and in the known reviews on the chemistry of adamantane and other cage compounds.[2–6] McKervey has also considered skeletal rearrangements of cage tricyclanes[7] and syntheses of polyadamantanes by isomerisation of penta- and hexacyclic hydrocarbons.[8] In recent years data have been obtained on the skeletal transformations of cage hydrocarbons, acting as intermediates in processes for the adamantisation of non-cage substrates, routes have been developed for the synthesis of a series of unique non-adamantane cage structures on the basis of skeletal conversions of actual cage compounds, and important general rules have become apparent for the skeletal reorganisations of cage compounds under the action of chemical reagents.

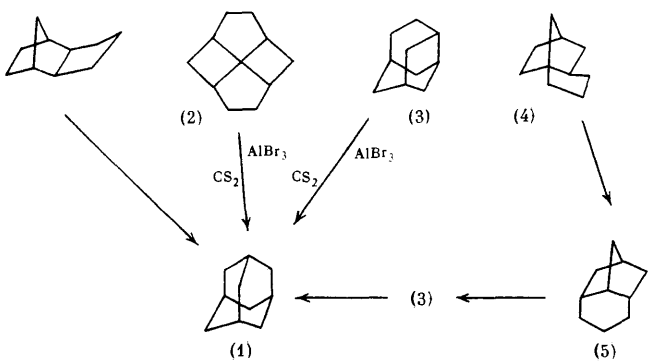
The present review is devoted to the correlation of data available at the present time on skeletal conversions of cage and thiacage compounds containing predominantly five- and six-membered rings. Systematisation of literature material has been carried out for a series of cage and polycyclic systems with the same number of rings and a single structural formula.

II. Skeletal transformations of cage tricyclanes

The discovery in 1975 of a single-stage method of synthesis of adamantane, and then of alkyladamantanes, by the isomerisation of available saturated tricycloalkanes with ten or more carbon atoms catalysed by strong Lewis acids, played an exceptionally important role in the development of the chemistry of adamantane itself and of cage compounds in general. Investigations on adamantisation of non-cage tricyclic precursors and especially of such hydrocarbons as *endo*-tetrahydrodicyclopentadiene (THDCP), perhydroacenaphthene and perhydrofluorene attracted much attention and culminated in the design of an industrial means of obtaining adamantane and preparative methods of synthesis of different alkyl homologues of it. Hydrocarbons of cage structure, represented mainly by isomers and homologues of adamantane, became the objects of further investigations on the thermodynamically controlled isomerisation of tricycloalkanes. Together with the isomerisation of the hydrocarbons indicated skeletal transformations of tricyclanes of cage structure also include skeletal rearrangements accompanying reactions of functional derivatives. Of the known types of similar rearrangements the present review includes mainly the transformations occurring without a change in the number of skeletal carbon atoms. Conversions of the 'adamantane–homoadamantane' and 'noradamantane–adamantane' types are not considered in the review.

1. Isomerisation of tricycloalkanes into adamantane hydrocarbons

The high thermodynamic stability of adamantane (1) in comparison with the stability of other structural isomers of $C_{10}H_{16}$-tricyclanes (Table 1) and the ability of certain Lewis acids to generate and support the concentration of cationic intermediates necessary to effect skeletal rearrangements form a basis for obtaining adamantane both from THDCP and from tricyclanes of cage structure. The isomerisation of the latter under the action of $AlBr_3$ proceeds under milder conditions and more rapidly than the isomerisation of THDCP which was shown for the example of twistane, tricyclo[4.4.0.0^{3,8}]decane, (2) [9] and protoadamantane, tricyclo[4.3.1.0^{3,8}]decane (3).[10] The latter together with 2,6-trimethylenenorbornane (5) are intermediates in the isomerisation of *exo*-1,2-trimethylenenorbornane (4).[11] The isomerisation of protoadamantane (3) into adamantane also occurs in the gas phase over Pd, Pt, and Rh at temperatures greater than 150 °C.[12]



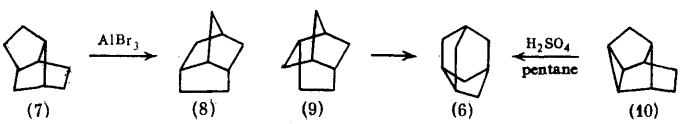


Table 1. Calculated data for the heats of formation of some $C_{10}H_{16}$-tricyclanes.[11]

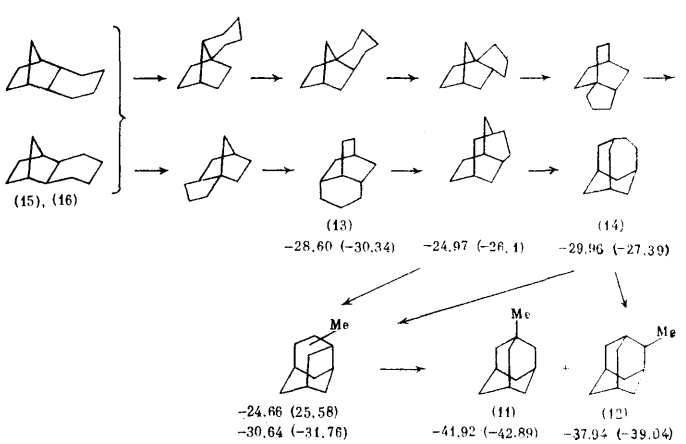
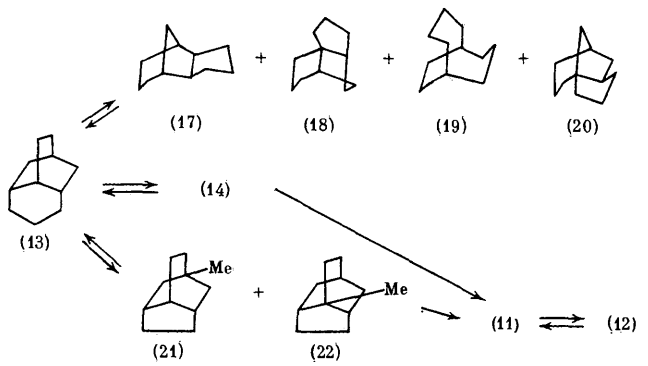


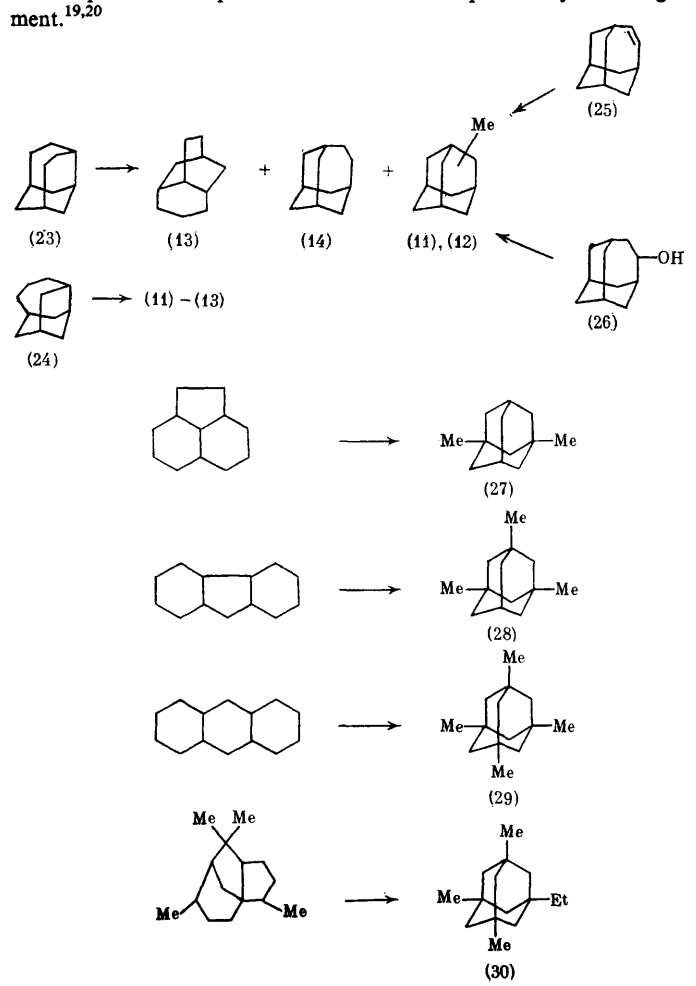
$C_{10}H_{16}$-isomers	H° (gas, 25 °C), kcal mol^{-1}
Adamantane (1)	−32.6
Protoadamantane (3)	−21.1
2,6-Trimethylenenorbornane (5)	−20.2
exo-1,2-Trimethylenenorbornane (4)	−16.7
Twistane (2)	−13.3
endo-Tetrahydrodicyclopentadiene	−16.8

The data presented are experimental confirmation of the theoretical mechanism proposed by Whitlock and Siefken for the conversion of THDCP into adamantane allowing for the heats of formation of the isomeric tricyclodecanes and based on a critical analysis of possible routes of conversion of intermediates (at least 2897 variants).[9] According to the indicated mechanism the process includes a series of sequential skeletal conversions of tricyclodecanes. The three final steps of this process are the conversions of (4) → (5) → (3) → (1).

An example of the isomersiation of C_9H_{14}-tricyclononanes to the lower homologue of adamantane is the conversion of brexane, tricyclo[4.3.0.0^{3,7}]nonane (7), under the action of $AlBr_3$ into noradamantane, tricyclo[3.3.1.0^{3,7}]nonane (6). The conversion indicated most probably proceeds through such intermediates as brendane, tricyclo[4.2.1.0^{3,7}]nonane (8), and twistbrendane, tricyclo[4.3.0.0^{3,8}]nonane (9).[13] The interaction of deltacyclane, tetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonane (10) with sulphuric acid also leads to noradamantane and is the result of fission of the cyclopropane ring and subsequent isomerisation.[14]



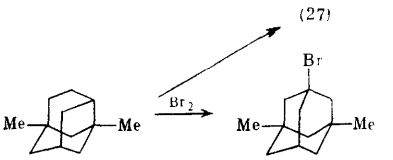
The isomerisation of C_{11}-tricyclic hydrocarbons into methyladamantanes (11) and (12) under the action of strong Lewis acids is similar to the isomerisation of $C_{10}H_{16}$-tricyclanes into adamantane and was described for the first time using non-cage precursors, viz. various tricycloundecanes and methyltricyclodecanes as examples. When studying these isomerisations 4-isohomotwistane, tricyclo[5.3.1.0^{3,8}]undecane (13), and homoadamantane, tricyclo-[4.3.1.1^{3,8}]undecane (14), were isolated and identified. Osawa and co-workers[15] have proposed the following mechanism for the isomerisation of tricycloundecanes (15) and (16) well-founded on calculated data for the thermodynamic stability of 69 isomeric C_{11}-tricyclanes. Values for the heats of formation of intermediates of carcase structure are given in the scheme.†



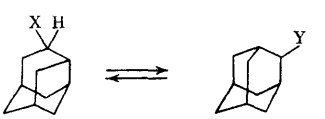
The isomerisation of 4-isohomotwistane (13) was the subject of a separate study carried out under kinetically controlled conditions using Brønsted acid (CF_3SO_3H, H_2SO_4). Under the action of these agents a complex mixture of isomeric tricyclanes was obtained from the compound indicated. The mixture contained tricycloundecanes (17)–(20), which are thermodynamically less stable than the initial compound, together with the more stable isomers,

† Here and subsequently data are given calculated according to Engler and in parentheses according to Allinger (in kcal mol^{-1}).

methylhomotwistanes (21) and (22) and homoadamantane (14), which is slowly converted into methyladamantanes (11) and (12).[16,17]



Definite differences were established between the conversions of the isomeric homoprotoadamantanes (23) and (24) under the action of CF_3SO_3H. Homoadamantane (14) predominates in the mixture of structural isomers obtained from hydrocarbon (23). The isomerisation of compound (24) under the same conditions leads predominantly to compound (13).[18] The latter also predominates in the mixture of isomers (11–14) formed on conversion of homoadamantene (25) and homoadamantanol (26) in conc. H_2SO_4 in the presence of pentane which is accompanied by rearrangement.[19,20]

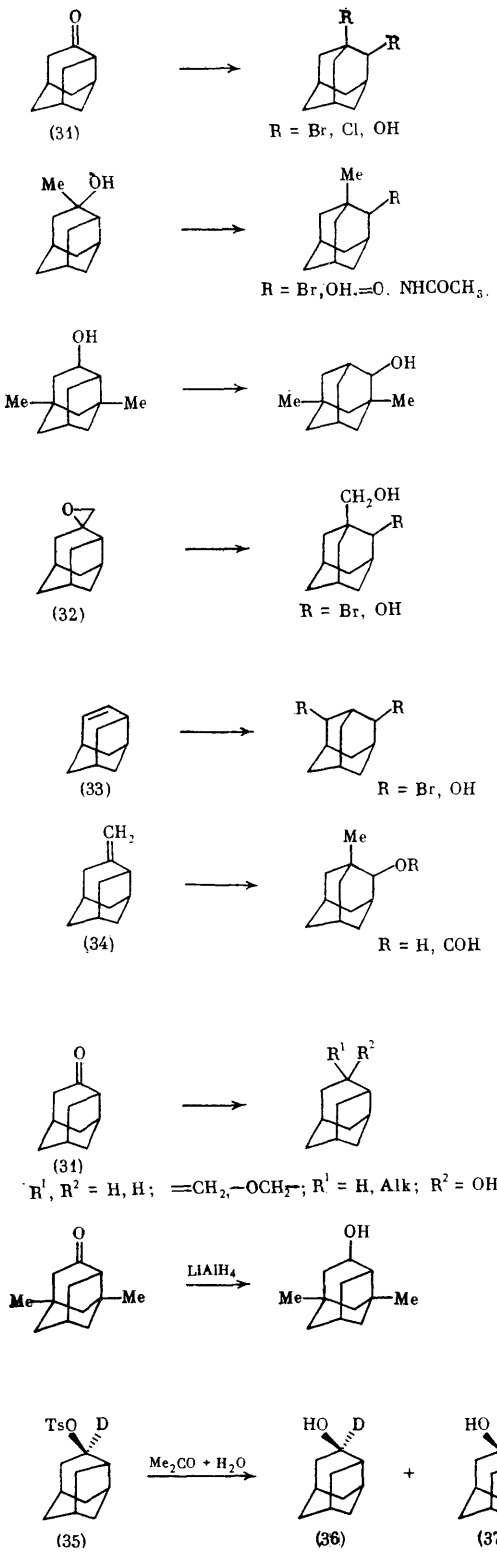


According to concepts[7] developed in recent years the isomeric polycycloalkanes with the same number of rings and same empirical formula are isomerised under the action of strong Lewis acids under thermodynamically controlled conditions to the most stable isomer of the given series, viz. the so-called stabilomer.

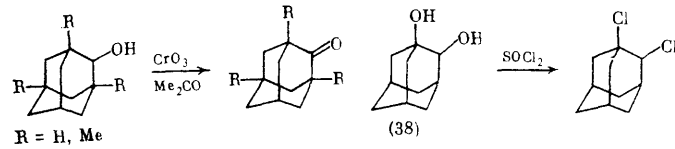
Thus adamantane is the stabilomer of the $C_{10}H_{16}$-tricyclanes, noradamantane is the stabilomer of the C_9H_{14}-tricyclane series and 1-methyladamantane of the $C_{11}H_{18}$-tricyclane series. The corresponding alkyl homologues of adamantane (27)–(30) play the role of stabilomers in the series of tricylanes from $C_{12}H_{20}$ to $C_{15}H_{26}$. Usually non-cage compounds serve as precursors of these compounds. Individual examples of the skeletal interconversions considered for compounds of cage structure are represented only in the $C_{12}H_{20}$ series.[7,21]

2. Skeletal interconversions of functionally substituted adamantanes and protoadamantanes

The thermodynamically controlled isomerisation of $C_{10}H_{16}$-tricyclanes comprises a cascade of rearrangements terminating in the rearrangement of protoadamantane into adamantane. The rearrangement indicated may be considered to be irreversible in the hydrocarbon series. In contrast to the hydrocarbons, the possibility of reciprocal skeletal conversions of the following type has been established for functionally substituted protoadamantanes and adamantanes.

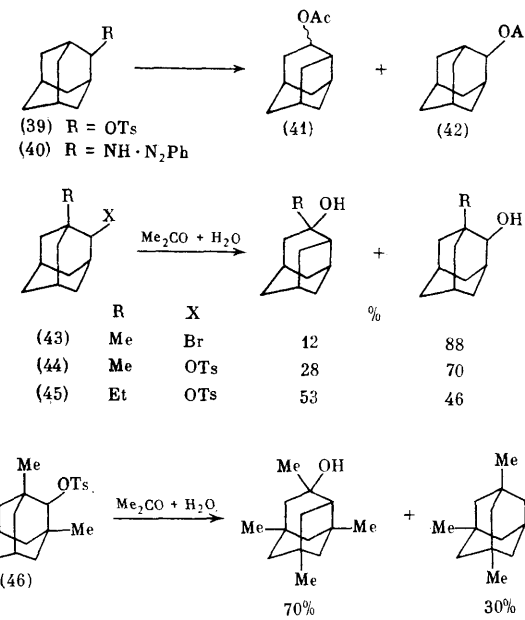


The 'protoadamantane → adamantane' rearrangement proceeds readily and completely in reactions of protoadamantan-4-one (31), its ethyleneketal,[10,22,23] alkyl substituted 4-hydroxyprotoadamantanes,[21,22,24–27,28] on interacting protoadamantane-4-spiro-oxirane (32) [28] with electrophilic reagents and also in reactions proceeding in the presence of acids. Some examples of reactions of the type indicated are shown below.



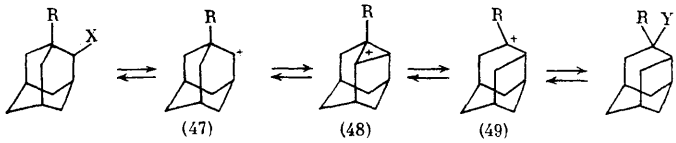
Rearrangement of the protoadamantane structure into adamantane also occurs in reactions of electrophilic addition to protoadamantene (33) [22,23,29] and to 4-methyleneprotoadamantane (34).[29]

The participation of compounds of the proto-structure in nucleophilic substitution reactions, in Grignard reactions and in the reduction of ketones with metal hydrides occurs with retention of the initial structure.[21–27,29–31]



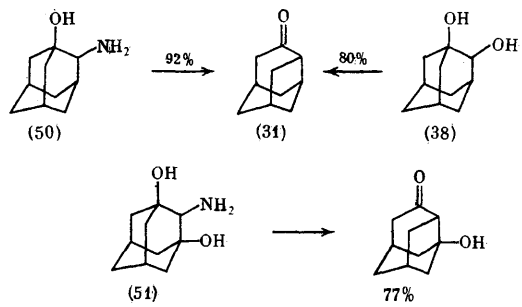
Hydrolysis of deuterated protoadamantyl tosylate (35) in 60% aqueous acetone leads to the isomeric alcohols (36) and (37). This result indicates the occurrence of a degenerate 'protoadamantane–protoadamantane' isomerisation.[10]

In the 2-substituted adamantane series the oxidation of alcohols[22,27] and the exchange of hydroxyl groups in diol (38) by Cl atoms under the action of $SOCl_2$ [22] proceed with retention of the adamantane structure.



The first example of an 'adamantane → protoadamantane' rearrangement was discovered by Whiting and co-workers[30,31] on acetolysis of 2-tosyloxyadamantane (39). The reaction product contained 0.4% acetate (41) of rearranged structure in addition to acetate (42) of the initial structure. On deamination of 2-aminoadamantane by the phenyltriazene method the yield of rearranged acetate from compound (40) was 7.5%. With the introduction of a substituent into the neighbouring junction position the tendency towards this rearrangement grows and was established for the examples of the hydrolysis of bromide (43) [32] and tosylates (44)–(46).[10,24,33–35]

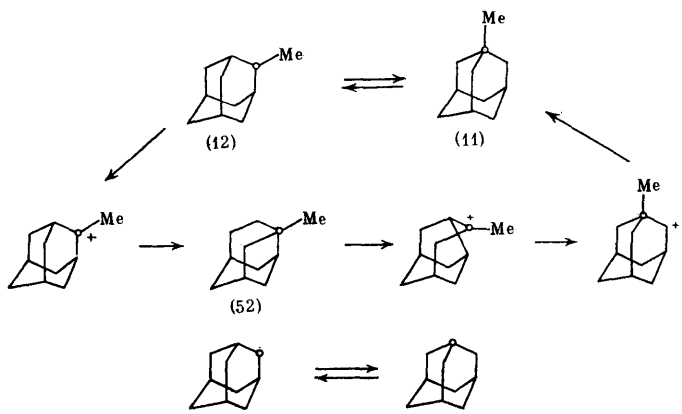
The mechanism proposed for the conversion of 2-substituted adamantanes into 4-substituted protoadamantanes in nucleophilic substitution reactions comprises the formation of 2-adamantyl cation (47) and its transformation through the bridging ion (48) into 1-protoadamantyl cation (49).



The presence of a substituent at the bridgehead position assists rearrangement since in this case the isomerised ion is tertiary which facilitates the course of a reaction by an S_N1 mechanism in difference to the initial secondary ion which reacts with difficulty in

a nucleophilic substitution reaction of S_N2 or S_N1 mechanism. Acids catalyse the reverse rearrangement.[33–37]

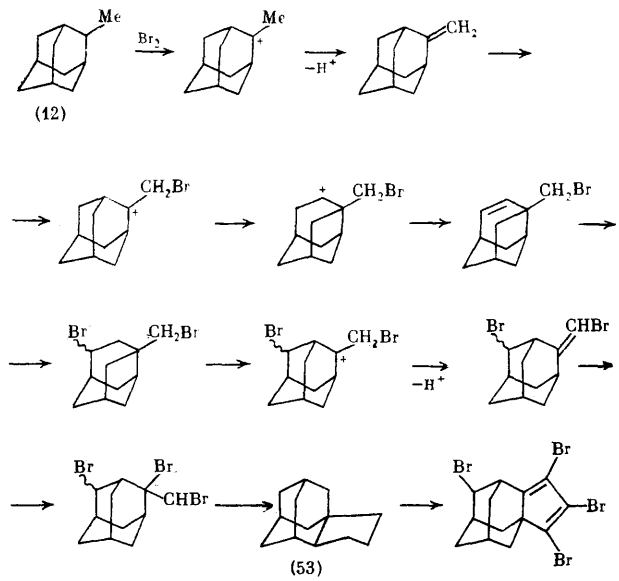
(47) (48) (49)



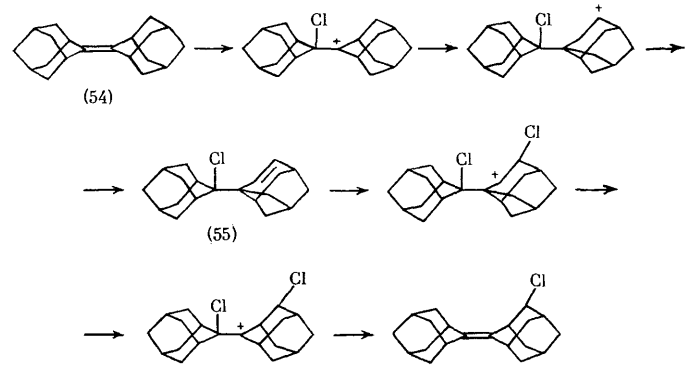
A high yield of rearrangement products is achieved on deaminating aminoalcohols (50) [10] and (51) [38] and on dehydration of alcohol (38) with dilute sulphuric acid.[22] In the case of compounds (38) and (50) the reaction indicated leads to the formation of protoadamantanone (31), a key compound in the protoadamantane series. However the conversion of the available 1-hydroxyadamantane under the action of $Pb(AcO)_2-I_2$ is chiefly used for obtaining preparatively the ketone indicated.[39,40]

(50) (31) (38)

(51) 77%



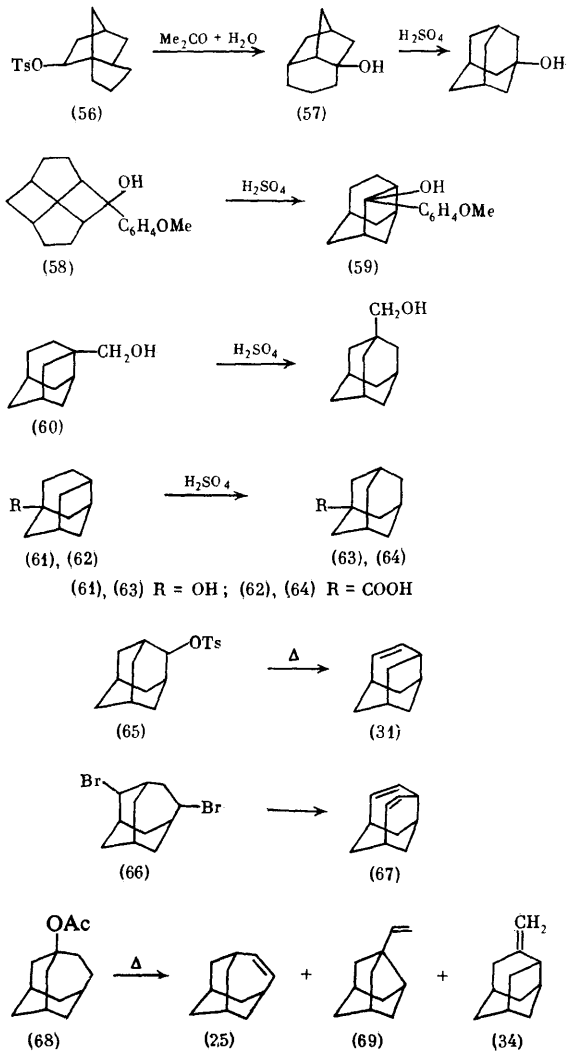
It is assumed that skeletal reorganisations of the type being considered proceed like certain conversions of 2-alkyladamantanes and of adamantane itself under the action of strong Lewis acids or with the participation of electrophiles. The isomerisation of 2-methyladamantane (12) into 1-methyladamantane (11) under the action of $AlBr_3$ comprises a conversion of the 'adamantane–protoadamantane–adamantane' type according to the mechanism proposed by Majerski and Schleyer.[41] The degenerate isomerisation of adamantane itself under the action of $AlBr_3$ most probably proceeds by an analogous mechanism.[42] These conclusions were drawn on the basis of results obtained using isotopic labels.



(12) (11)

(52)

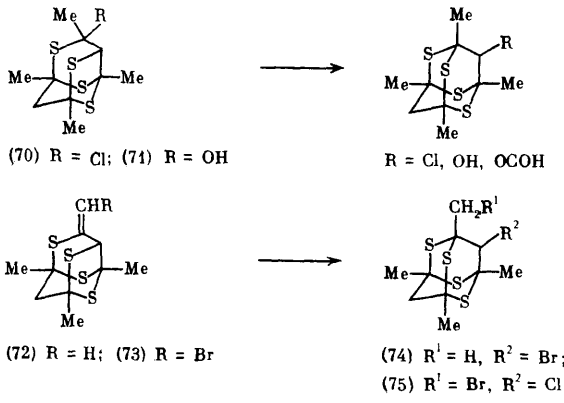
The course of the process through protoadamantyl intermediates is used to explain the formation of the unexpected bromination products from such adamantane hydrocarbons as 2-methyladamantane (12) [43] and 1,2-trimethyleneadamantane (53).[44]



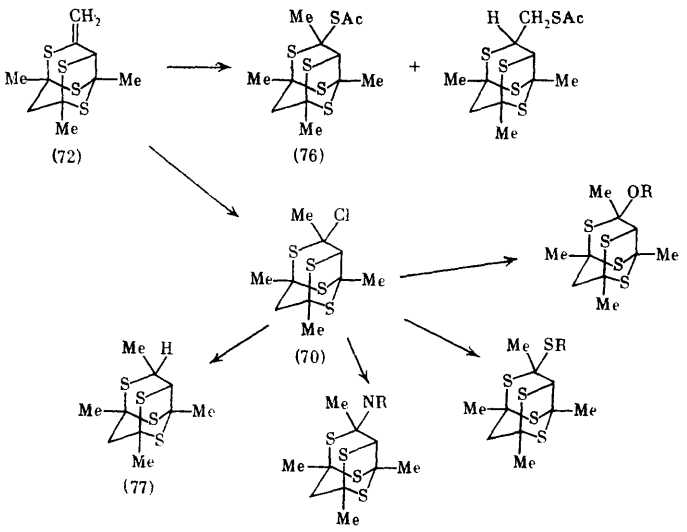
A mechanism has been proposed for the reaction of adamantylideneadamantane (54) with chlorine, the key stage of which is the formation of a protoadamantene-like intermediate (55).[45]

Individual examples of skeletal rearrangements of other types are known in addition to the interconversions of 2-substituted adamantanes and 4-substituted protoadamanatanes for functionally substituted protoadamantanes and cage tricyclanes of other structure considered in this section. Thus the hydrolysis of tosylate (56) with a 1,2-trimethylenenorbornane structure in aqueous acetone leads exclusively to alcohol (57) with a 2,6-trimethylenenorbornane structure as the rearranged product. The latter is isomerised into 1-adamantanol on storage in sulphuric acid.[46] Under the same conditions 2-*p*-anisyltwistan-2-ol (58) is isomerised into alcohol (59) with a protoadamantane structure,[9] but the bridge-substituted protoadamantanes (60)–(62) are isomerised into the corresponding bridge-substituted adamantanes.[21,47] A mechanism may be proposed

for the isomerisation of compound (61) which includes stages analogous to the conversion of (52) → (11).



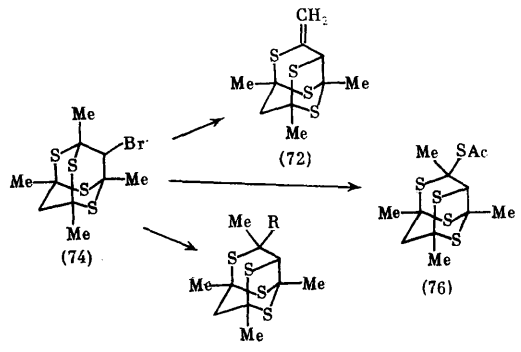
Rearrangements leading to olefins of related structure have been discovered in elimination reactions of derivatives of adamantane and homoadamantane. Thus pyrolysis of 2-adamantyl tosylate (65) leads to protoadamantene.[48] Dehydrobromination of dibromohomoadamantane (66) in hexamethylphosphoramide is accompanied by skeletal rearrangement and leads in 85% yield to diene (67) with the structure of a protohomoadamantane.[49] Olefins of rearranged structure, viz. 3-vinylnoradamantane (69) and 4-methyleneprotoadamantane (34), were also formed on pyrolysis of 1-acetoxyhomoadamantane (68) together with homoadamantene (25).[29]



3. Skeletal conversions in the 1,3,5,7-tetramethyl-2,4,6,8-tetrathia(proto)adamantane series

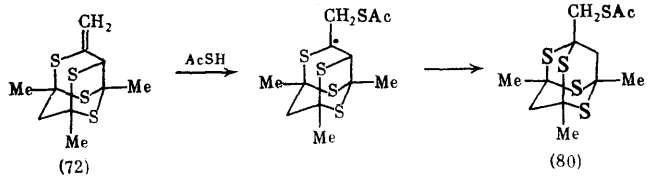
Interconversions of isomeric cage structures occur in reactions of 2,4,6,8-tetrathia-analogues of adamantane and protoadamantane methylated at the bridge position.

Compounds of rearranged structure are formed from chloride (70) and alcohol (71) with a tetrathiaprotoadamantane structure under conditions of acid solvolysis.[50] Isomerisation of the chloride indicated occurs spontaneously on storage in the solid form for 10 days and also by the action of an excess of dry HCl in ether and in AcOH.[51] A similar rearrangement accompanies the hydrohalogenation of olefins (72) and (73) in AcOH,[52] which leads to bromide (74) and bromochloro-compound (75) respectively with a tetrathiaadamantane structure.



The reaction of olefin (72) with thioacetic acid[53] and its hydrochlorination under mild conditions[51] occur with retention of the proto-structure. Chloride (70) reacts readily with nucleophiles with the formation of compounds of the same structure.[54] Reductive dechlorination of the same chloride with $LiAlH_4$ leads to an *endo*-1-methyl-3,5,7-trimethyl derivative (77) with the proto structure.[55]

A 'tetrathiaadamantane → tetrathiaprotoadamantane' rearrangement accompanies the reaction of bromide (74) with nucleophiles. Thus with AcONa/NaOH or pyridine a dehydrobromination occurs leading to olefin (72) as the sole reaction product, on interaction



with AcSH in the presence of NaOH a rearranged thiolacetate (76) is formed.[54] Hydrolysis of compound (74) in 80% aqueous dioxan gives a mixture of alcohol (78) and olefin (72) in the ratio 2.8 : 1, and in 85% aqueous methanol a mixture of compounds (72), (78) and methoxy derivative (79) in the ratio 0.8 : 1 : 1.9.[51]

(78) R = OH; (79) R = OMe

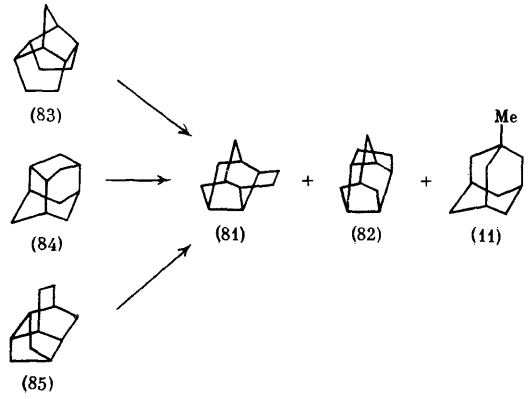
The occurrence under ionic reaction conditions of a rearrangement of tetrathia(proto)adamantanes is analogous to the rearrangement of the 'adamantane ⇄ protoadamantane' type considered in the previous section. Since the synthetic availability of key compounds proved to be different in the carbo- and thia-containing tricyclane series different cycles of conversions were carried out, however on comparing a single reaction type in the series indicated their identical structural direction was well marked. It is important to record that in comparison with compounds of the adamantane series the 9-substituted tetrathiaadamantanes displayed a greater tendency towards rearrangement.

The occurrence of a rearrangement under radical reaction conditions was established in the interaction of olefin (72) with 1 equiv. thioacetic acid in ether, leading to thiolacetate (80). The rearrangement indicated had no analogy in the adamantane series.[53]

III. Isomeric conversions of tetracyclic hydrocarbons

Investigations on the thermodynamically controlled isomerisation of tetracyclanes have been carried out in the $C_{11}H_{16}-C_{16}H_{26}$ series. Hydrocarbons of cage structure were used in the first three series of tetracyclanes indicated in difference to tricyclanes as starting materials.

An *a priori* prediction of the stabilomer among $C_{11}H_{16}$ tetracyclanes was impossible. In accordance with the calculated heats of formation of 16 not too strained isomers selected from 2486 theoretically possible tetracyclanes of the composition indicated it was concluded[56] that 2,4-ethanonoradamantane (tetracyclo-(5.3.1.$0^{2,6}$.$0^{3,9}$]-undecane) (81) and 2,8-ethanonoradamantane-(tetracyclo-[6.2.1.$0^{2,6}$.$0^{3,10}$]undecane) (82) had approximately equal and the highest thermodynamic stability in the given series (Table 2). Experimental data on the isomerisation of synthetically available isomers, viz. tetracyclo[6.3.0.$0^{2,6}$.$0^{2,9}$]undecane (83), noriceane(tetracyclo[5.3.1.$0^{1,6}$.$0^{4,9}$]undecane) (84) and methanotwistane (tetracyclo-[6.2.1.$0^{1,7}$.$0^{4,9}$] undecane) (85), enabled it to be established that 2,4-ethanonoradamantane (81) was the stabilomer in the series indicated. Thus isomerisation of tetracyclanes (83)–(85) under the action of $AlBr_3$ leads to a mixture of hydrocarbons (81) and (82) in the ratio 97 : 3 in addition to the disproportionation product (11).



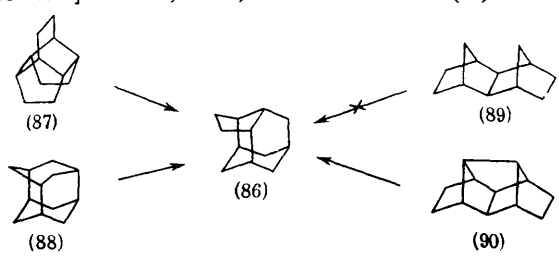


Table 2. Calculated data for the heats of formation of some $C_{11}H_{16}$-tetracyclanes.[56]

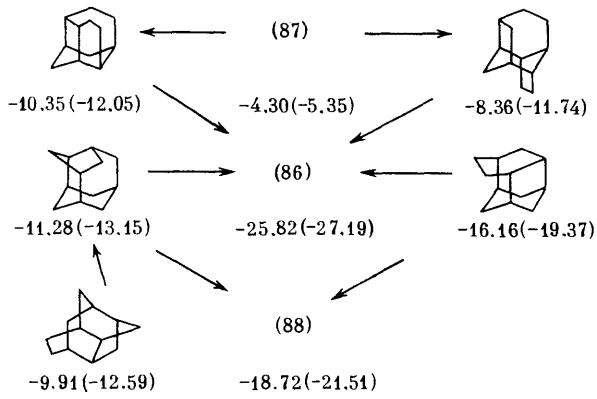
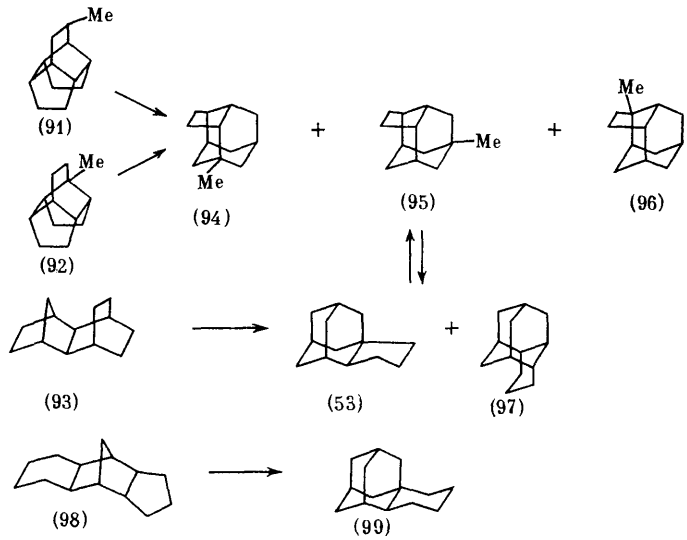


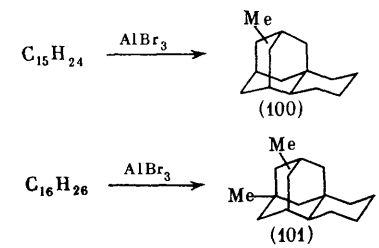
$C_{11}H_{16}$-isomers	$H°$ (gas, 25 °C), kcal mol^{-1}
2,4-Ethanonoradamantane (81)	−13.21 (−13.16)
2,8-Ethanonoradamantane (82)	−13.19 (−13.17)
Noriceane (84)	−7.21 (−10.42)
Tetracyclo[6.3.0.$0^{2,6}$.$0^{2,9}$]undecane (83)	−4.00 (−2.22)
Methanotwistane (85)	0.17 (−4.86)

The isomerisation of tetracyclanes (83) and (84) led directly to compound (81) while methanotwistane (85) was initially isomerised to hydrocarbon (82) which then isomerised slowly to (81). The formation of noriceane (84) was also recorded in the initial step of this process.

2,4-Ethanoadamantane, tetracyclo[6.3.1.$0^{2,6}$.$0^{5,9}$]dodecane (86), was detected for the first time by Landa and co-workers[57] in oil from Hodonin. Since compounds of the adamantane structure most probably arise in oil by isomerisation, Kent and Schleyer[58,59] put forward the hypothesis that 2,4-ethanoadamantane itself is the stabilomer in the $C_{12}H_{18}$-tetracyclane series. This was confirmed experimentally by carrying out the isomerisation of tetracyclo[6.4.0.$0^{4,12}$.$0^{5,9}$]dodecane (87) and iceane, tetracyclo-[5.3.1.$1^{2,6}$.$0^{4,9}$]dodecane,[88] to 2,4-ethanoadamantane (86) with $AlBr_3$.



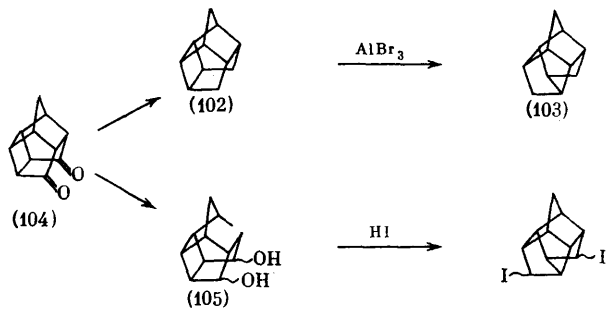
Possible routes for the rearrangement of $C_{12}H_{18}$ tetracyclanes are shown in the following scheme in which are given calculated values for the heats of formation of the hydrocarbons, i.e. for the initial, for possible intermediates and for the final isomerisation product.



As is seen, 2,4-ethanoadamantane is 21–22 kcal mol^{-1} more stable than tetracyclane (87) and 6.7 kcal mol^{-1} more stable than tetracyclane (88). The ease of the (87) → (86) rearrangement is undoubtedly due to the fact that both possible routes of conversion include only two 1,2-alkyl shifts. In the case of iceane the rearrangement most probably occurs by transformation of the carbocation resulting from the action of the Lewis acid.

In difference to tetracyclanes (87) and (88) which have the same composition, tetracyclane (89) does not undergo isomerisation under the action of $AlBr_3$ but disproportionates leading to a $C_{12}H_{20}$-alkyladamantane.[58] It is interesting to note that 2,4-ethanoadamantane is formed together with other tetra- and pentacyclanes as the disproportionation product of the $C_{12}H_{16}$ pentacyclane (90),[59] and of a structural isomer of the latter (see section V).

The isomerisation of $C_{13}H_{20}$-tetracyclanes leads to various products depending on the structure of the substrate and the reaction conditions. A mixture of three isomeric methylethanoadamantanes (94)–(96) in the ratio 5:3:2 was formed under mild conditions from methyltetracyclododecanes (91) and (92). Similarly tetracyclotridecane (93) gave a 97:3 mixture of 1,2- and 2,4-trimethyleneadamantanes (53) and (97). Under forcing isomerisation conditions the reciprocal conversion of the indicated two groups of products was observed and a mixture was formed of compounds (53) and (94)–(97) in the ratio 42:27:19:8:3 together with products of side reactions. The calculated heats of formation of the compounds indicated did not correspond with the experimental results which does not permit a conclusion to be drawn as to the stabilomer in the series under consideration. On the other hand in the $C_{14}H_{22}$-tetracyclane series the experimental data on the isomerisation of hydrocarbon (98) and the calculated data indicated unequivocally that 1,2-tetramethyleneadamantane (99) is the stabilomer in this series.[60] The latter is also formed as a disproportionation product on rearranging certain $C_{14}H_{20}$-pentacyclanes (see section V).

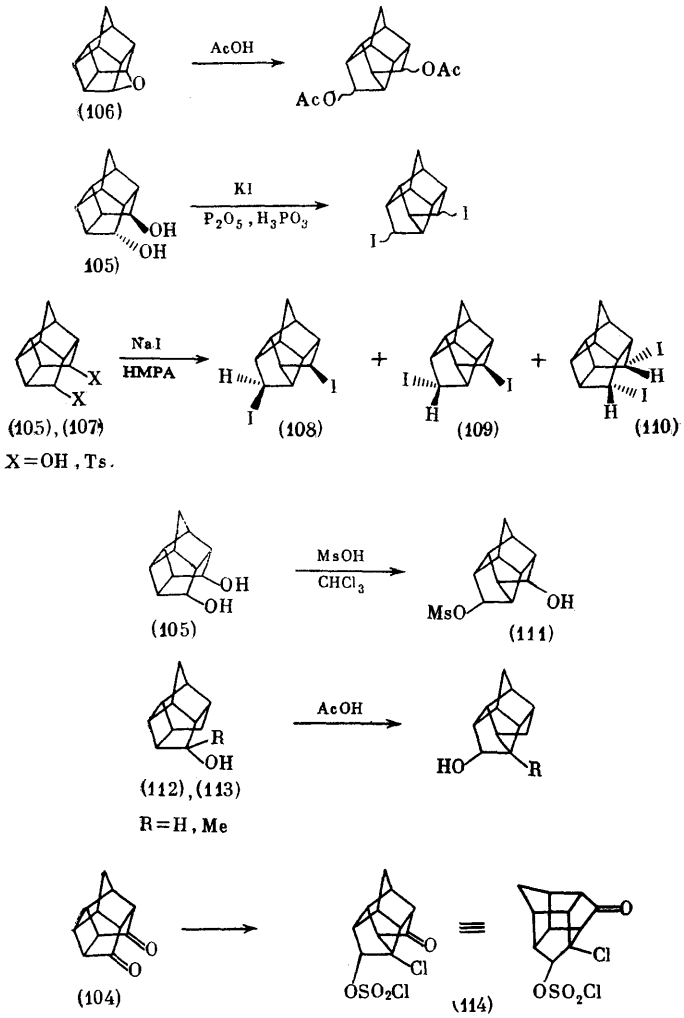


The isomerisation of tetracyclanes of composition $C_{15}H_{24}$ and $C_{16}H_{26}$ of non-cage structure with $AlBr_3$ leads to methyl- and dimethyl-substituted 1,2-tetramethyleneadamantanes (100) and (101) respectively.[61]

IV. Skeletal rearrangements of $C_{11}H_{14}$-pentacyclanes

Skeletal conversions in this series are mainly represented by the isomerisation of pentacyclo[6.2.1.0^{2,7}.0^{4,10}.0^{5,9}]undecane (102) into trishomocubane, pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane (103), and by analogous skeletal rearrangements in reactions of numerous functionally substituted derivatives of pentacyclane (102). The latter are convenient subjects for investigation since they may readily be synthesised from the available diketone (104), itself the product of the photocyclisation of the Diels-Alder adduct of *p*-benzoquinone and cyclopentadiene. Proceeding from the diketone indicated, first Underwood and Ramamorthy,[62] and then Eaton and co-workers[63] by another route, effected the synthesis of trishomocubane. The formation of the trishomocubane structure in these syntheses occurred by intramolecular cyclisation in the corresponding tetracyclic intermediate. In several recent studies approaches have been developed to trishomocubane, and its mono- and disubstituted derivatives, based on the skeletal rearrangement of C_{11}-pentacyclic substrates. Thus trishomocubane has been obtained by the

isomerisation of pentacyclane (102) with $AlBr_3$.[64] The same authors have described a rearrangement leading to the trishomocubane structure in the reaction of diol (105) with HI.[65]

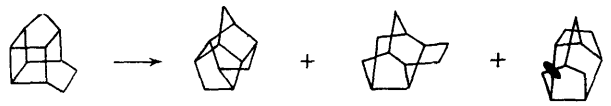


The interaction of diol (105) with a mixture of H_3PO_4, P_2O_5 and KI and fission of the oxygen bridge of the oxa-'bird-cage' (106) in AcOH is accompanied by rearrangement and leads exclusively to a trishomocubane derivative.[66] By reacting diol (105) and tosylate (107) with NaI in hexamethylphosphoramide, diiodides of rearranged structure (108) and (109) are formed together with diiodide (110) of initial structure.[67,68]

Table 3. Calculated data for the heats of formation of some $C_{11}H_{14}$-pentacyclanes.[65]

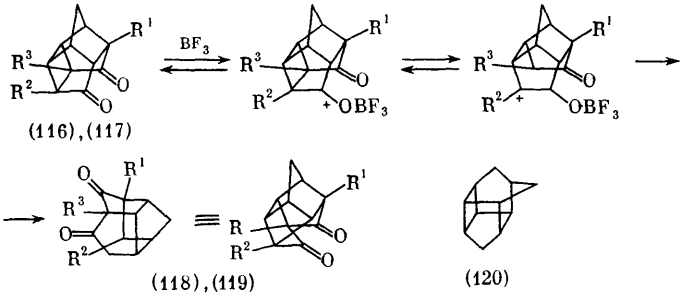
$C_{11}H_{14}$-isomers	H° (gas, 25 °C), kcal mol^{-1}
Trishomocubane (103)	9.38 (11.32)
Pentacyclo[6.2.1.0^{2,7}.0^{4,10}.0^{5,9}]undecane (102)	19.62 (21.93)
Pentacyclo[5.4.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane (120)	23.88 (26.58)
Homobasketane (115)	40.99 (43.82)

A rearranged hydroxymesylate (111) is formed on reacting diol (105) with methanesulphonic acid.[69] Alcohols (112) and (113) are isomerised into the corresponding compounds of the trishomocubane structure by reaction with acetic acid.[70]



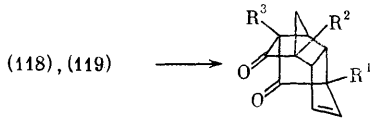
Compounds, which in their turn were obtained from diketone (104), are transformed in the above examples into the trishomocubane structure. The single example of a similar conversion of diketone (104) is its reaction with chlorosulphonic acid leading to a trisubstituted trishomocubane (114).[71–73]

Kent and co-workers[65] carried out an analysis of the stability of the isomeric cage $C_{11}H_{14}$-pentacyclanes which were selected from the 15358 possible cage isomers after excluding very strained structures. The results showed that trishomocubane itself is the thermodynamically most stable isomer in this series (Table 3). An insignificant difference in energy (10 kcal mol^{-1}) and the possibility of a (102) → (103) transition by a simple 1,2 shift in the secondary cation explains the ease of the considered rearrangement. It would be noted that examples of the reverse rearrangement, probable in reactions of functional derivatives of trishomocubane, have not as yet been described.



Results of studies[74] in which trishomocubane was obtained by isomerisation of homobasketane (115) with $AlBr_3$ are in agreement with the given theoretical analysis. The $C_{11}H_{16}$-isomers (81) and (82) were formed as well as compound (103) in the reaction indicated.

(115) (103), 82,0% (81), 6,4% (82), 11,1%

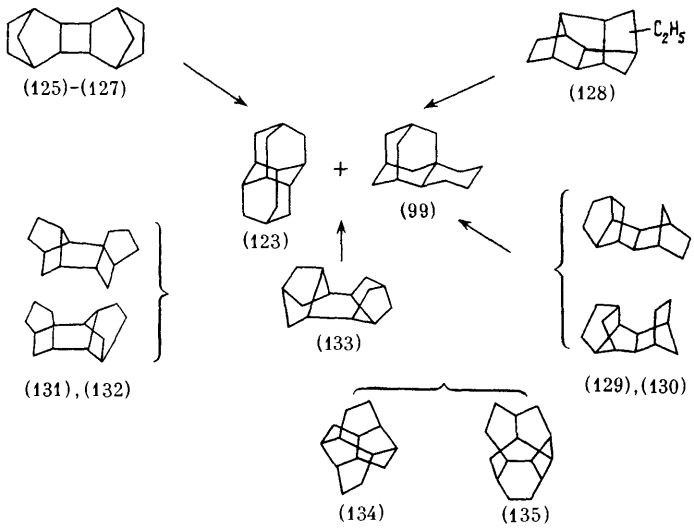


Introduction of alkyl groups at the α-position to the carbonyl group in diketone (104) may assist skeletal reorganisation which diketone (104) itself does not undergo. Thus dimethylketones (116) and (117) are isomerised by BF_3 etherate into compounds (118) and (119) respectively with the structure of a pentacyclo-[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,9}$]undecane.[75] The indicated isomerisation is even more interesting since the unsubstituted pentacycloundecane (120) is thermodynamically less stable than pentacycloundecane (102) (Table 3).

(116), (117) (118), (119) (120)

(116), (118) R^1=H ; R^2, R^3=Me ; (117), (119) R^1, R^2=Me, R^3=H.

The corresponding tetracyclic enediones (121) and (122) are obtained on pyrolysis of pentacyclic compounds (118) and (119).[75]

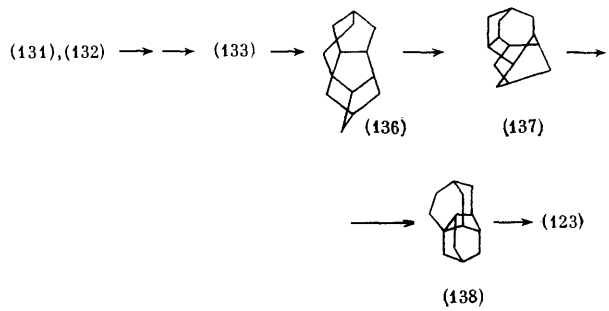


(118), (119) (121), (122)

V. Syntheses of polycage compounds of the condensed type based on skeletal transformations of monocage polycyclanes

The main principles of the thermodynamically controlled isomerisation of polycycloalkanes apparent in investigations on the synthesis of monocage structures have been further developed in approaches to polycage compounds of a condensed type of structure such as diamantane (123) and triamantane (124). In the same way that adamantane is the stabilomer of the $C_{10}H_{16}$-tricyclanes, diamantane is the stabilomer of the $C_{14}H_{20}$-pentacyclanes and triamantane the stabilomer of the $C_{18}H_{24}$-heptacyclanes. The problem of the selection of a suitable precursor proved to be a key issue in investigations on the synthesis of the polymantanes indicated.

Diamantane was isolated for the first time from Hodonin oil[57] and was synthesied at almost the same time by a [2 + 2] rearrangement of norbornene photodimers (125)–(127).[76] In this synthesis the yield of diamantane was 1 to 10% depending on which stereoisomer was used. 1,2-Tetramethyleneadamantane (99) formed by disproportionation of the starting materials predominated in the reaction product.[77,78]



(125)-(127) (128) (123) (99) (133) (131), (132) (129), (130) (134) (135)

The search for other precursors then led to cage pentacyclane (128) isomerisation of which gave diamantane in 30% yield.[77,78] Diamantane was obtained in 25% yield on using hydrogenated Katz dimers (129) and (130).[78] The most suitable precursor for diamantane proved to be tetrahydro-Binor-S (131) and (132). On isomerisation of the latter with $AlBr_3$ in CS_2 the yield of diamantane was 65% and with $AlBr_3$ in CH_2Cl_2 82%.[77–80] One of the intermediates, viz. *trans*-pentacyclo[8.2.1.$1^{2,5}$.$0^{3,7}$.$0^{8,12}$]tetradecane (133), was isolated and identified during the conversion.[78] Recently the synthesis of diamantane in high yield by isomerisation of hydrogenated dimers of cycloheptatriene (134) and (135) has been described.[81]

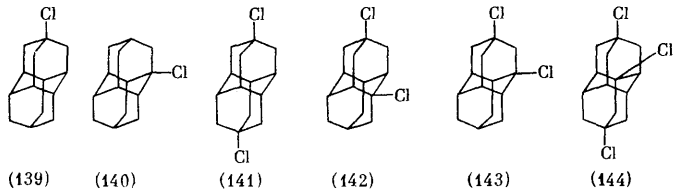


Table 4. Calculated data for the heats of formation of some $C_{14}H_{20}$-pentacyclanes.[82]

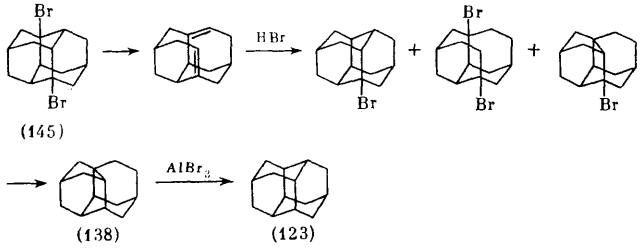
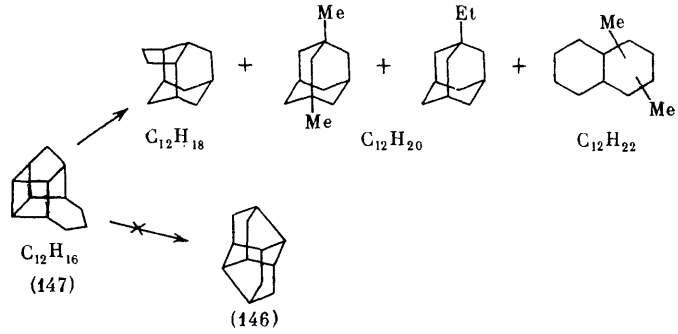
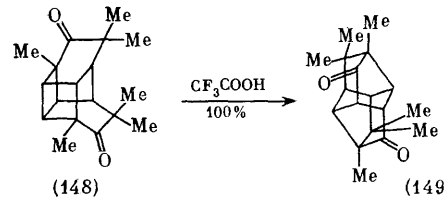
$C_{14}H_{20}$-isomers	$H°$ (gas, 25 °C), kcal mol^{-1}
Diamantane (123)	10.7
Protodiamantane (138)	31.1
Intermediate (137)	28.0
Intermediate (136)	40.8
Intermediate (133)	34.9
Tetrahydro-Binor-S (131)	62.16
(132)	54.15
(2+4)-dimers of norbornene (129)	49.77
(130)	57.15
(2+2)-dimers of norbornene *exo, trans, exo*-(125)	57.62
exo, trans, endo-(126)	62.57
endo, trans, endo-(127)	68.03



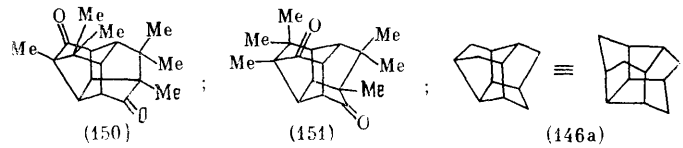
A theoretical analysis of the rearrangement of pentacyclotetradecanes into diamantane has been carried out.[82] According to the calculated data obtained for various precursors, for a vast number of possible intermediates and for diamantane itself, the latter was the thermodynamically most stable isomer among the $C_{14}H_{20}$-pentacyclanes (Table 4). A possible mechanism for the isomerisation of hydrocarbons (131) and (132) comprises the following sequence of skeletal conversions which is completed by the rearrangement of protodiamantane, pentacyclo[7.3.1.1^{4,2}.1^{1,7}.0^{6,11}]-tetradecane (138), into diamantane.



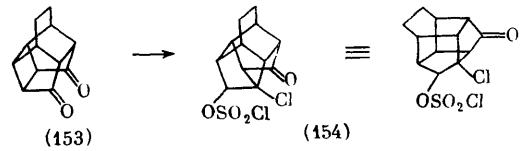
The possibility was shown in several examples of combining two steps, viz. the isomerisation of tetrahydro-Binor-S into diamantane and functionalisation of the latter. Thus chloroadamantanes (139) and (140) were obtained from tetrahydro-Binor-S with $AlCl_3$ and acetyl chloride, and dichloroadamantanes (141)–(143) were obtained on using $AlCl_3$ and paraformaldehyde.[80,83] Chlorosulphonic acid converts tetrahydro-Binor-S into 4,9-dichlorodiamantane (141) or into 1,4,9-trichlorodiamantane (144) depending on the duration of reaction.[84]



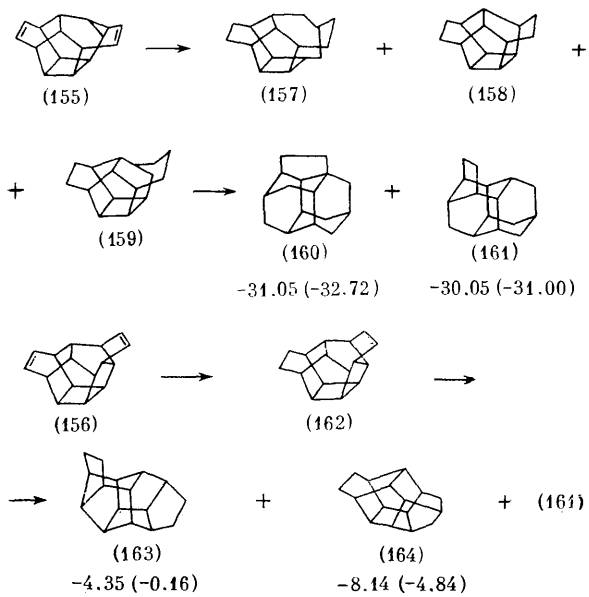
Gund and Schleyer[85] carried out the synthesis of protodiamantane (138) using dibromodiamantane (145) as starting material. Isomerisation of (138) into diamantane (123) proceeded readily with $AlBr_3$ or H_2SO_4 in methylcyclohexane.



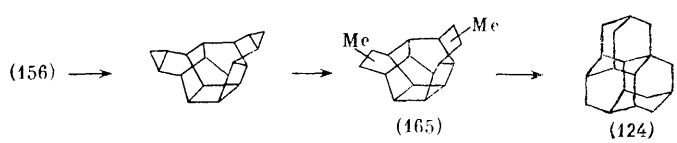
Attempts to obtain the lower homologue of diamantane, viz. bisnordiamantane (146) by the isomerisation of pentacyclo[5.5.0.0^{2,5}.0^{3,12}.0^{4,8}]dodecane (147) have been unsuccessful. The $C_{12}H_{16}$ hydrocarbon mentioned did not isomerise with $AlBr_3$ under mild conditions and under forcing conditions its conversion led only to a disproportionation product.[74]



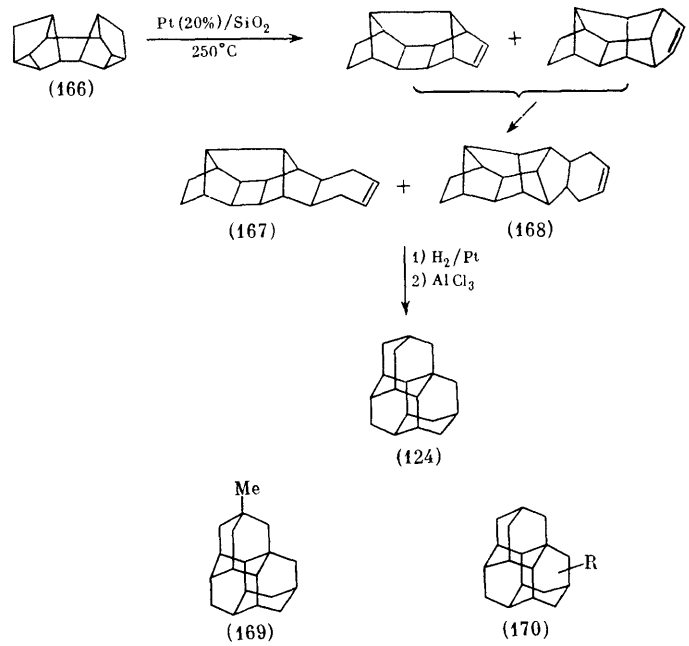
In contrast to hydrocarbon (147) the hexamethyldiketone (148) with the dihomobasketane structure, pentacyclo[6.4.0.0^{2,7}.0^{3,12}.0^{4,9}]-dodecane, readily isomerised in boiling trifluoroacetic acid or in benzene in the presence of toluene-*p*-sulphonic acid into compound (149) with the bisnordiamantane structure.[86] Theoretical analysis of the isomerisation showed that compound (149) is 3–6 kcal mol^{-1} less stable than isomers (150) and (151). In the C_{12} pentacyclane hydrocarbon series the stabilomer is pentacyclo[6.4.0.0^{2,6}.0^{3,11}.0^{4,9}]-dodecane (152), which is 8 kcal mol^{-1} more stable than bisnordiamantane (146).



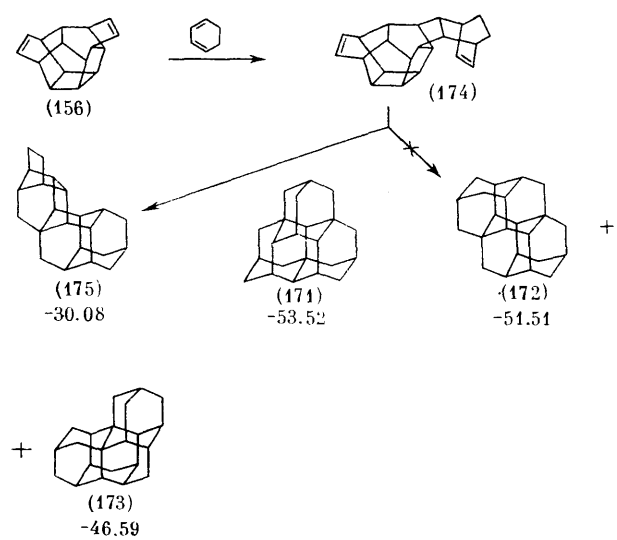
The fact that the isomerisation of compound (148) does not lead to the formation of the stabilomer is most probably explained by the absence of a suitable route for further skeletal isomerisation in this case.[87]



The reaction of diketone (153) with chlorosulphonic acid is accompanied by a skeletal rearrangement and leads to the chloroketo-sulphonyl chloride (154) with a pentacyclo[7.3.0.0^{2,7}.0^{3,11}.0^{6,10}]-dodecane structure. The formation of the stabilomer structure was not observed in this case either.[72]



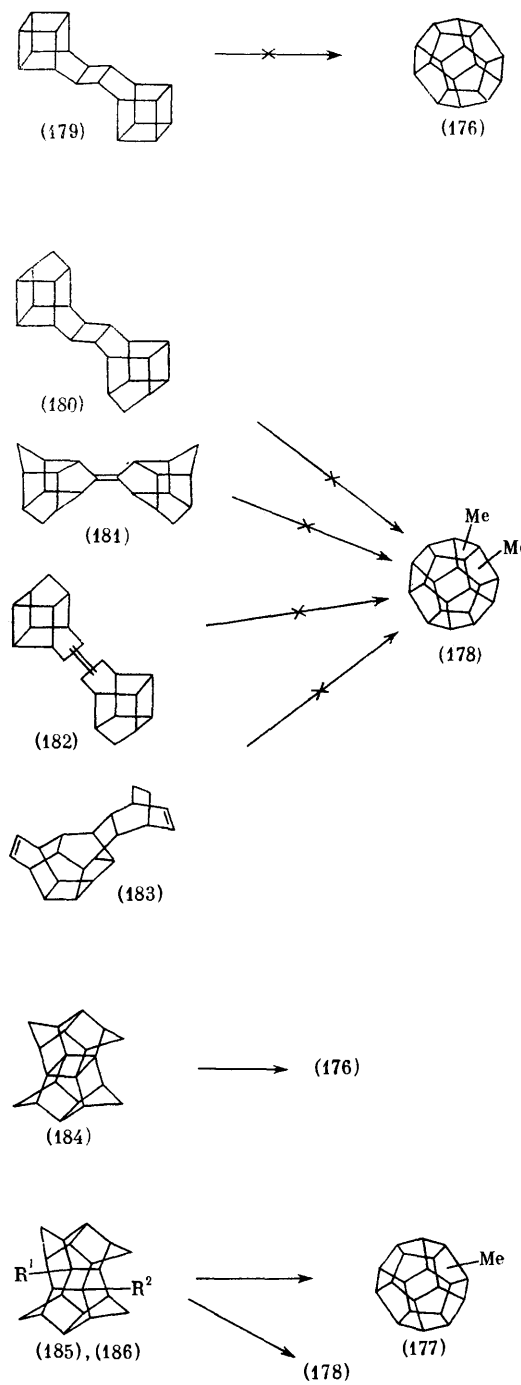
The synthesis of polymantanes of composition $C_{16}H_{20}$, isomers of ethanodiamantanes and diethanobisnordiamantane, was effected on the basis of the cage dimers of cyclooctatetraene (155) and (156). Hydrogenation of the first of these led to a mixture of hexacyclohexadecanes (157)–(159), the isomerisation of which with $AlBr_3$ gave a mixture of (C_1)-ethanodiamantane (160) (85%) and (C_s)-ethanodiamantane (161) (15%).[88] The first isomer is more stable than the second according to molecular mechanical calculations. From the product of hydrogenation of the second dimer, compound (162), a mixture was obtained of (C_2)-bisethano-bisnordiamantane (163) (73%) and compound (164) (13%) with a structure related to 'bird-cage'. Compound (161) (~20%) was also formed on using a complex containing $AlBr_3$ and t-butyl bromide and is the disproportionation product in the given reaction.



In the first synthesis of triamantane (124) by the isomerisation of $C_{18}H_{24}$ heptacyclanes Schleyer and co-workers[89] started from cyclooctatetraene dimer (156) which had served for the synthesis of polycyclane (165). Isomerisation of the latter with $AlBr_3$ led to triamantane in 1% yield.

Polycyclanes (167) and (168) obtained from Binor-S (166) proved to be the most suitable precursors of triamantane. Isomerisation of the dihydro derivatives of the latter led to triamantane (124) in 60% yield.[90] Methyltriamantane (169) and pentanotriamantane (170) were prepared by a modified diene synthesis using isoprene or cyclopentadiene as diene component.[8]

Attempts to obtain tetramantanes (171)–(173) by isomerisation of polcyclane (174), synthesised from cyclooctatetraene dimer (156), led only to a structural isomer of tetramantane, viz. bastardane (nonacyclo[11.7.1.1^{2,18}.0^{3,16}.0^{4,13}.0^{5,10}.0^{6,14}.0^{7,11}.0^{15,20}]-docosane) (175).[88] According to the calculated data shown in the scheme bastardane is less stable than tetramantanes (171)–(173). Thus the isomerisation process in the present example is not completed by the formation of the stabilomer but finishes at the stage of obtaining the kinetically stable structural isomer.



VI. Skeletal rearrangements of $C_{20}H_{20}-C_{22}H_{24}$ polycyclanes in approaches to the synthesis of dodecahedrane

The problem of the synthesis of dodecahedrane (176), a spherical system of composition $C_{20}H_{20}$, containing twelve repeatedly linked cyclopentane rings has attracted significant attention in the last decade.[91,92] Paquette and co-workers[93,94] reported the first preparation of dodecahedrane in 1982 by a 23 stage synthesis. Among the various approaches developed to achieve this goal were repeated attempts to obtain dodecahedrane and its alkyl homologues by the thermodynamically controlled isomerisation of polycage precursors. This synthetic route was exceptionally tempting since it might have enabled dodecahedrane to be obtained in one stage. Such an approach was based on the *a priori* hypothesis that dodecahedrane is the stabilomer of the $C_{20}H_{20}$ dodecacyclane series. The obtaining of the appropriate calculated data required to select the stabilomer in this series did not indeed seem possible in view of the astronomical number of isomeric cage structures.

Bicage compounds of various types were used as precursors in experimental attempts to isomerise dodecacyclanes into dodecahedrane or its alkyl homologues (177) and (178). The photodimer of basketane (179) [95] and the photodimer of homobasketane (180) [74] were subjected to isomerisation with Lewis acids. Attempts have also been described to isomerise bicage olefins (181) and (182) and also cage diene (183), obtained in the diene synthesis reaction of cyclooctatetraene dimer and cyclohexadiene.[74] They were all unsuccessful.

The bicage $C_{20}H_{20}$ dodecacyclane, 1,1,1,1-pagodane (184), recently attracted attention as a precursor of dodecahedrane. The former failed to isomerise to dodecahedrane with strong acids, however, the isomerisation was effected in the gas phase over a catalyst ($Pt/Re/Al_2O_3$, Pd/C, Rh/C, Pd/Al_2O_3).[96,97] The alkyl homologues of dodecahedrane (177) and (178) were obtained similarly. The corresponding compounds (185) and (186), with structures related to pagodane, were used as precursors.[97] This approach to the synthesis of dodecahedrane derivatives has been further developed.[98,99]

The data presented in the review demonstrate the wide synthetic possibilities of applying to cage compounds methods based on skeletal rearrangements and, most of all, on the thermodynamically controlled isomerisation of hydrocarbons. Investigations carried out up to the present time on the isomerisation indicated enable ideas to be formulated on stabilomer structure and applied in practice to the creation of new synthetic principles, previously unknown in organic chemistry. Doubtless further investigations in this area will serve as a basis for finding effective approaches to the many unique cage structures, including the hypothetical. It is also possible to suggest that further development of methods of synthesis of functional derivatives, including interconversions of isomeric structures may be found in the chemistry of cage and heterocage compounds.

Chemical dehydrohalogenation of halogen-containing polymers

S E Evsyukov, Yu P Kudryavtsev, Yu V Korshak
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. This review is concerned with the dehydrohalogenation of halogen-containing polymers as a method of obtaining polymers with a system of conjugated multiple bonds. Different dehydrohalogenating agents are described and the mechanism, kinetics and structure of the reaction products are examined.

The bibliography includes 159 references.

I. Introduction

Dehydrohalogenation of halogen-containing compounds has been studied in detail[1] in the field of organic chemistry and is widely used for the synthesis of unsaturated compounds.[2]

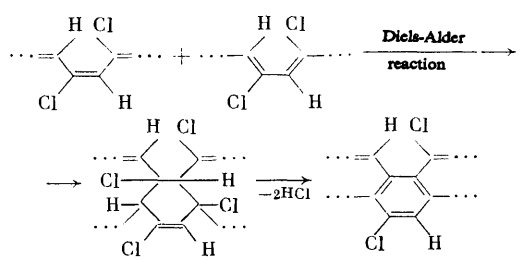
In the chemistry of macromolecular compounds the majority of studies on the dehydrohalogenation of halogen-containing polymers were carried out previously in order to find effective stabilisers for these polymers, in particular for poly(vinyl chloride) (PVC), because of their low resistance towards heat and light. A number of reviews have been devoted to the thermal degradation of PVC.[3–18]

Several methods for the dehydrohalogenation of halogen-containing polymers are known.[3] However, thermal and photodehydrohalogenation as well as dehydrohalogenation by means of X-radiation and γ-radiation result in the formation of cross-linked products with short sequences of conjugated multiple bonds. Dehydrohalogenation by chemical agents can give considerably longer segments of conjugation, particularly under mild conditions (at reduced temperatures).

At the beginning of the 1960's studies in which the directed dehydrohalogenation of halogen-containing polymers was investigated as a method of obtaining polymers that contain a system of conjugated multiple bonds in the main chain started to be published in the scientific literature. A considerable amount of experimental experience in this field of polymer-like reactions has been built up so far, but reviews devoted to the chemical dehydrohalogenation of polymers are absent from the literature. Therefore, the aim of the present reivew is to correlate the literature data on the dehydrohalogenation of halogen-containing polymers by different chemical agents and to examine the structure of the reaction products as well as the kinetics and mechanisms of the reactions that occur.

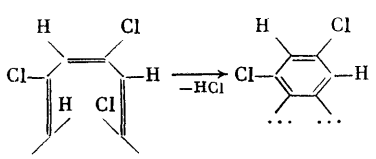
II. Dehydrohalogenation by alkalis

Alkali metal hydroxides, in particular those of Na and K, are widely used as dehydrohalogenating agents. However, aqueous solutions of NaOH and KOH only react effectively with halogen-containing polymers at high temperatures. Thus, for example, in order to dehydrochlorinate PVC completely with aqueous solutions of NaOH and KOH the reaction must be carried out at 250–270 °C.[19] At these temperatures the contribution from side reactions involving cross-linking and oxidation of the resulting sequences of conjugated double bonds increases considerably. At lower temperatures the reaction takes place extremely slowly. Thus, in the dehydrofluorination of poly(vinylidene fluoride) (PVDF) powder with an aqueous solution of NaOH at 90 °C for 5 h, there is only 7.8% elimination of HF.[20] Reactions with PVC [21] and vinylidene chloride–vinyl chloride copolymer[22] occurred in a similar manner.



1. Dehydrohalogenation in the presence of phase-transfer catalysts

By using quaternary ammonium and phosphonium halides[20–27] and hydroxide[28] and also crown ethers[20,29] as phase-transfer catalysts it was possible to increase significantly the rate of alkaline dehydrohalogenation of halogen-containing polymers.



In a number of studies the dehydrohalogenation of PVC,[21,26,27] poly(vinylidene chloride) (PVDC),[29] PVDF,[20,23,25,28] and vinylidene chloride–vinyl chloride copolymer containing 5–20% of the latter (Saran)[22,24] was investigated. A high degree of conversion was achieved on average after 15–20 h at 60–100 °C, although data exists on the surface modification of PVDF films[23,25] and the dehydrochlorination of PVC [21] and Saran[22] that were carried out at room temperature. The reactions were conducted using powders,[20,21,24,27,28] films,[20,21,23–26] and solutions[22] of the polymers.

In the dehydrochlorination of PVC in the presence of quaternary ammonium or phosphonium halides,[21,26] black compounds are formed that undergo aerial oxidation and which have a conjugated polyene structure of the *trans*-polyacetylene type. As the reaction takes place, characteristic absorption bands appear in the IR spectra of the products due to isolated (1670 cm^{-1}) and conjugated (1560 cm^{-1}) C=C double bonds as well as an absorption band at 580 cm^{-1} attributed to bending vibrations of C–H bonds in *trans*-olefinic bonding.[21]

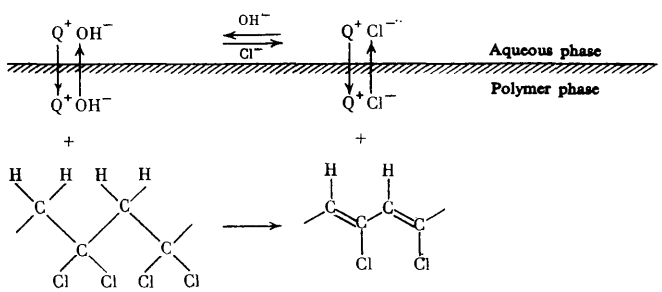
In the dehydrohalogenation of PVDC, Saran, and PVDF in the presence of onium salts, the reaction products are black powders or films that have the halogen-substituted polyene structure $-(-CX=CH-)_n-$, (X = Cl, F) and are stable towards aerial oxidation,[20,24] in contrast to dehydrochlorinated PVC.[21] In the IR spectra of the products from the dehydrohalogenation of poly(vinylidene halides) intense absorption bands occur in the region of 1600 cm^{-1} which correspond to stretching vibrations of conjugated C=C double bonds, and much less intense bands appear in the region of 2170 cm^{-1} that are attributed to the stretching vibrations of C≡C triple bonds which can be formed by the elimination of two molecules of hydrogen halide from a single vinylidene unit of the polymer.[20,22,24,29] In addition to that, in the IR spectra of the dehydrohalogenation products of these polymers, absorption bands have been recorded in the region of 865 and 3400 cm^{-1} that are attributed to aromatic structures and OH groups respectively. According to the authors of two studies,[24,29] aromatisation of the polyene sequences can occur via a Diels–Alder reaction followed by dehydrohalogenation of the resulting cyclohexene structures:

or as the result of intramolecular cyclisation via 1,6-elimination:

The authors attribute the low content of C≡C triple bonds in the dehydrohalogenation products at high degrees of conversion to aromatisation of the polyene sequences. Hydroxyl groups occur in the polymer as a result of nucleophilic substitution of the halogen atoms in the polymer by the hydroxyl ion.[24]

In the IR spectra of the dehydrohalogenation products with a high degree of conversion the absorption bands characteristic of the initial polymers have become very weak.

In several studies[20–22,24] a wide range of quaternary ammonium and phosphonium halides were used as phase-transfer catalysts; these differed according to the number of carbon atoms in the hydrocarbon substituents on the nitrogen or phosphorus atom—from tetramethylammonium bromide to an Adogen catalyst [trialkylmethylammonium (C_8-C_{10}) chlorides]. The activity of the onium salts in dehydrohalogenation reactions depends mainly on the number of carbon atoms in the catalyst molecule and is limiting in nature. For the dehydrohalogenation of PVC and PVDF the reaction occurred more rapidly and the conversion reached a maximum when tetrabutylammonium bromide (TBAB) was used as the catalyst. In the dehydrochlorination of Saran the best catalyst proved to be tetrapropylammonium bromide (TPAB). Similar results were obtained when the analogous phosphonium salts were used.



The limiting dependence of the activity of the catalyst on the number of carbon atoms in the substituents is accounted for using the concept of the hydrophile-lipophile balance (HLB). An increase in the lipophilic nature of the catalyst assists the reaction up to a given maximum. With a further increase in the number of carbon atoms the alkyl substituents of the catalyst inhibit its diffusion into the polymer. In two-phase aqueous organic reactions the negatively charged bases form ion pairs with the positive onium ions and are then extracted into the organic phase, where reaction takes place. Since exchange of anions at the phase boundary or in the aqueous phase occurs much more rapidly than the reaction between an ion pair and substrate (polymer), the rate of reaction mainly depends on the concentration of catalyst in the organic phase.[21] In the dehydrohalogenation of polymers a layer of reaction products that are insoluble is formed on their surface, significantly inhibiting diffusion of the dehydrohalogenating agent into the polymer, i.e., the reaction is self-inhibited.[25]

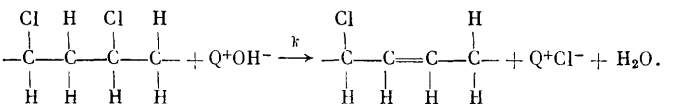
For a quantitative determination of the HLB the use of function D was proposed:

$$D = (\delta - \delta_w)^2/(\delta - \delta_o)^2,$$

where δ, δ_w, and δ_o are the solubility parameters of the onium salts, water (δ_w = 23.4) and the organic phase (polymer) respectively.[30] The catalytic activity of the onium salts increases with a decrease in the value of D,[24] in other words, it depends on the affinity of the ion pair for the organic phase (polymer), where dehydrohalogenation occurs. In the dehydrochlorination of Saran, TPAB had the greatest activity (higher and lower analogues were less active),[24] while in the dehydrohalogenation of PVC and PVDF, TBAB proved to be the most active.[20,21] This difference can be attributed to the more hydrophilic nature of PVDC compared to PVC and PVDF, which have similar solubility parameters.[20]

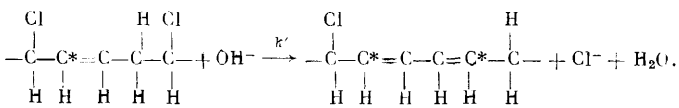
The mechanism of the dehydrohalogenation of PVDC under heterogeneous conditions in the presence of a phase-transfer catalyst (Q^+Cl^-) has been schematically represented.[24]

The ammonium hydroxide formed in the aqueous phase reacts with the polymer on the surface of the polymer particles according to an E_2 mechanism.[1] Molecules of Q^+OH^- penetrate the polymer phase and react with counterions of PVDC.



However, the empirically derived expression for the rate of dehydrochlorination of PVC [27] cannot be accounted for using this simple mechanism

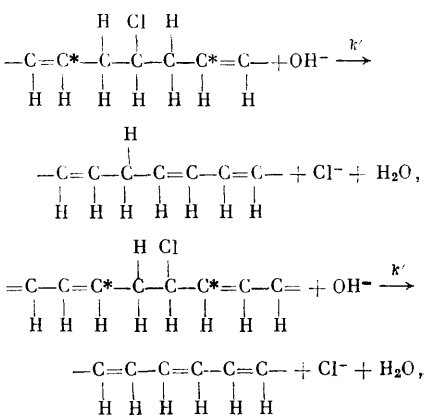
$$v = k.[TBAB]^{0.43}.[NaOH]^{1.1},$$



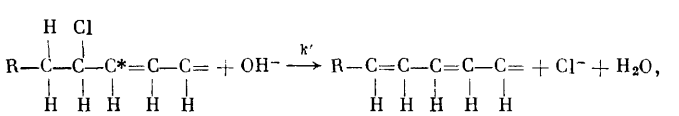
where [TABA] and [NaOH] are the concentrations of tetrabutylammonium bromide and alkali respectively. Therefore, Howang et al.[27] proposed the following mechanism of dehydrohalogenation that includes several stages in the case of PVC.

The initiation stage involves the elimination of HCl catalysed by a quaternary onium base (Q^+OH^-) with the formation of isolated

double bonds in the PVC chains



In the stage involving growth of the chain of conjugation, a vinyl chloride unit adjacent to a double bond in the presence of the OH^- anion readily loses HCl to form conjugated double bonds



The carbon atoms of the extending conjugation front are marked with an asterisk.

In the termination stage elimination stops when two conjugation fronts in the same polymer chain meet

or when the end of the chain is reached by the front

where R are terminal groups of PVC.[27]

Dehydrohalogenation of halogen-containing polymers is assumed[21,24,26,27] to occur by a chain mechanism (zip process), according to which the isolated and conjugated double bonds in the polymer macromolecule activate the hydrogen and chlorine atoms in the α-position by increasing their activity and capacity to undergo elimination (allylic activation).

An expression for the rate of dehydrochlorination of PVC has been derived theoretically[27]

$$v = d[Cl^-]/dt = A^{1/2}[TBAB]^{1/2}[CH_2{-}CHCl]^{1/2}[OH^-],$$

where

$$A = k' \cdot k \cdot k_e \cdot K/(1+K) \cdot (k_e[OH^-] + k \cdot [CH_2{-}CHCl]);$$

$$K = [Q^+]_T/[Q^+]_p —$$

is the HLB coefficient; k' and k are the rate constants of the fundamental stages of dehydrochlorination; k_e is the rate constant of anionic exchange at the polymer–solution phase boundary; $[Q^+]_s$ and $[Q^+]_l$ are the concentrations of catalyst in the solid phase and in solution respectively. This expression correlates well with the experimentally determined value, which provides support for this mechanism.

It should be noted that when the dehydrohalogenation of polymers is carried out in solution with agitation, a precipitate of partially dehydrohalogenated polymer rapidly forms and the reaction continues in a similar manner to the reaction with powder. In the absence of agitation, when the organic phase is a solution of polymer, the activity of the catalyst depends on the organic solvent. Thus, in the dehydrochlorination of Saran in tetrahydrofuran (THF) solution the most effective catalyst proved to be TBAB,[22] whereas for solid Saran (powders and films) TPAB was more effective.[24] This difference in catalytic activity in the dehydrochlorination of solid Saran and its solution in THF can be attributed to the different solubility parameters of the solid copolymer (δ = 13.4) and THF (δ = 9.32).[22] For PVC, δ = 9.4–10.8.[24] When *o*-dichlorobenzene was used as the solvent, the dehydrochlorination of Saran was almost completely suppressed, while when 1,4-dioxan was used the reaction was faster than in THF.[22]

The degree of conversion in the aqueous alkaline dehydrohalogenation of polymers also depends on the concentration of catalyst and alkali and on the reaction temperature. When the concentration of catalyst is increased, conversion increases to a given level, after which it remains unchanged. This type of dependence is related to the fact that at high concentrations of catalyst a portion of it separates out from the aqueous phase to form an oily layer—it becomes a three-phase system. Therefore, the effective concentration of catalyst in the aqueous phase remains unchanged. At high concentrations of alkali a third phase of catalyst is also formed, and the dependence of conversion on the concentration of alkali with a constant concentration of catalyst is in the form of a curve with a maximum. At first, as the concentration of alkali in the aqueous phase increases, the conversion increases and reaches a maximum value, after which it starts to decrease. The drop in conversion is due to a decrease in the effective concentration of catalyst in the aqueous phase on increasing the concentration of alkali.[20–22,24]

In the dehydrochlorination of Saran in THF solution, KOH proved to be a more effective dehydrochlorinating agent than NaOH under the same reaction conditions. An increase in the concentration of Saran in THF solution led to a decrease in conversion, since the increase in viscosity of solution inhibited diffusion of ammonium hydroxide into the organic phase.[22]

The dependence of conversion on reaction temperature in the dehydrochlorination of PVC is limiting in nature with a maximum at about 70 °C. On increasing the temprature from 70 to 90 °C, the degree of conversion falls sharply. Initially this phenomenon was attributed to decomposition of the onium salts in alkaline solution at temperatures above 70 °C,[21] but more recent studies[20,24] have demonstrated that in the dehydrohalogenation of Saran and PVDF the degree of conversion increases with an increase in temperature even up to 110 °C. Therefore, the limiting dependence of conversion on temperature in the dehydrochlorination of PVC is attributed[24] to a change in the physical properties of the polymers at temperatures above the glass-transition temperature of PVC (about 80 °C), which can lead to a reduction in porosity of the PVC particles and a decrease in the rate of diffusion of the ammonium hydroxide into the polymer, in other words, there is a decrease in the overall rate of reaction.

In one study[28] in order to create milder conditions in carrying out the dehydrofluorination of PVDF, tetrabutylammonium hydroxide in a solution of t-butyl alcohol was used directly as the

dehydrohalogenating agent, as a result of which it was possible to avoid scissions of the polymer chain and obtain a fluorine-substituted polyacetylene structure on the surface of PVDF.

Crown ethers constitute another class of phase-transfer catalysts that are used in the dehydrohalogenation of halogen-containing polymers. The use of 18-crown-6 and dibenzo-18-crown-6 in the dehydrochlorination of PVC with aqueous solutions of NaOH or KOH proved ineffective.[21] In the aqueous alkaline dehydrofluorination of PVDF the catalytic activity of 18-crown-6 proved to be much lower than that of TBAB; while an attempt to use the more lipophilic dibenzo- and dicyclohexyl-18-crown-6 was unsuccessful because of the low solubility of the latter in the aqueous phase.[20]

However, when the dehydrochlorination of PVDC was conducted in the presence of 18-crown-6 in benzene, the reaction took place rapidly up to high degrees of conversion.[29] Dehydrochlorination was carried out in the three-phase systems: PVDC (film) + benzene + 18-crown-6 + KOH (pellets) and PVDC (film) + benzene + 18- crown-6 + KF/CaO. The degrees of conversion for systems with KF/CaO and KOH were similar, but the concentration of the crown complex with KF/CaO was 6 times lower than the concentration of the crown complex with KOH because of its low solubility in benzene. Hence it may be concluded that the system KF/CaO – 18-crown-6 is more effective in the dehydrochlorination of PVDC films in benzene.

At 80 °C after 1 h, elimination of 0.97 chlorine atoms on average per monomer unit with the formation a chlorine-substituted polyene structure has occurred. When dehydrochlorination is carried out for a more prolonged period further elimination of HCl occurs, and after 14 h 1.6–1.7 chlorine atoms are eliminated on average per monomer unit.

In the IR spectra of the dehydrochlorination products absorption bands are detected at 2170 cm^{-1} and at 866 and 755 cm^{-1}, which are attributed to stretching vibrations of C≡C triple bonds and bending vibrations of C–H bonds in aromatic structures respectively. When KOH is used in the dehydrochlorinating system, mainly C≡C triple bonds are formed at high degrees of conversion, while when KF/CaO is used aromatic structures are mainly formed by the above-mentioned Diels–Alder and intramolecular 1,6-elimination types of reaction, which can be illustrated by the ratio of intensities of the absorption band at 2170 cm^{-1} to those at 866 and 755 cm^{-1}. Thus, for the system with KOH, $I_{2170}/(I_{866} + I_{755}) = 1.2$, while for the system with KF/CaO, $I_{2170}/(I_{866} + I_{755}) = 0.3$.[29]

The rate of dehydrochlorination depended to a considerable degree on the reaction temperature. While 0.97 chlorine atoms were eliminated on average per monomer unit at 80 °C, when the reaction was carried out at 20 °C only 0.15 atoms were eliminated.[29]

2. Dehydrohalogenation by alcoholic solutions of alkalis

Treatment of halogen-containing compounds with alcoholic solutions of alkali metal hydroxides is a traditional method of dehydrohalogenation that has been used in both organic chemistry and polymer chemistry.

A number of studies have been devoted to the dehydrohalogenation of PVC,[31–33,35,43,44,55,57] PVDC,[36–38,41,42,45,56] PVDF,[40–42] poly(vinylidene bromide) (PVDB),[41,42] and also a polymer that had the structure of poly(1,2-dibromoethylene), obtained by the dehydrochlorination and subsequent bromination of PVC.[53]

When the dehydrohalogenation of halogen-containing polymers is carried out in solution, with other conditions being equal the rate of reaction depends on the polarity of the solvent. Thus, when the dehydrochlorination of PVC is carried out in dimethylformamide (DMF) solution, the rate of reaction, the conversion, and also the length of the resulting polyenes were considerably greater than when the reaction was carried out in THF solution.[31,32]

In the IR spectra[31,33] of the dehydrochlorination products of PVC there are absorption bands at 1005 cm^{-1} and 3010 cm^{-1} which are characteristic of bending and stretching vibrations respectively of C–H bonds in long *trans*-polyenes.[34] In the Raman spectra intense lines occur in the region of 1100 and 1500 cm^{-1} that are typical for stretching vibrations of carbon–carbon single and conjugated double bonds respectively.[35]

At degrees of conversion of 50–60%, the length of the polyene sequences formed in PVC macromolecules under the experimental conditions reaches a maximum value (about 40 conjugated C=C bonds), and then as dehydrochlorination progresses it decreases.[31,32] Bowley et al.[31,32] account for this phenomenon as follows. At degrees of conversion up to 50–60%, the long conjugated polyenes formed in the PVC macromolecules are separated by sections of unreacted polymer. These sections of the initial polymer sterically shield the polyene sequences from interchain cross-linking.[31] As dehydrochlorination progresses the unreacted sections disappear and at the same time there is an increased probability of cross-linking on the double bonds with scission of the chain of conjugation and a decrease in the length of the polyenes.[32] In fact, in the IR spectra of completely dehydrochlorinated PVC absorption bands occur at 2845 and 2920 cm^{-1} that are characteristic of stretching vibrations of C–H bonds in saturated structures.[32]

It should be noted that the degree and rate of dehydrochlorination and also the structure of the reaction products does not depend on the tacticity of the initial polymer.[31,32]

The dehydrochlorination of PVDC powder has been investigated in three studies.[36–38] The highest visually recorded rate of reaction was reached when a solution of KOH in isopropyl alcohol was used as the dehydrochlorinating agent. Solutions of LiOH and NaOH in methanol and ethanol proved less effective. The reaction was carried out at room temperature. Since no absorption bands characteristic of conjugated dienes and trienes were detected in the IR spectra of the intermediates, the authors conclude that elimination of HCl does not occur randomly at the same time in several sites of many macromolecules but has the form of a chain reaction.[36] After the first 4 h more than half of the initial chlorine content has been eliminated from the polymer. For complete elimination of chlorine 40–50 h is required.[37,38] In the IR spectra of the reaction products there is a rapid increase in a broad absorption peak at 1630 cm^{-1}, attributed to C=C double bond vibrations, which is shifted to 1590 cm^{-1} when the reaction is continued in excess of 12 h. The authors attribute this shift to a change in the environment of the carbon atoms from aliphatic (1630 cm^{-1}) to aromatic (1590 cm^{-1}). In the IR spectra of the reaction products there are also absorption bands at 1720 and 3440 cm^{-1}, attributed to vibrations of O=C< and OH groups respectively.[36,38] The authors account for the absence of absorption bands characteristic of C≡C triple bond vibrations in the IR spectra of the dehydrochlorination products of PVDC by the fact that at the first stage of the reaction the resulting chlorine-substituted polyene structures $-(-CH=CCl-)_n-$ react with each other by a Diels–Alder-type reaction (see above). Subsequent dehydrochlorination of the reaction products results in the formation of aromatic structures.[36,38] According to the dehydrochlorination mechanism put forward by Barton et al.[38] elimination of HCl from the polymer chain occurs via the formation of an ether in a

Williamson reaction[39] followed by the elimination of a molecule of isopropyl alcohol and the formation of a C=C double bond.

In the dehydrofluorination of PVDF both at room temperature[40] and at 50–100 °C [20] by a solution of KOH in isopropyl alcohol, in addition to absorption bands in the IR spectra of the reaction products at 3400, 1580, and 1100 cm^{-1} that are characteristic of OH groups, conjugated double bonds (C=C), and C–O–C ether bonds respectively, there is an absorption band in the region of 2050–2200 cm^{-1}, attributed to stretching vibrations of C≡C triple bonds.

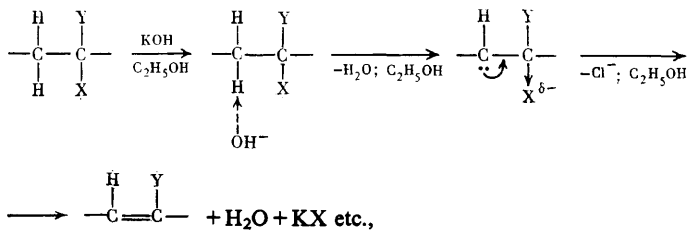
The dehydrohalogenation of poly(vinylidene halides) (PVDF, PVDC, and PVDB) by a mixture of a saturated solution (25 wt.%) of KOH in ethanol and THF has been studied.[41,42] By using THF in the mixture it is possible to carry out dehydrohalogenation under mild conditions—at room temperature and below—because of its specific solvating nature and complexing ability, which reduces to a minimum the contribution of side reactions involving cross-linking, degradation, and nucleophilic substitution of halogen atoms by hydroxyl and ethoxy groups. It should be noted that addition of certain polar solvents [dimethyl sulphoxide (DMSO),[43,44] pyridine[45]] to an alcoholic solution of alkali resulted in an appreciable acceleration of dehydrohalogenation of PVC and PVDC. Solvation of the alkali metal cation with THF molecules increases the reactivity of the hydroxyl ion, which assists the dehydrohalogenation reaction.[41,42] The role of THF involves not only its catalytic effect on the elimination of hydrogen halide but also changing the conditions of interaction in the system polymer–reactive medium. This manifests itself in the swelling of polymers in THF, which assists the diffusion of dehydrohalogenating agent into the polymer. The optimum ratio of the components of the dehydrohalogenating mixture, in which the maximum rate of reaction and degree of dehydrohalogenation are achieved, is: 40 wt.% alcoholic solution of KOH + 60 wt.% THF.[41,42]

The theoretical reaction scheme of the dehydrohalogenation of poly(vinylidene halides) can be shown as follows:[41]

$$-(-CH_2-CX_2-)_n- \xrightarrow[-nHX]{} -(-CH=CX-)_n- \xrightarrow[-nHX]{} \longrightarrow -(-C\equiv C-)_l- \ldots =(=C=C=)_m=,$$

where $l + m = n$ and X is a halogen.

A feature of the dehydrohalogenation of polymers under heterogeneous conditions is that the rate of reaction depends not only on the strength of the carbon–halogen bond but also on the rate of diffusion of the dehydrohalogenating agent into the polymer substrate.[41] Therefore, the reaction occurs much more rapidly with powders than with films because of the degree of dispersion and highly extended surface of powders. Thus, the dehydrohalogenation of PVDF powder at room temperature was complete after 10 h, that of PVDC was complete after 1 h, and that of PVDB after 30 min.[41,42] The dehydrohalogenation of PVDF and PVDC films takes place much more slowly. An increase in reaction temperature results in a marked acceleration of dehydrohalogenation. In addition to the accelerating effect of heat on the chemical reaction this is also due to swelling of the polymers in THF, which assists diffusion of the reactants. In all, poly(vinylidene halides) can be arranged in the following order with respect to their rate of dehydrohalogenation: PVDB > PVDC > PVDF.[41]

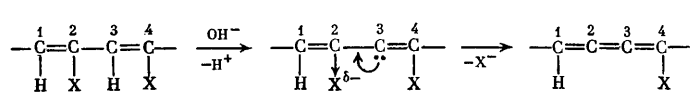


As the dehydrohalogenation of poly(vinylidene halides) takes place, in the IR spectra of the reaction products the absorption bands that are characteristic of vibrations due to the carbon–halogen bond over the frequency range 400–800 cm^{-1} disappear and new absorption bands appear in the region of 1600 cm^{-1} (very strong) and 2170 cm^{-1}, which are attributed to stretching vibrations of carbon–carbon double and triple bonds respectively.[41,42] A change of reaction temperature from –10 °C to 68 °C did not produce any appreciable change in the relative intensities of these bands. However, according to electronic Auger spectroscopy data, when the reaction is carried out at room temperature the dehydrochlorination products of PVDC contain about 15% cross-linked graphite-like structures, whereas at a lower temperature (–10 °C) products with a linear (one-dimensional) structure are formed. Evsyukov et al.[41,42] resolve the inconsistency between the IR and Auger spectroscopic data by assuming that in the chemical dehydrohalogenation of poly(vinylidene halides) a cumulene modification of carbyne (β-carbyne) is formed, and absorption of the cumulene structure appears in the region of 1600 cm^{-1}. This accounts for there being no differences in the IR spectra of poly(vinylidene halides) dehydrohalogenated at different temperatures since absorption of conjugated and isolated C=C double bonds also appears at about 1600 cm^{-1}.[46] It should be noted that previously the absorption band in the region of 2100–2200 cm^{-1} in the IR spectra of carbyne was attributed to vibrations due to polyyne structures while the band in the region of 1600 cm^{-1} was attributed to C=C double bond vibrations formed as a result of interchain cross-linking.[45,47] In order to confirm the validity of assigning the absorption bands in the region of 1600 cm^{-1} in the IR spectra to vibrations of cumulated double bonds of β-carbyne, a numerical calculation of the inherent vibrational frequencies of a cumulene chain was carried out,[48] taking into account ideas about the zigzag nature of a carbyne chain,[49,50] which at the present time have been experimentally confirmed.[51,52] The results of the calculation are in good agreement with the experimental IR spectra of the dehydrohalogenation products of poly(vinylidene halides).

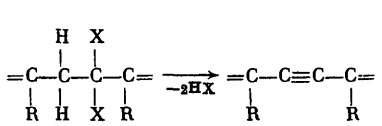
By studying the electronic structure of the dehydrohalogenation products of poly(vinylidene halides) using Auger spectroscopy and also electron characteristic energy loss spectroscopy, it was possible to obtain complete confirmation of their one-dimensional cumulene structure.[41,42] On the curve of density of the valence states of dehydrochlorinated PVDC there are three well-defined maxima at energies of 16, 19, and 25 eV, which relate respectively to the base of the π-sub-band and the ceiling and base of the σ-sub-band. This position of the maxima on the energy scale is typical for linear structures and is in good agreement with the results of a calculation of the density distribution of states in the valence band of carbyne.[53] The position of the base of the π-sub-band at 16 eV is a clear indication of the cumulene nature of the bonds in the dehydrohalogenation products. The threshold of the loss function in the electron characteristic energy loss spectrum, which corresponds to the width of the optical forbidden band, is equal to 1 eV, which is also consistent with the results of calculation of the electronic spectrum of cumulene chains.[41,42]

In the Raman spectra of the dehydrohalogenation products of poly(vinylidene halides), two lines occur at about 1550 and 2150 cm^{-1}, corresponding to stretching vibrations of cumulated C=C double bonds in the polymer chain.[54] On increasing the wavelength of exciting light from 457.9 to 647.1 nm, the positions of the lines are shifted to lower frequency, which suggests that there are chain distributions according to the effective lengths of conjugation in the carbyne obtained.

An ionic mechanism has been proposed[41,42,55] for the dehydrohalogenation of halogen-containing polymers by an alcoholic

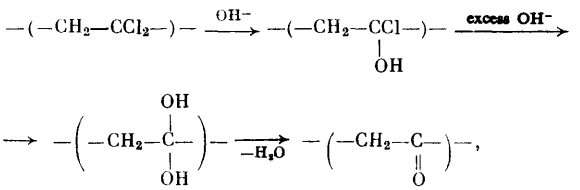


solution of alkali that is similar to the well-known mechanism in organic chemistry for the dehydrohalogenation of alkyl halides by bases.[1] According to this mechanism a hydroxide ion removes a proton from the chain of the initial polymer, leaving a free electron pair in its place. The halogen atoms on the neighbouring carbon atom acquire a partial negative charge as a result of the inductive effect and are readily detached by (alcohol) solvent molecules. The eliminated halogen ion is bound in solution to an alkali metal cation

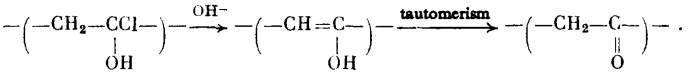


where X = Y is a halogen[41,42] or Y = H.[55]

Subsequent elimination of hydrogen halide from the units that are adjacent to the resulting double bond occurs with greater ease than for the initial polymer because of the allylic activation effect.[55]

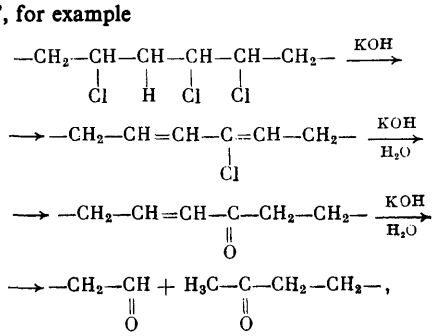


Using this mechanism, Evsyukov et al.[41,42] account for the formation of β-carbyne in the dehydrohalogenation of poly(vinylidene halides) in the following manner. At the first stage of the reaction a halogen-substituted polyene structure $-(CH=CX)_n-$ is formed. After removal of a proton from the resulting structure, a free electron pair is left in its place, according to the above mechanism. This pair causes a shift in electron density from the C(3) atom to the C(2) atom because the double bond between the C(3) and C(4) atoms prevents a shift in electron density to the C(4) atom. As a result of the redistribution of electron density the halogen atom on the C(2) carbon atom acquires a greater negative charge than the halogen atom on the C(4) carbon atom. As a result, elimination of a halogen ion actually takes place from the C(2) atom to form a cumulene structure.

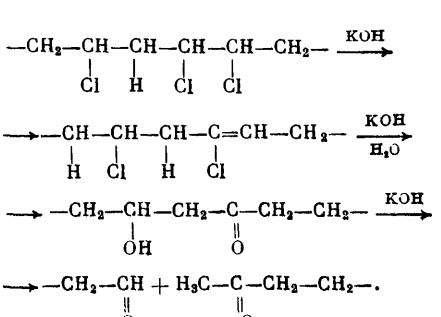


The C≡C triple bonds whose existence is indicated by the absorption band in the region of 2100–2200 cm^{-1} in the IR spectra of β-carbyne obtained by dehydrohalogenation of poly(vinylidene halides) occur as defect units in relation to the final cumulene structure. They can be formed by the elimination of two hydrogen halide molecules from the monomer units that occur in the polymer macromolecules between defect units[41,42]

These defects can comprise branching and "head-to-head" structures in the initial polymer as well as defects formed by side reactions involving cross-linking, oxidation, degradation, and nucleophilic substitution of halogen atoms by hydroxyl and alkoxy groups. The occurrence of hydroxyl groups in the polymer chain can lead to further side reactions[56]



or:



In a study[57] of the reaction between PVC and alkali, particular attention was given to the degradation of PVC with scission of the polymer chain. The reaction of PVC with an alcoholic solution of KOH was carried out in THF solution under specially selected conditions in order to prevent the rapid loss in solubility and precipitation of the polymer from solution. It was shown by Schwenk[57] that the Fikentscher coefficient determined by viscometry, which decreases during the reaction over a period of 90 min to 2/3 of its original value in the initial polymer, is not a reliable criterion of molecular weight in the case of branched polymer structures that are formed through side reactions involving cross-linking. For a more detailed study the author used gel permeation chromatography (GPC). However, in this case also a determination of the true molecular-weight distribution is made difficult by the presence of a colloidal fraction with intermolecular cross-linking in the solution of reaction products, which passes through a conventional filter but settles in a chromatographic column. Nevertheless, the GPC data clearly indicate the presence of a low-molecular weight fraction in the reaction products of PVC and KOH that is absent in the initial polymer.

From the analysis of model reactions Schwenk[57] has proposed different variants of the mechanism of the degradation of PVC with scission of the polymer chain by an alkali. In the opinion of Schwenk, it is most likely that degradation occurs at those sites of the polymer chain in which the monomer units are joined "head-to-head", for example

or

A reduction in the temperature of dehydrohalogenation leads to a decrease in the proportion of side reactions. Thus, for example, on treatment of a solution of PVC in THF with a solution of KOH in methanol at 60 °C, the reaction products contained 10 oxygen atoms for every 100 vinyl chloride units, whereas when the reaction was carried out at room temperature this was reduced to 2 oxygen atoms.[57]

A kinetic equation for the concentration of the polyenes formed by dehydrochlorination of PVC was derived by Shindo and Hirai[55]

$$[P_n] = K_n \cdot t^n,$$

where $[P_n]$ is the concentration of polyenes from n conjugated double bonds; t is the reaction time;

$$K_n = (1/n!)k_1k_2 \ldots k_n[KOH]^n.[PVC],$$

where $k_1, \ldots, k_n$ are the rate constants of the fundamental elimination reactions; [KOH] and [PVC] are the concentrations of KOH and PVC respectively.

A kinetic equation for the total concentration [E] of double bonds in the dehydrochlorination products of PVC was derived by Östensson and Flodin[44]

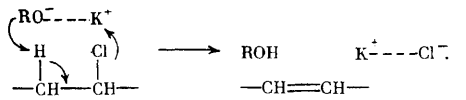
$$dE/dt = k_1([PVC]_0 - [E])([KOH]_0 - [E]),$$

which after integration gives

$$(1/\ln 10)([PVC]_0 - [KOH]_0).k_1t + \lg([PVC]_0/[KOH]_0) =$$

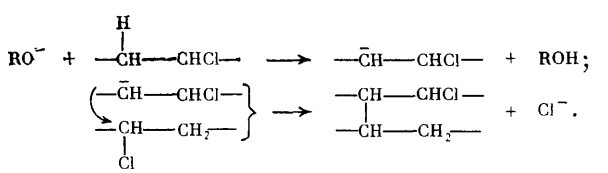
$$= \lg\{([PVC]_0 - [E])/([KOH]_0 - [E])\}.$$

In this case $[PVC]_0$ and $[KOH]_0$ are the initial concentrations of PVC and KOH respectively.



III. Dehydrohalogenation by alkali metal alkoxides

Alkali metal alkoxides (principally potassium t-butoxide) are used as widely as alkalis in the dehydrohalogenation of halogen-containing polymers. In a number of studies the dehydrohalogenation of PVC,[31,32,58–66] chlorinated PVC (CPVC),[65] PVDC,[56,66] and PVDF [40] by potassium t-butoxide[31,32,40,56,58–64] and sodium amoxide[65,66] was investigated.



When potassium t-butoxide (t-C_4H_9OK) the KOH were used as the dehydrochlorinating agent under the same conditions, the rates and degrees of dehydrochlorination of PVC were similar. However, when t-C_4H_9OK is used, much longer polyene sequences (more than 65 conjugated C=C bonds) are formed than when KOH is used under the same conditions (about 40 units).[31,32] The rate and degree of dehydrohalogenation increase with an increase in polarity of the solvent.[31,32,56]

A study[61] of the dehydrochlorination of PVC by t-C_4H_9OK using GPC and UV spectroscopy showed that at the early stages of the process, macromolecules appear in the reaction products with a molecular weight similar to that of the initial polymer but containing short polyene residues (P_2 products). The concentration of such macromolecules (P_2) increases up to a degree of conversion of 10% and remains unchanged up to a degree of dehydrochlorination of 20%. Then, as the reaction progresses the concentration of P_2 decreases and is reduced to zero when the degree of conversion is 100%. Starting from a degree of dehydrochlorination of 4%, P_1 macromolecules appear in the reaction products with a molecular weight higher than the initial PVC and containing long polyene sequences. The concentration of P_1 increases as the reaction continues right up to complete dehydrochlorination. At advanced stages of dehydrochlorination, a small number of P_3 polyene macromolecules appear in the reaction products with a low molecular weight (200–800), which are formed as a result of side reactions involving chain scission.[61] Thus, products P_2, which are formed at the early stages of dehydrochlorination by elimination of several HCl molecules from the macromolecules of the initial PVC, as the reaction progresses undergo a further conversion to form products P_1 with a higher molecular weight than that of the initial polymer and containing long polyene sequences. Products P_1, in turn, partly undergo alkaline degradation to form products P_3 with a low molecular weight but containing long polyene sequences.

Elimination of HCl by the action of t-C_4H_9OK in pure THF is an ion pair reaction with the simultaneous removal of a proton and Cl^- anion:

This accounts for the solubility (lack of cross-linking) of the reaction products at high degrees of conversion. Some increase in the molecular weight of the reaction products relative to the initial PVC is attributed by Dussoubs et al.[61] to association of polyconjugated macromolecules without the formation of chemical cross-linked structures. In the opinion of the authors, when alcoholic solutions of bases (alkoxides or alkalis) are used, elimination of HCl occurs by an ionic mechanism through solvation of Cl^- anions with alcohol molecules, which makes side reactions involving cross-linking possible:

When the reaction is carried out in the presence of oxygen, the products of the complete dehydrochlorination of PVC are soluble in polar solvents.[62] However, the presence of oxygen leads to a reduction in the rate of dehydrochlorination and in the length of the resulting polyene sequences, which is due to the formation of a stable ternary complex of THF–oxygen–PVC, that has an affect on the subsequent course of the reaction.[63] When the dehydrochlorination of PVC is carried out in an atmosphere of argon, products with a polyacetylenic structure that are close in composition to the formula $(CH)_x$ are formed,[62] whereas for the dehydrochlorination product in an atmosphere of argon/oxygen (50% O_2) the formula $(CHO_y)_x$, where $y = 0.0032$, was established.[63]

The vibrational spectra of the dehydrohalogenation products of PVC, PVDC, and PVDF by treatment with t-C_4H_9OK are similar to the spectra of the dehydrohalogenation products of the corresponding polymers from treatment with alkalis,[31,32,40,56,62] as described above in Section II. However, when CPVC and PVDC are dehydrochlorinated with sodium amoxide, chlorine-substituted polyene (chlorovinylene) structures are formed,[65,66] further dehydrochlorination does not occur, and in the IR spectra of the reaction products where is no absorption band in the region of 2100–2200 cm^{-1} characteristic of stretching vibrations of C≡C triple bonds. Moreover, during the dehydrochlorination of CPVC by sodium amoxide, a side reaction involving alkoxylation occurs,[65]

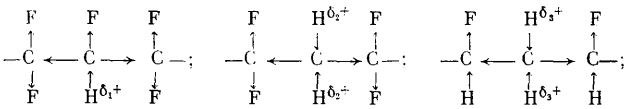
whereas in the dehydrochlorination of PVC by t-C_4H_9OK side reactions involving substitution were not observed.[60]

It was shown by Bowley et al.[31,32] that the rate and degree of dehydrochlorination of PVC as well as the structure of the reaction products do not depend on the tacticity of the initial polymer. However, it was concluded by Martinez et al.[64] from UV spectroscopic data that at the early stages of dehydrochlorination of PVC, elimination of HCl occurs selectively in isotactic and heterotactic triads. In the case of a *gauche* conformation in these triads, elimination occurs by a *syn* mechanism to give *cis* double bonds.

It should be noted that t-C_4H_9OK prepared directly during dehydrohalogenation exhibits considerably greater activity in the elimination of hydrogen halide than that prepared earlier. Thus, when tertiary butyl alcohol and metallic potassium are added to a solution of PVC in THF, on carrying out the reaction for 2 h at 60–65 °C the degree of dehydrochlorination reaches 95%, whereas when previously prepared t-C_4H_9OK is used under the same conditions only 30% dehydrochlorination is achieved.[67]

IV. Dehydrohalogenation by amines

The reactions of different halogen-containing polymers with amines have been widely studied and reported in the literature. A number of studies describe the dehydrohalogenation of PVC,[68–74] PVDC,[75,76] and their copolymers,[77] poly(vinyl bromide),[78] poly(α-chloroacrylonitrile),[79,80] as well as a number of fluorine-containing polymers[81,82] by aliphatic primary,[68,77,81] secondary,[68,75,81] and tertiary[68,74,78–81] amines, a wide range of aromatic amines such as aniline and its derivatives,[69,70,77,81] and also pyridine.[71–73,76,78,81]



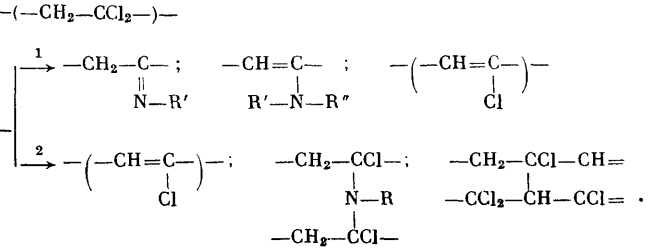
On reacting halogen-containing polymers with amines two competing processes occur—dehydrohalogenation and amination.[68–70,77,81,82] As the basicity of the amines used increases, the proportion of dehydrohalogenation reactions increases.[68,69,71,81] Amination can occur through the replacement of a halogen atom in the polymer chain[68,69,77] or addition to the double bonds formed by dehydrohalogenation.[81,82] Depending on the reaction conditions, the amination products can undergo intramolecular cyclisation[69,70] and intermolecular cross-linking.[68,69,77,82] Degradation of the macromolecules through the formation of carbocations[69] and aminolysis[81] is also possible. It should be noted that as the concentration of amine increases the proportion of amination reactions increases.[69]

Reactions between halogen-containing polymers and amines have been carried out over a wide temperature range—from room temperature to 200 °C. Aliphatic amines react with halogen-containing polymers even at room temperature[68,77] whereas a considerable increase in temperature is required for aromatic amines.[69,77]

The reactivity of halogen-containing polymers in dehydrohalogenation reactions increases with an increase in the number of halogen atoms in the fundamental unit. Thus, on treatment with n-butylamine at 78 °C, films made of poly(vinyl fluoride) $-(CH_2-CHF)_n-$ were inert towards the amine for 24 h. Films made of PVDF $-(-CH_2-CF_2-)-$ become black and brittle over a period of 4 h while for films made of polytrifluoroethylene $-(CHF-CF_2-)_n-$ this occurred over a period of 10 min.[81] Thus, these polymers can be arranged in the following order of reactivity:

$$-(-CHF-CF_2-)_n- > -(-CH_2-CF_2-)_n- > -(-CH_2-CHF-)_n-.$$

This effect is due to the fluorine (halogen) atoms having strong electron-withdrawing properties. As a result of the shift in electron density from the carbon atoms to the fluorine atoms, which in turn is compensated by a shift in electron density from the hydrogen atoms to the carbon atoms, the electrophilicity of the hydrogen atoms increases, thus assisting the removal of a proton by a base.[81] Thus, the reduction in reactivity in this series of fluoropolymers is caused by the reduction in electrophilicity of the hydrogen atoms:

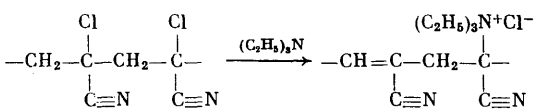


$\delta_1^+ > \delta_2^+ > \delta_3^+$.

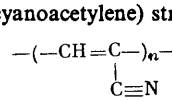
In the IR spectra of the reaction products there are absorption bands which are characteristic of stretching vibrations of conjugated C=C double bonds (in the region of 1600 cm^{-1})[68,69,77,79] as well as N–H bonds (at about 3400 cm^{-1}).[68,69]

An analysis of the UV and visible absorption spectra of the products of the reaction between vinylidene chloride–vinyl chloride copolymer and various amines in comparsion with the spectra of β-carotene has been carried out.[77] In the spectrum of β-carotene characteristic absorption bands occur at wavelengths of 435, 460, and 486 mμ, whereas in the spectra of the products of the reaction between the copolymer and amines, no specific absorption bands were detected. On the basis of this observation, Nakagawa[77] concluded that the chromophoric groups of the reaction products differ considerably from the corresponding group in β-carotene with quite a long chain (11 units) of conjugated C=C bonds, i.e., the sections of conjugation in the dehydrochlorination products of the vinylidene chloride–vinyl chloride copolymer are shorter in length. Nakagawa attributes this to the fact that this copolymer has the structure of a block copolymer and therefore propagation of the chain of conjugation during dehydrochlorination, which is initiated on the more reactive vinylidene chloride units, is terminated on the vinyl chloride units.[77] It should be noted that amination and cross-linking reactions can also be the cause of breaks in the chain of conjugation. With an increase in basicity of the amines used, the rate of reaction increases and the proportion of dehydrohalogenation reactions increases. Thus, in dehydrochlorination of the above-mentioned copolymer, the amines used were arranged in the following order of reactivity: n-butylamines > cyclohexylamine ≫ N-methylaniline > aniline > *N,N*-dimethylaniline.

Depending on the basicity of the amine, reactions that occur with halogen-containing polymers can be divided into two types in accordance with the following scheme (in the case of PVDC);[77]

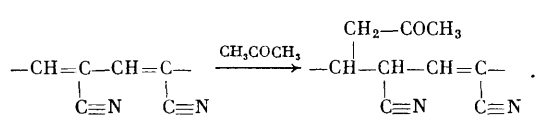


When an amine with low basicity (pK_a = 4–5) is used, the reaction takes place by scheme (*1*). In this case amination reactions occur to a considerable extent by a nucleophilic substitution mechanism (R′ = phenyl, R″ = methyl). When an amine with high



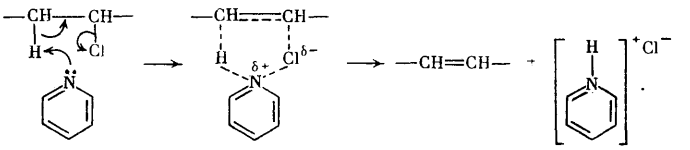
basicity is used (pK_a = 9–10) the reaction occurs by scheme (*2*). In this case dehydrochlorination is predominant at the initial stages of the reaction, while amination can occur by a mechanism involving the addition of amines (R = n-butyl, cyclohexyl) to the double bonds that are formed.[77]

Dehydrochlorination of poly(α-chloroacrylonitrile) (PCAN) in acetone solution by triethylamine results in the formation of a black polymer which is soluble in polar solvents and even in water.[79,80] In the IR spectra of the reaction products the absorption bands characteristic of C–Cl bond vibrations (640 cm^{-1}) in the initial polymer have disappeared and strong absorption bands at 1640 and 1730 cm^{-1}, characteristic of vibrations due to conjugated C=C bonds and O=C< carbonyl groups respectively, have appeared. In the region of 2100–2200 cm^{-1} appear two strong absorption bands that are characteristic of vibrations due to nitrile groups N≡C– that are conjugated (2215 cm^{-1}) and isolated (2250 cm^{-1}) relative to the main chain.[80]

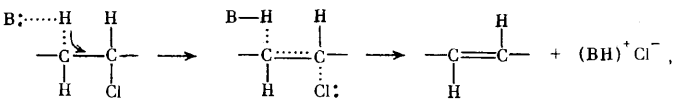


The solubility of the dehydrochlorination product of PCAN is caused by side reactions involving replacement of the chlorine atoms by a tertiary amine to form quaternary ammonium substituents

In fact, when the dehydrochlorination is heated for 4–5 h under vacuum at 180–190 °C triethylamine hydrochloride sublimes. At the same time there is a loss of solubility in water. In the IR spectrum of the thermally treated dehydrochlorination product the absorption band at 2250 cm^{-1} (isolated N≡C– groups) disappears and the strong band at 2200 cm^{-1} (conjugated N≡C– groups) remains. A very broad absorption band occurs over the range 1000 to 1700 cm^{-1} with a peak at 1630 cm^{-1}, which is characteristic of stretching vibrations due to conjugated C=C bonds of the polymer chain. Its complete solubility in DMF excludes the formation of cross-linked structures, so the final product of dehydrochlorination and thermal treatment of PCAN is assigned the polycyanopolyene (polycyanoacetylene) structure[80]



The presence of carbonyl groups in the dehydrochlorination products of PCAN is due to the occurrence of side reactions involving the addition of acetone to C=C double bonds, which is assisted by the strong electron-withdrawing effect of N≡C– groups:



Reversible alkoxylation on the C=C double bonds takes place in a similar manner when dehydrochlorination is carried out with alkali metal alkoxides.[80]

In the reaction between halogen-containing polymers and pyridine at elevated temperatures dehydrohalogenation mainly occurs.[71–73,76] Poly(vinyl chloride) and pyridine have different solubility parameters (9.4 and 10.7 respectively), but PVC readily dissolves in pyridine. This is possible only if there is a specific interaction between pyridine and PVC. Therefore, by analogy with the mechanism for dehydrochlorination of PVC in dimethylformamide,[84,85] a mechanism for dehydrochlorination was proposed which included the formation of an intermediate complex between pyridine and polymer, assisting the elimination of HCl in the form of pyridine hydrochloride:[71,72]

Subsequently, on the basis that the double bonds formed by dehydrohalogenation mainly have a *trans* configuration, the reaction mechanism scheme was refined in the following way:[73]

B = pyridine.

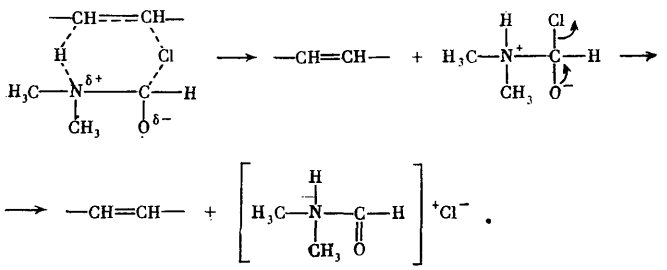
With an increase in reaction temperature and time the degree of dehydrochlorination increases steadily.[71] The length of the polyene sequences and the total number of double bonds in the reaction products also increase steadily with an increase in time of dehydrochlorination.[72]

At the advanced stages of dehydrochlorination the polymer is precipitated from the reaction solution, which Mukherjee and Gupta[71,72] assume to be due to intensive cross-linking. It should be noted, however, that with an increase in the length of conjugation in the chain, the solubility of the reaction products decreases, which can also be the cause of precipitation of the polymer from solution.

At high temperatures and a prolonged reaction time the dehydrochlorination and cross-linking processes compete. The authors proposed a scheme involving intermolecular dehydrochlorination for the cross-linking reaction.[72] However, taking into account the mechanism for dehydrohalogenation as described above, involving β-elimination in the polymer chain, it may be concluded that the probability of an interchain dehydrohalogenation occurring is much less than an intrachain one. It is more probable that cross-linking processes occur by the mechanisms proposed for polymers with a system of conjugated multiple bonds, for example, that of polyacetylene.[86]

It should be noted that in the IR spectra of the products of dehydrochlorination of PVDC by amines, absorption bands corresponding to the vibrations of triple (–C≡C–) or cumulated (=C=C=) carbon–carbon double bonds were absent.[75–77]

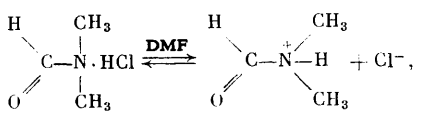
V. Dehydrohalogenation by dimethylformamide



Certain *N*-substituted amides, such as *N*-methylpyrrolidone, *N,N*-dimethylacetamide (DMAA), and *N,N*-dimethylformamide (DMF), are polar aprotic solvents that have basic properties. Even with a slight increase in temperature they can eliminate HCl from PVC to form polyene structures.[83] The dehydrochlorination of PVC in DMF solution has been studied in the greatest detail in this field.[83–85,87–92]

In a study of the degradation of PVC in solution at a high temperature (198 °C) it was found that the rate of dehydrochlorination in DMF was higher than the rate of reaction in other high-boiling solvents such as ethyl benzoate, tritoluyl phosphate, dibutyl phthalate, dioctyl phthalate, benzophenone, benzyl alcohol, and dichloronaphthalene by a factor of more than 10^2.[84,87]

Moreover, according to the UV spectroscopic data, the length of the polyenes formed when the reaction was carried out in DMF considerably exceeded the length of the chain of conjugation when the above-mentioned high-boiling solvents were used.[85,87]



This effect is due to an interaction between PVC and DMF. This conclusion is supported by the fact that PVC is readily soluble in DMF despite the considerable difference in solubility parameters (9.6 and 12.1 respectively).[85] The role of the amide in dehydrochlorination was supported experimentally when the degradation of PVC was carried out in ethyl benzoate in the presence of acrylamide.[84]

As a result of the formation of an intermediate complex between DMF molecules and the fundamental units of the polymer, the dissociation energy of the C–H and C–Cl bonds is reduced, assisting the elimination of HCl.[84,85,87] The HCl separated by dehydrochlorination binds to the solvent:

The dehydrochlorination of PVC in DMF is autocatalytic in nature. This is due not only to the action of DMF [88] but also to the effect of amine-type impurities[89,90] present in it as well as the reaction products (HCl and Cl^-) accumulating in solution.[90] Dimethylformamide, even when freshly prepared, always contains small quantities of dimethylamine, formic acid, and dimethylammonium formate,[93] the content of which varies from 10^{-3} to 10^{-2} mol litre^{-1}.[90] Moreover, at high temperatures DMF decomposes to dimethylamine and formic acid. The destruction of DMF can be accelerated by the HCl eliminated during dehydrochlorination.[94] Dimethylformamide hydrochloride,[95] formed during dehydochlorination, decomposes at temperatures above 90 °C to carbon monoxide and dimethylamine hydrochloride, which can also catalyse dehydrochlorination.[85] The rate of dehydrochlorination of PVC in dilute DMF solutions is directly proportional to the concentration of free dimethylamine. By extrapolation of the rate of reaction to zero concentration of dimethylamine, it is possible to estimate the dehydrochlorination of PVC in "absolutely pure" DMF. The rate of reaction in pure DMF is 10^2 times higher than the rate of degradation of PVC powder in the absence of a solvent with other conditions being equal.[90]

The dimethylformamide and dimethylamine hydrochlorides formed during dehydrochlorination in DMF solution are present in a dissociated state[96]

or

$$(CH_3)_2NH \cdot HCl \overset{DMF}{\rightleftharpoons} [(CH_3)_2NH_2]^+ + Cl^-.$$

Halide ions in dipolar aprotic solvents (such as DMF, DMAA, etc.) are both strong bases and strong nucleophiles[97] and can accelerate dehydrochlorination.[90]

Thus, the autocatalytic nature of the dehydrochlorination of PVC in DMF is due to the effect of amine-type impurities and the reaction products (HCl and Cl^-).

A kinetic equation for the autocatalytic dehydrochlorination of PVC in DMF solution which is in good agreement with the experimental data was derived empirically[88]

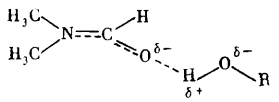
$$dX/dt = kX \cdot (1 - X),$$

where X is the number of moles of eliminated HCl per fundamental unit of HCl, k is the rate constant of the reaction. However, it was shown subsequently[91] that this equation is approximate and can only be used to represent the kinetics of dehydrochlorination of PVC in DMF at a high concentration of polymer and high reaction temperatures. At the initial stage, dehydrochlorination is initiated in a basic medium (pH 10–12) and results from the interaction between PVC and DMF and amine-type impurities. As HCl is eliminated the pH of solution is reduced to 4–2 and Cl^- and HCl become the main catalytic agents. Therefore, to represent the kinetics of the process Fikhman et al.[91] used an equation with two rate constants, proposed for the autocatalytic thermal degradation of PVC powder

$$q = \frac{K_1}{K_2}\left\{\exp\left[K_2\left(1+\frac{K_1}{K_2}\right)t\right]-1\right\}\Big/\left\{1+\frac{K_1}{K_2}\exp\left[K_2\left(1+\frac{K_1}{K_2}\right)t\right]\right\},$$

where q is the quantity of HCl eliminated from PVC after time t per fundamental unit of polymer; K_1 is the rate constant of dehydrochlorination of PVC due to the basicity of DMF; K_2 is the overall rate constant, including the catalytic effect of chlorine-containing products formed in solution.[92] This equation effectively represents the experimental results obtained in the dehydrochlorination of PVC in DMF over a wide range of temperatures, concentrations of polymer, and different added components used to inhibit or accelerate dehydrochlorination.[91]

In general the dehydrochlorination of PVC in DMF solution should be given by an S-shaped curve, which can arbitrarily be divided into three sections: 1) acceleration of dehydrochlorination catalysed by DMF and basic impurities; 2) the autocatalytic action of HCl and the Cl^- ion is superimposed on it in an acid medium; 3) dehydrochlorination is inhibited by cross-linking of dissolved PVC and the formation of long conjugated polyenes.[91] The first two sections are effectively represented by the kinetic equation with two constants. The energies of activation of dehydrochlorination calculated from the Arrhenius equation in two different studies[91,88] are similar (23.5 ± 0.5 and 22.2 kcal mol^{-1} respectively).



When dehydrochlorination was carried out under vacuum or in an atmosphere of nitrogen the length of the resulting conjugated polyenes amounted to 13–16 –CH=CH– units, whereas in the presence of oxygen it did not exceed 4–5 units, which is due to oxidation of the double bonds, leading to breaks in the chain of conjugation.[85]

On increasing the concentration of polymer in solution, the length of the resulting polyenes increases. As the reaction progresses dehydrochlorination slows down, which is due to partial cross-linking of the polymer as a result of side reactions and a reduction in activity of the macromolecular segments as well as the formation of polyenes with a long chain of conjugation.[91]

The degree of dehydrochlorination increases with an increase in reaction time. When THF is added to the reaction solution, the rate of reaction and degree of dehydrochlorination decrease in direct proportion to the concentration of DMF. On increasing the

concentration of polymer in solution the rate of reaction and degree of dehydrochlorination increase.[98]

Addition of water or methanol to the reaction solution results in considerable inhibition of dehydrochlorination, which is due to the formation of hydrogen bonds and hence a reduction in basicity of DMF:[98]

R = H or CH_3.

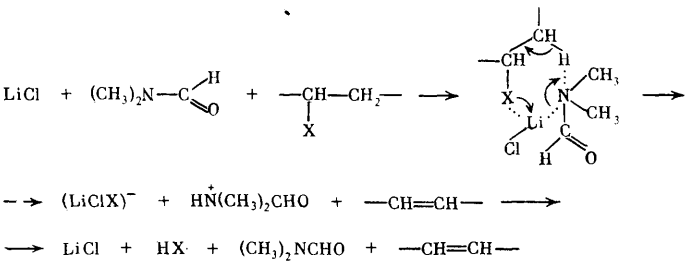
A study of the reaction of PVC in different solvents at temperatures of 100–170 °C showed that in solvents that have considerable nucleophilicity and basicity (pyridine, morpholine) dehydrochlorination and substitution reactions occur in parallel. In solvents that have considerable basicity but weak nucleophilicity (DMF, DMAA), elimination of hydrogen halide mainly occurs. In solvents that have weak nucleophilicity and basicity (THF, cyclohexanone, nitrobenzene), PVC remained unchanged. When solvents that have weak basicity but strong nucleophilicity are used (dioctyl phthalate, benzyl alcohol), substitution reactions occur to a considerable degree.[98]

VI. Dehydrohalogenation by complexes of *N*-substituted amides with metal salts

In a number of studies the dehydrohalogenation of PVC,[99–104,106,107,109–111] poly(vinyl bromide),[99] and also PVDC, CPVC, and vinylidene chloride–vinyl chloride copolymer[111] by complexes of *N*-substituted amides with metal salts has been investigated.

The structure of the dehydrohalogenation products depends on the reaction conditions, the structure of the initial polymer, and also on the nature of the solvent (amide) and salt used.

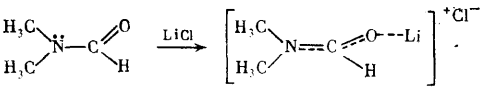
On increasing the content of the metal salts in solution, the concentration of polymer, and the reaction temperature (from 80 to 110 °C), the degree of dehydrohalogenation and the rate of reaction increase.[99–101] The degree of dehydrohalogenation also increases with an increase in reaction time[99,100] and the degree of polymerisation of the initial polymer.[102]



The presence of oxygen in the reaction mixture leads to a reduction in the rate of dehydrohalogenation and to the occurrence of side reactions involving degradation of the polymer.[102] Dilution of the reaction solution with tetrahydrofuran leads to a reduction in the degree of dehydrohalogenation and the rate of reaction.[99]

It should be noted that on reaching a degree of conversion of 30–40% the dehydrohalogenation products become insoluble and precipitate from solution.[99]

As dehydrochlorination of PVC takes place, in the IR spectra of the reaction products there is a decrease in intensity of the absorption band in the region of 690 cm^{-1} which is a characteristic of stretching vibrations due to C–Cl bonds in the initial polymer and new intense absorption bands appear in the region of 1000 and 1600 cm^{-1} that are characteristic of C–H bond bending vibrations in *trans*-polyenes and stretching vibrations due to conjugated C=C double bonds respectively.[101,103,104] A very weak band appears in the region of 730 cm^{-1} which could be attributed to bending vibrations of the C–H bonds on a C=C double bond in a *cis* configuration.[104] When dehydrochlorination is carried out in the presence of oxygen, an intense absorption band occurs in the IR spectra of the products at 1760 cm^{-1} which is characteristic of vibrations due to the O=C< group.[103]

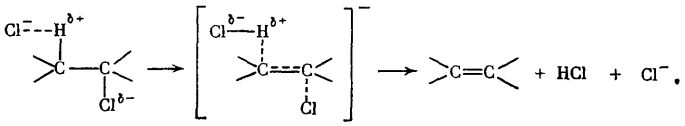


Dehydrochlorination of PVC in the system DMF–LiCl ($LiBr_2$, $MgCl_2$) resulted in the formation of long polyene structures with the number of conjugated double bonds $n > 14$. A broad maximum occurred at 550 mμ in the absorption spectrum in the UV and visible regions. In the spectra of the dehydrochlorination products of PVC in the system DMF–lithium acetate or magnesium chloride hydrate ($MgCl_2 \cdot 6H_2O$) a series of maxima that are characteristic of absorptions due to relatively short polyenes with the number of units $n = 4-14$ is observed. Zinc, copper, cobalt, nickel, and cadmium chlorides as well as lithium carbonate proved inactive in dehydrohalogenation.[99]

The system LiCl–DMF was first used in the dehydrobromination of bromoketosteroids,[105] and a mechanism for this was proposed that involved elimination of hydrogen halide as a result of the simultaneous attack by a lithium cation and DMF on alkyl halide and the concerted electron rearrangement in a six-membered ring including the halogen-containing compound, a DMF molecule, and a LiCl molecule:

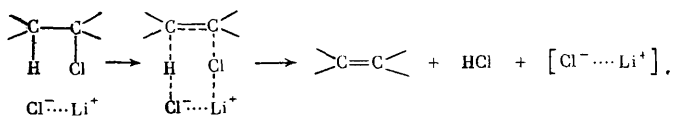
X = halogen.

However, this mechanism, in attaching most importance to the coordinating power of the cation, does not explain the activity of some salts and the inactivity of others in dehydrohalogenation.



Lithium chloride forms a stable complex with DMF,[101] which occurs in dissociated form in DMF solution. As was mentioned above in Section V, halide ions in dipolar aprotic solvents are strong bases and nucleophiles.[97] Therefore the main dehdyrohalogenating agents in the sytstem DMF–metal salts are anions (in particular Cl^-)[99] and their ion pairs.[106,107] Nucleophilic substitution of halogen atoms in polymers by Cl^- and Br^- atoms does not inhibit further dehydrohalogenation. But if irreversible substitution reactions with nonhalide ions occur, the length of the polyene sequences formed during reaction is limited by the presence of these substituents. Thus, when lithium acetate or magnesium chloride hydrate is used for dehydrohalogenation, substitution reactions by the acetate and hydroxyl groups lead to a decrease in length of the resulting polyenes.[99]

Despite their solubility in DMF, heavy metal salts do not dissociate,[108] which accounts for the inactivity of these salts in dehydrohalogenation. Moreover, some salts form stable complexes with DMF (such as $ZnCl_2$) and inhibit dehydrohalogenation.[90,102]



The rate of dehydrochlorination of PVC in the presence of LiCl and the structure of the reaction products depend to a considerable extent on the stereostructure (tacticity) of the initial polymer and the

polarity of the solvent.[102,106,109] When hexamethyltriamidophosphate (HMTP) is used as the solvent, the rate of reaction and length of the resulting polyenes are considerably greater than that when DMF is used.[106,109] Dehydrochlorination of syndiotactic PVC in both DMF and HMTP results in the formation of considerably longer polyene structures than with an atactic polymer. On increasing the syndiotactic content in the initial PVC, the rate of dehydrochlorination in DMF decreases (the energy of activation increases sharply), whereas in HMTP the rate of reaction increases and the energy of activation decreases.[106,109] This phenomenon is attributed to the existence of two parallel dehydrohalogenation mechanisms that are in an equilibrium which is shifted in favour of one of them depending on the stereostructure of the initial polymer and the polarity of the solvent.[106]

(A). Mechanism involving β-elimination $(E_2)^1$ by a halide ion (Cl^-):

(B). Mechanism involving dehydrohalogenation by a $[Cl^- \ldots Li^+]$ ion pair:

If the role of the solvent is ignored, it may be observed that a syndiotactic structure of the polymer is conducive to mechanism (A)' whereas an isotactic structure assists mechanism (B).

The concentration of unsolvated Cl^- anion and solvated Li^+ ion is considerably higher in HMTP than in DMF. Therefore the basic nature of Cl^- is more clearly defined in HMTP and hence, ionic mechanism (A) predominates in the dehydrochlorination of PVC, whereas in DMF mechanism (B), involving the action of an ion pair, is predominant.[106]

The energy of activation of dehydrochlorination in each specific case is the sum of the energies of activation of the respective mechanisms and depends on the tacticity of the initial polymer and the polarity of the solvent. The length of the polyene chains thus depends not only on the contribution from side reactions involving cross-linking, substitution, and oxidation but also on the equilibrium between the dehydrohalogenation mechanisms. Ionic elimination (A) leads to the formation of longer polyenes than with the ion-pair mechanism (B).[106]

On the whole, dehydrochlorination of PVC in the system DMF–LiCl involves two stages. At the first (rapid) stage dehydrochlorination of iso- and hetero-tactic structures in the macromolecules takes place with the formation of short polyene residues. At the second (slow) stage dehydrochlorination of the syndiotactic structures occurs with the formation of long sequences of conjugated C=C double bonds.[110] The variation in length of the polyenes formed during dehydrochlorination depending on the tacticity of the initial PVC is due to the stereospecific nature of the fundamental stages of elimination of HCl.[104,110]

The activity of the alkali metal salts depends on the electronegativity of the cation and the dipole moment of the salt. The rate of dehydrochlorination of PVC increases in the series LiI < NaI < KI < RbI. The solvating capacity of DMF relative to the cation of the ion pair $M^+(DMF)_nI^-$ (M = metal) increases as the electronegativity of the cation decreases (from 1.0 for Li to 0.8 for Rb). Therefore, as the electronegativity of the M^+ cation decreases, the contribution from the solvent increases and the anion of the ion pair approximates in nature to a free ion, in other words, its basicity increases.[107]

In a series of lithium halides the rate of dehydrochlorination increases in the following order: LiI < LiBr < LiCl.[107] Solvation of anions decreases as their diameter decreases,[97] hence the basicity of the anions in solution increases.

The use of lithium salts formed by anions having significant nucleophilicity (cyanide, thiocyanate, nitrite, as well as organic salts such as acetate, benzoate, phenate, and thiophenate) led to a reduction in the rate of dehydrochlorination compared to the system LiCl–DMF and the formation of short polyenes as a result of side reactions involving substitution.[101]

The rate of dehydrochlorination of PVC by the system LiCl–DMF is given by the equation[101]

$$dHCl/dt = k_1.[PVC].[LiCl] + k_2.[PVC]_1.[LiCl] + \ldots + k_n.[PVC]_{n-1}.[LiCl],$$

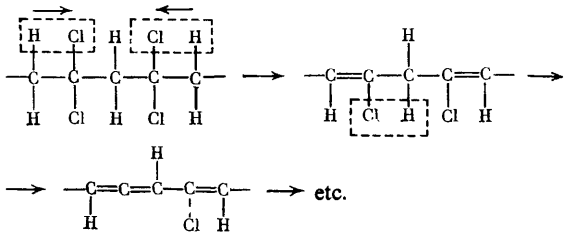
or

$$dHCl/dt = k_1.[PVC]_0.[LiCl].e^{-k.[LiCl].t},$$

where k_n is the rate constant of a simple elimination to form 1, 2, ... n conjugated double bonds; $[PVC]_0$ is the initial concentration of PVC; $[PVC]_n$ is the concentration of macromolecules containing 1, 2, ... n conjugated double bonds; [LiCl] is the concentration of LiCl; and t is the reaction time.

For the initial rate of reaction (when $t \to 0$) the kinetic equation has the form

$$dHCl/dt = k_1.n.[PVC]_0.[LiCl].$$



Dehydrochlorination of polymers containing more than one chlorine atom per monomer unit (PVDC, CPVC, and vinylidene chloride–vinyl chloride copolymer) occurs much more rapidly compared to pure PVC and reaches higher degrees of conversion (in the dehydrochlorination of PVDC about 1.4 chlorine atoms are eliminated on average per monomer unit).[111] This effect is consistent with the results obtained in a study of the dehydrofluorination of fluorine-containing polymers by amines[81] and is due to the increase in activity of the hydrogen atoms and a reduction in the dissociation energy of the carbon–halogen bond as the content of halogen in the polymer increases.

The structure of the reaction products during dehydrochlorination by the system LiCl–DMF also depends on the content of chlorine in the initial polymers. In the dehydrochlorination of polymers containing up to 64% chlorine, long polyene sequences are formed with the number of conjugated double bonds $n > 14$. However, dehydrochlorination of polymers containing more than 64% chlorine leads to the formation of relatively short polyenes ($n = 6-13$).[111] Laurent et al.[111] attribute this phenomenon to the "mutual restriction" of the growing polyene residues through their isolation by a methylene carbon atom:

$$-CH=CH-CH=CH-CH_2-CH=CH-CH=CH-.$$

With an increase in chlorine content in the polymer the rate of initiation of dehydrochlorination increases and therefore several growing polyene sequences can be formed at the same time in the polymer chain, which increases the probability of their "mutual restriction". However, this explanation of the interrruption of conjugation is acceptable only for PVC and poly(vinyl bromide).

Taking into account the degree of dehydrochlorination reached, where in the case of PVDC 1.4 Cl atoms are eliminated on average per monomer unit, it may be concluded that for polymers with a high chlorine content, the methylene and chloromethylene groups remaining in the polymer as a result of the "mutual restriction" of the growing polymers should undergo further dehydrochlorination:

The decrease in length of the resulting polyenes with an increase in chlorine content in the initial polymers is likely to be due to side reactions involving cross-linking at a relatively high temperature of dehydrochlorination (80–100 °C). Moreover, according to elemental analysis and IR spectroscopic data, the reaction products contain nitrogen- and oxygen-containing groups, which the authors assign respectively to free DMF retained by the precipitated polymer or to oxidised structures. However, it is possible that with an increase in the chlorine content of the polymer, the probability of substitution reactions taking place between the halogen-containing polymer and DMF or its degradation products is increased.

VII. Dehydrohalogenation by alkali metal amides

In a number of studies dehydrochlorination of PVC,[112–115] CPVC,[113,114] and PVDC [113,114,116–118] by alkali metal amides in liquid ammonia was investigated. The reaction has been carried out over a wide temperature range (from −60 to 50 °C) with polymer solutions and also powders and films. When dehydrohalogenation is carried out at temperatures above −33 °C (the boiling point of ammonia) an increase in pressure in the reactor is required.

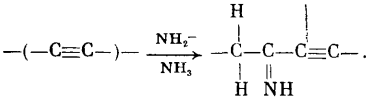
By using alkali metal amides it is possible to achieve complete dehydrohalogenation even at low temperatures, which reduces the contribution from side reactions involving cross-linking to a minimum and assists the formation of structures with long sequences of conjugated multiple bonds. Thus, for example, completely dehydrochlorinated PVC, which contains no chlorine, melts at a temperature of 395–410 °C,[112,115] which is an indication of the linear structure of the dehydrochlorination product (absence of spatial cross-linking).

Dehydrohalogenation of halogen-containing polymers in solution[114] occurs more rapidly than with powders or films.[45] The degree of dehydrohalogenation increases with an increase in temperature and reaction time as well as with an increase in concentration of the alkali metal amide.[113,114,117]

As dehydrochlorination takes place the absorption bands characteristic of the initial polymers in the IR spectra of the products disappear and absorption bands appear at 990, 1600, and 3030 cm^{-1}, characteristic of bending vibrations of C–H bonds on a *trans*-C=C double bond, stretching vibrations of conjugated C=C double bonds, and stretching vibrations of the C–H bonds on a C=C double bond respectively.[45,113–117] In the IR spectra of the dehydrochlorination products of PVDC and CPVC an absorption band also occurs at 2200 cm^{-1}, which is attributed to stretching vibrations of C≡C triple bonds.[45,113,114,116,117]

A study of the dehydrochlorination products of PVC using X-ray diffractometry showed that these products have a structure that is similar to that of noncrystalline *trans*-polyacetylene.[114,115]

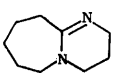
In the EPR spectra of the products of the complete dehydrochlorination of PVC a narrow solitary signal appears with a line width of 7–12 E.[112,114,115] As the degree of dehydrochlorination increases the line width decreases.[115] The value of the *g*-factor is 2.000 ± 0.005.[112] For the dehydrochlorination products of PVDC a narrower line in the EPR spectrum (5–9 E) is characteristic. As the degree of dehydrochlorination increases the spin-lattice relaxation time decreases and reaches a value of 10^{-6} s.[116]



From an examination of the EPR spectra it may be concluded that delocalisation of the unpaired electrons, which are stabilised by the long chain of conjugated multiple bonds, occurs in the dehydrochlorination products.[114] As the degree of conversion increases, the concentration of unpaired electrons increases and reaches a value of 1.4×10^{21} spin g^{-1} for the dehydrochlorination product of PVDC.[116]

It should be noted that dehydrochlorination of PVDC by alkali metal amides in liquid ammonia has been proposed as a counter-synthesis of carbyne[116] occurring by a two-stage mechanism[117]

$$-(-CH_2-CCl_2-)_n- \xrightarrow[-n\mathrm{HCl}]{} -(-CH=CCl-)_n- \xrightarrow[-n\mathrm{HCl}]{} \longrightarrow -(-C\equiv C-)_n-$$



In four studies[112–115] elemental analysis data are given according to which the sum of the content of carbon and hydrogen in products of the exhaustive dehydrochlorination of PVC, containing no chlorine, differs from 100%. The authors attribute this difference to the presence of oxygen that is formed in the dehydrochlorination products as a result of oxidation reactions. Moreover, completely dehydrochlorinated PVC and PVDC did not contain nitrogen.[112–115] However, in a study[117] of the dehydrochlorination of PVDC with sodium and potassium amides in liquid ammonia at −55 and 0 °C it was shown that the main process of HCl elimination is accompanied by amination as a side reaction. Thus, for example, when dehydrochlorination was carried out at 0 °C for 30 h, the reaction products contained 8.3% nitrogen. It was shown that the content of nitrogen in the reaction products rises with an increase in the time of dehydrochlorination, the concentration of alkali metal amide in solution, and the degree of dehydrochlorination.[117]

In fact, alkali metal amides have considerable nucleophilicity in addition to high basicity. Therefore, when the dehydrohalogenation of halogen-containing polymers by alkali metal amides in liquid ammonia is carried out, side reactions involving nucleophilic substitution of the halogen atoms are to be expected. In addition to this, addition reactions of ammonia to multiple bonds are also possible[117]

VIII. Dehydrohalogenation by 1,8-diazabicyclo-[5.4.0]undec-7-ene

In recent years studies in which the strong organic base 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)

is used as a dehydrohalogenating agent for halogen-containing polymers have made their appearance in the scientific literature.[58,119–122]

Soga et al.[58,119] studied the dehydrochlorination of samples of PVC with a varying degree of polymerisation by DBU in polar solvents. The solvents used were dimethyl sulphoxide, THF, HMTP, and DMF. The reaction was carried out at 65 °C for 20 h. It was shown that the degree of dehydrochlorination did not depend on the molecular weight of the initial PVC.

As a result of dehydrochlorination long sequences of conjugated C=C double bonds are formed. A determination of the length of the polyene sequences from the data of elemental analysis gave a value of 8–15 –CH=CH– units. Samples of dehydrochlorinated PVC contained 2.8–4.9% residual chlorine and also 5.0–7.5% nitrogen, which in the opinion of the authors, was due to the partial doping of the resulting polyene with DBU molecules.[58]

In the IR spectra of the dehydrochlorination products a very strong absorption band occurs at 1015 cm^{-1} which is characteristic of a *trans*-polyacetylene.[58,119] In the UV spectra a broad absorption band occurs in the region of 670 nm, which is attributed to $\pi \rightarrow \pi^*$ electronic excitations.[58] After partial hydrogenation of the dehydrochlorination product of PVC alloyed with potassium, absorption bands occurred at 240, 280, 310, 340, 380, 400, and 420 nm in the UV spectra, which were attributed by the authors to $\pi \rightarrow \pi^*$ transitions in $-(-CH=CH-)_n-$ structures, where n = 2, 3, 4, 5, 6, 7, and 8 respectively.[119]

In the X-ray diffraction spectrum of the polyenes obtained there is a weak halo at 2θ = 20–25 °C, which is an indication of the very low degree of crystallinity.[58] With an increase in molecular weight of the initial PVC the intensity of this halo decreases, which suggests a decrease in the degree of crystallinity.

The dehydrochlorination of PVC films was studied by Danno et al.[120,121] Dehydrochlorination was carried out in two stages. At the first stage the reaction was carried out in a mixture of DMF and methanol at a volume ratio of 2:3 at 50 °C for 36 h in a current of nitrogen, in order to prevent the PVC films dissolving in the reaction mixture. As dehydrochlorination took place, in the IR spectra of the reaction products the intensity of the absorption bands due to C–Cl bonds in the region of 600–700 cm^{-1} that were characteristic of the initial PVC decreased and new bands appeared at 1010 and 3015 cm^{-1}, characteristic respectively of bending and stretching vibrations of C–H bonds in *trans*-polyacetylene.

The degree of dehydrochlorination increases with an increase in concentration of DBU and also with an increase in reaction time up to 40 h, reaching a value of 0.8 and then remaining constant (at a molar ratio of DBU:Cl = 4:1).[120]

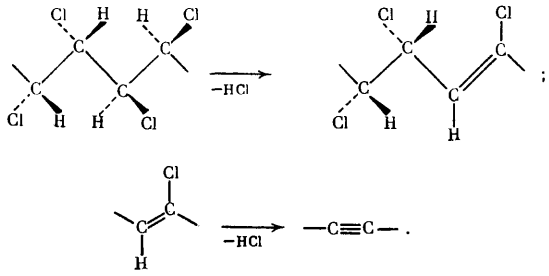
A well-defined absorption band occurs at 605 cm^{-1} in the IR spectra of the films after the first stage of dehydrochlorination. This band is absent in the spectra of the initial PVC, whereas a band is clearly defined at 615 cm^{-1}. The absorption bands in the IR spectra at 605 and 615 cm^{-1} are attributed to stretching vibrations of C–Cl bonds in crystalline and amorphous PVC respectively. Thus, during dehydrochlorination at the first stage, elimination of HCl mainly occurs in the amorphous phase of PVC whereas the crystalline region does not change. Therefore, the maximum degree of dehydrochlorination attained at the first stage (0.8) is due to the presence in the initial PVC of about 20% as a crystalline fraction, which is more resistant to dehydrochlorination.[120]

After the first stage of the reaction the films became insoluble, which made it possible to use pure solvents at the second stage. For this second stage the reaction was carried out in pure DMF at 50 °C for 24 h in a current of nitrogen. The authors anticipated that at the second stage the crystalline regions of PVC would swell in the solvent and undergo further dehydrochlorination. In fact, the degree of dehydrochlorination increases to 0.95 at the second stage. The absorption band at 605 cm^{-1} in the IR spectra of the reaction products almost completely disappears, which suggests that the crystalline fraction undergoes dehydrochlorination. In the spectra of the products, absorption bands occur at 1665, 1720, and 3450 cm^{-1}. The bands at 1665 and 1720 cm^{-1} are attributed to the absorption of α,β-unsaturated and isolated keto groups respectively. The band at 3450 cm^{-1} is attributed to the absorption of hydroxyl and hydroperoxide groups. The appearance of oxygen-containing groups in the reaction products is attributed by the authors to a reaction between polymer and DMF. When dehydrochlorination was carried out under similar conditions in cyclohexanone, methyl ethyl ketone, and THF, bands in the IR spectra corresponding to the absorption of oxygen-containing groups were absent or very weak.[120]

An increase in reaction time from 36 to 67 h at the first stage and from 24 to 48 h at the second stage did not produce any substantial changes in the degree of dehydrochlorination or the IR spectra of the products.[121]

A study of the dehydrochlorination products of industrial PVC using X-ray diffractometry showed that the resulting polyenes were completely amorphous,[120] whereas in the dehydrochlorination of syndiotactic PVC obtained by low-temperature polymerisation polycrystalline films of a similar polyene structure were obtained.[121]

The dehydrochlorination of stereospecifically chlorinated polyacetylene by DBU in different solvents was studied by Akagi et al.[122] In the IR spectra of the reaction products there are strong absorption bands in the region of 1640 and 2130 cm^{-1}, attributed to stretching vibrations of carbon–carbon double and triple bonds respectively. With an increase in polarity of the solvent used, the absorption band due to the triple bonds shifts from 2140 cm^{-1} (for toluene) to 2121 cm^{-1} (for dimethyl sulphoxide) and the degree of dehydrochlorination increases (from 80.8 to 100%). In the Raman spectra of the dehydrochlorination products, intense lines occurred in the region of 1550 and 1140 cm^{-1}, attributed to stretching vibrations of carbon–carbon double and single bonds respectively in conjugated *trans*-polyenes. The authors attribute the presence of these bands to incomplete chlorination of the initial polyacetylene. A line occurred at about 2150 cm^{-1} which was attributed by the authors to stretching vibrations of C≡C triple bonds in macromolecules of the polyyne modification of carbyne (α-carbyne). On increasing the wavelength of exciting light from 457.9 to 632.8 nm, the frequency of this line decreased from 2157 to 2113 cm^{-1} correspondingly. As a result of a numerical calculation from Raman spectroscopic data of the length n of the resulting polyynes using the empirical relationship



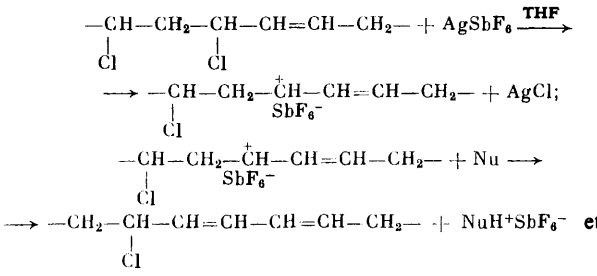
$$\nu_{C\equiv C} = 2104 + 698/(n_{C\equiv C} + 1)$$

values of n from 12 to 65 fundamental units were determined. Here $\nu_{C\equiv C}$ is the vibrational frequency of the C≡C bond in the Raman spectrum; n is the number of units of α-carbyne (–C≡C–).

In the UV spectra of the carbyne obtained there is a very broad absorption band from 350 to 700 cm^{-1}, which the authors attribute to overlap of the bands resulting from $\pi \rightarrow \pi^*$ excitations in the polyyne structures.[122]

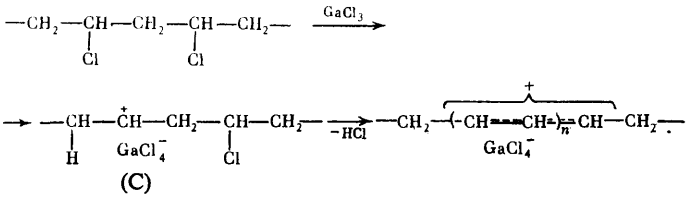
The authors concluded from the IR and UV spectroscopic data that α-carbyne was formed and proposed a mechanism involving

two-stage *trans*-elimination:



However, it should be noted that the results of vibrational spectroscopy alone are insufficient for an unequivocal conclusion about the type of bonding in the carbyne—polyyne or cumulene. Thus, according to calculated data which are good agreement with the experimental IR spectra, absorption bands in the region of 1600 and 2100–2200 cm^{-1} are characteristic of vibrations due to cumulene structures in β-carbyne molecules.[48] The absence of absorption bands at 1950 cm^{-1} in the IR spectra is not proof of the absence of a cumulene structure.[123,124] Moreover, assignment of the lines in the region of 1140 and 1550 cm^{-1} in the Raman spectra to vibrations of polyene structures[122] is only partly correct. Thus, while the line at 1140 cm^{-1} is due to the presence of polyacetylene residues in the sample, the intensity of the line in the region of 1550 cm^{-1} is disproportionately high for it to be assigned completely to vibrations of polyene structures.[125] The line in the region of 2150 cm^{-1} in the Raman spectrum was attributed by the authors to vibrations of the polyyne structures of α-carbyne. However, it was shown by Berdyugin et al.[54] that in the Raman spectra of β-carbyne obtained by dehydrohalogenation of poly(vinylidene halides) the lines in the region of 2150 and 1550 cm^{-1} correspond to vibrations of cumulated double bonds in the carbon chain. For a clear identification of the nature of the bonds in carbyne, a detailed study of its electronic structure is necessary.[33,41,42,51,52]

IX. Some other dehydrohalogenating agents



The chemical agents and systems that are widely used in the dehydrohalogenation of halogen-containing polymers are examined in Sections II–VIII. In the present section certain other chemical agents which are also active in hydrogen halide elimination reactions are described.

In the preparation of graft copolymers of isobutylene on PVC Kennedy and Davidson[126] found that organoaluminium compounds such as diethylaluminium chloride are able to dehydrochlorinate PVC to form a small quantity (2–5 mol%) of short $-(-CH=CH-)_n-$ polyene sequences, where $n \leqslant 5$ (according to UV spectroscopic data). In an attempt to obtain graft copolymers of THF on PVC it transpired that on treatment with silver hexafluoroantimonate dehydrochlorination of PVC occurred with the formation of polyene structures of 11 or more conjugated C=C double bonds,[127] while it was not possible to obtain graft copolymers. In the opinion of Kennedy[126] and Franta,[127] initiation of dehydrochlorination occurs at the sites of labile structures (mainly allylic chlorine atoms) present in the initial PVC. On replacement of the allylic chlorine atom by a SbF_6^- anion [or addition of a $(C_2H_5)_2AlCl$ molecule] a polymer carbocation is formed, which eliminates a proton by a β-elimination mechanism with reproduction of a chlorallylic structure, following which the process is repeated

where Nu is a nucleophile which can be a molecule of THF or another solvent.[127]

It was found by Myakov et al.[128] that PVC reacts with gallium trichloride with elimination of HCl at room temperature in the absence of a solvent. However, the degree of dehydrochlorination and the length of the resulting polyenes are small. Thus, for example, when the $GaCl_3$ content is 7.5%, the degree of dehydrochlorination only reaches 3%. With an increase in $GaCl_3$ content the degree of dehydrochlorination increases. In the UV spectra of the reaction products there are absorption bands at 317, 408, 470, and 535 nm, attributed to allylic, di-, tri- and tetra-enyl cations respectively. The formation of polyenyl cations in PVC macromolecules can be depicted by the following scheme:

(C)

The instability of PVC in the presence of $GaCl_3$ is due to the high ionising ability of $GaCl_3$ and also by the large energy gain in the elimination of HCl by the carbocation (C) through the formation of more stable allylic and polyenyl cations.[128]

On treatment of PVC in solution with different aromatic carbanions[129] obtained from organometallic compounds, the competing reactions of dehydrochlorination and nucleophilic substitution occur. The highest activity in dehydrochlorination was recorded for the phenylisopropyl carbanion $[C_6H_4(CH_3)_2C^-]$. According to UV spectroscopic data, the length of the resulting polyene sequences ranges from 5 to 12 conjugated C=C double bonds.[129]

When films of halogen-containing polymers under vacuum are brought into contact with antimony pentafluoride vapour, dehydrochlorination occurs vigorously to give long chains of conjugated double bonds.[130] On exposure of a PVDF film to SbF_5 vapour, the film darkens and then turns black. An increase of temperature was required in order to carry out the dehydrofluorination of polytrifluoroethylene, whereas a PVC flm turned black immediately on exposure to SbF_5 at room temperature. Taking into account the fact that SbF_5 is an effective dopant for polyacetylene,[86] it may be concluded that there is future potential in this method of dehydrohalogenation for obtaining organic semiconductor materials.

The reaction between PVC and the superoxide anion was studied by Osawa et al.[131,132] In order to achieve this, PVC in THF solution was treated with potassium superoxide in an atmosphere of nitrogen at 40 °C. In the IR spectra of the reaction products, absorption bands occur at 3300, 1680, 1620, and 765 cm^{-1}, attributed to hydroxyl groups, α,β-unsaturated keto groups, and polyene structures (1620 and 765 cm^{-1}) respectively. The UV spectroscopic data confirm the presence of conjugated polyene structures in the reaction products. According to the elemental analysis data, with an increase in the time of reaction between PVC and KO_2, the content of chlorine in the reaction products decreases while the oxygen content increases. In the opinion of the authors, initiation of the reaction between PVC and O_2^- occurs by a mechanism involving nucleophilic substitution of the chlorine atoms in chlorallylic groups present in the initial PVC.[131,132] The resulting peroxide macroradicals undergo secondary reactions to form α,β-unsaturated keto groups, hydroxyl groups, peroxide cross-linking, and also polymer alkoxy radicals. The alkoxy radicals can detach a proton from the polymer chain to form alkyl macroradicals which undergo further dehydrochlorination to form conjugated polyene structures.[131,132]

In these studies[79,80,133] a method was proposed for the dehydrohalogenation of halogen-containing polymers [poly(α-chloroacrylonitrile,[79,80,133] PVC, chlorinated polybutadiene, poly(2,3-dibromobutene) [133]] by alkali metal hydrides in DMF or dimethyl sulphoxide solution at 60–80 °C to form polymers with a system of conjugated double bonds.

— o0o —

The dehydrohalogenation products of halogen-containing polymers, as in the majority of polymers with a system of conjugation, have semiconductive properties and are of interest for their use in electrical engineering (sources of a current),[58,134,135] microelectronics ($p-n$ transitions, Schottky barriers, photoelectric cells[136]) optics (polarising films[137–144]), and also for the preparation of electrodes and membranes in electrochemistry, protective films in microwave technology,[145,146] and antistatic materials.[146,147]

The electrophysical properties of polymers with a system of conjugation obtained by dehydrohalogenation have been investigated in a considerable number of studies.[20,22,26,40,58,75,79,80,99,113,114,119–122,145–157] The specific electrical conductivity of the dehydrohalogenation products varies over a wide range ($10^{-12}-10^{-7}$ Ohm^{-1} cm^{-1}) depending on the nature of the initial polymer, the dehydrohalogenating agent, and the reaction conditions. Alloying (doping) of the reaction products with different electron-donating or electron-withdrawing components results in an increase in the electrical conductivity by a factor of 10^5-10^8 ($10^{-6}-10^{-1}$ Ohm^{-1} cm^{-1}). Iodine[20,22,26,40,119,120,122,150–152,154], $FeCl_3$,[26,151] SO_3,[58,119] BF_3,[26] AsF_5,[119] and also $(C_2H_5)_4NBF_4$ [156] and copper phthalocyanine[155] have been used as dopants.

From an examination of the results of the studies cited above it may be concluded that chemical dehydrohalogenation of halogen-containing polymers is a practicable and convenient method of obtaining carbon-chain polymers with a system of conjugation in the main chain, which can be used to obtain even crystalline polyacetylene.[158,159] The most effective dehydrohalogenating agents are hydroxides, alkoxides, and alkali metal amides. Dehydrohalogenation by DBU and SbF_5 also appears to have future potential.

P-Halogen-substituted phosphorus ylids

O I Kolodyazhnyi
Institute of Bioorganic Chemistry and Petrochemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. Literature data on methods of obtaining ylids containing halogen atoms on the phosphorus atom of the P=C group are arranged systematically and reviewed.

The bibliography contains 125 references.

I. Introduction

Phosphorus ylids are important reactants and are widely used in organic synthesis.[1] Among the various types of these compounds synthesised in recent years there is significant interest in *P*-hetero-substituted phosphorus ylids,[2–4] particularly in ylids containing halogen atoms on phosphorus, or *P*-halogenated ylids as they are usually called. The presence of labile halogen atoms determines the properties of these compounds, which are interesting from theoretical and preparative aspects.[2–7] With the aid of *P*-halogenated ylids such valuable substances for organic synthesis as phosphorus-containing ketenes, thioketenes, vinylphosphine oxides, allylphosphine oxides, etc. have been obtained. *P*-Halogenated ylids participate in various cycloaddition and heterocyclisation reactions and possess high phosphorylating ability.

In addition *P*-halogenated ylids are also convenient subjects for studying important theoretical problems of structure and reactivity of organophosphorus compounds.

Recently published review papers on *P*-halogenated ylid chemistry comprise material from only the author's work.[2,8–10] Latterly a significant number of publications has appeared describing new methods of synthesis and disclosing interesting properties of *P*-halogenated ylids as a result of which there is a need to review all the available information on this important type of organophosphorus compound. Results of investigations on *P*-halogenated ylid chemistry published up to 1990 are correlated in this review.

II. Synthetic methods

Detailed investigations on *P*-halogenated ylids have enabled convenient methods for their synthesis to be devised based on the following conversions. 1. 'Oxidative ylidation' of compounds of trivalent phosphorus comprising increasing the phosphorus coordination number to four by adding halogen and forming a P=C bond.[2] Such reactions include 1,2(C→P)-halogenotropic rearrangements and reactions of tertiary alkylphosphines with carbon tetrahalides to form *P*-halogenated ylids containing one atom of chlorine or bromine on the phosphorus atom. 2. The formation of a P=C multiple bond in a halophosphorane or halophosphonium salt by an elimination reaction. Various *P*-chloro- and *P*-fluoroylids were synthesised by this means, including some containing several halogen atoms on phosphorus. 3. Reactions of *P*-halogenated ylids with chlorine-containing electrophiles which proceed with replacement of hydrogen atoms at the α-carbon by various groups.

The methods listed have enabled *P*-halogenated ylids of practically any strucure to be obtained by simple operations using starting materials available in the laboratory.

1. Rearrangement of α-haloalkylphosphines into *P*-halogenated ylids

A halogen atom at the α-position of tertiary alkylphosphines is distinguished by high lability as a result of which it may possibly migrate to the phosphorus atom [1,2(C→P)-halogenotropic shift]. The valency of the phosphorus atom is increased as a result of halogen atom migration, a P=C bond is formed and the α-haloalkylphosphines (A) are converted into *P*-halogenated ylids (B).

$$\underset{\text{(A)}}{R_2P(X)-CR_2'} \longrightarrow \underset{\text{(B)}}{R_2P(X)=CR_2'},$$

X = Br, Cl.

Halogenotropy in a P–C diad depends on the substituents R and R′ on the phosphorus and carbon atoms, which influence the thermodynamic stability of the halogenotropic isomers (A) and (B). Consequently not only 1,2(C→P) but also 1,2(P→C)-halogenotropic rearrangements (see below) are possible with a particular choice of substituents. However α-haloalkylphosphines containing electron-accepting substituents on the α-carbon atom, stabilising the ylid function as a rule, are readily converted into *P*-halogenated ylids and in this case a 1,2(C→P)-halogenotropic rearrangement is a reliable means of obtaining them.

Halo-bis-(benzenesulphonyl)methanes, being comparatively strong CH-acids, react with chlorodiphenylphosphine in the presence of triethylamine in tetrahydrofuran at 0 °C with the formation of tertiary α-haloalkylphosphines (I). Compounds (I) rearrange smoothly into *P*-halogenated ylids (II), which are isolated in good yield as stable crystalline compounds and are used as reagents in various chemical conversions.[11]

$$Ph_2PCl + XCH(SO_2Ph)_2 \xrightarrow[-Et_3N\cdot HCl]{Et_3N} \underset{\text{(I)}}{Ph_2PC(X)(SO_2Ph)_2} \longrightarrow \underset{\text{(II)}}{Ph_2P(X)=C(SO_2Ph)_2}$$

X = Br, Cl.

The reaction of di-organochlorophosphines with metallochloromethanes (III) or (V) stabilised by sulphonyl or trimethylsilyl groups proceeds readily.[2,11–13] The resulting α-chloroalkylphosphines (IV) and (VI) are very unstable and rearrange into *P*-chloroylids at low temperature. For example, α-chloroalkylphosphine (VI), which was observed by its ^{31}P NMR (signal at δ_P 86.1 p.p.m.), exists at −110 °C in toluene but even at −90 °C is converted quantitatively into ylid (VII) (δ_P 65.5 p.p.m.).[13]

$$R_2PCl + LiCHSO_2CF_3 \xrightarrow[-LiCl]{} \underset{Cl}{\underset{|}{R_2PCHSO_2CF_3}} \longrightarrow \underset{Cl}{\underset{|}{R_2P{=}CHSO_2CF_3}},$$

(III) (IV) 60—75%

R = Et, iso-Pr, Ph,

$$(Me_2N)_2PCl + LiCHSiMe_3 \xrightarrow[-LiCl]{} \underset{Cl}{\underset{|}{(Me_2N)_2PCHSiMe_3}} \longrightarrow$$

(V) (VI)

$$\longrightarrow \underset{Cl}{\underset{|}{(Me_2N)_2P{=}CHSiMe_3}}.$$

(VII), 64%

Compounds of trivalent phosphorus containing a trichloromethyl group are comparatively stable. Lutsenko and co-workers obtained bis-(dimethylamino)trichloromethylphosphine, which is stable at room temperature, by an exchange reaction of dichloro(trichloromethyl)phosphine with diethylamine. The product was purified by distillation in vacuum and was then converted into *P*-chloroylid (VIII) by boiling in dichloromethane.[14]

$$Cl_2PCCl_3 \xrightarrow[-Me_2NH\cdot HCl]{Me_2NH} (Me_2N)_2PCCl_3 \longrightarrow \underset{Cl}{\underset{|}{(Me_2N)_2P{=}CCl_2}}.$$

(VIII)

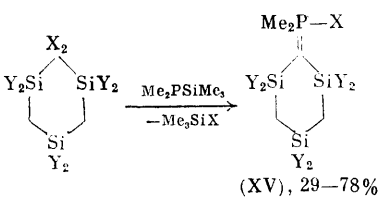
Pinchuk and co-workers have carried out the analogous rearrangement of bis-(diethylamino)trichloromethylphosphine (X) into ylid (XI).[15,16] Phosphine (X) was obtained by the reaction of chloro-bis-(diethylamino)phosphine with hexamethyltriaminophosphine and carbon tetrachloride. As was shown previously by Riesel[17] the ion pair (IX) is formed, containing the CCl_3^- anion, which is capable of reacting with chlorine-containing electrophiles. In this case the ion pair interacts with chloro-bis-(diethylamino)-phosphine with the formation of phosphine (X). Ylids (VIII) and (XI) were not isolated in a pure state. However their structures were confirmed spectroscopically and by hydrolysis.

$$(Me_2N)_3P + CCl_4 \longrightarrow \underset{(IX)}{[(Me_2N)_3\overset{+}{P}Cl\ CCl_3^-]} \xrightarrow{(Et_2N)_2PCl} \underset{(X)}{(Et_2N)_2PCCl_3} \longrightarrow$$

$$\longrightarrow \underset{(XI)}{(Et_2N)_2P(Cl){=}CCl_2} \xrightarrow{H_2O} (Et_2N)_2P(O)CHCl_2.$$

The *C*-silicon-substituted *P*-chloroylids (XIII) and (XIV) were obtained by reacting carbosilanes with lithio- or silylphosphines. α-Haloalkylphosphines (XII) rearrange into *P*-chloroylids extremely readily but they were not recorded spectroscopically. Nonetheless the formation of α-haloalkylphosphines is not in doubt as follows convincingly from the reaction scheme.[18,19]

$$Cl_{4-n}C(SiCl_3)_n \xrightarrow{Me_2PLi} Me_2PC(Cl_{3-n})(SiCl_3)_n \longrightarrow \underset{Cl}{\underset{|}{Me_2P{=}C(Cl_{2-n})(SiCl_3)_n}},$$



(XII) (XIII)

$n = 1, 2,$

$$Cl_2C(SiMe_3)_2 \xrightarrow[-Me_3SiCl]{Me_2PSiMe_3} Me_2PC(Cl)(SiMe_3)_2 \longrightarrow \underset{Cl}{\underset{|}{Me_2P{=}C(SiMe_3)_2}}.$$

(XIV)

The reaction of *C*-dihalo-1,3,5-trisilacyclohexanes with silylphosphines on boiling in dimethoxyethane gives *P*-halogenated ylids (XV) with fission of the Si—P bond. These are stable crystalline substances or liquids distillable in vacuum.[19] The structures of the *P*-chloroylids were proved by X-ray structural analysis. Compounds (XV) are molecules planar in structure with shortened lengths for the P=C and Si—C bonds as a result of delocalisation of the negative charge on the ylid carbon atom around the ring.[20]

(XV), 29—78%

X = Br, Cl; Y = Cl, F, Me.

In certain cases *P*-chloroylids (XVI) and (XVIII), formed by 1,2 (C→P)-chlorotropic rearrangement, then undergo a prototropic or silylotropic rearrangement being converted into imidophosphonic chlorides (XVII) and (XIX).[21–24]

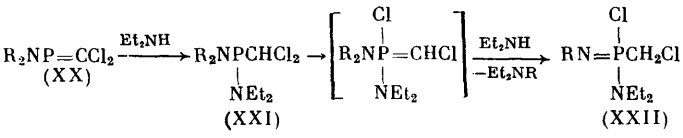
$$Cl_2PCHCl_2 \xrightarrow{RNH_2 + Et_3N} (RNH)_2PCHCl_2 \longrightarrow$$

$$\longrightarrow \underset{Cl}{\underset{|}{[(RNH)_2P{=}CHCl]}} \longrightarrow \underset{Cl}{\underset{|}{RNH{-}\overset{\overset{NR}{\|}}{P}CH_2Cl}},$$

(XVI) (XVII)

R = Alk,

$$\underset{Cl}{\underset{|}{Et_2NPCHCl_2}} \xrightarrow{(Me_3Si)_2NLi} \underset{(Me_3Si)_2N}{\underset{|}{Et_2NPCHCl_2}} \longrightarrow \left[\underset{(Me_3Si)_2N}{\underset{|}{\overset{Cl}{\overset{|}{Et_2NP{=}CHCl}}}}\right] \longrightarrow$$

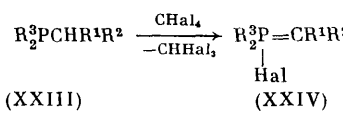


(XVIII)

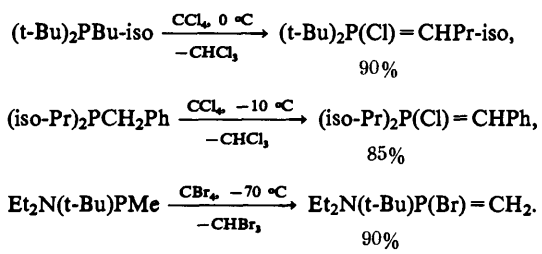
$$\longrightarrow \underset{Me_3SiN}{\underset{\|}{\overset{Cl}{\overset{|}{Et_2NPCH(Cl)SiMe_3}}}}$$

(XIX)

The phospha-ethylene (XX) is converted into trimethylsilylimidophosphonic chloride (XXII) on boiling in tetrahydrofuran with an excess of diethylamine. Seemingly diethylamine adds to the phospha-ethylene with the formation of dichloromethylphosphine (XXI) which rearranges to an unstable *P*-chloroylid. The latter gives



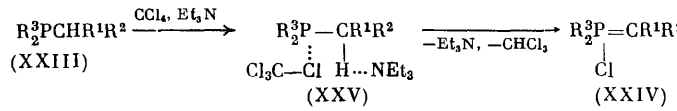
ylid (XXII) as a result of a silylotropic rearrangement and desilylation.[25,26]



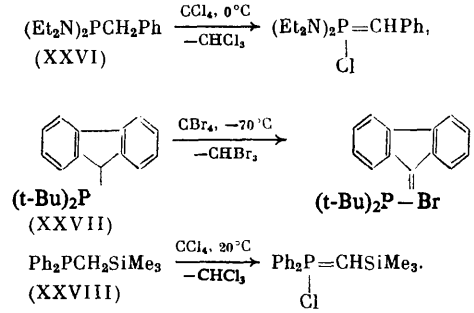
R = Me_3Si.

2. Reactions of tertiary alkylphosphines with carbon tetrahalides

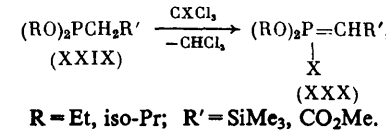
The reaction of tertiary alkylphosphines with carbon tetrahalides was first studied in the last century.[27,28] However *P*-halogenated ylids were not obtained from this reaction for a long time.[29–32] The reaction, which is very sensitive to conditions, proceeded only to the formation of a mixture of compounds difficult to identify.[32] Only in 1975–1977 was it established that by observing an appropriate temperature regimen and choice of solvent, tertiary alkylphosphines (XXIII) react with carbon tetrachloride or tetrabromide with the formation of *P*-halogenated ylids (XXIV).[33–36]



The interaction of compounds (XXIII) with carbon tetrahalides (CCl_4,[33,34] $CBrCl_3$, CBr_4 [34–37]) is usually carried out in pentane, diethyl ether[33–37] or dichloromethane[39] below 0 °C. Reaction with carbon tetrachloride occurs below 0 °C, and with CBr_4 and $CBrCl_3$ at −70 °C. The yields of *P*-halogenated ylids are high as a rule. *P*-Halogenated ylids are not isolated from the reaction mixture for preparative work, which appreciably simplifies handling. In this event it is sufficient to add carbon tetrachloride to the alkylphosphine in ether in order to obtain a reagent which is very reactive and ready to use.[9] However where necessary (for example for spectroscopic investigations) *P*-halogenated ylids may be purified by distillation in vacuum or by crystallisation from inert solvents.[9,40–43]

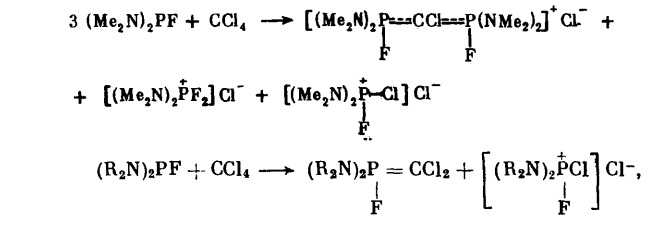


The substituents R^1 and R^2 in compound (XXIII) may be electron acceptors, groups, increasing the CH-acidity,[35–37,39–41] electron-neutral or electron-donating groups.[33,34,37,38] Compounds of trivalent phosphorus, containing at the α-carbon atom, alkyl groups, hydrogen atoms or trimethylsilyl or phenyl groups, which stabilise the ylid function, interact most actively with carbon tetrahalides. Yields of ylids obtained in this way are very high.[34,38,43–45] Strong electron-accepting groups at the α-carbon atom may reduce the nucleophilicity of the trivalent phosphorus atom since the rate of their interaction with carbon tetrahalides is reduced. For example, the introduction of one, two or three atoms of chlorine or bromine at the α-carbon atom of tertiary alkyl phosphines successively slows the reaction with carbon tetrachloride down to a complete stop. Electronegative alkoxycarbonyl or arylsulphonyl groups at the α-carbon atom of tertiary alkylphosphines also reduce the rate of interaction of the trivalent phosphorus atom with carbon tetrachloride.[35,40] However the reaction rate may in this case be increased by the addition to the reaction medium of tertiary amines the catalytic action of which is explained by participation in the formation of an intermediate reaction complex (XXV) (Scheme 1).[35,44] For example, compounds (XXIII) react readily with carbon tetrachloride in the presence of triethylamine in ether below 0 °C being converted in high yield into *P*-chloroylids (XXIV). In the absence of triethylamine at 20 °C the interaction is effected extremely slowly.[35]



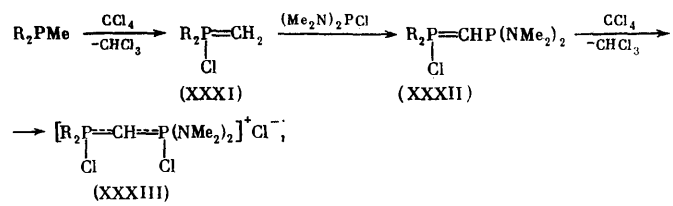
Scheme 1

Among tertiary alkylphosphines, compounds of the type of (XXVI)–(XXVIII) containing alkyl, phenyl or dialkylamino groups on the trivalent phosphorus atom react readily with carbon tetrahalides.[38,39,43–46]



Esters of alkylphosphonous acids (XXIX) react slowly even with an excess of carbon tetrachloride at 20 °C (R′ = $SiMe_3$, 14 h) while with CBr_4 or $CBrCl_3$ they react in ether at −70 °C and give high yields of *P*-bromoylids (XXX).[35–37,40,44]

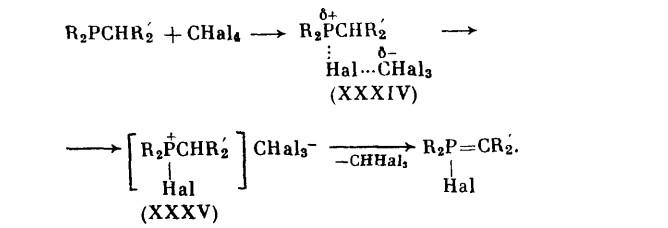
Acid chlorides and bromides of trivalent phosphorus do not react directly with carbon tetrahalides although fluorotetraalkyldiamino-phosphines react slowly with carbon tetrachloride at a ratio of 1:3



(R = Me) or 2:1 (R = Et, n-Pr) giving *P*-fluoroylids and phosphonium salts.[47]

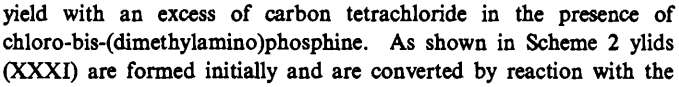
R = Et, iso-Pr.

Tertiary alkylphosphines give *P*-chloroylids (XXXIII) in high yield with an excess of carbon tetrachloride in the presence of chloro-bis-(dimethylamino)phosphine. As shown in Scheme 2 ylids (XXXI) are formed initially and are converted by reaction with the chlorophosphine into ylids (XXXII) containing a trivalent phosphorus atom. Reaction of the latter with CCl_4 gives *P*-chloroylid (XXXIII).[34]



Scheme 2

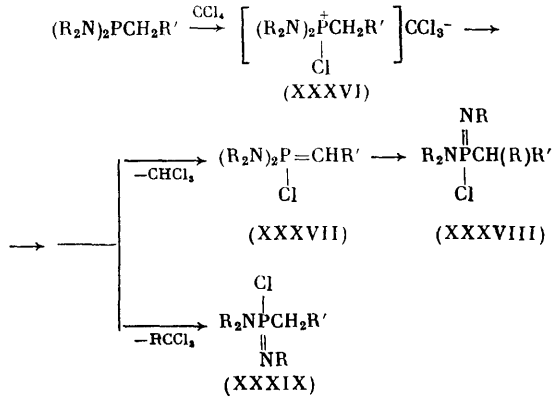
R = t-Bu, Et_2N.



It is assumed at present that the mechanism of the reaction of trivalent phosphorus compounds with carbon tetrahalides with few exceptions[48,49] has an ionic character.[50,51] The mechanism of the reaction of tertiary alkylphosphines with $CHal_4$ is not exceptional in this regard, although the presence of a labile hydrogen atom on the α-carbon determines some of its special features (Scheme 3).[34]

Scheme 3

Nucleophilic attack of the trivalent phosphorus by a halogen atom of the carbon tetrahalide leads through the intermediate formation of complex (XXXIV) to heterolytic fission of the readily polarised bond of $CHal_4$ and the formation of an ion pair (XXXV) containing trichloromethyl anion (Scheme 3). The highly basic $CHal_3$ anion deprotonates the α-carbon atom of the intermediate, the CH-acidity of which is fairly high due to the strong positive inductive effect of the phosphonium group, as a result of which halogenoform is eliminated and a *P*-halogenated ylid is formed.[9,34,52]

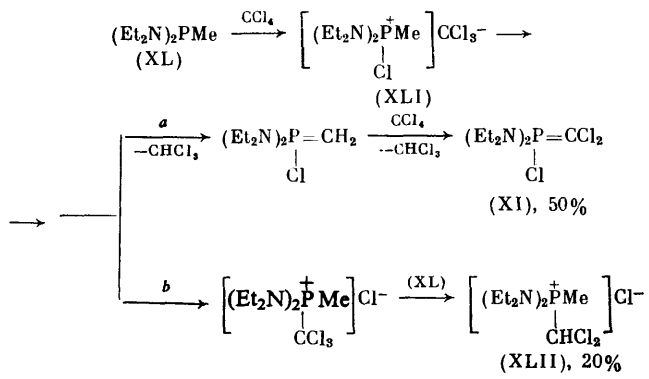


Scheme 3 demonstrates the reaction of sterically hindered trialkylphosphines with carbon tetrabromide as a result of which phosphonium salts containing tribromomethyl anion and stable at low temperature (−120 °C in pentane) are formed. The stability of the phosphonium salt is explained by steric hindrance to nucleophilic attack by the tribromomethyl anion on the phosphonium cation or on the α-proton. On increasing the temperature to −60 °C the phosphonium salts are converted into the corresponding *P*-bromoylids with elimination of chloroform. The structure of the phosphonium salts, particularly the presence in them of CBr_3 anion, was demonstrated by chemical reactions. Deuterobromoform was obtained on reacting the salts with deuterium chloride and tribromotrimethylsilylmethane was formed with chlorotrimethylsilane.[34]

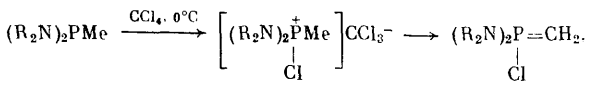
R = D, Me_3Si.

The route of the reaction of compounds of trivalent phosphorus (XXIII) with carbon tetrahalides and the character of the resulting products depends on the solvent.[53] Neilson and co-workers have shown that on reacting aminoalkyl-bis-(trimethylsilyl)phosphines with carbon tetrachloride in nonpolar solvents, chloroform is eliminated and *P*-chloroylids (XXXVII) are formed which then rearrange into iminophosphoranes (XXXVIII). However on carrying out the reaction in dichloromethane, trichlorotrimethylsilylmethane is eliminated and iminophosphoranes (XXXIX) are formed (Scheme 4). The dependence of the reaction route on the nature of the solvent is determined by the polarity of the medium on ion pair (XXXVI). In a polar solvent the ion pair separates and consequently the CCl_3^- anion attacks the exposed trimethylsilyl group. On the other hand in a nonpolar solvent a tighter ion pair (XXXVI) exists and consequently reaction of CCl_3 anion with the neighbouring hydrogen on the α-carbon atom and elimination of chloroform are readily effected.[54]

Scheme 4



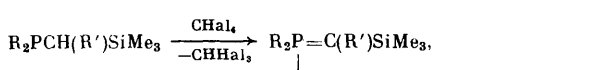
R = Me_3Si; R′ = H, Alk.



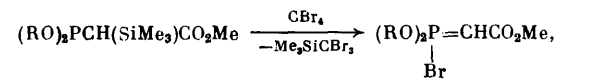
The reaction of compounds of trivalent phosphorus with carbon tetrahalides may under certain conditions occur with no elimination of halogenoform and no *P*-halogenated ylid formation but with attack of the trichloromethyl anion on the phosphonium cation and

formation of trichloromethylphosphonium salts.[55–57] The first reaction route occurs more frequently than the relatively rare second. As shown in Scheme 5, the reaction of bis-(diethylamino)methylphosphine (XL) with an excess of carbon tetrachloride occurs simultaneously in the two directions *a* and *b*, as a result of which a certain quantity of phosphonium salt (XLII) is formed in addition to ylid (XI).[57]

Scheme 5

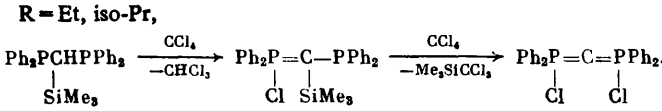


Branched groups on the phosphorus atom, which cause steric hindrance, hinder attack to $CHal_3^-$ on the phosphonium cation of ion pair (XLI). Consequently, in contrast to compound (XL), the reaction of bis-(diisopropylamino)methylphosphine with carbon tetrachloride in ether at 0 °C at a reactant ratio of 1:1 gives *P*-chloroylid (XLIII) in quantitative yield.[58] Tertiary alkylphosphines containing bulky t-butyl or isopropyl groups are smoothly converted into *P*-chloroylids. The groups mentioned not only facilitate ylid formation but also increase their stability.[9,33,34]

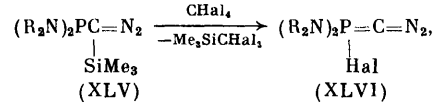


R = iso-Pr.

Tertiary alkylphosphines containing trimethylsilyl groups on the α-carbon atom very often react with carbon tetrahalides and are usually converted into ylids (XLIV).[20,34,37–40,46]

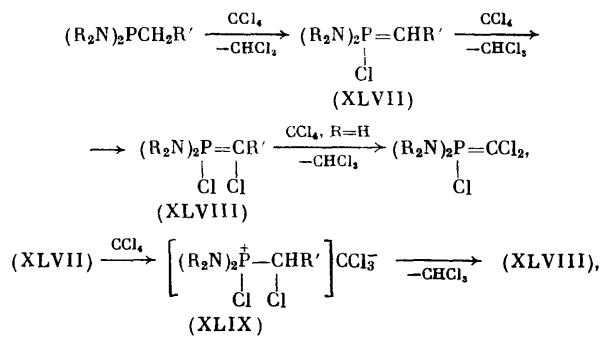


Hal = Br, Cl; R = Me_2N, Et_2N, $(iso\text{-}Pr)_2N$, Me, t-Bu, Ph, EtO, iso-PrO; R′ = $SiMe_3$, Ph.

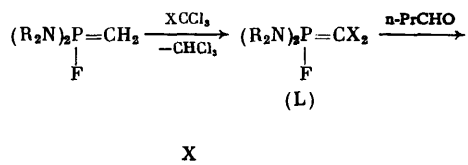


In certain cases trivalent phosphorus compounds containing trimethylsilyl groups on the α-carbon atom react with carbon tetrahalides with elimination of trihalotrimethylsilylmethane and not haloform. Trivalent phosphorus compounds containing a trimethylsilyl group at the sp^2-hybridised carbon atom are particularly readily desilylated.[59,60]

R = Et, iso-Pr,



Compound (XLV) eliminates trihalotrimethylsilylmethane on reaction with carbon tetrahalides being converted into *P*-halogenated ylids (XLVI) containing a diazo group on the ylid carbon atom.[61,62] Ylids (XLVI) are hygroscopic red oily liquids containing an absorption band at 2035 cm^{-1} in the IR spectrum. They are stable in solution for several days and are very reactive (see below).

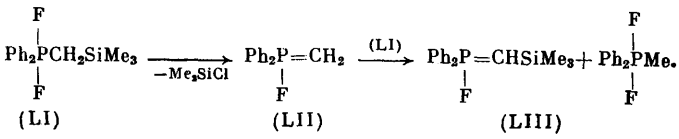


Hal = Br, Cl, R = iso-Pr.

P-Chloroylids formed by reaction of trivalent phosphorus compounds with carbon tetrachloride may react with a second molecule of CCl_4, exchanging a hydrogen atom on the α-carbon atom by an atom of chlorine. Thus reaction of bis-(dialkylamino)-alkylphosphines with an excess of carbon tetrachloride gives *C*-chloro-substituted *P*-chloroylids in yields of 70–80%.[57,63] Nucleophilic removal of a chlorine atom from carbon tetrachloride by the ylid carbon atom with the formation of ion pair (XLIX) is proposed, which is then converted into ylid (XLVIII) by elimination of chloroform.

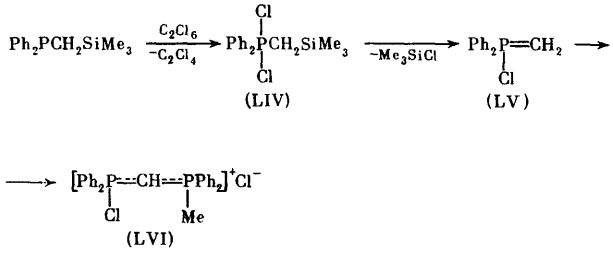
R_2N = Et_2N, $C_5H_{10}N$; R′ = H, Me, n-Pr, iso-Pr, Cl.

Exchange of hydrogen atoms on the ylid carbon atom by chlorine or bromine occurs on reaction of *P*-fluoroylids with carbon tetrachloride or tetrabromide in ether at −10 to +20 °C. *C*-Halogen-substituted ylids (L) are used in the synthesis of 1,1-dihaloolefins.[57]



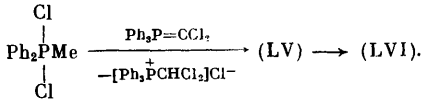
X = Br, Cl; R = Et, $C_5H_{10}N$.

The ability of *P*-halogenated ylids to react with carbon tetrachloride is appreciably reduced on introducing electron-accepting groups onto the ylid carbon atom thus reducing its nucleophilicity.[57]

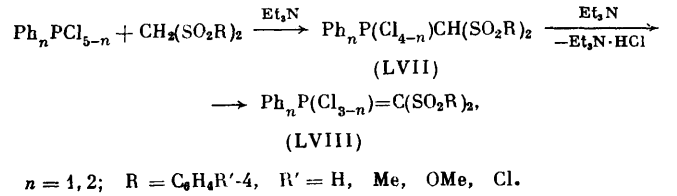


3. Synthesis of *P*-halogenated ylids from halophosphoranes

A comparatively simple method of obtaining *P*-halogenated ylids is the elimination of X—Hal (X = H, Hal, Me_3Si) from halophosphoranes or halophosphonium salts.[44–47]

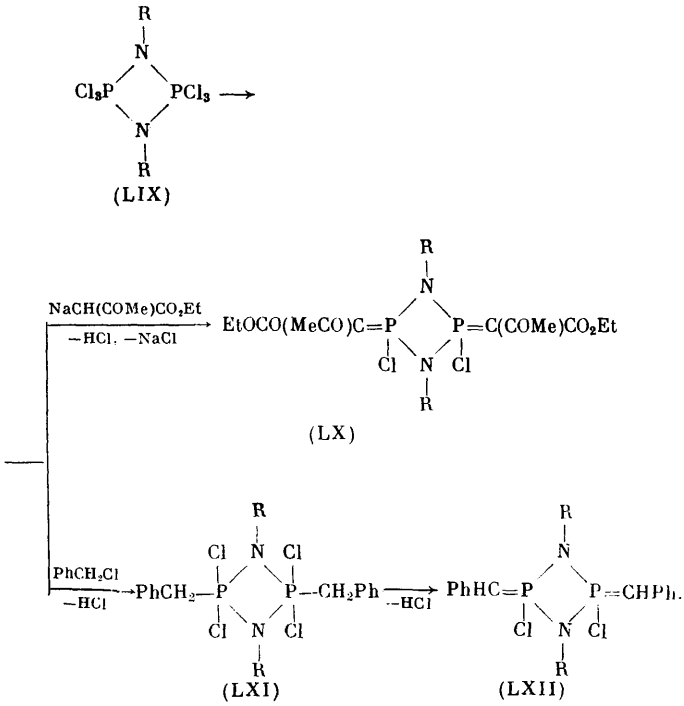


Difluorotrimethylsilylphosphorane (LI) eliminates fluorotrimethylsilane at room temperature with the formation of *P*-fluoroylid (LII) which enters into a transylidation reaction with difluorophosphorane (LI) being converted into *C*-silicon-substituted *P*-fluoroylid (LIII).[64]

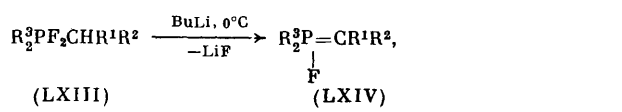


The dichlorophosphorane (LIV) formed from the reaction of diphenyltrimethylsilylmethylphosphine with hexachloroethane is converted into ylid-phosphonium salt (LVI). It is proposed that elimination of chlorotrimethylsilane from the dichlorophosphorane (LIV) gives *P*-chloroylid (LV) which dimerises and forms salt (LVI).[65] The difference in behaviour of *P*-chloro- and *P*-fluoroylids (LII) and (LV) is seemingly explained by the instability of the *P*-chloroylid.[65]

The dimerisation of ylid (LV) resulting on dehydrochlorination of dichloromethyldiphenylphosphorane with triphenylphosphonium-dichloromethylylid proceeds in a similar manner.[66]

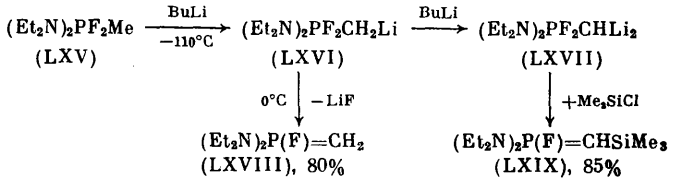


Polychlorophosphoranes react with bis-(arylsulphonyl)methanes in the presence of triethylamine through the formation of phosphonium salts (LVII) to give *P*-chloroylids with one or two chlorine atoms on phosphorus (LVIII).[67,68]

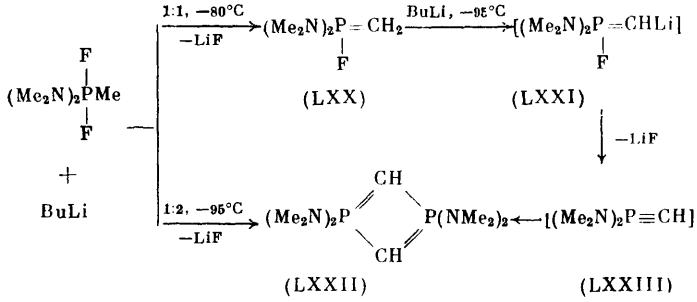


$n = 1, 2$; $R = C_6H_4R'$-4, $R' = H$, Me, OMe, Cl.

The reaction of dimers of trichlorophosphazo compounds (LIX) with sodio acetoacetic ester in boiling benzene as reported by Salman and co-workers proceeds with separation of hydrogen chloride and gives *P*-chloroylids with exocyclic P=C bonds (LX) in 4–56% yield. In precisely the same way the *P*-chloroylids (LXII) are formed in 12–48% yield on extended boiling in benzene of compounds (LIX) with an exess of benzyl chloride, hydrogen chloride being eliminated. It was proposed that phosphonium salts (LXI) are formed initially, which spontaneously eliminate hydrogen chloride, and are converted into *P*-chloroylids (LXII). The formation of ylids in the presence of HCl is remarkable, since these compounds are strong bases readily adding and firmly retaining hydrogen chloride.[69]



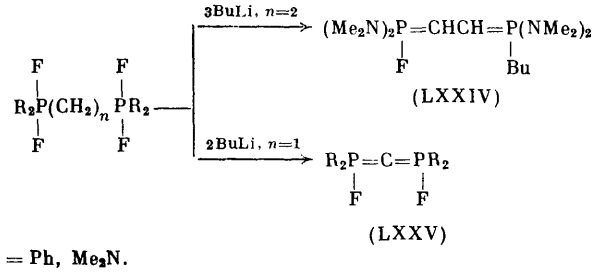
In several cases dihalophosphoranes were not converted into *P*-halogenated ylids on treatment with organometallic compounds. The main obstacle to successfully obtaining *P*-halogenated ylids in this way is the competing substitution of the halogen at phosphorus by an alkyl group. Nonetheless dehydrohalogenation of difluorophosphoranes (LXIII) with butyllithium or lithium hexamethyldisilazane proceeded quite smoothly and enabled the preparation of *P*-fluoroylids (LXIV) containing various substituents R^1, R^2 and R^3 on the phosphorus and carbon atoms of the P=C bond. To achieve high yields of *P*-fluoroylids (LXIV) it was necessary to carry out the reaction in ether at 0 °C, since a reduction of temperature down to −60 to −80 °C strongly reduced the yields and purity of the compounds.[64,70]



R^1, R^2 = H, Me, n-Pr, iso-Pr; R^3 = t-Bu, Et_2N.

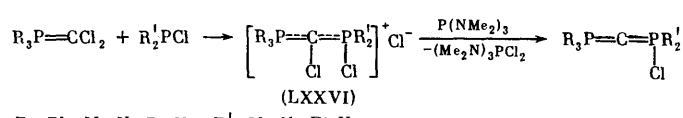
Reaction of the difluorophosphorane (LXV) with butyllithium gives the *C*-substituted difluorophosphorane (LXVI) which eliminates lithium fluoride at −20 to 0 °C but is stable at lower temperatures. At −60 °C and below, compound (LXVI) is readily

metallated by a second molecule of butyllithium with the formation of the dilithio-substituted difluorophosphorane (LXVII). On reaction of the difluorophosphorane with one equivalent of butyllithium a mixture is formed of mono- and dilithio-substituted difluorophosphoranes (LXVI) and (LXVII). In addition a portion of the difluorophosphorane (LXV) remains unreacted and after elimination of lithium fluoride leads to a complex mixture of final reaction products. On reacting difluorophosphorane (LXV) with two equivalents of chlorotrimethylsilane the *C*-silylated *P*-fluoroylid (LXIX) is obtained in high yield.[64]



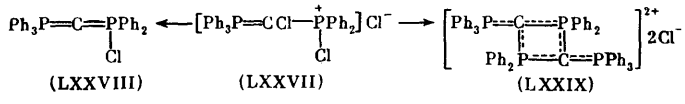
At a reactant ratio of 1:1 butyllithium dehydrofluorinates bis-(dimethylamino)methyldifluorophosphorane in pentane at −80 °C giving the *P*-fluoroylid (LXX) in 61.2% yield,[71,72] while on reacting the difluorophosphorane with two equivalents of butyllithium in pentane at −95 °C the diphosphacyclobutadiene (LXXII) is formed.[6,73,74]

It is proposed that butyllithium metallates the ylid carbon atom of the *P*-fluoroylid (LXX) with formation of compound (LXXI) which eliminates lithium fluoride and is converted into the phospha-acetylene (LXXIII). Dimerisation of the phospha-acetylene gives the diphosphacyclobutadiene.[72] It should be noted however that exchange of a hydrogen atom on the α-carbon of the P=C bond by lithium is achieved with great difficulty even at +20 °C or on heating. This is even less probable at −90 °C. The constitution of the diphosphacyclobutadiene was confirmed by X-ray structural analysis which showed particularly the planar structure of the cyclic portion of the molecule with completely uniform P−C bonds, the length of which were 172.5 pm.[72]



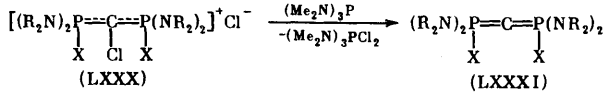
Diphosphacyclobutadiene (LXXII) is a reactive compound and readily participates in various cycloaddition reactions.[75−78]

The reaction of bis-(difluorophosphoranyl)ethane with butyllithium proceeds with dehydrofluorination of one difluorophosphorane group and replacement of a fluorine atom by a butyl group at the other, as a result of which the bis-ylid (LXXIV) is formed in good yield.[79] At the same time carbodiphosphoranes (LXXV) are obtained on reaction of bis-(difluorophosphoranyl)methane with butyllithium, the structure of which was shown by X-ray structural analysis.[80,81]



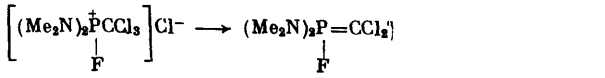
R = Ph, Me_2N.

Phosphoric acid triamides, possessing high dehalogenating ability, were used with success for converting halogenalkylphosphonium salts into *P*-halogenated ylids. For example, the dechlorination of the phosphonium salts (LXXVI) with tris-(dimethylamino)phosphine in dichloromethane at room temperature gives carbodiphosphoranes in high yield.[82]



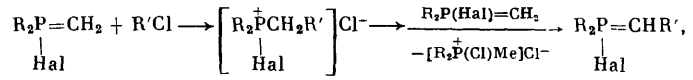
R = Ph, Me_2N, Et_2N ; R' = Me_2N, Et_2N.

The initial reaction conditions influence its course. Appel and co-workers established that the dechlorination of the salt (LXXVII) with tris-(dimethylamino)phosphine in toluene at −78 °C gives the chloropentaphenylcarbodiphosphorane (LXXVIII),[83] while in dichloromethane at room temperature the dimer of product (LXXVIII), viz. diphosphacyclobutadiene, is formed.[84] The structure of dimer (LXXIX) was established by X-ray structural analysis. Compound (LXXIX) contains a centrosymmetric cation with uniform endocyclic and exocyclic P−C bonds because all four phosphorus atoms participate in the delocalisation of the negative charge of the ylid carbon atom.[85]



Symmetrical *P*-halogen-substituted carbodiphosphoranes (LXXX) were obtained by the dechlorination of the halogenophosphonium salts (LXXXI) and tris-(dimethylamino)phosphine.[86−88]

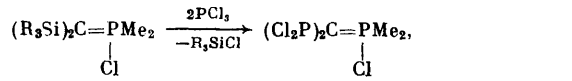
R = Me, X = F; R = Me, Et, n-Pr, X = Cl.



The dehalogenation of trichloromethylphosphonium salts with tris-(dimethylamino)phosphine gives *P*-halogenated ylids, containing a dichloromethylene group, in good yield.[47]

4. Other methos of synthesising *P*-halogenated ylids

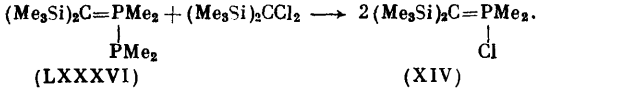
Hydrogen atoms and trimethylsilyl groups on the α-carbon atom of *P*-halogenated ylids are distinguished by a high lability and are readily replaced by various groups on interaction with electrophiles. Consequently reactions of *P*-halogenated ylids, having hydrogen or silicon on the α-carbon atom, with various chlorine-containing electrophiles is a convenient means of obtaining new *C*-substituted *P*-halogenated ylids of more complex structure than the starting materials.



The reaction of *P*-chloro- and *P*-fluoroylids with chlorotrimethylsilane and with acid chlorides of carboxylic, carbonic and phosphoric acids proceeds readily. Intermediate phosphonium salts (LXXXII) substituted at the α-carbon atom are formed in this way, the dehydrochlorination of which with a second molecule of the starting ylid gives new *P*-halogenated ylids (LXXXIII).[2,9] Dehydrochlorination of the phosphonium salt (LXXXII) occurs more readily the greater the electron-accepting ability of the group R′. Yields of *P*-halogenated ylids (LXXXII) containing trimethylsily, acyl, alkoxycarbonyl or phosphino groups at the α-carbon atom are between 50–85%.[9,34,71,89]

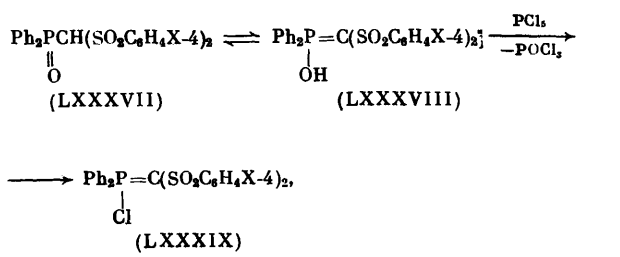
(LXXXII) (LXXXIII)

Hal = Cl, F; R′ = Me_3Si, $R_2''P$, R″C(O), AlkOCO.



On reacting ylids (LXXXIV) with phosphorus trichloride in benzene at room temperature the Si–C bond is readily broken and *P*-chloroylids with two dichlorophosphine groups on the phosphorus atom (LXXXV) are formed in good yield.[90]

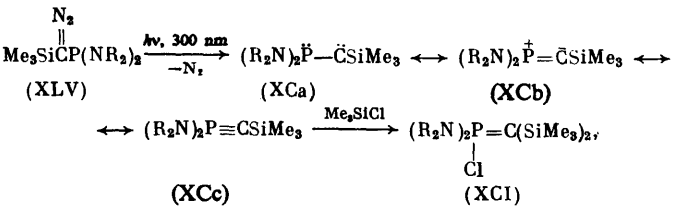
(LXXXIV) (LXXXV)



R_3Si = Cl_3Si, $Cl_2Si(CH_2SiCl_2)_2C$, $Me_2Si(CH_2SiMe_3)_2C$.

The ylid (LXXXVI) containing a very labile P–P bond is converted in good yield into the *P*-chloroylid (XIV) on reaction with dichloro-bis(trimethylsilyl)methane.[19]

(LXXXVI) (XIV)

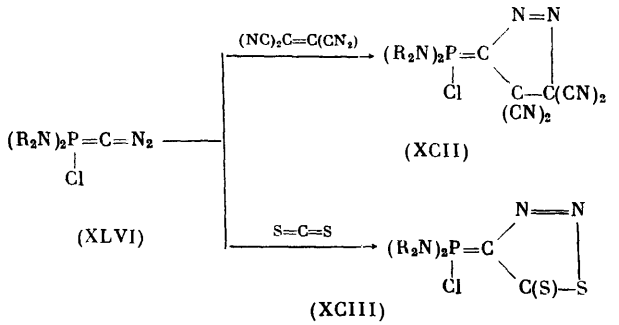


Ylids with OH groups on phosphorus (LXXXVIII), which are prototropic isomers of bis-(arylsulphonyl)methylphosphine oxides (LXXXVII), form *P*-chloroylids (LXXXIX) on boiling with phosphorus pentachloride in benzene.[68]

(LXXXVII) (LXXXVIII) (LXXXIX)

X = H, Me, OMe, Cl.

It has been reported that photolysis of phosphinodiazomethane (XLV) in benzene solution at room temperature in the presence of an excess of chlorotrimethylsilane gives the *P*-chloroylid (XCI) in almost quantitative yield.[91–94]

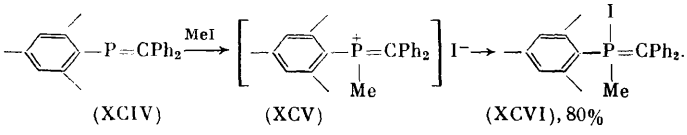


(XLV) (XCa) (XCb) (XCc) (XCI)

R = iso-Pr.

The carbene (XCa) is formed on photolysis of phosphinodiazomethane and has a certain degree of 'phospha-acetylene' character as a result of the contribution of resonance structures to the ground state of the molecule. The presence of an electron-rich trivalent phosphorus atom on the electron-deficient carbon atom determines the displacement of the lone pair of electrons on the phosphorus atom towards the carbon atom with addition of its electrons to the octet and formation of the dipolar structure (XCb), which makes the 1,2-addition of trimethylchlorosilane possible. Recently Bertrand and co-workers succeeded in obtaining the phosphinocarbene (XC) in stable form by flash photolysis of the phosphinodiazomethane (XLV) at 250 °C in vacuum and purified it by vacuum distillation [b.p. 75–80 °C (0.01 mmHg)].[94,95] According to its NMR spectrum the phosphinocarbene (XCI) partially possesses the structure of a phosphorovinyl-ylid and consequently enters into the various addition and cycloaddition reactions typical of a multiple bond. A characteristic is the low field ^{13}C chemical shift, δ_C 142.754 p.p.m., a doublet with $^1J_{CP}$ 159.3 Hz belonging to a two-coordinated carbon atom.

The phosphacumulene-ylid (XLVI) reacts with tetracyanoethylene and also with carbon disulphide forming *P*-chloroylids (XCII) and (XCIII) in quantitative yield. These are products of [2+2]-cycloaddition at the diazo group.[61,62]



(XLVI) (XCII) (XCIII)

R = iso-Pr.

Bickelhaupt and co-workers have shown that phospha-ethylene (XCIV) is converted into β-iodoylid (XCVI) in 80% yield on heating with an excess of methyl iodide in the dark. The reaction occurs by 1,1-addition of methyl iodide to the phosphorus atom. They

proposed that the phosphoniumalkene (XCV) is formed by nucleophilic attack of methyl iodide at the two-coordinated phosphorus atom and is then converted into the ylid (XCVI).[96]

(XCIV) (XCV) (XCVI), 80%

III. Physical and spectral properties

P-Halogenated ylids are crystalline substances or liquids. The majority of *P*-halogenated ylids are colourless and only some of them are coloured. For example, fluorenylids are intensely red and diphenylmethylids are an orange colour.[34]

The stability of *P*-halogenated ylids to heat depends on their structure. The most stable *P*-halogenated ylids store well in an inert atmosphere and are distillable in vacuum without decomposition. The less stable *P*-chloroylids can be distilled in vacuum in many cases and store well in an inert atmosphere at 0 °C. The still less stable *P*-bromoylids are successfully isolated and purified only in those cases when they contain electron-accepting groups at the α-carbon atom. The *P*-iodoylids are unstable compounds. Possibly for this reason only one stable *P*-iodoylid (XCV) is known which has been isolated and identified.[96] The stability of *P*-halogenated ylids is increased with increasing electron-accepting properties of the substituents at the α-carbon atom, reducing the negative charge centred on this atom, and also by introducing bulky substituents (e.g. t-butyl, isopropyl, diisopropylamino groups, etc.) at the phosphorus and carbon atoms, creating steric hindrance. Such substituents screen the P=C bond and hinder nucleophilic attack of the ylid carbon atom onto the positively charged phosphorus atom.

The structure of *P*-halogenated ylids has been investigated in detail by various spectroscopic methods including IR, UV, ^{1}H, ^{13}C, ^{31}P, and ^{19}F NMR and also by X-ray structural analysis.[18,19,72,80,85]

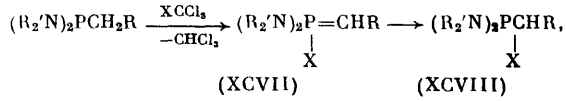
The ^{31}P chemical shifts for *P*-halogenated ylids are very close to the δ_P values of the corresponding phosphonium salts and depend on the substituents at phosphorus (to a larger degree) and carbon (to a lesser degree), viz. δ_P 50–70 (R = Alk_2N), 40–60 (R = Me), 90–100 (R = iso-Pr), 95–110 (R = t-Bu), 55 (R = Ph), 60 p.p.m. (R = AlkO). Signals of phosphorus nuclei of *P*-halogenated ylids are doublets, $^{1}J_{PF}$ 1000–1100 Hz.

The ^{13}C chemical shifts of the P=C carbon atom are in the region of δ_C 20–80 p.p.m. and are doublets with large values of the $^{1}J_{CP}$ constant of 150–200 Hz, which is in agreement with the carbanion character of the ylid carbon atom.

X-Ray structural analysis shows the effective delocalisation of the negative charge of the ylid carbon atom of *P*-halogenated ylids with atoms or groups of atoms added to it. The ylid portion of the majority of molecules studied has a planar structure. For example, in the molecule of (LXXV) the N–P–C–P–N bond system lies in one plane and the C–P–C angle is 134.8°.[80] The lengths of phosphorus–carbon multiple bonds of *P*-halogenated ylids are shortened.

IV. Chemical properties

P-Halogenated ylids are highly reactive entering into numerous conversions. The chemical properties of *P*-halogenated ylids are very unusual due to the presence in the molecule of a highly polar P=C bond and a labile halogen atom. Characteristic reactions for *P*-halogenated ylids occur with carbonyl compounds, proceeding with retention of the phosphorus–carbon bond, chlorotropic rearrangements in the P–C diad, conversions with reduction in the phosphorus coordination number and several other properties not met in the case of triphenylphosphonium ylids.



1. Conversions of *P*-halogenated ylids proceeding with a reduction in the phosphorus coordination number

A significant negative charge is centered on the α-carbon atom of *P*-halogenated ylids weakening the P–Hal bond. Consequently transition of a tetracoordinated into a tricoordinated phosphorus atom, which is extremely rare in organophosphorus chemistry, becomes possible.

a) Halogenotropy in the P–C diad

Halogen atoms in the P–C diad are capable of migrating between the phosphorus and carbon atoms as a result of which the interconversion of *P*-halogenated ylids and α-haloalkylphosphines may be effected. Various examples were shown in section II of conversions of α-haloalkylphosphines into *P*-halogenated ylids which were accompanied by the transition of three-coordinated into four-coordinated phosphorus and, as is known, give a significant energy gain.[97] It must be borne in mind that in this the electrically neutral four-coordinated α-carbon atom is converted into a negatively charged three-coordinate ylid carbon atom. But such a transition is one the other hand energetically unprofitable. Consequently changes in energies of coordination transitions of phosphorus and carbon atoms are mutually counterbalanced by one another. Therefore by varying the substituents on the phosphorus and carbon atoms of the P–C diad it is possible to influence the thermodynamic stability of the halogenotropic isomers and to create conditions for 1,2(C→P)- or 1,2(P→C)-migrations of halogen atoms.

1,2(P→C)-Chlorotropic rearrangements have been detected in the case of *P*-chloroylids containing diisopropylamino groups on the phosphorus atom. Bis-diisopropylamides of alkylphosphonous acids react with carbon tetrachloride with the formation of *P*-chloroylids (XCVII) stable in solution below 0 °C, which were observed by ^{13}C and ^{31}P NMR spectra. Above 0 °C, ylids (XCVII) are converted quantitatively into α-chloroalkylphosphines (XCVIII).[57,99] The reaction of bis-(diisopropylamino)alkylphosphines with bromotrichloromethane proceeds analogously. The resulting *P*-bromoylids (XCVII) are converted into the α-bromoalkylphosphines (XCVIII) significantly more rapidly than are the corresponding *P*-chloroylids. Nonetheless they were observed by ^{31}P NMR. α-Haloalkylphosphines (XCVIII) were isolated as crystalline substances in good yield.

(XCVII) (XCVIII)

X = Br, Cl; R = H, Me, n-Pr, iso-Pr, R′ = iso-Pr.

Bis-(diisopropylamino)methylphosphines with an excess of CCl_4 or $CBrCl_3$ in ether at 0 °C give *P*-halogenated ylids (XCIX) which readily rearrange into dihalomethylphosphines (C).[57]

$$(R_2N)_2PMe \xrightarrow[-CHCl_3]{XCCl_3} (R_2N)_2P(X)=CH_2 \xrightarrow[-CHCl_3]{XCCl_3} (R_2N)_2P(X)=CHX \longrightarrow$$

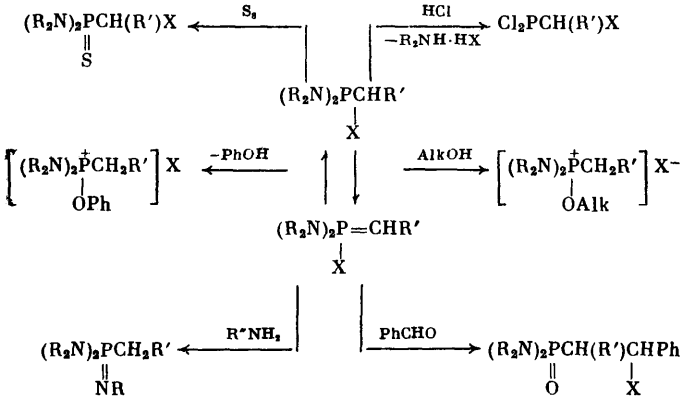
(XCIX)

$$\longrightarrow (R_2N)_2PCHX_2,$$

(C)

X = Br, Cl, R = iso-Pr.

Chlorotropic migrations (CI)⇄(CII) depend on the substituent at the carbon atom of the P–C diad in such a way that electron-accepting substituents (Ph, $SiMe_3$) favour a displacement of the chlorotropic equilibrium to the side of *P*-chloroylids (CI) but electron-donors (H, Me, n-Pr, iso-Pr) favour the side of chloroalkylphosphines (CII).[98–101]



$$(R_2N)_2P(Cl)=CHR' \rightleftharpoons (R_2N)_2PCl(CHR')$$

(CI) (CII)

R = iso-Pr; R' = H, Me, n-Pr, iso-Pr, Cl, Br, Ph, $SiMe_3$.

The α-chloroalkylphosphines (CII) display chemical properties characteristic of both compounds of trivalent phosphorus and of *P*-halogenated ylids, as a result of which they are considered as 'masked' *P*-chloroylids.[58,98] The chemical properties of α-chloroalkylphosphines (CII) correspond to the existence of a reversible phosphorus–carbon diad chlorotropy (C)⇄(CII). As is shown in Scheme 6, the α-haloalkylphosphines (CI), being compounds of trivalent phosphorus, add sulphur with the formation of α-haloalkylthiophosphonic acid derivatives and are split at the P–N bond by hydrogen chloride giving acid chlorides of phosphonic acid.[58] Like *P*-halogenylids, the α-haloalkylphosphines (CI) add alcohols and phenols with the formation of R-oxyphosphonium salts, they react with primary alkylamines and aniline being converted into imidophosphonic acid derivatives and give 2-chloroalkylphosphonic acid derivatives on reaction with carbonyl compounds.[58,98,101]

Scheme 6

X = Br, Cl; R = iso-Pr; R' = H, Alk, Cl, Br.

Kinetic measurements, carried out with ^{31}P NMR, showed that the 1,2(P→C)-chlorotropic rearrangement obeyed a first order reaction rate equation exactly at various concentrations of *P*-chloroylid and at various temperatures. The rate constant for the rearrangement increased in proportion to the increase in ionising ability of the solvent: $CH_3CN > Cl_2CHCHCl_2 > CHCl_3 > CH_2Cl_2 \gg C_6H_6 > C_6H_{14}$. Based on the kinetic characteristics and on the activation parameters, it was established that the 1,2(P→C)-chlorotropic rearrangement proceeds through the formation of phosphonium cation (CIII) resulting from dissociation of the ylid at the P–Cl bond. Stabilisation of the phosphonium cation was achieved by effective delocalisation of the positive charge by branched diisopropylamino groups.[58,100]

$$(R_2N)_2P(Cl)=CHR \longrightarrow [R_2N)_2P^+=CHR\ Cl^-] \longrightarrow (R_2N)_2PCl(CHR),$$

(CIII)

R = iso-Pr.

Kinetic investigations of the reverse 1,2(C→P)-chlorotropic rearrangement have been carried out using the chloromethylphosphine (CIV) as an example.

$$t\text{-}Bu(R_2N)PCH_2Cl \rightarrow t\text{-}Bu(R_2N)P(Cl)=CH_2$$

(CIV) (CV)

R = n-Bu.

Compound (CIV) is stable in nonpolar solvents (diethyl ether, hexane) however it is readily converted into ylid (CV) in dissociating solvents of the type of acetonitrile > tetrachloroethane > chloroform > dichloromethane. Kinetic investigations showed that the 1,2(C→P)-chlorotropic rearrangement of (CIV)→(CV), just like the 1,2(P→C)-chlorotropic rearrangement, obeyed a first order reaction rate equation. Analysis of the activation parameters for the rearrangement (E_a 77 kJ mol^{-1} and $\Delta S^{\neq}$ −67 kJ K mol^{-1}, at 30 °C in benzene + 15% chloroform) and the dependence of the rate constants on the dissociating ability of the solvent enabled a conclusion to be drawn on the decisive effect of solvolysis on the rearrangement, under the influence of which there was heterolytic fission of the C–Cl bond of chloromethylphosphine (Scheme 7).

Scheme 7

$$(R_2PCH_2Cl)_{solv} \rightleftharpoons (R_2PCH_2^+Cl^-)_{solv} \rightleftharpoons \left(R_2\overset{+}{P}=CH_2\ Cl^-\right)_{solv} \rightleftharpoons \left(R_2P(Cl)=CH_2\right)_{solv}$$

The values of the main kinetic characteristics and activation parameters for the 1,2(P→C)- and 1,2(C→P)-chlorotropic rearrangements proceeding through the same phosphonium intermediates and having a reversible character, were very close.

Dissociation of chloromethylphosphines at the C–Cl bond with the formation of phosphonium chlorides recalls the behaviour of chloromethylamines, existing in the ionised state as iminium

chlorides,[102] with the only difference that chloromethylphosphines are not as strongly ionised as chloromethylamines.

$$R_2NCH_2Cl \rightleftharpoons [R_2N{=}CH_2]Cl^-,$$

$$R_2PCH_2Cl \rightleftharpoons [R_2\overset{+}{P}{=}CH_2]Cl^-.$$

The formation of phosphinium salts from *P*-halogenated ylids is confirmed by various experimental data. *P*-Chloroylids (CVI) containing an alkoxy group on the α-carbon atom as a result of a 1,2(P→C)-migration of chlorine rearrange to α-chloroalkylphosphines or are converted into acylphosphines with loss of alkyl chloride. The structure of ylids (CVI) existing in solution below 0 °C was demonstrated by NMR and by chemical methods.[8,103]

$$(t\text{-Bu})_2PCH(R)OAlk \xrightarrow[-CHCl_3]{CCl_4} (t\text{-Bu})_2P(Cl){=}C(R)OAlk \rightarrow$$

(CVI)

$$\rightarrow \begin{cases} \xrightarrow{R=H} (t\text{-Bu})_2PCH(Cl)OAlk \\ \xrightarrow{R=Ph} (t\text{-Bu})_2PC(=O)Ph \end{cases}$$

Conjugation of the free electron pairs of oxygen with the P=C multiple bond stimulates fission of chloride ion and favours the formation of an intermediate phosphinium cation (CVII) which, depending on attack by chloride ion on the α-carbon or on the alkoxy group, is converted into an α-chloroalkylphosphine or eliminates alkyl chloride with the formation of acylphosphine. The formation of the cation is facilitated by effective delocalisation of the positive charge in the P–C–O triad.[8]

$$R_2P(Cl){=}C(R')-OAlk \longrightarrow \left[R_2\overset{+}{P}{=}C(R')-OAlk \leftrightarrow R_2P-C(R'){=}\overset{+}{O}Alk \right] Cl^-$$

(CVII)

b) Conversion into compounds of three-coordinate pentavalent phosphorus and two-coordinate phosphorus

Precisely the same as ylids with alkoxy groups (CVI) the *P*-chloroylids (CVIII) containing a dialkylamino group at the α-carbon atom are ionised with fission of the P–Cl bond. However in this case, as a result of more effective delocalisation of the positive charge in the P–C–N triad, stable phosphonium cations (CIX) are formed and were isolated as crystalline compounds.[104]

$$(t\text{-Bu})_2PCH_2NAlk_2 \xrightarrow[-CHCl_3]{CCl_4} (t\text{-Bu})_2P(Cl){=}CHNAlk_2 \rightarrow (t\text{-Bu})_2\overset{+}{P}{=}CH-NAlk_2\ Cl^-$$

(CVIII) (CIX)

Alk = Me, Et.

Compounds (CIX) are very soluble in polar and with difficulty in nonpolar solvents. They readily exchange chloride anion for perchlorate anion on reaction with sodium perchlorate in aqueous solution. The structure of phosphonium cations (CIX) was confirmed by the NMR spectroscopy. The values δ_P 21 p.p.m. corresponds to a three-coordinate phosphorus atom, and δ_C 207 p.p.m., a doublet with $^1J_{CP}$ 14 Hz to a sp^2-hybridised carbon atom on phosphorus. The δ_H signal at 10.5 p.p.m., a doublet with $^1J_{HP}$ 3 Hz, belongs to a proton on carbon in a P=C group.[8]

The synthesis of another phosphonium cation (CX) has been reported recently.[95]

$$\underset{(XC)}{(R_2N)_2\overset{+}{P}{=}\overline{C}SiMe_3} \xrightarrow{CF_3SO_2OSiMe_3} \underset{(CX)}{[(R_2N)_2\overset{+}{P}{=}C(SiMe_3)_2]CF_3SO_3^-},$$

R = iso-Pr.

On adding an excess of trimethylsilyl triflate to an ethereal solution of the carbene (XC) a salt-like product (CX) was isolated as a yellow crystalline substance. The ^{31}P chemical shift δ_P 76.5 p.p.m., a doublet with $^1J_{CP}$ 87.6 Hz, is in agreement with the proposed structure. The structure of the phosphinium cation (CX) was confirmed by X-ray structural analysis.

Various types of cations of three-coordinate pentavalent phosphorus are known which are obtained by the action of aluminium chloride on the acid chlorides of oxo-, thiono-, seleno- and iminophosphoric acids. Certain of them exist in the crystalline state as dimers as shown by X-ray structural analysis.[105]

$$Y_2P(Cl){=}X \xrightarrow{AlCl_3} [Y_2\overset{+}{P}{=}X]AlCl_4^- \rightleftharpoons \left[Y_2P\begin{smallmatrix} X \\ \diagup\diagdown \\ X \end{smallmatrix}PY_2 \right] AlCl_4^-,$$

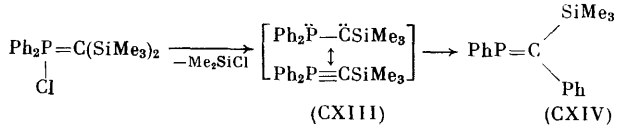
Y = Cl, NMe_2, NEt_2; X = O, NR, CR_2, S, Se.

It is assumed that phosphinium cations are generated by fission of the P–Cl bond in *P*-chloroylids by aluminium chloride. However this idea, with the exception of a short communication,[106] has not yet been developed.

$$(R_2N)_2P(Cl){=}CHSiMe_3 \xrightarrow{AlCl_3} [(R_2N)_2PCH(SiMe_3)]^+AlCl_4^-,$$

R = iso-Pr.

Appel obtained bis-(methylene)phosphoranes by dehalogenation of *P*-chloroylid (CXI) with a lithio-organic compound. These are compounds of three-coordinate pentavalent phosphorus containing two P=C multiple bonds. Bis-(methylene)phosphoranes (CXII) are stable compounds which enables their purification by crystallisation from inert solvents or by vacuum distillation.[107,108]



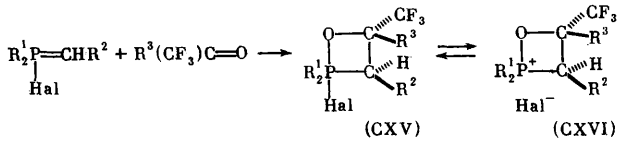
$$RPCl_2 \xrightarrow{LiCCl(SiMe_3)_2} RP[CCl(SiMe_3)_2]_2 \longrightarrow \underset{(CXI)}{RP(Cl)(Cl){=}C(SiMe_3)_2} \longrightarrow$$

$$\xrightarrow{LiCCl(SiMe_3)_2} \underset{(CXII)}{RP{=}C(SiMe_3)_2}$$

R = Alk, Ph, AlkO, AlkS, Alk_2N.

Conversions of *P*-chloroylids are also known which occur with reduction of the phosphorus coordination number to two. Thermolysis of a *P*-chloroylid containing two trimethylsilyl groups

on the α-carbon led to the formation of the phospha-alkene (CXIV). It was proposed that elimination of trimethylchlorosilane from the *P*-chloroylid initially gave a compound of three-coordinate pentavalent phosphorus, viz. the phospha-acetylene (CXIII), which was converted into a compound of two-coordinate phosphorus (CXIV) by migration of a phenyl group to the α-carbon atom (by a type of Curtius rearrangement).[5]



(CXIII) (CXIV)

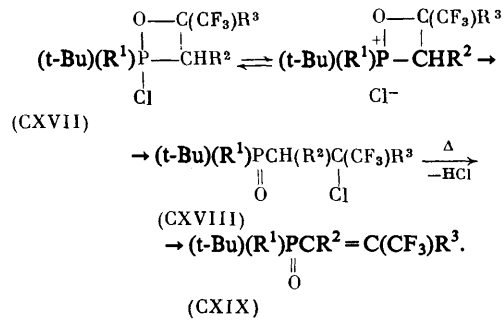
2. Reactions of *P*-halogenated ylids with carbonyl compounds

The reactions of *P*-halogenated ylids with carbonyl compounds are highly original. *P*-Halogenated ylids react with carbonyl compounds 'anomalously' without fission of the phosphorus–carbon bond, which opens wide possibilities for the synthesis of every kind of phosphorus-containing alkene. In addition *P*-halogenylids form comparatively stable products by [2+2]-cycloaddition of the C=O group to the P = C$^-$ bond.

a) [2+2]-Cycloaddition reactions

P-Chloro- and *P*-bromoylids with ketones containing a trifluoromethyl group with the formation of stable [2+2]-cycloaddition products, 2-chloro- or 2-bromo-1,2λ^5-oxaphosphetanes (CXV) which were isolated in yields close to quantitative as crystalline substances or as liquids distillable in vacuum.[8,42,109,110]

(CXV) (CXVI)



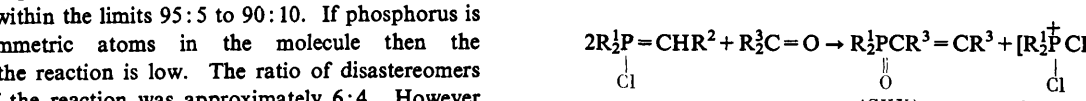
Hal = Br, Cl; R^1 = iso-Pr, t-Bu, Et$_2$N; R^2 = H, Me, Ph; R^3 = Ph, C$_6$H$_4$OMe-4, C$_6$H$_4$F-4.

The [2+2]-cycloaddition of *P*-halogenated ylids to ketones proceeds stereoselectively and leads predominantly to the formation of one of the possible diastereomers of 2-halooxaphosphetanes (CXV). It was established by NMR that the ratio of diastereoisomers of 2-halooxaphosphetanes containing asymmetric atoms at C(3) and C(4) was within the limits 95:5 to 90:10. If phosphorus is one of the asymmetric atoms in the molecule then the stereoselectivity of the reaction is low. The ratio of disastereomers after completion of the reaction was approximately 6:4. However on heating, as a result of permutational changes in the molecule, the ratio of diastereomers grew to a value of 95:5 in favour of the thermodynamically more stable diastereomer.[109,110]

2-Halo-1,2λ^5-oxaphosphetanes (CXV) dissociate in solution at the P–Hal bond with the formation of cyclic phosphonium salts (CXVI), as a result of which an equilibrium is established between the forms (CXV) ⇄ (CXVI) with five- and four-coordinate phosphorus atoms. Dissociation of 2-halooxaphosphetanes is enhanced with a reduction of the electron-accepting properties of substituents R^3 and also with a growth in solvent polarity.[110]

The stability of 2-halooxaphosphetanes changes in the same sequence of substituents R^3 at the endocyclic carbon atoms at position 4. The most stable are compounds, containing strong electron-accepting groups at C(4), drawing off electron density from the oxygen atom as a result of which the three-centre apical bond O–P–Hal is strengthened. 2-Chlorooxaphosphetanes (CXVII) containing two CF$_3$ groups at the α-carbon atom, are converted into vinylphosphonates (CXIX) with elimination of hydrogen chloride only at a temperature of 160–190 °C.[42,110]

2-Chloroxaphosphetanes, having less electron-accepting substituents at C(4), are dissociated to a large extent and correspondingly are converted into vinylphosphine oxide at a lower temperature. The 2-chlorooxaphosphatane (CXVII) (R^1 = t-Bu, R$_2$ = H, R^3 = C$_6$H$_4$OMe-*p*) is transformed quantitatively into the 2-chloroalkylphosphine oxide (CXVIII) at 20 °C in the course of several days. On heating compound (CXVIII) elimination of hydrogen chloride was observed and the (*E*)-olefin (CXIX) was obtained in high yield.[42]



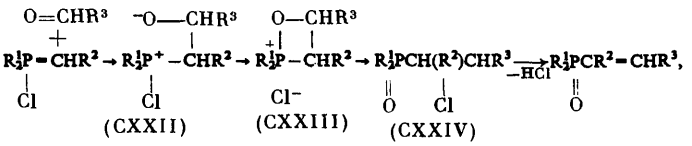
(CXVII) (CXVIII) (CXIX)

2-Bromooxaphosphetanes are more strongly dissociated at the phosphorus–halogen bond than 2-chlorooxaphosphetanes and consequently are less stable. Usually they are gradually converted at room temperature into vinylphosphine oxides.[110]

b) Synthesis of phosphorus-containing alkenes

P-Chloroylids are more reactive than triphenylphosphonium ylids. Unstabilised *P*-chloroylids (R^2 = H, Alk) are particularly reactive and react readily with alkyl- and arylaldehydes below 0 °C with the formation of various types of phosphorus-containing alkenes.[8]

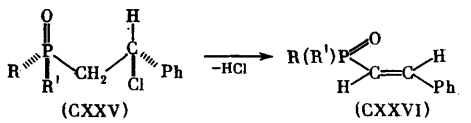
The reaction of *P*-chloroylids with aldehydes or ketones proceeds at a ratio of starting materials of 2:1. In this one molecule of *P*-chloroylid is consumed in binding hydrogen chloride isolated in the reaction process, as a result of which a phosphonium salt (CXXI) is formed in addition to olefins (CXX) and is separated in solid form and is readily removed by filtration.[8,42]



(CXX) (CXXI)

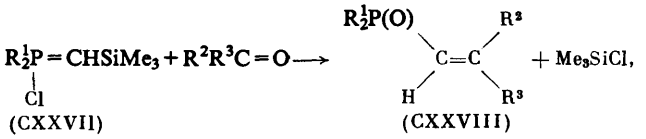
R^1 = Alk, Alk$_2$N; R^2 = H, Me, Ph; R$^3_2$C = Ph$_2$C, Ar(CF$_3$)C.

It was established by NMR spectroscopy at low temperature that *P*-chloroylids add aldehydes with the formation of zwitter-ions (CXXII), which are then converted into 2-chlorooxaphosphetanes (CXXIII). Compound (CXXIII) is strongly dissociated at the P–Cl bond and exists predominantly as cyclic phosphonium salt. They are stable in solution at −60 °C, but on increasing the temperature are



readily rearranged into 2-chloroalkylphosphine oxides (CXXIV). Compounds (CXXIV) are dehydrochlorinated by an excess of the initial *P*-chloroylid with the formation of vinylphosphine oxides.

(CXXII) (CXXIII) (CXXIV)

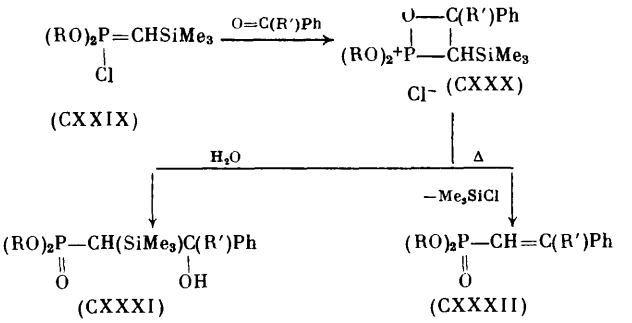


R^1 = Alk, Alk_2N; R^2 = H, Alk, Ph; R^3 = Alk, Ar.

In several cases the reaction of *P*-chloroylids with aldehydes occurs with the formation of 2-chloroalkylphosphine oxides (CXXIV) which are stable at room temperature and were purified by crystallisation from nonpolar solvents. On heating they lose hydrogen chloride and are converted in high yield into vinylphosphine oxides of (*E*)-configuration. 2-Chloroalkylphosphine oxides (CXXV) are usually obtained as *threo*-diastereomers and only in comparatively rare cases was a mixture of two diastereomers formed.[111] However elimination of HCl from these diastereomers occurs stereoselectively with the formation of only (*E*)-vinylphosphine oxides (CXXVI).

(CXXV) (CXXVI)

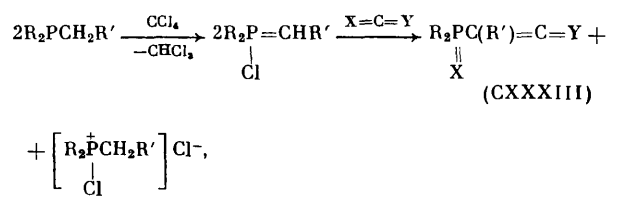
C-Silicon-containing *P*-chloroylids (CXXVII) react with aldehydes and ketones with elimination of chlorotrimethylsilane. The reaction proceeds at a ratio of initial reactants of 1:1 and gives vinylphosphine oxides (CXXVIII) in high yield.[112]



(CXXVII) (CXXVIII)

R^1 = Alk, AlkO, Alk_2N; R^2 = H, CF_3; R^3 = Alk, $C_6H_4R^4$-*p*; R^4 = H, OAlk, Cl, Br, CHO, CH=CHP(O)R_2.

Various aldehydes and ketones and dialdehydes react with *P*-chloroylids (CXXVII). On reacting *P*-chloroylids (CXXVII) with dialdehydes, one or two carbonyl groups were successfully 'olefinated' depending on the initial ratio of reactants. In all cases olefins of (*E*)-configuration were obtained with a high degree of stereoselectivity.[8,112]

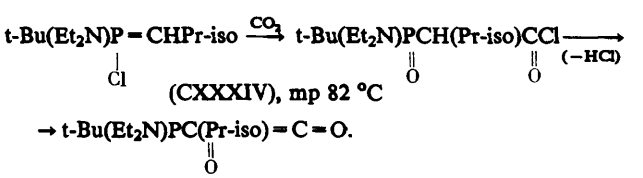


The cyclic phosphonium salts (CXXX) were obtained by reacting *P*-chloroylids (CXXIX) with aldehydes and ketones. Compounds (CXXX) were hydrolysed with the formation of 2-hydroxyalkylphosphine oxides (CXXXI) and on heating were converted into (*E*)-vinylphosphine oxides (CXXXII).[40]

(CXXIX) (CXXX) (CXXXI) (CXXXII)

R = Et, iso-Pr; R′ = H, CF_3.

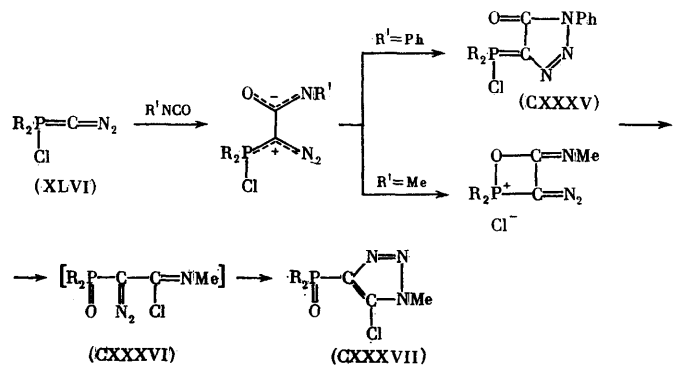
There is significant preparative interest in the reaction of *P*-chloroylids with carbon dioxide, carbon disulphide and isocyanates leading to the formation of phosphorus-containing ketenes, thioketenes and ketenimines.[33,42] The reaction of *P*-chloroylids with CO_2, CS_2 and RNCO proceeds at an initial ratio of starting materials of 2:1 and leads to the formation of phosphorus-containing heterocumulenes and chlorophosphonium chlorides. Phosphorus-containing heterocumulenes (CXXXIII) are conveniently obtained preparatively by a 'one-pot' method without isolating *P*-chloroylids by sequentially treating tertiary alkylphosphines with CCl_4 initially and then with CO_2, CS_2 or RNCO.[9,33,42,113]



(CXXXIII)

X = O, S; Y = O, S, NPh; R = t-Bu, Et_2N; R′ = H, Me, n-Pr, iso-Pr.

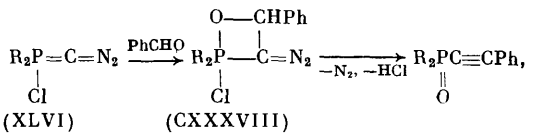
The phosphorus-containing heterocumulenes (CXXXIII) are distinguished by high stability on storage and on vacuum distillation, which is explained by the steric and electronic influence of the phosphoryl grouping. For example, thioketenes are unchanged on storage for several years.



It was established that the reaction of *P*-chloroylids with CO_2 proceeds through the formation of acid chlorides (CXXXIV) of carboxylic acids which were isolated in a pure state and were then converted by the action of triethylamine into phosphorus-containing ketenes.[9]

(CXXXIV), mp 82 °C

Phosphorus-containing ketenes and thioketenes are very reactive and enter into a variety of addition and cycloaddition reactions.[113]

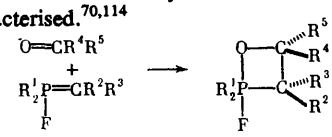


Phosphacumulene-ylids (XLVI) give addition products at the diazo group with isocyanates, the *P*-chloroylid (CXXXV) being formed with phenyl isocyanate and the triazenophosphonate (CXXXVI) with methyl isocyanate. It was proposed that initially nucleophilic attack of the ylid carbon atom on the carbonyl carbon gives a betaine, which depending on the relationship of the oxygen atom (or NR group) to nitrogen or phosphorus, is converted into products of 1,4- and 1,5-cyclisation. The unstable 1,4-cycloadduct is transformed initially into an α-diazoimine as a result of a 1,3-halogenotropic shift and then into the triazenophosphonate (CXXXVII).[61]

(XLVI) (CXXXV) (CXXXVI) (CXXXVII)

R = (iso-Pr)$_2$N.

Benzaldehyde gives the 2-chlorooxaphosphetane (CXXXVIII) with the ylid (XLVI) which readily eliminates hydrogen chloride and a molecule of nitrogen being converted into an acetylene phosphonate. This reaction is the first example of the direct formation of a carbon–carbon triple bond under the conditions of the Wittig reaction.[61]



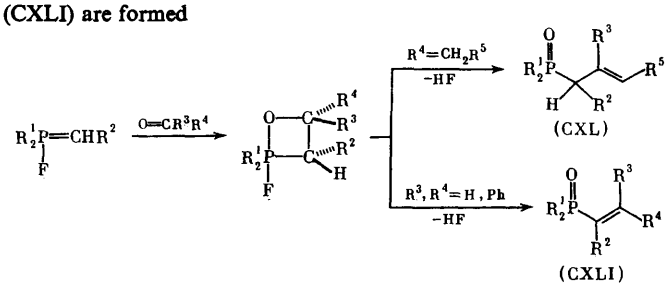
(XLVI) (CXXXVIII)

R = iso-Pr.

c) Reaction of *p*-fluoroylids with carbonyl compounds

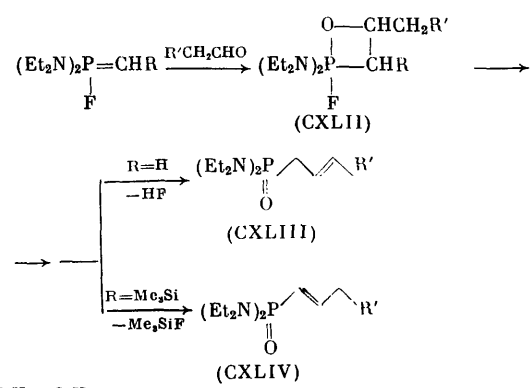
P-Fluoroylids add carbonyl compounds with the formation of 2-fluoro-1,2λ^5-oxaphosphetanes (CXXXIX) which are distinguished by their higher stability compared with 2-chlorooxaphosphetanes. Usually 2-fluorooxaphosphetanes are successfully isolated without difficulty and are purified by vacuum distillation. The stability of 2-fluorooxaphosphetanes is explained by the higher electronegativity of the fluorine atom in comparison with the electronegativities of chlorine and bromine. Consequently the P–F bond of 2-fluorooxaphosphetanes is stable and they do not dissociate with the formation of cyclic phosphonium salts as do the 2-chlorooxaphosphetanes.[70]

Various stable products of [2+2]-cycloaddition of 2-fluoroylids with alkyl and aryl isocyanates, alkyl and aryl ketones, carbon dioxide and isocyanates have been synthesised and characterised.[70,114]



(CXXXIX)

R^1 = Alk, Ph, Alk$_2$N; CR^{2}R^3=CH$_2$, CHAlk, CAlk$_2$, CHPh, CHSiMe$_3$, CCl$_2$, CBr$_2$; CR^{4}R^5=C=O, C=NPh, CHAlk, CAlk$_2$, CHPh, CPh$_2$, CH$_2$CH=CR$_2$.

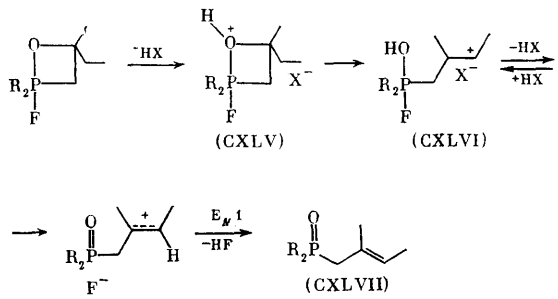


The reaction of *P*-fluoroylids with aldehydes and ketones is stereoselective and gives predominantly *threo*-diasteroisomers of 2-fluorooxaphosphetanes (CXXXIX),[64,70] the structure of which was demonstrated by spectroscopic methods. The content of *erythro*-diastereomers was small and did not exceed 5–10%.

On heating, 2-fluorooxaphosphetanes lost hydrogen fluoride and depending on structure were converted into allyl- or vinylphosphine oxides.[64,70,114,115] Allylphosphine oxides (CXL) are formed when there are hydrogen atoms on the carbon atom next to C(4) and a 1,4-elimination of HF can take place. If 1,4-elimination of HF cannot be effected because of structural features of the molecule than a 1,2-elimination of HF occurs and vinylphosphine oxides (CXLI) are formed

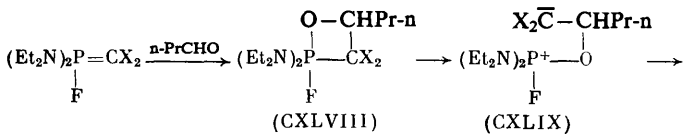
(CXL) (CXLI)

The reaction usually leads to the formation of isomers of allylphosphine oxides containing the maximum number of alkyl groups on the multiple C=C bond and is a convenient means of obtaining them. The route of the reaction may be guided in the direction of forming vinylphosphine oxides (CXLIV), which are isomers of the allylphosphine oxides (CXLIII), if a trimethylsilyl group is introduced at position C(3) of the oxaphosphetane ring. Silicon-containing 2-fluorooxaphosphetanes (CXLII) are obtained by the reaction of *C*-silyl-substituted *P*-fluoroylids with aldehydes. 1,2-Elimination of Me$_3$Si from fluorooxaphosphetanes (CXLII) proceeds with the formation of stereochemically pure (*E*)-vinylphosphine oxides (CXLIV).[64,114]



(CXLII) (CXLIII) (CXLIV)

R = C$_6$H$_{11}$, C$_6$H$_{13}$.



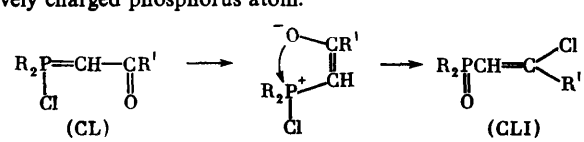
Lewis and Brønsted acids actively catalyse the conversion of 2-fluorooxaphosphetanes into allylphosphine oxides. In addition the reaction is autocatalytic since the hydrogen fluoride eliminated catalyses the transition of 2-fluorooxaphosphetanes into allylphosphine oxides.[114] Acids protonate the oxygen atom of 2-fluorooxaphosphetanes with the formation of oxonium salts (CXLV), which readily convert into carbenium intermediates (CXLVI), the deprotonation of which under E_N 1 elimination conditions gives allylphohphine oxides (CXLVII) (Scheme 8). The formation of carbenium intermediates (CXLVI) was shown by chemical methods.[64,115]

Scheme 8

(CXLV) (CXLVI) (CXLVII)

P-Halogenated ylids react with carbonyl compounds with the formation of phosphorus-containing alkenes as a rule. There is a single exception. 2-Fluorooxaphosphetanes (CXLVIII), containing chlorine or bromine atoms at C(3), decompose on heating with fission of the P–C bond and the formation of 1,1-diahloalkenes and fluorophosphine oxides. It is proposed that the electronegative halogen atoms favour transfer of the CX_2 group to an axial position as a result of which the phosphorus–carbon bond is broken and anion (CXLIX) is formed.[63,64]

(CXLVIII) (CXLIX)

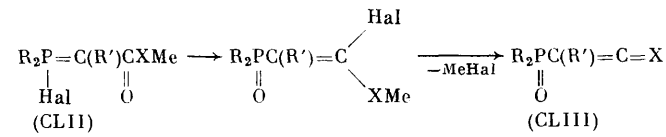


→ $X_2C{=}CHPr\text{-}n + (Et_2N)_2P(O)F$,

X = Br, Cl.

3. Conversions of *P*-halogenated ylids, containing C=O groups on the α-carbon

Conversions accompanied by transfer of the carbonyl oxygen to the phosphorus atom are characteristic of *P*-chloro- and *P*-bromoylids containing a carbonyl group at the α-carbon.

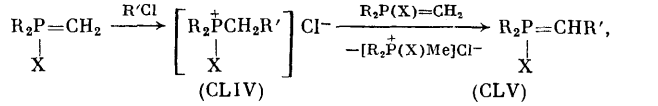


P-Chloroylids (CL) in which there is an acyl group at the α-carbon rearrange on heating into β-chlorovinylphosphine oxides (CLI). The rearrange-ments are effective intramolecularly by attack of the negatively charged oxygen atom of the C=O group on the positively charged phosphorus atom.[116]

(CL) (CLI)

R = t-Bu, Alk_2N; R′ = Alk.

The conversion of *P*-halogenated ylids (CLII) containing an alkoxycarbonyl group at the α-carbon proceeds by an analogous reaction scheme. They are converted at room temperature or on gentle heating into phosphorylated ketenes with separation of alkyl halide.[39,41,117] *P*-Bromoylids (CLII) with a dimethylaminocarbonyl group at the α-carbon are more stable. However they also split off methyl bromide on heating to 100 °C and phosphorus-containing ketenimines are formed in good yield.[116]

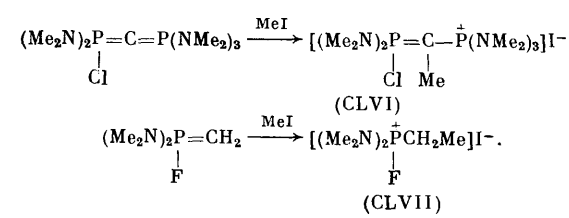


(CLII) (CLIII)

Hal = Br, Cl; X = O, NMe; R = iso-Pr, t-Bu, EtO, iso-PrO, Me_2N, Et_2N; R′ = Ph, CO_2Me.

4. Reactions of *P*-chloroylids with electrophiles

The P=C bond of *P*-halogenated ylids is strongly polarised as a result of which a significant negative charge is centred on the carbon atom. Consequently *P*-halogenated ylids readily add various electrophiles with the formation of the corresponding phosphonium salts or betaines.



Phosphonium salts (CLIV) formed by reaction of *P*-halogenated ylids with such electrophiles as chlorotrimethylsilane, chloroformates, or acid chlorides of carboxylic and phosphoric acids and having an electron-accepting substituent R′ at the α-carbon are readily dehydrochlorinated by the initial *P*-halogenated ylid, being converted into *C*-substituted *P*-halogenated ylids (CLV).[8,33,71]

(CLIV) (CLV)

X = Cl, F; R = Alk, Alk_2N; R′ = Me_3Si, RP(Cl), $(Me_2N)_2P$, $CF_3C(O)$, MeOCO, EtOCO.

At the same time the phosphonium salts (CLVI) and (CLVII) formed by the interaction of *P*-halogenated ylids with alkyl halides are not dehydrohalogenated by the initial ylid even in excess because the alkyl group reduces the lability of the hydrogen atoms at the α-carbon.[75,84,118]

(CLVI) (CLVII)

P-Halogenated ylids usually add Lewis acids (boron trifluoride, aluminium chloride) with the formation of betaines (CLVIII).[33] It has however been reported that phosphinium cations may be

formed by this.[100] The reaction of *P*-chloroylids with gaseous chlorine leads to the formation of phosphonium salts (CLIX).[88]

$$\underset{\underset{X}{|}}{R_2P{=}CHR'} \xrightarrow{MX_3} \underset{\underset{X}{|}}{R_2\overset{+}{P}CH(R')}\bar{M}X_3,$$

(CLVIII)

$$\underset{\underset{Cl}{|}}{(R_2N)_2P{=}CCl_2} \xrightarrow{Cl_2} \left[\underset{\underset{Cl}{|}}{(R_2N)_2\overset{+}{P}CCl_3}\right]Cl^-,$$

(CLIX)

X = Cl, F.

5. Reactions of *P*-halogenated ylids with nucleophilic reagents

a) Nucleophilic replacement of the halogen atom

The labile halogen atom of *P*-halogenated ylids, located on the electrophilic, positively charged phosphorus atom is capable of ready replacement by various groups on interaction with nucleophiles. Preparatively these reactions are very simple and open wide possibilities for the synthesis of ylids containing practically any substituent at phosphorus.

P-Chloro- and *P*-bromoylids react smoothly with lithium and magnesium alkyls in organic solvents below 0 °C and form *P*-alkyl-substituted phosphorus ylids in good yield.[18,35,116]

$$\underset{\underset{X}{|}}{R_2P{=}CR_2'} \xrightarrow[-MX]{AlkM} \underset{\underset{Alk}{|}}{R_2P{=}CR_2'},$$

R = Ph, Me, t-Bu; CR_2' = $CHSiMe_3$, $C(SiCl_3)_2$, $C(SO_2Ph)_2$; M = Li, MgBr.

The reaction of *P*-chloroylids with lithium phosphides proceeds readily. The *p*-chloroylid (XIV) containing trichlorosilyl groups on the α-carbon selectively exchanges the chlorine atom on phosphorus for a dimethylphosphine group on interaction with lithium dimethylphosphide. The trichlorosilyl groups are unaffected by this. In addition, during reaction of ylid (XIV) with lithium trimethylsilylmethylphosphide, the P–P-ylid (CLX) is formed which readily reacts with a second molecule of P–Cl-ylid and is converted into a double ylid with a P–P bond (CLXI).[119]

$$\underset{\underset{Cl}{|}}{Me_2P{=}C(SiCl_3)_2} \xrightarrow{R(Me)PLi}$$

(XIV)

$$\longrightarrow R(Me)P{-}P(Me)_2{=}C(SiCl_3)_2 \xrightarrow[-Me_3SiP(Me)Cl]{R = Me_3Si} (Cl_3Si)_2C{=}\underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{P}}{-}\underset{\underset{Me}{|}}{\overset{\overset{Me}{|}}{P}}{=}C(SiCl_3)_2,$$

(CLX) (CLXI)

R = Me, Me_3Si.

P-Chloroylids exchange the chlorine atom for an amino group on interaction with primary and secondary alkylamines, ammonia or aniline. Ylids (CLXII) containing a hydrogen atom at nitrogen exist in a state of prototropic tautomeric equilibrium with the corresponding iminophosphoranes (CLXIII).[9,43,120–122]

$$\underset{\underset{Cl}{|}}{R_2P{=}CR_2'} \xrightarrow[-Alk_2NH\cdot HCl]{Alk_2NH} \underset{\underset{Alk_2N}{|}}{R_2P{=}CR_2'}$$

$$\underset{\underset{Cl}{|}}{R_2P{=}CR_2'} \xrightarrow[-R''NH_2\cdot HCl]{R''NH_2} \underset{\underset{R''NH}{|}}{R_2P{=}CR_2'} \rightleftharpoons \underset{\underset{R''N}{||}}{R_2PCHR_2'}$$

(CLXII) (CLXIII)

Symmetrically substituted hexa(dimethylamino)carbodiphosphorane (CLXV) is obtained in high yield by the reaction of *P*-chlorocarbodiphosphorane (CLXIV) with lithium dimethylamide in toluene at 20 °C.[84]

$$\underset{\underset{Cl}{|}}{(Me_2N)_2P{=}C{=}P(NMe_2)_3} \xrightarrow[-LiCl]{Me_2NLi} (Me_2N)_3P{=}C{=}P(NMe_2)_3.$$

(CLXIV) (CLXV)

The labile halogen atom of *P*-chloro- or *P*-bromoylids are successfully replaced by alkoxyl, phenoxyl or thioalkyl groups by the action of alcohols, phenols or mercaptans in the presence of triethylamine, which leads to various types of *P*-substituted phosphorus ylids (CLXVI). Ylid (XIII, n = 2) exchanges the chlorine atom on phosphorus and one chlorine atom on silicon by methoxyl groups on reaction with methanol in the presence of diethylamine with the formation of ylid (CLXVII).[18]

$$\underset{\underset{Hal}{|}}{R_2^1P{=}CR_2^2} \xrightarrow[-Et_3N\cdot HHal]{R^3XH+Et_3N} \underset{\underset{R^3X}{|}}{R_2^1P{=}CR_2^2},$$

(CLXVI)

R^1 = Alk, AlkO, Ph; CR_2^2=$C(CO_2Me)_2$, $CHCO_2Me$, $C(SO_2Ph)_2$;

R^3 = Alk, Ph; Hal = Br, Cl; X = O, S,

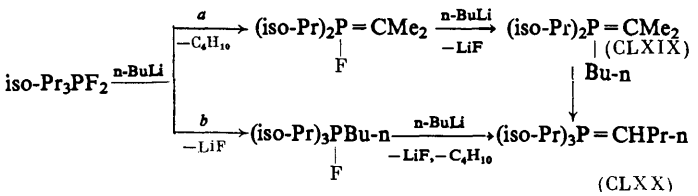
$$\underset{\underset{Cl}{|}}{Me_2P{=}C(SiCl_3)_2} \xrightarrow[-Et_2NH\cdot HCl]{MeOH+Et_2NH} \underset{\underset{MeO}{|}}{\overset{\overset{SiCl_3}{|}}{Me_2P{=}C{-}Si(OMe)Cl_2}}.$$

(XIII) (CLXVII)

Ylids (CLXVII) are formed in high yield on interacting *P*-chloroylids with sodium alkoxides or phenoxides. It is necessary to carry out the reaction at an equimolar reactant ratio since an excess of alkoxide or phenoxide converts ylids (CLXVIII) into phosphine oxides.[11]

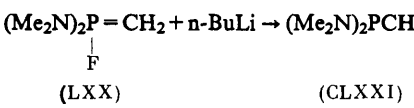
$$\underset{\underset{Cl}{|}}{R_2P{=}CR_2'} \xrightarrow{RONa} \underset{\underset{RO}{|}}{R_2P{=}CR_2'} \xrightarrow[-R_2O]{RONa} \left[\underset{\underset{O}{||}}{R_2P{-}\bar{C}R_2'}\right]Na^+ \xrightarrow{H^+} \underset{\underset{O}{||}}{R_2PCHR_2'},$$

(CLXVIII)



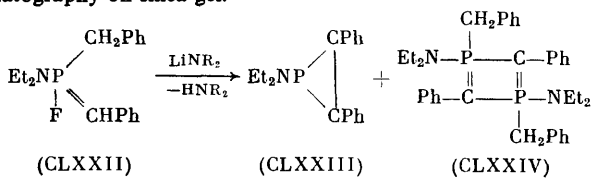
R' = SO_2Ph.

The hydrolysis of *P*-halogenated ylids proceeds extremely readily and even on interaction with moist air or the calculated amount of water they are, as a rule, converted in quantitative yield into the corresponding phosphine oxides. The hydrolysis reaction is



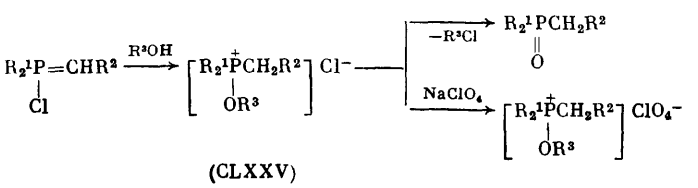
frequently used to prove the structure of *P*-halogenated ylids.[11,61,65,67,96,122]

There is no known convincing example of the replacement of fluorine by an alkyl group when interacting *P*-fluoroylids with lithium alkyls. It has been reported[123] that difluorotriisopropylphosphorane reacts with butyllithium with the formation of butylidenetriisopropylphosphorane (CLXX). It has been proposed that the reaction proceeds by route *a*, i.e. through the formation of *P*-fluoroylid, exchanging the fluorine atom for butyl, and subsequent rearrangement of the resulting ylid (CLXIX). However it is certain that there was no *P*-fluoroylid as intermediate. Consequently it may be suggested that the reaction proceeds by route *b* (Scheme 9).

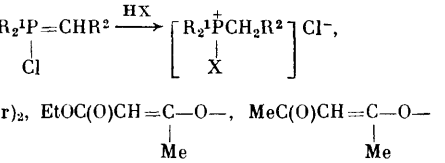


Scheme 9

Furthermore on reacting *P*-fluoroylids directly with lithium alkyls replacement of fluorine by the alkyl group does not occur. For example, the reaction of *P*-fluoroylid (LXX) with butyllithium gives a compound of trivalent phosphorus (CLXXI) only.[80]

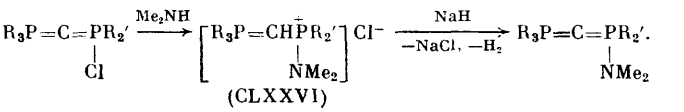


No product of nucleophilic replacement of fluorine was observed on reaction of *P*-fluoroylid (CLLXXII) with lithium amide. Only a mixture of diphenylphosphirane (CLXXIII) and diphosphetane (CLXXIV) was isolated which was separated by preparative chromatography on silica gel.[12]

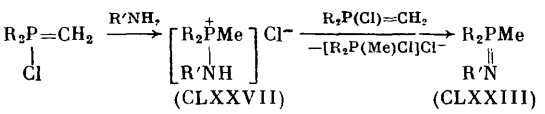


R = $SiMe_3$.

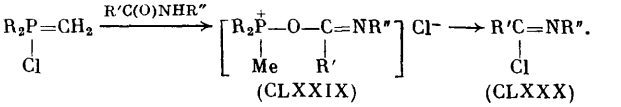
b) Addition reactions



P-Chloroylids add alcohols in ether or pentane below 0 °C, being quantitatively converted into unstable alkoxyphosphonium salts (CLXXV), difficult to achieve by other routes. Salts (CLXXV) were isolated as colourless crystalline substances or viscous liquids insoluble in nonpolar solvents. On heating, alkoxyphosphonium salts (CLXXV) were converted into phosphine oxides, and on reaction with aqueous sodium perchlorate solution gave stable alkoxyphosphonium perchlorates.[58,124]



Phosphonium salts differing in structure were obtained on reacting *P*-chloroylids with hydrogen halides, hydrazoic acid, ketoenols and CH-acids. Yield of phosphonium salts were very high in all cases so the given reaction may serve as a preparative method.[33,34,124]



P-Chloroylids add alkyl- and dialkylamines with the formation of aminophosphonium salts. Phosphonium salts [of type (CLXXVI)] containing a dialkylaminogroup may be converted into *P*-substituted phosphorus ylids by the action of butyllithium or sodium hydride.[9,43,84,125]

Phosphonium salts (CLXXVII), resulting on interaction of *P*-chloroylids with primary alkylamines or aniline, are dehydrochlorinated by an excess of the initial *P*-chloroylid, being converted into iminophosphoranes (CLXXVIII). The reaction of *P*-chloroylids with amides of sulphonic and phosphoric acids also leads to the formation of iminophosphoranes (CLXXVIII).[125]

The reaction of *P*-chloroylids with carboxylic acid amides proceeds through the formation of an *O*-phosphorylated intermediate (CLXXIX) as a result of which imidoyl chlorides (CLXXX) are formed. Compounds (CLXXX) having substitutents R′ = Ph_2CH or R″ = H are readily dehydrochlorinated by the initial *P*-chloroylids to ketenimines or nitriles. In this case *P*-chloroylids show themselves to be dehydrating agents.[125]

* * *

Such are the main achievements in the chemistry of phosphorus *P*-halogenated ylids. It may be concluded from the material considered that the accessibility, convenient means of preparation and the ability to take part in various conversions, justify the attention which is paid to *P*-halogenated ylids and guarantee further progress in this region of the chemistry of organophosphorus compounds.

The properties of solutions and complex formation reactions of amphoteric polyelectrolytes

E A Bekturov, S E Kudaibergenov, S R Rafikov
Institute of Chemical Sciences, Academy of Sciences of the Kazakh SSR, Alma-Ata

ABSTRACT. The review presents the experimental results of studies on the physicochemical and complex-forming properties of synthetic polyampholytes in dilute solution. The similarity of the behaviour of polyampholytes at the isoelectric point and polyelectrolyte complexes is demonstrated. Questions concerning the complex formation reactions of polyampholytes with inorganic and organic ions, polyelectrolytes, and proteins are discussed. The role of competing interactions in the formation of intramolecular and intermolecular polycomplexes is considered.

The bibliography includes 82 references.

V. Conclusion 417

I. Introduction

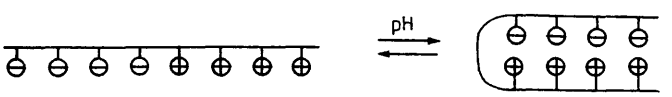
Polyampholytes belong to the class of polyelectrolytes containing acid and basic functional groups in the macromolecule.[1–8] They can include chains with strongly and weakly acidic or strongly and weakly basic groups in various combinations.[9–12] Depending on the type of distribution of the acidic and basic units in the chain, polyampholytes can have a statistical, alternating, graft, and block structure.

The interest in the study of polyampholytes is determined primarily by the fact that they include the most important natural polymers—proteins and nucleic acids.[13] Biopolymers have a specific structure, function, and properties, which are fully realised only in a living organism.[14] Nevertheless a series of individual properties of natural polymers can be modelled with the aid of their synthetic analogues.[15]

The question of the association of polyelectrolytes with high-molecular-weight and low-molecular-weight substances of different nature constitutes the basis of processes occurring in the organism such as replication of the DNA strands, denaturation of biopolymers, protein–lipid interactions, enzyme catalysis, etc. By virtue of the high content of ionogenic groups in the chain, polyampholytes have found extensive practical application as flocculants, complexones, polymeric catalysts, agents prolonging the action of medicinal preparations, semipermeable membranes, artificial vaccines, etc.[16–20]

In the present review, an attempt is made to analyse the experimental data accumulated in recent years in order to discover the prospects for the development and the possible applications of this interesting class of macromolecular compounds.

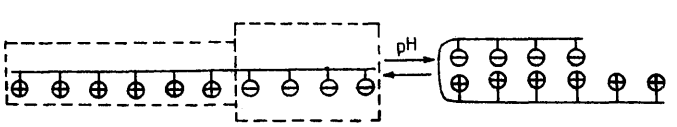
II. Characteristic features of the behaviour of synthetic polyampholytes in solution



The behaviour of polyampholytes is determined both by the nature of their functional groups and by the features due to their macromolecular nature. Depending on the pH of the medium, they behave as polymeric acids or as polymeric bases and therefore exhibit the properties of homopolyelectrolytes. The pH at which the charge of the macromolecule is zero corresponds to the isoelectric point (IEP) of the polyampholyte.

It is assumed that in the vicinity of the IEP an appreciable proportion of the acid and basic units condense into a compact globule, displacing the solvent.[21] Hydrogen bonds and hydrophobic interactions can participate together with intra-ionic contacts in the stabilisation of such compact species.[22] The compactness of the macromolecules at the IEP can depend on the contributions of the above interactions.

The state of the polyampholyte species at the IEP is described satisfactorily by the "fringed globule" model, which has been analysed theoretically in detail by Lifshits et al.[23] As predicted previously by the theory,[24] the structural organisation of the globule presupposes the presence of two phase regions—a dense core from which almost the entire solvent has been displaced and fluctuating loop-shaped sections of the molecule present in the solvent and forming the fringe round the globule. This feature makes it possible to regard polyampholytes as convenient objects for the study of the phenomenon of collapse[25,26] and of the phase state of polymer molecules.[27]



Information about the hydrodynamic and conformational properties of a series of amphoteric polyelectrolytes, soluble in the vicinity of the IEP, has been published.[28–37] The following features of the behaviour of synthetic polyampholytes of the IEP have been noted: (1) the "antipolyelectrolyte" effect, i.e. the increase in intrinsic viscosity with increase in the ionic strength of the solution; (2) the absence of intermolecular associated species (this is indicated by the similar average hydrodynamic molecular weights M_{η} calculated at different pH, including pH_{IEP}); (3) the anomalous dependence of the intrinsic viscosity on the molecular weight (in the Mark–Kuhn–Houwink equation, $a < 0.5$).

Polyampholytes with a block structure of the chains have a series of distinctive features, compared with the statistical and alternating analogues, due to the combination in the chain of long acidic and basic sequences. One of these features is the possibility of the formation of intramolecular polyionic complexes in the vicinity of the IEP. It has been shown for a diblock copolymer of sodium polystyrenesulphonate and poly-2-vinylpyridine[38] that the conformation of the macromolecules changes as a function of the degree of ionisation of the vinylpyridine blocks in the following manner: in the uncharged state ($\beta = 0$), they have a "segregated" structure with a core made up of vinylpyridine blocks maintained in water by the polystyrenesulphonate block; for low values of β, the structure consists of a coil "frozen" by rare ionic cross-links; for $\beta = 0.86$ (IEP), the macromolecules have the compact structure of a polyelectrolyte complex (PEC) stabilised by the cooperative interactions of the acidic and basic blocks. Polyelectrolyte complexes were also formed at the IEP by block copolymers based on poly-1-methyl-4-vinylpyridinium methochloride and polymethacrylic acid (P1M4VP-PMAA).[38] For example a broad region of insolubility (ΔpH ~3.5) in water is characteristic of P1M4VP-PMAA with an equimolar composition, the region becoming appreciably narrower and ultimately vanishing completely with increase in the ionic strength of the solution (Fig. 1). The precipitation of P1M4VP-PMAA in the vicinity of the IEP is evidently associated with the formation of an intramolecular stoichiometric PEC (S-PEC) as a result of the coooperative interaction of the acidic and basic blocks.

The dissolution of P1M4VP-PMMAA at a high ionic strength is caused by the decomposition of the S-PEC species as a result of the shielding of the oppositely charged units of the block polyampholyte by low-molecular-weight ions.

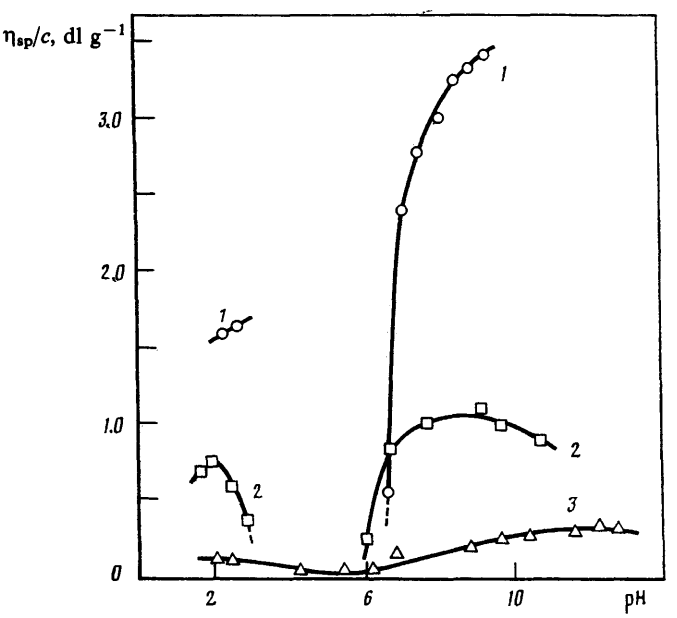
Block polyampholytes containing an excess of the acidic or basic block can be fully classified as intramolecular non-stoichiometric PEC (N-PEC). The relatively long cationic or anionic blocks can play the role of the lyophilising polyelectrolyte (LPE) in this instance, while the role of the blocking polyelectrolytes (BPE) is assumed by short acidic or basic blocks.

Such N-PEC species are maintained in solution and their precipitation is prevented by the hydrophilic fringe, consisting of unreacted cationic or anionic blocks. Calculation of the degree of conversion† in the N-PEC formation reaction showed that the process has a cooperative character.[39]

†The degree of conversion θ is the fraction of the intramolecular or intermolecular salt bonds formed relative to their maximum possible number.

III. Association of polyampholytes with transition metal ions, dyes, and surfactants

The study of the polyampholyte–metal complex formation processes is of interest from the standpoint of bioorganic chemistry.[40,41] A quantitative characteristic of the strength of the binding of metal ions to macromolecular ligands is the formation constant or the so-called formation function proposed by Bjerrum.[42]



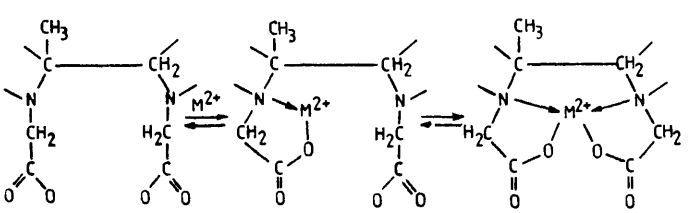


Figure 1. Dependence of the intrinsic viscosity of solutions of the block polyampholyte based on poly-1-methyl-4-vinylpyridinium methochloride and polymethacrylic acid (45:55 mol.%) on the pH in water (curve *1*) and in the presence of 0.01 M (curve *2*) and 0.3 M KCl (curve *3*); c_{BPA} = 0.045 g dl^{-1}.

Multidentate polyampholytes have been synthesised[43] and their chelating properties have been investigated. The polyampholytes react with metal ions in two stages:

As a consequence of the formation of five-membered rings, the polyampholyte–metal complexes have high stability constants. The stability of the chelate compounds varies in the sequence Zn^{2+} > Ni^{2+} > Cd^{2+} > Co^{2+} > Pb^{2+} > Fe^{2+} > Ca^{2+} > Mg^{2+}. It

identical with the stability series of the complexes of the same metals with EDTA.[44]

Depending on the pH of the medium, amphoteric polyelectrolytes are capable of forming several types of complexes with participation of carboxy- or amino-groups and also complexes of a mixed type.[8] The binding of Ca^{2+}, Mg^{2+}, Co^{2+}, Cu^{2+}, and Zn^{2+} ions by polyampholytes based on *N,N*-dimethylaminoethyl methacrylate and methacrylic acid (DMAEM-MAA) has been investigated by the potentiometric method.[45] The Mg^{2+} ion formed a stable complex at pH > 9.7, while Co^{2+} was bound to DMAEM-MAA in the range 7.5 < pH < 9.5. The formation of Cu^{2+} and Zn^{2+} complexes was observed in the region of pH 5.8 and 7.4 respectively. The Ca^{2+} ion showed no complex-forming capacity at any pH.

On the basis of theoretical studies and the intermolecular cross-linking of macromolecules, Plate et al.[46] were able to predict the principal characteristics of the complex formation reaction between macromolecules and metal ions in relation to the interaction of poly-N^{ε}-methacryloyl-*L*-lysine (PML) with copper(II) ions. Comparison of potentiometric titration, UV spectroscopic, and equilibrium dialysis data shows that at pH > 4.5 copper ions are bound to two lysine residues of PML. Two monomeric units of one macromolecule are involved predominantly in the process. Such a process is an example of an intramolecular cross-linking reaction.

In order to identify the structure of the copper complexes of aminocarboxypolyampholytes, the EPR spectra of the latter were compared[47] with those of copper–glycine and copper–alanine complexes. It was shown that the complexes formed in the amino-acid solutions at pH > 3 are analogous to the complexes in aminocarboxy-resins. Depending on the pH of the medium, copper ions are coordinated predominantly to carboxy-groups or carboxy- and amino-groups of the polyampholytes. The fraction of the structure of each type is determined by the pH of the solution.

Analysis of the EPR spectral lines for the 2-methyl-5-vinyl-pyridine-acrylic acid/copper(II) (2M5VP-AA/Cu^{2+}) complex revealed two types of spectra differing by the parameters $g_{\perp}$, $g_{\parallel}$, and $A_{\parallel}$.[48,49] In an acid medium, the signal characteristic of the type "A" structure with the parameters $g_{\perp} = 2.058$, $g_{\parallel} = 2.334$, and $A_{\parallel} = 136 \times 10^{-4}$ cm^{-1} predominates in the spectrum. On passing to the neutral region, the intensity of this line gradually falls and is replaced by an increase in the intensity of the EPR signal of a complex of another type (type "B") with the parameters $g_{\perp} = 2.035$, $g_{\parallel} = 2.298$, and $A_{\parallel} = 157 \times 10^{-4}$ cm^{-1}. Bearing in mind the similarity of the parameters of the "A" spectrum to those of the spectrum of the copper complex with polyacrylic acid and copper acetate, one may conclude that in an acid medium the carboxy-groups of the acrylic acid units are predominantly coordinated around the copper ions. The dependence of the average coordination number $\bar{n}$ on the pH of the medium shows that the formation of the complex ML_2 is completed at pH < 6.0. The higher value of $A_{\parallel}$ and the lower value of $g_{\perp}$ for the EPR signal in the spectrum of the "B" complex show that the coordination environment of copper includes, apart from two carboxy-groups, two pyridine units. These results permit the conclusion that a complex with $\bar{n} = 2$ and $\lg\beta = 13.5$ is formed at pH < 6.0, while a complex with $\bar{n} = 4$ and $\lg\beta = 21$ is formed in the range 6.0 < pH < 10.0.

A similar rearrangement of the coordination sphere of copper ions has been observed also for ternary polymer–metal complexes (TPMC), which have been examined in detail.[50–52] In particular, it was noted that two types of structures (A and B), differing in the structure of the coordination sphere of the central ion, are characteristic of the products of the interaction of polyacrylic acid (PAA), linear polyethyleneimine (PEI), and copper(II) ions. At high pH, the amino-groups of PEI are not protonated and the complex $Cu(PEI)_2^{2+}$ with a type A structure is mainly formed. As the pH is reduced, the nitrogen atoms of the PEI ligand are protonated and the fraction of the type A structure begins to diminish with the simultaneous increase in the fraction of the type B structure, in which one of the two amino-groups in the coordination sphere is replaced by two carboxylate ions of PAA: $(CuPEI)(PAA)_2$. Thus in this case too the number and type of functional groups of the polyampholytes in the coordination sphere of the metal ion are determined by the pH of the medium.

In the course of the study of the complex-forming properties of synthetic polyampholytes, we observed that polyampholytes based on piperidinol derivatives[53,54] are capable of binding metal ions at certain pH values and of liberating them strictly at the IEP. The principle of the action of polyampholytes at the IEP is apparently that, after the attainment of pH_{IEP}, the cooperative interaction forces between the acidic and basic groups become more effective, which leads to the "expulsion" of the previously bound metal ions from the bulk of the coil of the macromolecule. If the IEP of the polyampholyte is located in the alkaline region, then transition metal ions are precipitated while the polyampholyte remains in solution and can be regenerated and used anew. In this sense, the behaviour of polyampholytes at the IEP resembles that of TPMC.[50–52] For example, at certain pH values the nitrogen–metal coordinate bonds and carboxylate–metal ionic bonds in the polyethyleneimine–metal–polyacrylic acid system are replaced by cooperative polycation–polyanion salt contacts.[55] In contrast to the ampholyte, the PEC is then precipitated, while the metal ions remain in solution.

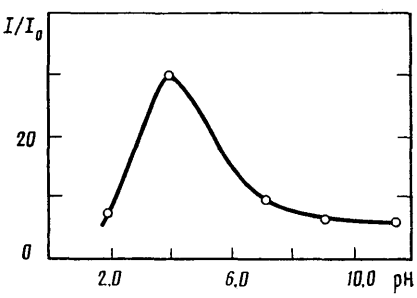

Figure 2. Dependence of the relative fluorescence intensity of 1-anilinonaphthalene-8-sulphonic acid on the pH in the presence of the 2,5-dimethyl-4-vinylethynyl-4-piperidinol–acrylic acid copolymer (DMVEP:AA = 45.2:54.8 mol.%); [DMVEP-AA]:[ANS] = 100:1; [ANS] = 5 × 10^{-5} M.[57]

The available literature data concern in the main the association of polymeric acids, polymeric bases, and non-ionic polymers with dyes and surfactants.[56] On the other hand the data obtained in studies of the interaction of synthetic polyampholytes with dyes and surfactants are virtually lacking. The results of the investigation of the dependence of the intensity of the fluorescence of 1-anilino-naphthalene-8-sulphonic acid (ANS) (I/I_0) in the presence of the polyampholyte over a wide pH range are presented in Fig. 2.[57] The

greatest increase in the intensity of the fluorescence of the dye is observed at pH 3–3.5, i.e. in the region of the intense ionisation of the basic groups of the polyampholyte. The sharp decrease of I/I_0 from 30 to 4 in the vicinity of the IEP of the polyampholyte (pH_{IEP} = 7.0) indicates the decomposition of the polyampholyte–ANS complex and the appearance of free dye molecules. The dye is liberated similarly after the addition of polyacrylic acid to the polydiallyldimethylammonium chloride–ANS system, as a consequence of the competing effect of the second macromolecular component.[58]

The mechanism of the "expulsion" of ANS at the IEP of the polyampholyte is apparently similar to the mechanism of the expulsion of the metal from the polyampholyte–metal system examined above.

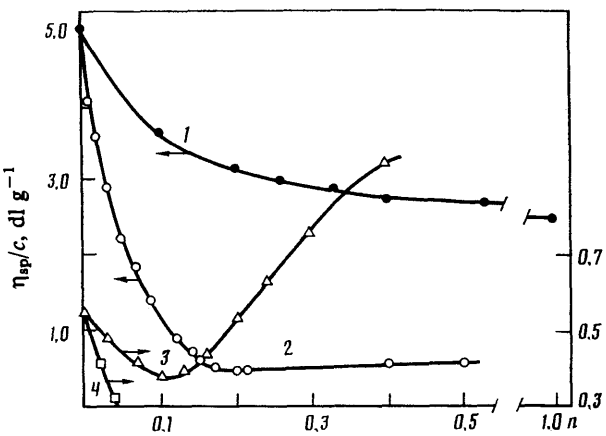

Figure 3. Dependence of the intrinsic viscosity of solutions of polyampholytes based on 1,2,5-trimethyl-4-vinylethynyl-4-piperidinol and acyrlic acid (TMVEP : AA = 40 : 60 mol.%) (curves *1* and *2*) as well as styrene and *N,N*-dimethylaminopropylmonoamide of maleic acid (S : DMAPMAMA = 50 : 50) (curves *3* and *4*) on the [surfactant] / [polyampholyte] = *n* molar ratio; [TMVEP-AA] = [S-DMAPMAMA] = 1 × 10^{-2} M.[59–61]

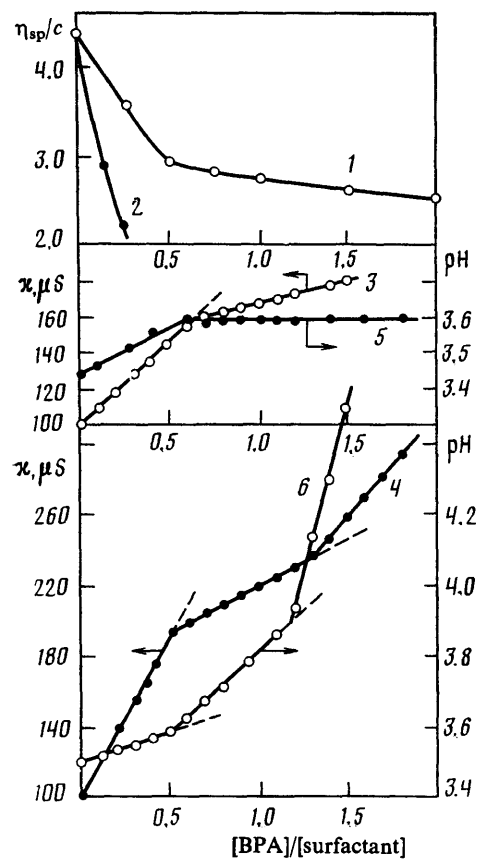
Synthetic polyampholytes have the ability to bind cooperatively anionic and cationic surfactants undergoing at the same time appreciable conformational changes.[59–62] The binding of anionic and cationic detergents by polyampholytes takes place mainly via electrostatic interaction, while the compact polymeric complex species is stabilised by the hydrophobic interactions of the long alkyl components of the surfactant and is maintained in solution and its precipitation is prevented by the hydrophilic components of the copolymers which have not been involved in the complex.[59–62] Fig. 3 illustrates the influence of sodium dodecyl sulphate (DDS) and cetyltrimethylammonium chloride (CTMA) on the hydrodynamic dimensions of the molecules of polyampholytes. The decrease in the intrinsic viscosity η_{sp}/c in the presence of surfactant is evidently associated with the formation of ampholyte–surfactant polymeric complexes. The results of the calculation of the degree of conversion in the formation reaction of the polyampholyte–surfactant complexes shows that the polymeric complexes are formed within a narrow pH range, which indicates the cooperative nature of the process.

In contrast to a statistical polyampholyte, the styrene–maleic acid, *N,N*-dimethylaminopropylmonoamide copolymer (S–MADMAPMA), with a regular structure, contains, together with hydrophilic groups, also styrene units (50 mol.%), which can intensify the hydrophobic interactions between the non-polar units of the copolymer and the hydrocarbon components of the surfactant. This feature of S–MADMAPMA is clearly manifested in relation to CTMA and DDS. The addition of even an insignificant amount of CTMA induces a sharp decrease in viscosity as far as the formation of an insoluble deposit. This is caused by the marked conversion of the macromolecules into a hydrophobic form, which leads to the formation of globular polymeric complex species. On titration of the same copolymer with DDS, the viscosity of the system passes through a minimum. This form of the viscometric curve can be accounted for by the fact that initially the detergent molecules are bound electrostatically by the polyampholyte which results in the formation of an intramolecular micelle-like structure, giving rise to a more coiled conformation of the polymer coils. Subsequently additional adsorption of surfactant molecules on the polymer chains takes place, which leads to charge transfer in the macromolecules and to the swelling of the polyelectrolyte.



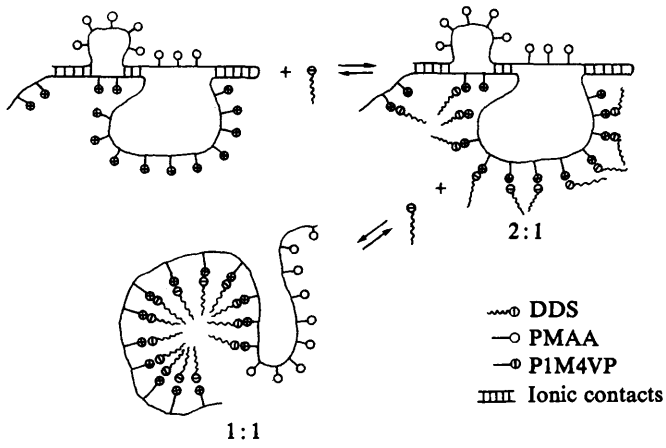


Figure 4. Viscometric (curves *1* and *2*), conductimetric (curves *3* and *4*), and potentiometric (curves *5* and 6) titration curves for a block polyampholyte based on poly-1-methyl-4-vinylpyridinium methochloride and polymethacrylic acid (64 : 36) the [BPA] / [surfactant] molar ratio: *1*, *3*, and *5*, [BPA]–[CTMA]; *2*, *4*, and *6*, [BPA]–[DDS]; [surfactant] = 5 × 10^{-2} M.

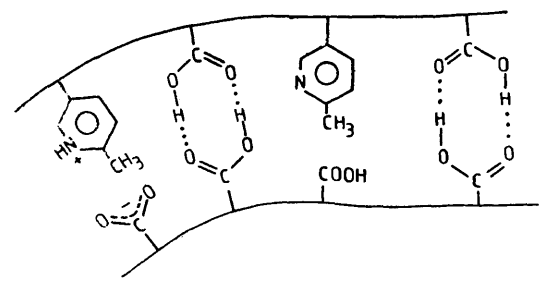
On potentiometric and conductimetric titration of an aqueous solution of a block polyampholyte (BPA) with a DDS solution, the formation of complexes with the ratios [BPA]:[DDS] = 2:1 and 1:1 was observed (Fig. 4). Initially only half of all the vinylpyridinium units enter into the reaction. On further addition of the ionic surfactant, the composition of the complex approaches the equimolar composition, which indicates the binding of an additional amount of DDS. It was shown previously by the luminescence quenching method[63] that micellar surfactants containing sulphogroups can compete with polymeric acids in polymeric complex formation reactions with linear synthetic polymeric cations. Consequently the mechanism of the interaction of BPA and DDS can be considered within the framework of competing reactions which occur in N-PEC/surfactant systems.[63] The formation of a 2:1 polymeric complex can be accounted for by the interaction of DDS with longer and shorter sections of the cationic block which do not enter into the formation reaction of the intramolecular N-PEC. The formation of the stoichiometric 1:1 polymeric complex is apparently due to the breakdown of the cooperative ionic contact between the acid and basic blocks ($COO^- - \overset{+}{N}\!\!\swarrow$) and their replacement by cooperative ionic contacts ($SO_3^- - \overset{+}{N}\!\!\swarrow$). Taking into account these considerations, the competing reaction of the anionic surfactant and BA can be represented schematically in the following way:



However, after the addition of a cationic surfactant, namely CTMA, to a solution of BPA, only an inflection corresponding to the 2:1 composition of the polymeric complex is observed on the potentiometric, conductimetric, and viscometric titration curves. This can be explained by the fact that the ionic contact with participation of the cationic surfactant cannot compete with the cooperative ionic contacts between the acidic and basic blocks, while the surfactant reacts only with the PMAA "loops" which constitute the "fringe" (see the scheme above). Thus the behaviour of the anionic surfactant–BPA system can be described satisfactorily on the basis of data obtained for the DDS–N-PEC system.[63]

It is of interest to trace the influence of organic additives on the behaviour of associating polyampholyte–surfactant systems.[59–62] In the case of the polyampholyte–DDS polymeric complex, a sharp increase in viscosity within a narrow range of variation of the solvent composition (in the range from 60 to 80 vol.% of methanol) was observed on the curve relating the intrinsic viscosity to the composition of the methanol–water solvent. In the remaining regions (above 80 and below 60 vol.% of methanol), the viscosity changes only slightly as the methanol content in the mixture is varied. These results can be interpreted in the following way. In pure water, the polymeric complex species acquire a compact structure stabilised by hydrophobic interactions. It persists up to a methanol content in the mixture of 60 vol.%. Further increase in the fraction of the alcohol induces a sharp increase in viscosity, which indicates the cooperative uncoiling of the compact structure as a consequence of the solvation of the hydrophobic components of the polymeric complex by methanol and of the hydrophilic components by water. In the latter case, we are dealing with an inverted micelle, which is formed as a result of the "precipitation" of the hydrophilic components of the copolymer by methanol. Thus the transition from one compact structure to another takes place via a stage involving rearrangement of the structure of the polymeric complex.

IV. Interpolyelectrolyte reactions with participation of synthetic polyampholytes

Considerable experimental data have accumulated hitherto on complex formation between synthetic polyelectrolytes. There have been surveys in a number of communications.[64–71] However interpolymer reactions with participation of synthetic polyampholytes have been studied very inadequately. Synthetic polyampholytes have the ability to bind cooperatively to both anionic (or cationic) and amphoteric macromolecules. Earlier Morawetz and Hughes[72] investigated the association of human serum albumin with the TMAEM–MAA copolymer. Kabanov et al.[73] investigated by potentiometric titration and turbidimetric methods the reactions between amphoteric 2M5VP-AA copolymers of different composition and PAA (5,6-ionene). The maximum turbidity of the system is observed in the pH range where the components are linked by the maximum possible, under the given conditions, number of ionic contacts and hydrogen bonds.

The stoichiometry of the 2M5VP-AA/PAA complex is independent of the composition of the copolymer and is 1:1. In contrast to the polyampholyte–polymeric acid system, 5,6-ionene forms a weak complex with the polyampholyte. According to the authors,[73] this is due to the impossibility of the formation in the polyampholyte–ionene system of a single cooperative sequence of ionic and hydrogen bonds between the interacting chains. The proposed structure of the polyampholyte–PAA polymeric complex can be represented as follows:

Interpolyelectrolyte reactions with participation of a sulpho-derivative of chitosan—a polyampholyte containing amino- and sulpho-groups in the chain—have been examined.[74] Fig. 5 presents curves for the turbidimetric titration of a solution of 2,5-ionene bromide with a solution of chitosan sulphate at pH 2.5 and 11.5. Evidently the compositions of the polyelectrolyte complex in the acid and alkaline regions differ significantly. In the acid region, only half of the OSO_3^- groups of chitosan sulphate ($Z' = 2$) participate in the formation of the polyelectrolyte complex. The remaining groups are incorporated in zwitter-ionic pairs with the amino-groups of a neighbouring glucoside ring. In an alkaline medium, the polyelectrolyte complex has the equimolar composition ($Z' = 1$), i.e. virtually all the sulpho-groups participate in the formation of the polyelectrolyte complex. In other words, as the pH of the medium is varied, there is competition between the formation of the zwitter-ions and the formation of the polyelectrolyte complex. The examples quoted above show that, by alternating the state of ionisation of the acidic and basic groups of polyampholytes, it is possible to vary within broad limits the composition and hence the structure and properties of the polyelectrolyte complex.

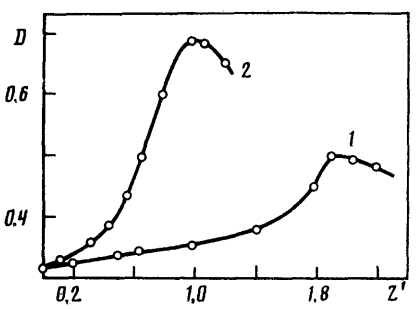


Figure 5. Curves for the turbidimetric titration of 2,5-ionene bromide with chitosan sulphate at pH 2.5 (curve *1*) and 11.5 (curve *2*); [2,5-ionene] = 5×10^{-4} M.[74]

The formation reaction of the polyelectrolyte complexes between synthetic polyampholytes (PAM) and polyacrylic acid was investigated previously[75] and the composition of the polymeric complexes was determined. The influence of the order of mixing of the polyelectrolyte components, the ionic strength of the solution, temperature, and the addition of an organic solvent on the composition and stability of the polyelectrolyte complexes was demonstrated.

The influence of the pH of the medium on the complex formation reaction between the equimolar 2,5-dimethyl-4-vinylethynyl-4-piperidinol–acrylic acid (DMVEP–AA) polyampholyte and PAA, polydiallyldimethylammonium chloride (PDADMAC), and human serum albumin (HSA) has been investigated.[76–78]

When aqueous solutions of polyelectrolyte components are mixed, the solution pH changes appreciably and this is accompanied by the appearance of turbidity in the system, which indicates the occurrence of the polyelectrolyte complex formation reaction. Fig. 6 illustrates the variation of the intrinsic viscosity of the polyelectrolytes and the polyelectrolyte complex as a function of the pH of the medium. The polyelectrolyte complex consisting of a polyampholyte and PAA is precipitated in the pH range from 3.0 to 5.5. The onset of the segregation of the reaction product as a separate phase corresponds to the onset of the ionisation of the amino-groups of the polyampholyte and to the partly ionised state of PAA. The dissolution of the polyelectrolyte complex in the strongly acid medium is apparently associated with its decomposition as a consequence of the suppression of the ionisation of the carboxy-groups of PAA and the formation of an ionic atmosphere around the positively charged nitrogen atoms caused by the excess inorganic acid. The precipitation of the polyelectrolyte complex consisting of a polyampholyte and polydiallyldimethylammonium chloride takes place at pH $\geqslant$ 8.2, i.e. with increase in the degree of ionisation of the carboxy-groups of the polyampholyte.

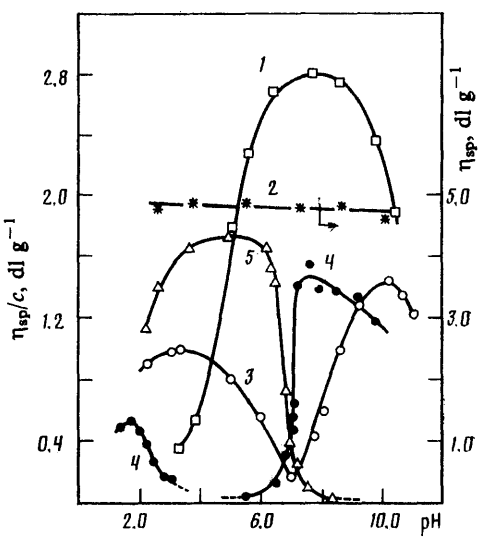

Figure 6. The influence of the pH of the solution on the intrinsic viscosity of polyacrylic acid (PAA) (curve *1*), polydiallyldimethylammonium chloride (PDADMAC) (curve *2*), the 2,5-dimethyl-4-vinylethynyl-4-piperidinol–acrylic acid copolymer (DMVEP : AA = 45.2 : 54.8) (curve *3*), and the polyelectrolyte complexes [DMVEP-AA] : [PAA] = 3 : 1 (curve *4*) and [DMVEP-AA] : [PDADMAC] = 3 : 1 (curve *5*); [DMVEP-AA] = 2.5×10^{-2} M.[77]

After the addition of human serum albumin to the polyampholyte, the quantity η_{sp}/c for the polyampholyte solution gradually diminishes, reaching a limiting value at $m_{HSA} : m_{PAM} = 3 : 2$. However, despite the appearance of a strong opalescence, phase separation does not take place in the system. The most favourable region of the interaction of the polyampholyte and human serum albumin corresponds to the pH range between their isoelectric points, since at these pH values the polyampholyte and human serum albumin macromolecules become positively and negatively charged respectively. The formation of a polyelectrolyte complex between the polyampholyte and human serum albumin apparently takes place as a result of the "adhesion" of more or less long sections of the polyampholyte chain to the surface of the

negatively charged protein globule.[79] It has been noted[80] that, on mixing aqueous solutions of natural polyampholytes—β-lipoprotein and γ-globulin—the formation of the polyelectrolyte complex is also observed. As in the interaction of a polyampholyte and human serum albumin, here the maximum degree of salt formation between the β-lipoprotein and γ-globulin takes place in the pH range between their isoelectric points.

There are literature data showing that the complexes of carbochain linear polyampholytes with proteins exhibit reduced immunogenic properties.[20] It has been found that the stability of the complexes formed depends on the composition of the 2-methyl-5-vinylpyridine–acrylic acid copolymer. According to the authors, hydrogen bonding and hydrophobic interactions play a decisive role in the formation of the polyampholyte–protein complex. However, against their background there is also a possibility of the formation of salt bonds by virtue of the induced ionisation of the corresponding ionogenic groups.

Thus the results obtained fully confirm the conclusion that[73] synthetic polyampholytes are capable of cooperative binding to both anionogenic or cationogenic and amphoteric molecules, differing significantly from homopolymers by the width of the spectrum of cooperative interactions.

Attention should be drawn to one of the characteristic features of the polyampholyte–polyelectrolyte complex, namely the sharp increase in viscosity occurring at the isoelectric point of the polyampholyte (pH_{IEP} 7.0) (Fig. 6). This phenomenon, which we called the "expulsion effect", occurs following a change in the pH of the medium induced by the coil–globule conformational transition in the polyampholytes. The process mechanism is apparently as follows.

Since the structure of the polyampholyte–polyelectrolyte complex consists of a double-stranded pair sequences formed by a single cooperative system of ionic and hydrogen bonds and also of defects of the loop ("fringe") type, it follows that, as the isoelectric point is approached, the cooperative interactions between the acidic and basic units of the polyampholyte, leading to the formation of intramolecular polyelectrolyte complexes (IAPEC), ultimately cause the decomposition of the polymeric polyampholyte–polyelectrolyte complex into individual components. The main driving force of the polyelectrolyte decomposition process at the isoelectric point of the polyampholyte is evidently the decrease in the Gibbs free energy as a consequence of the increase in the entropy of the system.

In order to demonstrate the cooperative nature of the decomposition of the polyelectrolyte complex species, sedimentation measurements were made. Fig. 7 illustrates the sedimentation diagrams for the 2,5-dimethyl-4-vinylethynylpiperidinol–acrylic acid (DMVEP-AA) polyampholyte, PAA, and the polyelectrolyte complex at different pH. At pH 6.1 and 6.9, a single peak with S = 4.75 and 4.18 Svedberg units can be seen on the sedimentogram. This shows that under these conditions the sedimenting particles are those of the polymeric complex. However, at pH $\geqslant$ pH_{IEP} (pH_{IEP} 7.0) two peaks appear on the sedimentogram with sedimentation coefficients of 1.9 ("slow" peak) and 5.6 Svedberg units ("fast" peak). Under identical conditions, the individual components have S = 1.06 (PAA) and 3.53 Svedberg units (DMVEP-AA). The appearance of the slowly and rapidly sedimenting particles within a fairly narrow pH range (ΔpH = 0.2) can be attributed to the cooperative decomposition of the polyelectrolyte complex species. However, in the presence of a low-molecular-weight salt, the cooperative nature of the decomposition is less marked. This is associated with the fact that the low-molecular-weight electrolyte leads to the shielding of the charges on the macromolecule and the loosening of the compact polyampholyte particles at the isoelectric point.

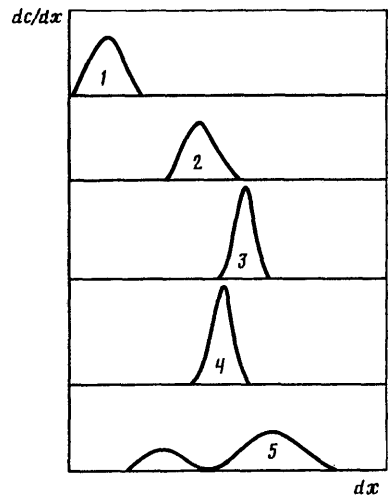

Figure 7. Sedimentograms for PAA (curve *1*), DMVEP-AA (curve *2*), and the [DMVEP-AA]:[PAA] = 3:1 polymeric complex (curves *3*–*5*) at different pH of the solution. Rate of rotation of the rotor 40,000 rev min^{-1}, T = 298 K, I = 0.005, τ = 60 min; pH: *1*, and *2*, 7.2; *3*, 6.1; *4*, 6.9; *5*, 7.1.

Polyampholytes with a block chain structure are capable of binding macromolecules with a more pronounced cooperative behaviour, in contrast to statistical and alternating polyampholytes.[39] The interpolymer complexes formed under these conditions can be stabilised by both ionic and hydrogen bonds. The compositions of the complexes, found from conductimetric, potentiometric, and viscometric titration curves, correspond to BPA:PAA = 1:1, where PAA may also be polybenzyltrimethylvinylammonium chloride (PBTMVAC), polyallyldimethylammonium chloride (PADMAC), or polyvinylpyrrolidinone (PVPD), and BPA:PEG = 2:1 (Fig. 8).

Calculation of the degree of conversion θ in the polyelectrolyte formation reaction between the block polyampholyte and an anionic (cationic) polyelectrolyte shows that the process is cooperative (Fig. 9, curves *1* and *2*). It is also noteworthy that the block polyampholyte is capable of forming a ternary polyelectrolyte complex by becoming "loaded" with cationic and anionic polyelectrolytes. However, the cooperative nature of such a reaction is less marked than that of the reaction quoted above, which is associated with the conversion of the macromolecules of the initial polyelectrolyte complexes into a compact form (Fig. 9, curve *3*). At the isoelectric point of the block polyampholyte, there is also a possibility of the existence of cooperative ionic contacts between the acid and basic blocks, leading to the formation of intramacromolecular polyelectrolyte complexes (Fig. 9, curve *4*). This justifies the assumption that, as the isoelectric point of the block polyampholyte is approached, the alternative possibilities of intramacromolecular and intermacromolecular

complex formation reactions may arise. If the first reaction is more cooperative than the second, then one cannot rule out the possibility of the decomposition of the interpolyelectrolyte complex and the formation of an intramolecular polyelectrolyte with subsequent liberation of the sorbed polyelectrolyte.

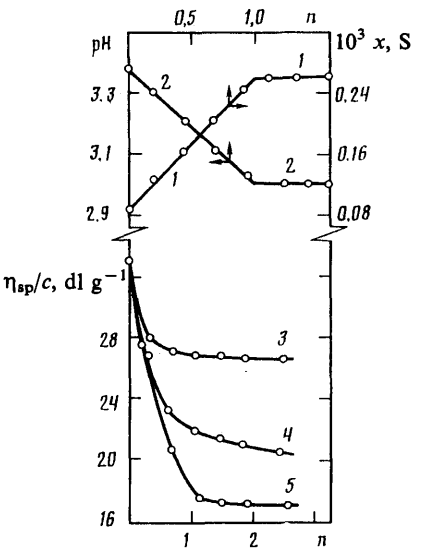

Figure 8. Variation of the electrical conductivity (curve *1*), pH (curve *2*), and intrinsic viscosity (curves *3*–*5*) with the molar ratio of the components *n*; *n*: *1*, and *2*, [BPA]/[PAA]; *3*, [BPA]/[PEG]; *4*, [BPA]/[PADMAC]; *5*, [BPA]/[PVPD].[39]

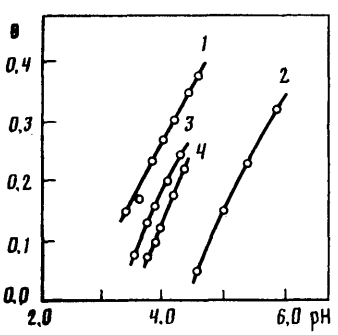

Figure 9. The profile of the dependence of θ on the pH for the BPA–PAA (curve *1*), BPA–PADMAC (curve *2*), and (BPA-PADMAC)–PAA (curve *3*) systems. Curve *4* corresponds to the formation of an intramolecular polyelectrolyte complex.[39]

The cooperative decomposition of the polyelectrolyte complex species at the isoelectric points of polyampholytes resembles the macromolecular substitution reaction, which is one of the important properties of interpolyelectrolyte complexes. In the case of interpolyelectrolyte complexes, the substitution process takes place as a result of the interaction of two complementary macromolecules with subsequent liberation of the third. In the case of polyampholytes, this reaction occurs within the limits of one macromolecule as a result of the formation of a single cooperative system consisting of intrachain ionic and hydrogen bonds and also hydrophobic contacts.

Thus the stability of the polymeric complexes formed from different polyampholyte–polyelectrolyte, polyampholyte–metal ions, and polyampholyte–dye pairs is apparently determined by the competing intramolecular and intermolecular complex formation reactions.

V. Conclusion

On the basis of the detailed study of the mechanism of the binding of metal ions by synthetic polyampholytes, the structures of the complexes, and the regions corresponding to their formation and decomposition, a new procedure has been proposed for the extraction of noble metal ions from dilute solutions.[54] It is based on the "expulsion effect" whose essential feature consists in the ability of synthetic polyampholytes to sorb transition metal ions and to liberate them in the vicinity of the isoelectric point.

A polyampholyte network with a controllable permeability to water and human serum albumin molecules has been synthesised.[53] As can be seen from Fig. 10, the maximum permeation of water molecules through the cross-linked polyampholyte is attained at the isoelectric point. It has been established that the maximum desorption (up to 96%) of the human serum albumin molecules takes place under these conditions. The mechanism of this process apparently consists in the alteration of the pore sizes in the polyampholyte network as a result of the electrostatic interaction of the acidic and basic units, leading to a change in the conformation of the macromolecules.

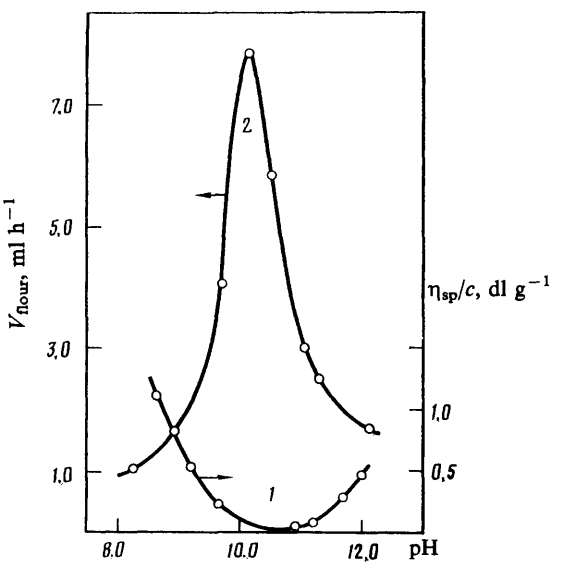

Figure 10. Variation of the intrinsic viscosity (curve *1*) and the permeability to water molecules (curve *2*) for linear (curve *1*) and cross-linked (curve *2*) polyampholytes based on DMVEP-AA with the pH of the solution.[53]

We may point to certain promising ways of using the "expulsion" effect. These are in the first place the creation of a pH-sensitive container which is capable of transporting specific immobilised substances (proteins, enzymes, antibiotics, and medicinal drugs) to the affected regions of the organism and also of "pH-muscles". The idea of creating pH-controlled containers is due to Frenkel'.[81] Let us suppose that a polyampholyte–medicinal drug associated species has been produced. The pH_{IEP} of the polyampholyte is "tuned" to a large section of the given body. So long as the polymeric polyampholyte–drug complex has not reached its "target" the medicinal drug should remain in the bound state. As soon as it reaches the affected region of the organism, whose pH is equal to pH_{IEP}, the drug begins to be released from the bulk of the macromolecular coil of the polyampholyte.

Microscopic conformational transitions are known to lead to macroscopic changes in the dimensions of solid polymers, which permits their use as converters of chemical energy into mechanical energy.[82] Bearing in mind that the polyampholyte–polyelectrolyte polymeric complex is formed cooperatively or decomposes within a very narrow pH range (for example, in the case of the system presented in Fig. 6 the range is 0.1–0.2 pH units), one may expect the creation of pH-muscles or pH-sensors.

We shall consider further the possibilty of creating self-regulating enzyme systems with the aid of polyampholyte–enzyme associated species or conjugates. The main principles governing the creation of a new generation of reversibly soluble immobilised enzymes with the aid of conjugates formed by enzymes with N-PEC have been described in detail.[67,68] On the basis of these principles, one can assume that the active centres of the enzyme bound to the polyampholyte can be "switched off" at the isoelectric point as a result of the formation of dense compact structures and can be "switched on" in the acid or alkaline reigons, i.e. when the chains are uncoiled to the maximum extent. If, for example, the pH of the medium changes as a result of the enzymic reaction, then, after the attainment of pH_{IEP}, the reaction should stop spontaneously.

The idea of using ampholytes with a block structure in matrix synthesis is also attractive. The mechanism of matrix polymerisation on a block polyampholyte chain should not differ fundamentally from the synthesis of polymers on polymeric acid or polymeric base matrices. However, when the reaction is carried out on a block polyampholyte, one may expect the following advantages: (1) the possibility of carrying out matrix polymerisation on individual blocks of the acid or base; (2) an increase in the degree of conversion in the reaction and the formation of water-soluble products maintained in solution and protected against precipitation by the hydrophilic "fringe"; (3) the possibility of separating the polymerisation products from the matrix at the isoelectric point of the block polyampholyte, after which the cyclic process is carried out.

In our view, the above examples and predictions by no means exhaust the theoretical and practical importance of the new property of polyampholytes at the isoelectric point. Further research on these lines is necessary.

ABSTRACT. Preparative methods, reactivity and biological action of *N*-substituted aminoamides of the monoacylated diamine type RCONH–CH(–)–(CH$_2$)$_n$N< are considered and systematised. An interconnection has been shown between structure, reactivity and the pharmacological activity of aminoamides.

The bibliography contains 201 references.

III. Reactivity of aminoamides 423
IV. Biological action of aminoamides 424

I. Introduction

The interest in aminoamides, organic compounds containing an amino and an amide group, is explained by the wide spectrum of their biological action. Aminoamides display various pharmacological activities and from them several medicinal preparations such as novocainamid, trimecaine, xycaine, flecainide, morphocycline, etc. have been produced in the USSR. A special place is occupied by compounds displaying antiarrhythmic activity, since disturbances of heart rhythm are the most widespread cardiovascular illnesses.

However in contrast to the amides of aminoacids which have been studied in detail, aminoamides of the monoacylated diamine type have received little investigation.

There are no literature reviews on the chemistry and biological action of *N*-substituted aminoamides. However information on individual compounds has been given in reviews.[1–3]

The increase observed in recent years in the number of publications on the development of synthetic methods, on the study of properties and especially on areas for their practical application, has caused a need for correlation and separate consideration of the accumulated information in this new trend in synthetic organic chemistry.

The methods for obtaining, the reactivity and the biological action of *N*-substituted aminoamides of the monoacylated diamine type RCONH–CH(–)–(CH$_2$)$_n$N< are discussed and systematised in the present review. An interconnection has been shown between structure, reactivity and the pharmacological activity of the aminoamides. Literature data published up to and including 1989 are discussed.

II. Methods of synthesis of *N*-substituted aminoamides

All the methods of synthesising aminoamides used at the present time may be provisionally divided into three types and will be considered in turn in this section.

1. Synthesis of aminoamides by introducing an amide group into an amine molecule

The most widespread means of obtaining aminoamides by the first type of method is the acylation of diamines.

$$R_2N(CH_2)_nNH_2 \xrightarrow{R^1COX} R_2N(CH_2)_nNHCOR^1.$$

Acylating agents used include carboxylic acids,[4–8] acid chlorides[9–12] and anhydrides,[13] and esters.[14–18]

Reactions are carried out in benzene, ether, chloroform or without solvent.

A series of aminoamides $RC_6H_4CONH(CH_2)_2NR^1R^2$ (I) has been obtained by acylation of the appropriate diamines with substituted benzoic acids in benzene or toluene in the presence of boron trifluoride and a strong organic base.[19] The yields of aminoamides were from 28 to 100%.

Diethylaminoethylbenzamide was synthesised in 81.8% yield by prolonged stirring of a mixture of the acid and amine in benzene over anhydrous magnesium sulphate.[20]

$$C_6H_5COOH + H_2N(CH_2)_2N(C_2H_5)_2 \xrightarrow[MgSO_4]{BF_3-(C_2H_5)_2O} C_6H_5CONH(CH_2)_2N(C_2H_5)_2.$$

Diamines have been acylated with substituted salicylic acids in dimethylformamide in the presence of ethyl chloroformate and triethylamine at room temperature.[21]

When using carboxylic acids of high molecular weight the reaction is carried out with heating and under pressure.[22]

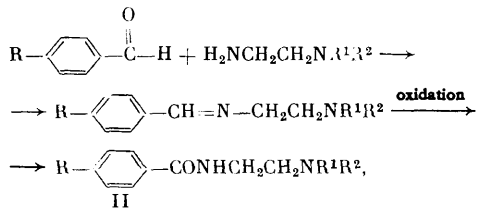
Carboxylic acid chlorides are most frequently used as acylating agents. Reactions are carried out both in aqueous alkaline medium by the Schotten-Baumann method and in anhydrous organic solvents.

An intermediate aminoamide in the synthesis of novocainamid is obtained by the Schotten-Baumann method,[23] sodium hydroxide is used as the hydrogen chloride acceptor.

A series of arylbenzamides[24] and amides of 2-thiophencarboxylic acid[25] has been obtained in the presence of alkali metal carbonates.

Acylation in organic solvents is frequently carried out in the presence of strong organic bases.[26–29]

However aminoamides contain a strongly basic centre (a tertiary amino group, as a rule) in the molecule and obviously this may serve as an acceptor of hydrogen chloride when obtaining them by the acylation of diamines. In this case the preparation of the hydrochlorides of these compounds in one stage has proved possible.



$$H_2N(CH_2)_nNR_2 + ArCOCl \longrightarrow ArCONH{-}(CH_2)_n{-}NR_2\cdot HCl.$$

The hydrochloride of *N*-(2-diethylaminoethyl)-*p*-nitrobenzamide was obtained from 2-diethylaminoethylamine and *p*-nitrobenzoyl chloride.[24] Aminoamides have also been obtained as hydrochlorides in dry chloroform[30] and dry ether.[31]

The acylation of diamines by the action of acetonitrile and water in the presence of sulphur or a catalyst generating sulphur in the reaction has been described.[32]

$$NH_2{-}(CH_2)_n{-}NR_2 + CH_3CN + H_2O \xrightarrow{S} CH_3CONH(CH_2)_nNR_2.$$

The condensation of a diamine with an aromatic aldehyde has been used for the synthesis of aminoamides (II).[33] The target aminoamide was obtained by the hydrogen peroxide oxidation of the aminoimine formed in the first stage of the reaction.

$R = NO_2$, $NR^1R^2 = N$⟨⟩; $R = CH_3O$, $NR^1R^2 = N(C_2H_5)_2$;

$R = NO_2$, $NR^1R^2 = N(C_2H_5)_2$.

The most widespread methods of synthesising diamines are reduction reactions.

The reduction of amino compounds containing a nitro group is carried out with metals in the presence of mineral acid or by catalytic hydrogenation.

$$R_2N(CH_2)_nNO_2 \xrightarrow{M,\ H^{\oplus}} R_2N(CH_2)_nNH_2.$$

The manufacture of paramion, liothyronine, ethmozine, novocainamid, etc. may serve as examples of the industrial application of this method.[34,35]

The reduction of nitriles of aminoacids is carried out with hydrogen in alcoholic-ammonia solution over a rhodium catalyst.[35]

The reductive amination of aminocarbonyl compounds is carried out either catalytically or with formic acid in the presence of ammonia and the amines.

Reductive amination over a platinum catalyst or Raney nickel proceeds usually under mild conditions, but yields differ appreciably.[36] The limitation of this method is the presence in the carbonyl compound or amine molecule of readily reducible groups, such as NO_2 or a double bond. Reductive amination by the Leuchardt reaction proceeds under fairly drastic conditions. Ammonium formate, formamide, and mixtures of them are used as aminating agents.[36] Best results are obtained in this reaction using a mixture of formamide with ammonium formate, occasionally with the addition of 90% formic acid.[37] The reducing action of formamide is enhanced in acidic media, better use is made of the ammonia formed in the reaction and the probability of side reactions occurring is reduced.[38]

$$RCO(CH_2)_nNR_2^1 + 2HCOONH_4 \longrightarrow RC(NHCHO)(CH_2)_nNR_2^1 + 2H_2O$$

$$+ NH_3 + CO_2 \longrightarrow RCH(NH_2)(CH_2)_nNR_2^1.$$

Diamines may be obtained from dibasic alcohols, dihalogen derivatives or halo-amines by a substitution reaction.[35]

Hydrolysis of urethanes or aminoamides is most frequently used.[35]

$$R_2N(CH_2)_nNHCOR^1 \longrightarrow R_2N(CH_2)_nNH_2.$$

In addition diamines are obtained by the interaction of aminoketones with hydroxylamine with subsequent reduction of the resulting amino-oxime.[39]

$$RCO(CH_2)_nNR_2^1 \xrightarrow{HONH_2} HON{=}C(R){-}(CH_2)_nNR_2^1 \xrightarrow{[H]} R{-}CH(NH_2){-}(CH_2)_nNR_2^1.$$

The synthesis of diamines has been described from ketonitriles through oximes by reduction with lithium aluminium hydride in absolute ether.[40]

$$RCO{-}(C)_n{-}CN \longrightarrow R{-}C(HO{-}N){-}(C)_n{-}CN \longrightarrow R{-}CH(NH_2){-}(C)_nNH_2.$$

Aminoamides may also be obtained by the action of primary or secondary amides on an amino-containing compound.[41] The similar reaction with amides proceeds with great difficulty and at increased temperature 170–180 °C, but on the other hand, with urea it proceeds readily and in high yield.[42]

$$RCONH_2 + X(CH_2)_nNR_2^1 \longrightarrow RCONH(CH_2)_nNR_2^1,$$

$X = OH$, Cl.

The addition reaction of acid amides to *N*-vinylamines leading to the formation of aminoamides is known.[43]

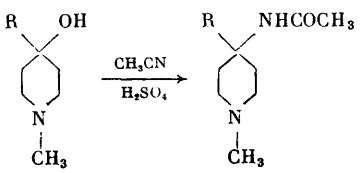
$$RCONH_2 + CH_2{=}CH{-}NR_2^1 \longrightarrow RCONHCH_2CH_2NR_2^1.$$

One of the most promising methods of obtaining branched aminoamides is the reaction of aminoalcohols with nitriles in the presence of strong mineral acid (Wieland-Ritter reaction),[44–46] which is widely used in the synthesis of various *N*-substituted amides and nitrogen-containing heterocycles.[47–48]

In addition to 100%[49] and fuming[50–52] sulphuric acid the following may be used as catalysts in the Ritter reaction: 85–96% sulphuric acid,[53–54] phosphoric acid,[55] benzene-sulphonic acid,[56] dichloroacetic acid,[57] toluene-*p*-sulphonic acid,[57] cyclohexane-sulphonic acid,[58] 90% formic acid,[58] 20% solution of sulphuric acid in glacial acetic acid,[59] 10% aqueous solution of hydrogen fluoride,[60] a mixture of concentrated sulphuric and formic acids,[61] and a mixture of sulphuric and phosphoric acids.[62]

The nature of the catalyst proves to have an appreciable influence on the temperature at which reaction occurs. When using sulphuric acid heating of the reaction mixture at 40–80 °C is required,[59,63,64]

but use of formic acid requires a boiling reaction mixture.[58] Depending on the nature of the reacting components the synthesis may be conducted at both low temperature (0 °C) and on heating to 90–175 °C under pressure.[66]

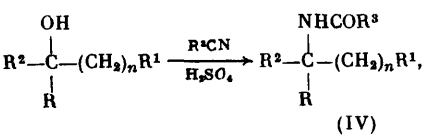


Acetic acid and dibutyl ether are frequently used as solvents in the Wieland-Ritter reaction.[63] The yield of amide is significantly reduced when using formic acid, dioxan, carbon tetrachloride and hexane, and in methyl and ethyl alcohols the reaction does not go at all (Table 1).[67]

Table 1. Influence of solvent on the yield of acrylic acid *N*-t-butylamide.

Solvent	Reaction time, h	Yield of amide, %
Acetic acid	16	98.4
Dibutyl ether	15	86.0
p-Dioxan	24	78.0
Methanol or ethanol	24	0

Ritter and co-workers and also other investigators have described the reaction of olefins and alcohols with various nitriles. Apart from aliphatic[60,66] and aromatic nitriles[45,57] nitriles of dibasic acids such as maleic, adipic, malonic, terephthalic and other acids are widely used in the Ritter reaction.[61] It should be noted that this reaction has been used in a very limited manner until recently for obtaining aminoamides.



There are definite data in the literature only on the preparation of aminoamides from 1-phenyl-3-piperidino-propanol,[68] diphenyl-(2-piperidylethyl)carbinol[69] and other heterocyclic aminoamides (III).[70]

(III)

R = CH_3, C_2H_5, C_4H_9.

A series of studies has been carried out on the preparation of aminoamides (IV) with various lengths of the methylene chain between the functional groups and with various substituents on nitrogen and in the main chain.[71–77]

(IV)

R = H, CH_3, C_2H_5, C_4H_9, R^1 = $NHCH_3$, NHC_2H_5, NHC_3H_7, NHC_4H_9, NH–⬡, $NHCH_2C_6H_5$, $N(CH_3)_2$, $N(C_2H_5)_2$, N⬡, N⬡O;

R^3 = CH_3, C_2H_5, C_4H_9, C_6H_5; R^3 = H, CH_3, $CH{=}CH_2$, C_6H_5, $CH_2C_6H_5$, $OCH_2C_6H_5$, $C_6H_4R^4$, n = 1–8.

Optimum conditions have been established for carrying out the reaction and it has been shown that in parallel with the main reaction product, viz. the *N*-substituted aminoamide, several side products are formed such as the unsubstituted amide and unsaturated compounds. The structure of the alcohol and especially the character of the susbtituents on the carbonyl carbon atom have a significant influence on the composition of the resulting reaction products. The reaction occurs fairly smoothly with secondary aminoalcohols with 50–70% main product and 15–20% olefin. However replacement of R = H with R = C_2H_5 leads to an increase in the side reaction. Diphenylcarbinols are converted into unsaturated compounds in yields of 70–80%. The influence of the length of the hydrocarbon chain of the aminoalcohol on the yield of the reaction proved to be much weaker (Table 2).[71–73]

The behaviour of nitriles in the Ritter reaction varies depending on their structure. Thus hydrocyanic acid, acetonitrile and benzyl cyanide give amides with both tertiary and secondary alcohols, but benzonitrile and phenoxyacetonitrile react only with secondary aminoalcohols and unsaturated compounds are formed in the remaining cases (Table 3).[74–77]

Table 2. Dependence of yield (as %) of aminoamides (IV) on structure of the initial aminoalcohol (R^2 = C_6H_5, R^3 = CH_3).

R	R^1 $N(CH_3)_2$			$N(C_2H_5)_2$		NC_5H_{10}	NC_4H_8O
	n 1	2	3	1	2	2	2
H	73	67	49	60	63	59	52
C_2H_5	26	25	25	43	29	23	22

Table 3. Dependence of yield (as %) of aminoamides (IV) on the nature of the nitrile [R = $N(CH_3)_2$, R^2 = C_6H_5; n = 2].

R	R^3				
	H	CH_3	C_6H_5	$CH_2C_6H_5$	$CH_2OC_6H_5$
H	52	67	42	42	22
C_2H_5	62	25	0	51	0

The aminoalcohols used in the Wieland-Ritter reaction may be synthesised by various methods.[78–79]

The most widespread means of synthesising aminoalcohols is the interaction of aminoketones and aminoaldehydes with Grignard reagents or by reduction. Variation of these reactants leads to the preparation of primary, secondary and tertiary alcohols. Reduction of aminoketones and aminoaldehydes is effected by catalytic means (platinum and palladium are usually used as catalysts). Reactions are carried out as a rule in alcohol or in aqueous alcohol solution,

mostly at room temperature and atmospheric pressure. The reduction products, viz. primary and secondary aminoalcohols, are formed in good yield. Hydrogenation in the presence of a nickel catalyst is used relatively rarely, since in this case increased pressure and high temperature are necessary.[78]

Lithium aluminium hydride and sodium borohydride are also used as reducing agents.[79] The present method enables reduction of aminoketones without preliminary purification which is accompanied by partial decomposition of the latter.

2. Synthesis of aminoamides by amination of amide-containing compounds

The most widespread example of this approach to the synthesis of aminoamides is the amination of amidoalcohols[80] which is carried out in aqueous solution at 100 °C or in glacial acetic acid at 75 °C.

$$R{-}CONH{-}\underset{|}{\overset{|}{(C)_n}}{-}OH + R_2^1NH \longrightarrow RCONH{-}\underset{|}{\overset{|}{(C)_n}}{-}NR_2^1.$$

It has been established[80] that monoamides are formed by this scheme only when using secondary amides. With primary amines the reaction does not stop at the stage of forming a monoaminoamide but goes further giving bis-aminoamides.

$$RCONHCH_2OH + H_2NCH_3 \longrightarrow (RCONHCH_2)_2NCH_3,$$
$$R = C_6H_5,\ C_6H_5CH_2,\ C_6H_5C_3H_6.$$

Acylketimines[81] and *N*-α-haloalkylamides[82] are also subject to amination.

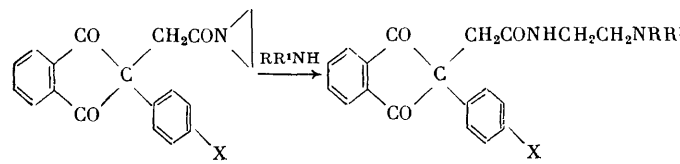
$$RCON{=}CAr_2 \xrightarrow{R_2^1NH} RCONHC(NR_2^1)Ar_2,$$
$$RCONHCHXR^1 + R_2^2NH \longrightarrow RCONHCH(NR_2^2)R^1.$$

A method has been described for obtaining aminoamides from aminonitriles[83] by acylation of the latter and subsequent reduction over Raney nickel.

$$Ar{-}\underset{|}{\overset{|}{CH}}{-}NH_2 \xrightarrow{RCOCl} Ar{-}\underset{|}{\overset{|}{CH}}{-}NHCOR \xrightarrow[Ni]{[H]} Ar{-}\underset{|}{\overset{|}{CH}}{-}NHCOR.$$
$$\quad\ CN \qquad\qquad\qquad CN \qquad\qquad\qquad\quad CH_2NH_2$$

3. Synthesis of aminoamides by the aminomethylation of acid amides

The most widely used method of synthesising aminomethylamides (V) is by condensation of primary amides with formaldehyde and amines.



$$RCONH_2 + CH_2O + NHR_2^1 \longrightarrow \underset{(V)}{RCONHCH_2NR_2^1}.$$

Condensation is carried out by the usual conditions for the Mannich reaction. It was established that the yield of aminoamide depends to a significant degree on the acidity of the amides and the basicity of the reacting amine.[82] The yield of aminoamide fell from 53% to 0 with an increase in pK_a of the corresponding amide from 1.25 for dichloroacetic acid amide to 4.27 for *m*-toluic acid amide. Such weak bases as aniline (pK_a 4.58), methylaniline (pK_a 4.85) and *o*-toluidine (pK_a 4.39) did not react. The yield of aminoamide reached 50% when using *N*-t-butylamine.

In addition to formaldehyde aromatic aldehydes may be used in the condensation. In this case aliphatic-aromatic aminomethylamines are obtained.

$$Ar{-}CONH_2 + Ar^1CHO + HNC_5H_{10} \longrightarrow ArCONHCH(Ar^1)NC_5H_{10}.$$

A method has been described for the synthesis of aminoamides through acid *N*-ethylenimides.[84] The *N*-ethylenimides having electron-accepting substituents on the nitrogen atom (so-called 'activated' *N*-ethylenimides) readily break the aziridine ring on reaction with amines.[85]

It follows from an analysis of the data mentioned above that the majority of methods of obtaining aminoamides are not universal. This is linked either with limitations peculiar to one or other synthetic method or to the availability of starting materials. Thus aminoamides with branched carbon atoms at the amide group but with a short methylene chain between the functional groups are synthesised by the aminomethylation of acid amides. Branched aminoamides with the most varied methylene chain length are obtined by amination of amide-containing compounds, but here there is a limitation linked with the use of secondary amines only. Aminoamides with a tertiary carbon atom at the amide group are obtained by the acylation of diamines. However in this case the main synthetic complexities are linked with the obtaining of unsymmetrically substituted *N*-t-alkyldiamines.

Of the existing methods the most promising is the Wieland-Ritter reaction for the synthesis of aminoamides with a branched carbon atom on the amide group and any length of methylene chain between the amide and amine groups.

III. Reactivity of aminoamides

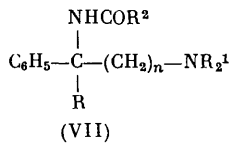
The most important feature of the structure of *N*-substituted aminoamides is their bifunctionality which undoubtedly shows up in all the properties of these compounds whether it be salt formation,[10,86] oxidation by peroxides at the amino group[7] or reduction[87] and hydrolysis of the amide group.[88] However there is special interest in those properties of aminoamides in which this influence is clearly shown and may be determined quantitatively. It seemed expedient to consider these in more detail.

It is known that all the properties of amino-containing compounds are determined primarily by their basicity. This depends on the electron density at the nitrogen atom, its steric accessibility and is extremely sensitive even to a small change in structure. Undoubtedly the basicity of aminoamides $RCONH{-}\underset{|}{\overset{|}{C}}{-}(CH_2)_nN\diagup\diagdown$ (VI) depends on the presence of the amide group, the character of the environment of the amino group and on the removability of the polar amide group.

In the general case several factors may influence the basicity of the resulting aminoamide on introducing an amide group into an amine molecule:

a) displacement of electron density to the amide group along the carbon chain (inductive effect, independent of steric obtacles and conformation) and the direct mutual interaction of the amino and amide groups through space (polar effect);

b) formation of an intramolecular hydrogen bond binding the unshared electron pair of the nitrogen atom;



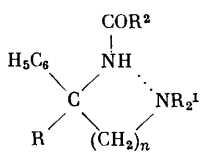
c) increase in the steric obstacles for conversion of the trigonal nitrogen atom into tetrahedral and in the steric difficulties of solvation;

d) formation of a hydrogen bond in the ammonium ion thereby stabilising it;

e) increase in the solvation of molecules due to the appearance of new polar groups.

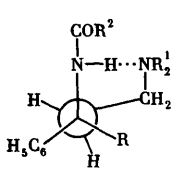
Factors (a–c) must cause a reduction in the basicity of aminoamides in comparison with simple amines and factors (d–e) an increase. The overall result is determined by their relationship. Data of several studies[89–93] indicate a reduction in the basicity of aminoamides in comparison with the simple amines which indicates the predominant influence of factors (a–c).

Analysis of the data on the basicity of *N*-substituted aminoamides



(VII)

in ethanol using correlation equations[92,94] enabled determination of the relationship of effects (a–c).

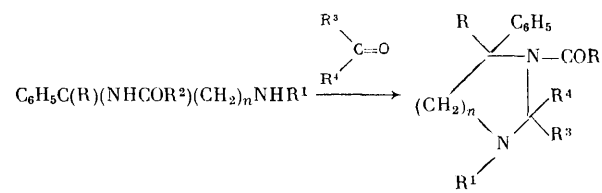


A good correlation was observed[94] between the pK_a values of aminoamides with the inductive constants σ for the influence of substituents.[95] This indicates that in amphoteric strongly solvating solvents aminoamides are in a free, open conformation and all the factors, except the inductive, are of little significance. The influence of the amide group (as for other substituents) is transmitted mainly along the chain of σ-bonds.

In aprotic non-solvating solvents (nitrobenzene, carbon tetrachloride, etc.) aminoamides exist in a folded cyclic conformation with a contiguous disposition of functional groups, stabilised by a hydrogen bond.[96–98]

Quantitative assessment of the stability of such a bond[97] showed that the latter is proportional to the number of CH_2 groups between the amine and amide groups, i.e. on transition from a 5- to a 6- or 7-membered ring the stability of the hydrogen bond was increased. This phenomenon is explained by the change in N–H...N angle, approaching 180° in a 7-membered ring which corresponds to maximum bond strength.

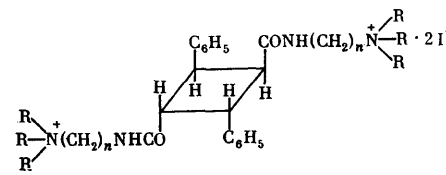
The introduction of a bulky substituent into the α-position to the amide group (R = C_2H_5) leads to strengthening of the hydrogen bond as a result of repulsion between R and $CH_2NR'_2$ and maximum approach of the NH and $CH_2NR'_2$ groups.



Due to the presence of two polar groups, an amide and an amine, in the aminoamide molecule they are able to form complexes differing in constitution and structure with metals.[99–100]

The complex-forming ability of *N*-lauroylethylenediamine with transition metals has been studied,[101] as has the ability of *N*-picolinoylethylenediamine to form complexes with copper.[102] It was shown with the aid of potentiometric titration and absorption spectra that in similar compounds the metal is bound both with the amide and with the amino group. Most probably the amide group is bound through nitrogen as a result of deprotonation and partially through the carbonyl oxygen.

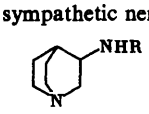
Investigations have been carried out on the complex-forming ability of several aliphatic-aromatic aminoamides (IV) with Cu, Co and Ni.[103] An analysis of the data obtained was conducted with the aid of correlation equations and enabled an assessment of the contributions of both polar groups to the ability of aminoamides to form complexes with these metals. It was concluded that aminoamides form chelate complexes with transition metals, i.e. both functional groups participate in this process. Furthermore, from the data obtained it proved to be possible to select compounds from the whole series with a high complex-forming ability for use as extractants of non-ferrous metals.[103]



Due to the presence of the amide and amine groups the *N*-substituted aminoamides are capable of cyclisation with aldehydes and ketones with the formation of imidazolidines and hexahydropyrimidines.[104,105]

IV. Biological action of aminoamides

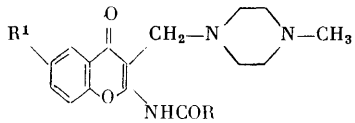
Aminoamides display various physiological activities. Among them substances are known which possess cholinolytic[106] and spasmolytic,[107] hypotensive,[108] antifibrillating[109] and curare-like[110] effects.



Investigations have shown that on transition from amides of monocarboxylic to dicarboxylic acids the curare-like action of compounds is increased.[110] The nature of the dicarboxylic acid plays an important role. Thus in difference to bis-aminoamides of dibasic alkylcarboxylic acids,[10] bis-aminoamides of α-truxilic acid of the type

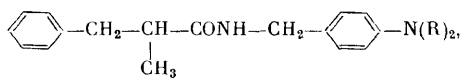
possess significantly more marked curare-like activity.[111]

It is possible to name aminoamides which are antibiotics (morphocycline),[112] display insecticidal[112] and bactericidal[113,114] properties and also fungicidal[12] and antiviral[115] effects.



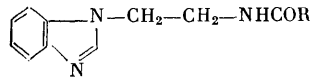
Study of 3-hydroxy- and 3-aminoquinuclidines (VIII)[116] showed that they show a ganglion-blocking action on the parasympathetic and sympathetic nervous systems.

(VIII)



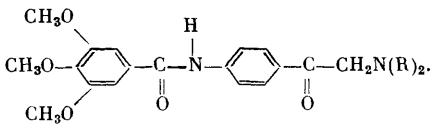
R=COC_6H_5; $COC_6H_4NH_2$.

Derivatives of 2-acylaminochromones[117] show a stimulating action but display high toxicity.

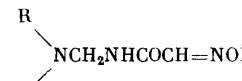


$R = OC_2H_5$, $R^1 = H$; $R = CHCl_2$, $R^1 = H$; $R = CCl_3$, $R^1 = H$; $R = C_6H_5$, $R^1 = H$; $R = OC_2H_5$, $R^1 = Cl$.

Aminoamides of β-phenylisobutyric acid have been synthesised in the search for new neurotropic agents.[118] In physiological action they proved to be antagonists of amphetamine and significantly potentiated the hypnotic effect caused by chloral hydrate and sodium amobarbital. The duration of amobarbital hypnosis was increased along the series $CH_3 \rightarrow C_2H_5 \rightarrow n\text{-}C_3H_7$.

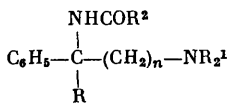


$R = CH_3$; C_2H_5; $n\text{-}C_3H_7$.



Several acyl derivatives of 1-(2-aminoethyl)benzimidazoles possess weak sedative and antiserotonin activity.[119]

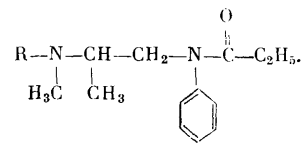
The α-amino derivatives of 4-(3,4,5-trimethoxybenzoylamino)-acetophenone are stimulants and depressants of the central nervous system.[120]



Amides of oximinoacetic acid are active reactivators of cholinesterase.[121] In many cases they are more active than their methiodides.

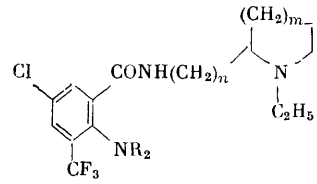
$R = R^1 = CH_3$; $R = R^1 = H$; $R = H$; $R^1 = CH_3$; $R = R^1 = C_2H_5$; $RR^1N = (CH_2)_4N$; $(CH_2)_5N$.

Introduction of a second quaternary ammonium group strengthens the reactivating properties to cholinesterase. Amides are more stable than esters in aqueous media and show a therapeutic action on contamination of animals by organophosphorus compounds (fosfakol). Compounds with a tertiary amino group are capable of penetrating the blood-brain barrier and show a pharmacological action on the central nervous system. In addition certain aliphatic-aromatic aminoamides display anticholinesterase properties.



$R = H$, C_2H_5; $R^1 = CH_3$, C_2H_5, C_3H_7, C_4H_9; $R^2 = CH_3$, $CH_2C_6H_5$, C_6H_5; $n = 1$ to 8.

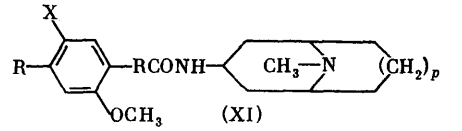
It was shown[122] that these compounds are reversible inhibitors of cholinesterase and their activity depends to a significant extent on the bifunctionality, the character of the amide and amine groups, the branching of the main chain and the distance between the functional groups.



Analgesic activity became apparent when investigating a series of amides of benzilic, diarylglycollic and substituted benzoic acids. It was established that the anaesthetising action depends on the character of the radicals on the tertiary nitrogen atom and on the number of methylene groups between the nitrogen atoms. Enhancement occurs on introducing a methyl group into the amide.[123]

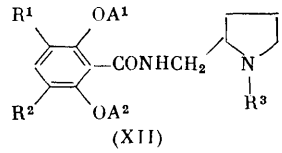
The analgesic activity of compounds (IX) depends on their configuration.[124] It was shown that the (+) (*S*)-isomer was more active than the (–) (*R*)- and (±)-isomers. This indicates that analgesics of the methadone type vary in the form of their bonding with receptors.

(IX)



Antitubercular[125] and antibacterial[126] properties have also been described for some aminoamides. Some compounds of this class of chemical susbtances are applied in stomatological practice for the prevention of deposits on teeth.[7] There are several reports on the use of aminoamides as preparations with a wide spectrum of biological action. Thus benzamides (X) are used as antiemetic and antiulcer preparations and also as anticonvulsants and neuroleptics.[127]

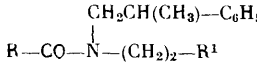
(X)



$n = 1.2$; $m = 1.2$.

It has been pointed out that azabicycloalkylbenzamides (XI) may find use in the treatment of arrhythmia, migraine, neuralgia, disturbances of bowel motility, and as antiemetic agents.[128]

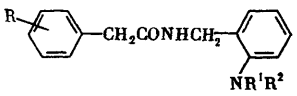
$R = NH_2$, acylamino; X = Cl, Br, alkylthio; $p = 0-1$.



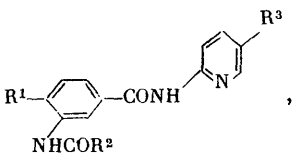
Benzamides (XII) possess psychotropic action and may be considered as potential drugs for psychiatric practice and also as antiemetic agents.[129,130]

(XII)

R^1, $R^- = H$, halogen; $R^3 = A^1 =$ lower alkyl; $A^2 = (C_1-C_6)$ acyl.



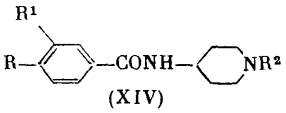
Compounds (XIII) proved to be depressants and analeptics.



(XIII)

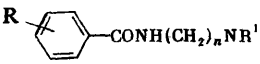
R = CH_3, *p*- and *o*-$CH_3OC_6H_4$; 3,4,5-$(CH_3O)_3C_6H_3$; R^1 = 2- or 4-pyridyl, 2- or 4-alkylated 2-pyridyl.

Diaklylaminoethylanilides[131] synthesised in the search for antihypertensive preparations proved to be active in the treatment of arrhythmia, migraine, hypertonia and glaucoma. Monoalkylated amides of phenylacetic acid[131,132] reduce blood sugar content and may find use in the treatment of diabetes.

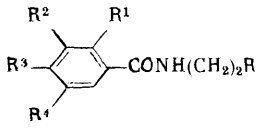


Aminoamides containing a pyridine ring may find use in stomatology.[133]

where R^1 = H, CH_3, OCH_3; R^2 = branched or unbranched C_2-C_8 alkyl, substituted or unsubstituted phenyl; R^3 = H, C_1-C_4 alkyl in various positions.



Benzamidopiperidines (XIV) display local anaesthetic and analgesic activity, they are used as antiemetic preparations, tranquilisers, and also in the treatment of diseases of the gastrointestinal tract.[6]

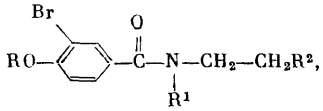


(XIV)

R = H, OCH_3, $NHCOCF_3$, $NHCOCH_2Cl$, R^1 = Cl, H, SO_2NH_2, CH_3SO_2NH, OCH_3; R^2 = H, *p*-$FC_6H_4CO(CH_2)_3$, CH_2CH_3.

Substituted anthranilamides are used as analgesics, antiulcer and antiinflammatory agents.[134]

N-Substituted benzamide derivatives (XV) possess a combination of analgesic, spasmolytic and antiemetic activity.[135]



(XV)

R = $N(C_2H_5)_2$, $R^3 = NO_2$, $R^1 = R^2 = R^4 = H$; R = $N(C_2H_5)_2$, R^1 = Cl, $R^2 = R^3 = R^4 = H$; R = $N(C_2H_5)_2$, $R^1 = R^4 = H$, $R^2 = R^3 = CH_3O$; R = NC_5H_{10}, $R^1 = R^2 = R^4 = H$, $R^3 = NO_2$.

The local anaesthetic activity of aminoamides has been studied widely.[136–139] Amides of heterocyclic acids have been studied in most detail,[140,141] to which group the known anaesthetic Sovcaine (dibucaine, cinchocaine) belongs. The activity of these compounds as a rule is increased on introducing a bulky alkyl group into the aminoamide molecule.[141] It is necessary to record that amides of 3-alkoxycinchoninic acid, unlike 2-alkoxy derivatives, do not display anaesthetic activity,[140] which probably indicates the influence of the geometry of the molecule on the physiological properties of the amides.

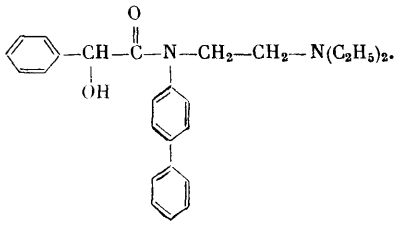
Alkyl and alkoxy groups aid the development of the pharmacological activity indicated not only in the series of Sovcaine analogues but also among amides of substituted benzoic acids previously considered to have little promise for practical application as drugs.[141] However di- and trimethylbenzamides proved to be effective.[142] The anaesthetic activity of *o*-alkoxy-, especially *o*-butoxy-,[138–143] and also *o*-benzoyloxybenzamides[144] is close to the activity of xylocaine. Compounds containing substituents in the *para*-position are usually less active but some of them are used in medicine because of their low toxicity.[145]

The use of aminoamides with a tertiary nitrogen atom in the amide group (XVI) has been described.[146,147]

(XVI)

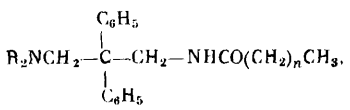
R = CH_3, R^1 = H, $R^2 = N(C_2H_5)_2$; R = CH_3, $R^1 = CH_3$, $R^2 = N(C_2H_5)_2$;

R = CH_3, R^1 = H, $R^2 = NC_5H_{10}$, R = CH_3, $R^1 = CH_3$, $R^2 = NC_5H_{10}$;



R = C_2H_5, R^1 = H, $R^2 = NC_4H_8O$;

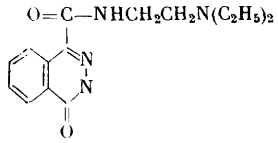
R = C_2H_5, R^1 = iso-C_3H_7, $R^2 = NC_4H_8O$.



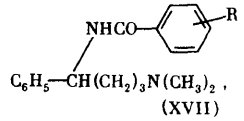
It was established that such compounds display enhanced pharmacological activity compared with compounds with a secondary nitrogen atom. In particular an increase in local anaesthetic and analgesic action was observed for aminoamides with an alkylated nitrogen atom in the amide group (XVI) (R^1 = CH_3, iso-C_3H_7) in comparison with compounds (XVI) (R^1 = H), in which the nitrogen atom is secondary.[146]

This tendency was more marked in aminoamides with *p*-butyloxy- and *p*-amyloxy- than with *p*-methoxy- and *p*-ethoxy-substituents in the phenyl ring. However the toxicity of compounds was not reduced by this.[146]

Arylation of the amide group also increases anaesthetic activity. It is asserted that the following compound is a strong anaesthetic.[147]



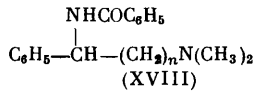
The local anaesthetic activity of γ-dimethylaminodiphenylpropylamides of acetic, propionic and butyric acids has been described.[148]



n = 0, 1, 2.

Aminoamides of 4-phthalazone-1-carboxylic acid possess high local anaesthetic activity at low toxicity.[149]

Dimethylaminobutylamides of substituted benzoic acids (XVII) proved to be extremely effective.[150]

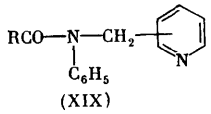


(XVII)

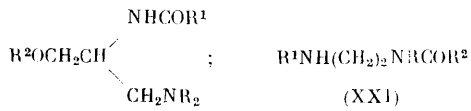
R = H, *p*-CH_3, *m*-NO_2, *p*-Cl, *p*-NH_2.

It was established that the local anaesthetic action of amides depends on the character of the substituent in the benzene ring. Compounds with R = *p*-CH_3 and *m*-NO_2 proved to be most effective and long-acting substances with low toxicity.

An important factor influencing the local anaesthetic activity of aminoamides is the distance between the amide and amino groups. The influence of the number of methylene groups between the nitrogen atoms on conduction, infiltration and terminal anaesthesia of benzamides (XVIII) has been investigated.[151]



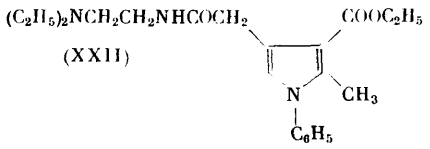
(XVIII)



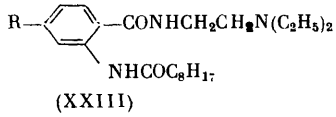
$n = 1$—6.

It was shown that there were maxima of local anaesthetic activity at n = 3, 4 and 6.

Among other active aminoamides it is possible to mention 4-alkoxyphthalimides,[152] 3,3-diphenylacrylamides,[153] amides (XIX),[154] (XX)[155] and *N*,*N*-disubstituted monoacylated ethylenediamines (XXI).[156]

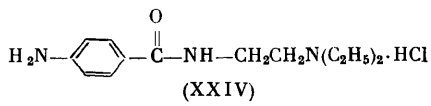


(XIX)



(XX) (XXI)

Preparation (XXII) is of interest, containing in its structure an aminoamide and an aminoacid ester, causing rapid, stable and extended anaesthesia.[157]

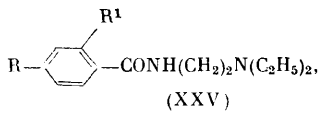


(XXII)

Diamide (XXIII) exceeds novocaine in local anaesthetic activity 200-fold.[158]

(XXIII)

Among other biologically active aminoamides it is possible to mention novocainamid (XXIV) (the β-diethylaminoethylamide of *p*-aminobenzoic acid).[112] It is close to novocaine in chemical structure. Novocainamid also has a similarity to novocaine in pharmacological properties and displays local anaesthetic activity.

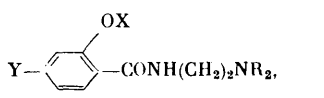


(XXIV)

However the most distinctive feature of (XXIV) is its ability to reduce the excitability of the myocardium and to retard the transmission of a nervous impulse in heart muscle and also to suppress the formation of impulses in ectopic foci of excitation. It is significantly more active than novocaine in this respect. The increased stability of novocainamid *in vivo* is explained by its slow breakdown to novocaine by blood plasma enzymes. It is also less toxic than novocaine. Novocainamid is used in various disorders of cardiac rhythm, viz. the paroxysmal form of ciliary arrhythmia, paroxysmal tachycardia, extrasystolia and other forms of rhythm disturbance. It is used for the prevention and treatment of disorders of cardiac rhythm in operations on the heart, large vessels and lungs.[112]

The (XXIV) molecule has been modified with the aim of increasing activity and reducing toxicity. All parts of the molecule have been changed, viz. the aromatic ring and its substituents, the length and branching of the hydrocarbon chain and the substituents on the nitrogen atom.

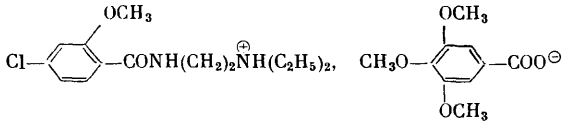
Replacement of the amino group in novocainamide (XXIV) by chlorine or an ethoxy group leads to loss of antiarrhythmic activity.



(XXV)

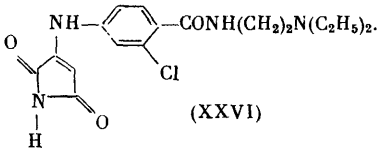
R = NH_2, OC_2H_5, Cl, $NHCOCH_3$; R^1 = Cl, H

Compounds (XXV) (R = NH_2, OC_2H_5, R^1 = Cl) possess an antiemetic action but the *ortho*-chloro derivative (XXV) (R = NH_2, R^1 = Cl) is active,[26,159] and also displays local anaesthetic activity more than 4 times greater than the activity of novocainamid (XXIV).[27] *N*-Acylated novocainamid (XXV) (R = $NHCOCH_3$, R^1 = H) is an active metabolite of novocainamid[160] and interrupts arrhythmia caused by aconitine.



On replacing the NH group in the (XXIV) molecule by a nitro or hydroxy group the antiarrhythmic activity is reduced.[28] The introduction of a methoxy group into the phenyl ring significantly increases the antiarrhythmic effect. 3,4,5-Trimethoxy-*N*-(2-diethylaminoethyl)benzamide is 4 times more active than novocainamid.[29]

Derivatives of salicylamide are active antiarrhythmics.

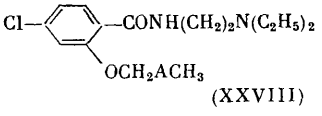


X = H, alkyl; Y = H, Cl, Br; R = alkyl.

The most active of these compounds is the 3,4,5-trimethoxybenzoate salt of 4-chloro-2-methoxy-*N*-(2-diethylaminoethyl)benzamide.[161].

Compound (XXVI), in which nitrogen is alkylated by substitution with a dehydropyrrolidinedione, is also more active than novocainamid.[162]

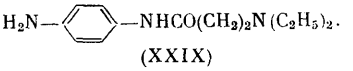
(XXVI)



Several derivatives (XXVII) were obtained by acylation at nitrogen. Of this series the acyl derivative with R = CH_2CH_3 shows the greatest activity in calcium chloride arrhythmia.[163]

(XXVII)

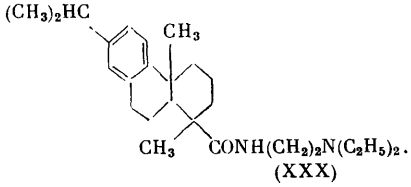
R = $ClCH_2$, Cl_2CH, CH_2CH_3, $C(CH_3)_3$, $CH(CH_3)_2$, $CH_2CH_2CH_3$.



Novocainamid derivatives (XXVIII) are used for stopping vomiting caused by chemotherapeutic preparations.[164]

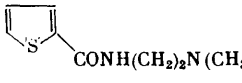
(XXVIII)

A = CHOH, C = NOH, C = $NOCH_3$.



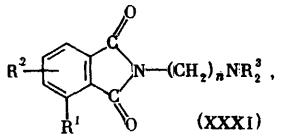
ortho-Methylation significantly increases antiarrhythmic activity.[165] Inversion of the amide group (XXIX) leads to loss of activity.[165]

(XXIX)



Replacement of the phenyl ring in the novocainamid molecule leads to the preparation of new compounds with various biological activities.

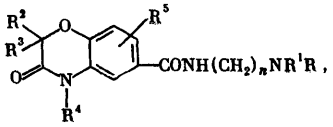
Compound (XXX) displays activity in strophanthin arrhythmia.[166]



(XXX)

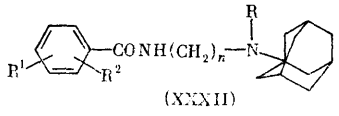
The thiophen analogue of novocainamide shows analgesic and spasmolytic activity.[25]

Analogues of novocainamid are known in which the benzene ring is replaced by another aromatic ring, such as quinoline.[167]



Phthalimides (XXXI) also display antiarrhythmic activity.[168,169] The most active is the compound with $n = 4$, $R^3 = C_2H_5$.

(XXXI)

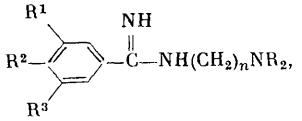


R^1 = H, *o*-alkyl; R^2 = *o*-, *p*-, *m*-NHR^4.

Amides of 1,4-benzoxazinecarboxylic acid, which are novocainamid derivatives, display marked antiarrhythmic properties.[170]

where NRR^1 = piperidino, morpholino, 4-*m*-tolyl-1-piperazine.

N-(Adamantylaminoalkyl)benzamides (XXXII) prevent ventricular fibrillation caused by chloroform.[30] They are less toxic than procainamide.

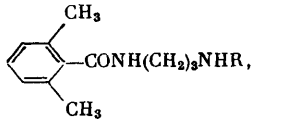


(XXXII)

R = H, C_2H_5; $n = 2, 3$; R^1 = H, Cl, CH_3; R^2 = NH_2, NO_2.

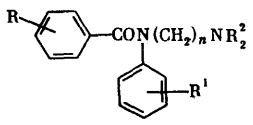
Compound (XXXII) (R = C_2H_5, R^1 = H, R^2 = *p*-NH_2, n = 2) proved to be the most active. The influence of the surroundings of the tertiary nitrogen atom on the antiarrhythmic activity of compounds has also been investigated.[171] Replacement of ethyl groups by another radical (isopropyl) significantly reduces activity, while replacement of one ethyl by an aromatic group significantly increases it.

Compounds (XXXIII) contain a benzimido group.



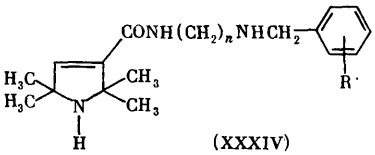
(XXXIII)

n = 2, 4; R = CH_3, C_2H_5 or NR_2 = 2-pyrrolidine; R^1 = H, CF_3, OCH_3; R^2 = H, CH_3, F, NO_2, NH_2, R^3 = H, OCH_3.



Of 28 *N*-substituted benzimidines synthesised 15 possess antirrhythmic activity, 4 compounds surpass novocainamid in activity and duration of action, display low toxicity and a weak cardiodepressant action.[172–174]

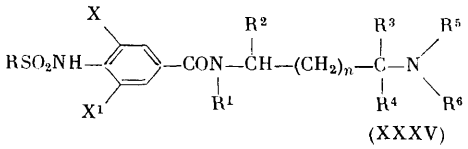
Aminoalkylpropylamides of 2,6-dimethylbenzoic acid interrupt tachycardia in dogs.[175]



R = C_2H_5, $CH(CH_3)_2$, C_6H_5—CH—$(CH_3)CH_2$.

Benzamides substituted at nitrogen display antiarrhythmic activity.[176]

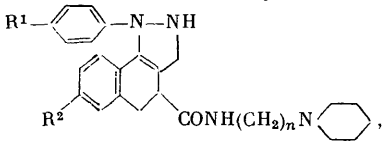
$n = 2, 3$; R = 3, 4, 5(OCH_3)$_3$, 2, 4,-(OCH_3)$_2$, 2-Cl;
R^1 = H, 2(4)-CH_3, 2(4)-C_2H_5;
NR_2^2 = morpholino, pyrrolidino, piperidino.



The antiarrhythmic activity of amides of tetramethylpyrrolidinecarboxylic acid (XXXIV) has been described.[177]

(XXXIV)

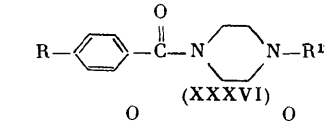
m = 2, 3; R = H, 4-Cl, 4-CF_3, 2-OCH_3, 2-OH, 4-OC_6H_5, 4-$OCH_2C_6H_5$ etc.



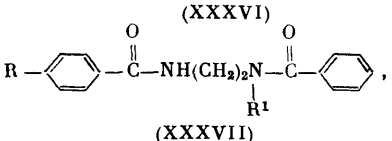
Some of them surpass quinidine in therapeutic index (aconitine arrhythmia model). Aminoamide (XXXIV) (n = 3 and R = $OCH_2CH{=}CH_2$) is 6.3 times more active than quinidine.[177] Substituted sulphonamidobenzamides (XXXV) display antiarrhythmic activity similar to that of novocainamid.[178,179]

(XXXV)

where X and X^1 = H, halogen; R^1, R^2, R^3, R^4 = alkyl, cycloalkyl, alkenyl; R = alkyl, cycloalkyl, benzyl, alkoxyl. Derivatives of (XXXV) containing a methanesulphonylamino group showed antiarrhythmic action of the cordarone type (class III antiarrhythmic preparations).[180] There is an indication of an increase in the duration of action of preparations (XXXV) in comparison with compounds containing an RSO_2 group (prolongation effect).[178]



Aminoamides of 4,5-dihydrobenz[d]indazole-3-carboxylic acids are able to retard the ventricular tachycardia induced by aconitine.

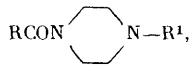


R^1 = H, CH_3O, F, Cl; R^2 = H, Cl, $(CH_3)_2N$, CH_3O; n = 2, 3.

A large group of aminoamides comprises compounds in which the tertiary nitrogen atom is linked with the amide function through a cyclic system.

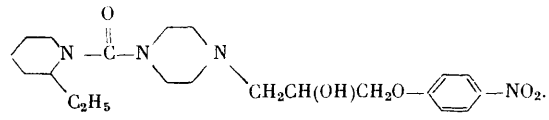
Cyclic analogues of novocainamid (XXXVI) and diacyl derivatives of ethylenediamine (XXXVII) have been investigated.[181]

(XXXVI)



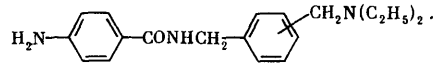
(XXXVII)

R = H, NH_2, NO_2, Cl, OCH_3; R^1 = C_2–C_5 alkyl.



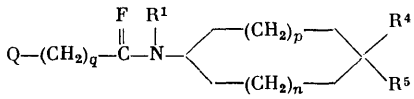
Replacement of the tertiary amino group in the novocainamid molecule by an amido group (XXXVII) leads to loss of antiarrhythmic action as does replacement of the amide and amino nitrogens by piperazine (XXXVI) R = NH_2, R^1 = C_2H_5. Derivatives (XXXVII) with R ≠ NO_2 display depressant activity. The action, like that of novocainamid, is displayed by compounds containing a chlorine atom (XXXVI) R = Cl.

Certain derivatives of piperazine display activity against the arrhythmia induced by adrenaline.[182]

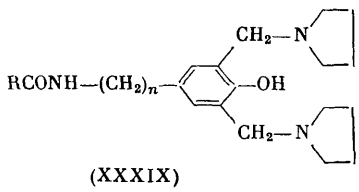


where R = 2-piperidinoethyl, $(C_6H_5)_2N$, 3,4,5-$(CH_3O)_3C_6H_2$. R^1 = phenoxy, piperidino, naphthoxy, 4-CH_3-piperidino, 2-hydroxypropyl, 3,4,5-$(CH_3O)_3C_6H_2CO$.

The most active compound is



Cyclic analogues of novocainamid (XXXVIII) proved to be weakly active as antiarrhythmics, however *meta*- and *para*-derivatives are 45 and 37 times more active than novocainamid in local anaesthetic action.[183]

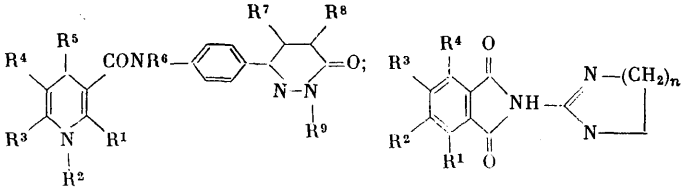


(XXXVIII)

Aminoamides containing saturated rings joining the amide and amino nitrogen atoms in the hydrocarbon chain may be potential antiarrhythmics.[184]

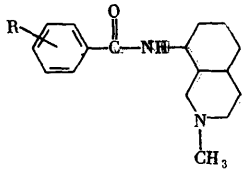
q = 0–4, p = n = (0–9); Q = 1-, 2-naphthyl, C_6H_3XY; R^1 = H, (C_1–C_3) alkyl; R^2 = H, (C_1–C_3) alkyl, branched alkyl; R^3 = alkyl, cycloalkyl; R^4 = H, OH, OCH_3, OC_2H_5, SH; R^5 = H, OH, (C_1–C_3) alkoxy; E = O or S; X = Y = halogen, C≡N, C_6H_5.

Substituted phenols (XXXIX) disclose antiarrhythmic activity and show action on the parasympathetic nervous system.[185]



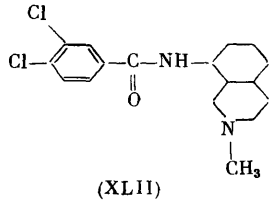
(XXXIX)

R = substituted phenyl or thienyl; n = 0 or 1.



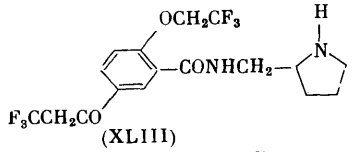
A correlation between antiarrhythmic activity and action on the nervous system was observed for this class of compounds.

Substituted amides of dihydropyridinecarboxylic acids (XL)[186] and phthalimides (XLI)[187] show antiarrhythmic activity in animal experiments.



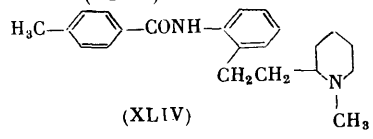
(XL) (XLI)

Certain derivatives of 5-, 6-, and 8-substituted 2-methyldecahydroquinolines surpass quinidine in anti-arrhythmic activity and therapeutic index.[188,189,167]

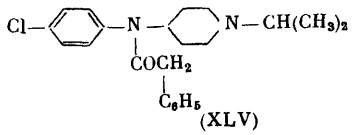


R=H, 4-Cl, 3,4-Cl_2, 4-OCH_3, 3,4-$(OCH_3)_2$, 3,4,6-$(OCH_3)_3$.

The most active compound is *cis*-(XLII), which is more than 2 times as active as quinidine, *trans*-(XLII) surpassed quinidine by almost 4 times in therapeutic index.

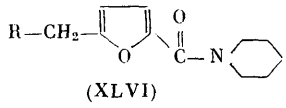


(XLII)



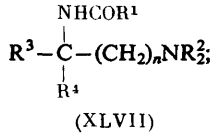
Study of cyclic analogues of novocainamid led to the design of new drugs for the treatment of disturbances of cardiac rhythm, viz. flecainide (XLIII),[190] encainide (XLIV) and lorcainide (XLV).[191]

(XLIII)



(XLIV)

(XLV)



Antiarrhythmic activity is possessed by preparations from the *N*-aryl-8-pyrrolidizinalkanamide[192] and 2-ethoxycarbonylaminophenothiazine[193] series. The synthesis of aminoamides of the furanoic acid series (XLVI) has been reported.[194] Investigations of coronary vasodilator activity showed that the citrates and hydrochlorides of these compounds increase the rate of coronary blood flow by 87–120%.[194]

(XLVI)

R = NC_5H_{10}, HN— etc.

Quite recently a communication[195] appeared on the synthesis and study of the antiarrhythmic and anaesthetic activity of aliphatic-aromatic aminoamide (XLVII) which are analogues of novocainamid with secondary and tertiary carbon atoms on the amide group and various lengths of carbon chain.

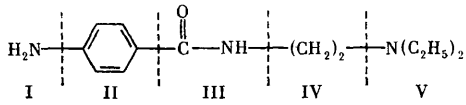
(XLVII)

R^1 = H, CH_3, $CH=CH_2$, C_6H_5, $CH_2C_6H_5$, $CH_2OC_6H_5$, RC_6H_4; cycloalkyl, adamantyl; NR_2^2 = $N(CH_3)_2$, $N(C_2H_5)_2$, piperidino, morpholine, $N(C_3H_7)_2$, $N(C_4H_9)_2$, R^3 = alkyl, C_6H_5, $C_6H_4R^5$; R^4 = H, alkyl; n = 1 to 8.

It was shown that removal of the amino or amide group led to loss of activity. Local anaesthetic and antiarrhythmic effects depend on the character of the amino group (NR_2^2) group and fell in the series

Maximum activity was detected for amides of substituted benzoic, adamantanecarboxylic and cyclohexanecarboxylic acids, and minimum for amides of acetic acid. Amides of phenylacetic and phenoxyacetic acids occupy an intermediate position. The introduction of substituents into the benzene ring (R) leads in the general case to a reduction in antiarrhythmic action and toxicity, but local anaesthetic activity depends on the nature of this susbtituent. Donor substituents reduce the activity and acceptor substituents enhance it, halogens increase the local anaesthetic action.

Substitution in the benzene ring of the main chain (R^5) leads to an increase in antiarrhythmic and local anaesthetic action along the series H→CH_3→Br→Cl. The determining influence on the pharmacological action of aminoamides (XLVII) proved to be multiple. All forms of activity have several maxima at various values of *n*.

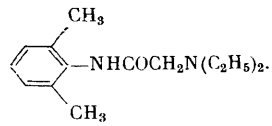


It follows from the data presented that aminoamides differing in chemical structure to a significant degree display antiarrhythmic activity.

Modification of the novocainamid molecule, as the first antiarrhythmic of the monoacylated diamine type of aminoamide, led to the design of a large number of compounds, among which are substances displaying high antiarrhythmic activity.

The multiplicity of chemical structures and the differences in methods of determining antiarrhythmic activity do not permit an unequivocal analysis of the influence of structure on activity. Quantitative data on activity and toxicity are frequently absent.

However it is possible to draw certain conclusions on the dependence of antiarrhythmic activity on the chemical structure of compounds.



It is possible to divide the novocainamid into five portions which are subject to modification.

I. Acylation of the NH_2 group by fatty acid derivatives leads to an increase in antiarrhythmic activity.[28,160,163] Alkylation also enhances it.[162] Sulphonation of the amino group prolongs the antiarrhythmic action of a preparation.[178] Replacment of the NH_2 group by chlorine or by an ethoxy group leads to loss of antiarrhythmic action.

II. Introduction of various substituents into the *ortho*-position of the benzene ring (Cl, *O*-alkyl, alkyl) increases activity.[27,161,165] The introduction of methoxy groups into the benzene ring increases activity significantly. However in a series of quinoline analogues of novocainamid chlorine substituted derivatives were more active than methoxy compounds.[167,180–189] Replacement of the benzene ring by non-benzenoid systems does not make a significant contribution to antiarrhythmic properties, although *ortho* substitution frequently leads to an increase of activity.[25,166,169,170,177]

III. Inversion of the amide group transforms monoacylated diamines into the aminoacid series. Simple inversion in the novocainamid molecule leads as a rule to a reduction in anti-arrhythmic effect.[165] However the known effective anti-arrhythmic lidocaine (XLVIII) is dimethylaminoacetylxylidine and a large number of its derivatives display antiarrhythmic activity.[3,167]

(XLVIII)

Replacement of the amide group by imido and sulphonamide groups leads to the appearance of new classes of potential anti-arrhythmics.[172–174,184] Arylation of the amide nitrogen in the novocainamid molecule also shows a positive influence on the antiarrhythmic properties of compounds.[176]

IV. An increase in the hydrocarbon chain leads to an increase in the activity of substances,[168,169] although several maxima in activity were observed at various chain lengths.[195] Antiarrhythmic action of compounds increases by several orders of magnitude in comparison with that of novocainamid. The introduction of alkyl[178,179] and aryl radicals[195] into the hydrocarbon chain has a positive influence on activity. Inclusion of nitrogen atoms in one saturated ring leads to loss of antiarrhythmic activity.[181] The inclusion of saturated rings in the hydrocarbon chain between the amino and amide groups may prove to be promising.[184,187–191]

V. The presence of an amino group in the amide molecule is very important for antiarrhythmic activity.[195] It may be secondary in character.[175,177,190] However the majority of the antiarrhythmics of the monoacylated diamine series contain a tertiary amino group in the form of a dialkylamino group, alkylarylamino groups or saturated cyclic amines. In several cases it was shown that cyclic saturated amines increase antiarrhythmic action,[119] replacement of one of the alkyl groups by an aromatic group is also useful.[171]

At the present time there is no conclusive hypothesis on the link between the structure of chemical compounds and their biological activity. It is evident that every change in the conformation of a molecule is accompanied by changes in physiochemical properties and influences its ability to be absorbed, to pass through a membrane to interact with cellular enzymes and receptors.

It has been reported[167,188,189] that among aminoamide derivatives of quinoline which are antiarrhythmically active the *trans*-isomer is as a rule more active.

There are data on the resolution of racemic aminoamides into optical antipodes.[124,184,195,196] Results of pharmacological testing show that the (+) (*S*)-isomer of propionic acid dialkylamino-ethylamide was more active in analgesic activity than the (–) (*R*)- and (±)-isomers.[124]

The preparation flecainide shows approximately the same antiarrhythmic activity for both enantiomers and the racemate.[196] A higher antiarrhythmic and local anaesthetic activity was noted for the (+) (*R*)-isomer than for the (–) (*S*)- and (±)-isomers in a series of dialkylaminopentylamides.[195] The enantiomers also differed in toxicity.

Conclusions have been drawn on the influence of basicity[190] and lipophilicity[197] on the antiarrhythmic properties of aminoamides. The more basic and the better soluble in lipids a substance is then the higher the antiarrhythmic activity it displays.

- - - o0o - - -

Several publications on the synthesis,[199,200] biological action[200] and study of the interconnection of structure and biological activity[201] of aminoamides have appeared since the manuscript was prepared for printing.

In spite of the large number of publications devoted to the search for promising antiarrhythmics and of the significant quantity of antiarrhythmic preparations used in therapy, the search for new active compounds is as pressing as ever.[3] There is a need for long-acting drugs with low toxicity. There is a requirement for preparations to treat post-infarct disturbances. One of the most rational approaches in the search for promising new compounds is the investigation of the dependence of activity on structure in chemical series among representatives of which active anti-arrhythmics have been detected.[198]

The available data on practically useful properties of *N*-substituted aminoamides and the interesting chemical and physicochemical properties discovered separate them into a discrete class of organic compounds which is of interest not only for chemistry but also for other regions of science and technology.

Amperometric sensors based on immobilised enzymes

G K Budnikov, E P Medyantseva, S S Babkina
Ul'yanov-Lenin Kazan State University

ABSTRACT. The state, problems, and prospects of the development of one of the new fields of analytical chemistry—"reagent-free" analytical methods—are described and surveyed using as an example enzyme-based amperometric sensors. Questions associated with the design of biosensors and the characteristics of their functioning under various conditions are examined. The applied aspects of the use of enzyme electrodes of this type in various fields of science and the national economy are noted.

The bibliography includes 134 references.

I. Introduction

One of the most important problems in analytical chemistry is the creation of sensitive and selective methods which would make it possible to analyse biological objects. In connection with ecological problems, the task has become of still more urgent interest. The use for these purposes of enzymes—preparations or biological materials containing them—which can be called new generation analytical reagents, proved to be attractive and promising.

Enzymes as biological catalysts exhibit a very high catalytic activity combined with a high specificity. These factors combined with the mild conditions under which enzyme reactions take place, the possibility of recording the useful signal, and also the advances achieved in the field concerned with the creation of stabilised enzyme preparations via immobilisation[1–6] have ensured the development of a new aspect of analytical chemistry—"reagent-free" analytical methods based on the use of biochemical sensors (biosensors).[7]

A biochemical sensor usually consists of some kind of physicochemical detector-sensor (electrochemical, solid-state, opticoelectronic, enthalpimetric, etc.) and a layer of immobilised enzyme fixed on its surface or near it. Many biosensors contain a semipermeable membrane.[7–9] The principle governing their activity is based on the diffusion of the substrate into a thin layer of biocatalyst, in which the enzyme reaction takes place, and on the determination of any component of the enzyme reaction (product or substrate) by some kind of sensor. If electrochemical sensors are used (ion-, gas-, and molecule-selective electrodes, etc.), then, depending on the measured quantity (current or potential), the biosensors (their initial name was "enzyme electrodes") are divided into potentiometric and amperometric.[10] The potentiometric biosensors exhibit a linear dependence of the potential on the logarithm of the concentration of the substance determined, while in the amperometric sensors the analytical signal is the current of the electrochemical reaction, which depends on the concentration of the compound to be determined.[10,11] Differences are observed in the range of the component concentrations determined and in the response time.

Since the first mention of enzyme electrodes in 1967 by Updike and Hicks,[12] the interest in this field of bioelectroanalytical chemistry has continuously grown. The number of publications has increased every year. Symposia and conferences devoted to electrochemical biosensors and related questions are held annually, i.e. the world interest in this problem is extremely high. This is in fact not surprising because enzyme electrodes make it possible to solve successfully a whole series of complex problems in the analysis of enzyme substrates, activators, and inhibitors; they are extremely promising in biochemical analysis, medicine, and pharmacology.[13,14] Furthermore, effective electroanalytical analysers have already been created on the basis of enzyme electrodes which combine the specificity of biocatalysts with the high sensitivity of electrochemical apparatus.[15]

This review is devoted to one of the types of biosensors with amperometric signal indication and covers the literature from 1977 up to the present time. A systematic account of earlier data has been given elsewhere.[7,8,10,11,16] It may be of interest to mention them in connection with the establishment of the field of electroanalytical chemistry and bioelectrocatalysis.[17] A whole series of subsequent reviews were devoted to the description of a large number of enzyme systems and a wide variety of amperometric sensors based on them.[18,19] Most attention has been devoted to the theoretical description and properties of various types of enzyme electrodes[18–24] and their components,[21] questions of the kinetics of enzyme reactions,[25–27] and the conditions under which electrodes operate (*in vivo* and *ex vivo*).[28,29] From year to year, the number of new enzyme electrodes has increased and the range of their applications has expanded.[30] However, despite the wide variety of enzyme sensors, there exist unique methodological approaches to their design and unique requirements as regards the function of the electrodes and also the methods for monitoring the stability and reproducibility of the readings.[31]

Modern enzyme electrodes make it possible to determine with a high sensitivity and selectivity many organic and inorganic substances which are enzyme substrates, inhibitors, and activators, i.e. direct and indirect participants in enzyme reactions. The sensitivity of many biosensors reaches in some cases several picomoles per litre.[30]

Reviews[32,33] as well as proceedings of symposia and conferences[13,34–39] have been devoted to problems of the practical application of enzyme electrodes in clinical research, microbiology, immunology, other branches of medicine, as well as ecology and agriculture. The undoubted economic gain in the application of

enzyme systems in analysis[37,40] and good prospects for the use of biosensors *in vivo* and *in vitro*[38,41] have been noted.

Despite the sudden rise in the interest shown by various investigators in this field of knowledge, which has been reflected in the publications mentioned above, one should note that the bibliography in the reviews, which appeared relatively quickly, reflects the "specific" interest of the authors and is as a rule not repeated, so that each review constitutes a supplement to the others.

II. Amperometric sensors based on various enzyme systems

Analysis of the literature on problems associated with the preparation of biosensors makes it possible to distinguish four main stages in the preparation of any enzyme electrode:[16] the choice of enzyme as a reactant; the preparation of the enzyme; the immobilisation of the enzyme; the construction of the enzyme electrode itself.

It is also necessary to note that the choice of the method of recording the useful signal, i.e. the choice of a particular (in the given instance electrochemical) sensor, is important in the preparation of the electrode. It is possible to make electrodes of three types: type A—dialysis membrane electrode; type B—with physical deposition of the enzyme on the surface; type C—with direct immobilisation of the enzyme on the membrane.[16]

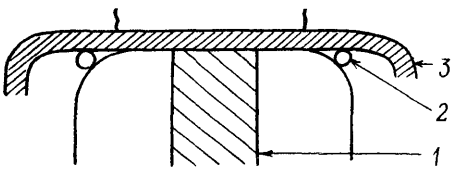

Figure 1. Schematic diagram of an enzyme glucose electrode prepared on the basis of a membrane oxygen sensor:[8] *1*, cathode; *2*, reference electrode; *3*, semipermeable Teflon membrane; 4, enzyme gel layer.

The first biosensor was a type A enzyme electrode for the determination of glucose, which was constructed on the basis of the Clark cell (electrode) where glucose oxidase was retained in the form of a thin layer between two dialysis membranes.[7,8] Subsequently the glucose oxidase solution was replaced by glucose oxidase immobilised in a polyacrylamide gel. The design of one of the first biosensors is illustrated in Fig. 1.[8] At the present time the enzyme electrode is represented by a two-membrane model (Fig. 2),[42] which makes it possible to obtain by theoretical analysis complete and approximate equations characterising the stationary behaviour of monoenzyme electrodes over the entire substrate concentration range. It is possible to estimate the influence of various factors, such as the diffusion layer and the ratio of the thickness of the enzyme-containing layer and of the outer membrane, on the working characteristics of the sensors.

It has also been suggested that the enzyme preparation be fixed on the surface of the stirrer or on the surface of an easily replaced stationary component placed within the enzyme reactor, which improves, according to the authors,[43] a number of analytical characteristics of such designs.

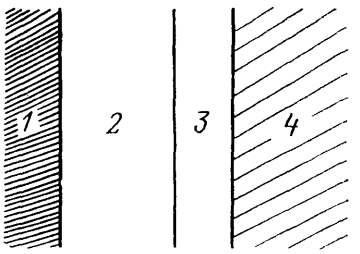

Figure 2. General schematic arrangement of the enzyme electrode:[42] *1*, indicator electrode (planar); *2*, layer of immobilised enzyme; *3*, outer membrane; *4*, substrate solution being analysed.

The operation of enzyme electrodes is based on the direct electron transfer between the active centre of the immobilised enzyme and the surface of the electrochemical sensor, which is frequently modified in some way. However, electron transfer can be effected also with the aid of special mediators.

The principal requirements which must be met by the mediators can be formulated as follows:[44,45] the stage in which the mediator interacts with the active centre of the enzyme must be rapid, i.e. the mediator must in essence behave as an enzyme substrate; the oxidation-reduction potential of the mediator must be low and must be independent of the pH; the mediator must be oxidised (or reduced) electrochemically at the electrode made from the given material under conditions close to reversibility; the electron transferring agent must be stable (its reduced form must not be oxidised, for example, by atmospheric oxygen).

Low-molecular-weight compounds characterised by a high mobility of the electrochemical equilibrium are most often employed as mediators. These are dyes, quinone type compounds, hexacyanoferrates-(II) and -(III), and conducting organic salts, i.e. molecules and ions which exist in solution in two forms corresponding to different oxidation states of one of their constituent elements.[21,25,26] Thus the choice of mediator constitutes a special problem.

1. Biosensors for the determination of glucose

It is noteworthy that the greatest number of various biosensors and the corresponding analytical devices have been created at the present time for the determination of glucose. This is associated with the need to monitor the sugar content in biological liquids not only for the diagnosis but also for the therapy of a whole series of diseases. Soviet designs for the industrial production of such analysers are already available.[9]

All the enzyme electrodes for glucose with amperometric indication, which employ the ability of glucose to be oxidised [Eqn. (1)], are constructed on the basis of Clark oxygen electrodes, peroxide electrodes, or certain other detectors.[46]

Electrodes made of platinum, gold, silver, or rhodium are used as indicator electrodes in Clark oxygen cells and its modifications. The electrode component is as a rule separated from the object analysed and the solution by a thin polymer film which is impermeable to both high- and low-molecular-weight compounds but is permeable to oxygen (Fig. 1).

The principle of the operation of such an electrode is simple: the enzyme catalyses the removal of oxygen from the solution at a rate which depends on the glucose content and this is indicated by the oxygen electrode:

$$\text{glucose} + O_2 + H_2O \xrightarrow{GO} \text{gluconic acid} + H_2O_2; \quad (1)$$

GO = glucose oxidase.

The principal advantage of oxygen sensors is the simplicity of their preparation, high stability, selectivity, and reproducibility of the readings, and a fairly high sensitivity.

The oxidation of hydrogen peroxide [Eqn. (2)] usually follows reaction (1), which can be detected by appropriate electrodes corresponding to hydrogen peroxide:

$$H_2O_2 \longrightarrow O_2 + 2H^+ + 2e\ . \quad (2)$$

Such sensors are made from various materials (platinum, gold, and nickel, graphite). A distinct diffusion current makes it possible to use reaction (2) for the quantitative determination of glucose (at a platinum electrode, this reaction is observed at 0.6–0.7 V relative to s.c.e.†). Analysers for hydrogen peroxide are distinguished by a short reponse time in the range 45–60 s (120 s for a continous flow-type blood analyser), but their selectivity is lower because at the H_2O_2 oxidation potentials a number of organic compounds, which may be present in the specimen, also undergo electrochemical reactions.

Apart from glucose analysers with an oxygen electrode and with a hydrogen peroxide electrode, devices have been developed in which the enzymic oxidation of glucose is effected not by oxygen but by another oxidant, for example potassium hexacyanoferrate(III):

$$CH_2OH(CHOH)_4CHO + H_2O + [Fe(CN)_6]^{3-} \longrightarrow$$

$$\longrightarrow CH_2OH(CHOH)_4COOH + [Fe(CN)_6]^{4-}. \quad (3)$$

The hexacyanoferrate(II) formed as a result of reaction (3) is oxidised at a platinum electrode:

$$[Fe(CN)_6]^{4-} \longrightarrow [Fe(CN)_6]^{3-} + e. \quad (4)$$

Reaction (4) takes place at a potential of −0.5 V relative to a silver,silver chloride reference electrode, which serves simultaneously as an auxiliary electrode.[46]

The hydrolysis of glucose takes place also with participation of quinone. The hydroquinone formed is usually detected by a platinum electrode. This principle is used in a glucose sensor with glucose oxidase (GO) immobilised on cellophane.[15] Enzyme electrodes for glucose, based on similar principles and developed previously, have been described in detail.[7,8,10,11] The use of various carbonaceous materials as the electrochemical sensor proper in similar devices has been described by Razumas et al.[21] A whole series of studies in this field have been described by Sorochinskii and Kurganov.[30]

The characteristics of various enzyme sensors, including those for the determination of glucose, are compiled in Table 1.

An enzyme electrode has been developed for the determination of glucose with the aid of which one can follow the variation of the H_2O_2 concentration in the molybdenum(VI)-catalysed reaction with iodide ions:

$$H_2O_2 + 2H^+ + 2I^- \xrightarrow{Mo(VI)} I_2 + 2H_2O. \quad (5)$$

By varying the rate of rotation of a disc electrode with a ring, on which glucose oxidase has been immobilised, one can determine the rate of mass transfer of the substrate and the rate of the catalytic reaction. The life of such an electrode is about 6 days.[47] The advantages of using rotating electrodes of the "disc with a ring" type in amperometric sensors have also been discussed by Guilbault.[20]

In the development of glucose sensors, glucose oxidase was immobilised in three ways: (1) by covalent grafting by means of a bifunctional reagent (glutaraldehyde) on a modified silica carrier Silochrome S-50; (2) with the aid of a synthetic water-soluble acrolein–vinylpyridine copolymer; (3) by oxidising the carbon components of the enzyme. The carrier with the immobilised enzyme was placed on the bottom of the cell under a porous nylon filter. With the aid of this type of enzyme sensor, it is possible to carry out in the course of two weeks more than 200 determinations of standard glucose solutions relative to a single calibration graph. The electrode response time is 10–15 s. The immobilised glucose oxidase preparation, obtained by oxidising the hydrocarbon components of the enzyme, was stored for more than two months at room temperature without loss of activity.[50] The relative standard deviation of a single determination (s_r) was about 0.03 in the substrate concentration range 0.18–0.10 g ml^{-1} and 0.13 for a substrate concentration of 0.005 mg ml^{-1}.[50] In order to increase the rate of electron transfer, various mediators are used, as mentioned above, in many biosensors. Thus a selective enzyme electrode has been proposed for the determination of glucose, the mechanism of the response of which is based on the selective oxidation of glucose to gluconic acid by $[Fe(CN)_6]^{3-}$ in the presence of glucose oxidase.[52] The $[Fe(CN)_6]^{4-}$ formed is reoxidised to $[Fe(CN)_6]^{3-}$ on the surface of the indicator enzyme electrode consisting of an aluminium rod whose end-face is coated with a graphite-containing material. A layer of gel with immobilised glucose oxidase, covered by a cellophane membrane, is deposited on the graphite. In the interval between measurements, the electrode was stored at 4 °C in phosphate buffer containing $K_3[Fe(CN)_6]$. The standard deviation s_r was 0.03–0.06 for the glucose concentration range 5×10^{-6}–5×10^{-5} M and was less than 0.03 for higher substrate concentrations.

The response time depends on the glucose concentration and amounts to 2–4 min for low concentrations. The operation of the electrode is stable for at least 3 weeks and the electrode has been used for determining glucose in blood serum and in urine relative to a calibration graph which was plotted daily. The presence of other enzymes, including catalase, does not interfere with the determination.

An enzyme electrode has been described for the determination of glucose in blood and plasma, where ferrocene and its derivatives, oxidised to ferrocenium ions, are used as the mediator between the immobilised glucose oxidase and the graphite electrode.[53] Flavin-adenine dinucleotide has been used for the same purpose.[54]

† Saturated calomel electrode (Ed. of Translation).

Table 1. Analytical possibilities of amperometric enzyme sensors.

Compound determined	Enzyme	Method of immobilisation	Amperometric detector	Range of concentrations determined	Refs.
Glucose	Glucose oxidase	Cross-linking by glutaraldehyde to the surface of the carbon paste containing added amines	Rotating disc electrode with a ring	—	[47]
	"	Cross-linking with albumin	Platinum H_2O_2 electrode	0.05 – 10 mM	[48]
	"	Entrainment in the electrode layer	Two platinum hexacyanoferrate electrodes	6.9 – 27.8 mM	[49]
	"	(a) Covalent grafting by glutaraldehyde on Silochrome S-50; (b) with the aid of a synthetic acrolein – vinylpyridine copolymer; (c) oxidation of hydrocarbon components of enzyme	Clark oxygen electrode	$3.10^{-5} – 1.10^{-3}$ M	[50]
	"	Covalent grafting to polyamide networks	Membrane O_2 electrode	0.1 – 7.0 mM	[51]
	"	Entrainment in the gel in the near-electrode layer	Aluminium rod with a graphite end face on which a layer of gel has been deposited, mediator – $K_3[Fe(CN)_6]$	$5.10^{-6} – 2.10^{-3}$ M	[52]
	"	Covalent grafting to graphite modified by 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide *p*-methyltoluene-sulphonate	Graphite electrode, mediator – ferrocene	1 – 30 mM	[53]
	"	Entrainment in near-electrode layer	Platinum disc covered by a semi-permeable membrane	0.01 – 7.00 mM	[54]
	"	Covalent grafting to collagen films	Platinum H_2O_2 electrode	$10^{-6} – 10^{-3}$ M	[55]
	"	Film with immobilised glucose oxidate	Cathode – silver, anode – platinum	0.8 mg ml^{-1}	[58]
	"	Electropolymerisation of pyrrole in the presence of the enzyme	Platinum or carbon glass electrode	$10^{-4} – 10^{-2}$ M	[57]
	"	Incorporation in a poly-*N*-methylpyrrole film	Platinum disc electrode	0.22 M	[58]
	"	Covalent grafting to a carbon glass electrode via the borate groups of 3-aminophenylboronic acid	Carbon glass electrode modified by 3-aminiphenylboronic acid	—	[59]
	"	Adsorption of glucose oxidase on a modified graphite electrode	Graphite electrode modified by the ionic sputtering of palladium and gold	$3.10^{-6} – 4.10^{-3}$ M	[60]
	"	Homogeneous membrane	Membrane O_2 electrode	1.0 – 5.0 M	[61]
	"	Glucose oxidase modified by the introduction of ferrocene derivatives	—	—	[28]
	"	Incorporation in a semipermeable membrane	Carbon paste electrode modified by *p*-benzoquinone	—	[62]
	"	Incorporation in a semipermeable membrane together with *p*-benzo-quinone	Gold electrode and platinum mesh electrode	—	[63]
	"	Attachment of *p*-benzoquinone-activated glucose oxidase to a cellulose acetate membrane with covalently bound bovine albumin	Platinum electrode	—	[64]
	"	Covalent binding to ferrocene-carboxylic acids	Carbon glass electrode	—	[65]
Uric acid	Uricase	Covalent binding to glutaraldehyde	Platinum electrode with a thin layer of immobilised enzyme	0.02 – 0.08% in serum, 0.25 – 0.75% in urine	[66]
	"	Covalent grafting to porous glass with the aid of glutaraldehyde	Platinum H_2O_2 electrode	2 – 8 mg/100 ml of serum	[67]

Table 1 (contd.).

Compound determined	Enzyme	Method of immobilisation	Amperometric detector	Range of concentrations determined	Refs.
Aromatic amines	Peroxidase	(a) Adsorption; (b) adsorption followed by treatment with glutaraldehyde	Epoxidised carbon glass electrode in a Teflon shell	0.1–3 μM	[68]
Cholesterol	Cholesterol oxidase	Incorporation in a collagen membrane	Membrane O_2 electrode	0–0.2 mM	[69]
	"	Entrainment in a 2-hydroxymethyl methacrylate gel treated with glutaraldehyde	Platinum O_2 electrode	0.4–12 mM	[70]
Ethanol	Alcohol oxidase	Entrainment in near-electrode layer under a nylon film	Platinum disc H_2O_2 electrode	10 mg in 100 g of the substance to be determined	[46]
Lactate ion (lactic acid)	Lactate monoxidase	In a gelatine gel	Clark-type O_2 probe	10^{-5}–6.10^{-4} M	[71]
	Cytochrome b_2	Cross-linking with albumin	Platinum hexacyanoferrate electrode	1.2 mM	[48]
	"	Adsorption on a current conducting matrix	Organic metals	2 mM	[72]
Galactose	Galactose oxidase	Cross-linking with albumin	Electrochemical H_2O_2 sensor	0–27.8 mM	[73]
Phenol	Polyphenol oxidase	Cross-linking with albumin	Membrane O_2 electrode	0–0.08 mM	[74]
Oxalate ion	Oxalate oxidase	Grafting to polyamide membrane	Platinum H_2O_2 electrode	10^{-7}–10^{-4} M	[75]
Pyruvate ion	Pyruvate oxidase	Immobilisation on nylon	Platinum H_2O_2 electrode, O_2 electrode	10^{-3} mM	[76]
Salicylate ion	Salicylate hydroxylase	Chemical immobilisation on the electrode surface	O_2 sensor	10^{-5}–2.10^{-3} M	[77]
Sucrose	Invertase	Adsorption and entrainment in the polymer matrix of poly(vinyl alcohol)	Pyrographite electrode	—	[78]
Acetylcholine, choline	Acetylcholinesterase, cholinesterase	Immobilisation on a nylon mesh in the near-electrode layer	Amperometric H_2O_2 sensor	1–10 μM	[79]
Butylrylthiocholine iodide (BTCI)	Cholinesterase	Incorporation in a polyacrylamide gel with the aid glutaraldehyde	Stationary amalgamated silver electrode	0.05–0.85 mg ml^{-1}	[80]
BTCI and CE inhibitors	Cholinesterase	Covalent grafting to nitrocellulose with the aid of glutaraldehyde	Stationary amalgamated silver electrode	10^{-3}–10^{-6} M 10^{-3}–$n\times10^{-11}$ M	[81] [82]
Indoxyl acetate	"	In a geletine gel on a cellulose hydrate membrane	Carbon glass rotating disc electrode	1.5×10^{-3} M -5.0×10^{-3} M	[83]
Hypoxanthine, xanthine, purine	Xanthine oxidase	Adsorption on the electrode	Conducting organic tetrathiofulvalene$^+$/tetracyanoquinodimethane$^-$ organic salts	10^{-5}–6×10^{-4} M	[84]
NADH	Glucose dehydrogenase	Adsorption on the electrode	*N*-methylphenazene$^+$/tetracyanoquinodimethane$^-$ conducting organic salts	—	[84]
α-Ascorbic acid	Ascorbic oxidase	Plate (5×5×2 mm) made of cucumber (pumpkin) skin	Clark oxygen electrode	—	[85]
Dopamine, dopaminequinone	Polyphenol oxidase	Tissue of banana fruit	Carbon paste electrode	1.3×10^{-6}– 9×10^{-5} M	[86]
Glycerophosphate	α,α-Glycerophosphate oxidase	Cross-linking with the surface of a Teflon membrane with the aid of serum albumin and glutaraldehyde	Clark oxygen electrode	—	[87]
Choline-containing lipids	Choline oxidase	Physical immobilisation—incorporation in a cellulose triacetate membrane	"	3.3×10^{-5}– 8.6×10^{-5} M	[88]
Maltose, glucose	Glucoamylase, glucose oxidase	Covalent grafting to collagen films	Platinum anode, H_2O_2 electrode	5×10^{-8} M (after two months, 2.5×10^{-7} M)	[55]
Cholesterol	Cholesterol oxidase, cholesterol hydrolase	Entrainment in a 2-hydroxymethacrylate gel treated with glutaraldehyde	Platinum oxygen electrode	4×10^{-4}– 12×10^{-3} M	[70]

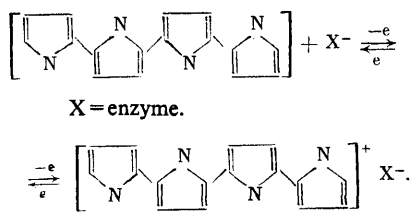

Table 1 (contd.).

Compound determined	Enzyme	Method of immobilisation	Amperometric detector	Range of concentrations determined	Refs.
Aromatic amides	Peroxidase, glucose oxidase	Covalent grafting of glutaraldehyde to the electrode surface	Carbon glass electrode	4.7×10^{-5} M	[68]
Glucose	Glucose oxidase, catalase	Entrainment in a homogeneous membrane in the near-electrode layer	Membrane oxygen electrode	1×10^{-3} M	[61]
Ethanol	Alcohol oxidase, peroxidase	Membrane in the near-electrode layer	Carbon glass electrode	—	[89]
Uric acid	Uricase, peroxidase	Covalent grafting to albumin with glutaraldehyde on a dialysis membrane	"	$(0.5-10)\times10^{-5}$ M	[90]
α-Lactate ions, pyruvate ions	Lactate oxidase, lactate dehydrogenase	Grafting to a Teflon membrane	Clark oxygen electrode	8×10^{-8}–8×10^{-6} M	[91]
Glucose, urea	Glucose oxidase and uricase	Covalent grafting by means of glutaraldehyde to graphite	Graphite electrode	$0-7\times10^{-6}$ M	[92]

Collagen films, on which the enzyme is immobilised, are subjected to preliminary activation by the acyl-azide method.[55] A platinum electrode is coated by a collagen membrane with immobilised glucose oxidase and is dried for periods ranging from 2 days to 2 weeks before measurements. Between measurements, the electrode is stored in air, since dehydration entails a denser coating of the platinum electrode by the membrane which facilitates the diffusion of H_2O_2 to the electrode. After inserting the electrode in the solution, the membrane remains tightly attached to the electrode. The resulting electrode is stable for a month or 160 days when the glucose content is measured. The response time before drying was somewhat more than 10 min, while after drying for 2 days it improved by 35% and was only 4–8 min.

In order to eliminate the interfering effect of ascorbic and uric acids, bilirubin, and aminoacids in the analysis of biological liquids for glucose, a cellulose acetate diaphragm permeable only to low-molecular-weight compounds with a small molecular size is introduced into the enzyme electrode between the membrane with the immobilised glucose oxidase and the platinum anode.[56] The standard deviation s_r in the determination of 0.20 mg ml^{-1} glucose was 2–3% (the number of determinations was 20).

One of the promising ways of obtaining enzyme electrodes involves the immobilisation of the enzyme in polymer coatings directly on the surface of the electrochemical sensor itself. The monomers, from which the polymer can be produced, are polymerised and the polymer macromolecules are cross-linked in the layer near the electrode. This new interesting method of immobilising glucose oxidase via electrochemical polymerisation has been described by Umana and Waller[57] and Bartlett and Whitaker.[58] For example, glucose oxidase is entrained by a polypyrrole film growing on the electrode surface.[57] This immobilisation procedure has a number of advantages. Polypyrrole, which is a conducting organic material, and the product of the enzymic reaction with glucose are in the immediate vicinity of the conducting material. The H_2O_2 concentration is also monitored from its reaction with the iodide anion (I^-), which is followed by the electrochemical reduction of iodine at a potential $\leqslant$0.2 V relative to the saturated calomel electrode:

X = enzyme. (6)

The electrode obtained is stable for 7 days. The preparation of immobilised glucose oxidase in a poly-*N*-methylpyrrole film for the preparative electrochemical oxidation of *N*-methylpyrrole on a platinum disc in the presence of 0.1 M $(C_2H_5)_4NBH_4$ supporting electrolyte in an aqueous phosphate buffer (pH 7.2) containing 1 μg ml^{-1} of glucose oxidase has been described.[53] It was shown that the H_2O_2 formed is oxidised on the rear surface of the platinum and not on the polymer film. The electrode response is observed at 0.95 V (relative to the saturated calomel electrode).

Direct electron transfer also takes place between glucose oxidase and the surface of a carbon glass electrode modified with 3-aminophenylboronic acid.[59]

An interesting electrode has been proposed by Jonsson and Gorton.[60] They noted that the partial removal of oxygen from the solution analysed lowers the electrode response, but the oxygen contained in the enzyme layer on the graphite electrode is sufficient to maintain the linearity of the calibration plot in the determination of glucose at concentrations $\leqslant$1 mM. The apparent rate constant for the Michaelis–Menten enzyme reaction is ~50 mmol. The stability of the response of the electrode obtained depends on the pH, the potential applied to the electrode, and the frequency at which samples are introduced.

A stable and fairly rapid response of the enzyme electrode is usually observed when only the glucose concentration is varied.[61] The same workers established that the response time can be reduced by diminishing the thickness of the membrane in the layer near the

electrode and by increasing the catalytic constant for the immobilised enzyme. In order to optimise the electrode response, variations in the thickness of the membrane and in the diffusion coefficient have been examined. Yet another model of the enzyme electrode for glucose has been proposed.[28] In this model, the electron-transferring agent is incorporated in the structure of glucose oxidase. Thus a modified glucose oxidase was obtained with the aid of ferrocene and its derivatives and was then deposited on the electrode. Glucose was oxidised even in the absence of oxygen directly on the electrode.

p-Benzoquinone, already mentioned, was used as the mediator.[62] It is introduced into the bulk of a carbon paste electrode whose surface is covered by a semipermeable membrane with the immobilised glucose oxidase. A similar procedure has been used also for other enzymes (gluconate dehydrogenase, ethanol dehydrogenase).

The possibility of using gold electrodes coated by a film of glucose oxidase with *p*-benzoquinone and of platinum mesh electrodes coated by a glucose oxidase film and covered by an oxygen-permeable membrane has been demonstrated.[63] One of the latest varieties of the glucose electrode has been described by Steruberg et al.[64] (Fig. 3). The immobilisation procedure proposed by the authors makes it possible to obtain membranes with a high surface activity, which are stable for a month and longer. Electrochemical monitoring and monitoring with the aid of radioactive labels demonstrated only a slight inactivation of the enzyme on immobilisation.

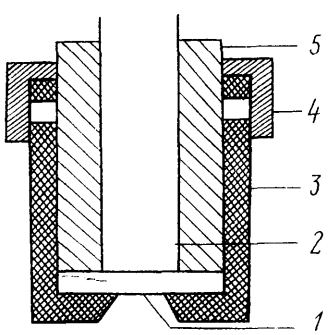

Figure 3. Schematic diagram of a rotating membrane glucose electrode:[64] *1*, membrane containing the immobilised enzyme; 2, platinum electrode (axis of rotating electrode); *3*, membrane holder; *4*, threaded lock ring; *5*, electrode shell.

The covalent binding of glucose oxidase to ferrocenecarboxylic acids has also been proposed.[65] The catalytic constant is a maximum when glucose oxidase is modified with ferroceneacetic acid.

The measurement of the response of a platinum electrode coated by a layer of immobilised glucose oxidase as a function of time and substrate concentration demonstrated a satisfactory correspondence between theoretical ideas and experiment.[93] The variation of the concentration profiles in the mathematical model of a multilayer enzyme sensor also agrees satisfactorily with the experimental findings for a commercial sensor for the determination of glucose.[94] These calculated concentration profiles describe the operation of the sensor more satisfactorily than the single-layer model.

2. The use of various enzymic reactions in biosensors

The glucose electrodes constitute the largest group of amperometric enzyme sensors. Other enzymes and enzymic reactions have so far been used much more rarely for such purposes (Table 1).

For example, uric acid is determined with the aid of enzyme sensors based on immobilised uricase:[66,67]

$$\text{uric acid} + O_2 + H_2O_2 \xrightarrow{\text{uricase}} \text{allantoin} + CO_2 + H_2O_2. \qquad (7)$$

A decrease in the amount of dissolved oxygen during the oxidation of the substrate has been detected at −0.6 V (relative to the saturated calomel electrode) by a platinum electrode with a thin layer of immobilised enzyme.[66] The error of the determination does not exceed 4% in the determination of uric acid in urine and 6% in its determination in blood serum. When the electrode is used several times per week, its activity diminishes by only 29% in the course of 100 days.

The use of covalent grafting of the enzyme to the porous glass of the electrode by glutaraldehyde has been described.[67] Such an electrode proved to be very stable during operation (~10 months), which permitted its employment under flow conditions.

The operation of electrodes with peroxidase is based on the oxidation of the hexacyanoferrate(II) ion by hydrogen peroxide catalysed by immobilised peroxidase:

$$H_2O_2 + 2[Fe(CN)_6]^{4-} + 2H^+ \xrightarrow{\text{peroxidase}} 2H_2O + 2[Fe(CN)_6]^{3-}. \qquad (8)$$

The hexacyanoferrate(III) ion formed is reduced at a carbon glass electrode at 0 V (relative to the silver,silver chloride electrode).[68] In the presence of aromatic compounds, which activate the peroxidase oxidation of hexacyanoferrate(II), the rate of the enzymic reaction and the cathodic current increase, which makes it possible to carry out the determination of, for example, a series of aromatic amines.[68] The range of the measured concentrations varies as a function of the type or substrate. The lower limits of the measurable concentrations of *o*-dianisidine and benzidine are 0.055 and 0.065 μmol, while for the remaining compounds investigated the limit is higher. The coefficient of the sensitivity of the above enzyme electrodes varies from 0.215 to 0.0022 μA μmol^{-1} on passing from *o*-dianisidine to 1,2-diaminobenzene. For electrodes of the second type (Table 1), this coefficient is higher, as a result of which the lower limit of the measurable contents of aromatic amines is appreciably reduced.

Cholesterol is one of the physiologically important components of blood. Under the influence of cholesterol oxidase, cholesterol is oxidised:

$$\text{cholesterol} + O_2 \xrightarrow{\text{cholesterol oxidase}} \text{cholest-4-en-3-one} + H_2O_2. \qquad (9)$$

A series of enzyme electrodes have also been developed for its determination.[46,69,70] The readings are based on the H_2O_2 reduction current at a platinum oxygen electrode on the surface of which a gel with the immobilised enzyme is deposited.[70] The gel is retained by two membranes: the inner membrane made of cellulose acetate and the outer membrane made of silk. The electrode response time is 0.5 min in the flow regime and 2 min in the static regime. The standard deviations s_r are 0.027 and 0.045 in each regime respectively.

Enzyme electrodes have been developed for the determination of ethanol in blood.[46] Alcohol oxidase is immobilised on the surface of a platinum disc electrode. At a potential of −0.6 V, the loss of oxygen, which is proportional to the ethanol content, is measured:

$$RCH_2OH + O_2 \xrightarrow{\text{alcohol oxidase}} RCHO + H_2O_2. \quad (10)$$

Alcohol dehydrogenase is used for the same purposes,[46] nicotinamide-adenine dinucleotide (NADH) and flavin mononucleotide (FMN) participating in the enzyme reaction and the chemical reactions associated with it. Reduced FMN is oxidised at a platinum anode, generating a current proportional to the ethanol concentration in the test solution. The enzyme–electrode processes occurring in the amperometric sensors based on membranes with immobilised lactate dehydrogenase are similar to the processes observed in the determination of ethanol with participation of FMN, but are used to determine lactic acid.[46]

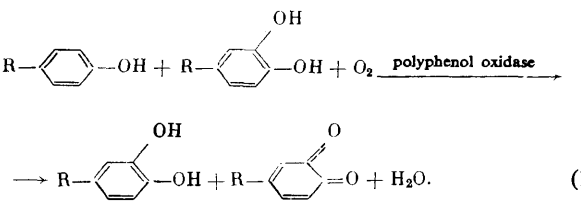
The lactate sensor makes it possible to avoid the use of NADH and FMN. The following enzyme reaction takes place in it:

$$CH_3CHOHCOO^- + 2[Fe(CN)_6]^{3-} \xrightarrow{\text{lactate dehydrogenase}} CH_3COCOO^- + 2[Fe(CN)_6]^{4-} + 2H^+. \quad (11)$$

The choice of the optimum parameters, especially the thickness of the membrane, makes it possible to determine the amount of lactate in blood in 1 min without preliminary preparation. Apart from the platinum electrode, gold or carbon working electrodes can be used.[46]

An automatic analyser with an enzyme sensor has been described for the determination of the concentration of lactate ions and the measurement of the activity of lactate dehydrogenase.[71] The enzyme sensor consists of the so called oxygen probe of the type of the Clark electrode on which is fixed a layer of gelatin where lactate monoxidase is immobilised. The standard deviation s_r is less than 0.01. The enzyme sensor operates stably for 55 days. After the addition of NADH and pyruvate ions to the sample, it is possible to carry out in succession a determination of the lactate ions and the estimation of the activity of lactate dehydrogenase, for which the calibration plot is linear in the range 2.7–54.0 units of biological activity per litre.

Apart from lactate dehydrogenase, the enzyme cytochrome b_2, which catalyses electron transfer to mediators, i.e. $[Fe(CN)_6]^{3-}$, can also be used for the determination of lactic acid in such analyses.[48,72]



Certain improvements to enzyme electrodes have been proposed.[95] The essential feature consists in the fact that ionic compounds (C_{10}–C_{30} carboxylic acids, etc.) or non-ionic compounds [4,4′-bipyridyl, 1,2-bis-(4-pyridyl)ethylene, etc.] are introduced into the electrically conducting support made from powdered graphite, pyrographite, and metals. Functional groups for the orientation and fixation of electroactive enzymes such as cytochrome b_2, cofactors, or other biocatalysts are then formed on the surfaces of such electrodes. The surfaces of the carbon-containing supports can be coated by functional oxygen-containing groups by simple chemical oxidation. The advantage of the proposed "functionalised" electrodes consists particularly in the fact that the biocatalysts are in direct contact with the support, i.e. with the electrode itself. The oxidation or reduction of organic substrates therefore takes place under the influence of enzymes without the additional introduction of oxidants, reductants, or mediators into the solution. Such electrodes can be used not only for electroanalytical purposes but also for specific electroorganic synthesis. Enzyme electrodes are also employed for the determination of aminoacids.[8,46] Here the membrane with the covalently immobilised amino-oxidase catalyses the reaction

$$RCHNH_2COOH + O_2 + H_2O \xrightarrow{\text{amino-oxidose}} RCOCOOH + NH_3 + H_2O_2. \quad (12)$$

The enzyme exhibits group specificity and catalyses the oxidation of all the *L*-aminoacids present in the liquids analysed.

For the determination of galactose[73] and phenols,[74] enzyme electrodes have been developed whose operation is based on the reactions

$$\text{galactose} + O_2 \xrightarrow{\text{galacto-oxidase}} \text{galactosoaldehyde} + H_2O_2, \quad (13)$$

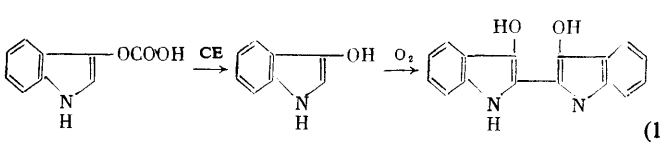
(14)

A simple and rapid method for the determination of oxalate ions in food products with a minimum of auxiliary operations has been developed. It is based on the use of a new voltammetric enzyme sensor.[75] Oxalate oxidase is immobilised on a commercial polyamide membrane. The response time of the sensor ranges from 20 to 60 s depending on the concentration of $C_2O_4^{2-}$ ions. The analytical signal is stable for almost 150 days.

A sensor, whose operation is based on the oxidation of pyruvate by dissolved atmospheric oxygen in the presence of HPO_4^{2-} ions with formation of H_2O_2, is used in clinical analysis for the determination of pyruvate ions. The process is monitored with the aid of an oxygen or H_2O_2 electrode.[76]

An enzyme electrode for the determination of salicylates in blood serum has been developed on the basis of salicylate hydroxylase immobilised on the surface of an oxygen electrode. In the determination, the enzyme sensor is immersed in a solution of a mixture of phosphate buffer with Complexon III (pH 6.75). Next the coenzyme β-NADH is added, after 5–10 min the substrate is introduced, and after 1–6 min the current is measured as a function of the salicylate concentration with the aid of the enzyme electrode[77] (s_r = 0.013–0.106).

Invertase is an enzyme which cleaves sucrose catalytically into *D*-glucose and *D*-fructose. It was immobilised by being incorporated in polymeric coatings at the instant of their formation directly on the surface of the electrode.[78] Polymeric coatings on pyrographite and aluminium electrodes can be obtained by cathodic polarisation in solution in poly(vinyl alcohol) containing boric acid.



Selective biosensors based on immobilised cholinesterase (CE) and the determination of acetylcholine and choline in a 0.1–1 ml sample have been described.[79] The response time is about 1–2 min. The possibility of the simultaneous determination of these compounds in a single sample with the aid of two sensors under both stationary conditions and in a flow system has been demonstrated.

An enzyme electrode has also been proposed for the determination of the concentration of thiocholine esters.[80] The authors used, as the cholinesterase substrate, butyrylthiocholine iodide, which hydrolyses in the presence of cholinesterase:

$$C_3H_7COSCH_2{-}CH_2{-}\overset{+}{N}(CH_3)_3I + H_2O \xrightarrow{CE} C_3H_7COOH + HSCH_2{-}\overset{+}{N}(CH_3)_3I. \quad (15)$$

The determination is based on the electrochemical activity of the hydrolysis product—a thiol. the volume of the solution analysed is 4–5 ml. The error of the determination does not exceed 9%. With the aid of this electrode, it is possible to determine also other thiocholine esters as well as cholinesterase inhibitors, for example, phosphorus-containing pesticides, which is extremely important for the solution of the problem of monitoring the environment. Various procedures for the immobilisation of cholinesterase have been assessed: incorporation in a polyacrylamide gel accompanied by treatment with glutaraldehyde and adsorption on carriers—silica gel, activated charcoal, and various films.[80] The advantages and disadvantages of this procedure as regards use in enzyme sensors have been indicated. An improved model of such a sensor makes it possible to determine phosphorus-containing pesticides and certain physiologically active substances down to very low concentrations of the order of $n \times 10^{-11}$–$n \times 10^{-12}$ M.[81,82]

A number of synthetic compounds, including indoxyl acetate, are also hydrolysed in the presence of cholinesterase. Indoxyl, the product of the hydrolysis of indoxyl acetate, dimerises in the presence of atmospheric oxygen in an alkaline medium (pH 7.5–8.0). The rate of oxidation of indoxyl acetate has been studied with the aid of a carbon glass rotating disc electrode with immobilised cholinesterase:[83]

(16)

Enzyme sensors with conducting organic salts, functioning as the electrode material, have been developed. The possibility of determining hypoxanthine, xanthine, and purine in blood plasma with the aid of xanthine oxidase immobilised on the tetrathiofulvalene$^+$/tetracyanoquinodimethane$^-$ electrode has been demonstrated. The response and stability of the sensor are influenced by temperature, pH, and traces of oxygen. Glucose dehydrogenase, immobilised on the *N*-methylphenazine$^+$/tetracyanoquinodimethane$^-$ electrode, is used to determine NADH.[84]

Various enzyme-containing plant materials, rather than preparations of the enzymes themselves have recently come to be used increasingly in the development of the enzyme electrodes. Plant tissues in biosensors function as sources of catalytic enzyme activity. For example, an enzyme sensor consisting of a Clark electrode and a plate comprising a cucumber or pumpkin skin, which serve as sources of ascorbic oxidase, has been devised for the amperometric determination of α-ascorbic acid.[85] The determinations are carried out in a buffer solution (pH 6.0) with 0.5 mM EDTA. The enzyme activity is sufficient to ensure 50–80 determinations. The plates can be stored, without loss of activity, in 50% glycerol for a year. Phenols, acids, and vitamins B do not interfere with the determination. Ascorbic acid has been determined with the aid of this electrode in juices and pharmaceutical preparations with $s_r = 0.03$.

A similar principle has been used in another study.[86] The tissue of the banana fruit is introduced into a carbon paste electrode and dopamine is determined. The response time of this biosensor is not more than 12 s. The catalytic reaction current increases with increase in the content of the plant tissue in the paste. The optimum content of the tissue is 5.5%. Catechol and hydroquinone interfere with the determination.

Among the latest designs of amperometric sensors based on the Clark electrode, mention may be made of sensor systems for glycerophosphate and choline-containing lipids.[87,88]

New attempts have been made to improve the components of the enzyme oxygen electrode. A film permeable to H_2O_2 and impermeable to substrates has been proposed for this purpose. It is made from polyamides, polyurethane, cellulose acetate, and other polymers or copolymers.[96] Enzymes whose reaction with substrates proceeds with formation of H_2O_2 are immobilised on the porous surface of such films. They include, for example, glucose oxidase, uricase, xanthine oxidase, *D*- and *L*-aminoacid oxidases, as well as enzymes producing substrates for enzymic reactions with liberation of H_2O_2, for example, lipase, mutarotase, and phosphorylase. The smooth side of the film is applied to the surface of a silver anode (other metals are also employed). Such films are very strong, are satisfactorily joined to the electrode, and ensure an effective contact between the enzyme and the substrate, selective permeability, and a high accuracy of the measurements.

3. Polyenzyme biosensors

In those cases where the products or substrates of an enzymic reaction are electrochemically inactive, successive reactions of the substrates with the aid of several immobilised biocatalysts are used in the construction of amperometric sensors. Dienzyme reactions are most often employed. For example, the operation of electrodes sensitive to disaccharides is based on this principle.[10] Two enzymes are usually employed for the determination of lactose and maltose: glucose oxidase, which oxidises glucose via reaction (1), and β-galactosidase or maltase. The disaccharide, diffusing through the membrane, splits off glucose under the influence of the corresponding enzyme and the glucose is then oxidised by glucose oxidase to gluconic acid. The consumption of O_2, which is proportional to the content of the disaccharide in the solution analysed, is measured with an oxygen electrode:

$$\text{lactose} + H_2O \xrightarrow{\beta\text{-galactosidase}} \text{glucose} + \text{galactose}, \quad (17)$$

$$\text{maltose} + H_2O \xrightarrow{\text{maltase}} \text{glucose}. \quad (18)$$

In order to determine sucrose, it is necessary to have an additional enzyme which epimerises α-glucose—a sucrose hydrolysis product—to the β-form, which is oxidised by glucose oxidase:

$$\text{sucrose} + H_2O \xrightarrow{\text{invertase}} \alpha\text{-D-glucose} + \text{fructose} \quad (19)$$

$$\alpha\text{-D-glucose} \xrightarrow{\text{mutarotase}} \beta\text{-D-glucose}. \quad (20)$$

The rate of the non-enzymic mutarotation is high and it is therefore possible to abandon the use of mutarotase. The sensitivity of the electrode to the disaccharide is then greatly reduced.[10]

The joint immobilisation of glucoamylase and glucose oxidase is also employed for the determination of maltose:[55]

$$\text{maltose} + H_2O \xrightarrow{\text{glucoamylase}} 2\beta\text{-D-glucose}. \quad (21)$$

It has been suggested that a system comprising two immobilised enzymes, cholesterol oxidase and cholesteric ester hydrolase, be used for the determination of cholesterol esters.[70] The solution analysed is initally acted upon by cholesterol hydrolase and then cholesterol oxidase, after which the total amount of cholesterol is found.

For the determination of aromatic amines, the enzyme electrodes are prepared using glucose oxidase in order to replace the unstable substrate H_2O_2. A mixture of peroxidase and glucose oxidase in 0.02 ml of the basis buffer solution is deposited on a carbon glass electrode and treated with a 2.5% solution of glutaraldehyde (12–14 h, 4 °C). In the presence of 0.1 mM glucose and 1.0 mM potassium hexacyanoferrate(III) in the buffer solution, the parameters of these electrodes are close to those of the corresponding monoenzyme electrodes. They exhibit the highest stability, retaining 45–62% of their sensitivity for 40 days at 18–22 °C. During the functioning of these dienzyme electrodes, hydrogen peroxide is formed under the influence of glucose oxidase and hexacyanoferrate(III) is generated by the peroxidase. Under conditions where the peroxidase reaction is rate-limiting (at a glucose concentration about 0.1 mM), the activators (aromatic compounds) increase the rate of the process and the current in the system increases. At a lower glucose concentration, the glucoside reaction becomes rate-limiting and activators do not affect the electrode current. The dienzyme electrodes obtained are more convenient for practical use in view of their higher stability. They are used to determine aromatic amines, for example, *o*-dianisidine,[68] glucose,[61] ethanol,[89] uric acid,[90] and α-lactate and pyruvate ions.[91]

In order to determine ethanol, the electrolysis is carried out in a buffer solution (pH 7–8) with subsequent measurement of the reduction current.[89] Potassium hexacyanoferrate(III) at a concentration of 1.0–1.5 mM is introduced into the test solution before electrolysis to increase the selectivity of the determination. Uric acid is determined in the diagnosis of haematological diseases with the aid of an electrode based on immobilised microbial urease and peroxidase.[90] In a borate buffer solution containing 1 mM potassium hexacyanoferrate(III), the residual current does not exceed 1–2 mA when an enzyme electrode is used. After the addition of uric acid to the solution, the current increases appreciably. The dependence of the stationary current on the substrate concentration is linear up to 0.30–0.35 mM. The duration of the determination is 2–3 min.

These dienzyme electrodes exhibit a high specificity and a satisfactory reproducibility in the determination of uric acid in urine, blood, and serum. The electrodes are also very stable, retaining their initial sensitivity at the level of 50% under the conditions of daily 5 h use and on storage in buffer solution at 20–22 °C for 70 days.

The introduction of α-lactate or pyruvate ions into a phosphate buffer solution (pH 7.4) containing 10^{-3} M NADH induces an appreciable decrease of the dienzyme electrode current (ΔI = 0.5 μA), whereas in the absence of NADH in the solution ΔI < 8 mA.[91]

The mechanisms of the enzyme-catalysed reactions in the layer near the electrode are presented below:

$$O_2 + 2e \xrightarrow{\text{lactate oxidase}} H_2O_2, \quad \alpha\text{-lactate} \xrightarrow{-2e} \text{pyruvate}, \quad (22)$$

$$H^+ \xrightarrow{\text{lactate dehydrogenase}} NAD^+ + 2e, \quad \text{pyruvate} + 2e \rightarrow \alpha\text{-lactate}. \quad (23)$$

This enzyme electrode "does not distinguish" α-lactate and pyruvate ions and can be used for the quantitative determination of lactate only in those specimens where the concentration of pyruvate ions is much lower than that of lactate. The duration of the determination is 3–5 min and the electrode is stable for more than 10 days with a reproducibility of the determination of ±10%.

A dienzyme electrode with glucose oxidase and uricase, the latter being necessary to suppress the interfering influence of urea, can be employed to determine glucose and urea.[92]

An enzyme electrode with trypsin and glucose oxidase, adsorbed on the surface on a graphite electrode modified by aluminium, titanium, and zirconium oxides, has also been described.[97]

III. Flow analysers based on immobilised enzymes

The concept of monitoring, continuous *on line* and *in line* type analysis with the aid of physicochemical and biological procedures, which can ensure mathematical checks on a real time scale, has acquired very great importance in the methodology of analytical chemistry.

Studies on the development of the so called enzyme reactors or analysers with immobilised enzymes have become important for the continuous analysis of various substances to determine their content of enzyme substrates, inhibitors, and activators, for making possible the automatic monitoring of the composition of air, water, and other objects in the environment, and for the determination of components in a flow. They usually contain a fairly large amount of an enzyme immobilised on a carrier, in the form of layers or rings, which makes it possible to convert the entire substrate in the specimen into the product during the relatively short time interval when the specimen is in the reactor.

Three types of reactors, differing in form and in the disposition of the carrier, the immobilised enzyme, and the specimen, have been differentiated: a tubular reactor for gaseous specimens; a reactor filled with layers of spherical beads containing the immobilised enzymes; a tubular reactor filled with solid spherical beads made up of fibres with the immobilised enzyme.[24] Reactors for the determination of glucose and lactose with amperometric detection have been developed on the basis of such principles.

Reviews have been devoted to the study of the structure and properties of enzyme membranes for bioreactors obtained by the immobilisation of one or several enzymes on natural or synthetic carriers.[24,98] Flow enzyme reactors can be used also for the continuous recording of the kinetics of enzymic reactions.[7] Industrial specimens of enzyme reactors and the mechanisms of their functioning have been described in a review devoted to the use of immobilised enzymes in analytical chemistry.[99]

The employment of enzyme reactors and various enzyme electrodes in a version of the flow-injection analysis is extremely promising.[100] Mathematical models of the functioning of such analysers have been developed in relation to the determination of glucose with the aid of an indicator oxygen electrode consisting of a platinum disc to the surface of which two cellulose membranes were attached. Glucose oxidase in a polyurethane layer is placed between the membranes. The proposed mathematical model has been almost fully confirmed experimentally.[101] With the aid of this system, it is possible to determine glucose in almost 300 specimens (sample volume 1.5 ml) in the course of 1 h and the linear relation between the current and glucose concentration holds in the range 0.01–100 mM.

Platinum macroelectrodes and microelectrodes with glucose oxidase immobilised on a nylon mesh, placed tightly against the platinum electrode or immobilised directly on the surface of the platinum wire, have also been used.[102] The calibration plots are linear in the glucose concentration ranges $1 \times 10^{-5}-3 \times 10^{-3}$ and $1 \times 10^{-4}-2 \times 10^{-2}$ M respectively.

In order to determine glucose in the flow-injection version of analysis, use is also made of graphite electrodes, both a glass mesh electrode[103] and an electrode modified by the ionic sputtering of palladium and gold[60] (Table 1), with covalently immobilised or adsorbed glucose oxidase. The productivity of the reactor varies from 30 to 77 samples per hour with $s_r = 0.02$ as the flow rate varies from 0.5 to 2 ml min^{-1}. In the glucose concentration range 2.5–10 mM, a linear calibration graph is observed.[103] The electrode retains 30% of its initial activity for 40 days during storage at 2 °C.

There exists an example of the use of a flow-injection system based on a spherical enzyme reactor for the study of the kinetics of the mutarotation of *D*-glucose in the presence of phosphate ions and *D*-galactose.[104] Glucose, fructose, and sucrose present jointly in the given system can be determined with the aid of a series of enzyme reactors arranged in parallel and a multichannel potentiostat.[105] In the determination of glucose, a reactor with immobilised glucose oxidase was placed ahead of the corresponding reactor in order to eliminate the interfering effect of glucose. In this case, hydrogen peroxide was detected amperometrically. The interfering effect of ascorbic acid was fully eliminated by using a reactor with immobilised ascorbate oxidase. In the analysis of fructose, potassium hexacyanoferrate(II) was detected. The reproducibility of the system was 1.6–1.8%.

One of the latest devices of this type for the determination of free and total cholesterol (ChL) in blood serum is of great practical importance.[106] After the introduction of the microsample into the carrier stream containing a phosphate buffer solution, $K_4[Fe(CN)_6]$, and Triton X-100, the stream is divided into two components, one of which is passed through a column with immobilised cholesterol esterase, after which the two streams are combined and are passed through a column with immobilised cholesterol oxidase.

The amperometric detector with two polarised electrodes records two peaks: the first corresponds to the content of free cholesterol and the second corresponds to the total cholesterol in the sample ($c_L = 8 \times 10^{-7}$ and 3×10^{-6} mM respectively‡).

Apart from the flow-injection systems enumerated, there also exist a whole series of examples of the use of enzyme electrodes in a continuous regime. Thus it has been suggested that a platinum mesh electrode subjected to a preliminary treatment with 3-aminopropyltriethoxysilane and containing an immobilised mixture of enzymes—glucose oxidase and catalase or glucose oxidase and peroxidase with bovine albumin and glutaraldehyde—be used for the determination of glucose in blood serum and urine.[107] The calibration graph is linear in the range 20–800 mg $litre^{-1}$ for a sample volume of 5 μl (glucose oxidase–catalase) and 30–40 mg $litre^{-1}$ for a sample volume of 1 μl (glucose oxidase–peroxidase).

The possibility of using sensors for glucose, lactate, and urea in systems with constant sampling of blood for the continuous express monitoring *in vivo* of blood metabolites has been examined.[27,28] The aim of the authors of the above investigations was in essence to create, on the basis of such systems, sensors implanted in the patient's organs.

‡ c_L represents the lower limit of the measured concentrations.

Under flow conditions at a flow rate of 7 ml min^{-1}, an enzyme electrode with uricase immobilised on porous glass was used to determine uric acid.[67] With the aid of this device, it is possible to analyse up to 100 specimens per hour with an accuracy to within 2–4%. The enzyme then remains active for a long time and loses 70% of its initial activity only after 10 months.

Flow analysers based on alcohol, lactate, and glutamate dehydrogenases with regeneration of the NADH cofactor, capable of being used in repeated measurements, have been proposed.[108] The enzyme with immobilised NADH is retained between a platinum electrode and a semipermeable membrane. NADH is regenerated either by a direct electrochemical procedure or with the aid of the electrochemical oxidation of phenazine methosulphate. The linearity of the calibration plot is observed up to a concentration of 1.5 mM for lactate, 0.5 mM for glutamate, and 40 mM for ethanol. The enzyme flow analyser based on dehydrogenases is illustrated schematically in Fig. 4. A reactor based on immobilised cholinesterase has been used for the continuous monitoring of air and running water for the content of cholinesterase inhibitors—insecticides based on organophosphorus compounds and carbamates. Cholinesterase is immobilised by being entrained in a starch gel and is fixed on the surface of a mixed polyurethane carrier placed in the electrochemical cell (Fig. 5).[99] A theoretical description of the inhibitor analytical method using an enzyme flow system, which has recently acquired increasing importance in connection with the need to monitor an increasing number of toxic compounds, has been published.[109]

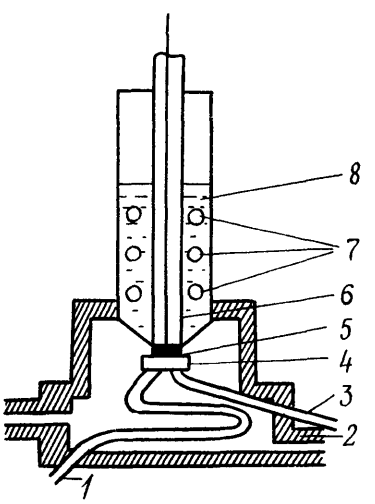


Figure 4. Schematic diagram of an enzyme flow electrode based on dehydrogenases: *1*, inlet for the flow of the test solution; *2*, heat exchanger; *3*, outlet for the products of the enzymic reaction and the stream containing the test substance; *4*, microchamber; *5*, semipermeable membrane; *6*, platinum electrode (disc); 7, auxiliary electrode; *8*, buffer solution.

One of the latest versions of the reactor for enzymic reactions has been proposed by Cerkasov and Linek.[43] The enzyme preparation is fixed on the surface of the stirrer or on the surface of a readily removable stationary component placed within the reactor.

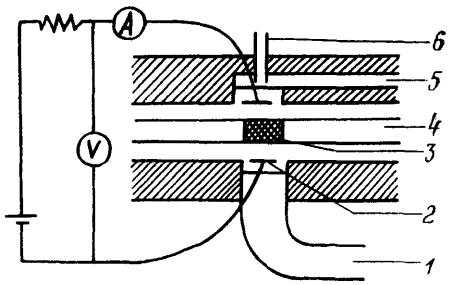

Figure 5. Schematic diagram of an electrochemical cell with an enzyme electrode based on immobilised cholinesterase: *1*, outlet for the products of the enzymic reaction; *2*, platinum electrode; *3*, immobilised cholinesterase; *4*, compartment (holder) for the immobilised cholinesterase; *5*, inlet for the stream of water or air supplied; *6*, inlet for the stream of substrate supplied.

IV. Amperometric sensors in immunoenzyme analysis

The ability of antibodies to interact highly specifically with various compounds and the ability of enzymes to accelerate chemical reactions are widely used in immunoenzymology.[7] As an alternative to radioimmunological analysis, approximately 15 years ago enzyme-markers were used in a quantitative immunological method,[110–112] which was called immunoenzyme analysis (IEA). This method is safe as regards health and the useful life of enzyme-markers is several years. It is applicable to all antigen (hapten)–antibody (AG–AB) systems and is extremely sensitive. Immunoenzyme analysis (IEA) makes it possible to detect antigens, antibodies, and other substances in biological systems at negligibly low concentrations of $10^{-14}-10^{-12}$ M.[113–118] There are two varieties of IEA: the heterogeneous solid-phase variety and the homogeneous variety. In the homogeneous IEA, the activity of the enzyme-marker changes during the immunological response. In this case, the stage involving the physical separation of the AG–AB complexes, required in the heterogeneous version, is unnecessary. With the aid of the homogeneous version of the analysis, it is possible to determine only substances with a relatively low molecular weight, for example, medicinal drugs and hormones.[113] A more clear-cut classification of IEA procedures has been given in a review.[117] It is based on the fact that, in any version of the IEA, it is possible to measure the enzyme activity of the labelled compound present either in a specific immune complex or in a complex with free binding centres which do not enter into the reaction. The majority of the immunoenzyme tests are based on spectrophotometric and fluorimetric methods for the determination of enzyme activity.[117] The use in IEA of electrochemical sensors, combining the principles of the action of analytical systems based on immobilised enzymes and immunoenzyme analytical methods, merit attention from the practical point of view. Such systems, which have been called immunoenzyme electrodes, are extremely promising because of the possibility of automating immunoenzyme methods and creating compact immunoenzyme analysers. However, one should note that the concept of "immunoenzyme electrodes" is not used quite correctly in our view. For example, the electrodes described in a number of studies[113–117] do not always contain a layer of immobilised enzyme and it would therefore be more correct to classify this procedure as immunoenzyme analysis with amperometric (voltammetric) indication of the analytical signal. Such systems usually contain an immobilised antigen or antibody.

The oxygen sensor described above was one of the first to be used in competitive solid-phase IEA.[118] A capron mesh, containing immobilised antigens against human serum albumin (anti-HSA) or insulin, was fixed on the surface of an oxygen electrode. In a solution containing HSA or insulin, the immobilised antibodies react with the antigen. If an enzyme is grafted beforehand to HSA or insulin (catalase to HSA and glucose oxidase to insulin), then an anti-HSA.HSA-E or an anti-insulin.insulin-E, where E is the enzyme, is formed on the capron mesh. When the solution contains, together with the labelled antigen molecules, also the antigen without enzymes, then mixed complexes are formed where the amount of enzyme is higher the lower the concentration of the unlabelled antigens. Under conditions where the response of the oxygen electrode depends on the enzyme concentration, the readings of the electrode are proportional to the antigen concentration in solution. The response time for such a system is 2 min. The overall duration of the determination, including the regeneration of the membrane by treatment with a glycine buffer solution, is 10 min. The antibody immobilised on the capron mesh retains its activity for several days.

It has been suggested that one should use alkaline phosphatase as the marker of the α-acid glycoprotein antigen fixed by glutaraldehyde in a competitive IEA method involving the binding of the excess antigen and the enzyme-labelled antigen to a limited number of highly specific antibodies:[119]

$$\begin{array}{lll} \mathrm{AG} & \nearrow & \mathrm{AG:AB} \\ & +2\mathrm{AB} & \\ \mathrm{AG^*} & \searrow & \mathrm{AG^*:AB} \end{array} \qquad (24)$$

The "bound" and "free" labelled antigens are separated under the conditions of heterogeneous IEA and a calibration plot of the ratio of the "bound" and "free" antigens against the antigen concentration is plotted (the standard deviation s_r = 0.03–0.05). A carbon paste electrode is used as the electrochemical sensor.

The heterogeneous version of IEA has also been applied to the determination of immunoglobulin G.[120] In this case the determination is carried out directly on the surface of the carbon glass electrode on which the antibodies had been adsorbed. The surface of the electrode then functions as the immunological solid phase and the electrochemical detector proper. The enzyme-marker is glucose oxidase with benzoquinone as the mediator. Procedures have been developed for the regeneration of the electrode surface after the determination, which is important for the automation of the IEA procedure.

The current arising in the electrochemical cell with serum as the electrolyte and a carbon glass disc working electrode, coated by the immobilised immunoglobulin or anti-immunoglobulin combined in a complex with immunoglobulin, increases following the addition of the serum containing immunoglobulin (the serum–immunoglobulin system) or anti-immunoglobulin (the serum–immunoglobulin–anti-immunoglobulin system).[121] It has been suggested that the complexes formed have a double-layer structure, which induces an increase in the current.

A flow immunoreactor with a platinum electrode and a flow rate of 0.5 ml min^{-1} has also been proposed for the determination of immunoglobulin G. In this case, the immunoglobulin was

immobilised on a carrier and the marker was glucose oxidase attached with the aid of *p*-benzoquinone. The analyser works stably for almost three months with an error in the determination of $\pm 3\%$.[122]

An amperometric immunodetector, based on the oxidation of glucose by immobilised glucose oxidase with ferrocenium ions playing the role of a mediator and an antigen marker simultaneously, has been used to determine the medicinal drug lidocaine (α-diethylamino-2,6-dimethylacetanilide), whose concentration in plasma must be carefully monitored.[123] Under the conditions of homogeneous competitive IEA, the antigen–ferrocenium ion complex then plays the role of an electron acceptor for glucose oxidase. The catalytic current arising in the enzymic oxidation of glucose diminishes after the binding of the antigen–ferrocene complex to the antibody. This inhibition is reversible when the free antigen is added. The duration of the determination does not exceed 15 min ($s_r = 0.03-0.06$).

In another case, in the study of the same immune complex (lidocaine–anti-lidocaine), glucose-6-phosphate dehydrogenase was used as the antigen marker. Its activity was determined from the rate of oxidation of NADH at a platinum electrode.[124]

An amperometric sensor of the flow type has been developed[125] for the determination of α-asparaginase. The enzyme-marker was horseradish peroxidase. Its enzyme activity was estimated with the aid of a carbon electrode and an I_3^- depolariser. The concentration c_L for α-asparaginase is in the case 1.8×10^{-10} M, which corresponds to clinically significant enzyme concentrations. The analyser was tested on a wide range of objects: immunoglobulin, α-amylase, the antibody to the HIV virus and the X virus of the potato, egg albumin, and cell suspensions.[126] The results of the determination are consistent with the results of spectrophotometric analysis. The productivity of the sensor (more than 350 tests per hour) makes it possible to use it to estimate the influence of biotechnical manufacturing processes on the environment and man.

The analytical possibilities and advantages of the flow-injection immunological analysis, which consists in injecting the substrate (10–20 μl) into a stream of liquid flowing through a microreactor with an immobilised enzyme covalently bound to the antigen (antibody) have been examined in two communications.[127,128] The degree of the immunological reaction is estimated, for example, from the oxidation current of the products of the enzymic reaction at a platinum electrode.[127] Under these conditons, c_L for the substrate is 10^{-15} M. After suitable treatment of the immunosorbent, it is possible to carry out 500–600 determinations for almost three months with high metrological characteristics.[128]

An analyser based on glucose oxidase immobilised on a gel support as a result of an immunlogical reaction has also been used in the flow-injection version of analysis.[129] Such indirect immobilisation makes it possible to replace the carrier readily and to regenerate easily the system after the determination with only a 5% loss of the initial activity. The entire procedure takes less than an hour. The reversible immobilisation of the enzyme is achieved by a different sequence of reactions including the antigen–antibody interaction.[129] The ranges corresponding to the linearity of the calibration plots are $1.1 \times 10^{-9}-1.1 \times 10^{-5}$ and $1.1 \times 10^{-10}-1 \times 10^{-6}$ M. Three principles are combined in such devices: an enzyme electrode, a flow system, and an immunological reaction.

In all the versions of the IEA examined, the enzyme is used as an antigen or antibody marker, whose redistribution between the solid and liquid phases depends on the concentration of the test compound. New IEA systems, based on the fact that the appearance of the enzyme in solution is a consequence of a specific antigen–antibody interaction, are being developed nowadays.[130] One of the ways of creating such systems involves the incorporation of the enzyme within liposomes on the surfaces of which the antigen is attached chemically. The addition to the system of an antibody and of a complement- (set of enzymes) containing solution leads to the formation of the antigen–antibody complex on the liposome and its lysis by the action of the complement bound to the antibody fragments. The lysis is accompanied by the transfer of the enzyme to the solution. The addition to the system of the antigen to be determined inhibits the lysis as a consequence of the attachment to the liposome of a smaller number of antibody and complement molecules. The rate of appearance of enzyme activity in the solution serves as a characteristic of the initial antigen concentration.[131] The duration of the analysis of theophylline (liposomes with peroxidase) is 15 min and the sensitivity is 4×10^{-9} M for the electrochemical recording of the peroxidase activity in the oxidation of NADH.[132] Apart from enzymes, electrochemically active marker species (ions, substrates) can be incorporated in liposomes.

The principal data characterising the properties and the design of the immunoenzyme electrodes described above are presented in Table 2. It is noteworthy that the chemical amplification of the signal, which occurs under the influence of enzymes, can be used also for the determination of hormones, certain medicinal drugs, neuromediators, cyclic nucleotides, and certain biologically important compounds, whose concentration in the organism is less than 10^{-6} M.[131] A series of reviews has also been devoted to these and other problems concerning the use of immunoenzyme sensors.[20,21,25,26,114,119,133,134]

In conclusion one should note that the problem under discussion is of extremely great current interest. At the present time there exist very many devices (biosensors) of different designs with amperometric indication of the analytical signal and based on immobilised enzymes. In many instances, both potentiometric and amperometric enzyme sensors are constructed for such purposes, the latter finding more extensive applications because they usually exhibit a greater range corresponding to the linearity of the analytical signal and a lower limit of the concentrations which can be determined. Furthermore, in the amperometric version of the biosensor, in contrast to its potentiometric analogue, it is possible to immobilise the enzyme directly on the electrode surface by incorporating it in a polymer film which can be produced in the course of electropolymerisation.

The present review concerning the state of the problem of amperometric biosensors is naturally far from being able to cover exhaustively the entire literature published at the present time. There is no need to compare in it the advantages and disadvantages of a particular biosensor, because each biosensor is usually constructed for the solution of some kind of practical problem, normally operates under specific conditions, and is usually applicable to the determination of specific compounds in a specific medium. One may say with much confidence that detectors with immobilised enzymes, a wide variety of which exist, supplement one another. Only practice can provide an answer to the question of which biosensor is best or worst in each specific case depending on the operating conditions and the nature of the object to be analysed.

The need for the biosensors under consideration is rapidly and continuously increasing and the requirements as regards their operating properties are becoming more stringent. Further development of theoretical and practical aspects of their application involves the expansion of the assortment of the industrially produced enzymes and the improvement of the methods for their

Table 2. Characteristics of immunoenzyme electrodes.

Substance determined	Compounds used		Immobilisation procedure	Electrochemical sensor	Range of concentrations determined	Refs
	AG(AB)	Enzyme (marker)				
Human serum albumin (HSA), insulin	AB (anti-HSA), anti-insulin	Catalase for HSA, glucose oxidase for insulin	AB on capron mesh	Membrane oxygen electrode	Less than 10^{-8} M HSA; Less than 10^{-6} M insulin	[118]
α-Acid glycoprotein	AG	Alkaline phosphatase	Treatment with glutaraldehyde	Carbon paste electrode	1.0–10.0 ng ml^{-1}	[119]
Rabbit immunoglobulin G	Anti-immunoglobulin G	Glucose oxidase—AG marker	AB adsorbed on the surface of a carbon glass electrode	Carbon glass electrode	4×10^{-16} mol cm^{-2} of electrode surface	[120]
Immunoglobulin G	"	Glucose oxidase—AG marker (attached with the aid of *p*-benzoquinone)	Immobilisation on a carrier	Platinum electrode in a flow immunoreactor		[122]
Lidocaine	Antilidocaine	Glucose oxidase with ferrocenium ion—AG marker and mediator simultaneously	Covalent grafting to a carrier	Gold disc working electrode, platinum gas counterelectrode	5–50 mM	[123]
α-Asparaginase	Anti-asparaginase	Horseradish peroxidase—AG marker	Immobilisation of AB to asparaginase in hollows on polystyrene plates	Graphite electrode in a flow analyser	1×10^{-11}–4×10^{-10} M	[125]

immobilisation, an increase in the sensitivity and stability of the electrochemical sensors themselves, and improvement of the materials used for their preparation. Various modifications of the electrode surface play a major role in this connection.[135–136]

It has been suggested that biosensors constitute the future of analytical chemistry and the present revolution in this field of science has been expected for some time. One of the reasons for this view is apparently the large volume of research into biosensors.

Norbornadiene–quadricyclane — an effective molecular system for the storage of solar energy

V A Bren', A D Dubonosov, V I Minkin, V A Chernoivanov
Scientific-Research Institute of Physical and Organic Chemistry, Rostov State University

ABSTRACT. The results of studies on intramolecular interconversions in systems of norbornadiene ⇄ quadricyclane and their derivatives are classified and discussed. The mechanisms of the forward photoreaction and reverse thermal process in relation to the nature of the substituents and carbocycles, type of sensitiser and catalyst, and properties of the medium are discussed in detail and classified. An analysis is made of the influence of these factors on the spectroscopic, kinetic, and thermodynamic properties of this system as an accumulator and converter of light energy. Methods of improving its chararacteristics — light absorption, the quantum yield of the photoreaction, and stability of the photoproduct — have been established.

The bibliography includes 188 references.

I. Introduction

According to the calculation of specialists, with the most economical consumption of fuel, all of its forms used by man at the present time (coal, oil, natural gas, uranium) will be exhausted after 130 years.[1,2] This period is allotted to changing over to the use of alternative, ecologically clean energy sources — solar, wind, and oceanic energy.

The extent of utilisation of solar radiation is very considerable. Solar energy is used to operate high-temperature units that concentrate a stream of radiation by means of mirrors, where the accumulators of energy used are either physical heat-carriers or inorganic compounds that can undergo cyclic thermal decomposition–synthesis reactions (oxides, hydrates, sulphates, carbonates). Systems of a different type convert radiant energy into electrical, heat, or chemical reaction energy by means of photophysical or photochemical processes.[1,3,4]

At the present time the following methods of photochemical conversion of solar energy (SE) have been widely studied:

— the photocatalytic decomposition of water using metal-complex compounds as catalysts;[2,5]

— the development of "solar photoelectrolysers" based on photoelectron transfers, the photogalvanic effect, stabilisation of the products of photoelectron transfers in the electrical double layer at a phase boundary, etc.;[2,5–7]

— photosynthesis[2,7,8] — the most efficient biochemical method of storing solar energy.

A comparative analysis of the possibilities and prospects of these trends in the use of SE has been carried out in a number of monographs and reviews.[2,4,9–11] An aspect of the abiotic conversion of SE that has been less studied is its storage as strain energy in metastable photoisomers of organic compounds followed by its release in the form of heat energy.

In a number of review articles[12–16] devoted to a study of this aspect of solar energy conversion and an analysis has been carried out of the requirements to be met by a photochromic compound A, its photoform B, and the parameters of the process by which storage and conversion of solar energy occurs.

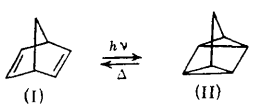
$$A \underset{\Delta}{\overset{h\nu}{\rightleftarrows}} B + \Delta H. \qquad (1)$$

1. The initial compound A must absorb in the UV and visible region of the spectrum (from 400–600 nm) since more than 50% of the sun's light energy that reaches the earth is distributed over the region 300–700 nm (380–170 kJ per Einstein). The photoisomer B, on the other hand, should be colourless so as to avoid photoinitiation of the reverse reaction. Both components of reaction (1) should be nonluminescent compounds.

2. The energy level of the ground state of compound B formed in photoreaction (1) must lie sufficiently above the level of the ground state of A for the liberation of heat ΔH in the reverse reaction to be considerable (>300 J g^{-1}), exceeding the heat stored in the solar warming (ΔT = 50 °C) of water (ΔH = 209 J g^{-1}), sand (ΔH = 42 J g^{-1}) and salt hydrates (ΔH = 250 J g^{-1}).

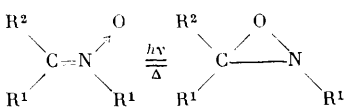
3. For prolonged conservation of energy stored by photoisomer B the activation barrier of the thermal transition B → A ($\Delta H^{\pm}$) must be sufficiently high — of the order of 85–105 kJ mol^{-1}.

4. The photochemical reaction A→B must have a high quantum yield, the transition B→A, which liberates stored energy, must be susceptible to catalytic acceleration or thermal initiation. High chemical yields and the absence of by-products are necessary for both processes.



5. Compounds A and B must be sufficiently cheap, available, nontoxic, nonexplosive, incombustible, and chemically stable towards air and atmospheric moisture.

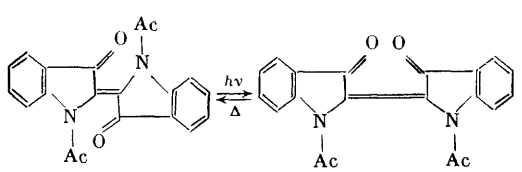
Some of these requirements can be expressed quantitatively in the form of Eqn. (2), which reflects the efficiency of a system that is capable of storing and converting SE.[17-19]



$$\eta_e = \frac{\Delta H \Phi}{E_{h\nu}} \cdot \frac{\int_0^{\lambda_{lim}} I_\lambda(\lambda/\lambda_{lim})d\lambda}{\int_0^{\infty} I_\lambda d\lambda} \eta_{abs} 100, \quad (2)$$

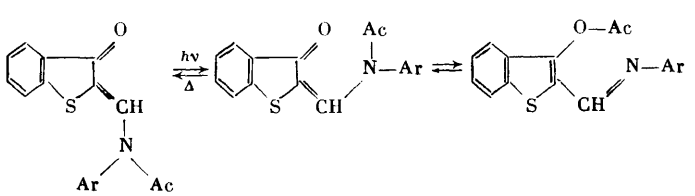
where η_e is the efficiency of the photochrome; ΔH is the difference in enthalpy between the initial compound A and its photoform B; Φ is the quantum yield of photoreaction (1); $E_{h\nu}$ is the energy of the photons (per Einstein) of absorbed light (for λ_{max} of compound A); λ_{lim} is the long-wavelength limit of absorption of compound A; I_λ is the distribution of power of solar radiation by wavelength; η_{abs} is the coefficient of absorption (ratio of the number of photons absorbed by compound A to the total number of photons in the solar spectrum with $\lambda \leqslant \lambda_{lim}$. For a more precise determination of the efficiency of photochromes as SE accumulators it is necessary to take into account the energy capacity of the material W, i.e., the quantity of energy stored per gram of initial compound and the number of working cycles [reaction (1)] without appreciable decomposition of the compound. Quite a wide range of photochromic organic compounds have been studied up to the present time. Amongst the most important reactions of A ⇄ B are the following:

1) valence isomerisation, for example, that of norbornadiene–quadricyclane (3)[20] or nitrone–oxaziridine (4) systems:[21]



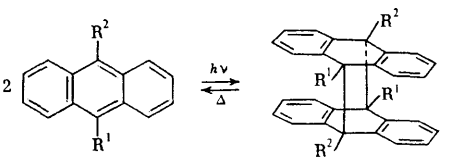
(I) (II) (3)

(III) (IV) (4)



R¹, R² = H, Alk, Ar.

2) geometric (*Z*) ⇄ (*E*) isomerisation, for example, that of indigo derivatives:[22,23]



(V, *E*) (V, *Z*)

3) geometric isomerisation followed by intramolecular rearrangement, as in the case of *N*-acylated aminovinyl ketones of the type (VI):[24]

(VI, *Z*) (VI, *E*) (VII)

4) thermally reversible photodimerisation reactions, for example, those of anthracene derivatives:[19]

(VIII) (IX)

R¹, R² = H, Alk.

A summary of the results concerning these and other systems acting as accumulators of light energy appears in a monograph.[25] Table 1 indicates the parameters of some of the most efficient photochromic systems from which it is possible to determine whether they satisfy the requirements imposed on photochemical accumulators of SE.

Cyclic photodecomposition–thermal recombination reactions are also characteristic of certain inorganic systems that can also store light energy. The reaction of nitrosyl chloride can serve as an example:

$$NOCl \underset{\Delta}{\overset{h\nu}{\rightleftarrows}} NO + {}^1/_2Cl_2.$$

Although nitrosyl chloride has optimal spectroscopic data (λ_{lim} = 600 nm) and the quantum yield Φ of the photoreaction is close to unity, it is necessary to separate the photoproducts NO and Cl_2 to prevent too rapid a reverse reaction occuring in parallel with the forward process.

The main advantage of organic photochromes over inorganic ones is the possibility of extensive variation of their molecular structure in order to improve their properties as accumulators and converters of SE, namely: increasing the long-wavelength limit λ_{lim} of the absorption spectrum, increasing the quantum yield Φ of the photoreaction A → B, increasing the exothermicity ΔH of the dark reaction, and the choice of an effective catalyst for the reaction B → A, which causes the liberation of heat.

Intensive investigations in recent years have shown that the most promising development in optimising all of the required parameters is the modification of systems that are characterised by photoinitiated valence isomerisation involving ($2\pi + 2\pi$) cycloaddition, primarily in relation to the readily available norbornadiene derivatives (I). Thus, the main advantage of the norbornadiene–quadricyclane system is the very high exothermicity of the thermally forbidden ($2\sigma + 2\sigma$)-cyclodecomposition of quadricyclane (II) (-110 kJ mol^{-1})[26] (see Table 1). The aim of the present review is to analyse the main approaches to improving the characteristics of this system and to bring them into possibly closer correspondence with the above-mentioned requirements.

II. Optimisation of the spectroscopic properties of the system norbornadiene–quadricyclane

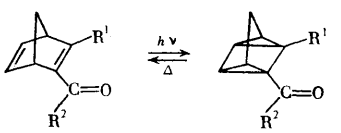
The valence isomerisation of norbornadiene to quadricyclane (3) was first studied by Hammond et al.[20,27] The storage of energy in this photoreaction occurs through the formation of the metastable quadricyclane structure (II), which contains the highly strained cyclobutane and two cyclopropane rings. The following advantages of this photochromic system may be noted: 1) the forward reaction

Table 1. Parameters of certain photochromic systems that can store solar energy.

System	λ_{lim}, nm	Φ	ΔH, kJ mol^{-1}	Q, %	η_A	η_e, %	W, mW g^{-1}	Properties of form B	
								Thermal stability*	Photostability (Φ_{irr})
(I) ⇄ (II) (CuCl sensitiser) CuCl)	388	0.4	110(1200)	14	0.015	0.21	1.75	14 h (140 °C)	~0
(V, *E*) ⇄ (V, *Z*)	610	0.2	34(109)	3.5	0.27	0.95	300	200 s (25 °C)	0.1
(VI) ⇄ (VII) (Ar = Ph)	460	0.6	23(79)	6.2	0.09	0.56	230	20–30 days (25 °C)	0
Photosynthesis	700	0.1	467	26	0.36	8 **			

* Thermal stability — period of half-decomposition for the reaction $B \xrightarrow{\Delta} A$ at the temperature indicated.
** Theoretical value of efficiency; in real systems η_E approximately equals 0.1–0.3%.

can be sensitised and there are effective catalysts for the reverse reaction; 2) the reverse reaction has a high activation barrier (half-decomposition time of (II) is equal to 14 h at 140 °C);[27] 3) the starting products for the synthesis of norbornadiene (I) and its derivatives are amongst those produced by large-scale synthesis; 4) both forms (I) and (II) are liquids, which provides a number of production benefits.



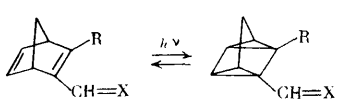
However, there are also considerable disadvantages in system (3). Thus, photochrome (I) has an absorption at too short a wavelength (about 300 nm),[28] in the absence of a sensitiser the quantum yield of the photoreaction is very small, and chemical modification of the structure of norbornadiene often results in irreversible secondary photoreactions.

Thus, in order to improve the properties of the photoconversion of norbornadiene–quadricyclane it is necessary, first of all, to shift the long-wavelength limit of absorption of norbornadiene to longer wavelength in the spectrum [improve λ_{lim} in Eqn. (2)] and at the same time increase the quantum yield of Φ of the photoisomerisation of (I) → (II).

In order to resolve this problem substituents with various chromophoric groups are introduced into the norbornadiene molecule. Three possible ways of "colouring" norbornadiene are known: 1) the introduction of electron-withdrawing substituents or an electron-donating and electron-withdrawing substituent into one of the double bonds of norbornadiene; 2) the introduction of electron-donating and electron-withdrawing substituents into the different double bonds of norbornadiene, resulting in the appearance of a charge-transfer band; 3) the formation of charge-transfer complexes of norbornadiene with transition metal compounds.

1. Norbornadienes containing substituents on one of its C=C double bonds

For the majority of known norbornadiene with simple electron-withdrawing groups (COOH, COOMe, CN, etc.) at the 2- and 3-positions, λ_{lim} does not exceed 365 nm.[29–35] 2-Aroyl-3-aryl-norbornadienes (X),[36] in which charge transfer occurs from the aryl group to the aroyl group thus increasing the efficiency of the photo-reaction for formation of quadricyclanes (XI), absorb at longer wavelength.



(X) (XI) (5)

R¹, R² = Ar.

Compounds (X) have λ_{max} = 320–370 nm (Table 2), which corresponds to λ_{lim} = 400 nm, while for the norbornadiene (X, *f*), λ_{lim} = 450 nm. Irradiation of norbornadienes (X) with light of wavelength 350 nm yields the corresponding quadricyclanes with high quantum yields (Φ = 0.3–0.6). Electron-donating groups in the aroyl residue assist both an increase in λ_{max} and the quantum yield Φ, while a nitro group, although increasing λ_{max}, sharply reduces the efficiency of photoisomerisation.

3-Phenylnorbornadiene-2-carbaldehyde and its imines (XII) have spectroscopic properties which are similar to compounds (X).[37]

(XII) (XIII) (6)

R = Ar; X = O, NAr.

The absorption maxima of (XII) are grouped in the region of 310–370 nm, the limit of the long-wavelength band reaching 420 nm (Table 2). However, in contrast to norbornadienes (X), the nature of the photoreaction of imines (XII) is determined by the type of solvent; in nonpolar aprotic solvents only isomerisation on the C=N bond occurs, while in proton-donating solvents quadricyclanes (XIII) are formed.

Table 2. Spectroscopic properties of norbornadienes and quantum yields of photoreactions (5)–(11).

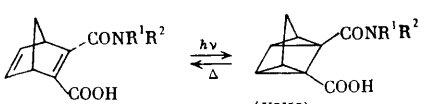
Norbornadienes containing benzo- or naphtho-quinone residues [for example, (XIV)] absorb in the region of 340–410 nm (Table 2) and they have λ_{lim} = ~460 nm.[38,39] Methyl or methoxyl substituents in the quinone part of the molecule displace λ_{lim} to longer wavelengths with a constant quantum yield.

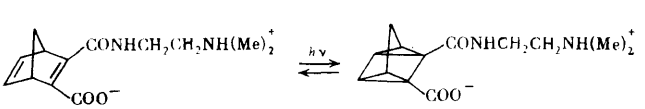


(XIV) (XV) (7)

R¹, R² = H, Me, OMe.

Irradiation of (XIV) with light with λ > 410 nm yields photoproducts (XV) in almost quantitative yield (Φ ~ 0.2). We should note that in earlier studies[40,41] the formation of quadricyclanes was not established.

Carbonyl substituents displace λ_{lim} appreciably to longer wavelengths.[41–45] The presence of carbamoyl and carboxyl groups at the 2- and 3- positions of the norbornadiene molecule makes it possible to carry out the photoisomerisation of (XVI) → (XVII) not only in organic solvents but also in weakly alkaline aqueous solutions.

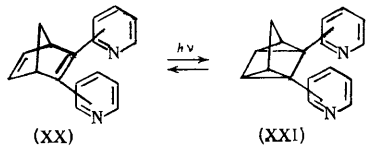


(XVI) (XVII) (8)

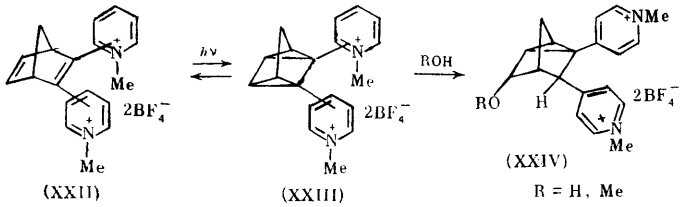
R¹, R² = H, Alk, Ar.

In the electronic spectra of compound (XVI) absorption bands occur at 280–340 nm (see Table 2) $\lambda_{lim} \approx 370-400$ nm, while for norbornadiene (XVI, *i*), λ_{lim} = 430 nm. *N*-Alkylamides absorb at longer wavelength than *N,N*-dialkylamides, although they, in turn, are inferior to *N*-arylamides in this respect.

On irradiation of compounds (XVI) in aqueous Na_2CO_3 solutions, quadricyclanes (XVII) are formed with quantum yields of 0.1–0.6. By studying system (XVI) it is possible to establish an important principle of the photochemical behaviour of norbornadienes of this type, namely, displacement of λ_{lim} to longer wavelength in the spectrum results in a decrease in quantum yield Φ of photocyclisation.[45]



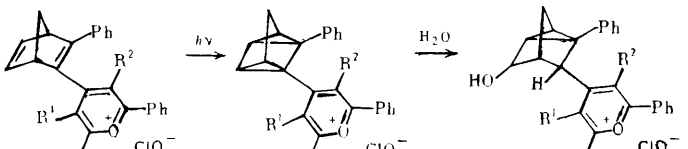
Further modification of carbamoyl-substituted norbornadienes led to the preparation of the first compound that was soluble in water.[46] For the bipolar ion (XVIII), λ_{lim} = 370 nm, but there was no information about the quantum yield of (XIX).[46]



(XVIII) (XIX)

Norbornadienes containing heterocycles or heterocyclic cations as substituents are described in three studies.[47–49] The long-wavelength absorption of dipyridylnorbornadienes (XX) [47,48] reaches $\lambda_{lim} \approx$ 380 nm and irradiation with light of wavelength 334 nm results in

the formation of quadricyclanes (XXI) with high quantum yields (0.7–0.8).

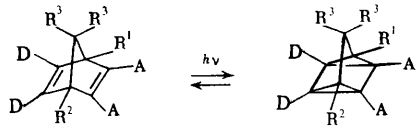


(XX) (XXI) (9)

(XXII) (XXIII) (XXIV) R = H, Me (10)

Quaternary salts of dipyridylnorbornadienes (XXII) have a considerably longer wavelength absorption up to $\lambda_{lim} \sim 470$ nm (see Table 2). However, when they are irradiated with light with $\lambda = 350$ nm, a photostationary state is established between the initial compounds and the photoreaction products in the ratio 12:88 (XXII, *b*) and 30:70 (XXII, *c*), which is apparently due to an absorption in the region of 350 nm that is present in the resulting quadricyclanes. In the presence of traces of water and methanol, norbornadiene (XXII *a*) under these conditions forms the adduct (XXIV).

Record values of λ_{lim} (from 550 to 580 nm) occur in norbornadienes (XXV) containing pyrylium cations at the 2-position[49] (see Table 2). Photoconversion of (XXV) to the corresponding quadricyclanes occurs rapidly and effectively even in diffuse light, but the reaction is very sensitive to traces of moisture, so the final products are adducts (XXVII).



(XXV) (XXIV) (XXVII)

R^1, R^2 = H, Me (11)

2. Norbornadienes with electron-donating and electron-withdrawing substituents on the different double bonds

The theoretical possibility of increasing λ_{lim} in a norbornadiene through a charge-transfer band that occurs by interaction of the electron-donating and electron-withdrawing substituents on the different double bonds was substantiated in two studies.[50,51] The geometric strain in the norbornadiene molecule leads to an interaction of the π-orbitals of the double bonds in the molecule through space, resulting in a considerable convergence of the energy levels of the frontier molecular orbitals.[52,53] This manifests itself spectroscopically in unsubstituted norbornadiene absorbing at longer wavelength than does a compound with two isolated C=C bonds.[28] The presence of electron-donating substituents on one of the two double bonds of norbornadiene and electron-withdrawing substituents on the other causes a further bathochromic shift of the long-wavelength absorption band.

Depending on the nature of the substituents D and A in (XXVIII) molecules, λ_{lim} can vary from 345 to 558 nm (Table 3), and the quantum yield of compounds (XXIX) remains high (0.26–0.96)

(XXVIII) (XXIX)

D = H, Me, Ar; A = CN, COOMe, CONHPh; R^1, R^2, R^3 = H, Me.

A bathochromic shift of the long-wavelength absorption band of norbornadienes (XXVIII) occurs[51,54,55] when the electron-donating and electron-withdrawing capacities of substituents D and A are increased [cf. compounds (XXVIII, *b*) and (XXVIII, *c*); (XXVIII, *d*) and (XXVIII, *f*); (XXVIII, *j*) and (XXVIII, *k*) in Table 3]. The most important characteristic of compounds (XXVIII) is that, in contrast to norbornadienes containing substituents on one of the double bonds, the increase in λ_{lim} is in many cases not accompanied by any significant decrease in quantum yield of the photoreaction (XVIII) → (XXIX). Quadricyclanes (XXIX) are formed quantitatively even in the presence of oxygen in solution. In the opinion of Hirao et al.,[54] norbornadiene (XXVIII, *k*), for which $\lambda_{lim} = 558$ nm, $\Phi = 0.75$, is the most suitable for storage of SE.

* in MeCN; ** λ_{irr} = 313 nm.

Photoconversions of the system (XXVIII) ⇄ (XXIX) can be carried out in poly(methyl methacrylate) films,[55] the magnitude of λ_{lim} and Φ remaining virtually unchanged, and the number of working cycles of (XXVIII) ⇄ (XXIX) without a change in extinction of the initial compound is 10^3. According to the results of Miki et al.,[65] with the same number of cycles the losses of working compound in solution can amount to 20%.

In order to increase the thermal stability of the quadricyclane structures, Hirao and Yamashita[56] proposed the introduction of stabilising acceptor groups (A = CF_3, CF_2Et, CHFEt) into the initial norbornadienes. However, the details of conducting the photoreaction have not been reported.

3. Complexes of norbornadiene with transition metal salts

A further method of increasing λ_{lim} is to use complexes of norbornadiene with different transition metals instead of the unsubstituted compound (I). In this case a new band appears in the electronic spectra of the resulting compounds at a longer wavelength than the absorption compound (I).[15] However, an efficient photoconversion of such systems to quadricyclane (II) only occurs for complexes of norbornadiene with univalent copper salts. The mechanism of such reactions is examined in Section III. We should merely note that λ_{lim} for complexes of norbornadiene with CuX (X = Cl, Br, I, OAc) is no greater than 360 nm. The main disadvantage of this method of inceasing λ_{lim} is the tendency of Cu(I) salts to undergo mild oxidation to bivalent copper salts, which no longer form complexes with norbornadiene.

---o0o---

By comparing the above approaches to increasing λ_{lim}, the following conclusions can be drawn. The use of norbornadiene complexes with Cu(I) salts displaces λ_{lim} to 360 nm with a satisfactory quantum yield. The main problems of this method are the high sensitivity of the complexes of atmospheric moisture and the lack of scope for varying the structure.

In the case of norbornadienes that contain substituents on one of the two double bonds, λ_{lim} is shifted into the visible region as far as 400–470 nm (even to 580 nm in some cases). The main disadvantage of this method is the sharp decrease in quantum yield Φ of the photoreaction with an increase in λ_{lim}.

By using norbornadienes with electron-donating and electron-withdrawing substituents on the different double bonds it is possible to shift λ_{lim} to even longer wavelength (500–600 nm), and in this case it is possible at the same time to achieve high values of both λ_{lim} and Φ. This approach would appear to have the greatest potential, although, as before, there remain three disadvantages that are difficult to overcome: 1) the reduction in quantity of stored energy per gram of substance because of the increase in molecular weight of the substituted norbornadiene; 2) the relative complexity of the synthesis of such compounds; and 3) their high cost.

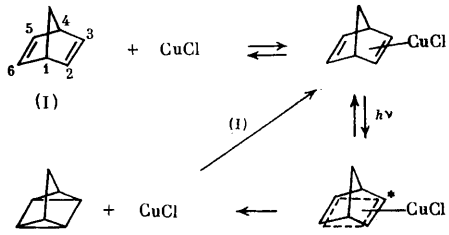
III. Methods of increasing the quantum yield of photoisomerisation of norbornadiene to quadricyclane

The photoconversion of unsubstituted norbornadiene to quadricyclane is characterised by quite a low quantum yield (Φ = 0.05),[28,55] but it can be increased substantially with the use of sensitisers. The following methods of sensitisation have been used: 1) formation of complexes between transition metal compounds and norbornadiene that are stable in the electronic ground state; and 2) interaction of a sensitiser (S) in an electronically excited state with norbornadiene (I), resulting in energy transfer and the formation of charge-transfer complexes or the addition-elimination of sensitiser.

In the first case the stable complex that is initially obtained undergoes photoexcitation

$$S + (I) \rightarrow [S\cdots(I)] \xrightarrow{h\nu} S + (II). \qquad (12)$$

The following requirements should be met by the transition metal compound S used as sensitiser:[57]



1) The transition metal in compound S must be in a low oxidation state and coordinated with a single norbornadiene molecule (the coordination of S with two norbornadiene molecules assists its dimerisation):

2) the [S···(I)] complex must absorb in the visible region:

3) S must not catalyse the reverse reaction (II) → (I);

4) S must not participate in secondary photochemical reactions.

Despite the fact that many transition metals are capable of forming complexes with norbornadiene,[15] only univalent copper compounds satisfy these requirements to a sufficient degree.[58–62] The photoisomerisation mechanism has been studied in the greatest detail in the case of the complex between norbornadiene and CuCl:

(13)

The initial components—norbornadiene (I) and CuCl—do not absorb in the region >300 nm, whereas the complex formed by them has an intense charge-transfer band with λ_{lim} = 350 nm. Photoexcitation of this complex by light with wavelength 313 nm results in the formation of quadricyclane as the sole product (Φ = 0.2–0.4, depending on the solvent). It is assumed that photoexcitation in the charge-transfer band of the [(I)...CuCl] complex causes the bonds between the C_2-C_3 and C_5-C_6 atoms in norbornadiene to become weaker and the bonds between the C_2-C_6 and C_3-C_5 atoms to become stronger. Subsequent relaxation of the excited state gives either norbornadiene again or quadricyclane. The latter does not form complexes with Cu(I) salts, so catalytic quantities of CuCl are sufficient for conversion of all of the norbornadiene to quadricyclane. The formation of quadricyclane when CuBr, CuI, CuOCOMe,[61,62] and also certain complex Cu(I) compounds are used occurs by a similar mechanism.[63,64] The quantum yields of the photoconversion (I) → (II) on irradiation of complexes of norbornadiene with $CuBr(Py)(PPh_3)$ and $Cu[HB(Pz)_3]$ (Py = pyridine, Pz = 1-pyrazolyl) with light at λ = 313 nm are 0.1–0.2 (in benzene) and (0.37–0.65) (in hexane) respectively, and $\lambda_{lim} \approx 370$ nm.

The second possible way of sensitising the reaction (I) → (II) is by interaction of a sensitiser S with norbornadiene according to the mechanism

$$S + (I) \xrightarrow{h\nu} {}^*S + (I) \rightarrow S + (II). \qquad (14)$$

In the opinion of Juris et al.[57] this type of sensitiser must satisfy the following requirements: 1) not form complexes with norbornadiene in the ground state; 2) absorb in the visible region, with the lifetime of the excited state *S being sufficiently long for the bimolecular reaction (14) to occur; 3) not catalyse the reverse reaction (II) → (I); 4) not participate in secondary photochemical reactions. The latter two requirements match those represented in scheme (12).

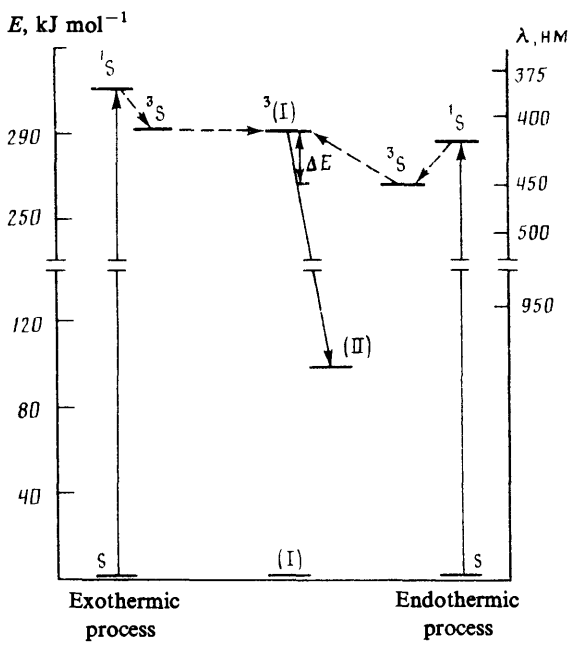
Since the conversion of norbornadiene to quadricyclane occurs in a triplet state,[65,66] the greatest efficiency of photoreaction (I) → (II) is to be expected with triplet sensitisation, which consists of the following stages:[67]

$$S \xrightarrow{h\nu} {}^1S \rightarrow {}^3S + (I) \rightarrow S + {}^3(I) \rightarrow (II). \qquad (15)$$

At the first stage the sensitiser S undergoes photoexcitation to a

singlet state, at the second stage the intersystem crossing $^1S \rightarrow {}^3S$ occurs, at the third stage there is a triplet transfer of energy from ^3S to (I), and finally at the fourth stage (II) is formed from triplet-excited (I).

Such a transfer of energy is only favourable for sensitisers with a triplet state energy higher than in norbornadiene (i.e., $E_T > 293$ kJ). However, in this case, as can be seen from Fig. 1,[15] even a small value of the singlet-triplet splitting of such systems will correspond to $\lambda_{lim} \leqslant 400$ nm. The condition $E_T > 293$ kJ is met by a relatively small number of sensitisers,[20,27,68–72] the range of these being mainly limited to carbonyl compounds (Table 4). As expected, the highest values of Φ were found for acetophenone ($E_T = 309.6$ kJ, $\Phi = 0.91$) and benzophenone ($E_T = 289.5$ kJ, $\Phi = 0.45$,[66], 0.8 [69]), with λ_{lim} equal to 366 and 380 nm respectively.



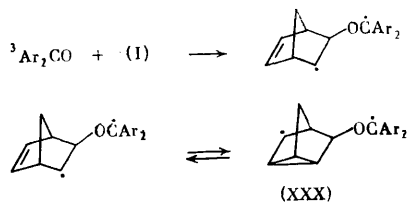


Figure 1. Energy levels of norbornadiene (I) and sensitiser (S).

For sensitisers with $E_T < 293$ kJ the transfer of energy from ^3S to norbornadiene is unfavourable (endothermic process in Fig. 1); nevertheless, efficiency sensitisation of reaction (I) → (II) even occurs in this case, which is due either to the formation of a [*S- - -(I)] complex in an excited state[15] or to the formation of covalent bonds between *S and (I).[73,74] Strong arguments in favour of the latter mechanism have only been established for substituted benzophenones. In fact, in a number of cases the value of Φ is not wholly determined by the magnitude of E_T (Table 4). With similar values of E_T the quantum yield is higher for benzophenones with electron-donating groups (compared to unsubstituted benzophenone) and less for benzophenones with electron-withdrawing groups. Arai et al.[74] conclude from kinetic data that in this case the following process competes with the energy transfer mechanism:

(16)

$$(XXX) \rightarrow (II) + Ar_2CO,$$
$$(XXX) \rightarrow (I) + Ar_2CO.$$

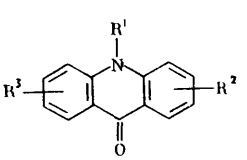

Table 4. Quantum yields of the sensitised photoreaction (I) ⇄ (II).

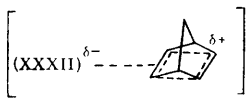
However, the most common mechanism of sensitisation is the formation of [*S- - -(I)] complexes between the sensitiser (with $E_T < 293$ kJ) in an excited state and norbornadiene.[15,63]

The substituted acridunones (XXXI) acting by this type of mechanism absorb at longer wavelengths (λ_{lim} = 360–420 nm) than benzophenone[75] and have Φ(I)→(II) = 0.4–0.7 (see Table 4).

(XXXI)

a) R^1 = Me, R^2 = 3-NMe_2, R^3 = 6-NMe_2;
b) R^1 = Me, $R^2 = R^3$ = H;
c) R^1 = H, R^2 = 2-Br, R^3 = 7-Br;
d) R^1 = Me, R^2 = 2-Br, R^3 = 7-Br;
e) $R^1 = R^3$ = H, R^2 = 3,4-C_6H_4.



A general disadvantage of using carbonyl-containing compounds for sensitisation of the reaction (I) → (II) is the formation of products obtained by their photoaddition to norbornadiene or quadricyclane.[75–79] Moreover, they promote the polymerisation of norbornadiene, although this can be avoided by adding certain phenols such as 2,6-di-t-butyl-*p*-cresol to the solution.[70,72]

There are also reports on complex compounds of univalent copper that do not form complexes with norbornadiene in the ground state but effectively sensitise the reaction (I) → (II) [80,81] presumably by an endothermic route (Fig. 1) through the thermally activated transfer of energy from S to (I).[15,82] The value of λ_{lim} for $Cu[PPh_2Me]_3BH_4$, $Cu[PPh_3]_2BH_4$, Cu(prophos)BH_4 [prophos = 1,3-bis(diphenylphosphino)propane] is about 330 nm, while the Φ values in benzene at λ_{irr} = 313 nm are equal to 0.56, 0.76, and 0.88 respectively.

By incorporating groups that provide chromaticity into the molecule of the sensitiser Ph_3PCuXL (X = Cl, Br; L = 2,2′-dipyridyl, *o*-phenanthroline, phthalazine, pyridine) it is possible to conduct the reaction (I) → (II) on exposure to light of wavelength 313 nm and 366 nm.[41,83] The quantum yields in ethanol and THF constitute 0.03–0.13 (λ_{irr} = 313 nm) and 0.008–0.011 (λ_{irr} = 366 nm). The use of the compounds $[Cu(PPh_3)_2(dpk)]NO_3$, $[Cu_2I_2(PPh_3)_2(dpk)]$, and $Cu_4I_4(dpk)_3$] (dpk = di-2-pyridyl ketone)[84] as sensitisers results in λ_{lim} being shifted to 500–600 nm and with quantum yields in dichloromethane equal to 0.17, 0.25, and 0.36 respectively (λ_{irr} > 320 nm).

Certain sensitisers can form complexes with norbornadiene in both the ground state and an excited state.[85,86] On irradiation of norbornadiene with light with λ_{irr} > 270 nm in the presence of $Cu_2Br_2(AsPh_3)_3$ and $[CuCl(AsPh_3)]_4$, the quantum yield of the reaction in chloroform is 0.17 and 0.45 respectively, and the limiting value of Φ = 0.75 is reached with high concentrations of norbornadiene.[85] Sensitisation with the complexes $(Ph_2PCH_2CH_2.PPh_2)CuCl$, $(Ph_3P)_3CuX$ and $(MePh_2P)_3CuX$ (X = Cl, Br, I) makes it possible to reach the maximum quantum yield of $\Phi_{(I)\rightarrow(II)}$ = 1.0 in concentrated solution,[86] but dilution sharply reduces the quantum yield.

In a number of studies[57,62,87–89] there are reports on sensitisers containing other transition metals: $Ru(bipy)_3^{2+}$, $Ru(phen)_3^{2+}$, *cis*-$Ir(phen)_2Cl_2^+$, $Rh(phen)^{2+}{}_3$, where bipy = di-2-pyridyl, phen = 1,10-phenanthroline. However, in these cases $\Phi_{(I)\rightarrow(II)}$ does not exceed 0.006 (λ_{irr} = 366 nm). Only in the case of $Ir(bipy)_2.(bipy')^{3+}$ (XXXII) does the quantum yield amount to 0.72, which Grutsch and Kutal[89] relate to the formation of a charge-transfer complex in an excited state

By comparing the properties of the sensitisers described above it may be concluded that when compounds that form a ground state complex with norbornadiene are used, it is difficult to expect large values of λ_{lim} for the system [S- - -(I)], so that a considerable proportion of solar radiation cannot be utilised.

The action of triplet sensitisers such as acetophenone (with E_T > 293 kJ) is limited by the value λ_{lim} = 400 nm. It would appear that the development of sensitisers that have E_T < 293 kJ, absorb in the visible region, and are capable of forming charge-transfer complexes in the excited state with norbornadiene has the greatest future potential.

Although both processes (forward and reverse) for converting norbornadiene to quadricyclane are effected with kinetic control, surmounting the energy barrier of the counter reactions is achieved by different methods. The photochemical forward reaction is complemented by a dark thermal process whose efficiency is determined in many respects by the choice of catalyst.

IV. Catalysis of the thermal reaction quadricyclane → norbornadiene

A necessary condition for creating systems that store light energy is the kinetic stability of the product of the photoreaction. For the thermal conversion of quadricyclanes to norbornadiene, the high value of the energy barrier is dictated by the orbital restriction on the (2σ + 2σ)-cycloaddition reaction. The height of this barrier can be reduced when transition metal compounds and Lewis acids are used as catalysts and also by carrying out the conversion via radical cation intermediates.

Table 5. Catalytic activity of square-planar complex compounds in the isomerisation of quadricyclane to norbornadiene.

Ligand	Electronic structure of metal ion							
	d^5	d^6	d^7	d^8		d^9		d^{10}

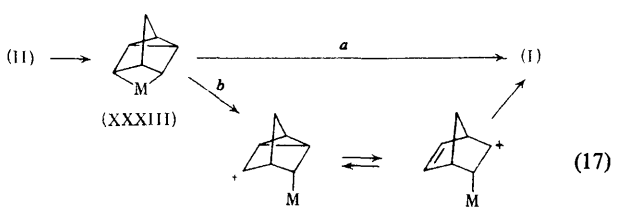
N,N′-Ethylenebis(salicylidenimine)			+	–		–		–

Note. + = reaction goes to completion; – = no reaction.

1. Catalysis of unsaturated coordination transition metal complexes

The mechanism of catalysis of symmetry-forbidden electrocyclic reactions by transition metals was first analysed by Mango and Schachtschneider[90] and subsequently examined in more recent studies.[91–95] According to three studies[90,94,95] the role of the transition metal is that with a suitable orientation its *d* orbitals can form combined MOs with the delocalised σ-orbitals of the cyclobutane ring of quadricyclane and the π-MOs of the double bonds of norbornadiene. The change in symmetry of the frontier MOs resulting from this leads to a removal of the orbital restriction on the thermal reaction. According to another view of the role of the catalyst,[91] the transition metals make available their orbitals that are intermediate in energy between the HOMOs and LUMOs of the initial compounds and the reaction products, which results in a decrease in the energy of activation of the process, which remains forbidden.

The dependence of the catalytic activity of transition metal complexes on the extent of occupancy of the *d* shell and the geometric configuration was studied by Manassen.[96] It follows from the results given in Table 5 that metal complexes with a d^6–d^8

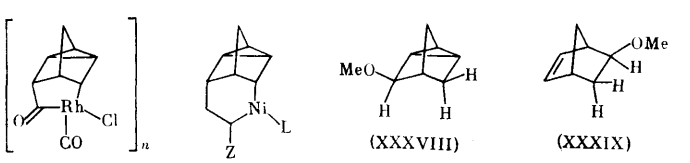


electronic shell in which there is either a vacant d_{zy} orbital or a higher populated p orbital that is similar in energy to an occupied d orbital are effective catalysts. In complex compounds of d^{10} elements [Cu(I), Ag(I)] all of the bonding orbitals are occupied by electrons and these complexes cannot catalyse a concerted opening of the cyclobutane ring.[93]

Another necessary condition for catalytic activity to occur in transition metal complexes is a square-planar structure of their molecules,[96] providing ease in additional coordination.

The available data on the opening of the cyclobutane residue catalysed by transition metal compounds are consistent with a multistage mechanism.[93,97,98] Depending on the properties of the central atom of the metal complexes, two main mechanisms for the multistage catalysed rearrangement of quadricyclane to norbornadiene can be distinguished:

1) an oxidative addition mechanism, which involves the insertion of a metal atom into the strained carbon–carbon bond to form the metallocyclobutane intermediate (XXXIII) followed by elimination of the catalyst[94,99,100] (route *a*);



2) a mechanism through which carbocations (XXXIV) and (XXXV) are formed[97,101,102] (route *b*).

(17)

The ability of the catalyst to induce a particular reaction mechanism is determined by the magnitudes of the electron affinity and promotion energy (Table 6). While the first mechanism is typical for the initial members of the series—Ni(0), Pd(0), Pt(0), Rh(I)—the use of metal compounds with large values of these parameters—Pd(II), Pt(II), Cu(I), Ag(I), Zn(II), Hg(II)—leads to the formation of carbocation intermediates (XXXIV) and (XXXV). This is due to the fact that in the metallocycle (XXXIII) the metal atom is in a higher oxidation state and is quite a strong oxidising agent, resulting in heterolytic cleavage of the metal–carbon bond.

The choice between these two mechanisms can be made by analysing the reaction products. For the isomerisation of quadricyclane to norbornadiene catalysed by $[Rh(CO)_2Cl]_2$, complexes of the type (XXXVI) were isolated,[91] being formed by insertion of a carbonyl ligand into the metal–carbon bond of intermediate (XXXIII).

(XXXVI) (XXXVII) (XXXVIII) (XXXIX)

(I)

The formation of subsidiary nickel complexes (XXXVII) as intermediates in the reaction between quadricyclane and bis(acrylonitrilo)nickel has been postulated.[100] It should be noted that the organorhodium compounds (XXXVI) were only detected when rhodium dicarbonyl chloride dimer was used, which may be due to the specific properties of carbon monoxide as a ligand. In other cases the formation of metallocyclic intermediates was not established directly but followed from an analysis of the reaction products and the kinetic data. The formation of the derivatives of nortricyclane (XXXVIII) and norbornene (XXXIX) during isomerisation of quadricyclane by silver(I) and palladium(II) compounds in proton-donating solvents[104] is an argument in favour of reaction (17) occurring by route *b*. A similar dependence of the reaction products on the oxidising properties of the metal ion were found in the isomerisation of cubane catalysed by transition metal compounds.[105]

Table 6. Electron affinities and promotion energies of certain atoms or ions.

Electronic configuration	Atom or ion	Promotion energy, eV*	Electron affinity, eV

* Energy of transition beween the levels:

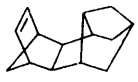
$$nd^{10} \rightarrow nd^9(n+1)p \text{ and } nd^8 \rightarrow nd^7(n+1)p.$$

The isomerisation of quadricyclane to norbornadiene catalysed by transition metal complexes was first reported in 1967.[106] It was shown that on treatment of a solution of quadricyclane with di-*m*-chloro-bis(norbornadiene)dirhodium in chloroform at −26 °C the time of half-conversion is 45 min [without a catalyst $\tau_{1/2}$ (140 °C) ≈ 14 h].[27] Other complexes of Rh(I) [90,104,106–109] and also Ni(0) [100,110] and Pd(0) [104,106,108,111] have similar properties.

The rate constants for isomerisation of quadricyclane in the presence of the norbornadiene complex [(I)RhCl], which were obtained by Cassar[99] do not depend on the concentration of norbornadiene and have values of 2.2 mol^{-1} s^{-1} and 1.8 mol^{-1} s^{-1} in chloroform and carbon tetrachloride respectively. However, it was shown previously[112] that this dimeric complex is decomposed by norbornadiene;

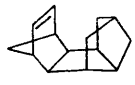
$$[(I)RhCl]_2 + 2(I) \rightleftarrows 2(I)_2RhCl. \quad (18)$$

This apparent contradiction was clarified by Taylor and Jennings.[109] From data on the position of equilibrium at different temperatures it follows that at 40 °C it is shifted quite considerably to the left, so there is no effect from norbornadiene. On lowering the temperature the equilibrium concentration of the monomeric complex $(I)_2RhCl$ increases, and because of its greater activity compared to the dimer, the rate of isomerisation increases by a factor of 1.7. The



dependence of the equilibrium constant of (18) on temperature with a ratio of (I):$[(I)RhCl]_2$ = 4:1 is given below.

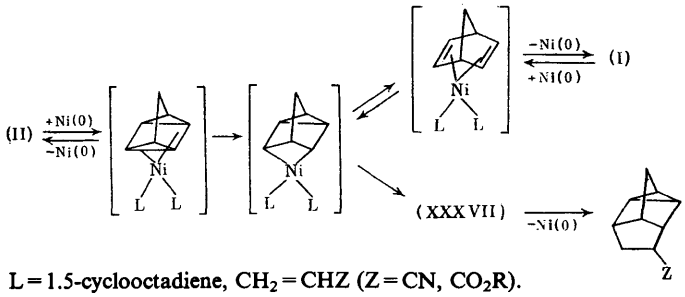
T, K	203	208	213	218	223	228	233
K	1.39	0.73	0.44	0.11	0.07	0.03	0.01



Replacement of a chloride ligand in $[(I)RhCl]_2$ by acetate results in a new equilibrium being established:

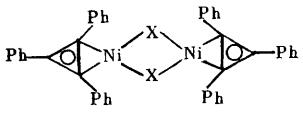
$$[(I)Rh(OAc)]_2 + (I) \rightleftarrows (I)_3Rh_2(OAc)_2. \quad (19)$$

Isomerisation of quadricyclane catalysed by the complexes $[(I)Rh(OAc)]_2$ and $(I)_3Rh_2(OAc)_2$ leads to the formation of the novel products (XL) and (XLI):[107]



(XL)

(XLI)



On the other hand, when carbonyl ($[Rh(CO_2)Cl]_2$) and norbornadiene complexes of univalent rhodium are used, norbornadiene is formed in quantitative yield.[104,113]

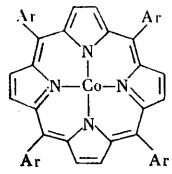
The formation of by-products (norbornadiene dimers, products of the insertion of ligands into the metal–carbon bond) occurs in the rearrangement of quadricyclane to norbornadiene catalysed by Ni(0) complexes:[100,114]

L = 1.5-cyclooctadiene, $CH_2=CHZ$ (Z = CN, CO_2R).

Derivatives of triphenylcyclopropenylnickel ($Ph_3C_3Ni(CO)X$, X = Cl, Br) (XLII) are active catalysts for the isomerisation of (II) → (I).[110] The initial rate of reaction depends on the concentration of catalyst and quadricyclane and comprises 2–4 (mol cat)$^{-1}$ s^{-1}. The data obtained indicate that the nickel complex (XLII) readily loses its carbonyl ligand and the reactive species is the square-planar dimeric complex (XLII).

(XLIII)

The ability of (XLIII) to form complexes with both quadricyclane and norbornadiene results in steady-state conditions being established.

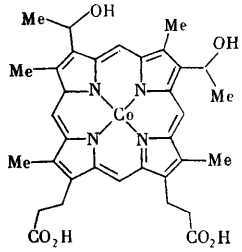


Replacement of the carbonyl in (XLII) by ligands that form stronger bonds with the metal atom [THF, $P(OPh)_3$, $PPhCl_2$, PPh_2Cl, $P(OPr\text{-}iso)_3$, $P(OMe)_3$, py, bipy] and an increase in the ratio of L:Ni in the molecule of the complex compound lead to a reduction in catalyst activity.

The relatively high activity of triphenylpropenylnickel complexes compared to other Ni(II) derivatives (also square-planar) may be due to the tendency of the cyclopropene ring to acquire a positive charge, and at the same time nickel becomes relatively negative. Thus, because of the unusual properties of the cyclopropene ligand, the Ni atom in $Ph_3C_3Ni(L)X$ will be sterically similar to Ni(II) and electronically similar to Ni(0).[110]

Because of the comparatively low value of the promotion energy of the palladium atom (4.23 eV) an oxidative addition mechanism can be proposed for the isomerisation of (I) → (II) catalysed by Pd(0) complexes. Analysis of the reaction products indicates the similarity of the intermediates formed by Rh(I) and Pd(0) complexes.[111]

Thus, only in rare cases do the above-mentioned process for the isomerisation of quadricyclane which are induced by Rh(I), Ni(0), and Pd(0) complexes result in the quantitative formation of norbornadiene. For the most part, by-products are formed.



Some of the most widely studied and effective catalysts of the rearrangement of quadricyclanes to norbornadienes are the square-planar unsaturated coordination complexes of cobalt(II) with porphyrin (XLIV)–(LI), phthalocyanine (LII)–(LIV) and bis(azomethane) (LV, n = 2) ligands[51,96] (extending the methylene bridge in complexes (LV) by just one CH_2 group leads to deviation from a planar structure of the chelate centre and a loss of catalytic properties).

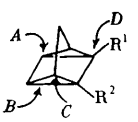
(LIII): R = SO_3H (Co-PcS_4),
(LIV): R = CO_2H (Co-PcC_4).

(LV)

The active catalytic site in these molecules occurs in the axial position (relative to the plane of the chelate CoN_4- or CoN_2O_2-centre); shielding of this reduces the efficiency of the catalyst:[115,116]

Co-TPP ~ Co-TPP(*p*-Me) > Co-TPP(*o*-Me) > Co-TMP.

In studies of the catalytic activity of Co(II) porphyrin and phthalocyanine complexes it was found that: 1) introduction of electron-withdrawing substituents into the ligand molecule increases the efficiency of the catalyst;[51,117] 2) the catalysts are effective in both aqueous solution and organic media (except for pyridine bases, which block the axial positions of the complexes);[96,118] 3) cobalt(II) porphyrin complexes in aqueous solution are more active than phthalocyanine complexes because of the ability of the latter to undergo aggregation.[118]



An increase in the hydrophobic properties of quadricyclanes—replacement of amide and carboxyl hydrogen atoms by alkyl or aryl groups—increases their reactivity, since the process that limits the rate of isomerisation in aqueous solution is approach of the quadricyclane to the hydrophobic environment of the active site of Co(II) porphyrin catalysts (Table 7).[118]

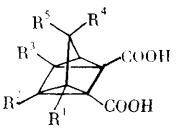
* in acetone-d_6.

It follows from the data given in Table 8 that an increase in steric hindrance to the approach of substrate and catalyst along direction *A* in (LVI) significantly reduces the rate of isomerisation. This direction of attack by cobalt(II) porphyrin catalysts is different from the direction of attack on quadricyclane by rhodium and nickel catalysts (routes *B* and *C*):[99,100]

(LVI)



(LVII)

The ability of cobalt(II) porphyrin complexes to catalyse the isomerisation of quadricyclane is due to the presence of an unpaired electron in the d_{z^2} orbital of cobalt(II).[119] The existing literature data[120,121] are consistent with a radical mechanism for the process which involves the formation of the radical intermediates (LVII).

The advantage of cobalt catalysts is their quantitative conversion of quadricyclanes to norbornadienes in both organic solvents and water, but at the same time it should be borne in mind that there is a possibility of cobalt(II) being oxidised to cobalt(III), whose square pyramidal complexes, although more active,[122–124] are capable of inducing side reactions.

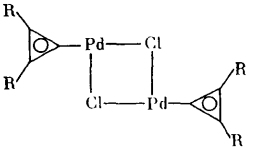
2. Carbocation mechanism of isomerisation

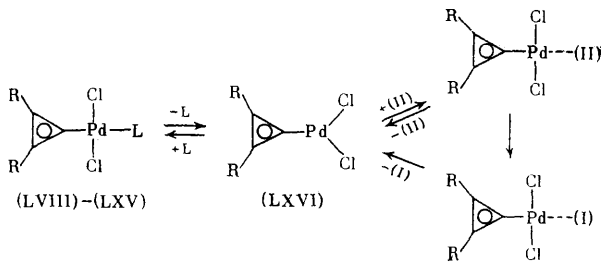
It was shown earlier that when transition metal complexes with a high electron affinity and promotion energy are used as catalysts, the reaction occurs via the formation of carbocation intermediates.



The ratio of isomerisation products of quadricyclane when the reaction is carried out in the presence of palladium dichloride and its complex compounds depends on the nature of the solvent used; in aprotic media only norbornadiene is formed,[104,111,126] while in proton-donating solvents (in methanol, for example) there is a mixture of products consisting of norbornadiene (40%), methanol adducts, and compounds of an undetermined structure.[104]

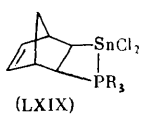
The Pd(II) cyclopropene derivatives (LVIII)–(LXI) are effective catalysts of the quadricyclane → norbornadiene process.[125]

(LVIII)–(LXIII)



(LVIII): R = t-C_4H_9 R^1 = H; (LXI): R = iso-C_3H_7, R^1 = H;
(LIX): R = t-C_4H_9, R^1 = Me; (LXII): R = iso-C_3H_7, R^1 = Me;
(LX): R = t-C_4H_9, R^1 = CN; (LXIII): R = iso-C_3H_7, R^1 = CN.

(LXIV), (LXV)



(LXIV): R = t-C_4H_9;
(LXV): R = iso-C_3H_7.

The catalytic activity of the complexes (LVIII)–(LX), (LXIV), and (LXV) is comparable to the activity of $[(I)RhCl]_2$, but in contrast to the latter they are not susceptible to oxidation. The active species in this case are unsaturated coordination complexes of the type (LXVI).

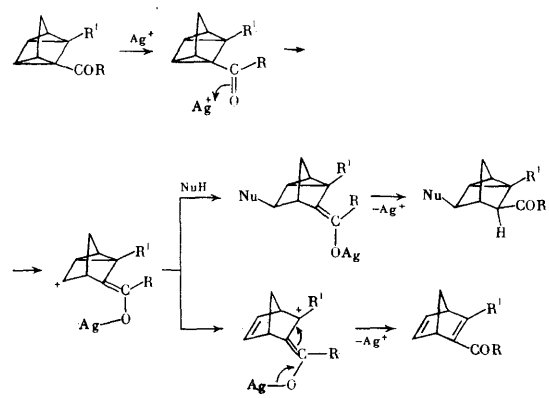
The efficiency of catalysts of this type depends on the tendency of the initial forms to dissociate—an increase of the electron-withdrawing properties of the ligands increases the catalytic activity. The dimeric complexes (LXIV) and (LXV) are more active than the monomeric (LVIII)–(LXIII) because of their higher dissociation constants.

The values of the ionisation potential and electron affinity of tin(II) (11 ± 5 and 14.6 eV respectively) provide an indication that Sn(II) ions are moderately good acceptors and poor donors of electrons. Hence it may be expected that metallocyclobutane complexes of the type (XXXIII, M = Sn) will be unstable. Only one form of complex between $SnCl_2$ and norbornadiene was detected using ^{119}Sn NMR.[126] The activation parameters for isomerisation of (II) → (I) catalysed by $SnCl_2$ are: $\Delta G^{\neq} = 94.05$ kJ mol^{-1}; $\Delta H^{\neq} = 58.10$ kJ mol^{-1}, $\Delta S^{\neq} = -120$ J deg^{-1} mol^{-1}. The less negative value of the entropy of activation compared to that for $PdCl_2$ (-230 J deg^{-1} mol^{-1}) may result from a reaction mechanism that is different from that represented by scheme (17). The bonding of $SnCl_2$ in the complexes with phosphine ligands $Me_3P{=}SnCl_2$ (LXVII) and $Ph_3P{=}SnCl_2$ (LXVIII) increases the catalytic activity of Sn(II) compounds—the half-conversion time of (II) → (I) in these cases is about 5 s (compared to 1 min for $SnCl_2$). Adducts (LXIX) or charge-transfer complexes may be reaction intermediates.[127]

The conversion of quadricyclane to norbornadiene accelerated by $HgCl_2$ that occurs in quantitative yield at 18–20 °C has also been reported.[128] The process mechanism involves chloromercuration of the substrate during a rapid initial stage in which 60% conversion is achieved [the Hg(II) compound acts as a catalyst]. Further conversion takes place slowly and is represented by zero-order kinetics.

The action of Ag(I) ions on quadricyclane and its derivatives has been reported in sufficient detail.[104,129–133] It was found[129] that the formation of norbornadiene, nortricyclane (XXXVIII), and norbornene (XXXIX) is accompanied by the reduction of Ag(I) ions, which is due to higher value of the ionisation potential of Ag(I) (7.57 eV)[101,129] compared to quadricyclane (7.40 eV).[134] Quadricyclanes with electron-withdrawing substituents have higher ionisation potentials, which inhibits the reduction of Ag(I).

The formation of carbocation species can occur not only via cyclic intermediates but also by direct addition of a catalyst ion to the substrate,[130] as in the case of catalysis by protic acids.[51,54,130,135,136]



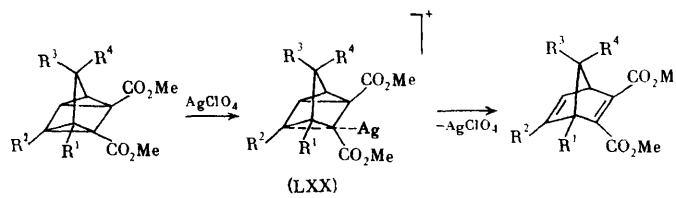


Table 9. Rate constants for isomerisation in reaction (20) catalysed by Ag(I).

H	Me	H	H	$2.4 \cdot 10^3$	–
H	H	Me	H	1	40
H	H	H	Me	0	1
H	H	Me	Me	0	0.7

* Apparent initial second-order rate constants.

A different view is expressed in studies by Maruyama and Tamiaki.[131–133] It follows from the results given in Table 9 [131] that an increase in steric hindrance that makes *exo* attack by the catalyst on the 2-position of quadricyclane difficult results in a considerable slowing down of the reaction, since in this case attack by silver ions occurs along direction *D* (see above) to form the cation (LXX).

(20)

The reaction mechanism does not change when organic solvents are replaced by water.[132] The introduction of methyl substituents into the 6-position of quadricyclane-2,3-dicarboxylic acids and their esters considerably increases the rate of their isomerisation [through stabilisation of intermediate (LXX)] and it suppresses side reactions involving the addition of nucleophiles.

The rearrangement of 2,3-bis(trifluoromethyl)quadricyclane to the corresponding norbornadiene in the presence of a tungsten catalyst ($PhWCl_3-AlCl_3$) occurs with yields that are almost quantitative.[137]

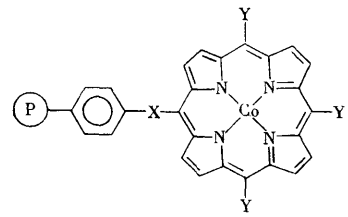
3. Heterogeneous catalysis

The processes presented above involving valence isomerisation of quadricyclanes to the corresponding norbornadienes are carried out under conditions of homogeneous catalysis, which may have only limited practical application. In order to achieve a cyclic recurrence of the process of storage and release of light energy by the norbornadiene–quadricyclane system, it is necessary to fulfil at least two conditions—separation of the catalyst and the light-sensitive medium and to achieve a yield of virtually 100% for the thermal reaction. It follows from an analysis of the literature data that this is feasible under conditions of heterogeneous catalysis.[138] Transition metal complex compounds immobilised on various types of supports and also inorganic compounds were investigated as catalysts of this type.

While crystal hydrate chlorides of Sn(II) and Pd(II) are effective catalysts under conditions of homogeneous catalysis, only anhydrous salts of these metals are active during heterogeneous catalysis,[140] which is due to the blocking of the active sites on the surface of crystals of the catalyst by water molecules.

Anhydrous copper(II) sulphate has similar properties to those of anhydrous Sn(II) and Pd(II) chlorides,[140] while in the case of copper(II) halides a secondary redox process occurs, giving nortricyclane halides and univalent copper salts (with sufficiently high concentrations of CuX_2 this process predominates). The catalytic activity of copper salts results from the formation of charge-transfer complexes between quadricyclane and CuX_2 in which both rearrangement to norbornadiene and the reduction of Cu(II) to Cu(I) and addition of halogen to quadricyclane may occur.

Table 10. Classification of oxides according to their ability to accelerate the isomerisation of (XXIX, *j*).



Group of catalysts	Time of reaction for the given group of catalysts	Oxide*
I	10 min	ReO_3 (24.7), MoO_3 (23.4), WO_3 (22.1), As_2O_5 (22.0), Sb_2O_5 (20.9), PtO_2 19.8, RuO_2 (19.8), TeO_2 (18.9), V_2O_5 (17.6), Nb_2O_5 (17.6)
II	24 h	Ta_2O_5 (16.5), SiO_2 (16.2), GeO_2 (16.2), SnO_2 (16.2), PbO_2 (16.2)
III	isomerisation has not occurred after 24 h	Rh_2O_3 (15.4), MnO_2 (13.5), TiO_2 (13.5), Sb_2O_3 (13.3), Bi_2O_3 (13.3), Tl_2O_3 (12.6), Fe_2O_3 (12.6), Ni_2O_3 (12.6), ZrO_2 (12.6), In_2O_3 (11.9), Co_3O_4 (11.4), Cr_2O_3 (11.2), Ga_2O_3 [11.2), HgO (9.5), AgO (9.5), CuO (9.5), CdO (8.5), ZnO (8.0), BaO (4.5)

* Electronegativity values of metals (χ_i) are given in brackets.

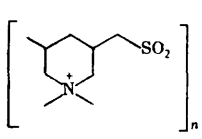
Inorganic oxides have the ability to accelerate effectively the isomerisation of quadricyclane to norbornadiene.[140–142] It was demonstrated that the catalytic activity of the latter varies in the same way as the electronegativity value of the metal[142] (Table 10). Such a correlation makes it possible to assume that the metal oxides act in the same manner as a proton, whose behaviour has been described by Hirao et al.,[54] namely, the first stage of catalysis is attack by the metal on the carbonyl oxygen atom. An increase in solvating power of the solvent reduces the activity of the catalyst, and a solvent such as pyridine completely suppresses it. The use of an oxide mixture increases the efficiency of the catalytic system (a mixture of TiO_2 and ZnO correspond approximately to SiO_2 in efficiency), which is due to the increase in acidic properties of such a mixture.[143,144]

Immobilised transition metal complexes also have the ability to catalyse the isomerisation of (II) → (I).[145–147] The catalysts of this type known at the present time are obtained either by the adsorption of transition metal compounds on various types of supports or by their complexation with polymer-bound ligands.

The properties of covalently bonded Co(II) complexes have been studied by different groups of chemists.[118,14]

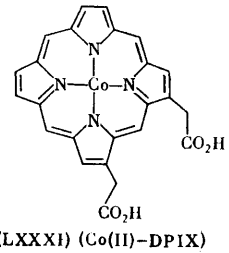
(LXXI)–(LXXIX)

P = polymer support



Compound	–X–	Y
(LXXI)	–NHCO–	CO_2Me
(LXXII)	$-NHSO_2-$	SO_2Me
(LXXIII)	$-CH_2NHCOC_6H_4-$	$C_6H_4CO_2H$-*p*
(LXXIV)	$-CH_2COC_6H_4-$	$C_6H_4CO_2H$-*p*
(LXXV)	$-COC_6H_4-$	$C_6H_4CO_2H$-*p*
(LXXVI)	$-CH_2-\overset{+}{N}(C_6H_4)-$	C_6H_4Me-*p*
(LXXVII)	$-CH_2-\overset{+}{N}Me_2-C_6H_4-$	4-C_5H_4N
(LXXVIII)	$-CH_2-\overset{+}{N}Me_2-C_6H_4-$	$C_6H_4NMe_2$-*p*
(LXXIX)	$-CH_2NHC_6H_4-$	$C_6H_4NH_2$-*p*

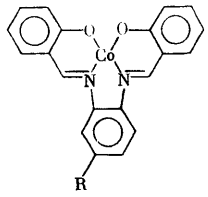
During the reaction the catalyst gradually loses its activity, which is due to the partial oxidation of Co(II) as well as its reaction with impurities. Treatment of the spent catalyst with reducing agents increases its activity. The rate of isomerisation of quadricyclane by such catalysts is virtually independent of the residue X, but the properties of the latter determine the stability of the catalyst under different conditions. Catalysts (LXXI)–(LXXIV) are hydrolysed in aqueous alkaline solution.



In addition to polymer-bound cobalt complexes, heterogeneous catalysts obtained by adsorption of complexes (XLIV)–(LV) on ion-exchange resins and inorganic materials have been studied.[118] In contrast to catalysts of the type (LXXI)–(LXXIX), Co(II) phthalocyanine and porphyrin complexes immobilised on carbon are less prone to a loss of activity during the process. Thus, for Co-TPPC (see IV.1) it is halved only after 10^4 cycles. Simple washing of the spent catalyst with boiling tetrahydrofuran completely restores the catalyst's efficiency.

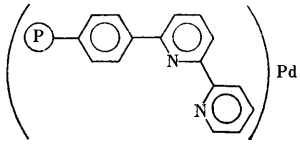
Square-planar Co(II) complexes immobilised on aluminium oxide modified with polyaminosulphone (LXXX) are very promising

catalysts for the isomerisation of quadricyclanes. As in the case of cobalt porphyrins immobilised on carbon

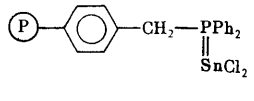


(LXXX) (PAS)

(LXXXI) (Co(II)-DPIX)



they are sufficiently effective, undergo slow deactivation, and are readily regenerated by heating under vacuum at 200 °C. However, the catalysts Co(II)-TPS/PAS/Al_2O_3 and Co(II)-DPIX/PAS/Al_2O_3 are not very active towards substituted quadricyclanes,[149] which is due to the steric repulsion between the equatorial ligands and the polysubstituted nortricyclane derivative (LVII). Complexes Co(II) such as (LV) (n = 2) and (LXXXII)–(LXXXV), with ligands that are more flexible than porphyrins, do not have these disadvantages.[150] In addition to activated carbon and alumina, poly(methacrylic acid), Florisil, magnesium silicate, and silica are also suitable as supports.



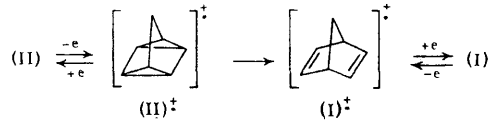
(LXXXII): R = H,
(LXXXIII): R = Me,
(LXXXIV): R = CO_2Me,
(LXXXV): R = CO_2H

(LXXXII)–(LXXXV)

The disadvantage noted for polymer-bound Co(II) porphyrin complexes are also typical for Pd(0), Pd(II), Sn(II) complexes fixed on polystyrene.

(LXXXVI)

(LXXXVII)



Thus, complex (LXXXVI) is deactivated during isomerisation as a result of oxidation and leaching of the metal.[127,128,152] Initially this catalyst is 30 times more active than palladium on carbon, but after two cycles their activities become equal.

Even less successful was the attempt to fix [Pd(MeCN)Cl_2] on a diphenylphosphine derivative of polystyrene. The activity of this type of catalyst proved to be much lower than for soluble [Pd(PPh_3)Cl_2] and it decreased even further on repeated introduction of this catalyst into the cycle.[152]

4. Radical cation mechanism for isomerisation

The barrier for many pericyclic reactions that occur via radical cation intermediates is known to be low in comparison with the barrier of similar reactions between neutral molecules.[153,154] When applied to the present problem of the catalysis of the isomerisation of quadricyclane, this method of lowering the activation barrier has the additional advantage of the ability of a radical cation of norbornadiene to oxidise quadricyclane and hence to the involvement of a redox chain mechanism.[155–160]

The generation of a radical cation of quadricyclane can be achieved, firstly, by oxidation of substrate with a photochemically generated oxidising agent,[161–165] secondly, by oxidising it with electronically excited sensitisers,[166,167] and finally, by electrochemical anodic oxidation of quadricyclane.[168] In each of these cases the $(II)^{+\cdot}$ radical cation is isomerised to the corresponding norbornadiene derivative $(I)^{+\cdot}$, which participates in the development of a redox chain reaction, so that the quantum yield (or yield based on current) of the reaction is greater than 1 (the isomerisation of quadricyclane to norbornadiene catalysed by dimethyldioxirane is also a chain process).[169]

$(II)^{+\cdot}$ $(I)^{+\cdot}$

Ikezawa and Kutal[161] showed that irradiation of n-type semiconductors (CdS, TiO_2, ZnO) in the presence of quadricyclane results in the formation of norbornadiene [$E^{Ox}_{1/2}(I)$ = 1.56, $E^{Ox}_{1/2}(II)$ = 0.91 V relative to a standard calomel electrode (SCE)].[162] The role of the oxidising agent in such systems is fulfilled by photogenerated holes that migrate to the surface of the semiconductor (Fig. 2*a*).

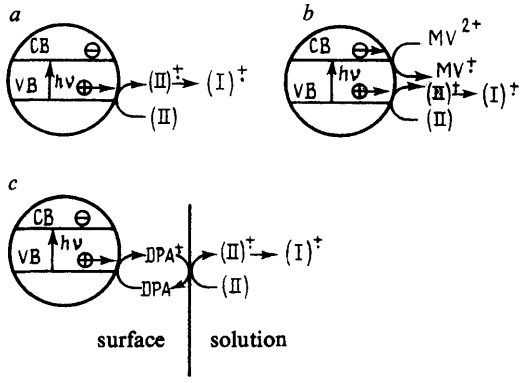


Figure 2. Schematic representation of the radical-cation mechanism of isomerisation of (II) → (I) on the surface of a semiconductor being irradiated. Adopted notation: CB = conductivity band; VB = valence band; MV^{2+} = methylviologen dication; DPA = diphenylamine.

The yield of norbornadiene is inversely proportional to the width of the forbidden band and varies in the series CdS > TiO_2 ⩾ ZnO. It can be increased by the addition of a methylviologen dication, which binds photogenerated electrons and thus prolongs the lifetime of the holes in the valence band (Fig. 2*b*). Addition of diphenylamine (DPA) ($E^{Ox}_{1/2}$ = 0.83 V), which acts as intermediate agent between the holes of the valence band and the quadricyclane molecules in solution (Fig. 2*c*) slightly increases the yield of norbornadiene. However, the ability of $DPA^{+\cdot}$ to dimerise to *N,N'*-diphenylbenzidine inhibits the cyclic processes [a more suitable intermediate agent may be tri-*p*-tolylamine ($E^{Ox}_{1/2}$ = 0.75 V)]. Although the attempts undertaken did lead to an increase in the yield of norbornadiene, the latter was still small (6–10%).

The results on the dependence of the rate of isomerisation of quadricyclane on the presence of oxygen in the system, obtained by Draper and de Mayo,[170] are different from those published by Kutal.[169] They found that when zinc was used, the rate of formation of norbornadiene increased in the presence of oxygen, which was due to the increase in lifetime of the photoinduced hole through bonding of an electron in a superoxide radical anion.[171] When CdS and TiO_2 were used the reverse effect occurred.[161,170,172,173] This may be due to predominating concurrent processes that involve the reduction of a radical cation by the superoxide anion, blocking of the surface of the semiconductor, and also the donation of an electron by chemisorbed oxygen to the photoinduced hole. The dark formation of norbornadiene (about 30%) in the presence of CdS was also detected.

Dichloronorbornadienepalladium molecules that are excited on exposure to radiation can act as oxidising agents. Irradiation of (I)$PdCl_2$ complexes in the presence of quadricyclane leads to isomerisation of the latter to norbornadiene with a yield exceeding 85%.[167,168,174] The quantum yield of the process is inversely proportional to the value of the half-wave oxidation of the strained hydrocarbon and for unsubstituted quadricyclane reaches a value of several hundred (Table 11), which is clear evidence in favour of a redox chain mechanism. For organic sensitisers the quantum yield is less than 1.[88,158,166,175–177]

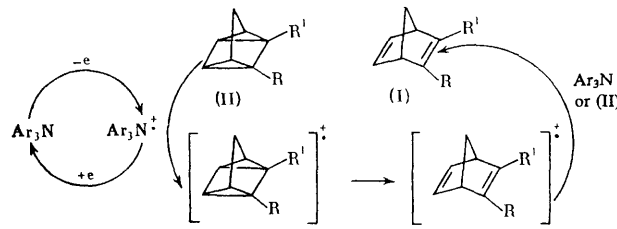

Table 11. Quantum yields of isomerisation of substituted quadricyclanes in the presence of (I)$PdCl_2$ (solvent—CH_2Cl_2, λ_{irr} = 405 nm).

Compound	$E^{Ox}_{1/2}$, V (vs. SCE)	Φ
Quadricyclane	0.91	230
2-Carbomethoxyquadricyclane	1.2	3.0
2,3-Dicarbomethoxyquadricyclane	1.64	0.06

Table 12. Electrochemical conversion of (II) → (I) (solvent—CH_2Cl_2).

Quantity of electricity passed through solution, $F \times 10^5$	Quantity of (II) before electrolysis, mol × 10^3	Quantity of (I) obtained mol × 10^3	Yield based on current	Quantity of (I) + (II) after electrolysis
2.1	0.97	0.16	7.6	1.02(±1.8%)
2.1	0.97	0.14	6.7	0.94(±0.7%)
0.89	0.42	0.056	6.3	–
4.1	1.52	0.45	11	1.83(±1.5%)

In the isomerisation processes examined above a preliminary stage—derivation of the active form of the catalyst—is required. A more convenient method is the direct generation of $(II)^{+\cdot}$ by anodic oxidation. The results obtained by Kutal et al.[168] (Table 12) show that: 1) electrolysis is quite suitable for obtaining norbornadiene; 2) the reaction is a catalytic process; 3) the yield based on current increases with an increase in concentration of quadricyclane; and 4) the conversion is sufficiently selective. A drawback of this method is contamination of the anode with a polymer film, which inhibits further reaction. This can be remedied with the use of an intermediate agent such as triarylamine, which is first oxidised at the anode and then reacts with quadricyclane.[178,179]

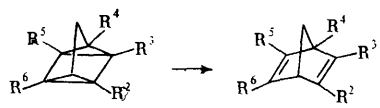
Better results were obtained for unsubstituted quadricyclane in the presence of tri-*p*-bromophenylammonium hexachloroantimonate ($E^{Ox}_{1/2}$ = 1.05 V). The introduction of substituents into the quadricyclane molecule and the use of the salts $(p\text{-}C_6H_4Br)_3N^+GaCl_4^-$ and Ph_3PMeX^- (X = $SbCl_6$, $GaCl_4$) increases the isomerisation time considerably and reduces the yield of product.[180]

5. Comparative properties of catalysts

It may be concluded from an analysis of the literature data on the efficiency of catalysts for the isomerisation of quadricyclane to norbornadiene that those with the greatest potential are square-plane complexes of bivalent cobalt. Their activity under conditions of both homogeneous and heterogeneous catalysis is usually comparable to the activity of compounds of other transition metals and in a number of cases substantially exceeds it. Moreover, when Co(II) catalysts are used, side reactions are absent in virtually all cases, in contrast to catalysis with cobalt(III) compounds. Amongst the disadvantages of catalysts of this type it is necessary to include the ease with which the oxidative process Co(II) → Co(III) takes place and the reduced efficiency of Co(II) towards quadricyclanes that are substituted with electron-withdrawing groups. These disadvantages do not occur in the carboxyl derivatives (LXXXV) on inorganic supports (activated carbon, alumina). An undoubted advantage of catalysts (LXXXV) is the possibility of regenerating them by relatively simple methods.

Metal oxides have very promising catalytic properties, but as yet no data exists on the possibility of carrying out cyclic processes with them.

Electrochemical oxidation of quadricyclanes is a fairly convenient method of accelerating the isomerisation of quadricyclanes to the corresponding norbornadienes. In the opinion of Gassman et al.,[178,179] some of these systems are feasible for use in real cases. Nevertheless, we should note that the conditions for the quantitative derivation of norbornadienes with this method have so far not been found.



V. Exothermicity of the thermal reaction

As was mentioned in Section II, the exothermicity of the isomerisation of quadricyclane to norbornadiene satisfies the requirements imposed on photochemical materials that can store solar energy—it amounts to ~10^3 kJ kg^{-1}. The introduction of

substituents, while improving the spectroscopic properties of norbornadiene, results in an increase in molecular weight and hence causes a worsening of the energy parameters of the system.

The amount of energy accumulated by the photochemical isomerisation of norbornadienes to the corresponding quadricyclanes is determined both indirectly (from the difference between the heats of hydrogenation[181–183] and combustion[184] of both isomers) and by direct methods (by different scanning calorimetry[185] through measuring the enthalpy of isomerisation of quadricyclanes by homogeneous and heterogeneous catalysts[26,44,118,150] and by photocalorimeter). Photocalorimetry involves the measurement of energy absorbed by the system when the photoreaction is conducted directly in a calorimeter.[186] The results obtained are given in Table 13.

Table 13. Heats of isomerisation of the process

R^2	R^3	R^4	R^5	R^6	ΔH, kJ mol^{-1}	Refs.
H	H	H	H	H	96*	
H	H	H	CONHPh	CO_2H	59±4	[44, 118]
H	H	H	$CONHC_6H_4Cl$-*p*	CO_2H	60±4	[44]
H	H	H	$CONHC_6H_4Me$-*p*	CO_2H	60±5	[44]
H	H	H	$CONHC_6H_4OMe$-*p*	CO_2H	59±4	[44]
H	H	H	CONHMe	CO_2H	52±4	[44]
H	H	H	CO_2Me	CO_2Me	105.4±14.6	[186]
H	H	H	CO_2Me	CO_2Me	77.1±1	[185]
H	H	H	CN	CN	92.0±9.6	[186]
Me	Me	Me	CN	CN	88.0±8.0	[151, 186]
Me	Me	H	CO_2Me	CO_2Me	80	[51]
Me	Me	H	CN	CN	88	[51]
Me	Me	H	CN	CN	92	[51]

*Average value given. The values obtained by different methods are (in kJ mol^{-1}): 100,[181] 91.42,[182] 91.63,[183] 41.64,[184] 88.7 ± 0.8,[185] 110 ± 1, 113 ± 1,[26] 92 ± 4,[185] 59 ± 4,[186] 81 ± 1.[118]

The experimentally determined values of the heats of isomerisation of quadricyclane (ΔH) are virtually independent of the method used, except in two cases.[184,186] The low value of ΔH = 59 ± 4 kJ mol^{-1} obtained by calorimetry is attributed to an interaction of norbornadiene and quadricyclane with the sensitiser (acetophenone).

A comparison of the exothermicities of the rearrangements of substituted quadricyclanes shows that the introduction of methyl, cyano, and carboxymethyl groups has hardly any effect on the value of ΔH, whereas carboxyl and carboxamide groups reduce it by ~20 kJ mol^{-1}.

VI. Conclusion

The practical value of the system norbornadiene (I) ⇄ quadricyclane (II), if it is characterised by high values of λ_{lim} and Φ, is obvious. Information is available[51] on engineering studies carried out in Japan aimed at developing small-scale experimental systems operating on norbornadiene to heat buildings, garden houses, and greenhouses and to generate electrical energy.

However, in progressing towards the large-scale utilisation of heat energy liberated by the catalytic conversion of quadricyclane to norbornadiene there are certain difficulties, in particular those of an economic nature. The operating scheme of a system for absorbing solar energy followed by the production of low-pressure steam[12,13,187] is depicted in Fig. 3. Norbornadiene stored in tank *1* is transmitted by pump *2* at a pressure slightly above atmospheric through a planar collector *3* (possibly with an immobilised sensitiser). The quadricyclane obtained by the photoreaction is stored in tank *4*, from which it can pass at a required pressure (pump *5*) into heat-exchanger *6*. The latter is necessary only if the reverse reaction (II) → (I) is carried out thermally (for example, on heating quadricyclane to 140 °C). The heat liberated is used to obtain low-pressure steam (or hot water) in reactor-boiler *7*, which is supplied with immobilised catalyst *8* in order to carry out the conversion of (II) → (I).

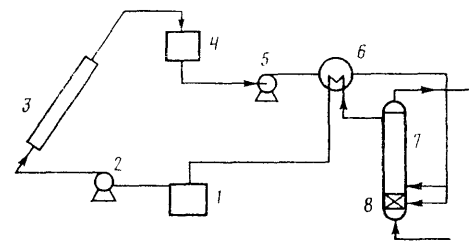


Figure 3. Operating scheme of a system for absorbing solar energy and the production of low-pressure steam (hot water): *1*, *4*, storage tanks; *2*, *5*, pumps; *3*, collector; *6*, heat-exchanger; *7*, reactor-boiler; *8*, immobilised catalyst.

Table 14. Cost of the unit shown in Fig. 3 with output of 100 kW (at 1981 prices).[187]

Equipment	Dimensions	Cost, in dollars
Collector *3*	Area 116000 m^2, depth 2 cm	2320000
Storage tanks *1* and *4*	120 m^3 each	60000
Heat-exchanger *6*	length 102 m	2500
Reactor-boiler *7*	27 tubes each of length 4.7 m	15000
Pumps *2* and *7*	—	4000
	Total	2410000

The norbornadiene used in such a system must be stable so that a large number of cycles of (I) ⇄ (II) can be achieved. 1440 cycles is considered to be the optimum number (corresponding to 99.99%

regeneration of norbornadiene per cycle and a total degree of discoloration of the initial material of 25%), and the cost of norbornadiene should not exceed 0.003 dollars per gram according to 1979 estimates.[188] We should note that in the light of the results of Yoshida et al.,[51,55] the required degree of cyclic recurrence does not seem impracticable nor does the reduction in price of the production of substituted norbornadienes (Table 14).

Taking into account the fact that the cost of steam obtained on such a system is substantially higher (by a factor of about 50) than the cost of steam produced by alternative methods, the main direction of efforts at the present time remains the development of less powerful small-scale units.

Kinetics and mechanism of the oxidation of organic compounds with hydrogen peroxide

V N Kislenko, A A Berlin
Lvov Polytechnic Institute

ABSTRACT. The literature data on the kinetics and mechanism of the oxidation of organic compounds of various nature with hydrogen peroxide in aqueous solution have been analysed. A generalised kinetic scheme is described for the radical–chain decomposition of hydrogen peroxide in the presence of organic compounds for which a rate equation for the process has been found by the method of quasi-steady-state concentrations for long chains. Partial expressions have been obtained for the rate of oxidation of various organic compounds with hydrogen peroxide allowing for the nature of the organic compound.

I. Introduction

Hydrogen peroxide is an available and effective oxidising agent and is widely used as a bleaching agent in the textile,[1] cellulose–paper industries[2] and in other fields.[3–5] Dilute solutions of hydrogen peroxide are used in medicine as an antiseptic and a disinfectant.[6,7] In addition H_2O_2 is used in the preparation of organic peroxides,[8] in the purification of effluent from substances oxidisable under mild conditions such as phenols,[9] and in the delignification of wood pulp.[10]

Hydrogen peroxide is a component of oxidation–reduction systems which are sources of free radicals in the initiation of free radical processes.[11]

Hydrogen peroxide is widely used as an initiator of radical polymerisation processes with unsaturated monomers[12] and also in the grafting of them to cellulose or its derivatives[13] and to water-soluble lignin preparations.[14] The efficiency of graft polymerisation and the extent of grafting are determined to a significant extent by the initiation stage which in fact is the reaction of hydrogen peroxide and its radicals with the initial polymer and with its macroradicals with subsequent interaction of the radicals obtained with the monomer.

Decomposition of hydrogen peroxide by radicals resulting on oxidation of certain oxygen-containing organic compounds (alcohols for example) with oxygen leads to further initiation of oxidation processes and co-oxidation of organic substances.[15]

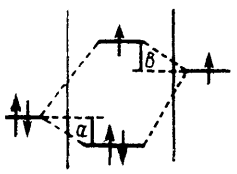
Hydrogen peroxide often reacts with various types of organic compounds when used as an oxidising agent. Without a study in depth of the chemical mechanism of such practically important processes it is impossible to find optimum conditions for carrying them out, to effect target-directed control of them or to increase their efficiency.

II. Initiation of the oxidation of oxygen-containing organic compounds by hydrogen peroxide

Depending on conditions, the decomposition of hydrogen peroxide in aqueous media proceeds by a radical–chain or ion–molecule mechanism and by a heterogeneous catalytic mechanism on the reactor surface.[16–22] Hydrogen peroxide reacts with organic compounds in aqueous solution predominantly by a radical–chain mechanism which is indicated by the inhibition of such processes by unsaturated monomers and other acceptors of free radicals. Initiation with hydrogen peroxide of the radical–chain oxidation of oxygen-containing organic substances may occur by homolysis of H_2O_2 according to reaction (1) or by the direct interaction of hydrogen peroxide with the organic compound.[15]

$$H_2O_2 \rightarrow 2^{\cdot}OH, \qquad (1)$$

The energy of activation for the homolysis of H_2O_2 according to reaction (1) is close to the energy for the decomposition of the O–O bond in hydrogen peroxide (202 kJ mol^{-1}). In particular the energy of activation for the process in the gas phase at 470–540 °C, when decomposition of unimolecular H_2O_2 predominates, is in the range 170–210 kJ mol^{-1} which is close to the theoretical limit.[23] In an aqueous medium at fairly low temperatures it is significantly less, of the order of 84 kJ mol^{-1}.[21,24]



The reduction in the energy of activation may be explained by the formation of a complex of hydrogen peroxide with the solvent. The possibility of complex formation with the participation of hydroxyl-containing compounds has been shown.[24,25] If the H_2O_2 molecule participates in the formation of hydrogen bonds as a proton donor then the H–O and O–O bonds in it will be weakened, as was noted for hydroperoxides.[26]

In organic solvents capable of forming hydrogen bonds with H_2O_2 the decomposition of hydrogen peroxide with the formation of $^{\cdot}OH$ radicals is characterised by a reduced energy of activation

(84–105 kJ mol^{-1}) in comparison with the O–O bond energy in hydrogen peroxide.[27] This is explained by the interaction of H_2O_2 with hetero atoms of the solvent and by the formation of hydrogen bonds which generate favourable conditions for the interaction of electrons from the solvent (Solv) with the unbonded orbital of the radical arising on fission of H_2O_2. This leads to the formation of a complex.

$$\text{Solv...H—O—O—H...Solv} \rightarrow 2(\text{Solv...}^{\cdot}\text{OH}). \quad (2)$$

The energy level diagram for the complex between a hydroxyl radical and the electron-donating solvent is shown in Fig. 1. It is known that the splitting of energy levels on complex formation is greater the closer they are to one another, i.e. in the case in question the energy of complex formation grows with the increase in basicity of the solvent[28] and must increase in the series ketone–alcohol–water.

Solvent Complex Radical

Figure 1. Diagram of the energy levels of a complex between a radical and an electron-donating solvent.[27]

Several physicochemical investigations also show the formation of complexes of hydrogen peroxide with water. Liquidus diagrams for the system hydrogen peroxide–water indicate the presence of two eutectic points for the mixtures of ice–$H_2O_2.2H_2O$ and $H_2O_2.2H_2O$–solid hydrogen peroxide.[29] A deviation was established in such complexes for the atomic concentration (number of atoms per unit volume) from that calculated by the additivity rule.[30] A maximum is observed in the dielectric constant–composition isotherms for this $H_2O_2.2H_2O$ complex.[31]

At low concentrations of hydrogen peroxide in water the decomposition process is described by a kinetic equation which is first order with respect to H_2O_2.[10,25] When investigating the decomposition of concentrated solutions of hydrogen peroxide it was discovered that an increase in the water concentration in the system leads to a growth in the ratio of reaction rate to initial H_2O_2 concentration.[1] The order of the reaction with respect to water found from the data[1] proved to be 1.99 ± 0.41.[22] It was suggested[22] that the decomposition of H_2O_2 in water proceeds through the stage of forming the complex $H_2O_2.2H_2O$.

$$H_2O_2 + 2H_2O \underset{k_{-к}}{\overset{k_к}{\rightleftharpoons}} H_2O_2 \cdot 2H_2O, \quad (3)$$

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2^{\cdot}OH \cdot H_2O. \quad (4)$$

The concentration of complex at steady-state-concentrations is

$$[H_2O_2 \cdot 2H_2O] = k_к (k_{-к} + k_d)^{-1} [H_2O_2][H_2O]^2. \quad (5)$$

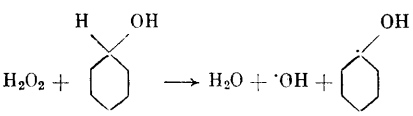
From which it is possible to obtain an expression for the rate of decomposition of H_2O_2

$$w = k_к k_d (k_{-к} + k_d)^{-1} [H_2O_2][H_2O]^2, \quad (6)$$

which corresponds with the experimental data.[1]

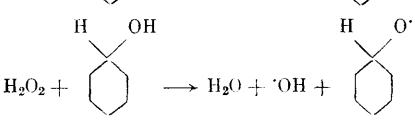
The reduction in activation energy to 84 kJ mol^{-1} for the decomposition of hydrogen peroxide in aqueous solution may therefore be explained by the formation of a complex of H_2O_2 with water.

It may be shown that at low concentrations of hydrogen peroxide when $k_K (k_{-K} + k_d)^{-1}[H_2O]^2 \gg 1$, the position of the equilibrium is shifted practically completely to the side of forming the complex, so that $[H_2O_2.2H_2O]_0 = [H_2O_2]_0$ and the rate is practically equal to



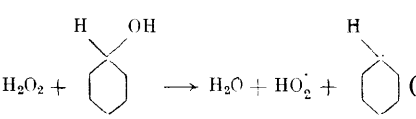
$$w = k_d [H_2O_2], \quad (7)$$

which corresponds with the experimental data.[22]



In the opinion of authors,[32] who studied the decomposition of H_2O_2 in cyclohexanol solution at 120–140 °C, the initiation of the oxidation of cyclohexanol with hydrogen peroxide may include the reactions given below:

$$H_2O_2 \rightarrow 2^{\cdot}OH \ (\Delta H = 210 \text{ kJ mol}^{-1}), \quad (8)$$



$$2H_2O_2 \rightarrow {}^{\cdot}OH + H_2O + HO_2^{\cdot} \ (\Delta H = 95 \text{ kJ mol}^{-1}), \quad (9)$$

$(\Delta H = 57 \text{ kJ mol}^{-1})$, (10)

$(\Delta H = 141 \text{ kJ mol}^{-1})$, (11)

$(\Delta H = 265 \text{ kJ mol}^{-1})$. (12)

The rate found experimentally for the initiation of the oxidation of cyclohexanol with hydrogen peroxide is described by the expression[32]

$$w_i = k_1 [H_2O_2] + k_2 [H_2O_2]^2, \quad (13)$$

where

$$k_1 = 8.9 \times 10^6 \exp(-98700/RT), \text{ sec}^{-1},$$

$$k_2 = 6.8 \times 10^9 \exp(-122000/RT), \text{ litre mol}^{-1} \text{ sec}^{-1}. \quad (14)$$

The initiation of the oxidation of propan-2-ol with hydrogen peroxide is represented[33] by a reaction of first order with respect to H_2O_2 with rate constant

$$k_1 = 1.1 \times 10^7 \exp(-96600/RT), \text{ sec}^{-1}. \quad (15)$$

Since

$$E_{act} \geqslant \Delta H, \quad (16)$$

for endothermic reactions, the second term in expression (13) may correspond to reaction (9). Consequently the first term in expression (13) may correspond to reactions (8), (10)–(12).

In the opinion of the investigators[32,33] the formation of radicals from H_2O_2 by unimolecular decomposition [reaction (8)] in a non-aqueous medium requires a significant consumption of energy (about 210 kJ mol^{-1}) and must proceed very slowly. The observed

activation energy for the initiation of oxidation of alcohols with hydrogen peroxide is significantly lower and is about 100 kJ mol^{-1}. The latter enabled the authors to propose that this reaction proceeds with the participation of alcohols [reactions (10)–(12)] disposed to form complexes with H_2O_2. However the heat of reaction for (11) and (12) is significantly greater than that of reaction (10) and approaches the heat of reaction for H_2O_2 homolysis. Consequently it was proposed[32] that radicals may be formed only by the bimolecular reaction (10). In addition a hypothesis has also been expressed[32,33] as to the possibility of carrying out a trimolecular reaction through the stage of complex formation.

$$H_2O_2 + 2ROH \rightleftharpoons ROH\ldots\underset{\underset{H}{|}}{O}\!\!-\!\!\underset{\underset{H}{|}}{O}\ldots HOR \longrightarrow 2H_2O + 2RO^{\cdot}. \quad (17)$$

Thermodynamic calculations[32,33] allowing for the stability of the O–H bond in the alcohol, the O–O in H_2O_2 and the H–O in water showed that

$$\Delta H = 2\times 428 + 210 - 2\times 495 = 76 \text{ kJ mol}^{-1}. \quad (17A)$$

It follows that reaction (17) is also energetically more advantageous than reactions (8), (9), (11) and (12) and the size of its heat of reaction relates to the experimentally found activation energy in accordance with expression (16).

In order to determine the reaction order with respect to alcohol for the initiation of oxidation of alcohols with hydrogen peroxide experiments were carried out using dilution of the reaction mixture with an inert solvent (chlorobenzene or decane).[32] However the results obtained, as calculated by the investigators, did not permit an unequivocal answer to the problem posed, since the dilution of the reaction mixture over wide limits (2–10 times) caused practically no change in reaction rate. This may be explained by the fact that in non-polar solvents, in which the solubility of hydrogen peroxide is insignificant, the latter is in the form of associates with cyclohexanol.

Investigation of the kinetics of the decomposition of hydrogen peroxide in an aqueous solution of phenol[25] at 115–160 °C showed that the initiation reaction rate was

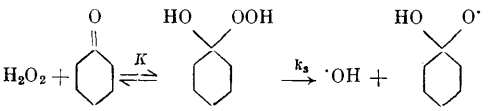
$$w_i = k_1 [H_2O_2] + k_2 [H_2O_2][C_6H_5OH], \quad (18)$$

where

$$k_1 = 7.1\times 10^8 \exp(-99500/RT), \text{ sec}^{-1},$$

$$k_2 = 7.3\times 10^{10} \exp(-111000/RT), \text{ litre mol}^{-1} \text{ sec}^{-1}. \quad (18A)$$

The proportionality of the reaction rate in the first step to the concentrations of both peroxide and of phenol at an excess of the latter enabled the suggestion,[25] that initiation of the reaction of hydrogen peroxide and phenol is predominantly a bimolecular reaction.



$$H_2O_2 + C_6H_5OH \rightarrow {}^{\cdot}OH + H_2O + C_6H_5O^{\cdot}. \quad (19)$$

It may be proposed that this reaction also includes a complex-forming step.

A thermodynamic calculation of the heat of reaction allowing for the bond stability in phenol (336 kJ mol^{-1}) led[25] to a value of ΔH = 50 kJ mol^{-1}, which according to (16) is in satisfactory agreement with the value of the activation energy found experimentally.

A feature of the decomposition of hydrogen peroxide in alcohols in the presence of ketones, in particular for cyclohexanol in the presence of cyclohexanone,[34] is the ability of the latter to form peroxides and hydroperoxides with H_2O_2 and consequently the initiation of oxidation may be described by the reactions

$$2ROH \ldots H_2O_2 \xrightarrow{k_1} 2RO^{\cdot} + 2H_2O, \quad (20)$$

(21)

The initiation rate of the process in this case is[34]

$$w_i = k_1 [H_2O_2] + k_3 [R(OOH)OH]. \quad (22)$$

The authors[34] noted that the rate of the unimolecular decomposition of the resulting hydroperoxide significntly exceeds the decomposition rate of hydrogen peroxide. Considering that the concentration of cyclohexanone hydroperoxide is proportional to the concentration of both hydrogen peroxide and of cyclohexanone

$$[R(OOH)OH] = K [H_2O_2] [R{=}O], \quad (23)$$

and the experimentally found overall initiation rate is proportional to the concentration of active oxygen, then the apparent rate constant for initiation may be described by

$$k_i = \frac{w_i}{[H_2O_2] + [R(OOH)OH]} = \frac{k_1 + k_3 K [R{=}O]}{1 + K [R{=}O]} \quad (24)$$

This permitted experimental determination of the rate constants of the individual reactions

$$k_1 = 8.9\times 10^6 \exp(-98700/RT), \text{ s}^{-1},$$

$$k_3 = 2.2\times 10^4 \exp(-68000/RT), \text{ s}^{-1}, \quad (24A)$$

and the equilibrium constant

$$K = 2.2\times 10^{-5} \exp(28100/RT), \text{ litre mol}^{-1}. \quad (24B)$$

The formation of acetone hydroperoxide on reaction of hydrogen peroxide with acetone has been observed.[35] At an acetone:H_2O_2 ratio <0.07 the hydroperoxides $(CH_3)_2C(OH)OOH$ and $(CH_3)_2C(OOH)_2$ were mainly formed but a further increase of this ratio as a result of interaction of hydroperoxides led to the appearance of peroxide $HOOC(CH_3)_2OOC(CH_3)_2OOH$ as a product.

Aliphatic acids are also inclined to form hydroperoxides. The reaction forming peroxyacids from hydrogen peroxide and acids is first order with respect to both components.[36–39] It is necessary to record that the reaction is reversible. For example the rate constant for the direct reaction of H_2O_2 with formic acid at 20 °C is 2.1 × 10^{-4} litre mol^{-1} s^{-1} and for the reverse 2.4 × 10^{-4} litre mol^{-1} s^{-1}.[36]

It has been recorded that sulphuric acid catalyses the formation of peroxyacids.[38] A study of the reaction of hydrogen peroxide with several aliphatic acids showed that the the reaction rate is determined mainly by the length and structure of the hydrocarbon radical of the acid. Comparison of the kinetics of forming mono-, di- and trichloroperoxyacetic acids[39] indicated that the reaction rate constants increased with the increase in the number of chlorine atoms in the acid molecule.

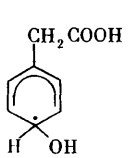
It may be concluded from the above that the activation energy for the decomposition of hydrogen peroxide in the presence of water and of hydroxyl-containing organic compounds may be significantly lower than the energy for fission of the O–O bond in hydrogen peroxide because of the formation of a complex between H_2O_2 and the hydroxyl-containing compound. The reduction of the activation

energy for hydrogen peroxide decomposition in the presence of ketones is explained by the formation of organic peroxides and hydroperoxides.

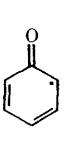
III. Interaction of hydroxyl radicals with organic substances

On oxidation of organic substances with hydrogen peroxide by a radical mechanism an important role is played by their reaction with hydroxyl radicals. Reaction may occur either through addition of ·OH radicals at a multiple bond or by direct abstraction of a labile hydrogen atom from the organic substance with the formation of a molecule of water or as a result of 'adhesion' of the hydroxyl radical to the aromatic ring. In particular the initiation by ·OH radicals of the polymerisation of unsaturated monomers has been fairly well studied. This includes the addition of hydroxyl radicals to substances containing double bonds.[12]

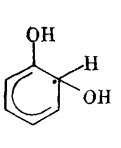
The addition of hydroxyl radical to benzene and some of its derivatives is also possible,[40–43] as a result of which hydroxy derivatives of cyclohexadiene are formed. The course of hydroxylation of benzene, its halogen derivatives and phenol was shown in a study[40] of the IR spectra of the radicals obtained in aqueous organic media under the action of a pulse of electrons.



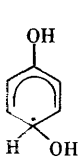
The reaction of benzene and its derivatives with hydroxyl radicals occurs by addition of the latter to the aromatic ring with a rate constant of 4.3×10^9 litre mol^{-1} s^{-1} (at 23 °C). In the presence of oxygen of the air, the nascent radicals add oxygen with the formation of peroxy radicals which in turn decompose into phenol or its derivatives and $HO_2^{\cdot}$ radicals.[40]



In view of the high reactivity of ·OH radicals displayed on direct addition of them to the aromatic ring of benzene and its derivatives, the rate constants of these reactions may be expected to be close to one another.[41] In reality the rate constants for the addition of hydroxyl radicals to benzene, toluene and benzoic acid at 25 °C lie within a fairly narrow range (2.1 to 3.3) $\times 10^9$ litre mol^{-1} s^{-1}.

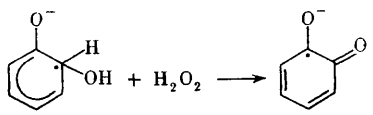


Rate constants for the addition of hydroxyl radicals to several benzene derivatives have been measured[42] and it was shown that they are reduced on going from amino and hydroxy substituted derivatives to nitro and sulphonate derivatives.



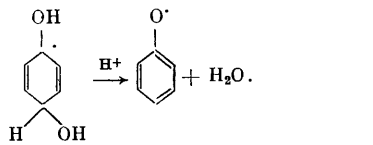
The interaction of hydroxyl radicals with phenylacetic acid[44] leads, according to ESR data, to the formation of radical (I). In acidic medium (I) decomposes with the formation of carbon dioxide, water and the benzyl radical.

The addition of hydroxyl radicals to phenol leads to the formation of various products depending on the solution pH.[43] Radicals (II) are formed in acid solution at pH $\approx$ 1. An increase of pH to 3.9–7 leads to the appearance of hydroxycyclodienyl radicals (III) and (IV) which are ionised in alkaline solution.



(I)

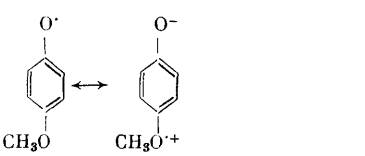
(II)



(III)

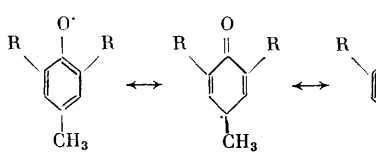
(IV)

Under the action of hydrogen peroxide the latter are oxidised by the following reaction.[43]



(25)

It was proposed[43] that on interaction of phenol with ·OH radicals in acid media, phenoxyl radicals arise as a result of the elimination of water from the resulting hydroxy-cyclodienyl radicals by the following reaction.

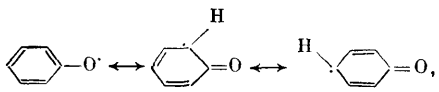


(26)

A broad review of the methods of preparation, structure and isomerisation of phenoxyl radicals resulting on reaction of phenol and its derivatives with hydroxyl radicals has appeared.[45] It was shown that the electron density in phenoxyl radicals is distributed over the aromatic ring and substituent atoms. In phenoxyl radicals the carbon atoms of the ring and the substituent atoms in the *ortho* and *para* positions may be reaction centres in addition to the phenoxyl oxygen.

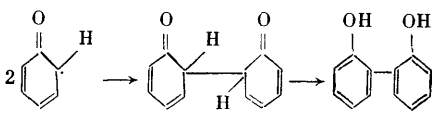
Study of the ESR spectra of several phenoxyl radicals has enabled their hyperfine structure to be analysed and splitting constants have been found for ring protons and nuclear substituents. Methoxyl and some other similar groups reduce the splitting constants for the ring protons particularly in the *ortho* position to a far greater extent than alkyl groups. This implies that a significant portion of the electron density of such radicals is located on the two oxygen atoms.

(27)



Introduction of a deuterium isotopic label into the hydroxyl group[47] and into the *p*-methyl group of ionol[48] enabled rearrangement of phenoxyl radicals containing a methyl group in the *para* position to benzyl radicals (R = t-C_4H_9) to be demonstrated with rearrangement of hydrogen from the *p*-methyl group to oxygen.

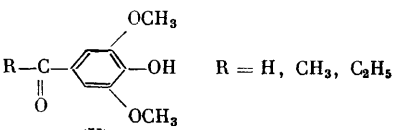
(28)



The possibility of such a rearrangement was also confirmed by ESR spectroscopic investigations of the kinetics of the consumption of *p*-alkylphenoxyl radicals.[45]

The dimerisation of phenoxyl radicals on oxidative oligomerisation of phenol is also accompanied by migration of a proton.[49] According to IR spectroscopic data phenolic structural units linked by C–C bonds in the *ortho* and *para* positions are found in the resulting oligomer. The process occurs stepwise by dimerisation of

phenoxyl radicals with subsequent enolisation according to the following scheme.



(29)

(30)

Compounds of type (V)

(V)

give stable phenoxyl radicals with an average half-life of about 5 h. In the case of vanillin and its derivatives no ESR signals or only weak ESR signals were observed.[50] The stability of phenoxyl radicals of the syringyl series is explained, in the opinion of the authors,[50] by the presence of two *ortho* substituents and a CO group in the *para* position (in vanillin there is only one *o*-methoxy group). Stable phenoxyl radicals are slowly converted into red products, probably *o*-quinones.

Hammett's rule, which describes the relationship of reaction rate constants to the type of substituent (Figs. 2 and 3), is obeyed in addition reactions of hydroxyl radicals to various derivatives of benzene and benzoate ion. The size of the reaction constant ρ is close to −0.4 which shows the electrophilic character of the ·OH radical in these reactions.[42]

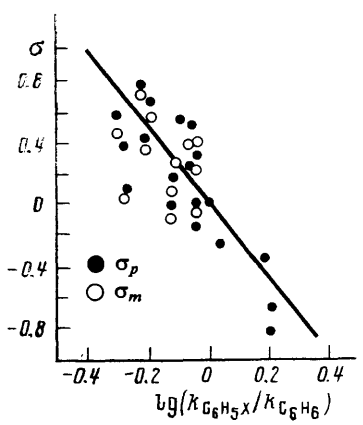


Figure 2. Relationship between the logarithm of the relative rate constant for the reaction of hydroxyl radical and a substituted benzene and the Hammett constant for the substituent.[42]

The reaction of ·OH with aldehydes has been investigated.[51] The interaction of hydroxyl radicals with acrolein and methacrolein occurs by addition of ·OH at the double bond, while reaction with crotonaldehyde includes abstraction of a hydrogen atom from the methyl group.

The kinetics of the consumption of hydroxymethyl radicals formed by reaction of methanol with ·OH radicals obtained by photolysis of hydrogen peroxide has been studied by ESR.[52] The following scheme was proposed for the process:

$$H_2O_2 \xrightarrow{h\nu} 2^{\cdot}OH, \quad (31)$$

$$^{\cdot}OH + CH_3OH \rightarrow {}^{\cdot}CH_2OH + H_2O, \quad (32)$$

$$2^{\cdot}OH \rightarrow H_2O_2, \quad (33)$$

$$^{\cdot}OH + {}^{\cdot}CH_2OH \rightarrow CH_2(OH)_2, \quad (34)$$

$$2^{\cdot}CH_2OH \rightarrow HOCH_2CH_2OH. \quad (35)$$

The rate constant for reaction (35), equal to 3.5×10^8 litre mol^{-1} s^{-1} was measured by flash photolysis and recording of the kinetics of the decrease in the ESR signal.[53] The rate constants for reactions (33) and (34) were found to be 1.5×10^8 and 2.8×10^8 litre mol^{-1} s^{-1} respectively (at 213 K). The rate constant for reaction (32) was 8.4×10^8 litre mol^{-1} s^{-1}.

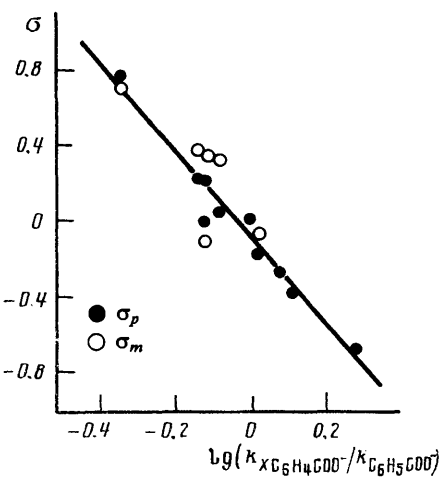

Figure 3. Relationship between the logarithm of the relative rate constant for the reaction of hydroxyl radical and a substituted benzoate ion and the Hammett constant for the substituent.[42]

The structure of the radicals resulting from the reaction of organic acids and ethers with hydroxyl radicals has also been investigated by ESR.[54] In the reaction between ·OH radicals and aliphatic acids and their halogen and hydroxy derivatives, removal of a hydrogen atom is mainly observed with the formation of a radical with the unpaired electron on the carbon atom in the α-position to the carboxyl group. However in the case of formic and malonic acids removal of a hydrogen atom from the carboxyl group occurs. The reaction is accompanied by decarboxylation in the latter case. Acids containing double bonds, such as maleic and methacrylic, add hydroxyl radicals at the multiple bond with the formation of a radical with an unpaired electron on the adjoining carbon atom. When reacting ethers with hydroxyl radicals, radicals are mainly formed with an unpaired electron on the α-carbon atom in relation to oxygen.

Analysis of the reaction between alcohols and ·OH radicals[55] showed that reaction (36) only occurred to a small extent. Process (37) predominates (more than 90%) for methanol, ethanol and propan-2-ol. Reaction (38) is also possible for *n*-propanol, *n*-butanol and isobutanol.

$$R_2CH—CH(R')—OH + {}^{\cdot}OH \begin{cases} \longrightarrow R_2\dot{C}H—CH(R')—O^{\cdot} & (36) \\ \longrightarrow R_2CH—\dot{C}(R')—OH & (37) \\ \longrightarrow R_2\dot{C}—CH(R')—OH & (38) \end{cases}$$

Several rate constants have been found for the removal of a hydrogen atom from aliphatic compounds by hydroxyl radicals.[56] When reacting ·OH radicals with aliphatic acids the reaction rate constant increases with the increase in the number of hydrogen atoms in the acid molecule. This constant may be calculated by the additivity rule for partial activities of hydrogen atoms in various positions in relation to the carboxyl group. The contributions to the reaction rate constant of H atoms in the α-position to the carboxyl group of CH_3COO^-, RCH_2COO^- and R_2CHCOO^-, are 0.14×10^8, 1.75×10^8 and 5.3×10^8 litre mol^{-1} s^{-1} (per atom) respectively and the contributions of H atoms of CH_3R, RCH_2R and R_2CHR groups in other positions are 0.36×10^8, 3.0×10^8 and 8.4×10^8 litre mol^{-1} s^{-1} (per atom) respectively. It is necessary to note that cyclic carboxyl-containing compounds are less reactive than the corresponding acyclic compounds.

Alcohols possess greater reactivity than acids when reaction with ·OH radicals, however the character of the relationship of reaction rate constant to hydrocarbon chain length is preserved.[56] The partial contributions of the activity of hydrogen atoms in the α-positions of CH_3OH, RCH_2OH and R_2CHOH groups are 1.8×10^8, 5.0×10^8 and 8.8×10^8 litre mol^{-1} s^{-1} respectively. An increase in the number of hydroxyl groups in the alcohol molecule leads to a reduction in reaction rate which is explained by hydration of the alcohol.

The reaction rate constants measured for the reaction of hydroxyl radicals with ethers[56] were, in contrast to the constants given in study,[57] somewhat lower than the reaction rate constants for the corresponding alcohols.[56] The partial activities of hydrogen atoms in the α-position of CH_3OR, RCH_2OR, $(RO)_2CH_2$, $(RO)_2CHR$ and $ROCR_2CH_2OH$ groups are 0.6×10^8, 1.4×10^8, 0.5×10^8, 0.9×10^8 and 1.65×10^8 litre mol^{-1} s^{-1} respectively. A good correlation was also recorded between the rate constants for the reaction of hydroxyl radicals with the aliphatic compounds investigated and the Hammett constants for substituents. The value for the ρ factor was −0.96, i.e. the ·OH radical attacks the aliphatic compound as an electrophilic reagent.

The reaction of aliphatic compounds of various classes with ·OH radicals obtained on radiolysis of water by ^{60}Co has been studied and a series of rate constants for these reactions has been found.[57] In particular it was established that the additivity rule for the contributions of CH_2 groups of the compounds investigated to the reaction rate constant was fulfilled only for a fairly small group of substances containing up to 4–6 carbon atoms. On further increasing the hydrocarbon chain length the growth in reaction rate constant slowed (Fig. 4). A significant increase in rate constant was also recorded for the reaction of hydroxyl radicals with amines and carboxylic acids depending on the increase in pH, the greatest values being achieved in the region of the pK_a of the acid. Evidently this confirms that carboxylate radicals (and not radicals with an unpaired electron on adjacent carbon atoms) are formed predominantly by the reaction of hydroxyl radicals according to the reaction

$$RCOO^- + {}^{\cdot}OH = RCOO^{\cdot} + OH^-, \quad (39)$$

and the one-electron oxidation of the carboxylate ion of a salt to the corresponding carboxyl radical occurs more readily than removal of a hydrogen atom from the carboxyl group of the corresponding carboxylic acid.

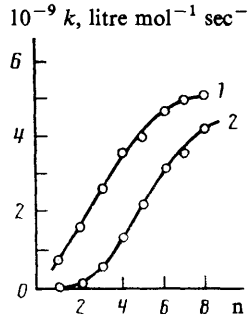

Figure 4. Relationship of the rate constants for the reaction of hydroxyl radicals with *1*, aliphatic alcohols and *2*, dicarboxylic acids to the number of atoms in the hydrocarbon chain.[57]

IV. Decomposition of hydrogen peroxide in the presence of oxygen-containing aliphatic compounds

Study of the kinetics of the oxidation of organic compounds with hydrogen peroxide using ESR showed that decomposition of hydrogen peroxide by radicals of organic compounds is observed in addition to the formation of radicals of organic substances by reaction with hydroxyl radicals (see section III) and recombination of the radicals under specific conditions.

Two types of radicals (VI) and (VII) were detected when investigating the kinetics of oxidation of dimethoxymethane with the system hydrogen peroxide–titanium(III) using ESR spectroscopy.[58]

$$Ti(III) + H_2O_2 \rightarrow Ti(IV) + OH^- + {}^{\cdot}OH, \quad (40)$$

$${}^{\cdot}OH + CH_3OCH_2OCH_3 \rightarrow \underset{(VI)}{{}^{\cdot}CH_2OCH_2OCH_3} + H_2O, \quad (41)$$

$${}^{\cdot}OH + CH_3OCH_2OCH_3 \rightarrow \underset{(VII)}{CH_3O\dot{C}HOCH_3} + H_2O. \quad (42)$$

The change of radical concentration with time showed that the order of the reaction with respect to radicals was close to $^3/_2$. Rate constants for the consumption of radicals (VI) and (VII) calculated from the Arrhenius equation were respectively

$$k_1 = 4 \times 10^{14} \exp(-61800/RT) \text{ litre}^{1/2} \text{ mol}^{-1/2} \text{ s}^{-1}, \quad (43)$$

$$k_2 = 1 \times 10^{14} \exp(-54300/RT) \text{ litre}^{1/2} \text{ mol}^{-1/2} \text{ s}^{-1}. \quad (44)$$

The rate of consumption of radicals did not depend on the initial titanium(III) concentration and was proportional to the initial H_2O_2 concentration in the first stages. Gas chromatographic analysis of the reaction products showed the presence of formaldehyde, formic

acid and methanol. Dimers of dimethoxymethane were not detected, on the basis of which the authors came to the conclusion that chain termination by radicals (VI) and (VII) does not occur in practice.[58]

It was also established by ESR spectroscopy that the decomposition of radicals (VI) and (VII) did not play an appreciable role. Based on the data, a kinetic scheme for the process was proposed which included reactions (40)–(42) and provided for the decomposition of H_2O_2 by reactions (45) and (46) and possible chain termination with the participation of radicals (VI), (VII) and ·OH.

$$\cdot CH_2OCH_2OCH_3 + H_2O_2 \rightarrow HOCH_2OCH_2OCH_3 + \cdot OH, \quad (45)$$

$$CH_3O\dot{C}HOCH_3 + H_2O_2 \rightarrow CH_3OCH(OH)OCH_3 + \cdot OH, \quad (46)$$

$$\cdot CH_2OCH_2OCH_3 + \cdot OH \rightarrow HOCH_2OCH_2OCH_3, \quad (47)$$

$$CH_3O\dot{C}HOCH_3 + \cdot OH \rightarrow CH_3OCH(OH)OCH_3. \quad (48)$$

However the orders found for the reactions are not substantiated by an analysis of the given kinetic scheme.[58]

The oxidation of propan-2-ol by the H_2O_2–Ti(III) system has been investigated.[59] The formation of radicals of two types, viz. $(CH_3)_2\dot{C}OH$ (VIII) and $\cdot CH_2CH(CH_3)OH$ (IX), was shown by ESR spectroscopy. With an excess of hydrogen peroxide in the system the kinetic relationships of the change of radical concentration with time are linearised by a first order equation or an order of $^3/_2$ with respect to radicals. The order with respect to hydrogen peroxide for radicals (VIII) and (IX) proved to be 1.1 and 1.2 respectively. The investigators proposed that consumption of these radicals occurs in reactions causing decomposition of peroxide.

$$\underset{(VIII)}{(CH_3)_2\dot{C}OH} + H_2O_2 \rightarrow (CH_3)_2CO + \cdot OH + H_2O, \quad (49)$$

$$\underset{(IX)}{\cdot CH_2CH(CH_3)OH} + H_2O_2 \rightarrow CH_2{=}C(CH_3)OH + \cdot OH + H_2O. \quad (50)$$

The product of the second reaction is the enol form of acetone. The heats of reaction for (49) and (50) (ΔH) are –205 and –165 kJ mol^{-1} and the energy of activation 48.1 and 48.5 kJ mol^{-1}.

At low hydrogen peroxide concentrations, consumption of alcohol radicals occurs according to a second order equation which indicates the bimolecular termination of these radicals. However the authors considered that the radicals resulting from reactions (49) and (50) have relatively low reactivity in relation to the substrate, consequently the radical–chain process does not play an appreciable role. There remains the unclarified reasons for the different reactivity of ·OH radicals formed by reactions (49) and (50) and by reaction (40) of titanium(III) with H_2O_2.

It has been noted[60] that at a low rate of initiation, corresponding to a low titanium(III) concentration, the concentration of radicals (IX) exceeds the concentration of radicals (VIII) and at a high initiation rate, corresponding to a high titanium(III) concentration, the reverse relationship is observed in the initial stages. It was proposed that radicals (VIII) participate in a radical–chain process occurring at low rates of initiation and the chain length increases with the growth in concentration of hydrogen peroxide. Evidently this indicates that only radicals (VIII) may cause additional decomposition of hydrogen peroxide.

The change in concentration of radicals as a function of reactant concentration in the oxidation of propan-2-ol by hydrogen peroxide has been described.[61] This process was initiated by oxidation–reduction systems containing H_2O_2 and a metal of variable valency, such as vanadium(IV), titanium(III), chromium(II) or iron(II). On increasing the hydrogen peroxide concentration in the system the concentration of propan-2-ol radicals passed through a maximum (Fig. 5), while an increase in the variable valency metal concentration led to a significant drop in the concentration of radical (VIII) and practically no change in the concentration of radical (IX). The change of concentration of alcohol radicals obtained on radiolysis of H_2O_2 as a function of the initial reactant concentrations indicated that decomposition of H_2O_2 by radicals (VIII) may be possible at various ranges of reactant concentration. A mechanism for the process was proposed, analogous to that described previously, the only difference being that chain termination by alcohol radicals predominates over termination of the latter by reaction with ·OH radicals. It was shown that chain length in the hydrogen peroxide decomposition process grows according to the increase of hydrogen peroxide concentration.

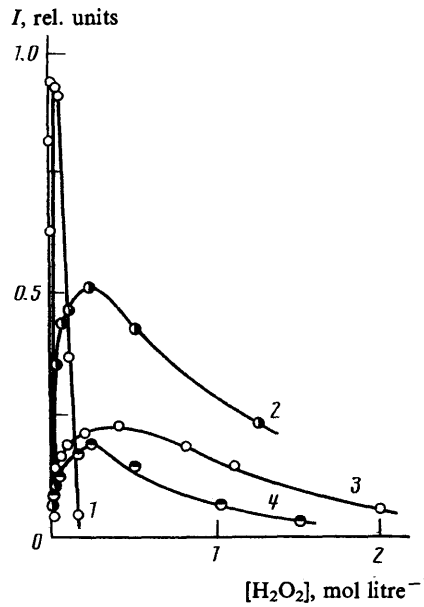

Figure 5. Relative intensity of the ESR signal for radicals formed in reactions of hydrogen peroxide with propan-2-ol in the presence of *1*, titanium(III) at pH 1, *2*, vanadium(IV) at pH 3, *3*, iron(II) at pH 1 and *4*, at pH 3. Concentrations of propan-2-ol and metal were 2.5 mol litre^{-1}.[61]

Investigation of the influence of the concentration of $HO_2^{\cdot}$ radicals on the concentration of alcohol radicals in this system showed[61] that perhydroxyl radicals show no appreciable influence on the content of other radicals. Consequently the authors considered hydroxyl radicals to be the main reactive species.

The mechanism of the interaction of hydrogen peroxide with alcohols has been investigated with initiation of the process by radiolysis of H_2O_2.[62] The concentration of propan-2-ol radicals in the system was found by ESR spectroscopy. With an increase in hydrogen peroxide concentration the overall content of radicals in the system was practically unchanged, while the ratio of the concentrations of radicals (IX) and (VIII) was increased. An

increase in the rate of initiation by increasing the radiation intensity led to growth of both these parameters. On increasing the propan-2-ol concentration the concentration of radical (IX) and the overall concentration of radicals passed through maxima even at low alcohol content while the concentration of radical (VIII) grew constantly. The authors considered[62] that the oxidation of propan-2-ol proceeded by a radical–chain mechanism, comprising decomposition of peroxide according to reaction (53) and termination with the participation of radicals (VIII) and (IX) (54)–(56).

$$^{\cdot}OH + (CH_3)_2CH{-}OH \xrightarrow{k_s} H_2O + (CH_3)_2\dot{C}{-}OH, \quad (51)$$

$$^{\cdot}OH + (CH_3)_2CH{-}OH \xrightarrow{k_{s1}} H_2O + {}^{\cdot}CH_2CH(OH)CH_3, \quad (52)$$

$$(CH_3)_2\dot{C}{-}OH + H_2O_2 \xrightarrow{k_{in}} {}^{\cdot}OH + H_2O + (CH_3)_2CO, \quad (53)$$

$$2(CH_3)_2\dot{C}{-}OH \xrightarrow{k_t} \quad (54)$$

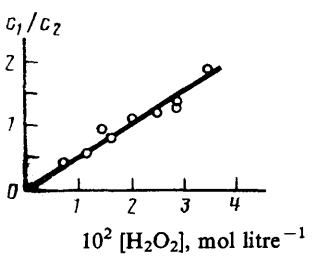
$$(CH_3)_2\dot{C}{-}OH + {}^{\cdot}CH_2CH(OH)CH_3 \xrightarrow{k_t} \text{chain termination.} \quad (55)$$

$$2{}^{\cdot}CH_2CH(OH)CH_3 \xrightarrow{k_t} \quad (56)$$

It was claimed that in view of the high initiation rate the chain length was not large, the concentrations of radicals (VIII) and (IX) were comparable and chain termination by all radicals is possible. An expression for the ratio of the concentrations of the radicals in the system was derived on the basis of the given scheme.[62]

$$[IX]/[VIII] = k_{s1}k_{in}\,(k_s + k_{s1})^{-1}(2k_t w_i)^{-1/2}[H_2O_2] \quad (57)$$

(w_i is the initiation rate) which was confirmed by the experimental data (Fig. 6).



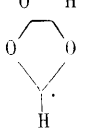


Figure 6. Dependence of the relative concentrations of $^{\cdot}CH_2CH.(OH)CH_3$ (c_1) and $(CH_3)_2\dot{C}OH$ (c_2) radicals on hydrogen peroxide concentration during photolysis of the latter in an aqueous solution of 0.68 mol litre^{-1} acetone and 0.65 mol litre^{-1} propan-2-ol at 30 °C.[62]

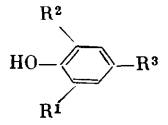
Indirect confirmation of the lack of participation of radical (IX) in the decomposition of H_2O_2 is the observation that t-butyl alcohol does not cause decomposition.

An analogous mechanism has been proposed to describe the reaction of hydrogen peroxide with other oxygen-containing compounds (methanol, ethanol, tetrahydrofuran, dioxan, diethyl ether, etc.). Some rate constants for the decomposition of peroxide are given in Table 1.

When initiating the reaction of hydrogen peroxide with alcohols with the H_2O_2–titanium(III) system radical decomposition of peroxide was observed only at high concentrations of it and the chain length was not very large.[63] This is evidently linked with the high rate of the reaction between H_2O_2 and titanium(III). Similar results have been obtained elsewhere.[64]

Table 1. Rate constants for the decomposition of hydrogen peroxide by various radicals at 20 °C.

Radical	$10^{-4}k$, litre mol^{-1} s^{-1}	Refs.
$^{\cdot}CH_2OH$	35	[62]
	5	[63]
	4	[66]
	2.3	[67]
	4	[68]
$CH_3\dot{C}HOH$	18	[64]
	15	[69]
$(CH_3)_2\dot{C}OH$	51	[62]
	50	[63]
$^{\cdot}CO_2^-$	70	[70]
	3	[67]
	6	[67]
$CH_3\dot{C}HOCH_2CH_3$	5.5	[67]
$^{\cdot}CH(OCH_3)_2$	110	[67]



The decomposition of hydrogen peroxide may therefore take place under the action of radicals in which an unpaired electron is present on the α-carbon atom of oxygen-containing compounds. The chain length in this process may vary within wide limits depending on the initiation rate.

The rate constant for the decomposition of hydrogen peroxide by radicals of organic compounds may be increased by reducing the oxidation–reduction potential of the latter. This is observed in their interaction with benzoyl peroxide.[65]

V. Oxidation of phenolic compounds with hydrogen peroxide

Interest in this question is linked with the need to clarify the mechanism of action of phenolic antioxidants, the mechanism of the initiation by hydrogen peroxide of graft polymerisation of monomers to natural polyphenolic compounds such as lignin and its derivatives,[14] and also the chemical mechanism of the delignification of wood by hydrogen peroxide.[10] Lignin macromolecules of coniferous wood contain structural units of 4-hydroxy-3-methoxyphenylpropane (guaiacylpropane) and there are also 4-hydroxy-3,5-dimethoxyphenylpropane (syringylpropane) structures in wood lignins from deciduous species.[71] Consequently phenolic compounds

may serve as the simplest models of the guaiacyl and syringyl structures of lignin units.

$R^1 = H,\ OCH_3;\ R^2 = OCH_3;$
$R^3 = H,\ CH_2OH,\ CHO$ etc.

(X)

The kinetics of the oxidation of guaiacol (X, $R^1 = OCH_3$, $R^2 = R^3 = H$) with hydrogen peroxide at pH 4.0 in an inert atmosphere have been investigated.[22] Guaiacol markedly accelerates the decomposition of H_2O_2, the order of the reaction with respect to the latter is close to 1 and with respect to guaiacol to $^1/_2$, the effective energy of activation being 90 kJ mol^{-1}. Monomer (acrylamide) slows the reaction rate to the rate of decomposition of H_2O_2 in water, which indicates a radical–chain mechanism for the process and its initiation by homolysis of hydrogen peroxide.

To substantiate the results obtained, a kinetic scheme was proposed[22] for the peroxide oxidation of guaiacol and other phenols which provides for the formation of phenoxyl radicals, their subsequent isomerisation into aryl radicals and the decomposition of H_2O_2 under the action of the latter.

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d^t} 2{}^{\bullet}OH + 2H_2O, \quad (58)$$

$$^{\bullet}OH + Ar{-}OH \xrightarrow{k_s} Ar{-}O^{\bullet} + H_2O, \quad (59)$$

$$Ar{-}O^{\bullet} \xrightarrow{k_r} {}^{\bullet}Ar{-}OH, \quad (60)$$

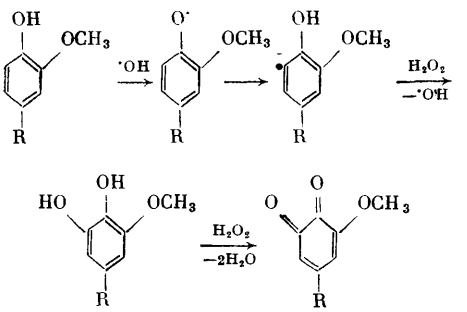
$$^{\bullet}Ar{-}OH + H_2O_2 \xrightarrow{k_{in}} {}^{\bullet}OH + Ar', \quad (61)$$

$$^{\bullet}Ar{-}OH + {}^{\bullet}OH \xrightarrow{k_{12}} \text{chain termination}, \quad (62)$$

where Ar′ is the oxidation product of the phenolic compound. Eqn. (63) for the consumption of H_2O_2 is obtained from this scheme using quasi-steady-state concentrations.

$$w = k_d \{^1/_2 + (^1/_4 + k_s k_{in} (k_d k_{12})^{-1}[Ph])^{1/2}\}[H_2O_2], \quad (63)$$

where [Ph] is the concentration of phenolic compound. It may be rearranged into (64) which is in agreement with the experimental data.



$$w^2/(k_d [H_2O_2]^2) - w/[H_2O_2] = (k_s k_{in}/k_{12})[Ph]. \quad (64)$$

If the rate of decomposition of H_2O_2 by (61) is significantly greater than the rate of its homolysis then Eqn. (63) reduces to expression (65) which corresponds to the order of the reaction found experimentally.[22]

$$w = (k_d k_s k_{in}/k_{12})^{1/2}[Ph]^{1/2}[H_2O_2]. \quad (65)$$

Proposals on the mechanism of initiation by hydrogen peroxide of the grafting of monomers to lignin were also made on the basis of kinetic investigations on the polymerisation of monomers in the presence of phenolic compounds modelling the structural units of lignin.[72–74] A comparison of the influence of guaiacol and veratrole (*o*-dimethoxybenzene),[72] vanillin sulphonate (3-methoxy-4-hydroxybenzyl sulphonate), *p*-hydroxybenzyl sulphonate and veratryl sulphonate (3,4-dimethoxybenzyl sulphonate),[73] guaiacol and 2,6-dimethoxyphenol[74] on the rate of polymerisation of monomers led investigators to the conclusion that the kinetics of the process depend on the presence of a phenolic hydroxyl and a vacancy in the *ortho* position to the phenol in the structure of the model compound.[75]

The kinetic scheme (58)–(62) also provides for homolytic fission of the OH bond of the phenolic compound with subsequent isomerisation of phenoxyl radicals having no substituent in the *ortho* position into aryl radicals capable of inducing chain decomposition of H_2O_2.[76]

(66)

According to this scheme, the accumulation of quinones must correspond to the reduction in the content of phenolic hydroxyls and is not accompanied by demethylation of the starting material. The formation of one mole quinone must consume two moles H_2O_2. However functional analysis of the oxidation products of guaiacol showed,[76] that the reduction in content of phenolic hydroxyls is in good agreement not only with the accumulation of quinone but also with the fall in methoxy group content and the consumption of hydrogen peroxide (Table 2), which contradicts the scheme (66). In the oxidation of guaiacol to quinone an equimolecular (and not double) quantity of H_2O_2 is consumed and the quinone is formed predominantly by demethylation of guaiacol and not as a result of the formation of appropriate bonds in the vacant *ortho* (or *para*) positions to the phenolic hydroxyl as shown in the scheme (66).[76]

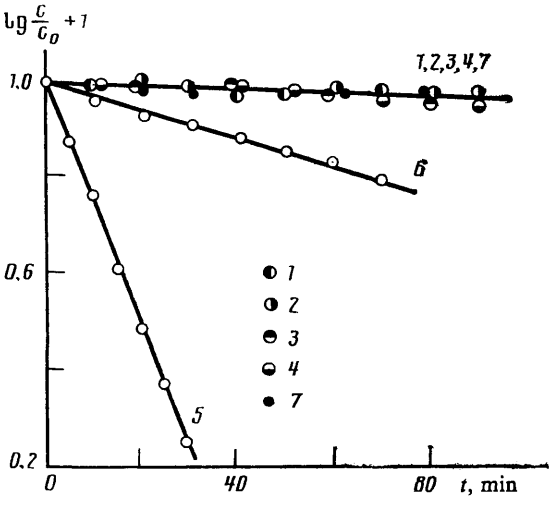
Table 2. Relationship between the functional composition (in mmol g^{-1} guaiacol) of the oxidation products of guaiacol and hydrogen peroxide concentration.[76]

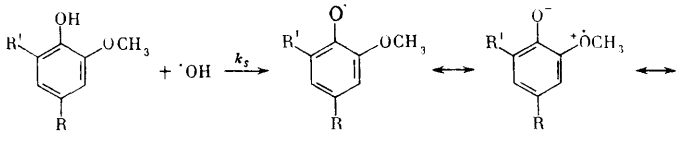
$[H_2O_2]$, mmol g^{-1} guaiacol	[OH]	[OCH_3]	[Quinones]	$-\Delta$[OH]	$-\Delta$[OCH_3]
0	8.06	8.06	0	0	0
1.90	6.61	6.51	1.40	1.45	1.55
3.81	4.66	3.96	3.56	3.40	4.10

Footnote. Reaction conditions: guaiacol concentration 161 mmol litre^{-1}, temperature 70 °C, reaction time 1.5 h.

These concepts were confirmed by investigations on the kinetics of the interaction of hydrogen peroxide with phenol, veratrole and syringaldehyde (3,5-dimethoxy-4-hydroxybenzaldehyde), compounds which model the structures with vacant *ortho* and *para* positions relative to a free phenolic hydroxyl and to a hydroxyl included in an ester bond. The investigations showed that of these only syringaldehyde was able to cause decomposition of H_2O_2 (Fig. 7). Consequently in order to carry out the radical–chain decomposition of peroxide the presence of an unsubstituted phenolic hydroxyl

group in the benzene ring is necessary the presence in the ring of other substituents and a vacant position *ortho* or *para* to them is not obligatory.[76]





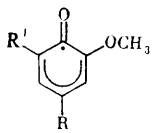


Figure 7. Semilogarithmic plot of the kinetic curves for the consumption of H_2O_2 *1*, in water, in solutions of *2*, veratrole, *3*, phenol, *4*, guaiacol in the presence of acrylamide 0.141 mol litre^{-1}, *5*, guaiacol, *6*, syringic aldehyde, and *7*, syringic aldehyde in the presence of acrylamide 0.282 mol litre^{-1} at pH 4, 70 °C, and initial concentrations of H_2O_2 1.06 mmol litre^{-1} and of phenolic compound 4.03 mmol litre^{-1}.[76]

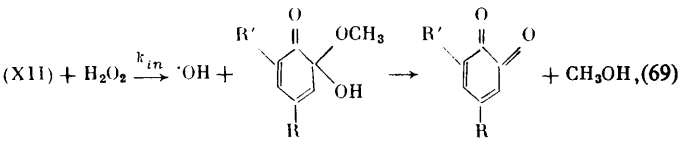
Allowing for what has been said, the experimental data[22,76] may be described by the kinetic scheme (67)–(70) which includes the decomposition of H_2O_2 by the phenoxyl radical according to reaction (69) since the electron density of its unpaired electron is distributed predominantly between the two oxygen atoms[46] (see section III).



$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2{}^{\cdot}OH + 2H_2O, \qquad (67)$$

(XI) (XII)

(68)

$$(XII) + {}^{\cdot}OH \xrightarrow{k_{12}} \text{chain termination.} \qquad (70)$$

Calculations on this scheme using quasi-steady-state concentrations for the interaction of H_2O_2 with guaiacol (XI, R, R′ = H) lead to Eqn. (63) compatible with the kinetic results presented above.

Investigation of the oxidation of vanillin with hydrogen peroxide[77] enables assessment of the effect of carbonyl and methoxy groups in addition to a phenolic hydroxyl in the benzene ring on the kinetics of the process. Vanillin may also serve, as a first approximation, as a model of the guaiacol structural units of lignin with carbonyl groups in the side chain. The rate of consumption of H_2O_2 in the presence of vanillin is greater than the rate of decomposition of peroxide in water under analogous conditions and markedly less than in a solution of guaiacol. Experiments with acrylamide added to the system confirmed the radical–chain mechanism of the reaction. Experiments were also carried out on the oxidation of benzaldehyde and of mixtures of it with guaiacol in order to clarify the influence of substituents in the benzene ring on the kinetics of the process. These showed the ability of aldehyde groups to interact with hydroxyl radicals with the formation of radicals causing no chain decomposition of H_2O_2.

A study of the functional composition of the oxidation products of vanillin with hydrogen peroxide showed[76] that the quantity of quinones formed corresponds approximately to the reduction in the content of hydroxyl and methoxyl groups, carbonyl groups are oxidised to carboxyls, and the consumption of H_2O_2 corresponds to the overall accumulation of quinone and carboxyl groups (Table 3). Vanillic acid was identified in the oxidation products by thin layer chromatography.

This indicates that two reaction centres participate in the oxidation of vanillin, viz. the phenolic hydroxyl and the aldehyde group.

Table 3. Relationship between the functional composition (in mmol g^{-1} vanillin) of the oxidation products of vanillin with hydrogen peroxide and the concentration of the latter.[76]

$[H_2O_2]$, mmol g^{-1} vanillin	[COOH]	[OH]	[OCH_3]	[Quinones]	[COOH]+ [Quinones]	−Δ[OH]	−Δ[OCH_3]
0	0	6.53	6.57	0	0	0	0
1.75	0.93	5.80	6.09	0.72	1.65	0.73	0.48
3.50	2.02	5.44	5.68	1.22	3.24	1.09	1.11
7.00	4.13	4.64	4.26	2.14	6.27	1.89	2.31

Footnote. Reaction conditions: vanillin concentration 63.4 mmol litre^{-1}, temperature 80 °C, reaction time 6 h.

The reaction is first order with respect to hydrogen peroxide since the initial rate of H_2O_2 consumption is proportional to its concentration (Fig. 8). The relationship of the apparent reaction rate constant to vanillin concentration has a complex character. It increases with the growth in concentration of the latter tending to a limiting value (Fig. 9) so that the reaction order with respect to vanillin is changed from $^1/_2$ to zero. The apparent activation energy is 97 kJ mol^{-1}.

The data enable the oxidation of vanillin (XI, R = CHO, R′ = H) with hydrogen peroxide to be described by the kinetic scheme

(67)–(70) supplemented by reaction equations (71) and (72) for the oxidation of vanillin at the aldehyde group.

$$HO{-}C_6H_3(OCH_3){-}CHO + {}^{\cdot}OH \xrightarrow{k_{s1}} \rightarrow HO{-}C_6H_3(OCH_3){-}\dot{C}O + H_2O, \quad (71)$$

$$HO{-}C_6H_3(OCH_3){-}\dot{C}O + {}^{\cdot}OH \xrightarrow{k_{12}} HO{-}C_6H_3(OCH_3){-}COOH. \quad (72)$$

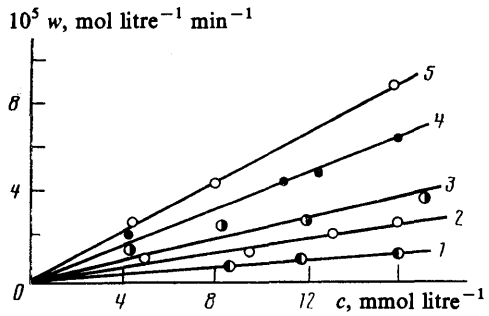


Figure 8. Relationship between the rate of consumption of H_2O_2 during the oxidation of vanillin and the initial concentration of hydrogen peroxide at 70 °C and initial vanillin concentrations of *1*, 0.66, *2*, 3.29, *3*, 6.58, *4*, 32.9, *5*, 65.8 mmol litre^{-1}.

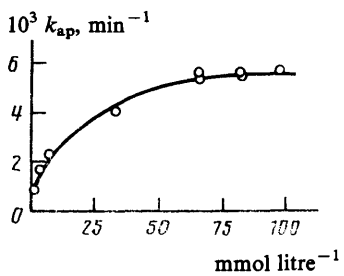

Figure 9. Influence of the initial vanillin concentration during its oxidation by H_2O_2 on the apparent rate constant for the consumption of hydrogen peroxide at 70 °C.

A mathematic model for the kinetics of the process may be obtained from schemes (67)–(72) using quasi-steady-state concentrations.

$$w = k_{ap}[H_2O_2], \quad (73)$$

where w is the rate of H_2O_2 consumption in the oxidation of vanillin.

$$k_{ap} = (2k_{12})^{-1}\{(F^2 + 4k_d k_{in} k_s k_{12}[Ph])^{1/2} - F\},$$
$$F = k_{in}k_{s1}[Ph] - k_d k_{12}. \quad (74)$$

Eqn. (73) is in agrement with the kinetic results given in Fig. 8.

At low vanillin concentrations $k_{in} \gg k_d k_{12}(4k_s[Ph])^{-1}$ and expression (73) simplifies to

$$w = (k_d k_s k_{in}/k_{12})^{1/2}[Ph]^{1/2}[H_2O_2], \quad (75)$$

which is in agrement with the experimentally found partial reaction orders (at vanillin concentrations up to 33 mmol litre^{-1}).

At fairly high vanillin concentrations the relationship (76) may be obtained by expansion of (73) into an exponential series and corresponds to the partial reaction order found by experiment under these conditions.

$$w = k_d(1 + k_s/k_{s1})[H_2O_2]. \quad (76)$$

It is seen from Fig. 9 that the apparent reaction rate constant tends to a limit on increasing the vanillin concentration. It may be shown that the limit of function (74) is determined by the expression

$$\lim_{[Ph]\to\infty} k_{ap} = k_d k_s / k_{s1}. \quad (77)$$

Combinations of rate constants for the individual reactions $k_d k_s/k_{s1}$ and k_s/k_{s1}, equal to 5.56 × 10^{-3} min^{-1} and 12.5 respectivley (at 70 °C), are found from the data given in Fig. 9 using Eqn. (77).

Transformation of relationship (74) leads to the equation

$$(k_{ap} + k_d)/[Ph] = -k_{in}k_{s1}/k_{12} + (k_d k_{in} k_s/k_{12})\,(1/k_{ap}), \quad (78)$$

which describes the kinetic data well as is evident from Fig. 10. The relationships of the rate constants for the individual reactions are found from the intercept and the slope of the straight line in Fig. 10 and $k_d k_s/k_{s1}$, k_s/k_{s1}, $k_d k_{in} k_s/k_{12}$, $k_{in}k_s/k_{12}$ are 6.38 × 10^{-3} min^{-1}, 14.4 and 1.70 × 10^{-3} litre mol^{-1} min^{-2} and 3.84 litre mol^{-1} min^{-1} respectively at 70 °C. The values obtained from Eqns. (77) and (78) are close to one another. This indicates the adequacy of the mathematical model (73) and (74) describing the kinetic experimental data for the oxidation of vanillin with hydrogen peroxide over a wide range of reactant concentrations.

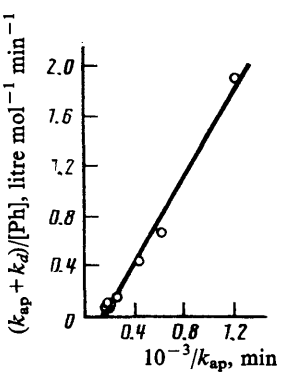

Figure 10. Relationship between the apparent reaction rate constant for the oxidation of vanillin with hydrogen peroxide and vanillin concentration at 70 °C in the coordinates of Eqn. (78).

A feature of the hydrogen peroxide oxidation of vanillyl alcohol (4-hydroxy-3-methoxybenzyl alcohol), modelling the structural units of lignin with benzyl hydroxyls, is the transfer in the initial stage of the reaction centre from the phenolic oxygen of the aromatic ring to

the carbon atom in the α-position.[78] This is indicated by the constant nature of the content of phenolic hydroxyls in the initial stage of the reaction and the correspondence of the quantity of H_2O_2 reacted to the overlall accumulation of carbonyl and carboxyl groups (Table 4) (vanillin was identified as the product of oxidation of vanillyl alcohol by thin layer chromatography).

Table 4. Change of functional composition (in mmol g^{-1} vanillyl alcohol) of the oxidation products of vanillyl alcohol with hydrogen peroxide in relation to the quantity of H_2O_2 reacted.[78]

Quantity of H_2O_2 reacted, mmol $litre^{-1}$ vanillyl alcohol	$[OH_{phenol}]$	$[OCH_3]$	[COOH]	[CHO]
0	6.49	6.47	0	0
0.39	6.49	6.38	0	0.45
0.98	6.49	6.43	0	0.92
1.23	6.57	6.43	0.08	1.01
1.47	6.63	6.46	0.17	1.13

Footnote. Reaction conditions: vanillyl alcohol concentration 66.1 mmol $litre^{-1}$, H_2O_2 concentration 87.5 mmol $litre^{-1}$, temperature 80 °C.

The kinetic investigations showed the acceleration of hydrogen peroxide decomposition in aqueous media in the presence of vanillyl alcohol. Acrylamide suppressed the decomposition of peroxide which indicates the radical–chain mechanism of the process. Partial orders of the reaction were 1 with respect to peroxide and $^1/_2$ with respect to vanillyl alcohol. The apparent activation energy was 92 kJ mol^{-1}.

The results obtained are in agreement[78] with the kinetic scheme (79)–(85). In this, attack by the radical initiator of the phenolic hydroxyl and the C–H bond of the alcohol group is proposed, then rearrangement (82) of phenoxyl to benzyl radical, which was confirmed by ESR spectroscopic investigations on the kinetics of the consumption of *p*-alkylphenoxyl radicals (see section III).[45,79]

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2\,{}^{\cdot}OH + 2H_2O, \tag{79}$$

$$^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}CH_2OH \xrightarrow{k_s} {}^{\cdot}O{-}C_6H_3(OCH_3){-}CH_2OH + H_2O, \tag{80}$$

$$^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}CH_2OH \xrightarrow{k_{s1}} HO{-}C_6H_3(OCH_3){-}\dot{C}HOH + H_2O, \tag{81}$$

$$^{\cdot}O{-}C_6H_3(OCH_3){-}CH_2OH \xrightarrow{k_r} HO{-}C_6H_3(OCH_3){-}\dot{C}HOH, \tag{82}$$

$$HO{-}C_6H_3(OCH_3){-}CHOH + H_2O_2 \xrightarrow{k_{in1}} {}^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}CHO + H_2O, \tag{83}$$

$$\left.\begin{aligned} {}^{\cdot}O{-}C_6H_3(OCH_3){-}CH_2OH + {}^{\cdot}OH &\xrightarrow{k_{12}} \\ HO{-}C_6H_3(OCH_3){-}\dot{C}HOH + {}^{\cdot}OH &\xrightarrow{k_{13}} \end{aligned}\right\} \text{chain termination.} \tag{84, 85}$$

Using a quasi-steady-state approach for long chains and the condition that

$$k_r\,(k_s + k_{s1})\,k_{13} \gg k_{in1}k_sk_{12}\,[H_2O_2] \tag{86}$$

It follows that

$$w = \{k_dk_{in1}\,(k_s + k_{s1})/k_{13}\}^{1/2}[Ph]^{1/2}[H_2O_2], \tag{87}$$

which is in agreement with the partial reaction orders given above.

The kinetics have also been investigated for the reaction of hydrogen peroxide with the phenolic carboxylic acids (X), containing a phenolic hydroxyl and a carboxylic acid group, viz. ferulic (R^1 = H, R^2 = OCH_3, R^3 = CH=CH–COOH), syringic (R^1 = R^2 = OCH_3, R^3 = COOH), gallic (R^1 = R^2 = OH, R^3 = COOH) and protocatechuic (R^1 = H, R^2 = OH, R^3 = COOH) acids.[80,81]

It was established that the rate of consumption of H_2O_2 in a solution of ferulic acid increases with the increase in acid concentration (in the range 0.05–15.5 mol $litre^{-1}$) and in a solution of gallic acid the reaction rate increases with the increase in concentration of the latter only up to 0.29 mmol $litre^{-1}$ and then remains practically constant. In the presence of a monomer (acrylic acid) a reduction in the rate of the process practically to the rate of homolysis of peroxide in water indicates the radical–chain character of the reaction and its initiation by homolysis of H_2O_2.

From the initial rate of consumption of peroxide in the presence of the phenolic acids mentioned the reaction order found with respect to H_2O_2 was close to 1, with respect to ferulic acid to $^1/_2$, with respect to protocatechuic and syringic acids it was zero and with respect to galic acid it varied from $^1/_2$ (at concentrations up to 0.29 mmol $litre^{-1}$) to zero (at higher concentrations). The apparent activation energies for the oxidation of ferulic and gallic acids were 72 and 79 kJ mol^{-1} respectively. The data obtained[81] are in agreement with the kinetic scheme of (88)–(96) which proposes the formation of carboxyl and aryl radicals in addition to phenoxyl radicals.

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2\,{}^{\cdot}OH + 2H_2O, \tag{88}$$

$$^{\cdot}OH + HO{-}Ar{-}COOH \xrightarrow{k_s} H_2O + {}^{\cdot}O{-}Ar{-}COOH, \tag{89}$$

$$^{\cdot}OH + HO{-}Ar{-}COOH \xrightarrow{k_{s1}} H_2O + HO{-}Ar{-}COO^{\cdot}, \tag{90}$$

$$^{\cdot}O{-}Ar{-}COOH \xrightarrow{k_r} HO{-}Ar{-}COO^{\cdot}, \tag{91}$$

$$HO{-}Ar{-}COO^{\cdot} \xrightarrow{k_c} CO_2 + HO{-}Ar^{\cdot}, \tag{92}$$

$$^{\cdot}O{-}Ar{-}COOH + H_2O_2 \xrightarrow{k_{in}} {}^{\cdot}OH + \text{products}, \tag{93}$$

$$\left.\begin{aligned} {}^{\cdot}O{-}Ar{-}COOH + {}^{\cdot}OH &\xrightarrow{k_{12}} \\ HO{-}Ar{-}COO^{\cdot} + {}^{\cdot}OH &\xrightarrow{k_{13}} \\ HO{-}Ar^{\cdot} + {}^{\cdot}OH &\xrightarrow{k_{14}} \end{aligned}\right\} \text{chain termination} \tag{94, 95, 96}$$

Although oxidation of syringic aldehyde leads to the formation of stable phenoxyl radicals, the oxidation of syringic and sinapic (R_1 = R_2 = OCH_3, R_3 = CH=CH–COOH) acids leads to the observation of only a weak ESR signal[50] since seemingly their phenoxyl radicals are capable of conversion into reactive carboxyl and aryl radicals.[81] These facts point in favour of the occurrence of reactions (91) and (92). The reaction products of (93) are *o*-quinones which was confirmed by their colour reactions with ethylenediamine.

An expression was obtained from the kinetic scheme (88)–(96) for the rate of the radical–chain decomposition of H_2O_2 by the method of quasi-steady-state concentrations.[80,81]

$$w = k_{in}\{(F_1^2/4 + F_2)^{1/2} - F_1/2\}[H_2O_2], \quad (97)$$

$$F_1 = k_r(k_s + k_{s1})[Ph](k_{in}k_{12}[H_2O_2])^{-1} + k_s k_{12}^{-1}[Ph],$$

$$F_2 = k_d(k_s + k_{s1})(k_{in}k_{12})^{-1}[Ph].$$

At low concentrations of the phenolic carboxylic acid the expression (97) is simplified and takes the form of (98),[81] which corresponds to the experimental data given above for the decomposition of hydrogen peroxide in the presence of ferulic and gallic (at concentrations below 0.29 mmol litre^{-1}) acids.

$$w = \{k_{in}k_d(k_s + k_{s1})/k_{12}\}^{1/2}[Ph]^{1/2}[H_2O_2]. \quad (98)$$

At higher concentrations of phenolic carboxylic acids and hydrogen peroxide the Eqn. (97) is transformed into (99).[81] The empirical partial reaction orders given above for the hydrogen peroxide oxidation of protocatechuic, syringic and gallic acids (at concentrations of the latter above 0.29 mmol litre^{-1}) are in agreement with this equation.

$$w = \{k_d(k_s + k_{s1})/k_{s1}\}[H_2O_2]. \quad (99)$$

The oxidation of lignosulphonic acid (LSA) with hydrogen peroxide is first order with respect to H_2O_2 and about $^1/_2$ with respect to LSA. The apparent activation energy (58 kJ mol^{-1}) is significantly less than in the oxidation of model compounds of lignin.[82] The deceleration of the reaction by stable 2,2,6,6-tetramethylpiperidin-1-oxyl radicals indicates its radical–chain mechanism.

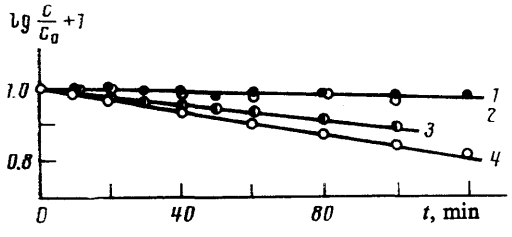

Figure 11. Semilogarithmic plot of the kinetic curves for the consumption of H_2O_2 in *1*, water, in solutions of lignosulphonic acid methylated *2*, with dimethyl sulphate and *3*, with diazomethane and *4*, in a solution of the initial LSA at concentrations of H_2O_2 2.6 mmol litre^{-1} and LSA 4.24 mmol litre^{-1} at 70 °C.[83]

An absorption band in the IR spectrum of LSA oxidised with peroxide appears at 1730 cm^{-1}, characteristic of a carbonyl group.[83] With an increase in the initial H_2O_2 concentration the content of acidic OH^- and carbonyl groups in the reaction products increases significantly, the quantity of quinone groups increases insignificantly and the content of methoxy groups is almost unchanged. This supports the hypothesis that the oxidation of LSA with hydrogen peroxide occurs in the side chain to a significant extent. In order to clarify whether phenolic hydroxyls participate in the oxidation, the kinetics of the interaction of H_2O_2 with lignosulphonic acid were investigated[83] after only the acidic OH groups had been methylated with diazomethane or after all the hydroxyl groups had been methylated with dimethyl sulphate. In the first case the rate of peroxide consumption was somewhat lower than in a solution of the initial unmethylated LSA but in the second case it approached the rate of decomposition of H_2O_2 in water (Fig. 11). This supports the proposal that the decomposition of hydrogen peroxide occurs only partially with the participation of phenoxyl radicals but to a significant extent with the participation of radicals with an unpaired electron in the side chain.

The kinetic scheme of (100)–(106) corresponds to the results obtained. In this it is proposed that the accumulation of carbonyl compounds and quinones occurs by reactions (103) and (104) and of acidic OH groups by secondary oxidation processes.

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2{}^{\cdot}OH + 2H_2O, \quad (100)$$

$${}^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}R(X)H \xrightarrow{k_s} {}^{\cdot}O{-}\underset{(XIII)}{C_6H_3(OCH_3)}{-}R(X)H + H_2O, \quad (101)$$

$${}^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}R(X)H \xrightarrow{k_{s1}} HO{-}\underset{(XIV)}{C_6H_3(OCH_3)}{-}\dot{R}(X) + H_2O, \quad (102)$$

$$(XIII) + H_2O_2 \xrightarrow{k_{in}} {}^{\cdot}OH + O{=}\langle\rangle{-}R(X)H + CH_3OH, \quad (103)$$

$$(XIV) + H_2O_2 \xrightarrow{k_{in1}} {}^{\cdot}OH + HO{-}C_6H_3(OCH_3){-}RO + \text{products}, \quad (104)$$

$$\left.\begin{array}{ll}(XIII) + {}^{\cdot}OH \xrightarrow{k_{12}} & (105)\\ (XIV) + {}^{\cdot}OH \xrightarrow{k_{13}} & (106)\end{array}\right\} \text{chain termination.}$$

An equation was obtained for the rate of consumption of H_2O_2 in LSA solution[83] from this scheme using a kinetic model for unbranched radical–chain processes[84] in a quasi-steady-state approach for long chains.

$$w = (k_s + k_{s1})(k_d k_{in} k_{in1})^{1/2}(k_s k_{in1} k_{12} + k_{s1} k_{in} k_{13})^{-1/2}[LSA]^{1/2}[H_2O_2]. \quad (107)$$

This is in agreement with the reaction orders with respect to LSA and hydrogen peroxide found experimentally.

On reacting hydrogen peroxide with nitrolignin (NL) the reaction order with respect to H_2O_2 was close to 1 and with respect to NL close to $^1/_3$, the apparent energy of activation was 75 kJ mol^{-1}.[24] The marked deceleration of H_2O_2 consumption in a solution of NL under the influence of an unsaturated monomer indicated the radical–chain mechanism of the reaction and the fact that the reaction rate in this case exceeds the rate of peroxide homolysis points in favour of initiation of the process by an associate of nitrolignin with hydrogen peroxide according to reaction (108).

According to data from gel permeation chromatography (GPC) the polydispersity (from 2.96 to 10.30) and the mean molecular mass MW (from 3190 to 11470) of nitrolignin are increased by oxidation with hydrogen peroxide. In the opinion of the authors,[24] this occurs as a result of recombination of NL macroradicals by chain termination reactions (112)–(114). The kinetic scheme proposed[24] involves the isomerisation of an aroxyl radical having a vacant *ortho*

position into an aryl radical (criticism of such ideas is given above). The possibility of carrying out the previously considered rearrangement of aroxyl radical into a radical with an unpaired electron in the side chain is disregarded.[78] Allowing for what has been said the kinetic scheme for the oxidation of NL with peroxide may be described by the equations

$$H_2O_2 + HO{-}Ar{-}RH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2O_2 \ldots HO{-}Ar{-}RH \xrightarrow{k'} 2{}^{\cdot}OH + HO{-}Ar{-}RH, \quad (108)$$

$${}^{\cdot}OH + HO{-}Ar{-}RH \xrightarrow{k_s} H_2O + {}^{\cdot}O{-}Ar{-}RH, \quad (109)$$

$${}^{\cdot}O{-}Ar{-}RH \xrightarrow{k_r} HO{-}Ar{-}R^{\cdot}, \quad (110)$$

$$HO{-}Ar{-}R^{\cdot} + H_2O_2 \xrightarrow{k_{in}} {}^{\cdot}OH + \text{products}, \quad (111)$$

$$\left.\begin{aligned} 2{}^{\cdot}O{-}Ar{-}RH &\xrightarrow{k_0} \\ {}^{\cdot}O{-}Ar{-}RH + HO{-}Ar{-}R^{\cdot} &\xrightarrow{\sigma k_0} \\ 2HO{-}Ar{-}R^{\cdot} &\xrightarrow{\sigma^2 k_0} \end{aligned}\right\} \text{chain termination} \quad (112)\text{–}(114)$$

It is possible to obtain an equation for the rates of the radical–chain decomposition of H_2O_2 from the given scheme using quasi-steady-state concentrations taking geometric means and corresponding to that given previously.[24]

$$w = \frac{k_{in}k_r(2k/k_0)^{1/2}[NL]^{1/2}[H_2O_2]^{3/2}}{k_{in}[H_2O_2] + \sigma k_r + \sigma(2kk_0[NL][H_2O_2])^{1/2}}, \quad (115)$$

where $k = k_1k'(k_{-1} + k')^{-1}$. Proceeding from the proposed different contributions of radicals with an unpaired electron in the side chain and aroxyl radicals to chain termination, the reaction order with respect to NL and H_2O_2 must be intermediate between 0 and $^1/_2$ and between $^1/_2$ and $^3/_2$ respectively according to expression (115).[24] This is in agreement with the partial reaction orders found empirically, so that in the system investigated radicals with an unpaired electron in the side chain and aroxyl radicals from nitrolignin evidently participate in chain termination. High molecular weight fractions of NL appear as a result and this was confirmed by GPC data.

The oxidation with hydrogen peroxide of water-soluble lignin derivatives and of compounds modelling units of its structure proceeds according to a radical–chain mechanism with the participation of both phenolic hydroxyls and of functional groups in the side chain.

VI. Analysis of the kinetic scheme for radical–chain oxidation of phenolic compounds with hydrogen peroxide

The results of the kinetic investigations considered above enable the conclusion to be drawn that the interaction of hydrogen peroxide with organic substances, particularly phenolic compounds, usually proceeds by a radical–chain mechanism. This is indicated by the acceleration of peroxide decomposition in the presence of organic compounds, the frequently encountered fractional partial reaction orders, the dependence of the form of the rate equation on the relative concentrations of organic compound and peroxide and by the sensitivity of the reaction to the action of small amounts of catalysing or inhibiting substances.

The kinetic schemes given above for the oxidation of phenolic compounds with hydrogen peroxide are in fact partial variants of the general scheme of (116)–(126) which comprises chain initiation by homolysis of peroxide (116), interaction of hydroxyl radicals with the phenolic compound with the formation of phenoxyl radicals (117) and radicals with an unpaired electron in the side chain (118), rearrangement of the former to the latter (119), decomposition of hydrogen peroxide by these radicals (120) and (121) and chain termination with the participation of these radicals and of hydroxyl radicals.

$$H_2O_2 \cdot 2H_2O \xrightarrow{k_d} 2{}^{\cdot}OH + 2H_2O, \quad (116)$$

$${}^{\cdot}OH + HO{-}Ar{-}R(X)H \xrightarrow{k_s} H_2O + {}^{\cdot}O{-}Ar{-}R(X)H, \quad (117)$$

$${}^{\cdot}OH + HO{-}Ar{-}R(X)H \xrightarrow{k_{s1}} H_2O + HO{-}Ar{-}\dot{R}(X), \quad (118)$$

$${}^{\cdot}O{-}Ar{-}R(X)H \xrightarrow{k_r} HO{-}Ar{-}\dot{R}(X), \quad (119)$$

$${}^{\cdot}O{-}Ar{-}R(X)H + H_2O \xrightarrow{k_{in}} {}^{\cdot}OH + \text{products}, \quad (120)$$

$$HO{-}Ar{-}\dot{R}(X) + H_2O_2 \xrightarrow{k_{in\,1}} {}^{\cdot}OH + \text{products}, \quad (121)$$

$$\left.\begin{aligned} {}^{\cdot}O{-}Ar{-}R(X)H + {}^{\cdot}OH &\xrightarrow{k_{12}} \\ HO{-}Ar{-}\dot{R}(X) + {}^{\cdot}OH &\xrightarrow{k_{13}} \\ 2{}^{\cdot}O{-}Ar{-}R(X)H &\xrightarrow{k_{22}} \\ {}^{\cdot}O{-}Ar{-}R(X)H + HO{-}Ar{-}\dot{R}(X) &\xrightarrow{\sigma k_{22}} \\ 2HO{-}Ar{-}\dot{R}(X) &\xrightarrow{\sigma^2 k_{22}} \end{aligned}\right\} \text{chain termination} \quad (122)\text{–}(126)$$

The rate equation for each process depends mainly on the chain length and on the relative contributions of chain propagation reactions (117)–(121). It is expedient in this connection to conduct an analytical calculation of the given kinetic scheme using the quasi-steady-state concentrations under conditions when the chain length is sufficiently large.

1. Analytical calculation of a kinetic scheme with the long-chain approach

A general rate equation for long-chain oxidation of phenolic compounds with hydrogen peroxide has been derived using a kinetic model of the unbranched radical–chain process.[84] It is possible to represent the topology of the kinetic scheme (116)–(126) by the diagram shown in Fig. 12. The total chemical reaction proceeds by three routes, i.e. the first includes reactions (117) and (120), the second reactions (118) and (121) and the third reactions (117), (119) and (121).

The overall rate equation for the consumption of hydrogen peroxide is obtained by summation of the rates for each route.[83]

$$w = (2k_dk_{in\,1})^{1/2}(k_s + k_{s1})\,F_3[Ph]^{1/2}[H_2O_2]/(2F_3F_4 + F_5F_6)^{1/2}, \quad (127)$$

where

$$F_3 = k_r + k_{in}[H_2O_2],\ F_4 = k_{12}k_{in\,1}k_s[H_2O_2] + k_{13}(k_{s1}F_3 + k_rk_s),$$
$$F_5 = k_{22}k_s[Ph],\ F_6 = k_{in\,1}k_s[H_2O_2] + \sigma(k_{s1}F_3 + k_rk_s). \quad (128)$$

It may be shown that on satisfying the condition

$$[Ph] \gg 2F_3F_4/(k_{22}k_sF_6) \quad (129)$$

chain termination by substrate radicals according to reactions

(124)–(126) predominates. In this case equation (127) is transformed into (130).

$$w = (2k_d k_{in\,1})^{1/2}(k_s + k_{s1})\,(k_{22}k_s)^{-1/2}F_3[H_2O_2]/F_6^{1/2}. \quad (130)$$

However from this expression a first order equation with respect to peroxide, compatible with the experimental data, may be derived when $k_{in} = 0$ and $k_{in1} = 0$ [i.e. reactions (120) and (121) for the chain decomposition of H_2O_2 at any reaction centre do not play an appreciable role], which contradicts the result given in section V.

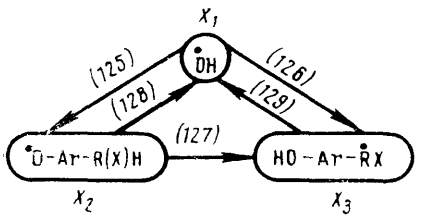

Figure 12. Diagram representing the topology of the kinetic scheme for the oxidation of phenolic compounds with hydrogen peroxide.

At the same time under conditions the reverse of (129) chain termination by hydroxyl radicals [reactions (122) and (123)] must predominate and the reaction rate will be described by Eqn. (131), following from (127).

$$w = (k_d k_{in\,1})^{1/2}\,(k_s + k_{s1})\,F_3\,[Ph]^{1/2}[H_2O_2]/F_4^{1/2}. \quad (131)$$

Partial reaction orders with respect to peroxide and to substrate may be obtained from the equation given and correspond to the results of experiments. This points in favour of the hypothesis on the preference under selected experimental conditions (see section V) for chain termination by reactions (122) and (123). In reality is follows from Eqn. (131) that the reaction order with respect to substrate is $^1/_2$, but with respect to peroxide it may be less, equal to or greater than 1 depending on the peroxide concentration and the values of the rate constants for the individual reactions (117)–(123). Such partial reaction orders were observed on oxidation of lignosulphonic acid, vanillyl alcohol and guaiacol. It may be shown that the rate equations obtained for these processes (see section V) are partial instances of the general dependence (131).

For example $k_r = 0$ in the system lignosulphonic acid–hydrogen peroxide (this is indicated by kinetic data on the oxidation of initial and methylated LSA, see Section V). Under this condition Eqn. (131) is in fact transformed into (107).

It follows from the data given in Section V on the change of functional composition of the products that $k_{in} = 0$ for the oxidation of vanillyl alcohol with hydrogen peroxide. In this case, allowing for the condition (86), Eqn. (131) is simplified to (87).

Finally, on oxidising guaiacol, which has only one reaction centre due to the absence of a side chain, it is possible to set rate constants k_r and k_{s1} to zero. Eqn. (131) is then transformed into (65). This confirms the correctness of Eqn. (131), which may aid (by drawing on results obtained by other methods) an adequate choice for the kinetic scheme and the corresponding expressions for reaction rates.

2. Analysis of a kinetic scheme at an arbitrary chain length

On oxidising certain phenolic compounds (vanillin, phenolic carboxylic acids) with hydrogen peroxide a first order is retained with respect to H_2O_2 while the order with respect to the organic substance may vary depending on the reaction conditions. This is not explained within the framework of the long-chain approach.

It is possible to analyse the kinetic scheme for the process at arbitrary chain length by the method of quasi-steady-state concentrations. However it is impossible to solve the system of nonlinear equations for the quasi-steady-state in explicit form in the present case consequently it was proposed to reduce it from a stationary reaction rate to a kinetic polynomial.[85] Application of such an approach to the kinetic scheme (116)–(123) enables the following polynomial to be obtained in the form represented by the equation:

$$F_7^2F_8 = c_1 + c_2/[H_2O_2] + c_3F_7F_8 + c_4F_7 + c_5[Ph]\,F_7/k_d, \quad (132)$$

where

$$c_1 = k_{in}k_{in\,1}(k_s + k_{s1})^2(k_{12}k_{13})^{-1},\ c_2 = k_r k_{in\,1}(k_s + k_{s1})^2(k_{12}k_{13})^{-1},$$
$$c_3 = -(k_s + k_{s1})\,k_r k_{12}^{-1},\ c_4 = (k_{in}/k_{12} + k_{in\,1}/k_{13})\,(k_s + k_{s1}),$$
$$c_5 = -(k_{in}k_{s1}/k_{12} + k_{in\,1}k_s/k_{13}),$$
$$F_7 = w\,[H_2O_2]^{-1}[Ph]^{-1},\ F_8 = wk_d^{-1}[H_2O_2]^{-1} - 1. \quad (133)$$

The kinetic polynomial (132) may be used in the analysis of the results obtained for discriminating between the kinetic hypotheses and in the choice of a variant of the kinetic scheme (116)–(123) for appropriate experiment. The following partial cases are considered.

1. If rearrangement of phenoxyl radicals into radicals with an unpaired electron in the side chain (119) is not feasible then substitution of $k_r = 0$ in polynomial (132) leads to the expression

$$F_7^2F_8 = c_1 + \left\{c_4\frac{w}{[H_2O_2]} + \frac{c_5}{k_d}\left(\frac{w}{[H_2O_2]}\right)^2\right\}\frac{1}{[Ph]} \quad (134)$$

In this case the dependence of reaction rate on the concentration of phenolic compound (at constant initial H_2O_2 concentration) must be linear in the coordinates of Eqn. (134) and enables exclusion of Eqn. (119) from the kinetic scheme (Table 5).

2. If $k_r = 0$ and $k_{in1} = 0$ also, i.e. the radicals with an unpaired electron in the side chain do not cause decomposition of hydrogen peroxide (121), then allowing for (133) $c_1 = 0$ and expression (134) reduces to Eqn. (135). It also follows from this that the experimental data in the coordinates of Eqn. (134) must be described by a straight line passing through the origin of coordinates.

$$F_7F_8 = c_4 + (c_5k_d^{-1}[H_2O_2]^{-1})\,w. \quad (135)$$

In this case the relationship between reaction rate and the concentration of the phenolic compound (at constant initial H_2O_2 concentration) must be linear in the coordinates of Eqn. (135). The passing of the straight line of (134) through the origin indicates fulfilment of the conditions $k_r = 0$ and $k_{in1} = 0$ and enables reactions (119) and (121) to be excluded from the overall kinetic scheme (Table 5).

3. If the condition $k_{s1} = 0$ is fulfilled in addition to $k_r = 0$ and $k_{in1} = 0$ then $c_5 = 0$ and Eqn. (135) is transformed into

$$wF_8/[H_2O_2] = (k_{in}k_s/k_{12})\,[Ph]. \quad (136)$$

It also follows from this that the experimental straight lines must be parallel to the abscissa axis in the coordinates of Eqn. (135) and must pass through the origin in the coordinates of Eqn. (134). Linearity of the experimental data in the coordinates of Eqn. (136)

combined with the line of (135) being parallel to the abscissa axis and the line of (134) passing through the origin indicates that the conditions $k_r = 0$, $k_{in1} = 0$ and $k_{s1} = 0$ are fulfilled and reactions (118), (119) and (121) may be excluded from the overall kinetic scheme (Table 5).

Table 5. Discrimination between kinetic hypotheses when oxidising phenolic compounds with hydrogen peroxide in aqueous solution.

Variant number	Determining conditions	Linear relationships	Discriminating reactions
1	$k_r = 0$	(134)	(119)
2	$k_r = 0$, $k_{in\,1} = 0$	(134) *, (135)	(119), (121)
3	$k_r = 0$, $k_{in\,1} = 0$, $k_{s\,1} = 0$	(134) *, (135) **, (136) *	(118), (119), (121)
4	$k_{in\,1} = 0$	(137)	(121)
5	$k_{in} = 0$	(138)	(120)

*The straight line in the coordinates of the given equation passes through the origin.
**The straight line in the coordinates of the given equation is parallel to the abscissa axis.

4. If only the condition $k_{in1} = 0$ is fulfilled then polynomial (132) allowing for (133) reduces to the equation

$$F_7F_8 = c_4 + (c_3/[H_2O_2] + c_5/k_d)\,F_8. \qquad (137)$$

Linearity of the data in the coordinates of Eqn. (137) indicates the fulfilling of the condition $k_{in1} = 0$ and points in favour of excluding reaction (121) from the overall kinetic scheme (Table 5).

5. If there is no decomposition of hydrogen peroxide by phenoxyl radicals, i.e. $k_{in} = 0$, then when $k_{ap} \gg k_d$ the kinetic polynomial (132) is transformed into the linear relationship

$$[Ph]/(k_{ef}^2[H_2O_2]) = (c_6 - c_7) + c_8(k_{ef}/[Ph]),$$

Where

$$c_6 = \{k_{in\,1}/k_{13} + k_r/(k_{12}[H_2O_2])\}\,k_{12}k_{13}\,(k_dk_{in\,1}k_r)^{-1}(k_s + k_{s1})^{-1},$$
$$c_7 = k_{s1}k_{12}\,(k_dk_r)^{-1}(k_s + k_{s1})^{-2},$$
$$c_8 = k_{12}k_{13}\,(k_dk_{in\,1}k_r)^{-1}(k_s + k_{s1})^{-2}. \qquad (138)$$

Linearity of the experimental data in the coordinates of Eqn. (138) indicates that $k_{in} = 0$ and points in favour of the exclusion of reaction (120) from the experimental scheme (Table 5).

The analysis of the kinetic polynomial (132) enables a purpose-directed discrimination to be made between kinetic hypotheses and may facilitate appreciably the choice by experiment of an appropriate variant of the kinetic scheme (116)–(123). Such an approach enables a simplified kinetic scheme of the actual process being investigated to be obtained from the complete scheme (116)–(123) by discarding individual reactions which make little contribution to the kinetics of the process.

What has been said enables the kinetic polynomial (132) to be used for the analysis of the kinetic scheme for the oxidation of phenolic compounds with hydrogen peroxide and may give desirable information on the mechanism of the process under investigation. This is illustrated by some examples.

When oxidising guaiacol with hydrogen peroxide linear relationships are observed for (134), (135) and (136). The straight lines in the coordinates of (134) and (136) pass through the origin of coordinates (Fig. 13, *1*) and (Fig. 14, *3*) and the straight line in coordinates of Eqn. (135) is parallel to the abscissa axis (Fig. 14, *1*). This corresponds to case 3 (Table 5) and indciates that reactions (118), (119) and (121) do not play a significant role in this system. In reality the structure of the guaiacol molecule and the change in its functional composition in the process of peroxide oxidation (see Section V) confirm this conclusion. What has been said enables exclusion of reactions (118), (119) and (121) from the kinetic scheme (116)–(123) and is in agreement with the scheme for the oxidation of guaiacol considered in Section V. When $k_r = 0$, $k_{in1} = 0$ and $k_{s1} = 0$ the general Eqn. (132) reduces to expression (63).

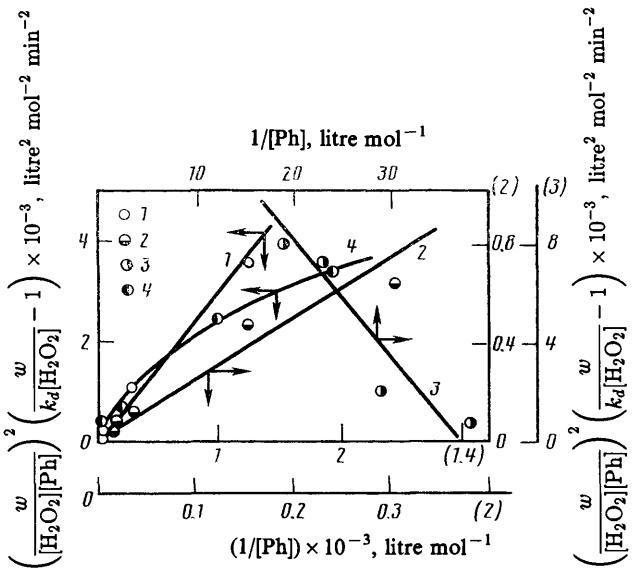

Figure 13. Relationship of the rates of oxidation with hydrogen peroxide of *1*, guaiacol, *2*, vanillin, *3*, LSA and *4*, ferulic acid to the concentration of phenolic compound in the coordinates of Eqn. (134) at 70 °C.[22,76,81]

Similarly when oxidising ferulic acid with hydrogen peroxide the relationship (134) is not linear (Fig. 13, *4*) but relationship (137) is linear (Fig. 15, *1*) which corresponds to case 4 (Table 5). The latter indicates that induced decomposition of H_2O_2 by reaction (121) does not occur in practice in the system being investigated. This enables reaction (121) to be excluded from the kinetic scheme (116)–(123) and is in agreement with the oxidation scheme for phenolic carboxylic acids given in Section V. When $k_{in1} = 0$ the overall Eqn. (132) is transformed into expression (97).

Investigation of the kinetics of the interaction of H_2O_2 with LSA and its methylated derivatives showed that in this system chain decomposition of peroxide by radicals in the side chain and by phenoxyl radicals occurs (see Section V). In this case a linear relationship was observed for (134) while the straight line did not pass through the origin of coordinates (Fig. 13, *3*). This

corresponds to case 1 (Table 5) and indicates that reaction (119) does not play an appreciable role in the system under investigation. What has been stated enables exclusion of reaction (119) from the overall scheme (116)–(123) and is in agreement with the kinetic scheme for the oxidation of LSA considered in Section V.

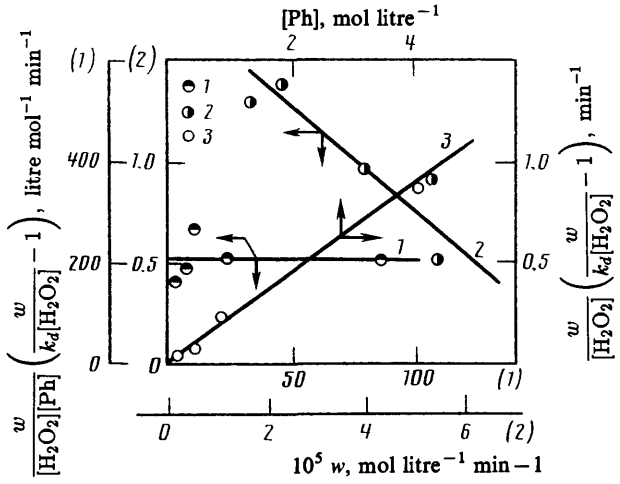

Figure 14. Relationship of the reaction rates of hydrogen peroxide with *1*, *3*, guaiacol and *2*, vanillin to their concentrations in the coordinates of Eqn. (135) *1*, and *2*, and of Eqn. (136) (*3*) at 70 °C and a hydrogen peroxide concentration of 1.06 mmol litre^{-1}.[22,76]

When oxidising vanillin with hydrogen peroxide a linear relationship was observed for (134) and (135). Although the straight line drawn from the experimental data in the coordinates of Eqn. (134) passes through the origin of coordinates, the straight line in coordinates of Eqn. (135) is not parallel to the abscissa axis (Fig. 13, *2*; Fig. 14, *2*) This corresponds to case 2 (Table 5) and indicates that reaction (119) and the decomposition of H_2O_2 by radicals with an unpaired electron on the carbon atom of the carbonyl group (121) do not make significant contributions to the kinetics of the process. These conclusions are confirmed by data on the kinetics for the decomposition of hydrogen peroxide in solutions of benzaldehyde, guaiacol, and mixtures of them (see Section V). Consequently reactions (119) and (121) may be excluded from the overall kinetic scheme in this case which is in agreement with the scheme given in Section V for the oxidation of vanillin. When k_r = 0 and k_{in1} = 0, the general Eqn. (132) reduces to expression (71).

Analysis of the functional composition of the oxidation products of vanillyl alcohol with hydrogen peroxide showed that the content of phenolic hydroxyls and methoxyl groups was practically unchanged in the oxidation process, while the alcohol is oxidised to a carbonyl group (see Section V). This indicates that the decomposition reaction (120) does not make an appreciable contribution to the kinetics of the process. The linearity of relationship (138) (Fig. 15, *2*) confirms this conclusion and enables assignment of this system to case 5 (Table 5). Reaction (120) may therefore be excluded from the overall kinetic scheme (116)–(123) in agreement with the oxidation scheme for vanillyl alcohol represented in Section V. When k_{in} = 0 and allowing for (86) the overall Eqn. (132) is transformed into expression (87).

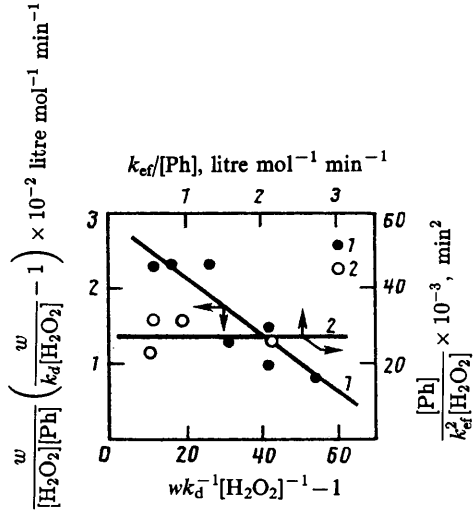

Figure 15. Relationship of the rates of oxidation with hydrogen peroxide of *1*, ferulic acid and *2*, vanillyl alcohol to reactant concentration in the coordinates of *1*, Eqn. (137) and *2*, Eqn. (138) at 70 °C.[78,81]

The rate equations given in Section V for the oxidation of phenolic compounds with hydrogen peroxide are partial cases of the general relationship (132) obtained by analysis of the kinetic scheme (116)–(123). This confirms the correctness of the chosen kinetic schemes to describe the oxidation processes of phenolic compounds with hydrogen peroxide in aqueous medium.

Mass spectrometry of derivatives and heterocyclic analogues of 9,10-dihydroanthracene

A I Mikaya, A V Varlamov, V G Zaikin, N S Prostakov
A V Topchiev Institute of Petrochemical Synthesis, Academy of Sciences of the USSR, Moscow
P Lumumba Peoples' Friendship University, Moscow

ABSTRACT. The fragmentation of derivatives of 9,10-dihydroanthracene and of its heterocyclic analogues containing atoms of O, S, N, P, Si, As, Se and Te at positions 9 and/or 10 is examined. The conditions reviewed are electron impact and chemical ionisation with recording of positive and negative ions. It has been shown that depending on its nature, the heteroatom may be eliminated together with substituents from the molecular ion or a substituent may be lost both as a radical and together with an additional H atom. The fragmentation of compounds in which the substituting groups are adjacent to the hetero atom is explained by the '*peri*-effect'. The elimination of substitutents from phenylene rings, at the *meso* position and at the hetero atom occurs in a similar manner to elimination in the corresponding aromatic derivatives.

The bibliography contains 114 references.

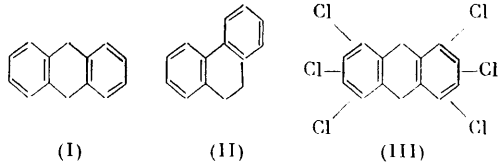
IV.	Analogues of 9,10-dihydroanthracene with heteroatoms at positions 9 and 10	495

I. Introduction

Derivatives of 9,10-dihydroanthracene and its heterocyclic analogues are widely distributed in nature. The anthracyclines, which are antibiotics possessing antitumour activity, belong to this class. The aglycone of the anthracyclines is a tetrahydronaphthacenequinone which contains an anthraquinone fragment. Phenothiazine derivatives possess various physiological activities and are applied in medicine as antihistamine preparations, for the treatment of Parkinsonism and also for the treatment of psychiatric disorders (Aminazine). Antibiotics of the actinomycin series possess strong bactericidal properties and contain a dibenzoxazine (phenoxazine) ring in the molecule. Up to the present a large number of analogues of 9,10-dihydroanthracene have been synthesised which contain in positions 9 and 10 not only the traditional heteroatoms O, N, S and P but also the elements Si, Se, Te, As, etc.

While possessing specific chemical properties the derivatives of 9,10-dihydroanthracene and its heterocyclic analogues also differ in their specific fragmentation under conditions of electron impact (EI). First there are processes eliminating fragments of the central ring, leading to its contraction and the formation of dibenzohetarene ions. No less important fragmentation processes are fission of this ring and elimination of substituents depending on their nature and disposition in the molecule. Knowledge of the rules for dissociation on ionisation is necessary when studying the reactivity of ions in the gas phase and in the solution of structure-analytical problems (the establishment of the composition and structure of molecules, the determination of trace amounts of the appropriate physiologically active compounds and the products of their metabolism).

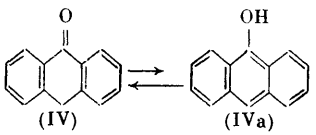


There are no special reviews in the literature of studies in which the features of the dissociation of 9,10-dihydroanthracenes and their heterocyclic analogues on ionisation have been correlated and systematised. The EI mass spectra of anthraquinones are considered only in old monographs[1,2] and the mass spectral characteristics of individual types of heterocyclic analogues of 9,10-dihydroanthracene have been given in a monograph.[3] It should be noted that in this review the EI method is implied even when not specially stipulated.

II. 9,10-Dihydroanthracene and its derivatives

The mass spectrum of 9,10-dihydroanthracene (I) contains three most significant peaks corresponding to the ions M^+, $[M-H]^+$ and $[M-2H]^+$ with a ratio of intensities 92:100: 63. A similar triplet of peaks also dominates the mass spectrum of 9,10-dihydrophenanthrene (II), however in this case the ratio of intensities is 100:55:30. The higher intensity peak for the $[M-H]^+$ ion in the case of compound (I) is explained by the fact that on elimination of a hydrogen atom from a methylene group a carbocation is formed with two benzyl group fragments in the stabilisation of which both phenylene rings participate. In the analogous carbocation which is formed from compound (II) there is one benzyl fragment and only one phenylene ring participates in its stabilisation. In addition there are seven resonance forms possible for the $[M-H]^+$ ion for compound (I) and four for compound (II).

The $[M-2H]^+$ ions (I) and (II) have the structures of anthracene and phenanthrene ions respectively.[4]

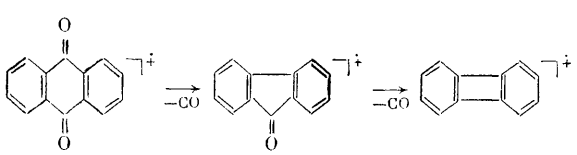


There are low intensity peaks for $[M-CH_3]^+$, $[M-C_2H_4]^+$, $[C_7H_5]^+$ and $[C_6H_4]^+$ ions in the mass spectrum of compound (I) and others the formation of which is linked with the isomerisation of M^+ and the fission of bonds in the central ring.

(I) (II) (III)

Detection of the toxic hexachloro-9,10-dihydroanthracenes (III) with chlorine atoms at various positions in the phenylene rings was effected by gas chromatography-mass spectrometry (GC-MS). Two of the most intense peaks with *m/z* 388 and 390 were used out of the multiplet of peaks of their molecular ions.[5]

9(10H)-Anthracenone, anthrone (IV), is characterised by a tautomeric equilibrium with 9-hydroxyanthracene, anthrol (IVa). The keto form is thermodynamically the more favourable and anthrone predominates in the gas phase.

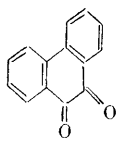


(IV) (IVa)

It was established that the enthalpy of formation of anthrone is 3 kcal mol^{-1} less than for anthrol and the enthalpy of formation of M^+ for the keto form is 77 kcal mol^{-1} greater than that of M^+ of the enol form.[6] Consequently the main decomposition of M^+ for compound (IV) is linked not with ejection of CO (as is characteristic of cyclic ketones) and the formation of a fluorene cation radical but with loss of HCO. However this process does not occur in practice in the case of 10,10-diaryl-9-anthrones.[7]

Much work has been devoted to the mass spectrometric study of anthraquinone (V) and its derivatives.[2] The main routes for the decomposition of anthraquinone on EI are determined by the sequential elimination of two CO groups, which was established by ^{18}O-labelled analogues,[8] with the formation of ions of fluorenone and biphenylene (Scheme 1).

Scheme 1



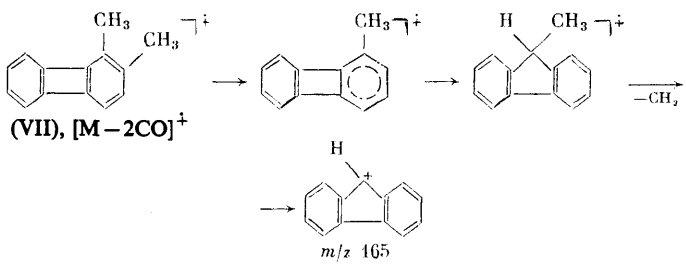
M^+, (V) $[M-CO]^+$ $[M-2CO]^+$

This fragmentation scheme for anthraquinone has become classical and is cited in many monographs and original papers.[1-3] The individual steps of this reaction sequence have been separated in the various field free regions of a reversed geometry double focussing mass spectrometer.[8] It was established that different amounts of energy are liberated in the formation of $[M-CO]^+$ ions depending on where they are generated, either in the ion source or in a field free region. But this in its turn means that $[M-CO]^+$ ions formed in these two regions have different structures. The structure of the ion in the second case is unknown. The $[M-CO]^+$ ions generated in the ion source most probably have the structure of the fluorenone ion since the mass spectrum of the latter is very similar to the spectrum of anthraquinone below the peak with *m/z* 180, which corresponds to the $[M-CO]^+$ ion. Attempts to detect all of the two-step reaction

$$M^+ \rightarrow [M-CO]^+ \rightarrow [M-2CO]^+$$

in the first field free region proved to be unsuccessful, which indicates the low rate of the second stage.

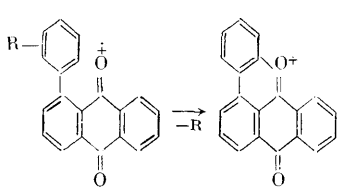
9,10-Phenanthrenequinone (VI) is decomposed on EI by an analogous scheme. Ejection of the first molecule of CO is predominant which is explained by the ease of the initial fission of the C–C bond between the α-diketo groups.[9]



(VI)

It must be mentioned that anthracene is readily oxidised to anthraquinone on chemical ionisation in a mixture of $O_2/N_2/CO_2$ gases. Only the M^+ peak of anthraquinone was present in the negative ion mass spectrum recorded in this manner.[10]

In the case of 1(2)-methyl- and 1,2-methyl-9,10-anthraquinones (VII) a complex skeletal rearrangement occurs in the $[M-2CO]^+$ ions with the formation of a fluorene cation (Scheme 2).[11]



Scheme 2

(VII), $[M-2CO]^+$ *m/z* 165

The presence of a carbonyl group in anthraquinones has a special influence on fragmentation at the expense of substituents in the aromatic ring. In the spectra of 1-aryl derivatives of anthraquinone (VIII) containing an *ortho* substituent there was a main peak with *m/z* 283 caused by elimination of this substituent from M^+ (Scheme 3).[1]

Scheme 3

M^+, (VIII), R = H, *o*-CH_3, *o*-OCH_3, *o*-NO_2 *m/z* 283

This type of dissociation on ionisation has been investigated in detail[12] in a study of *o*, *m* and *p* isomers in a series of 1-aryl-anthraquinones (VIII, R = CH_3, OCH_3, F, Cl, Br, and NO_2). A substituent in the *ortho* position of the aryl group is readily eliminated by the process shown in Scheme 3. The same substituent in the *meta* or *para* position leaves with difficulty. In this case a hydrogen atom is readily lost from the *ortho* position (Table 1).

The main routes of fragmentation of 1- and 2-chloroanthraquinones and also of 1,5- and 1,8-dichloroanthraquinones on EI are linked with the loss of two molecules of CO from M^+. The $[M-CO]^+$ ions also exist as two structures in all these cases.[8]

After the ejection of two CO groups monohydroxyanthraquinones eliminate a third CO molecule and HCO.[13] Using [9,10-di-^{18}O]-1-hydroxy-9,10-anthraquinone as an example it was established[8] that the M^+ of this compound gives up $C^{16}O$ and $C^{18}O$ in the ratio 1:4, i.e. the elimination of CO from the carbonyl groups is preferred to elimination from the hydroxyl group. The $[M-C^{18}O]^+$ ions give up

$C^{16}O$ and $C^{18}O$ with a proability ratio of 1:5. The ejection of a second CO molecule from $[M-C^{18}O]^+$ ions is similar to that which occurs on decompositon of [9-^{18}O]-1-hydroxy-9-fluorenone.

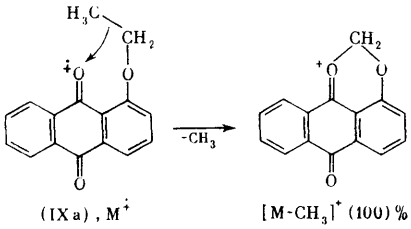


Table 1. Intensities ($\%\sum_{60}$) of peaks of characteristic ions in the mass spectra of compounds (VIII).

R	M^+	$[M-H]^+$	$[M-R]^+$	R	M^+	$[M-H]^+$	$[M-R]^+$
o-CH_3	6.5	1.5	36.5	*o*-Cl	0	0.2	43.0
m-CH_3	8.0	11.3	15.4	*m*-Cl	14.1	23.9	12.2
p-CH_3	8.6	12.2	8.3	*p*-Cl	16.4	26.5	9.4
o-OCH_3	3.0	0.3	36.5	*o*-Br	0	0.02	35.9

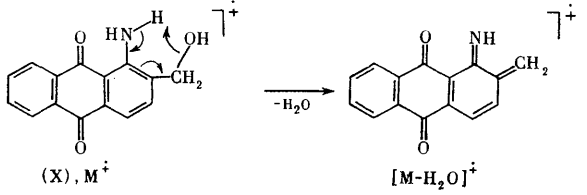
p-OCH_3	10.4	9.7	8.3	*p*-Br	13.9	19.6	10.6
o-F	12.8	14.0	15.0	*o*-NO_2	0.02	0.09	39.6
m-F	15.8	27.4	2.8	*m*-NO_2	5.8	6.8	7.4
p-F	18.6	33.3	2.2	*p*-NO_2	2.3	2.6	3.5

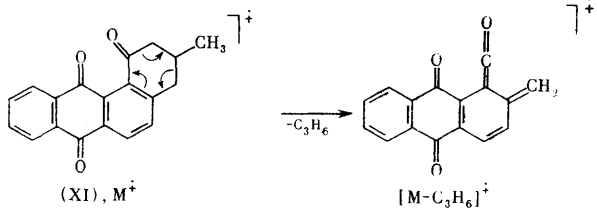
The ease of formation of $[M-OH]^+$ ions in the case of dihydroxanthraquinones depends on the disposition of the hydroxyl groups.[13] The corresponding peaks were much more intense if the OH groups were in different rings. It was noted[13] that anthraquinones containing an OH group at positions 2, 3, 6, or 7 were more inclined to eject an OH radical from M^+ than were the 1, 4, 5 or 8 isomers for which the formation of an intramolecular hydrogen bond is possible.



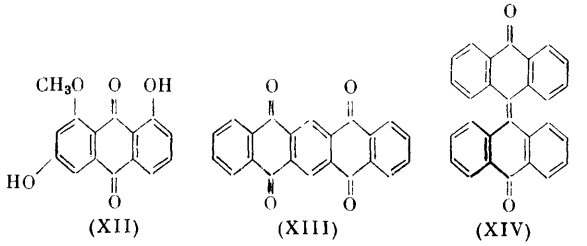
Marked differences were observed between the spectra of 1- and 2-methoxyanthraquinones.[13] Peaks for $[M-OH]^+$ and $[M-H_2O]^+$ were present only in the first case. The generation of the second ion is caused by the *peri* disposition of the CH_3O and CO groups providing migration of two H atoms to the carbonyl group. The principal differences between the mass spectra of the higher 1- and 2-alkoxyanthraquinones are explained by the *peri*-effect.[14] With the aid of 1- (IXa) and 2-ethoxyanthraquinones (IXb) labelled with deuterium in the ethyl group it was shown that the *peri* effect determines the loss of a CH_3 radical from compound (IXa) (Scheme 4), while in the case of compound (IXb) fragmentation of the ethoxy group is linked only with ejection of C_2H_4.

Scheme 4

In the general case substituted anthraquinones decompose on EI like the corresponding derivatives of aromatic compounds although the character of the fragmentation is determined by the nature of the substituent.[15] The double elimination of CO from M^+ typical of anthraquinones is, as a rule, completely suppressed but the CO molecules may be ejected from the fragment ions formed on elimination of substituents. For example the main decomposition of 1-amino-2-hydroxymethylanthraquinone (X) is linked with the elimination of a molecule of water (Scheme 5) and the elimination of CO is effected from the dehydrated ion.[16]



Scheme 5



The decomposition of 1-arylamino- and 1,4-di(arylamino)anthraquinones on EI is linked with expulsion of the ArNH group from position 1. The resulting ions $[ArNH_2]^+$, $[ArNH]^+$ and $[M-ArN]^+$ may decompose further and the latter is capable of eliminating CO twice.[17]

The presence of an additional annelated ring on the anthraquinone molecule may introduce specificity into the character of the decomposition. For example in the case of the methyl ester of ochromycinone (XI) in addition to decarbonylation of M^+ there is also elimination of a C_3H_6 particle probably by a retrodiene decomposition (Scheme 6). Later OH, CO and HCO may be lost from the $[M-C_3H_6]^+$ ion.[18]

Scheme 6

An anthraquinone fragment is often encountered in natural compounds such as anthraquinone antibiotics in whose structure determination mass spectrometry was used.[19–25] For example on analysis of the mass spectrum, in which $[HOC_6H_3CO]^+$, (*m/z* 120, 12%) and $[HO(CH_3O)C_6H_3CO]^+$ (*m/z* = 150, 2%) ions were detected, the pigment isolated from the bacterium *Xenorhabdus luminescens* was assigned the structure 1,6-dihydroxy-8-methoxyanthraquinone (XII) and not 1,3-dihydroxy-8-methoxyanthraquinone.[26]

Fragmentation on EI of more complex anthraquinones of the type of pentacene-5,7,12,14-diquinone (XIII)[27] and 9,9′-dianthraquinone (XIV)[2,28] is also linked with repeated expulsion of a molecule of CO from M^+ and also of HCO at some stage.

III. Analogues of 9,10-dihydroanthracene with a heteroatom at position 9(10)

The mass spectral characeristics of heteroanalogues of 9,10-dihydroanthracene containing only one heteroatom (N, O, S, Si, P, etc.) in the central ring are considered in this section. Both general and specific routes of decomposition on EI are characteristic of compounds of this series depending on the nature of the heteroatom at position 9. One of the frequently encountered routes of fragmentation is the expulsion of the heteroatom from position 9 or the carbon atom with substituents from position 10. In both cases contraction of the central ring occurs with the formation of fluorene structures or their 9-hetero analogues (Scheme 7). The presence in the molecule of substituents inclined towards independent fragmentation may suppress these processes or cause them to occur in the later stages of ion fragmentation resulting in loss of the substituent. Some compounds of the type under consideration (XV) for which the disappearance of position 9 and/or 10 occurs at the first fragmentation of M^+ are shown in Table 2.

Scheme 7

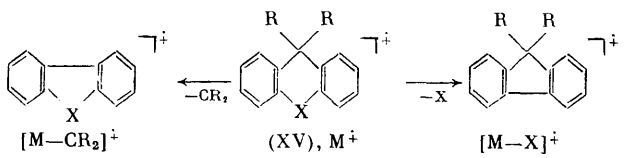


Table 2. Characteristic ions in the EI mass spectra of compounds (XV) (intensities are given in % maximal peak).

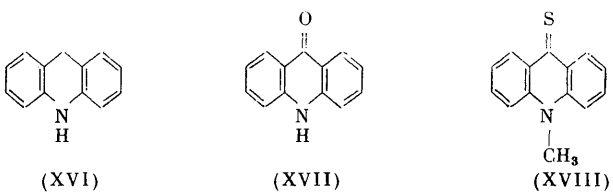

CR_2	X	Other substituents	$J_{[M-CR_2]^+}$	$J_{[M-CR_2]^+}/J_{M^+}$	$J_{[M-X]^+}$	$J_{[M-X]^+}/J_{M^+}$	Refs.

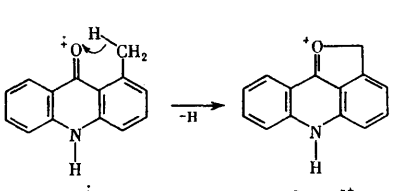
In one of the first studies on the mass spectrometric investigation of thioxanthene (XV, $CR_2 = CH_2$, X = S) and its 10,10-dideutero analogue it was established that their M^+ readily lose CH_2 and CD_2 (the corresponding peak has 60% intensity). This result was extremely unexpected since ejection of a carbene particle under EI conditions is energetically not favoured. In fact in more recent work[30,31,38] on the investigation of xanthene (XV, CR_2, CH_2, X = O), thioxanthene and their 10,10-dideutero analogues no peaks corresponding to ejection of $:CH_2$ and $:CD_2$ were detected. The elimination of CO from M^+ is a common process for carbonyl derivatives of these compounds.

In certain cases the process of forming $[M-X]^+$ ions is not a single step. This is a characteristic for example of phosphorus compounds [XV, $CR_2 = CH_2$, CO and X = P(O)OH or $P(O)OCH_3$] the molecular ions of which lose OH, OCH_3 and PO sequentially.[35]

After elimination of the heteroatom X from compounds (XV, $CR_2 = CH_2$) leading to a fluorene cation-radical, the fission of H is often a characteristic accompanied by the formation of a more stable fluorenyl cation.

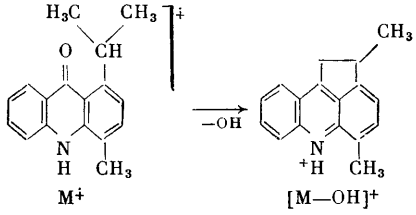


9,10-Dihydroacridines (acridanes). The mass spectrum of acridane (XVI) contains two peaks for M^+ (51%) and $[M-H]^+$ (100%) ions the intensities of which fell to 6–7% in the spectrum of 9-n-propylacridane where the base peak was the $[M-C_3H_7]^+$ ion. The character of the fragmentation is practically unchanged in the case of 4-ethyl- and 4-phenylacridanes, but in the case of 4-ethylacridane a noticeable peak for the $[M-1-28]^+$ ion appeared which is caused by the ejection of a molecule of ethylene from the C_2H_5 group as a result of a McLafferty rearrangement in the $[M-H]^+$ ion.[34]

(XVI) (XVII) (XVIII)

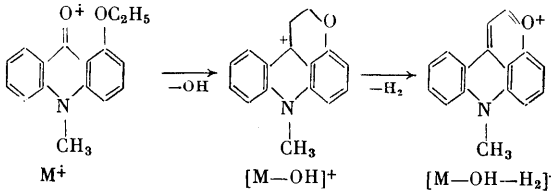
The mass spectral date of some acridones are given in Table 2. The molecular ion of acridone (XVII) may lose H and HCN after ejection of CO and the formation of a carbazole ion-radical.[32,33] Elimination of CS is a characteristic of 10-methylthioacridone (XVIII).[3] Competition between fragmentation of the side chain and ejection of CO was observed on fragmentation of substituted acridones (1-, 2-, 3-, and 10-methyl, 2-ethyl, 2-n-butyl, 4-isopropyl, 4-t-butyl, 1-isopropyl-4-methyl). In all cases apart from the methylacridones, β-fission (benzylic) dominates accompanied by loss of part of the alkyl substitutent.[33,39] It was proposed[34] that this process in the M^+ of 1-methylacridone is facilitated by the possibility of forming an oxonium ion (Scheme 8). In all these cases the ejection of CO occurs after the given reactions.

Scheme 8



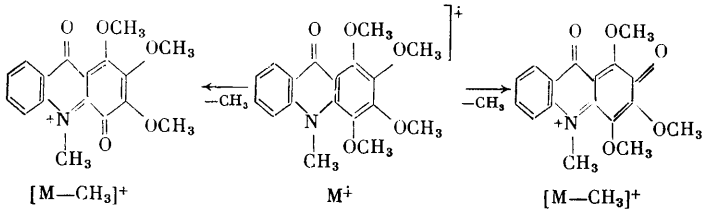
M^+ $[M-H]^+$

A special feature of the dissociation of 1-isopropyl-4-methylacridone on ionisation is the ready formation of the $[M-OH]^+$ ion, the peak of which reached 80%.[34] The composition of this ion was



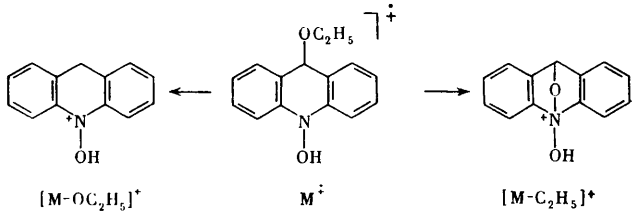
proved by high resolution mass spectrometry, and the one-step character of its formation by the presence of the appropriate metastable peak (Scheme 9).

Scheme 9



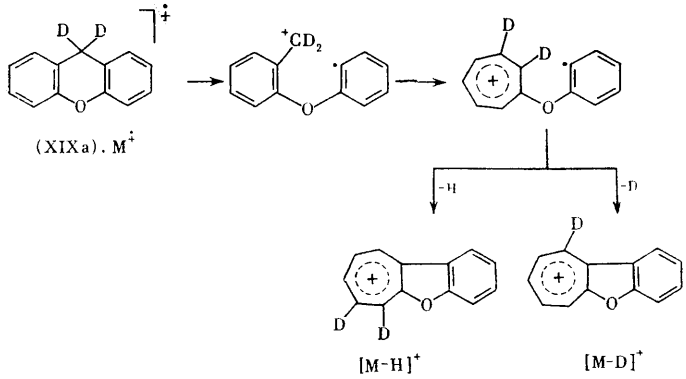
A series of specific fragmentation routes was discovered for alkoxy substituted acridones,[32] which in the general case decompose as alkylaryl ethers. Stepwise expulsion of OH and H_2 is a characteristic of 2-ethoxyacridone. It was proposed that the driving force of these reactions is the formation of cyclic oxonium ions (Scheme 10).[32,40]

Scheme 10



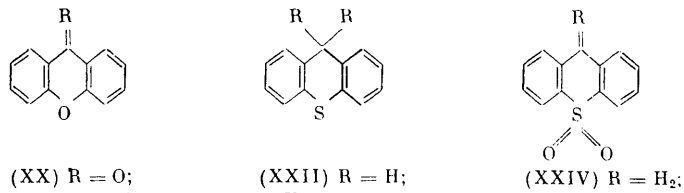
The form of the decomposition of 1,2,3,4-tetramethoxy-10-methylacridone is an example of the high regioselectivity of fragmentation. It was shown that deutero analogues that in this case the elimination of CH_3 occurs only from positions 2 and 4 in a 60:40 ratio. Such selectivity of fragmentation is caused by the possibility of forming well-stabilised ions (Scheme 11).

Scheme 11



Like the 9-alkylacridanes, 9-ethoxy-10-hydroxyacridane loses the substituent from position 9 very readily on EI leading to the maximum peak in the mass spectrum. A less intense peak corresponds to loss of C_2H_5 from M^+ (Scheme 12).[41]

Scheme 12



Xanthenes. The mass spectrum of unsubstituted xanthene (XIX) is very sparse and contains the base peak of the $[M-H]^+$ ion together with an M^+ peak (~45%).[30,42] In the spectrum of 9,9-deuterated xanthene (XIXa) in place of the expected peak for the $[M-D]^+$ ion a doublet was observed of peaks for $[M-H]^+$ and $[M-D]^+$ ions which were close in intensity.[31] Thus randomisation of H atoms occurs in the M^+ of xanthene even before decomposition, possibly according to the following scheme (Scheme 13).

Scheme 13

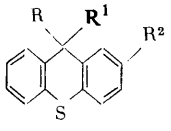
The mass spectra of complex derivatives of xanthene[43–45] and of tetrachloroxanthene[42] have been described in the literature. A series of papers is devoted to a detailed mass spectrometric investigation of xanthone (XX) and its dimethyl, hydroxy and methoxy derivatives.[29,46,47] The sequential elimination of two molecules of CO is a characteristic feature of the decomposition of the M^+ of xanthone (XX). It was shown[29] with an ^{18}O-labelled analogue that the first molecule of CO is wholly ejected from the carbonyl group. However it was discovered[8] that ejection of CO from M^+ in the second field free region of the reversed geometry mass spectrometer may also proceed with the participation of the ether oxygen in the first act of CO elimination. It must be noted that the molecular ion of thioxanthone (XXI) readily loses CS.[3]

A correlation was observed in the case of dihaloxanthones between elimination of CO and the halogen from M^+. In a series of fluorinated, chlorinated, brominated and iodinated derivatives it was shown that the stronger the C–Hal bond the higher became the intensity ratio $[M-CO]^+/[M-Hal]^+$.[29] The decomposition rule described has enabled ready detection of tetrachloroxanthone among environmental contaminants[42,48]

(XX) R = O;
(XXI) R = S

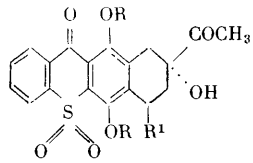
(XXII) R = H;
(XXIII) R = CH_3;
(XXV) R + R = O

(XXIV) R = H_2;
(XXVI) R = O



Thioxanthenes. Thioxanthene (XXII) is readily distinguished from xanthene by the character of the fragmentation involving ring fission since its M^+ loses S and HCS. However the peak of the $[M-H]^+$ ion is the base peak and exceeds the intensity of M^+ almost twofold in the mass spectrum of thioxanthene,[30] while in the spectrum of 9,9-D_2-thioxanthene the same doublet of peaks for $[M-H]^+$ and $[M-D]^+$ ions was observed as in the spectrum of deuteroxanthene. Thus the same mechanism for the fission of H occurs for thioxanthene as for xanthene (Scheme 13).[31] It must be

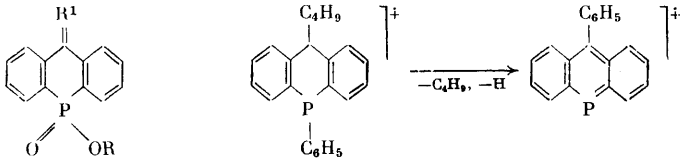
noted that in the mass spectrum of 9,9-dimethylthioxanthene (XXIII) the peak for the $[M-CH_3]^+$ ion possesses maximal intensity and may then lose S.[49]



Decomposition of thioxanthene S,S-dioxide (XXIV) on EI proceeds by several parallel routes, viz. sequential elimination of 1) OH, CO and H, 2) SO and H and 3) SO_2 and H (the latter process leads to the maximal peak in the mass spectrum).[30] As was shown[31] with the aid of the 9,9-dideutero analogue of compound (XXIV) the H atom from position 9 participates in the expulsion of OH. At the same time $[M-SO_2]^+$ ions preferentially split off a H atom from the benzene ring and, to a lesser extent, from position 9.[31]

The main decomposition of the M^+ of thioxanthone (XXV) is linked with the sequential expulsion of CO and S, and also of CO, CS, and H.[30] In the case of thioxanthone S,S-dioxide (XXVI) the main reaction is the elimination of SO, seemingly as a result of isomerisation into the sulphonate form.[50]

On investigating chlorprothixene (XXVII) and its analogues (XXVIIa, b) by chemical ionisation (CH_4 as gas reagent) and negative ion recording, the unexpected formation of $[M+H]^-$ was detected in addition to the normal $[M-H]^-$ ion.[51] The generation of the former is caused by the presence of an S atom in the molecule. The strong formation of $[M+H]^-$ ions was also noted in a study of sulphur-containing anthracycline compounds (XXVIII) by secondary ion mass spectrometry (Cs^+, 12 and 23 keV) and negative ion recording.[52]

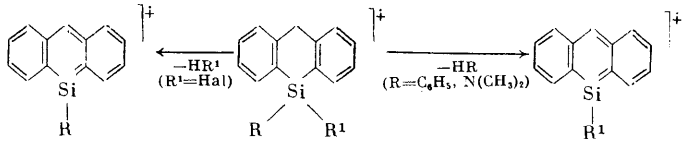


(XXVII) R + R^1 = $CHCH_2CH_2N(CH_3)_2$; R^2 = Cl;
(XXVIIa) R + R^1 = $CHCH_2CH_2N(CH_3)_2$, R^2 = H;
(XXVIIb) R = $CH_2CH_2CH_2N(CH_3)_2$, R^1 = H, R^2 = Cl

(XXVIII) R = H, CH_3, R^1 = H, OCH_3

9,10-Dihydro-9-phosphanthracenes. The individual routes for the fragmentation of these compounds are given above in Table 1. The molecular ion of compound (XXIX) is able to lose H_2O and then PO with the formation of the fluorenyl cation. The latter is also formed from the M^+ of ester (XXIXa) by the stepwise expulsion of CH_3 and PO_2H or $HOCH_3$ and PO.[35] The molecular ion of ketone (XXX) may sequentially lose CO and OH or PO_2H and CO. The seqential elimination of CH_2O and PO is a characteristic of the methoxy derivative (XXXa).[35]

Scheme 14



(XXIX) R = H, R^1 = H_2; (XXXI), M^+
(XXIXa) R = CH_3, R^1 = H_2;
(XXX) R = H, R^1 = O;
(XXXa) R = CH_3, R^1 = O.

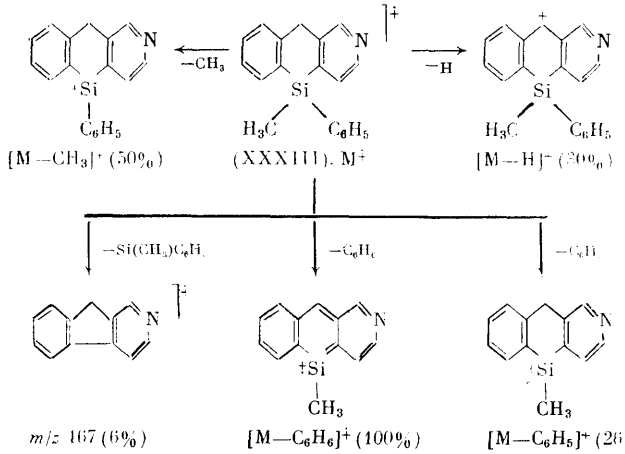
The stepwise elimination of C_4H_9 and H (Scheme 14) is observed for 9-phenyl-10-t-butyl-9,10-dihydro-9-phosphanthracene (XXXI), in addition to expulsion of C_4H_8 as a result of a McLafferty rearrangement. It was proposed that transannular 1,4-migration of the phenyl group occurs in this process.[53]

9,10-Dihydro-9-silanthracenes. In the simplest compounds of this series (XXXII) the character of the fragmentation on EI depends on the nature of the substituent at the silicon atom. The molecular ion of 9,10-dihydro-9-silanthrene (XXXII, R = R_1 = H) decomposes by the sequential elimination of three H atoms with the formation of a fluorenyl cation. Derivatives containing alkyl groups on the silicon atom undergo fragmention like alkylsilanes. For example the weakly stable M^+ of 9,9-diethyl-9-sila-9,10-dihydroanthracene (XXXII, R = R^1 = C_2H_5) sequentially loses C_2H_5 (causing the base peak) and C_2H_4.[54]

A new fragmention route was detected for compounds (XXXII) with halogen substituents at the silicon atom such as (R = CH_3, R^1 = Cl),[36] (R = R^1 = Cl) and (R = H, R^1 = Cl),[54,55] (R = R^1 = F) and [R = $N(CH_3)_2$, R^1 = Cl][54] and (R = C_6H_5, R^1 = Cl or Br).[56–58] The molecular ions of such compounds readily lose hydrogen halide with the formation of silanthracene cation-radical which, in the case of compounds containing halogen and phenyl or a dimethylamino group, may also arise as a result of parallel expulsion of molecules of C_6H_6 and $(CH_3)_2NH$ respectively (Scheme 15). Both these ions are able to lose SiR and SiR^1 which leads to a fluorenyl cation (*m/z* 165).

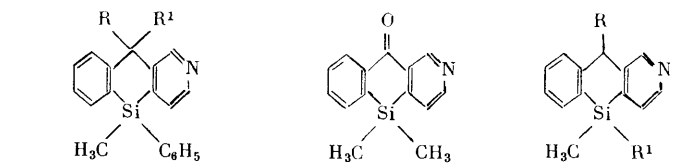
Scheme 15

(XXXII), M^+



Elimination from M^+ of the substituent from the silicon atom together with an additional H atom from position 10 is also observed in the case of other types of substituent such as in compounds (R = R^1 = OCH_3) and [R = R^1 = $N(CH_3)_2$].[54] In the first case CH_3OH is readily lost (then CH_3 or CH_2O) and in the second, initially $(CH_3)_2NH$ [$N(CH_3)_2$ to a lesser extent] and then $N(CH_3)_2$.

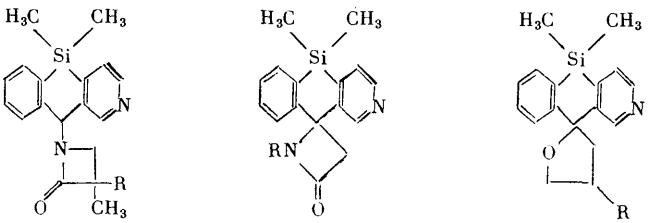
Similar routes for fragmentation by EI also occur in the case of 10-methyl-10-phenyl-9,10-dihydro-10-sil-2-azanthracene (XXXIII). Two processes compete, viz. elimination from M^+ of a CH_3 radical and of a molecule of C_6H_6.[59,60] It was shown that with the aid of 9,9-dideutero analogues of compound (XXXIII)[59] that elimination of a hydrogen atom and also of a molecule of C_6H_6 occurs solely with the participation of hydrogen from position 9. These and several other decomposition processes for compounds of the 10-sil-2-azanthracene series are shown in Scheme 16.



The character of the dissociation on ionisation of more complex analogues of compound (XXXIII) containing substituents or functional groups at position 9 is determined by the latter to a significant extent. Thus the presence of a carbonyl group in the molecule of 10-methyl-10-phenyl-10-sil-2-azanthrone (XXXIV) inhibits the expulsion of C_6H_6 mentioned above and the most intense peaks in the mass spectrum are the peaks for $[M-CH_3]^+$ (100%) and $[M-C_6H_5]^+$ ions. Expulsion of CO from M^+ for the compound in question is not important but a more significant reaction takes place accompanied by the elimination of H_2O,

$SiOCH_3$ and $Si(CH_3)C_6H_5$.[59] A series of specific fragmentation routes, facilitating the identification of regioisomers, was detected in the mass spectra of 4-, 5-,. 6-, 7- and 8-nitro-10,10-dimethyl-10-sil-2-azanthrones (XXXV).[61]

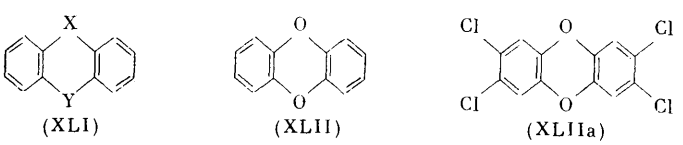
Scheme 16



The tertiary alcohol (XXXVI) behaves specifically on EI. Its molecular ion is capable of losing two CH_3 radicals sequentially (contrary to the even-electron rule) with the formation of a silazanthracenyl ion.[59] Other decomposition routes are linked with the sequential elimination of CH_3 (maximum peak) and H_2O, CH_3 and C_6H_6. The fission of OH and H_2O from M^+ occurs weakly. The oxime obtained from ketone (XXXIV) is capable on EI of losing OCH_3, and also 1) CH_3 and H, 2) CH_3 and H_2O and 3) H, CH_3 and C_6H_5 sequentially.[59]

The main decomposition of substituted 9,10-dihydro-10-sil-2-azanthracenes (XXXVII) is caused by the loss of long alkyl substituents of the alkyl type from position 9 (loss of CH_2CH_2CN, $CH_2CH_2CH_2NH_2$ from M^+) or by the elimination of the substituent from the silicon atom (expulsion of CH_3 or C_6H_6). In the case of amines (R = NH_2) the intensity of the peak for $[M-H]^+$ ions is sharply increased and in contrast to the previous compounds significant peaks appear for $[M-SiR_2]^+$ ions. Decomposition at the expense of the amide substituent is characteristic of amides.

Compounds containing an azetidine substituent at position C(9) (XXXVIII) and also spiranes with azetidine (XXXIX) or tetrahydrofuran (XL) groups undergo fragmentation by fission of the four- and five-membered heterocycles respectively but a CH_3 radical is split away from the Si atom most frequently in the later stages of the decomposition.[63] For the derivatives (XXXVIII) for example the main process is elimination of the azetidine ring from M^+. Also typical is fission of the four-membered ring into two halves which occurs readily in $[M-CH_3]^+$ ions (formation of $[M-CH_3-CH_2CRCH_3]^+$ and $[M-CH_3-COCRCH_3]^+$ ions).



In spiro-compounds (XXXIX) fragmentation is caused mainly by the typical fission of the four-membered ring into two halves,[64] as a result of which $[M-RNCO]^+$ and $[M-CH_2CO]^+$ ions are formed and then lose a CH_3 radical. Ions with *m/z* 222 and 224, obtained by elimination of $RCHCH_2O$ and CH_2CRCH_3 from M^+, are diagnostically important in compounds of the (XL) series.

IV. Analogues of 9,10-dihydroanthracene with heteroatoms at positions 9 and 10

The character of the dissociation of the type of compound represented by general formula (XLI) on ionisation is determined by the nature of the substituents in the aromatic ring and on the heteroatoms at positions 9 and 10. In the simplest representatives of this series the primary decomposition of M^+ is expulsion of carbenoid particles X or Y, the ease of eliminating which increases with an increase in the stability of the latter. As in the previous section these typical routes for decomposition leading to a heterocyclic analogue of fluorene ion-radicals are demonstrated in the example of compounds in which it occurs most (Table 3).

Compounds of this series may contain the same or different heteroatoms at positions 9 and 10. In view of this further consideration will be given to their mass spectral characteristics.

1. Analogues of 9,10-dihydroanthracene with the same heteroatoms at positions 9 and 10

Dibenzo-*p*-dioxins. Unsubstituted dibenzo-*p*-dioxin (XLII) possesses a very stable M^+ which is not capable of losing the heteroatom with the formation of the dibenzofuran system. The M^+ expels only two molecules of CO or HCO and CO to a marked extent.[67,77] The fragmentation of 2-nitrodibenzo-*p*-dioxin is linked with elimination of CO, HCO, NO_2 and also NO_2 + CO and NO_2 + HCO.[77]

Much work has been carried out on the mass spectrometric investigation of polychlorinated dibenzo-*p*-dioxins, the detection and identification of which in the environment has become an important problem in recent years. The exception toxicity of some of the isomers reinforces the need to develop highly sensitive, selective and isomer-specific analytic methods. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (XLIIa) possesses such high toxicity that even standards of

this substance are not recommended to be held in analytical laboraties.

It has been shown using 2,7- and 1.6-dichloro-, 1,3,6-trichloro- and 1,2,3,4,6,7,8,9-octachlorodibenzo-*p*-dioxins and compound (XLIIa) as examples that their decomposition on EI is linked with the sequential elimination of CO and Cl. There are also marked peaks for $[M-2COCl]^+$ ions.[77,78] These features of the fragmentation are used for creating highly sensitive methods for the detection of compound (XLIIa) and its isomers chiefly using gas chromatography-mass spectrometry.[5,48,79–84] Mass spectrometry with chemical ionisation (gas-reactant O_2 or CH_4/NO_2) and negative ion recording possesses the greatest sensitivity and isomer specificity.[85–88] No less sensitive and specific is the method of tandem mass spectrometry (MS/MS) which was applied to M^+ and M^- ions generated from (XLIIa).[48,89] Decomposition of M^+, activated by collision with argon, leads to $[M-COCl]^+$ and $[M-2COCl]^+$ ions which characterise tetrachlorodibenzo-*p*-dioxins but do not permit their isomers to be distinguished. On activation by collision with argon, only $[M-Cl]^-$ and Cl^- ions are formed from M^-, which are not suitable for structural assignment. However with low energy collisions M^- ions form $[M-Cl+O]^-$, $[C_6H_{4-n}O_2Cl]_4^-$, $[M-HCl]^-$ and $[Cl]^-$ ions. With these, either directly or on the basis of peak intensity ratios, discrimination between 1,2,3,4-, 1,2,3,6-, 1,2,3,7- and 2,3,7,8-tetrachlorodibenzo-*p*-dioxins has been successful.[90]

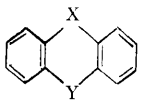


Table 3. Intensities of $[M-X]^+$ and $[M-Y]^+$ ions (as % maximal peak) in the mass spectra of compounds (XLI).

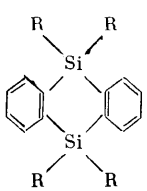
*Spectra were recorded on a laser microprobe mass spectrometer.

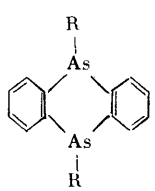
Some polybromo[91] and polybromochlorodibenzo-*p*-dioxins[92] have also been investigated by EI. It was shown that the M^+ of polybromo compounds lose Br, COBr, (Br + COBr) and (2Br + COBr). The formation of a large quantity of doubly charged ions was recorded.

Thianthrenes. The molecular ion of unsubstituted thianthrene (XLIII) is very stable and is capable of losing only S, CSH or S and CSH sequentially.[65,76] A similar type of fragmentation is also characteristic for diazathianthrene (XLIV).[66]

(XLIII) X = Y = S;
(XLV) X = S, Y = SO;
(XLVI) X = Y = SO;
(XLVII) X = S, Y = SO_2.



(XLIV)

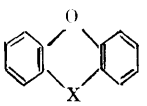


The sequential expulsion of S and H from M^+ was also observed for 2,3,7,8-, 1,4,6,9- and 1,3,7,9-tetramethylthianthrenes but elimination of CS and CSH was insignificant. The molecular ions of these compounds also lose CH_3 and then S.

The dissociation of the monosulphoxide (XLV)' and the disulphoxide (XLVI) of thianthrene on ionisation is fairly simple and is linked with the elimination of O and SO. In both cases the ion-radical of dibenzothiophene is formed in such processes and is generated from the M^+ of sulphone (XLVII) on expulsion of SO_2. SO is eliminated from the M^+ of (XLVII) as a result of skeletal rearrangment.[93]

Other compounds. The character of the fragmentation of 9,10-disila-9,10-dihydroanthracenes (XLVIII) depends on the nature of the substituents on the Si atoms.[54] The stable M^+ of the ancestor compound (R = H) may lose up to four H atoms, while seemingly $:SiH_2$ is lost from $[M-H]^+$ ions. The tetramethyl derivative (XLVIII, R = CH_3) has a weakly stable M^+ which readily loses CH_3 and then $:Si(CH_3)_2$. Decomposition of the tetramethoxy derivative (XLVIII, R = OCH_3) on EI is more complex. In this case the peaks for $[M-HSi(OCH_3)_2]^+$ and $[M-HSi(OCH_3)_2-CH_2O]^+$ ions are the most intense. In the case of the tetrahalogen compounds (XLVIII, R = F, Cl) the process of expelling dihalodisilyene from M^+ is clearly expressed and continues in the case of fluoride by elimination of H_2SiF_2 and of chloride by loss of a Cl atom.

(XLVIII)

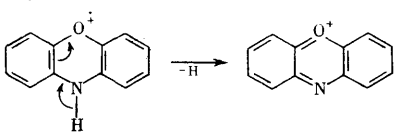


(XLIX) R = CH_3;
(L) R = Cl.

A specific character was observed for the fragmentation of derivatives of dihydroarsanthracenes (XLIX) and (L).[94] The molecular ion of the methyl derivative (XLIX) readily loses CH_3 and then As, CH_3 and As sequentially. In the case of the dichloro compound (L) the ions $[M-Cl]^+ \rightarrow [M-2Cl]^+ \rightarrow [M-2Cl-As]^+ \rightarrow [M-2Cl-2As]^+$ were formed sequentially from M^+ (the peak for the $[M-2Cl-As]^+$ ion possesses maximal intensity).

2. Analogues of 9,10-dihydroanthracene with different heteroatoms in positions 9 and 10

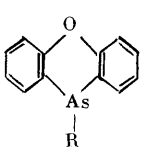
Phenoxathiins. The molecular ion of phenoxathiin (LI) is very stable and is capable of expelling CO, CHO and S and CHO sequentially.[67] 2,3,7,8-Tetramethylphenoxathiin is also stable on EI and the most marked decomposition of its M^+ is linked with the



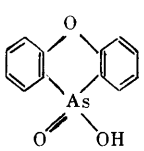
elimination of CH_3 and S or CH_3.[65] The main decomposition of its S-oxide (LII) is linked with ejection of SO, the M^+ loses an O atom to an insignificant extent. Sulphone (LIII) loses SOC in preference to SO_2 in the first stage of the decomposition.[93]

(LI) X = S;
(LII) X = SO;
(LIII) X = SO_2.

Phenoxazines. Phenoxazine (LIV) possesses a very stable M^+ the noticeable decomposition of which begins with fission of H (Scheme 17), after which CO is lost.[95,96] Nitro substituted phenoxazines lose a NO_2 group, 4,6-dinitro derivatives and a molecule of HNO_2 from the M^+.



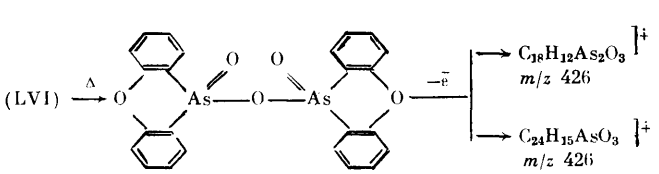
Scheme 17



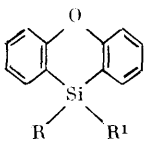
(LIV), M^+ $[M-H]^+$

In the latter case $[M-OH]^+$ ions are also formed with the participation of a hydrogen atom from the NH group.[95]

Phenoxarsines. Peaks for M^+ were recorded in the mass spectra of a large series of phenoxarsines (LV) and (LVI) which decomposed with the formation of $[M-R]^+$ and $[M-AsR]^+$ independent of the nature of the substituent R in the case of the compounds (LV) (the latter ions corresponding to dibenzofuran may be formed both in one step or several)[68,97]

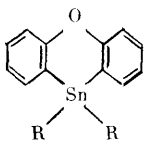


(LV) R = Cl, *p*-ClC_6H_4, 2-$C_6H_5OC_6H_4$, *p*-ClC_6H_4O.



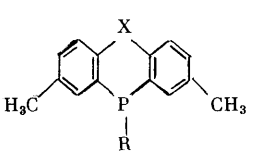
(LVI)

An interesting temperature dependence was observed for the mass spectrum of compound (LVI). At an ion source temperature below 350 °C it decomposed in a similar manner to compound (LV) with the formation of M^+ and $[M-HAsO_2]^+$ (*m/z* 243) ions. However at 390 °C condensation of two molecules occurred with elimination of water and a peak of M^+ with *m/z* 534 was present in the recorded mass spectrum and also a peak with *m/z* 426 corresponding to $[M-C_6H_4O_2]^+$ and $[M-AsO_2H]^+$ ions which decomposed further to ions with *m/z* 243 (Scheme 18).

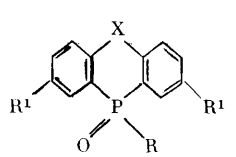


Scheme 18

Phenoxasilines and phenoxastannines. Decomposition on EI of 10,10-dimethyl- (LVII) and 10,10-diphenylphenoxasilines (LVIII) occurs mainly by expulsion of CH_3 and C_6H_5.[49,98] Fission of H and CH_3 from M^+ also leads to the most intense peak in the spectrum of their 10-methyl analogue (LIX).[54] However in the latter case $HSiH_3$ is lost from M^+ to a noticeable extent and such a process is not a characteristic of the first two compounds (here the formation of $[SiRR^1]^+$ ions is marked). A large number of rearrangement processes occurs on fragmentation of compounds (LVII) and (LVIII), in particular expulsion of SiO from $(M-R-R^1]^+$ ions or CH_2O, SiH_2O and SiHO from $[M-R]^+$ ions. The main and only fragmentation process for dichloro compound (LX) is ejection of $:SiCl_2$ from M^+.[54]



(LVII) R = R^1 = CH_3;
(LVIII) R = R^1 = C_6H_5;
(LIX) R = H, R^1 = CH_3;
(LX) R = R^1 = Cl.

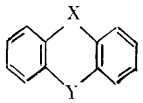


(LXI)

The nature of the substituent on the tin atom appreciably influences the fragmentation of the phenoxastannines (LXI) although the formation of $[M-R]^+$ ions is natural for all of them.[49,99,100] After elimination of radical R in the case of compounds (LXI, R = C_2H_5 and C_4H_9), olefin (R−H) is readily lost and the resulting ion then eliminates C_6H_4 two times. The methyl and phenyl derivatives (LXI, R = CH_3 and C_6H_5), after expulsion of R, lose fragments C_6H_4O, $C_{12}H_8O$ or C_6H_4. Fission of $SnCl_2$ is the main fragmentation route for the M^+ of dichloro compound (LXI, R = Cl).

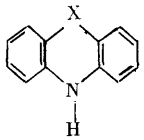
Phenoxaphosphines and phenothiaphosphines. Phenoxaphosphines (LXII) and phenothiaphosphines (LXIII) are similar in their character of dissociation on ionisation.[101−104] Loss of RHP is a characteristic of their M^+.

(LXII) X = O, R = C_6H_5;
(LXIII) X = S, R = C_6H_5,
p-$CH_3C_6H_4$



(LXIV) X = S, R = OH, OCH_3, R^1 = CH_3;
(LXV) X = SO_2, R = CH_3, C_6H_5,
p-$CH_3C_6H_4$, R^1 = F, Cl, CH_3.

The oxides of derivatives (LXIV) form very stable M^+ which may lose PO_2H and SH (when R = OH). The loss of SH is insignificant for the corresponding esters (R = OCH_3) but OCH_3 is readily eliminated and then S or PO. The peaks for M^+ and $[M-CH_3]^+$ ions possess the greatest intensity in the mass spectra of compounds (LXV). In all cases noticeable peaks were encountered for $[M-HPOR]^+$ ions.[102,103]



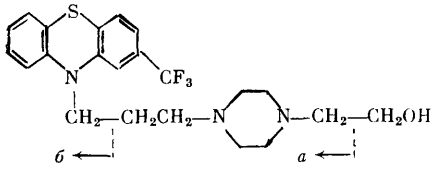
Phenoselenine (LXVI) and phenotellurine (LXVII) are fairly stable on EI and the sole primary route for their decomposition is expulsion of Se and Te respectively.[67] The resulting dibenzofuran

ions lose CO and CHO. A similar decomposition is characteristic of their sulphur analogues (LXVIII).[105]

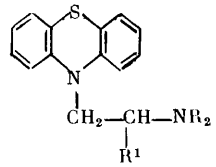
(LXVI) X = O, Y = Se;
(LXVII) X = O, Y = Te;
(LXVIII) X = S, Y = Se, Te

Phenothiazines. This series of compounds is of interest since it includes a large number of pharmacologically active compounds, particularly tranquilisers. Unsubstituted phenothiazine (LXIX) possesses a very stable M^+, the most noticeable decomposition of which is caused by elimination of H, S or SH.[30,71] Its *S*-oxide (LXX) and *S,S*-dioxide (LXXI) differ fairly strongly in fragmentation character.[30] The former is intensively decomposed with the formation of $[M-O]^+$, $[M-OH]^+$, $[M-CO]^+$, $[M-CO-H]^+$ (base peak) and $[M-SO]^+$ ions and the second has a very stable M^+ which loses OH, CO, SO and H, SO and CO or SO_2.

(LXIX) X = S;
(LXX) X = SO;
(LXXI) X = SO_2



(LXXII) R = H;
(LXXIII) R = Cl.

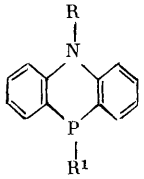


The main peaks in the mass spectra of the large series of physiologically active compounds of the phenothiazine series, among which are promazine (LXXII) and chlorpromazine (LXXIII),[71,72,106] are caused by ions formed on breaking the α-C−C bond relative to the nitrogen of the side chain, e.g. $CH_2=\overset{+}{N}(CH_3)_2$ (*m/z* 58) for (LXXII) and (LXXIII). The groups $HN(CH_3)_2$ or $H_2N(CH_3)_2$ may be lost from M^+ and also the substituent from the exocyclic nitrogen atom with migration of H atom to the heterocyclic ion. In the case of methoxyphenothiazines decomposition begins with expulsion of a CH_3 group and continues with loss of CO and S. Fragmentation of phenothiazine *S*-oxides with *N*-alkyl groups is complicated due to decomposition involving the sulphoxide group.[106,107]

The fragmentation regularities recorded for phenthiazine are used for the determination of chlorpromazine (LXXIII) metabolites in man.[108]

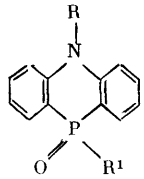
The GC−MS method (EI) in combination with silylation is used for the quantitative determination of the tranquiliser fluorphenazine (LXXIV) in plasma at the 50 pq ml^{-1} level.[109] It is proposed to carry out the determination with ions *a* and *b*.

(LXXIV)



(LXXV) R = R^1 = CH_3;
(LXXVI) R = C_2H_5, R^1 = CH_3;
(LXXVII) R = C_2H_5, R^1 = H.

The metabolites of promazine (LXXII), which are volatile with difficulty, have been investigated with combinations of microliquid chromatography and mass spectrometry to provide mass spectra by chemical ionisation. Previously, using (LXXIII), 2-hydroxy- and acetopromazine as examples, it was shown that such mass spectra contain practically only peaks for $[M+H]^+$ ions.[110]

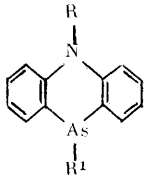


Mass spectra were obtained for a large series of phenothiazines under conditions of chemical ionisation (gas reagent was NH_3, CH_4/N_2O) recording negative ions.[111] For the majority of these compounds among which are (LXXII), (LXXIII), promethazine (LXXV), propiomazine, prochlorperazine, ethopropazine (LXXVI) and diethazine (LXXVII), the presence of peaks for $[M-H]^-$ ions in such spectra is characteristic.

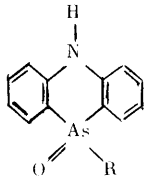
The peaks for $[M-CH_2CH_2CH_2N(CH_3)_2]^-$ ions were the base peaks in the spectra of compounds of the type of (LXXII) and (LXXIII) with three C atoms between the nitrogen atoms. In the case of compounds of type (LXXV)−(LXXVII), containing two C atoms between the nitrogen atoms, the base peaks in the spectra corresponded most frequently to $[M-H_2NR_2]^-$ ions although peaks for $[M-CH_2CHR^1NR_2]^-$ ions were also present.

9,10-Dihydrophenophosphazines. The EI mass spectra of 9,10-dihydrophenophosphazines (LXXVIII) have stable M^+ which decompose by loss of R^1 and then R, since $[M-R^1]^+$ ions are the base peaks even at low electron energies. In the case of the 10-oxide derivative (LXXIX) the stability of M^+ is increased but the most noticeable dissociation processes are caused by the elimination of R^1 and PO.[74,112]

(LXXVIII)



(LXXIX)



The adiabatic ionisation potentials of compounds (LXXVIII, R = CH_3, R^1 = CH_3, or C_6H_5) and (LXXIX, R = CH_3, R^1 = CH_3, or C_6H_5) were measured by photoionisation mass spectrometry. They were 7.03, 6.90, 7.50 and 7.40 eV respectively. Comparison of these values shows that the influence of the substituent is transmitted in the same way through both a trivalent and a pentavalent phosphorus atom.[113]

9,10-Dihydrophenarsazines. The EI mass spectra of substituted 9,10-dihydrophenarsazines (LXXX) contain M^+ peaks which readily lose the R^1 radical with the formation of the base ion and the latter ejects an As atom.[73−75,114] In some cases the one-step nature of the $M^+ \rightarrow [M-AsR^1]^+$ transition was demonstrated with metastable ions. In the case of (LXXX, R = H, R^1 = SCN) the formation was recorded of $[M-HSCN]^+$ ions which later eliminate As.[114]

The mass spectra of compounds (LXXXI, R = CH_3, C_6H_5, 2-ClC_6H_4) [74] and (LXXXI, R = OH) [114] contain M^+ peaks but the base peaks were of $[M-R]^+$ ions in the first case and $M-H_2O]^+$ ions in the second.

(LXXX) R = H, CH_3, C_6H_5; R^1 = Cl, OCH_3, CH_3, C_6H_5, 2-ClC_6H_4

(LXXXI)

* * *

The main influence of the fragmentation on the EI of derivatives and heterocyclic analogues of 9,10-dihydroanthracene therefore proved to be the nature of the heteroatom, the character of the substitution at positions 9 and 10 and also the type of substituent in the phenylene rings. In the case of such derivatives of dihydroanthracene as anthraquinones and also its analogues containing heteroatoms of the type S, SO, SO_2, Se, Te and also substituted Si, P, and As atoms in positions 9 or 10, the principal be the elimination of particles of the carbene type from these positions with contraction of the central ring to a five-membered ring. The ease of this process increased with the increase in stability of the eliminated carbenoid particle. For example the elimination of dihalosilyene, and of AsCl, Te, Se and P(O)OH determines the main character of the decomposition of the corresponding analogues of 9,10-dihydroanthracene.

A specific route for the fragmentation of 9-alkyl- or aryl-substituted 9,10-dihydro-9-silanthracenes is the expulsion from M^+ of the corresponding alkane or arene. It is possible that silanthracene ions are formed containing a Si=C double bond having no analogue in the unionised state.

Fragmentation of substituents in the series being considered depends on their location in the molecule. If the substituting group is side-by-side with the heteroatom the '*peri*-effect' is decisive. Fission of substituents in the phenylene rings and also in the *meso* position or at the heteroatom occurs in a similar manner to the decomposition of the corresponding aromatic or heterocyclic derivatives.

Perfluoroalkyl(aryl)acetylenes

E S Turbanova, A A Petrov
The Lensovet Technological Institute, Leningrad, USSR

ABSTRACT. Methods of preparing perfluoroalkyl(aryl)acetylenes, their physical properties, and chemical reactivity have been reviewed. Synthetic routes to aliphatic, alicyclic, aromatic and heterocyclic compounds from perfluoroalkyl(aryl)acetylenes have also been examined.

The bibliography contains 361 references.

I. Introduction

The study of fluorine-containing compounds is a key aspect of modern laboratory and industrial chemistry. Such compounds are placed in prominent position in the economies of the developing nations, and their varied structural types and unique properties are evident in the synthesis of such materials as fluorinated polymers, Freons, herbicides, drugs and dyes. The physiological activity of fluorine-containing compounds is so broad that they are used both medicinally and as highly toxic agents.

An enormous amount of data is available on fluorine-containing compounds, which has been reviewed in many well-known monograph series as well as in the journal literature.[1–4]

The chemistry of perfluoroalkyl(aryl)acetylenes has developed only in the last 40 years. Only the literature up to 1977 has been adequately reviewed,[5–7] while coverage of more recent information has been rather fragmentary.[8–10] This new field of organic chemistry has not been reviewed as an isolated topic.

In the present article we have sought to cover this field of chemistry with particular reference to the last ten years, which, as yet, has not been adequately studied as a review topic in the literature. We have excluded those properties of perfluoroalkyl-(aryl)-substituted acetylenes, such as oxidation and hydrogenation, which have already been analysed in depth in earlier reviews, and concentrated only on recent developments in this area; this review also excludes routine functional group interconversions involving this structural type. Information on the physical properties of the individual perfluoroalkyl(aryl)acetylenes, of which more than 300 are known to date, can be obtained from those references where synthetic details are reported.

II. Methods of preparation

Most synthetic routes to perfluoroalkyl(aryl)acetylenes are based on perfluoroalkyl(aryl) iodides which in many countries are commercially available and frequently used. Direct fluorination methods have been used to a lesser extent.

There are two classical multi-step routes to perfluoroalkyl-acetylenes. The first step in these methods is the addition of perfluoroalkyl iodides to olefins or acetylenes. The final step in the first method is dehalogenation of an intermediate perfluoro-dibromoalkene, which is normally carried out with zinc in ethanol or dimethyl sulfoxide.[11–13]

$$R_FCH_2CH_2Hal \xrightarrow{KOH,\ C_2H_5OH} R_FCH{=}CH_2 \xrightarrow{Br_2,\ h\nu}$$

$$\longrightarrow R_FCHBrCH_2Br \xrightarrow{KOH,\ C_2H_5OH} R_FCBr{=}CH_2 \xrightarrow{Br_2,\ h\nu}$$

$$\longrightarrow R_FCBr_2CH_2Br \xrightarrow{KOH,\ C_2H_5OH} R_FCBr{=}CHBr \xrightarrow{Zn} R_FC{\equiv}CH,$$

$R_F = CF_3,\ C_4F_9,\ C_6F_{13},\ C_8F_{17}.$

In certain countries perfluoroalkylethylenes are currently commercially available. They may be converted to perfluoroalkyl-acetylenes by an alternative scheme.[14,15]

$$R_FCH{=}CH_2 \xrightarrow{Cl_2,\ h\nu} R_FCCl_2CCl_3 \longrightarrow \Big]\xrightarrow{Zn}$$

$$CCl_3CCl{=}CCl_2 \xrightarrow{SbF_3/SbF_5} CF_3CCl{=}CCl_2 \longrightarrow \Big]$$

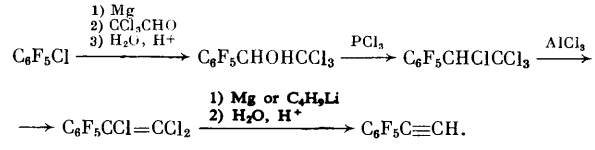
$$\longrightarrow [R_FC{\equiv}CZnCl + (R_FC{\equiv}C)_2Zn] \xrightarrow{H_2O,\ H^+} R_FC{\equiv}CH,$$

$R_F = CF_3,\ C_4F_9,\ C_6F_{13},\ C_8F_{17}.$

The debromination with zinc may be accompanied by partial prototropic isomerisation.[16]

Debromination of 1,3,3,3-tetrafluoro-1,2-dibromopropene with zinc in dioxane or with copper at 260 °C affords perfluoro-propyne.[17–19]

Dehalogenation is also the final step in the synthesis of perfluoro-2-butyne and other symmetrically substituted perfluoroacetylenes.[20–24]



Trifluoromethylperfluoroalkoxyacetylenes have been prepared via elimination of BrCl with Zn/Cu couple in adiponitrile.[25]

$$F_3CC{\equiv}CCl \xrightarrow[H^+]{RCOF,\ AgF} \begin{matrix} F_3C & & OCF_2R \\ & C{=}C & \\ H & & Cl \end{matrix} \xrightarrow{Br_2}$$

$$\longrightarrow F_3CCHBrCClBrOCF_2R \xrightarrow{(C_2H_5)_3N} F_3CCBr{=}CClOCF_2R \xrightarrow{Zn/Cu}$$

$$\longrightarrow F_3CC{\equiv}COCF_2R,\ R = F,\ C_2F_5.$$

Dehalogenation is also a key step in the synthesis of pentafluorophenylacetylene.[26,27]

Chloropentafluorophenylacetylene is obtained if one equivalent of butyllithium is used in the last step instead of two equivalents.[27] A mixture of pentafluoro- and 2,3,5,6-tetrafluoro-phenylacetylene was obtained from the product formed by treatment of acetophenone with PCl_5.[28]

Reaction of pentafluorophenyllithium with alkenyl halides affords chloropentafluorophenylacetylenes (from CFCl=CFCl or CF_2=CHCl) and decafluorotolan (from CF_2=CFH or CF_2=CFBr). In this case, dehalogenation is accompanied by nucleophilic substitution of fluorine in the *p*-position, as a result of which tolan derivatives are formed with either one or two 2,3,5,6-tetrafluorophenyl rings.[29]

Treatment of pentafluorophenylcopper with iodotrifluoroethylene to give decafluorotolan is also accompanied by dehalogenation,[30] as well as by action of copper on pentafluorophenyltribromomethane at 570 °C (70% yield).[31]

Methods of preparing fluorine-containing alkynes by dehydrohalogenation of (a) (perfluoroalkyl)alkenyl halides, obtained normally by radical addition of perfluoroalkyl iodides to alkynes, or (b) dihalogenated perfluoroalkanes, obtained from the corresponding alkenes, are limited by the nature of the perfluoroalkyl (or perfluoroaryl) substituent.[32] Thus, in spite of the fact that the number of steps is normally smaller, such dehydrohalogenative methods are not always preferred to the dehalogenative routes described above. Anhydrous base or ethanolic base (with cooling) or trialkylamines have been used as dehalogenating agent.[13,33–35]

R_F=CF_3 (Refs.33, 34), C_2F_5 (Ref.12), $(CF_3)_2CF$ (Ref.35),

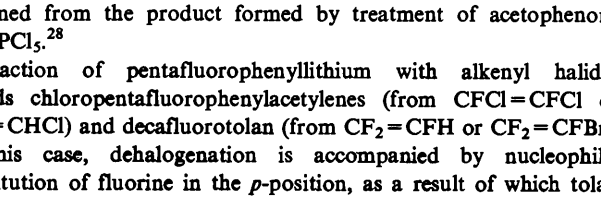
C_nF_{2n+1} (n=4, 6, 8) (Ref.13).

There was no increase in the yield of perfluoroalkylacetylenes with KF/18-crown-6-ether as dehydroiodinating agent.[36]

Dehydroiodination of 4,4,4-trifluoro-2-iodo-1-butene with alcoholic KOH gives a 1:2 mixture of the corresponding acetylene and allene.[37] Hexafluoro-2-butyne,[38,39] perfluoro-2,5-dimethyl-3-hexyne,[40] perfluoroalkylated acetylene-alcohols[41–43] and -thioethers,[44] and α-halogenoperfluoroalkylacetylenes[18,45] have all been prepared by dehydrohalogenation with alcoholic KOH or anhydrous base.

Perfluoroacetylenic tertiary alcohols, $R_2C(OH)C{\equiv}CR_F$ (R_F = C_4F_9, C_6F_{13}, C_8F_{17}), have been prepared by dehydroiodination of the corresponding iodides and converted to the corresponding perfluoroalkylacetylenes by Favorskii cleavage.[42,46,47]

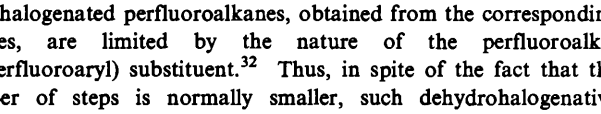
Aryltrifluoromethylacetylenes[48] have been isolated in 65–78% yield by 2-step dehydrobromination of 3,3,3-trifluoro-1,2-dibromo-1-arylpropanes, and *bis*(trifluoromethyl)trifluoropropynylamine has been prepared by 2-step dehydrobromination of *N,N-bis*(trifluoromethyl)-3,3,3-trifluoro-1,2-dibromopropylamine.[49]



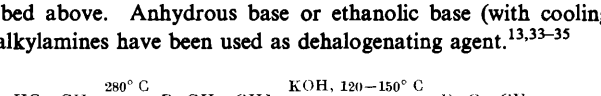
Aryltrifluoromethylacetylenes with a variety of substituents in the benzene ring have been synthesised under mild conditions. The dehydrochlorination in the second step has been carried out with $NaNH_2$ in *tert*-butanol/benzene at room temperature.[50,51]

R=X-C_6H_4, X=4-Cl, 2-Cl, 4-OCH_3, 4-NH_2, 4-C_6H_5; 3-pyridyl, 1-naphthyl and others.

In certain cases, dehydrohalogenation is accompanied by decarboxylation. Treatment of perfluoroalkylacetyl chlorides with strong base leads to perfluoroalkylacetylenes.[52]



In an alternative synthesis, treatment of perfluorocarboxylic acid chlorides with triethyl phosphite leads to perfluoroalkylacetylenes with the same number of carbon atoms (60–66% yield).[53]

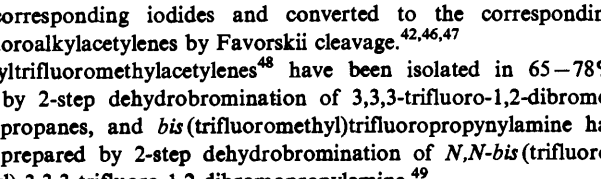


R_F = C_2F_5, C_6F_{13}, C_8F_{17}, $HCF_2(CF_2)_8$.

Aldol-type adducts are formed if the dephosphonylation is carried out in the presence of aldehydes[53] or their trimethylsilyl enol ethers.[54]

A new route to perfluoroalkylacetylenes is based on radical addition of perfluoroalkyl iodides to trimethylethynylsilanes in the presence of *tert*-butyl peroxide at 120 °C, followed by dehydroiodination and desilylation with potassium *tert*-butoxide at –20 °C. The yield exceeds 90%.[55]

Non-conjugated perfluorodiacetylenes are obtained by this method if the starting material is a diiodoperfluoroalkane:[55]



n = 2, 4, 6, 8, 10, 12.

The same products are obtainable from *bis*(trimethylsilyl)acetylene.

Organometallic compounds have also been widely used in the synthesis of perfluoroalkyl(aryl)acetylenes. There are two possible routes: one based on perfluoroalkyl(aryl) halides with intermediate formation of organometallic compounds, and the other based on alkylation of non-fluorinated acetylides with perfluoroalkyl(aryl) halides. Substituted and functionalised perfluoroalkyl(aryl)acetylenes are often obtained from perfluoroalkyl(aryl)acetylides. Such routes differ in the choice of the starting metal and the conditions. Organo-magnesium or -lithium compounds are normally used, although in certain cases the best results are obtained with organocopper, -zinc or -tin compounds.

Thus, perfluoroalkylacetylenes are prepared in up to 70% yield by the following scheme:[56,57]

R_F=C_4F_9, C_6F_{13}; R=C_2H_5, C_4H_9, C_8H_{17}, C_6H_5, *o*-$CH_3C_6H_4$, $CH_2CH{=}CH_2$.

The somewhat unexpected initial stages of this reaction, as proposed by the authors, was confirmed by the ultimate formation of $R_FCF=CHF$ on hydrolytic work-up.

Perfluorotolan was obtained in 56% yield by reaction of pentafluorophenylmagnesium bromide with diiodoacetylene in the presence of $CoCl_2$.[58]

Treatment of α-halogenoacetylenes with perfluoroalkyl(aryl)-copper reagents affords the corresponding perfluoroalkyl(aryl)-acetylenes.[59–61]

The interaction of hexafluorobenzene with lithium or magnesium acetylides proceeds with replacement of one or two fluorine atoms to give a mixture of perfluorophenylacetylenes.[61–63] Such reactions are facilitated by the addition of cerium and ytterbium salts.[63] *p-Bis*-(ethynyl)tetrafluorobenzene, for example, is obtained as follows:[61]

$$(C_2H_5)_3SiC\equiv CH \xrightarrow{C_6F_6} p\text{-}(C_2H_5)_3SiC\equiv CC_6F_4C\equiv CSi(C_2H_5)_3 \xrightarrow[H_2O/CH_3OH]{NaOH}$$

$$\rightarrow p\text{-}HC\equiv CC_6F_4C\equiv CH.$$

The same product is formed by treatment of trimethylsilylacetylene with bromo(iodo)pentafluorobenzene in the presence of Pd(0) and Cu(I).[64]

$PdCl_2-CuI$ may be used effectively in the reaction of iodoperfluorobenzene with terminal acetylenes.[65,66]

$$p\text{-}RC_6F_4X + HC\equiv CR' \xrightarrow{PdCl_2[(C_6H_5)_3P]_2,\ CuI} p\text{-}RC_6F_4C\equiv CR'$$

X = I, Br; R = F, OCH_3, $N(CH_3)_2$ etc.;
R' = C_6H_4X', X' = H, *p*-CO_2CH_3, *p*-NO_2;
$Si(C_2H_5)_3$; $(CH_2)_nCH_3$, $n=2-5$, etc.

Treatment of pentafluorochlorobenzene with lithium alkyl- or phenylacetylides affords the corresponding *p*-chlorotetrafluorophenylacetylenes.[67] Thus, reaction takes place by preferential replacement of fluorine not chlorine.

Coupling of lithium and magnesium acetylides may proceed with perfluoroalkyl(phenyl)iodonium triflates in place of perfluoroalkyl halides.[68] The highest yield was recorded for n = 8.

$$RC\equiv CM \xrightarrow[-78 \text{ to } -30\ ^\circ C,\ THF]{R_FI(C_6H_5)OSO_2CF_3} RC\equiv CR_F,\ M = Li,\ MgX;\ R_F = C_nF_{2n+1},$$

n = 2, 3, 6, 8; R = C_6H_5, C_6H_{13-n}.

The interaction of pentafluoroiodobenzene and 4-substituted tetrafluoroiodobenzenes with cuprous 3-(tetrahydropyran-2-yloxy)-prop-1-ynide in pyridine affords the corresponding fluorophenyl-substituted propargyl alcohols which are converted to the corresponding terminal acetylene derivatives on oxidation with NiO_2.[69]

$$p\text{-}RC_6F_4I + CuC\equiv CCH_2-O-\text{(THP)} \longrightarrow$$

$$\rightarrow p\text{-}RC_6F_4C\equiv CCH_2OH \rightarrow p\text{-}RC_6F_4C\equiv CH,$$

R = F, H, CH_3, CF_3, OCH_3, NH_2, $N(CH_3)_2$.

Reaction of perfluoroalkyl iodides with trimethylstannylacetylenes proceeds on UV irradiation in the presence of azodiisobutyronitrile or transition metal complexes to give perfluoroalkylacetylenes.[70–73]

$$R_FI + (CH_3)_3SnC\equiv CR \rightarrow R_FC\equiv CR,$$

R_F = CF_3, C_3F_7, $CF(CF_3)_2$, C_4F_9, C_6F_{13};
R = $C(CH_3)_3$, C_6H_{13}, C_6H_5, $Sn(CH_3)_3$, $C\equiv CSn(CH_3)_3$.

Iotsich reagents prepared from perfluoroalkyl(aryl)acetylenes have been used in the synthesis of allyltrifluoromethylacetylenes,[74] propargyltrifluoromethylacetylenes,[75,76] pentafluorophenyl-*tert*-butylacetylene,[77] acetylenic alcohols[78,79] and α-halogenoacetylenes,[80] as well as a number of elementoorganic compounds.[77,81–85] for example:

$$R_FC\equiv CMgX + R_nEX \rightarrow R_FC\equiv CER_n,$$

R_F = CF_3, C_6F_5; E = Si, Ge, Sn, As; R = CH_3, C_2H_5, C_3H_7, C_4H_9.

Lithium perfluoroalkylacetylides are more effective than the corresponding magnesium acetylides in certain cases.[86–89] Thus, lithium perfluoroalkylacetylides have been used for the preparation of a number of primary, secondary and tertiary acetylenic[27,42,86,87] and non-conjugated diacetylenic alcohols,[87] as well as certain perfluoroalkyl(aryl)acetylenic acids or esters[27,88,89,90] and the corresponding phosphine and arsine derivatives.[91]

Zinc perfluoroalkylacetylides[15,92] may also be used for the synthesis of perfluoroalkyl compounds, notably aryltrifluoromethylacetylenes,[92] α-halogenotrifluoromethylacetylenes,[25,93] vinylperfluoroalkylacetylenes,[94] and *bis*(trifluoromethyl)diacetylenes.[93]

Perfluoroalkyl(aryl)alkynylstannanes have been used to prepare perfluoroalkyl(aryl)alkynyl-silanes and -germanes in >90% yield.[95–97]

$$R_FC\equiv CSnR_3 + R'_3EX \xrightarrow[HMPT]{80\ ^\circ C} R_FC\equiv CER'_3 - R_3SnX,$$

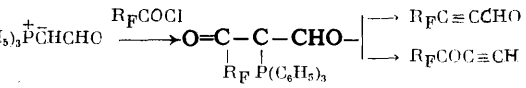
E = Si, Ge; X = Cl, Br.

Reaction does not take place in the absence of solvent.[98] Specific solvating effects are responsible for polarisation of the E–X and Sn–C bonds in the starting materials.[96,99,100]

A similar reaction has been used for the replacement of one acetylenic stannyl group by another (trans-stannylation),[101,103] and for the synthesis of α-halogenoacetylenes.[104]

Trifluoromethylacetylene was prepared as long ago as 1959 by treatment of propiolic acid with SF_4 (60% yield).[105] Hexafluoro-2-butyne was obtained similarly by treatment of acetylenedicarboxylic acid with SF_4.[106] However extension of this method to other perfluoroalkylacetylenes is limited since the corresponding acetylenic acids are not readily available.

The intramolecular Wittig reaction, which is a well-known route to a variety of acetylenes,[107,108] has been applied to the synthesis of perfluoroalkyl(aryl)acetylenes as well as a number of functionalised derivatives: aryltrifluoromethylacetylenes,[109,110] perfluoroalkylpentafluorophenylacetylenes,[111] *bis*(pentafluorophenyl)acetylene,[112] aryloxyperfluoroalkylacetylenes,[113] arylthiotrifluoromethylacetylenes,[114] α-thienylperfluoroalkylacetylene,[115] perfluoroalkylacetylenic aldehydes and ketones,[116,117] esters,[118] thioesters,[119] and nitriles,[120] perfluoroalkylacetylenic acids and perfluoroalkylacetylenic phosphonates.[121] This is illustrated by the synthesis of thioester derivatives:[119]



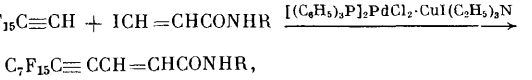
$$(C_6H_5)_3P + BrCH_2CSCH_3 \longrightarrow [(C_6H_5)_3\overset{+}{P}CH_2CSCH_3]\,Br^- \xrightarrow{NaOH}$$

$$\rightarrow (C_6H_5)_3\overset{+}{P}\overset{-}{C}HCSCH_3 \xrightarrow{R_FCOCl} (C_6H_5)_3\overset{+}{P}-C(-O-C(=O)-R_F)=C(-SCH_3)-C\equiv CR_F \xrightarrow[-(C_6H_5)_3PO]{180-220\ ^\circ C}$$

$$\rightarrow R_FC\equiv CC(=O)SCH_3$$

R_F = C_2F_5, C_3F_7, C_7F_{15} etc.

On hydrolysis of C-perfluoroacylformylmethylenetriphenylphosphoranes, the corresponding aldehydes and ketones are obtained in approximately equal amounts. In this case, the reaction proceeds in two directions as a result of charge delocalisation.[116]



$R_F = CF_3$, C_2F_5, n-C_3H_7.

Perfluoroalkyl(aryl)acetylenes are also formed on hydrolysis of perfluoroalkyl(aryl)-substituted triazines[122] and pyridazines.[123,124] The latter are obtained by a multistep route from readily available tetrafluoropyridazine.[125] Yields are not high by this route, but it is interesting in that a variety of perfluoroalkyl groups can be introduced from accessible starting materials.

There is also reference in the literature to the formation of perfluoroalkylacetylenes by pyrolytic processes. For example, hexafluoro-2-butyne is obtained in high yield by pyrolysis of perfluorocyclobutene in a flow system over CsF or KF at 510–590 °C.[126] Perfluoroalkynes are formed by pyrolysis of various sodium perfluoroalkenoates,[127,128] as well as by pyrolysis or photolysis of certain sulphur-containing three- and five-membered heterocyclics.[129]

Trifluoromethylarylacetylenes may also be prepared by replacement of halogen by fluorine in trihalogenomethylacetylenes.[130]

Catalysts play an important role in the conversion of terminal acetylene derivatives to acetylenes containing two conjugated or non-conjugated multiple bonds. Conjugated enynes were thus obtained in the presence of a palladium catalyst:[47]

$R = CH_2CH(CH_3)_2$.

In recent years the Cadiot-Chodkiewicz reaction has been generally applied to the synthesis of conjugated trifluoromethyldiynes, as illustrated in the following variant:[131,133]

$$R = CH(CH_3)_2,\ C(CH_3)_3,\ C(OH)(CH_3)_2.$$

The yield (around 35%) is lower than in the preparation of simple, non-fluorinated, diynes since the resulting fluorinated diyne reacts to some extent with the nucleophiles (amines, methanol) which are present in the medium. Attempts to conduct this reaction under different conditions, notably by using alkylbromoacetylenes and trifluoropropynes, have been unsuccessful.

The first member of this class of perfluoroalkyldiyne—hexafluoro-2,4-hexadiyne—has been prepared by oxidative dimerisation of zinctrifluoromethylacetylide with $CuCl_2$ in dimethylformamide.[93]

A number of *bis*(perfluoroaryl)-1,3-butadiynes (including *p*-substituted derivatives) has been obtained by oxidative dimerisation in the presence of $CuCl_2$ or NiO_2.[61,66,69,134]

III. Characteristic physical properties

Many of the physical properties of perfluoroalkyl(aryl)acetylenes are typical of fluorine-containing compounds in general. By comparison with non-fluorinated acetylenes having the same number of carbon atoms, the boiling points and refractive indices are lower and the density is somewhat higher.[16,17,24,74,91,93,131–133]

The stereochemistry of certain perfluoroalkyl(aryl)acetylenes has been determined by gas-phase electron diffraction, microwave spectroscopy[135–145] and X-ray analysis.[146] The calculated C–C and C≡C bond lengths are in no way anomalous by comparison with those of simple alkynes.

The high polarity of unsymmetrically substituted perfluoroalkyl-(aryl)acetylenes is a result of the high electron-accepting property of the perfluoroalkyl and perfluoroaryl groups.[77,104,132,133,147–149] Perfluoroalkyldicetylenes have an unusually high polarity by comparison with non-fluorinated analogues (~3.8 D).[132,133,149]

The UV spectra of several perfluoroalkyl(aryl)acetylenes have been recorded.[29,58,62,93,112,150,151]

By comparing the IR spectra of perfluoroalkyl(aryl)acetylenes with those of non-fluorinated analogues, it is notable that the triple bond absorption in the former compounds is very high as a consequence of the high polarity.[17,25,35,48,55,61,74,93,123,131–133,143,151–158] The value of this absorption is shifted some 20–40 cm^{-1} into the short-wavelength region. By comparing the IR spectra of α-halogenotrifluoromethylacetylenes, the absorption of the triple bond is shifted into the long-wavelength region on passing from chlorine to iodine. The force constants for these compounds have been calculated.[156,157] The Δν(OH) shift values for phenol on complex formation with the triple bond of $Me_3MC{\equiv}CC_6H_5$ and $Me_3MC{\equiv}CC_6F_5$ increase in each case in the order M = C, Si, Ge, Sn, although the spectral shift in the spectra of the latter compounds is approximately half.[159]

Microwave[5,135,143,160] and infrared[143,155–157] spectral data have also been obtained for a number of trifluoromethylacetylenes.

In the ^{19}F NMR spectra the signals of the ^{19}F atoms in the trifluoromethyl group depend on the position of fluorine in the molecule. In the spectra of trifluoroalkanes, the signals are in the region 2–6 p.p.m.; for trifluoromethylethylenes they are in the region 10–15 p.p.m., and for trifluoromethylacetylenes in the region 25–29 p.p.m. (using CF_3COOH as standard).[161] Thus in acetylene derivatives the fluorine atom is least shielded.[5,15,17,18,35,74,93,123,131–133,143] The change in the chemical shift of the fluorine nucleus in the α-position relative to the triple bond is around 1.8 p.p.m. and is dependent on the polarity of the solvent.[162,163]

By comparing the ^{19}F NMR spectra of stannanes substituted with one to four $C{\equiv}C{-}C_6F_5$ groups, the chemical shift of the ^{19}F nucleus decreases with increase in the number of $C{\equiv}C{-}C_6F_5$ groups with a corresponding increase in the coupling constant from 2.4 to 3.5 Hz. This is in accord with the distribution of the electron density in the benzene ring.[84,164]

In the ^1H NMR spectra the signals of the hydrogen atom at the acetylene terminus are almost identical with those of non-fluorinated analogues. The signals from the protons of the CH_3 and CH_2 groups in the α-position relative to the triple bond are split (~4 Hz) as a result of remote interaction of the fluorine atoms through the triple bond; for the protons of the methine group in the spectra of 1,1,1-trifluoro-6-methyl-2,4-heptadiyne the value is ~1.2 Hz.[5,35,74,75,132,165]

In studying the chemistry of perfluoroalkyl(aryl)acetylenes, particular attention has been paid to their ^{13}C NMR spectra since the position of the signals from the carbon atoms is an indication of the distribution of electron-density in the molecule. The shielding of the carbon atoms of the triple bond is quite the reverse when a trifluoromethyl group is appended, by comparison with the shielding in the non-fluorinated analogue. This is an indication of an increase

in the polarisation of the triple bond in perfluorinated acetylenes.[149,165] Replacement of hydrogen in 3,3,3-trifluoropropyne by chlorine significantly affects the distribution of electron density. In unsymmetrical diynes the polarisation of a non-trifluoromethylated triple bond is the same as in the corresponding non-fluorinated diyne.[149]

The values of the spin-spin coupling constants for the C–F bond in the spectra of trifluoromethylacetylenes are as follows: $J_{CF}(CF_3)$ 256.9 Hz, $J_{C(1)F}$ 53–55 Hz, $J_{C(2)F}$ 6.5–7 Hz.[17,18,149,165,166]

The ^{13}C chemical shifts and spin-spin coupling constants have also been determined for perfluoropentylacetylene[167] and β-substituted trimethylethynyl-stannanes and -silanes containing CF_3 and C_6F_5 groups.[168,169]

A study has also been made of the photo-electron spectra of a number of trifluoromethylacetylenes, $CF_3C{\equiv}CX$ (where X = H, CF_3, C≡CF, Br, I, CN, SF_5,[170–173] $C(CH_3)_3$, $Si(CH_3)_3$ and $Ge(CH_3)_3$,[150,174,175] and of the X-ray spectrum of hexafluoro-2-butyne (300–800 eV).[176]

Electron-impact mass spectra have been recorded for many perfluoroalkyl(aryl)acetylenes and perfluorinated diynes.[17,19,30,89,91,132,143,153,155,177–183] Characteristically, the intensity of the molecular ion is less than that of non-fluorinated alkynes and alkadiynes. In most spectra the $[M-CF_3]^+$ ion is the most intense. The $[M-F]^+$ ion is also characteristic. ΔHf(g.) values (found or calculated) for the ion $[CF_3C{\equiv}CE(CH_3)_2]^+$ (E = C, Si, Ge, Sn) have been derived from the energy of the $[M-CF_3]^+$ ion as recorded by photoionisation mass-spectrometry. It has been shown that the CF_3 group has a similar stabilising effect to the cyano group in the analogous cation.[182] The introduction of a CF_3 group into the molecule increases the π-orbital ionisation potential (9.59 eV for 2-butyne and 12.36 eV for hexafluoro-2-butyne).[183]

Studies have also been made of the mass spectrum of negative ions from hexafluorobutyne.[184,185]

Quantum chemical calculations are also available for perfluoroalkyl(aryl)acetylenes and perfluorinated diynes.[109,144,147,149,186–191] Although independently computed data for σ- and π-charge density are not entirely consistent from one study to another, the calculations do confirm the charge distribution as determined from the $\delta(C^{13})$ chemical shift values.[149]

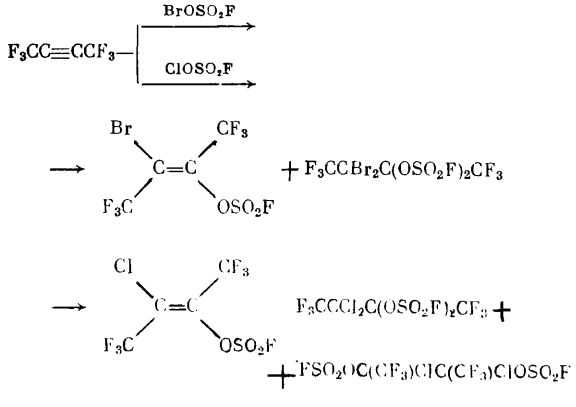
For complexes formed between acetylene derivatives of the type $R_FC{\equiv}CSnMe_3$ (R_F = CF_3, C_6F_5) and electron-donating solvents the stability constants decrease in the order: hexamethylphosphoramide > methyl tetramethylphosphorodiamidate > dimethyl sulfoxide > pyridine > acetonitrile > acetone.[85,192,193]

IV. Chemical properties

Normally, a mechanistic criterion is used as the basis for the classification of the chemical conversions of organic compounds. However, with perfluoroalkyl(aryl)acetylenes, reaction mechanisms have only been established with certainty in a few cases. Thus, in the present article, we have based the classification on the most likely mechanism, taking account of the nature of the reagent and the reaction conditions.

The polarisation of the triple bond by the perfluoro-alkyl or -aryl group largely determines the reactivity of perfluoroalkyl(aryl)-acetylenes. These groups are strong electron acceptors, primarily as a consequence of their inductive effect. The effect of the CF_3 group is readily transmitted through double and triple bonds, the $CF_3C{\equiv}C$ group being a stronger electron acceptor than the $CF_3CH{=}CH$ group and significantly greater in this respect than the CF_3 group.[8] By comparing the orientation of addition of nucleophiles to the system $CF_3CH{=}CHX$ where X is also an electron-accepting group), the relative electron-accepting effect of the CF_3 group is in the order: 2 × CF_3 > COOH > CF_3.[194] A comparison of the electron-accepting effect of the CF_3 group with that of other groups has been made elsewhere.[195] The CH-acidity of terminal acetylenes substituted by perfluoroalkyl groups is clearly greater (by a factor of *ca.* 2) than that of non-fluorinated terminal acetylenes.[78]

1. Electrophilic addition



In their addition reactions, alkynes are less nucleophilic than alkenes,[196] and with perfluoroalkyl or perfluoroaryl substitution the nucleophilicity of the triple bond is even lower. Thus, electrophilic reagents do not readily react with perfluoroalkyl(aryl)acetylenes.

There are several reports on the interaction of perfluoroalkyl-(aryl)acetylenes with halogens in the absence of radical initiators or irradiation. However, strictly speaking, such reactions cannot be classified as electrophilic additions.[26,33,58,93,197]

Quite recently, information was published on the conjugate electrophilic addition of I_2 and mixed halides and pseudohalides—ClI, BrI, and ICN—to terminal perfluoroalkylacetylenes. Here, there is a sharp contrast with the results obtained on the interaction of other electrophiles to such compounds.[198] Electrophilic iodine attacks the terminal carbon atom. This fact is very important to the theory of addition to multiple bonds and can only be explained by a different mechanism of addition (via a carbenium or onium ion). Thus, in such polarised compounds hydrogen and halogen may attack different carbon atoms. There have been a few reports in the literature which substantiate this fact.[199]

Bromine adds to propargyltrifluoromethylacetylene at the mono-substituted acetylene group, while addition to the non-fluorinated analogue—propargylmethylacetylene takes place at the disubstituted acetylene group.[75] Allyltrifluoromethylacetylene and its homologues are brominated at the double bond (at –15 °C), as would be expected.[74]

Below –20 °C hexafluoro-2-butyne reacts with chlorine and bromine fluorosulphate to give the corresponding *trans*-monoadducts (in 38.8 and 34.9% yield) together with products formed as a result of addition of two molecules of the fluorosulphate: with $ClOSO_2F$ the di-adduct is a 3:2 mixture of regioisomers while that formed from two molecules of $BrOSO_2F$ is a single regioisomer:[200]

Trifluoromethylacetylene is more reactive towards hydrogen halides than trifluoromethylethylene,[78,201] just as non-fluorinated acetylenes react more smoothly than ethylenes. Trifluoromethyl-acetylene adds hydrogen halides under comparatively mild conditions

in accordance with the polarisation of the multiple bond, i.e. in the same manner as hydrogen halides add to the analogous perfluoromethylethylenes.[78,202]

The rate of addition of HBr and HI is significantly enhanced in the presence of aluminium halides as catalyst, under which conditions an electrophilic mechanism clearly obtains.

Hydrogen chloride adds to 1,1,1-trifluoro-2-butyne in the presence of $AlCl_3$ to give 1,1,1-trifluoro-2-chloro-2-butene.[16]

The addition of hydrogen halides to hexafluoro-2-butyne is considerably slower and requires (except with HF) a catalyst which promotes electrophilic addition, such as an aluminium halide.[24,202]

Hydrobromination of $CF_3C{\equiv}CN(CF_3)_2$ in the presence of $AlBr_3$ in the dark gives [*Z*]-2-bromo-3,3,3-trifluoroprop-1-enyl-*N*,*N*-*bis*-(trifluoromethyl)amine together with 7% of the regioisomer as an impurity.[197] The regioselectivity of the addition of HBr is explained by the fact that the amine forms with $AlBr_3$ a stable complex in which the polarisation of the triple bond is in the reverse direction by comparison with the uncomplexed amine.

Both geometrical isomers of $F_3CCBr{=}CHSF_5$ are formed by addition of $BrSF_5$ to 3,3,3-trifluoropropyne at 100 °C. However, the mechanism of this reaction has not been established.[44,203]

In the presence of a catalyst, substituted allyltrifluoromethylacetylenes add HBr only across the double bond, the regioselectivity of the reaction depending on the structure of substrate in such a way that the more stable carbonium ion is formed in the initial step.[204]

$$F_3CC{\equiv}CCH_2C(CH_3){=}CH_2 \xrightarrow{HBr} F_3CC{\equiv}CCH_2CBr(CH_3)_2,$$

$$F_3CC{\equiv}CCH_2CH{=}C(CH_3)_2 \xrightarrow{HBr} F_3CC{\equiv}CCH_2CH_2CBr(CH_3)_2$$

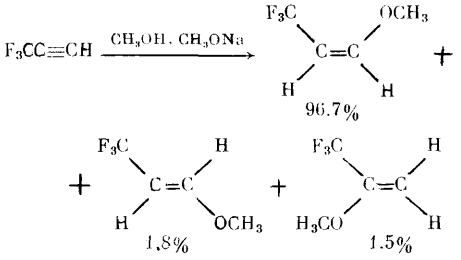
3,3,3-Trifluoropropyne is not hydrated with dilute H_2SO_4 at 100 °C. Trifluoroacetone is formed in low yield (19%) on treatment with $HgSO_4$ in water at 130 °C. Under the conditions of the Kucherov reaction (in the presence of $HgSO_4$ and H_2SO_4) a 1:2 mixture of the corresponding aldehyde and ketone is obtained at room temperature.[12] Under similar conditions 1,1,1-trifluorobutyne affords 4,4,4-trifluoro-2-butanone,[16] while perfluorohexylacetylene gives $C_6F_{13}COCH_3$.[205]

Hexafluoro-2-butyne is hydrated without a catalyst in sulfolane at 110 °C to give 1,1,1,4,4,4-hexafluorobutanone in high yield.[206]

Pentafluorophenylacetylene is hydrated very slowly under the Kucherov conditions with the formation of pentafluoroacetophenone (8% yield over 8 days).[26] *p*-amino-β,β,β-trifluoropropiophenone is obtained by hydrolysis of *p*-(trifluoropropynyl)phenyl isocyanate.[48]

Catalytic hydration can only be considered as an electrophilic process in a formal sense.

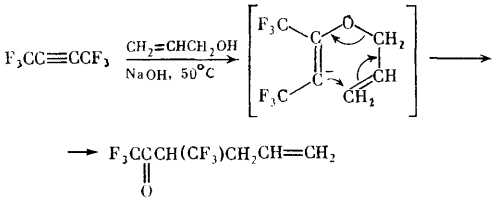
2. Reactions with nucleophilic reagents



Nucleophilic addition is more characteristic of perfluoroalkylacetylenes since the R_F group significantly enhances the electrophilic character of the triple bond.

a) Addition of *O*-nucleophiles

Studies have been made of the addition of alcohols, phenol and organic acids of perfluoroalkylacetylenes. Non-fluorinated alkynes add such *O*-nucleophiles only in the presence of a catalyst on prolonged heating.[196] Perfluoroalkyl(aryl)acetylenes react with *O*-nucleophiles in the absence of catalyst on moderate heating or at room temperature in the presence of a catalyst.



3,3,3-Trifluoropropyne does not add water either in the presence or absence of base. However, hexafluoro-2-butyne adds water in the presence of trimethylamine at room temperature with the predominant formation of *bis*(hexafluoro-2-butenyl) ether.[207]

Alcohols are added to 3,3,3-trifluoropropyne only in the presence of alkoxide or triethylamine at room temperature or lower to give the corresponding *Z*-propenyl ethers.[78,202,208]

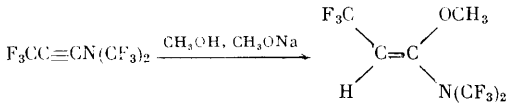
In contrast to 3,3,3-trifluoropropyne, hexafluoro-2-butyne adds alcohols in the absence of catalyst at 95–100 °C. The proportion of (*Z*)- and (*E*)-enol ethers which are formed depends significantly on the nature of the solvent: without solvent the (*Z*)-isomers predominate, while in ether or sulfolane the (*E*)-isomers are principally formed (independent of the nature of the alcohol).[206] The (*Z*)-isomers are obtained almost exclusively on treatment with base, independent of the temperature and the nature of the solvent. On increasing the molecular weight of the alcohol, the proportion of (*E*)-isomer increases slightly.[206] There is a detailed discussion in the literature on the effect of the reaction conditions on the mechanism of this reaction.[206,208]

Allyl alcohol adds to hexafluoro-2-butyne with allyl rearrangement:[209]

Bis(pentafluorophenyl)actylene does not add methanol in the presence of NaOH: reaction proceeds by replacement of both *p*-fluoro atoms by an alkoxy group.[58] Such substitution by nucleophilic reagents is characteristic of perfluoroarylacetylenes.[66,69,190]

The addition of phenol to trifluoromethylacetylene in the presence of potassium *tert*-butoxide in alcoholic media at 25 °C (under kinetic control), or on heating at 150 °C (under thermodynamic control) leads to the exclusive formation of the corresponding (*Z*)-enol ether, as would be expected on the groups of polarisation of the triple bond.[210,211]

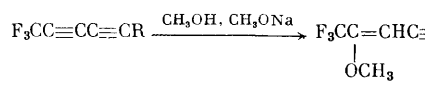
Acetic acids adds to hexafluoro-2-butyne in the same way as alcohols on heating at 60–100 °C (in the presence of sodium acetate as catalyst) to give the corresponding mono- and di-esters.[212] Dialkyl phosphites and thiophosphites also add to a variety of perfluoroalkylacetylenes at 50–100 °C:[213–214]



$$F_3CC{\equiv}CX \xrightarrow{(RO)_2PYH}$$

$$\longrightarrow F_3CCH{=}CXYP(OR)_2 \rightarrow F_3CCH{=}CXP(Y)(OR)_2,$$

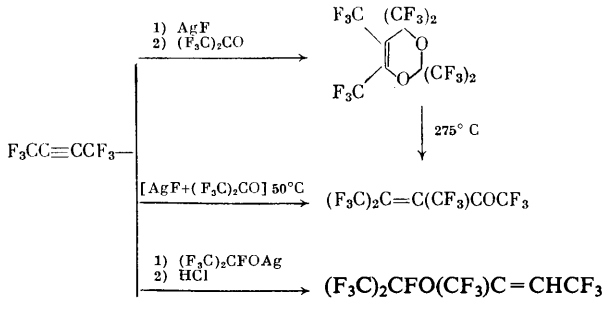
X = H, Cl, Br, CF_3;



Y = O, S; R = C_2H_5, $CH(CH_3)_2$, CH_2CH_2Cl.

Methanol does not add to $CF_3C{\equiv}CN(CF_3)_2$ in neutral or acidic media. However, even at room temperature, treatent with alkoxide affords the corresponding (*Z*)-aminoacetal in 96% yield with 4% of the regioisomer.[197]

Stabilisation of the intermediate carbanion is facilitated by the inductive effect of the trifluoromethyl groups, as would be anticipated.



Recently, a study was made of the addition of methanol to isopropyltrifluoromethyldiacetylene in the presence of sodium methoxide at 55–60 °C.[132,133] In this case, the methoxy group is added to the acetylenic carbon substituted by the trifluoromethyl group, i.e. not in accordance with the polarisation of the system (see Section III). In a similar way, under still milder conditions (at room temperature with evolution of heat), alcohols add to trifluoromethyl-substituted diacetylenic alcohols.[133] The regioselectivity is the same as that observed for the addition of other nucleophiles to trifluoromethyldiacetylenes.

$$R = CH(CH_3)_2,\ C(OH)(CH_3)_2.$$

The regioselectivity of addition of alcohols to keto derivatives and to esters of trifluoroalkyl-substituted acetylenic acids is determined by the mesomeric effect of the carbonyl group.[80,118]

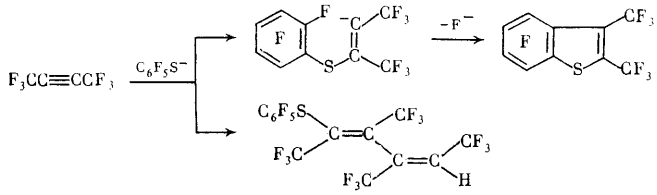
Typically, perfluoroalkylacetylenes react with perfluoro substituted carbonyl compounds—perfluoroanhydrides and perfluoroacetone—in the presence of metal fluorides (AgF). In the case of fluoroanhydrides, the anion $R_FCF_2O^-$ adds across the triple bond (see above).[25] Depending on the conditions, the reaction between hexafluoro-2-butyne and hexafluoroacetone in the presence of AgF (with intermediate formation of the anion $(CF_3)_2CFO^-$) leads to various products (see Ref. 6, Vol. 3, p. 124).

b) Addition of *S*-nucleophiles

The addition of *S*-nucleophiles to acetylenes is more characteristic than addition of *O*-nucleophiles. The rate of addition of *S*-nucleophiles to perfluoroalkylacetylenes is also greater than the rate of addition of *O*-nucleophiles.

Trifluoromethylacetylenes readily add thiols and thiophenols at room temperature (using sodium alkoxide or triethylamine as catalyst) as would be anticipated from the polarisation of the triple bond:[210,211215,216]

$$F_3CC{\equiv}CX \xrightarrow{RSH} F_3CCH{=}CX(SR),$$
$$X = H,\ C_2H_5,\ CF_3,\ Cl,\ Br,\ N(C_2H_5)_2;$$
$$R = C_2H_5,\ C_4H_9,\ HOC_2H_4,\ C_6H_5.$$



For the reaction 1-chloro-3,3,3-trifluoropropyne with thiols in the presence of alkoxide, 1,1-*bis*(alkylthio)-3,3,3-trifluoropropenes are formed as by-product.[215]

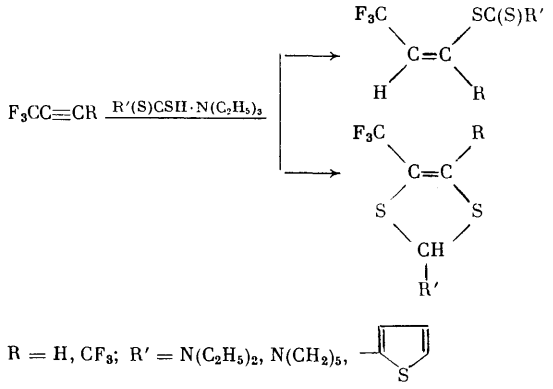
The addition of mercaptopurines in the presence of sodium methoxide leads exclusively to the formation of the corresponding (*Z*)-thioenolethers which rearrange to the (*E*)-isomers on UV-irradiation.[216]

The addition of alkyl mercaptans to allyltrifluoromethylacetylenes proceeds across the triple bond to give, initially, $CF_3CH{=}C(SR)CH_2CR{=}CR_2$ which isomerises to the corresponding 1-alkylthio-1,3-dienes, $CF_3CH_2C(SR){=}CHCR{=}CR_2$ under the conditions of the reaction.[217]

The addition of thiophenol to phenyltrifluoromethylacetylene under kinetic control (at 25 °C with sodium *tert*-butoxide as catalyst) leads to the (*Z*)-thioenolether, while a 23:64 mixture of (*Z*) and (*E*)-isomers is formed under thermodynamic control (at 150 °C). The geometry of the phenol and thiophenol adducts is different since with phenol the (*Z*)-isomer is stabilised by orbital interaction of the aryloxy group with the trifluoromethyl group.[211]

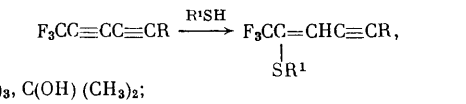
The reaction of lithium pentafluorophenylthiolate with hexafluoro-2-butyne at –70 °C gives a complex mixture of products, from which 4,5,6,7-tetrafluoro-2,3-*bis*(trifluoromethyl)benzo[*b*]thiophene and *trans,trans*-1-pentafluorphenylthio1,2,3,4-tetrakis(trifluoromethyl)butadiene have been isolated in 11% and 2% yield, respectively.[218]

Thiophosphites and esters of thio- and dithio-phosphoric acids add to trifluoromethylacetylene and hexafluoro-2-butyne in the same manner as mercaptans.[213,219]

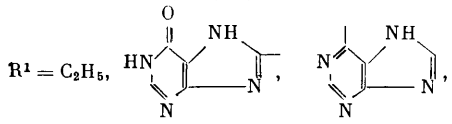


A study has also been made of the addition of methyl mercaptan to esters of perfluoroalkylacetylenic acids in the presence of NaOH. (Z)-Adducts are formed, and methyl mercaptan is liberated as a result of hydrolysis of the corresponding thioester.[220]

$$R_F = C_2F_5,\ C_3F_7,\ C_3F_7OCFCF_3,\ Cl(CF_2)_3,\ Cl(CF_2)_5.$$



Thus, the orientation of addition, as in other related examples, is determined by the mesomeric effect of the carbonyl group.

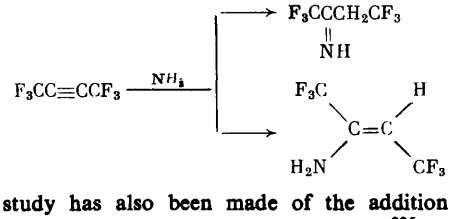


Trifluoromethylacetylenes and hexafluoro-2-butyne react with salts of dithiocarboxylic acids to give, depending on their structure, products arising by nucleophilic addition or 1,3-anionic cycloaddition.[221,222] Only the linear (*Z*)-adducts are obtained by addition of *N,N*-diethyl- and *N*-pentamethylene-dithiocarbamic acids salts,

while salts of 2-thienyldithiocarboxylic acid form 1,3-cycloadducts (see below) or a mixture of both linear and cyclic adducts.[221,222]

The nucleophilic addition of thiols and thioacids to trifluoromethyldiacetylenes has been studied during the last ten years. The reaction proceeds at room temperature with the same regioselectivity as the addition of alcohols, i.e. not in the same manner as the addition to perfluoroalkylacetylenes.[131–133,216,222] With diacetylenic alcohols it is necessary to perform the reaction in the cold (–20 °C), the product being formed in a matter of minutes.[133]

R^2(S)C; $R^2 = N(C_2H_5)_2$, $N(CH_2)_5$.



Molecular sulphur also serves as nucleophile in its addition to hexafluoro-2-butyne (at 110 °C in sulpholane) and to decafluorotolan (at 190 °C in benzene). The respective products are *tetrakis*-(trifluoromethyl)- and *tetrakis*(pentafluorophenyl)-thiophene.[58,206]

c) Addition of *N*-nucleophiles

The reaction of perfluoroalkylacetylenes with *N*-nucleophiles (ammonia, primary and secondary amines, and *N*-heterocyclics with an NH group) have been studied quite extensively, as well as the addition of secondary phosphines and arsines.

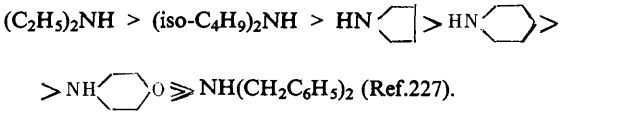
Trifluoromethylchloroacetylene reacts with ammonia at –78 °C to give 2,2,2-trifluoropropionitrile, while excess of ammonia at 50–60 °C yields malononitrile.[223]

Ammonia adds to hexafluor-2-butyne in ether at 0 °C to give a 3:5 mixture of the corresponding imine and (*Z*)-enamine.[224]

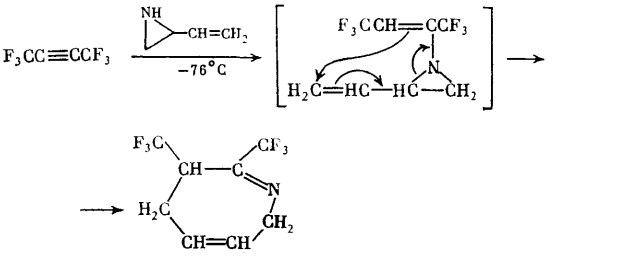
A study has also been made of the addition of ammonia to trifluoromethyl-substituted acetylenic ketones.[225]

Ethylamine and aniline add to 3,3,3-trifluoropropyne at –70 °C to give a mixture of the corresponding imine and enamine.[210]

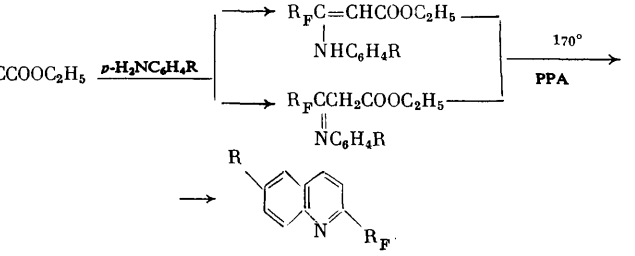
The addition of primary amines to other perfluoroalkylacetylenes at 0 °C is accompanied by dehydrofluorination. The enamines thus obtained are hydrolysed to the corresponding enaminoketones:[226]



$R_F = C_5F_{11}$, C_7F_{15}; R = C_3H_7, C_4H_9.



Secondary amines, such as aromatic nitrogen-containing heterocyclics—pyrazole, benzimidazole, pyrimidine, and purine—add to perfluoroalkylacetylenes at room temperature or on cooling in a number of different solvents to give the corresponding (*E*)-enamines.[202,227–229]



The rate of reaction is determined by the basicity of the amine and decreases in the order:[227]

The addition of vinylaziridine to hexafluoro-2-butyne is accompanied by opening of the 3-membered ring with the formation of a 7-membered ring.[230]

Primary aromatic amines add to perfluoroalkylacetylenecarboxylic acid esters at 40 °C (30 h) to give the expected mixture of enamine and imine. The regioselectivity of addition is the same as that resulting on addition of amines to non-fluorinated acetylenic esters.[88]

$R_F = C_4F_9$, C_6F_{13}, C_8F_{17}; R = H, OCH_3, Cl.

Secondary phosphines and arsines add to trifluoromethylacetylene and hexafluoro-2-butyne at 20 °C with the same regioselectivity as in the addition of amines. The product contains a mixture of (*Z*)- and (*E*)-isomers in varying proportion.[207,228,231]

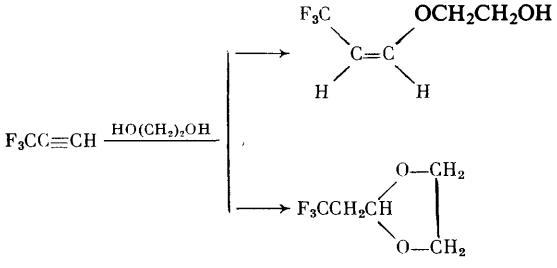
There is an isolated example of the addition of dimethylamine to a mono-substituted perfluoroalkyldiacetylene. At –30 to –40 °C in ether, addition takes place only at the terminal triple bond, the

regioselectivity being in accord with the polarisation of the bond, as is the case with the addition of such secondary amines to perfluoroalkylacetylenes.[232]

$$C_3F_7C{\equiv}C-C{\equiv}CH \xrightarrow{(CH_3)_2NH} C_3F_7C{\equiv}CCH{-}CHN(CH_3)_2$$

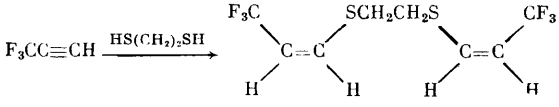
However, in the case of di-substituted alkyl(trifluoromethyl)diacetylenes, secondary amines attack exclusively the carbon atom bearing the trifluoromethyl group, i.e. not in accord with the charge distribution in the compounds.[132,133]

$$F_3CC{\equiv}CC{\equiv}CR \xrightarrow{R_2'NH} F_3CC{=}CHC{\equiv}CR, \quad \begin{matrix} | \\ NR_2' \end{matrix}$$



R = $CH(CH_3)_2$, $C(CH_3)_3$, $C(OH)(CH_3)_2$; R′ = CH_3, C_2H_5

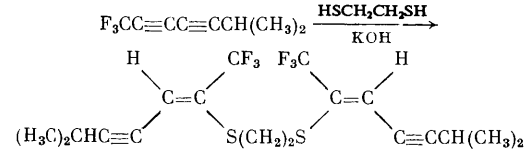
Where the orientation of addition *O*-, *S*- and *N*-nucleophiles to trifluoromethyldiacetylenes is not in accord with the polarisation of such molecules, it is assumed that the regioselectivity is a function of increased stabilisation in the transition state (and intermediate) since it is only by such an orientation of addition that the entire conjugated system can participate and exert a stabilising effect.[149] If such shifts in electron density arise by a mesomeric effect, and not by an inductive effect, as is the case, for example, with diacetylenic acids[233] or phosphates,[149] the most stable transition state results by attack of the nucleophile at the terminal carbon atom furthest from the polarising group.[149]



d) Addition of *O*, *S*- and *N*-dinucleophiles

The reactions of perfluoroalkylacetylenes with dinucleophiles is potentially interesting from the view-point of preparing perfluoroalkyl-substituted heterocyclics with high biological activity. Studies have been made of the reactions of perfluoroalkylacetylenes and perfluoroalkyldiacetylenes with compounds containing two hydroxyl groups, two sulfhydryl and two amino groups, as well as with compounds containing either a hydroxyl and a sulfhydryl group or a hydroxyl group and an amino group. The regioselectivity of these reactions is determined by the nature of the nucleophile.

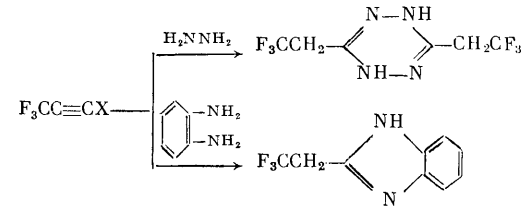
Glycols react with trifluoromethylacetylene at –78 to 80 °C (in the presence of KOH) to give a 4:1 mixture of the corresponding (*Z*)-enolether and 1,3-dioxalane.[210]



Under the same condition 1,2-dithiols react by a different pathway. (*Z,Z*)-1,2-*Bis*(vinylthio)ethanes are formed predominantly, together with small amounts of the corresponding dithiolane if the reaction is carried out in a non-polar solvent.[210]

The contrasting mode of addition of glycols and 1,2-dithiols to diacetylenes is because the activity of the triple bond of the second diyne molecule is significiantly greater than the activity of the double bond arising as a result of the initial addition of the 1,2-dithiol molecule.

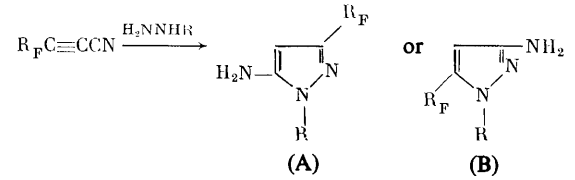
Trifluoromethyldiacetylenes react with ethanedithiol, irrespective of the conditions, to give linear (*Z,Z*)-*bis*-adducts. However, the orientation of addition of ethanedithiol is the reverse of that observed with perfluoroalkylacetylenes.[165]



Monothioglycol adds to trifluoromethylacetylene to give only the corresponding thioenolether as a 7:1 mixture of (*Z*)- and (*F*)-isomers.[210]

The reactions of perfluoroalkylacetylenes with nitrogen-containing binucleophiles (e.g. hydrazine and its derivatives, ethylenediamine, phenylenediamine, guanidine and hydroxylamine) have been studied quite extensively.

Hydrazine reacts with trifluoromethylacetylene at –70 °C to give 3,3,3-trifluoropropanal hydrozone (as a 10:1 mixture of (*Z*)- and (*E*)-isomers), which is converted to the corresponding azine in the presence of an excess of trifluoromethylacetylene.[210]



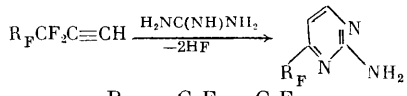
Treatment of hexafluoro-2-butyne with hydrazine affords 1,1,1,4,4,4-hexafluoro-2-butanone hydrazone.[224]

α-Halogenotrifluoromethylacetylenes interact with hydrazine at –60 °C with participation of both the triple bond and α-halogen to give 3,6-*bis*(2,2,2-trifluoroethyl)-1,4-dihydro-*s*-tetrazine. *o*-Phenylenediamine reacts in a similar way to give 2-(2,2,2-trifluoroethyl)benzimidazole.[234]

X = Cl, Br.

Perfluoroalkylacetylenes react with hydrazine, methylhydrazine and phenylhydrazine on heating in methanol according to the following scheme:[235,236]

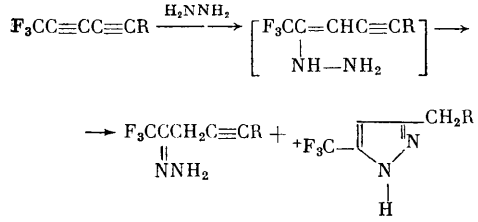
(A) (B)



$R_F = C_7F_{15}$; R = H, CH_3 (A), C_6H_5 (B).

Ethylenediamine adds to trifluoromethylacetylene at –70 °C to give the corresponding imidazole exclusively. Total replacement of fluorine takes place at a higher temperature to give the hydrofluoride salt of ethylenediamine and tarring.[210]

The reaction of trifluoromethylacetylene with *o*-phenylenediamine proceeds at room temperature during 5 days to give the corresponding substituted benzimidazole as the main product. This is accompanied by small amounts of isomeric enamines,



$CF_3CH=CHNHC_6H_4NH_2$ and $CF_3C(NHC_6H_4NH_2)=CH_2$, in 8:1 proportion.[210]

The addition of guanidine to perfluoroalkylacetylenes at 0 °C in THF/water leads to perfluoroalkylaminopyrimidines. The atoms of fluorine of the CF_2-group participate in the reaction.[237]

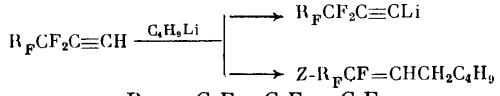
$R_F = C_5F_{11}$, C_7F_{15}.

Trifluoromethyldiacetylenes react with hydrazine at −10 to −20 °C to give, initially, an enehydrazine which readily isomerises to the corresponding non-conjugated hydrazone or cyclises to a pyrazole derivative.[132,133]

The proportion of hydrazone and pyrazole depends on the nature of the radical, R, which affects the electrophilicity of the triple bond. The hydrazone:pyrazole ratio is 2:1 for R = Pr-*i*, and 1:10 for R = $Me_2C(OH)$.

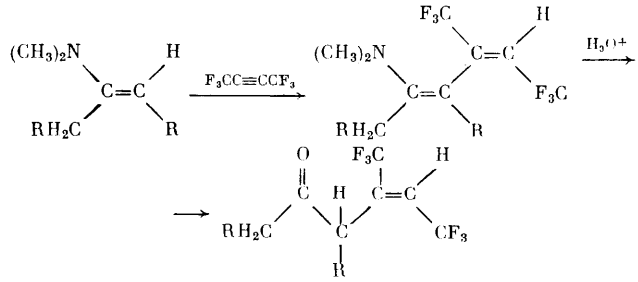
The reaction of trifluoromethyldiacetylenes with ethylenediamine, the basicity of which is greater than that of hydrazine, proceeds in the absence of solvent at −60 °C with the formation of the corresponding trifluoromethyldiazepine exclusively. Both linear and cyclic products are formed in THF.[238]

The reaction of perfluoroalkylacetylenes with *N,O*-dinucleophiles has only been studied with hydroxylamine.[237] At 35 °C in ether/ethanol containing Et_3N, an oxime is formed during 20 h by elimination of HF.[237]



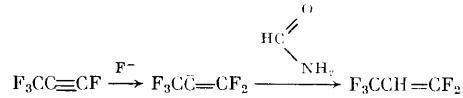
d) Addition of *C*-nucleophiles

Reactions with *C*-nucleophiles are not as well defined as those with *O*-, *S*- and *N*-nucleophiles since in the majority of cases there are no mechanistic details.



Alkyllithiums are normally selected for studies involving the interaction of unsaturated compounds with *C*-nucleophiles.

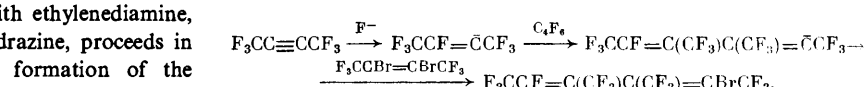
Treatment of terminally unsubstituted perfluoroalkylacetylenes with butyllithium in THF at −60 °C leads to replacement of the acidic hydrogen by lithium or addition to the triple bond to give an anomalous by-product:[89]



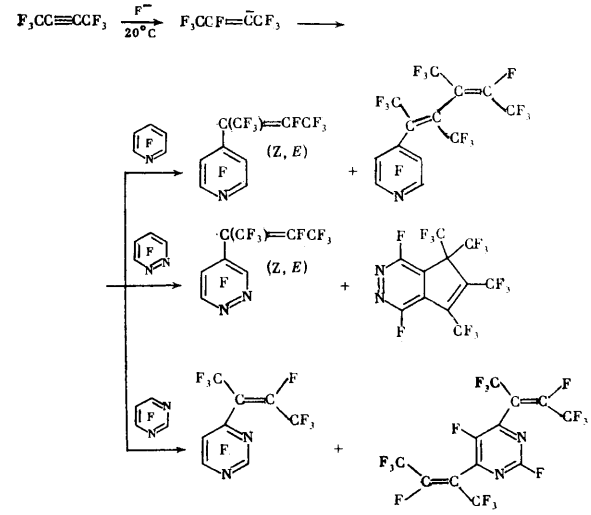
$R_F = C_3F_7$, C_5F_{11}, C_7F_{15}.

Certain enamines serve as *C*-nucleophiles in their reactions with perfluoroalkylacetylenes. Reaction is exothermic and proceeds by attack of the carbon atom at the β-position relative to nitrogen.[239]

R, R = $(CH_2)_3$; R = CH_3.



The fluoride ion of certain metallic fluorides (AgF, CsF, HgF_2) adds to perfluoroalkylacetylenes to give *C*-nucleophilic species. In the presence of a proton donor these are quenched to effect nucleophilic hydrofluorination, as shown below with perfluoropropyne.[18]



If there are no added reagents to intercept the formed carbanion, hexafluoro-2-butyne polymerises in sulpholane on treatment with CsF.[240–242]

However, reaction can be stopped at the stage of dimerisation if a suitable electrophile, e.g. $F_3CBr=CBrCF_3$, is present:[240,243]

The intermediate obtained by reaction of hexafluoro-2-butyne with fluoride ion is an extremely reactive nucleophile, which participates in nucleophilic substitution with a number of *N*-heterocyclics—perfluoro-pyridine, -pyridazine and -pyrimidine.[240,244]

Anionic telomerisation (n = 2,3) also takes place with perfluoropyridine, while in the case of perfluoro-pyridazine and -pyrimidine

an additional product arises as a result of nucleophilic attack at two electrophilic ring positions.

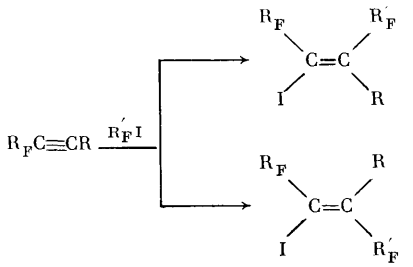
1-Chloro-3,3,3-trifluoropropyne reacts smoothly with perfluoroisobutylene in the presence of fluoride ion. The latter initiates the formation of perfluoro-*tert*-butyl anion which readily displaces chlorine.[245]

$$(F_3C)_2C{=}CF_2 \xrightarrow{F^-} (F_3C)_3C^- \xrightarrow[-Cl^-]{F_3CC\equiv CCl} F_3CC{\equiv}C\dot{C}(CF_3)_3.$$

The reaction of HCN with 3,3,3-trifluoropropyne in the presence of KCN and Cu_2Cl_2 at 110–120 °C possibly involves nucleophilic addition.[202]

$$F_3CC{\equiv}CH \xrightarrow{HCN} F_3CCH{=}CHCN \xrightarrow{10\%NaOH,\ H_2O} F_3CCH{=}CHCOONa.$$

3. Radical polymerisation and addition



Various polymeric products—linear, cyclic (including benzene derivatives by trimerisation) and tetramers—are formed from perfluoroalkyl(aryl)acetylenes on photochemical activation, heating, or on treatment with peroxides or complex metal catalysts.[246–256]

UV-irradiation of hexafluoro-2-butyne affords tetramers of different structural type, amongst which perfluoro-octamethylcubane, perfluoro-octamethylsemibulvalene and perfluoro-octamethyloctatetraene have been identified.[252] It is thought that all of these products arise via UV-irradiation of the two geoisomeric forms of the simple tetramer, perfluoro-octamethylcyclo[4.2.0.0^{2,5}]-3,7-octadiene, or the dimer, perfluorotetramethylcyclobutadiene. It is possible that reaction proceeds via other cyclic systems.[243,252,253]

Certain linear fluoro-polymers and -copolymers with other monomers have been used as stable plastic materials, although they are not as useful as Teflon.[25] Polymers based on fluorine-containing diacetylenes have been used in the manufacture of heat-sensitive materials with improved surface characteristics. These have been applied domestically and scientifically in the design of electronic and optical probes.[256–268]

Examples of radical halogenation[24,34,38,48,259] and hydrobromination[197,202,260] of perfluoroalkylacetylenes have been reported. In the latter reaction, the regioselectivity of addition is the same as that of electrophilic hydrobromination.[197]

Perfluoroalkyl iodides add to perfluoroalkylacetylenes under photochemical or thermal activation as follows:[22,40,261–266]

$R_F = CF_3,\ C_3F_7,\ C_6F_{13},\ C_8F_{17};$
$R = H,\ CF_3;\ R'_F = CF_3,\ C_2F_5,\ C_3F_7,\ CF(CF_3)_2.$

Hydrolysis of the resulting perfluoroiodoalkenes in the presence of freshly precipitated copper leads to perfluoroallenes.[263] Iodotrichloromethane reacts with trifluoromethylacetylenes in the same way as iodotrifluoromethane.[266]

The addition of $I(CH_2)_2O(CF_2)_2SO_2F$ to 3,3,3-trifluoropropyne in the presence of benzoyl peroxide at 195 °C leads to a 3 : 1 mixture of the corresponding (*Z*)- and (*E*)-iodoethylenesulfonyl fluorides.[267]

In the photochemical reaction of perfluoropropyne with trichlorosilane, the Cl_3Si radical attacks primarily the C_2 atom, whereas in the reaction with trimethylsilane attack is predominantly at the C_1 atom. In the case of 3,3,3-trifluoropropyne, both radicals attack primarily the terminal carbon atom.[268]

Trifluoronitrosomethane interacts with 3,3,3-trifluoro-1-propynyl-*N,N-bis*(trifluoromethyl)amine at 95 °C to give a 97% yield of 1 : 1 adduct as follows:[269]

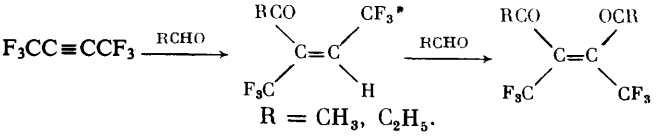
$$F_3CC{\equiv}CN(CF_3)_2 + F_3CN{=}O \longrightarrow \underset{96\%}{F_3CN{=}C(CF_3)CN(CF_3)_2} + \underset{4\%}{F_3CCC{=}NCF_3}$$
(O; O; $N(CF_3)_2$)

The stable *bis*(trifluoromethyl)nitroxyl adds to perfluoroalkylacetylenes at 85 °C with the formation predominantly of the corresponding perfluorinated carbonyl and dicarbonyl compounds.[270]

$$R_FC{\equiv}CR \xrightarrow{(F_3C)_2NO} R_FC{=}CR \longrightarrow R_FCOCOR + R_FCOC[ON(CF_3)_2]_2R$$
($(F_3C)_2NO$; $ON(CF_3)_2$)

$R_F = CF_3,\ C_6H_5;\ R = H,\ F,\ CF_3,\ C_6H_5.$

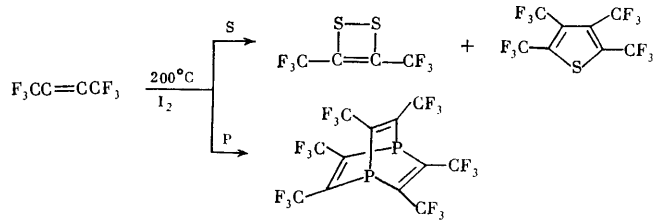
N-Chlorodimethylamine adds to hexafluoro-2-butyne by a radical mechanism.[207] Several products are obtained by radical addition of *N*-bromo-*bis*(trifluoromethyl)amine to 3,3,3-trifluoropropyne: (*Z*)-2-bromo-3,3,3-trifluoro-1-propenyl-*N,N-bis*-(trifluoromethyl)amine is the main product (52%), formed together with 21% of the corresponding (*E*)-isomer and a mixture of (*E*)- and (*Z*)-regioisomers in 3% and 11% yield, respectively.[197]



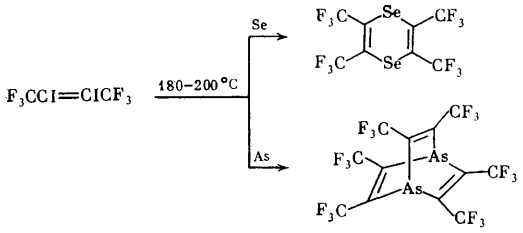
Perfluoroalkylacetylenes add perfluorohydrazine by a radical mechanism to give *N,N*-perfluorodiamines which rearrange on heating to imines:[271,272]

$$F_3CCCF(NF_2)R \text{ (NF)} \quad \text{and} \quad F_3CCF(NF_2)CR \text{ (NF)}$$

Hexfluoro-2-butyne reacts similarly with tetraphenyldiphosphine.[207]

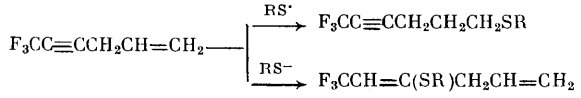


The reaction of 3,3,3-trifluoropropyne with atomic oxygen has also been studied.[273] Radical addition of methanol and 2,2,2-trifluoroethanol to hexafluoro-2-butyne under γ-irradiation affords *trans*-4,4,4-trifluoro-2-trifluoromethyl-2-buten-1-ol (12%) with the former alcohol and, with the latter, a 1 : 1 mixture of *cis*- and *trans*-1,1,1,5,5,5-hexafluoro-3-trifluoromethyl-3-penten-2-ol.[174]

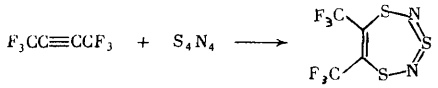


The radical addition of acetaldehyde and propionaldehyde to hexafluoro-2-butyne has also been studied (under γ-irradiation or in the presence of benzoyl peroxide). Reaction proceeds with the formation of adducts in 1 : 1 and 1 : 2 proportion.[274]

$R = CH_3,\ C_2H_5.$

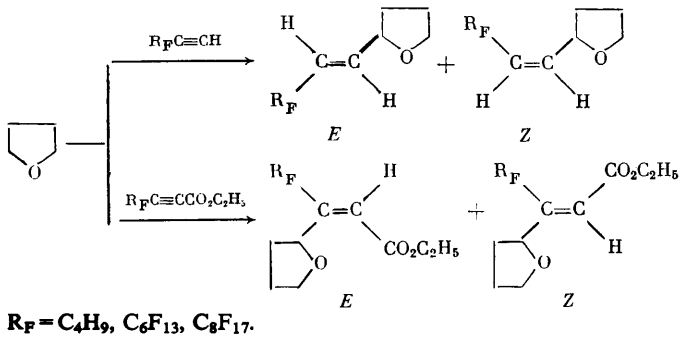


Sulphur and phosphorus react with hexafluoro-2-butyne in the presence of iodine to give heterocyclic compounds. Selenium and arsenic only form heterocyclic compounds with 2,3-diiodohexafluoro-2-butene.[259,275,276]



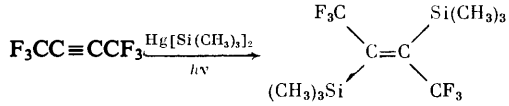
Hydrogen sulphide reacts with 3,3,3-trifluoropropyne and hexafluoro-2-butyne on irradiation to give stable enethiols, $F_3CCH=CHSH$ and $F_3CCH=C(SH)CF_3$.[277] On UV-irradiation of these same perfluoroalkyacetylenes with methyl mercaptan, 1:2 adducts of the type, $CF_3CH(SCH_3)CH_2SCH_3$, are formed.[278]

The addition of alkyl mercaptans to allyltrifluoromethylacetylene and its homologues in the presence of *tert*-butyl peroxide takes place across the double bond. The thiiyl radical thus attacks the terminal carbon atom, while nucleophilic addition of mercaptide anion takes place across the triple bond:[217]



Dimethyl disulphide reacts with hexafluoro-2 butyne on UV-irradiation at 100 °C to give a high yield of 2,3-*bis*-(methylthio)hexafluoro-2-butene as a mixture of (*Z*)- and (*E*)-isomers.[279]

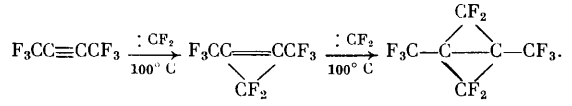
Hexafluoro-2-butyne condenses with tetrasulphur tetranitride to give *bis*(trifluoromethyl) derivatives of a trithiadiazepine. However, the mechanism of this reaction has not been established.[280]



Perfluoroalkylacetylenes and esters of perfluoroalkylpropiolic acid add tetrahydrofuran (on heating) according to the following scheme:[281]

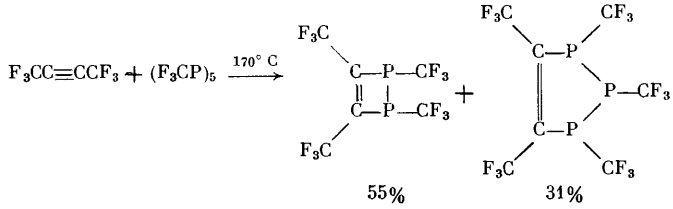
$R_F = C_4H_9$, C_6F_{13}, C_8F_{17}.

The regioselectivity of the reaction between tetrahydrofuran and perfluoroalkylpropiolic acid esters is a consequence of the mesomeric effect of the carboxyl group. In both cases, (*E*)-isomers are formed (80 and 70% yield, respectively).



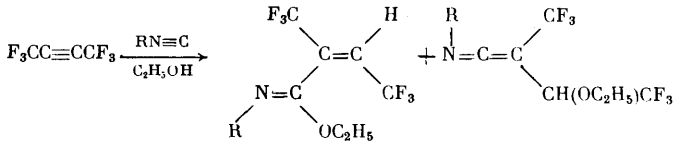
The possibility of silylating perfluoroalkylacetylenes has also been investigated. This is exemplified by the following scheme:[282]

Flash-photolysis of 3,3,3-trifluoropropyne is reported to give HF.[283]



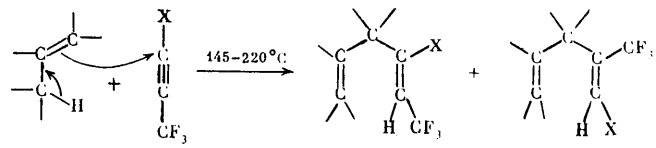
4. Reactions with carbenes and related compounds

Difluorocarbene, obtained by pyrolysis of $(CF_3)_3PF_2$ at 100 °C adds to hexafluoro-2-butyne in the gas phase as follows:[284]



3,3,4,4-Tetrafluoro-3-trifluoromethyl-1-butyne, $CF_3C\equiv CH$ and $C_2F_5C\equiv CH$ react with difluorocarbene, obtained by heating $(CH_3)_3SnCF_3$ at 150 °C, to give the corresponding cyclopropenes in low yield.[35] Hexafluoro-2-butyne reacts with dichlorocarbene, generated by thermal decomposition of CCl_3SiF_3, to give a mixture of 3,3-dichloro*bis*(trifluoromethyl)- and 1,3-dichloro*bis*(trifluoromethyl)-cyclopropene.[285]

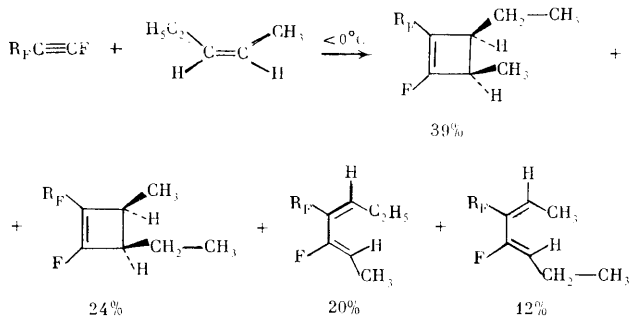
A mixture of four- and five-membered phosphorus-containing heterocyclics is obtained by reaction of hexafluoro-2-butyne with phosphenes.[286]



Treatment of hexafluoro-2-butyne with isonitriles in ethanol affords a mixture of iminoesters and ketenimines. The proportion of each depends on the nature of the isonitrile (see Ref. 6, Vol. 3, p. 121).

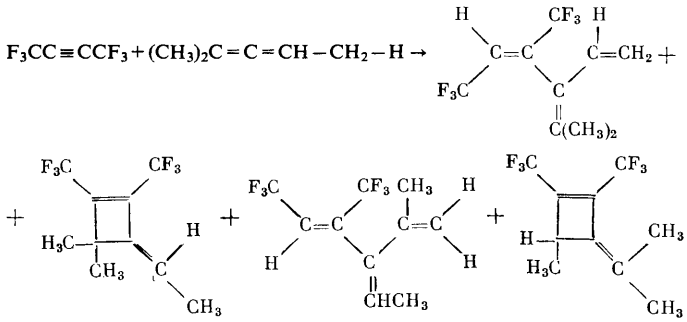
5. Condensation with alkenes

The high electrophilicity of the triple bond of perfluoroalkylacetylenes and the high nucleophilicity of the double bond of alkenes favour interaction between these compounds:[287]



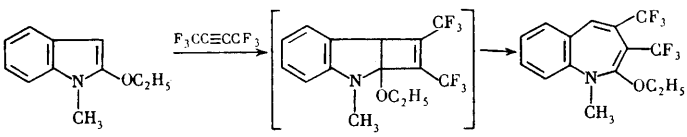
X = H, CF_3.

Thus, reaction of 3,3,3-trifluoropropyne with alkenes leads to a regioisomeric mixture of two non-conjugated 1,4-alkadienes. With substitution of the alkene at C_1 and C_2, several isomeric adducts may be formed.

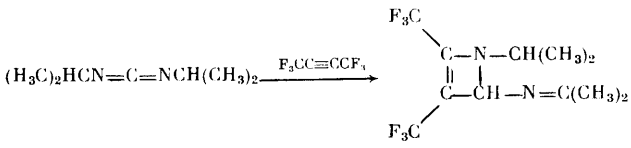


A 1:1 and 1:2 adduct are obtained by reaction of hexafluoro-2-butyne with isobutene.[287]

The interaction of perfluoro-3-methyl-1-butyne with the (*Z*)- and (*E*)-isomers of 2-pentene affords a [2+2]-cycloadduct together with lesser amounts of acyclic compounds formed as a result of ring cleavage of a σ-bond.[122]

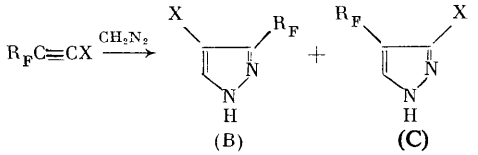


Phenylperfluorohexylacetylene reacts similarly with tetrafluoroethylene. Ring opening of the intermediate cycloadduct yields 1,1,4,4-tetrafluoro-2-perfluorohexyl-3-phenyl-1,3-butadiene.[32]



The direction of the related reaction of hexafluoro-2-butyne with allenes depends on the substitution of the latter.[288] Thus, reaction of 3-methyl-1,2-butadiene with hexafluoro-2-butyne affords only a [2+2]-cycloadduct,[289] while trimethylallene gives a mixture of products as follows:[290]

Hexafluoro-2-butyne condenses with *N*-methyl-2-ethoxyindole to give a 1-benzazepine via transannular cyclobutene ring opening.[291]

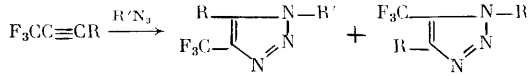


Heterocumulenes, such as diisopropylcarbodiimide, also participate in [2+2]-cycloaddition (see Ref. 6, Vol. 4, p. 121), e.g.

6. 1,3-Dipolar and anionic cycloaddition

Perfluoroalkyl(aryl)acetylenes have been widely used as active dipolarophiles in their reactions with such octet-stabilised dipoles as diazoalkanes, alkyl or aryl azides, nitrile oxides, nitrilimines, sydnones and nitrones. In this way a variety of perfluoroalkyl-substituted heterocyclics have been prepared, primarily with a view to studying the effect of perfluoroalkyl substitution on the biological activity of heterocyclics. Such 1,3-dipolar cycloadditions proceed under much milder conditions than the corresponding reactions with non-fluorinated acetylenes or perfluoroalkylethylenes.[1,6,196,201]

The reaction of perfluoroalkylacetylenes with diazomethane proceeds regioselectively at room temperature to give only one of the two possible cycloadducts. Isomer (B) is formed where X = H, and isomer (C) where X = COOEt. Thus, in the former, the perfluoroalkyl group determines the regioselectivity, while in the latter it is the carbethoxy group.[292,293]



$R_F = CF_3, C_4H_9, C_6H_{13}, C_8H_{17}$; X = H, *n*-$CH_3OC_6H_4$, *n*-$NO_2C_6H_4$, $COOC_2H_5$.

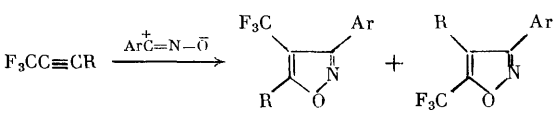
Treatment of aryltrifluoromethylacetylenes with one equivalent of diazomethane gives a 19:1 mixture of the corresponding pyrazoles (B) and (C). Thus, condensation proceeds in accordance with the polarisation of the reactants. The regioselectivity of the reaction is not affected by electron-donating (e.g. OMe) or electron-accepting (e.g. NO_2) substituents in the benzene ring, but the yield of adduct is higher in the latter case.[109]

3,3,3-Trifluoropropyne react with trifluoromethyldiazomethane to give 3,5-*bis*(trifluoromethyl)pyrazole (and a trace of regioisomer in 6% yield), while hexafluoro-2-butyne affords 3,4,5-*tris*(trifluoromethyl)pyrazole.[294]

The addition of diphenyldiazomethane to perfluoropropyne proceeds non-selectively: a 1:1 mixture of isomeric pyrazoles is obtained.[295] The addition of diazocyclohexane,[296] tetraphenyldiazocyclopentadiene[297] and diazofluorene[298] to hexafluoro-2-butyne has also been studied.

Normally, organic azides interact with substituted acetylenes to give a mixture of regioisomeric triazoles. Activation of the triple bond by electron-accepting substituents facilitates this process.[299] Thus, the addition of aliphatic and aromatic azides to trifluoromethylacetylenes proceeds with the predominant formation of 4-trifluoromethyl-1,2,3-triazoles, the permitted R and R′ values being shown below.[109,300–302]

R = H, CF_3, C_6H_5, 4-$NO_2C_6H_4$, 4-$CH_3OC_6H_4$, Br, $CH(OH)_2C_2H_5$, $C{\equiv}CC(CH_3)_3$, $C \equiv CC(OH)(CH_3)_2$;
R′ = CH_3, C_6H_5, 4-$NO_2C_6H_4$, 4-$CH_3OC_6H_4$.



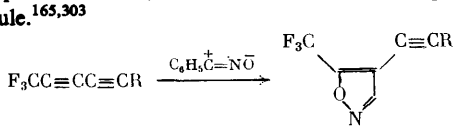
In exactly the same way, phenylperfluorohexyl-[32] and phenylpentafluorophenyl-acetylene[300] react with phenyl azide to give the corresponding 1-phenyl-4-perfluorohexyl- and 1-phenyl-4-pentafluorophenyl 1,2,3-triazoles.

Azides react similarly with non-fluorinated acetylenes.[299] Thus, in such additions, the regioselectivity is not determined by the distribution of electron-density in the substrate.

It is reported[93] that hexafluoro-2,4-hexadiyne readily reacts with two molecules of *p*-dimethylamino- and *p*-methoxy-phenyl azide to give a high yield of the corresponding *bis*(triazoles) with the trifluoromethyl groups in the 5- and 5′-positions. Here, the regioselectivity is different to that observed with the addition of azides to simple perfluoroalkylacetylene (see above), and the data requires corroboration.

Biologically active perfluoroalkyl(aryl)-substituted isoxazoles, which are normally difficult to prepare, are obtained by treatment of the corresponding perfluoroacetylenes with nitrile oxides.

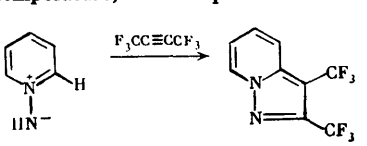
In all reactions of trifluoromethylacetylenes with arylnitrile oxides, the regioselectivity is in accordance with the polarisation of the reactants and independent of the nature of the substituents either in the trifluoromethylacetylene or the benzene ring. The selectivity reaches 99% in certain cases:[50,165,303]



R = H, Br, CF_3, X—C_6H_4 (X = 2-Cl, 4-CH_3O, 4-NO_2, 4-NH_2); Ar = C_6H_5, 4-ClC_6H_4, 2,6-$Cl_2C_6H_3$, 3-pyridyl.

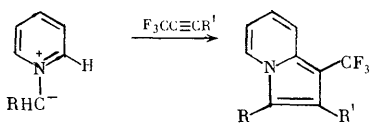
Non-fluorinated acetylenes take part in this reaction under harsher conditions, and the regioselectivity is in the opposite sense.[50] Thus, treatment of pentafluorophenylacetylene with benzonitrile oxide affords 3-phenyl-4-pentafluorophenylisoxazole,[304] while phenylacetylene gives 3,5-diphenylisoxazole.[305] If the reaction is conducted in the presence of triethylamine, there is partial replacement of the *p*-fluorine atom by the triethylammonio group.[304]

In the reaction of perfluoroacetylenecarboxylic acid ethyl esters with nitrile oxides, the regioselectivity is determined by the mesomeric effect of the carbethoxy group.[306]



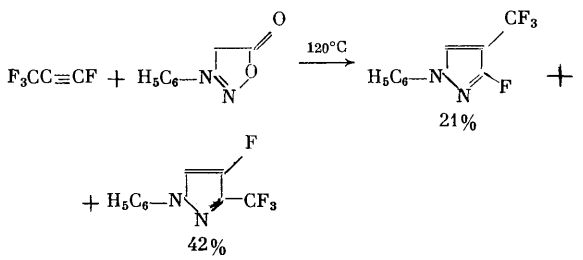
Quinoline and isoquinoline *N*-oxides react with hexafluoro-2-butyne in a more complex manner with intermediate formation of the expected ylids.[307]

Non-conjugated, methylene-bridged trifluoromethyldiacetylenes having a terminal triple bond react with nitrile oxides predominantly at the terminal bond, as is the case with non-fluorinated analogues. However, if the non-fluorinated triple bond is disubstituted, addition takes place predominantly at the acetylene group substituted by the trifluoromethyl group, as is normally the case.[165,308] This bond is also highly activated in conjugated trifluoromethyldiacetylenes. Thus, the regioselectivity of the reaction, as is the case with nucleophilic addition, is not in accord with the polarisation of the molecule.[165,303]

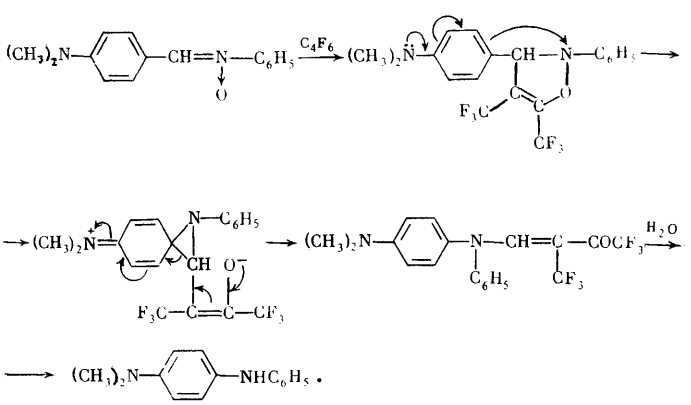


The kinetics of the reaction of 3,3,3-trifluoropropynyldiphenylphosphine with *C,N*-diphenyl- and *C*-acetyl-*N*-phenyl-nitrilimine has also been studied, although there was no product analysis.[309]

N-Nitrilimines (azomethine imides) based on pyridine, quinoline[310] and pyrazoline[311] interact smoothly with hexafluoro-2-butyne at room temperature, for example:[310]

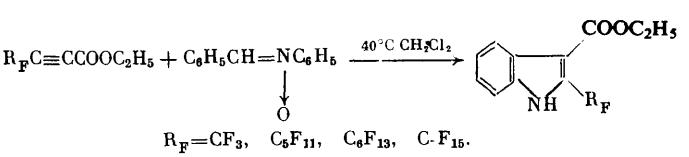


The reaction of trifluoromethylacetylenes with related ylids[312] and with *N*-(2,2,2-trifluoroethyl)pyridinium salts[313] proceeds in the same way, although by-products have also been isolated:



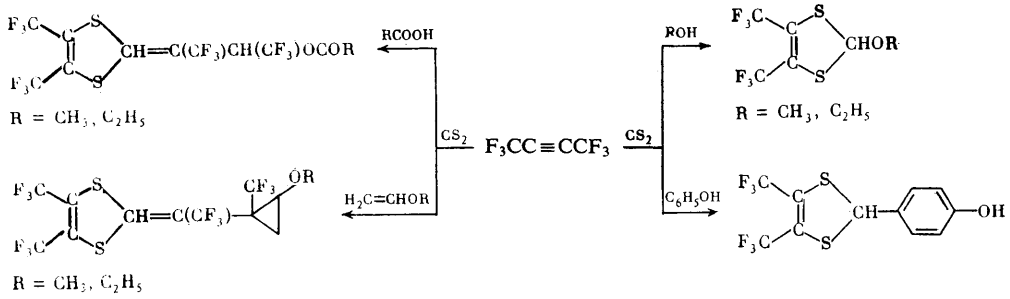
R = CF_3, COF_3; R′ = H, CF_3.

Perfluoropropyne reacts with *N*-phenylsydnone non-selectively:[302]

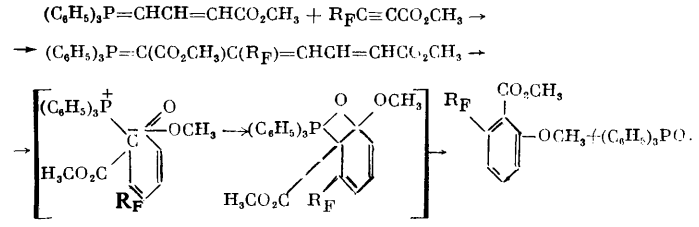


Hexafluoro-2-butyne affords 3,4-*bis*(trifluoromethyl)-1-phenylpyrazole with this same sydnone.[302]

The interaction of hexafluoro-2-butyne with phenyl-, *p*-anisyl-, *p*-nitrophenyl-, *p*-*N,N*-dimethylaminophenyl-nitrone has also been reported.[314] In all reactions, an isoxazoline is formed initially, but the ring is further transformed as reaction progresses. With the first three nitrones, re-cyclisation and hydrolysis takes place to give the corresponding 2,3-*bis*(trifluoromethyl)indole. *C*-(*p*-*N,N*-dimethylaminophenyl)-*N*-phenylnitrone condenses with hexafluoro-2-butyne as follows:[314]



In the reaction of *C, N*-diphenylnitrone with perfluoroacetylenecarboxylic acid ethyl esters, the orientation of addition is determined largely (90%) by the carbethoxy group.[315]



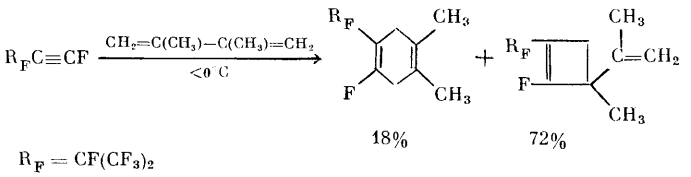
Anionic cycloaddition has only been studied with dithio-acids. Aminodithiocarbamates react with trifluoromethyl-acetylenes and -diacetylenes by nucleophilic addition (see above). 1,3-Anionic cycloaddition only takes place with 2-thienyldithiocarbamates.[221,222]

Hexafluoro-2-butyne and CS_2 participate in a variety of 1,3-anionic cycloadditions,[316–318] for example:

The reactions of perfluoroacetylenecarboxylic acid esters with phosphonium and arsonium ylids have been studied in recent years.[319–321] Thus, interaction of phosphorane (D) with methyl perfluoroalkylactylenecarboxylates takes place via intramolecular Wittig reaction to give the corresponding perfluoroalkyl-substituted *o*-methoxybenzoates:[319]

7. Diene synthesis

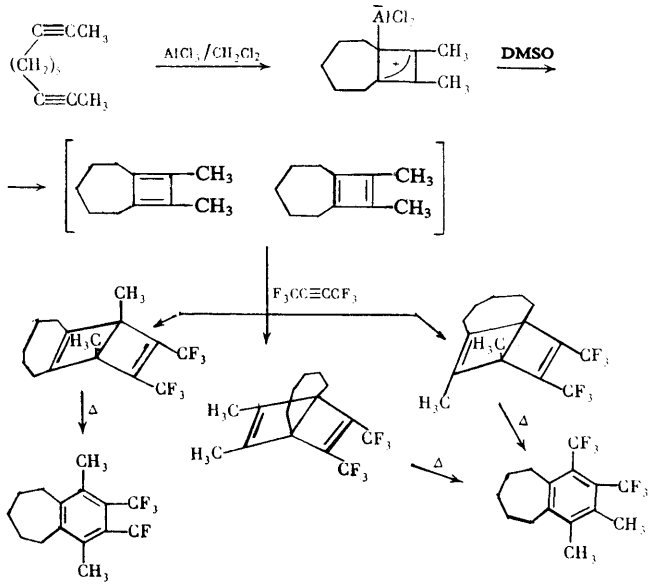
Alkynes and aryl-substituted acetylenes react as dienophiles with 1,3-alkadienes, but only under forcing conditions. Perfluorinated analogues, however, often react at room temperature. Under certain conditions they may even react with diene systems which are normally unreactive, such as aromatic hydrocarbons. Diene synthesis with perfluoroalkyl(aryl)acetylenes plays an important role in the preparation of mono- and poly-cyclic compounds, including heterocyclics substituted by perfluoro-alkyl and -aryl residues. Such products have potential biological activity, and the incorporation of polarising substituents is synthetically useful.



The interaction of 3,3,3-trifluoropropyne with 1,3-butadiene was first mentioned in 1956, but detailed experimental data was not presented.[5]

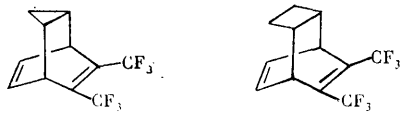
Recently it was shown that 3,3,3-trifluoropropyne reacts with cyclopentadiene even at room temperature, and with 1,3-butadiene and 2,3-dimethyl-1,3-butadiene on heating at 100 °C.[76] The reactions of 3,3,3-trifluoropropyne and hexafluoro-2-butyne with hexafluoro- and perfluoro-1,3-cyclohexadienes (at 200 °C) affords the expected cycloadduct together with products formed by dimerisation of the cycloalkadienes.[322,323] Bromo-3,3,3-trifluoropropyne interacts exothermically with cyclopentadiene at room temperature, while reaction with 1,3-butadiene and 2,3-dimethylbutadiene requires heating (100 °C). These thermal cycloadditions are accompanied by tarring and dehydrogenation to give aromatic compounds.[76]

Phenylperfluorohexylacetylene readily reacts with divinyl on heating.[32]



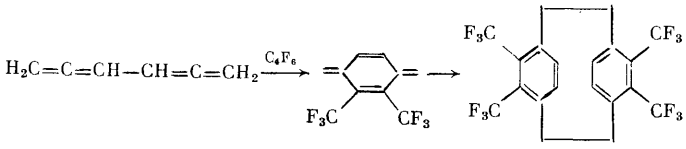
The most studied dienophile is hexafluoro-2-butyne. The latter reacts with 1,3-butadiene or 2,3-dimethyl-1,3-butadiene at room temperature or at temperatures in the region 28–100 °C.[324] The corresponding benzenoids are formed via dehydrogenation of the adducts at 700–800 °C. The major by-products are trifluoromethylbenzene and 2,3-*bis*(trifluoromethyl)-1,3-butadiene.[324]

With perfluoroacetylenes, however, [2+2]-cycloaddition prevails over [4+2]-cycloaddition,[122] as illustrated below.



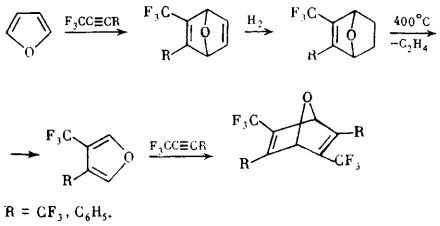
Reference has also been made to the reactions of hexafluoro-2-butyne with cyclic conjugated alkadienes having a four-, five-, six-, seven- or eight-membered ring.

Dimethylpentamethylenecyclobutadiene initially affords a 1:1 adduct which subsequently isomerises as follows:[325]



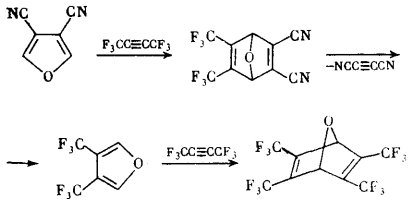
Reaction proceeds in the normal way with cyclopentadiene and variedly substituted cyclopropylfulvenes to give 2,3-*bis*(trifluoromethyl)bicyclo[2.2.1]hepta-2,5-diene[326,327] and the corresponding cyclopropyl derivatives, respectively.[328,329] With cycloheptatriene,[326] its 7-cyano derivative,[330] and with cyclooctatetraene (at 150 °C),[326]

transannular ring closure of the initial cycloadducts yields the following compounds:

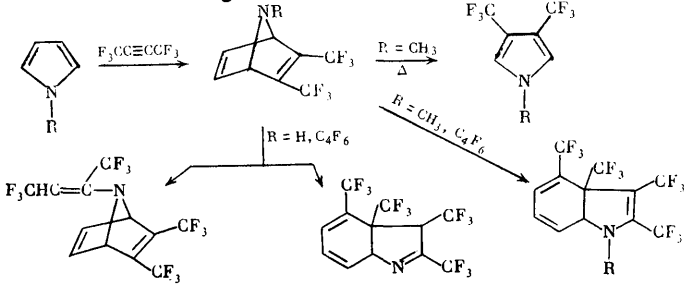


Bis(pentafluorophenyl)acetylene and pentafluorophenylacetylene react with tetraphenylcyclopentadiene to give, predominantly, hexaarylbenzenes.[112]

The adduct formed from hexafluoro-2-butyne and 1,2,3,5-hexatetradiene dimerises to give the corresponding paracyclophane:[331]

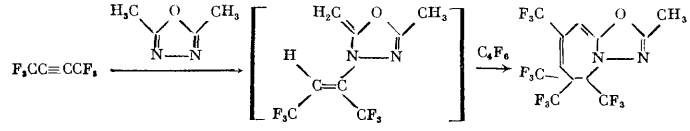


Perfluoroalkylacetylenes readily react with furan, pyrrole, triazine and substituted derivatives of these heterocyclics. At 100 °C in THF furan affords the expected [4+2]-adduct, which, after partial hydrogenation, eliminates ethylene on heating. The resulting 3,4-disubstituted furan then reacts with a second molecule of perfluoroalkylacetylene as follows:[110,332,333]



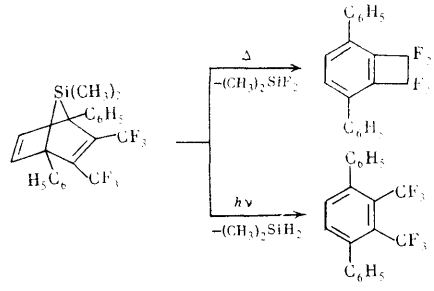
R = CF_3, C_6H_5.

In a similar way, cycloaddition of hexafluoro-2-butyne with 3,4-dicyanofuran is accompanied by elimination of dicyanoacetylene:[332]



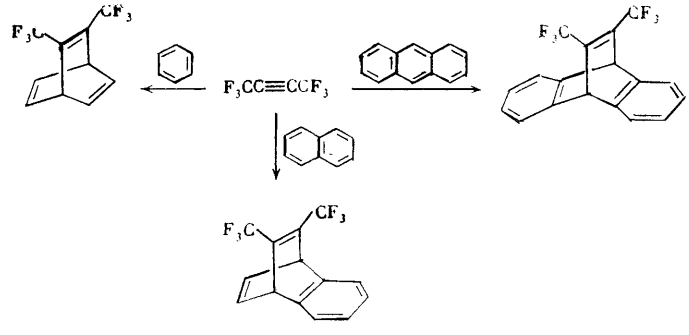
Novel and interesting cycloadducts have been obtained by reaction of furan with [α,α-*bis*(3,3,3-trifluoropropynyl)]benzyl benzoate and [1,1-*bis*(3,3,3-trifluoropropynyl)]ethyl acetate.[90]

Normally, pyrrole reacts with dienophiles by ene synthesis rather than [4+2]-cycloaddition. However, the latter prevails with hexafluoro-2-butyne, the initial cycloadduct reacting subsequently as shown in the following scheme:[334]

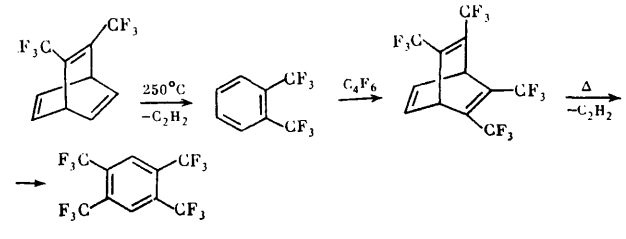


The products formed by heating hexafluoro-2-butyne with *N*-benzoyl-2,5-dialkylpyrroles at 300 °C eliminate acetylene to give the corresponding tetra-substituted *N*-benzoylpyrroles.[335]

Hexafluoro-2-butyne reacts with 2-phenyl-4,6-diaryl-1,2-dihydro-*s*-triazines to give the corresponding 4,5-*bis*-(trifluoromethyl)-2,6-diarlypyrimidines.[336] An unusual condensation of hexafluoro-2-butyne with 2,5-dimethyl-1,3,5-oxadiazole has also been reported:[337,338]

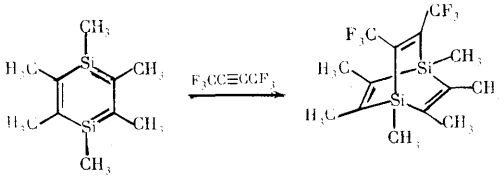


The structure of the product was established by X-ray analysis. The reaction of hexafluoro-2-butyne with five-membered and six-membered silacyclodienes proceeds in the first phase to give the expected [4+2]-adduct, which may be transformed on heating, as exemplified below:[339,340]



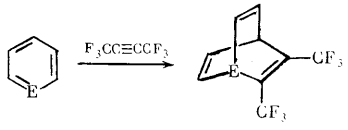
The reaction with germanium-containing analogues proceeds in the same way.[341]

Hexafluoro-2-butyne serves as an active dienophile towards aromatic hydrocarbons: benzene, toluene, xylene, 1,2,5-trimethylbenzene, durene, *p*-(polymethylene)benzenes, naphthalene and anthracene. The cycloaddition takes place at 150–200 °C.[342–344]

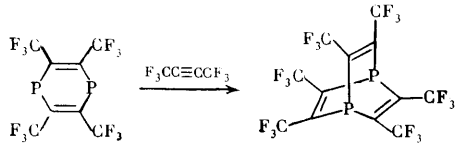


1,12-Dihydroeicosafluoro-6-dodecyne also reacts with aromatic hydrocarbons.[343]

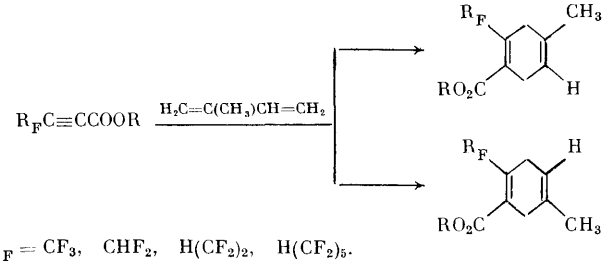
On increasing the temperature, the adducts eliminate acetylene to give, for example, 1,2-*bis*- and 1,2,4,5-*tetrakis*-(trifluoromethyl)-benzene:[343]



The reaction of hexafluoro-2-butyne with a number of six-membered heteroarenes has also been reported. Here, the conditions of the cycloaddition are dependent on the nature of the heteroatom.



Hexamethyl-1,4-disilabenzene reacts with hexafluoro-2-butyne in the same way as benzene:[345]



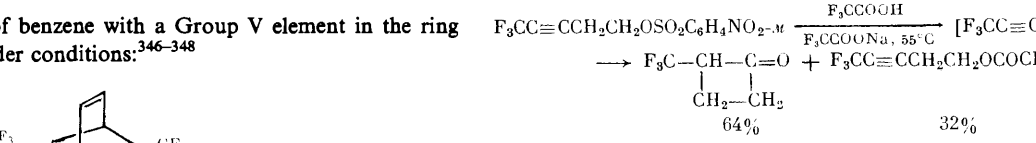
Hetero-analogues of benzene with a Group V element in the ring react under much milder conditions:[346–348]

E = P (at 100 °C); As (at room temp.); Sb, Bi (at 0 °C)

Diene syntheses with perfluoroacetylenecarboxylic acids and their esters as dienophile have been carried out with cyclopentadiene,[349] isoprene, 2,3-dimethylbutadiene and furan.[144] The carboxyl group determines the orientation of cycloaddition, as in other reactions with such acetylene derivatives. In the case of isoprene, the ratio of regioisomers is in the range 2.7 to 1.8, the ratio decreasing as the size of the substituent increases.[144] The resulting products have been used for the synthesis of substituted phthalic acids.[350]

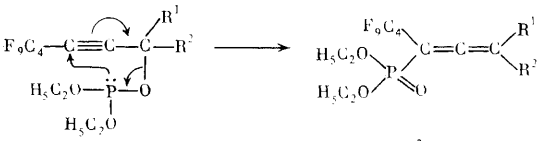
R_F = CF_3, CHF_2, $H(CF_2)_2$, $H(CF_2)_5$.

Diene synthesis with trifluoromethyl-substituted diacetylenes has been studied with two non-conjugated compounds—1,1,1-trifluoro- and 1,1,1-trifluoro-4,4-dimethyl-2,5-heptadiyne—and two conjugated compounds—1,1,1-trifluoro-6-methyl- and 1,1,1-trifluoro-6,6-dimethyl-2,4-heptadiyne.[76,151] There was no reaction between non-conjugated diynes and cyclopentadiene at room temperature. Only the triple bond substituted by the trifluoromethyl group is active at 100–150 °C. Dicyclopentadiene is formed as a by-product. Conjugated alkadiynes react with cyclopentadiene even at room temperature, again with participation of only the trifluoromethyl-substituted triple bond.[76,151]



8. Molecular rearrangements

Trifluoromethyl-acetylenes,[16,202] -diacetylenes,[75] and allyltrifluoromethylacetylenes[217] undergo prototropic isomerisation in the presence of a catalytic amount of base. The triple bond is thus shifted away from the trifluoromethyl group:



Perfluoropropyne isomerises to perfluoroallene on treatment with CsF.[17] The same isomerisation takes place during the preparation of other perfluoroacetylenes.[128]

β-Carbenium ions, formed from perfluoroalkylacetylenes, are converted to cyclobutane derivatives as a consequence of the high electron-accepting character of the perfluoroalkyl group.[86]

Acetylene-allene rearrangement takes place with certain functionalised perfluoroalkylacetylenes, for example:[351]

$R^1 = R^2 = CH_3$; $R^1 = CH_3$, $R^2 = C_2H_5$; $R^1 = R^2 = H$; $R^1 = H$, $R^2 = CH_3$.

9. Complex formation

As a result of the high electrophilicity of perfluoroalkyl(aryl)-acetylenes, the latter undergo complex formation with metals of the platinum sub-group (Pt, Pd, Ir, Ru, Rh, Os), the iron group (Fe, Co, Ni), and many other metals (Mo, W, V, Ti, Mn, Au). Group VIII complexes with hexafluoro-2-butyne have been studied most of all. The chemistry of these complexes has already been reviewed in detail,[5,6,352–354] and the volume of data in this field is too great to be incorporated in any way in this review.

Partial protection of multiple bonds by complexation with $Co_2(CO)_8$ has been widely applied in recent years as a device to increase the regioselectivity of reactions with such compounds.[355,356] However, complexes formed from trifluoromethyl- and pentafluorophenyl-substituted alkynes do not demetalate by the usual routes, and thus have a limited synthetic value.[357–361] However, such complexes may undergo certain reactions which the parent alkynes do not. For example, complexes formed with trifluoromethyl- and pentafluorophenyl-acetylenealcohols readily dehydrate to novel conjugated trifluoromethyl- and pentafluorophenyl-alkenynes, which are converted to the corresponding nitroalkenynes on treatment with $Fe(NO_3)_3.9H_2O$.[358–360] Dehydration of the trifluoromethylacetylene-alcohols is accompanied by partial dimerisation of the resulting enyne complex.[361]

- - -o0o- - -

In this review, it has been noted that perfluoroalkyl(aryl)-acetylenes do not readily add halogens by an electrophilic mechanism. Such additions require radical conditions. In the addition of mixed halogens (IF, ICl) and pseudohalogens (e.g. ICN) to terminal perfluoroalkylacetylenes, the regioselectivity is not determined by the polarisation of the triple bond: attack by the cation proceeds at the terminal carbon atom. However, hydrogen halides add quite smoothly to perfluoroalkyl(aryl)acetylenes in the

presence or absence of catalysts normally used for electrophilic addition. Here, the regioselectivity of the process is in accord with polarisation factors.

Contrasting with the reactions of electrophilic reagents, nucleophiles add to perfluoroalkyl(aryl)acetylenes more readily than to alkynes, even at low temperatures. Here also, the regioselectivity is in accord with the polarisation of the triple bond.

Fluoride ion plays an important role in the reactions of perfluoroalkyl(aryl)acetylenes. The anions formed as a result of addition of fluoride ion (to reagent or substrate) participate readily in a variety of additions and cyclisations.

The addition of nucleophiles to trifluoromethyldiacetylenes does not proceed in a manner as would be anticipated with a strongly polarised conjugated system. The triple bond substituted by a trifluoromethyl group is more active than a non-perfluoroalkylated triple bond. Only by nucleophilic attack of the trifluoromethylated triple bond does a transition state develop with the participation of the entire conjugated system.

Perfluoroalkyl(aryl)acetylenes are highly active in pericyclic reactions. They participate in diene syntheses, even at room temperature, and take part in both 1,3-dipolar and anionic cycloaddition. The regioselectivity of the cycloaddition of perfluoroalkylacetylenes to unsymmetrically substituted dienophiles and dipolarophiles is in accord with polarisation factors, but with perfluoroalkyldiacetylenes mixtures of regioisomers are formed.

A special mention has been made of the usual reactions of perfluoroalkyl(aryl)acetylenes with non-metals—sulphur, selenium, phosphorus and arsenic—from which heterocyclic compounds have been isolated.

The study of addition reactions with perfluoroalkylacetylenes and perfluoroalkyldiacetylenes has made a significant contribution to the generalised theory of addition to unsaturated compounds: the regioselectivity of addition is not always in accord with polarisation factors, even where the triple bond is highly polarised, as has been seen in certain reactions with perfluoroalkylacetylenes and, especially, with diacetylenes.

Many of the properties of perfluoroalkyl(aryl)acetylenes have been widely utilised in organic synthesis, and there is much potential for even broader application. Undoubtedly, these compounds will play a more significant role in the next ten years in various fields of research as more and more is understood of the effect of perfluoroalkyl and perfluoroaryl substitution on chemical, physical and physiological properties.

The structure of equimolar complexes of acyl halides with Lewis acids

A V Orlinkov, I S Akhrem, M E Vol'pin
Institute of Organoelement Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The results of studies on the structures of equimolar complexes of acyl halides with Lewis acids in the solid state and in solutions are surveyed. The methods for the identification of acylium salts and donor–acceptor complexes as well as the factors influencing the equilibrium between them are examined. Communications reporting the formation of complexes of other types in acyl halide–Lewis acid systems are reported and are discussed critically.

The bibliography includes 102 references.

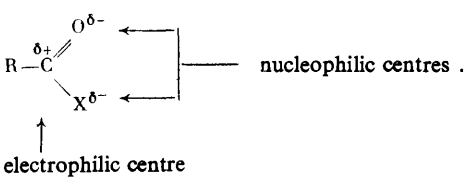
I. Introduction



The discovery by Friedel and Crafts towards the end of the past century of the activating effect of aluminium chloride on acid halides initiated the fruitful application of the $RCOX-MX_n$ systems (RCOX = acyl halide, MX_n = Lewis acid) in organic synthesis. The continued interest in these systems is associated mainly with their use in the acylation of arenes, which is a classical method of synthesis of aromatic ketones.[1–4] The systems $RCOX.MX_n$ have also found applications in reactions with olefins, acetylenes, and other unsaturated compounds, which lead to saturated and unsaturated ketones, aliphatic haloketones, oxonium and pyrylium salts, etc.[2,5,6] The reactions of the complexes $RCOX.MX_n$ with unsaturated compounds have not lost their immediate interest, the region of their application is being expanded, and the study of their mechanisms is being continued at the present time.[5–16]

By virtue of studies on the $RCOX.MX_n$ systems, initiated as early as the beginning of the century and developed to the greatest extent in 1960's–1970's by Susz, Cook, Olah, Carpentier, Boer, Weiss, Corriu, and others, considerable advances have been achieved in the understanding of the mechanism of the interaction of acyl halides with Lewis acids and in the determination of the structures of the complexes formed under these conditions. However, even now many important problems concerning the structures of these complexes remain unsolved.

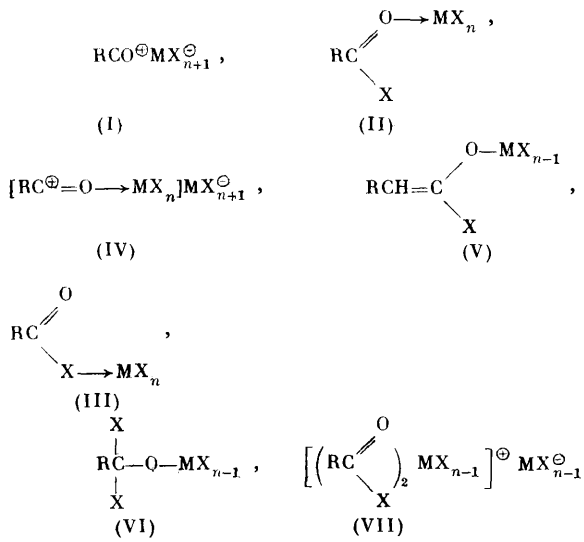
The structure of the complexes $RCOX.MX_n$ has been the subject of many reviews and chapters in monographs.[2,5,7,17,18] Unfortunately none of them is sufficiently complete and many unsolved problems and contradictory data have not been dealt with in the reviews quoted. Such reviews are lacking in the Soviet literature. Furthermore, during the last decade the interest in the complexes of acyl halides with Lewis acids has increased greatly because it has been found that the conversion of the complexes $RCOX.MX_n$ into the complexes $RCOX.2MX_n$ is accompanied by an abrupt increase in their reactivity. The complexes $RCOX.2MX_n$, which have been called aprotic organic superacids, have higher reactivities in reactions with alkanes and cycloalkanes than all the known systems based on AlX_3 (including $RCOX.MX_n$) and also, as a rule, the strongest protic superacids.[19] Taking the foregoing into account, we believe it useful to publish a review on this topic. The structure of aprotic organic superacids (the complexes $RCOX.2AlX_3$), the types of reactions of alkanes and cycloalkanes initiated by them, and also the nature of the superacid properties of these complexes will not be considered here. That range of problems merits an independent review.

II. Interaction of acyl halides with Lewis acids. The structures of the postulated complexes

Acyl halides are amphoteric and are capable of reacting as both Lewis acid and Lewis bases:

The electrophilic centre of the molecule is the carbonyl carbon atom, while the nucleophilic centres are the oxygen and halogen atoms, the greatest electron density being concentrated on the oxygen atom.[5,20]

In conformity with their nucleophilic nature, acyl halides react with a wide range of Lewis acids. The first well characterised complex having the composition $RCOX.MX_n$ was obtained in 1943 by Seel[21] in the reaction of AcF and BF_3. On the basis of the results of elemental analysis and conductimetric measurements, the ionic salt structure $CH_3CO^{\oplus}BF_4^{\ominus}$ was attributed to the complex. It was



subsequently confirmed by other physicochemical methods. Certain 1:1 $RCOX.MX_n$ complexes and their constants are presented in Table 1.

Table 1. The properties of certain adducts $RCOX.MX_n$ (1:1).

Adduct	M.p., °C	Decomp. temp., °C	Refs.
$CH_3COCl \cdot AlCl_3$	65	–	[22]
$2\text{-}CH_3C_6H_4COCl \cdot AlCl_3$	55	–	[23]

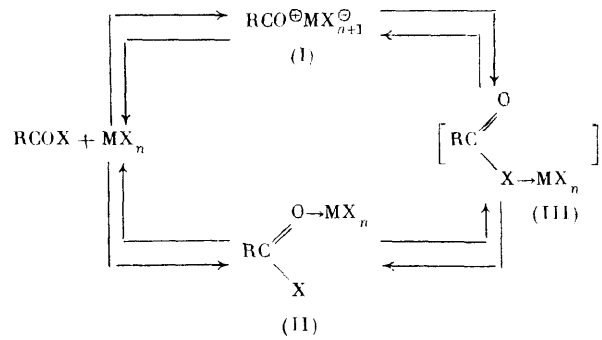
$CH_3COF \cdot PF_5$	–	30	[25]
$PhCOF \cdot PF_5$	–	–15	[25]
$CH_3COF \cdot SbF_5$	173	–	[25]
$PhCOF \cdot SbF_5$	150	–	[25]
$(CH_3)_3CCOF \cdot SbF_5$		20	[27]
$F_2CHCOF \cdot SbF_5$	–	50	[28]

The reactions of acyl halides with the halides of Group III–V elements (BF_3, BCl_3, $AlCl_3$, $AlBr_3$, $GaCl_3$, $GaBr_3$, $TiCl_4$, SbF_5, $SbCl_5$, AsF_5, PF_5, etc.), which lead, as a rule, to the equimolar adducts $RCOX.MX_n$, have been the most thoroughly investigated. The structures proposed for the adducts are presented in Scheme 1 below.[17]

Scheme 1



(I) (II) (IV) (V) (III) (VI) (VII)

It has now been shown by IR and NMR spectroscopy and also by X-ray diffraction that the stable 1:1 adducts $RCOX.MX_n$ exist in one of two forms: either as acylium salts (I) or as coordination complexes (II).[1,5–7,17,18] None of the postulated complexes (II)–(VII) has been detected in the study of a wide range of $RCOX.MX_n$ systems. In the study of the $FCH_2COF-SbF_5$ system by NMR, Olah[28] demonstrated in only one instance that three complexes coexist simultaneously in the system and attributed to them the structures of complexes (I), (II), and (III), (Scheme 2).[28] However, the final conclusion concerning the existence of type (III) complexes can apparently be reached only if its structure can be demonstrated by direct method.

The conversion of acyl halides by Lewis acids into the "Illary complexes" (V) has been postulated.[29,30] Susz and co-workers[31] investigated very carefully the possibility of the presence of the "Illary complex" in the $AcCl.AlCl_3$ system and showed that it is not formed at room temperature. Thus type (V) complexes as well as the other hypothetical complexes (IV), (VI), and (VII) could not be detected in any of the systems investigated.

The formation of the acylium salt (I) and of the coordination complex (II) corresponds to two possible pathways in the reactions of acyl halides with a Lewis acid. Attack on the first nucleophilic centre of the RCOX molecule (the halogen atom), accompanied by the heterolysis of the C–X bond, leads to the acylium salts (I), whilst attack on the second nucleophilic centre (the oxygen atom of the carbonyl group) leads to the formation of a donor–acceptor complex (II) as a result of the coordination of MX_n to the *n*-electron pair of the oxygen atom.

Scheme 2

The position of the equilibrium (I) ⇄ (II) depends on many factors: the strength of the Lewis acid MX_n, the nature of the groups R and X in RCOX, temperature, and (in solutions) also on the nature of the solvent (see Section VI).

All these factors determine whether or not the $RCOX.MX_n$ system exists exclusively as one of the complexes (I) or (II) or whether an equilibrium is established in which both structures contribute appreciably.

III. Acetylium cations. Quantum-chemical calculations

The simplest ionic products of the interaction of acyl halides with Lewis acids are acetylium salts containing the cation $CH_3CO^{\oplus}$, because the first member of the homologous series — the formylium cation $HCO^{\oplus}$ — could not be obtained as part of the composition of a stable compound.[32]

The cation having the empirical formula $C_2H_3O^{\oplus}$ can have a series of isomeric structures,[33–35] but only the cation $CH_3C^{\oplus}=O$ and the 1-hydroxyvinyl cation $CH_2=C^{\oplus}-OH$, which exist in the form of stable long-lived species, have been detected directly. Calculations

of the energies of the ions $C_2H_3O^{\oplus}$ by the *ab initio* method showed that the cation $CH_3C^{\oplus}=O$ corresponds to the minimum energy and that the ion $CH_2=C^{\oplus}-OH$ is the second as regards stability.[34,36]

The acetyl cation can be regarded as a hybrid of the three resonance structures (A'), (A"), and (A"'), which correspond to different locations of the positive charge (Scheme 3). In the carboxonium ion (A') the charge is concentrated on the oxygen atom, in the oxocarbenium ion (A") it is concentrated on the carbonyl carbon atom, while in the ion of the C-protonated ketene (A"') it is concentrated on the hydrogen atoms of the methyl group (hyperconjugation of the C–H β-bonds and the cationic centre):

Scheme 3

$$\underset{(A')}{CH_3C{\equiv}O^{\oplus}} \longleftrightarrow \underset{(A'')}{CH_3C^{\oplus}{=}O} \overset{H^{\oplus}}{\longleftrightarrow} \underset{(A''')}{CH_2{=}C{=}O}\ .$$

The foregoing is valid also for other ionic structures $RCO^{\oplus}$. The contribution of each resonance form to the real structure of the ion $RCO^{\oplus}$ depends to a large extent on the nature of the group R linked to the carbonyl and will be considered in Sections (IV.1) and (V.2).

IV The structure of equimolar complexes of acyl halides with Lewis acids according to X-ray diffraction data

1. The structure of acylium salts $RCO^{\oplus}MX^{\ominus}_{n+1}$

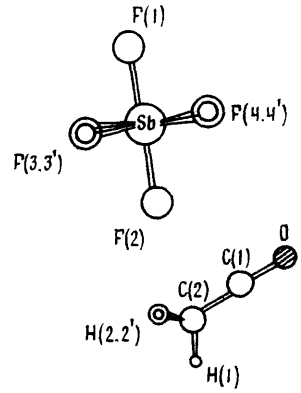
The existence of the ionic complexes (I) and the donor–acceptor complex (II) has been demonstrated by the direct X-ray diffraction method.[37–49] The first crystallographic determination of the structure of an acylium salt was achieved for acetylium hexafluoroantimonate by Boer.[45,46] Although the accuracy of this study, carried out by a photomethod, and the conclusions concerning the electron density distribution obtained on its basis are doubtful,[17] its principal result, indicating a truly ionic structure of the acylium salt, is incontrovertible.

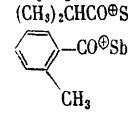
Fig. 1 presents the structure of the acylium salt. Table 2 summarises the principal results of X-ray diffraction studies on ionic acylium salts (I).

As can be seen from Fig. 1 and Table 2, there is a chemical bond between the cation and the anion in the acylium salts. The C(2)–C(1)–O fragment has a linear structure corresponding to the *sp* hybridisation of the carbonyl carbon atom C(1). Thus the C(2)–C(1)–O angles are in all cases close to 180° and the C(1)–O bonds (~1.11 Å) are appreciably shorter than the $C_{sp^2}=O$ bond (1.20 Å for ketones and 1.17 Å for haloacyls[50,51]); the C(1)–O bonds in acylium cations are actually somewhat shorter than in the CO molecule (1.128 Å [45]) (Table 2).

The structure of the anionic fragment is close to a tetrahedron ($AlCl_4^{\ominus}$ and $GaCl_4^{\ominus}$) or an octahedron ($SbX_6^{\ominus}$) and the Al–Cl, Ga–Cl, and Sb–Cl bond length are close to the corresponding values for inorganic salts.

It follows from Table 2 that the C(1)–O bond lengths in various acylium salts are similar (~1.11 Å). On the other hand, the C(1)–C(2) bond length depends to a considerable extent on the nature of the group in which the C(2) atom is incorporated. For R = alkyl, the bond length is in the range 1.44–1.45 Å [the unduly short length quoted for the C(1)–C(2) bond in the compound $CH_3CO^{\oplus}SbF_6^{\ominus}$ is doubtful]. The closeness of these values to the $C_{sp^3}-C_{sp}$ bond length in the isoelectronic $CH_3C{\equiv}CH$ and $CH_3-C{\equiv}N$ molecules (1.46 Å [43,50]) does not provide grounds for the assertion that the resonance ketene form (A"') makes a contribution (see Scheme 3) to the structure of acylium salts in the crystal.[43,47,48] This conclusion is wholly confirmed by the ideal tetrahedral geometry at the C(2) atom.





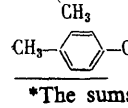


Figure 1. The structure of acetylium hexafluoroantimonate $CH_3CO^{\oplus}SbF_6^{\ominus}$.

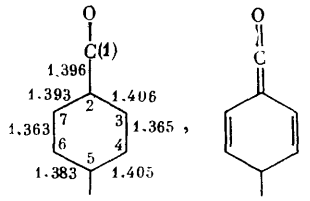
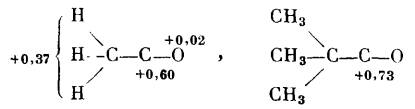
Table 2. Geometrical parameters of the acylium salts $RCO^{\oplus}MX^{\ominus}_{n+1}$ (I) according to X-ray diffraction data.



$RCO^{\oplus}MX^{\ominus}_{n+1}$	Bond lengths, Å		Minimum distances between non-bonded atoms*, Å			C(2)–C(1)–O angle, deg	Refs.
	C(1)–O	C(1)–C(2)	Cl–C(1)	Cl–O	Cl–C(2)H$_3$		
$CH_3CO^{\oplus}SbCl_6^{\ominus}$	1.109	1.452	3.34	3.58	3.55	180.0	[43,44]
$CH_3CO^{\oplus}AlCl_4^{\ominus}$	1.11 *	1.45 *	3.33	3.43	3.49	179.8	[43]
$CH_3CO^{\oplus}SbF_6^{\ominus}$	1.108	1.385				177.2	[45,46]
$CH_3CH_2CO^{\oplus}GaCl_4^{\ominus}$	1.099	1.435	3.42	3.43	3.51	177.7	[47]
$(CH_3)_2CHCO^{\oplus}SbCl_6^{\ominus}$	1.116	1.439	3.27	3.43	3.58	175.7	[47,48]
	1.111	1.387	3.31	3.42		178.7	[49]
	1.097	1.396	3.29	3.35		179.4	[41]

*The sums of the van der Waals radii are $r(C_{sp^2}-Cl)$ = 3.4 Å, $r(Cl-O)$ = 3.2 Å, and $r(C_{sp^3}-Cl)$ = 3.8 Å.

**Only the C(2)–O distance has been determined (2.56 Å). However, taking into account the constancy of the C(1)–O distances (1.11 Å), the C(2)–C(1) bond length was assumed to be 1.45 Å.[43]



The structural data for the aryl cations $ArCO^{\oplus}$ leads to the opposite conclusion. It follows from Table 2 that in this case the C(1)–C(2) bond is somewhat shorter (~1.39 Å) than the $C_{sp^2}-C_{sp}$

bond in the isoelectronic PhC≡N (1.42 Å [50,51]). At the same time a shortening of the C(3)–C(4) and C(6)–C(7) bonds in benzene rings has been observed, which indicates a contribution by ketene-like structures:

X-Ray diffraction data also yield valuable information about the distribution of electron density in acylium cations. Thus comparison of the distances in the intramolecular contacts between non-bonded atoms shows that the C(1)–Cl and CH_3–Cl distances are almost always smaller than the sum of the corresponding van der Waals radii. On the other hand, the Cl–O distances exceed the sum of the van der Waals radii of Cl and O (Table 2). Thus structural data show that the positive charge in the cation $CH_3CO^{\oplus}$ is located mainly on the C(1) atom and the hydrogen atoms at C(2), which confirms the importance of the resonance forms (A″) and (A‴) [but not (A′)] in the crystal structures of acylium salts (see Scheme 3).

This conclusion agrees with the results of quantum-chemical calculations of the distribution of electron density in the cations $CH_3CO^{\oplus}$ and $(CH_3)_2CHCO^{\oplus}$ by the *ab initio* method,[33] whose results are presented below:

Calculation shows that the positive charge in the acylium cation is concentrated mainly on the carbon atom, while the oxygen atom is almost electrically neutral and the hydrogen atoms acquire an appreciable positive charge, shielding the C(2) atom.

It is noteworthy that the quantum-chemical calculations for the $RCO^{\oplus}$ structure (R = alkyl)[33] agree well with experimental bond lengths and angles quoted above (Table 2) for the $CH_3CO^{\oplus}$ cation. Another distribution of electron density in the $CH_3CO^{\oplus}$ ion, obtained on the basis of Boer's results,[45] appears less likely, since, according to these data, the charge on the hydrogen atoms (+0.07) in $CH_3CO^{\oplus}$ is close to the charge on the hydrogen atoms in ethane, which conflicts with the results of other studies indicating an appreciable deshielding of these atoms.

2. The structure of the donor–acceptor complexes RC(X)=O → MX_n

Fig. 2 illustrates the structure of the donor–acceptor complex and Table 3 lists the principal geometrical parameters of the type (II) complexes investigated.

X-Ray diffraction data demonstrate that the Lewis acid is coordinated to the electron pair of the oxygen atom. This is confirmed unambiguously by the presence of the M–O bonds. Thus the Al–O bond lengths in the type (II) complexes (1.820–1.847 Å) exceed only slightly the Al–O bond lengths in stable compounds such as aluminosilicates (1.79 Å). On the other hand, the Sb–O bonds (2.3–2.4 Å) in complexes (III) are significantly longer than, for example, in the complexes $Cl_3P{=}O \rightarrow SbCl_5$ (2.17 Å [52]) and $Me_3P{=}O \rightarrow SbCl_5$ (1.94 Å [53]), which indicates a lower stability of the complexes of acyl halides with acids such as $SbCl_5$ compared with $AlCl_3$.

Complex formation via the oxygen atom leads to the lengthening of the C(1)–O bond (1.21–1.24 Å) compared with the length 1.17 Å in the non-coordinated RCOX,[50] the C(1)–O bond lengths [as well as the C(1)–Cl bond lengths] in the adducts being distinguished by a marked constancy, which apparently indicates a similar strength of the C(1)–O bonds in type (II) complexes.

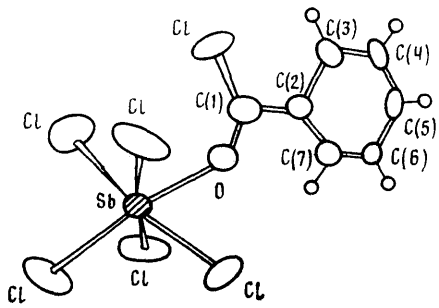


Figure 2. The structure of a type (II) coordination complex: $PhC(Cl){=}O \rightarrow SbCl_5$.

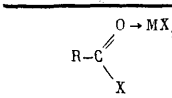
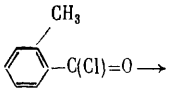
The C(1)–C(2) bond length in the CH_3CH_2–C(Cl)=O → $AlCl_3$ is close to the length of the classical C_{sp^3}–C_{sp^2} bond (1.49 Å [54]), while the Ar–C(1) bonds in ArC(X)=O → MX_n are appreciably shortened compared with C_{sp^2}–C_{sp^2} (1.47 Å [50]).

An important feature of the geometry of the donor–acceptor complexes is the appreciable increase of the M–O–C(1) angles (142–176°) compared with the value 120° characteristic of the sp^2-hybridised oxygen atom. Such a marked distortion of the angles has been attributed[41] to the steric effects observed in the packing of the crystal. On the other hand, the deformations of the angles at the carbonyl carbon atom C(1) are small. The $OAlCl_3$ and $OSbCl_5$ fragments have the geometries of a somewhat distorted tetrahedron and octahedron respectively.





Thus the X-ray diffraction method yields valuable information about the structures of complexes (I) and (II) in the crystalline state.

V. Spectroscopic studies on the structures of the complexes RCOX.MX_n

1. ^{81}Br NQR study of the complex AcBr.$AlBr_3$

A single example of the application of the ^{81}Br NQR method to the study of the structures of complexes of the type RCOX.MX_n, namely AcBr.$AlBr_3$ at 77 K, has been described.[55] The spectrum of this complex lies in the same frequency range as that of the salt $KAlBr_4$.[56] Frequencies in the region corresponding to the vibrations of the C–Br bonds are not then observed at all, so that the presence of free AcBr and of the coordination complex $CH_3C(Br){=}O \rightarrow AlBr_3$ can be fully excluded. Thus at 77 K the complex AcBr.$AlBr_3$ consists of the ionic acetylium salt $Ac^{\oplus}AlBr_4^{\ominus}$. It follows from the multiplicity and relative intensities of the lines

Table 3. Geometrical parameters of the donor–acceptor complexes $RC(X)=O \rightarrow MX_n$ (II) according to X-ray diffraction data.

* The C–Cl bond lengths are similar for all the complexes, amounting to 1.71–1.72 Å.

that the unit cell contains two crystallographically independent $AlBr_4^{\ominus}$ anions. Above 77 K, the NQR spectrum cannot be observed, probably owing to the intense molecular movements in the crystal.

The same complex, obtained in an excess of CH_2Br_2, retains in the solid state its acylium structure, which differs, however, from the structure of the complex obtained in the absence of CH_2Br_2. The difference consists in the fact that, in the complex obtained in CH_2Br_2, the anion $AlBr_4^{\ominus}$ is additionally coordinated to the CH_2Br_2 molecule, i.e. the complex formed has the structure $Ac^{\oplus}[AlBr_4 \rightarrow CH_2Br_2]^{\ominus}$. Such interaction of the anion with a solvent molecule is manifested by a hypsochromic shift of the four lines corresponding to $AlBr_4^{\ominus}$ and by a decrease in the vibration frequency of the C–Br bond of methylene bromide.

However, the most extensive information about the structure of the complexes $RCOX.MX_n$ in the solid state and even more so in solution has been obtained by NMR and IR spectroscopy.

2. Identification of acylium salts by vibrational spectroscopy

As already mentioned, complex formation has an appreciable influence on the length of the C=O bond in RCOX, whose multiplicity increases in the acylium salts (I) and decreases in the donor–acceptor complexes (II). Accordingly, the formation of the acylium salt (I) is accompanied by a hypsochromic shift of the stretching vibration frequencies [ν(CO)] in RCOX, while the formation of complex (II) is accompanied by a bathochromic shift of this frequency.

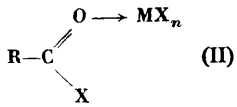
Acylium salts can be clearly identified from the manifestation of an intense absorption in the frequency range 2200–2300 cm^{-1} corresponding to the stretching vibrations of the $[C=O]^{\oplus}$ bond (Table 4) and the vibrations of the M–X bonds in the anions $MX_4^{\ominus}$ or $MX_6^{\ominus}$.[1,5,7,17] This is accompanied by the disappearance of the stretching vibration frequencies of C=O [ν(CO) = 1750–1850 cm^{-1}] and C–X of the non-coordinated RCOX, while the stretching vibration frequencies of the C–H and C–C bonds are altered.

Although the appearance of a new high-frequency absorption undoubtedly indicates the formation of complexes (I), a complete interpretation of the absorption bands in the above region encountered serious difficulties for a long time. The point is that not one but two frequenices are very frequently observed in the range 2200–2300 cm^{-1} (Table 4).

In order to account for the presence of two frequencies, at ~2300 and ~2200 cm^{-1}, in the $AcCl.AlCl_3$ system, Cook[63,68] suggested that, apart from the acylium salt, complex (IV) is present (Scheme 1). In this complex the electron-deficient $CH_3CO^{\oplus}$ cation is additionally coordinated to the $AlCl_3$ molecule:

$$\underset{(I)}{CH_3CO^{\oplus}AlCl_4^{\ominus}} \quad \underset{(IV)}{[CH_3C^{\oplus}=O \rightarrow AlCl_3]Cl^{\ominus}}$$

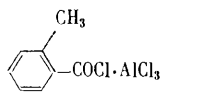
$\nu(CO) = 2203\ cm^{-1}$, $\nu(CO) = 2307\ cm^{-1}$.

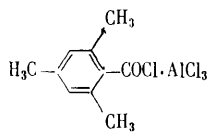


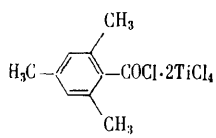
In contrast to Cassimatis's assignment,[62,66] Cook assigned to the $CH_3CO^{\oplus}$ cation the vibration with frequency ν(CO) = 2203 cm^{-1}, while frequency ν(CO) = 2307 cm^{-1} was assigned to complex (IV).[63,68]

Assuming that the formation of complex (IV), via the complex formation reaction between the electron-deficient species $CH_3CO^{\oplus}$ and the Lewis acid, is unlikely, Cassimatis[62,66] proposed the existence in equilibrium with the acetylium salt of its resonance hybrid, the cationic form (A‴) predominating:

$$\underset{2200\ cm^{-1}}{CH_3CO^{\oplus}} \rightleftarrows \underbrace{\{\underset{(A')}{CH_3C{\equiv}O^{\oplus}} \longleftrightarrow \underset{(A'')}{CH_3C^{\oplus}=O} \longleftrightarrow \underset{(A''')}{CH_2=C=O\overset{H^{\oplus}}{\}}}}_{2300\ cm^{-1}}.$$







However, the hypothesis of the existence of two resonance structures as two individual complexes appears to be at least peculiar.

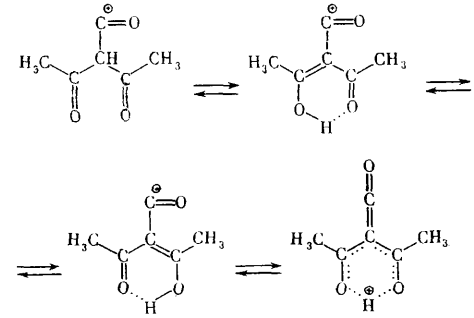
*This frequency is discussed in the text.

The controversial problem of the nature of the complex responsible for the appearance of the second absorption band in the range 2200–2300 cm^{-1} was successfully solved by Germain et al.[70,71] after it had been shown that, together with the acetylium salt $CH_3CO^{\oplus}AlCl_4^{\ominus}$ [ν(CO) = 2300 cm^{-1}], the product of the self-acylation of this salt—diacetylacetylium tetrachloroaluminate $(CH_3CO)_2CHCO^{\oplus}AlCl_4^{\ominus}$ [ν(CO) = 2200 cm^{-1}]—can be formed in the $AcCl-AlCl_3$ system. This process, which proceeds via the formation of the ketene form is illustrated in Scheme 4.



Scheme 4

ν(CO) = 2200 cm^{-1}.

The bathochromic shift of the absorption band of the $[C=O]^{\oplus}$ bond [ν(CO)] in the doubly acylated acylium salts relative to the corresponding bond in RCO^+ (R = alkyl) is quite reasonable if one takes into account the fact that in the given instance one should expect an appreciable contribution by the ketene-like limiting structure in which the $[C=O]^+$ bond has been lengthened:

Scheme 5

ν(CO) = 2200 cm^{-1}.

Both complexes, $CH_3CO^{\oplus}AlX_4^{\ominus}$ and $(CH_3CO)_2CHCO^{\oplus}AlX_4^{\ominus}$, were isolated in a pure form and were characterised. The self-acylation of the acetylium ion depends on the conditions under which the complexes are prepared, the nucleophilicity of the anion (thus self-acylation is not observed in the case of the weakly nucleophilic anion $SbF_6^{\ominus}$), and on the nature of R in $RCO^{\oplus}$ ($ArCO^{\oplus}$ does not form diacylated salts). The presence of the second frequency in the range 2200–2300 cm^{-1} is therefore not always observed (Table 4).

It follows from the foregoing that at the present time the IR spectra make it possible to detect reliably the formation of the ionic complexes (I). Table 5 lists the observed IR frequencies of the $CH_3CO^{\oplus}$ and $CD_3CO^{\oplus}$ ions and their assignments.[62]

Table 5. The assignments of the frequencies in the IR spectra of the cations $CH_3CO^{\oplus}$ and $CD_3CO^{\oplus}$.[62]

Frequency, cm^{-1}		Assignment
$CH_3CO^{\oplus}$	$CD_3CO^{\oplus}$	
2940 s	2209 s	ν(CH_3) (asym.)
2870 s	2049 s	ν(CH_3) (sym.)
2295 s	2297 s	ν(C=O)
1360 w	980 w	δ(CH_3) (asym.)
1319 s	1056 s	δ(CH_3) (sym.)
950 s	834 s	ν(C–C)
390 m	370 m	ν(C–C)

Analysis of the data in Table 4 shows that, with increase in the positive inductive effect of the group R in $RCO^{\oplus}$, which diminishes the charge on the carbonyl carbon atom, a bathochromic shift of the ν(CO) frequency is observed. For example, a bathochromic shift is

observed with increase in the number of methyl groups at the α-carbon atom:

	$(CH_3)_3CCO^{\oplus}$	$(CH_3)_2CHCO^{\oplus}$	$CH_3CH_2CO^{\oplus}$
ν(CO), cm^{-1}	2260	2270	2290

increase of the $+I$ effect of the group R

The factors promoting the stabilisation of the ketene form (A‴) also reduce the C–O bond order and hence lead to a bathochromic shift of the absorption band of this bond. Thus the lower frequencies [ν(CO) $\simeq$ 2200 cm^{-1}] for the cation $(CH_3CO)_2CHCO^{\oplus}$ or the cations $ArCO^{\oplus}$ compared with aliphatic acylium ions (Table 4) are due to the significantly greater contribution of the ketene structure.

3. Identification of donor–acceptor complexes by vibrational spectroscopy

As already mentioned, the formation of the $C=O\rightarrow MX_n$ donor–acceptor bond is accompanied by a bathochromic shift of the carbonyl group frequency (from 1750–1850 to 1560–1640 cm^{-1}).[1,5,7,17,18]

However, as can be seen from Table 4, not one but two frequencies are often observed in the range 1560–1640 cm^{-1}. The question of the assignment of these frequencies has been widely discussed in the literature but the situation is still not entirely clear. Different workers attribute different frequencies to the $\nu(C=O\rightarrow)$ vibration for the same complexes $RC(X)=O\rightarrow MX_n$: in the range 1560–1570 cm^{-1} according to Susz and Wuhrmann[31] and Cassimatis and Bonnin[62] or in the range 1620–1640 cm^{-1} according to the assignment by other workers.[43,63,64,68] Thus, in a study of the $AcCl.AlCl_3$ system in the solid state, Susz[31] observed in the IR spectrum, together with the intense frequency due to the acylium ion, a weak frequency at 1540 cm^{-1} and a very weak frequency at 1640 cm^{-1}. He suggested that the former refers to $\nu(C=O\rightarrow)$ for a type (II) donor–acceptor complex and the latter is caused by the formation of the product of the decomposition of the acylium salt—a type (V) "Illary complex" $CH_2=C(Cl)OAlCl_2$ and represents the stretching vibration frequency of the C=C bonds. However, the synthesis of the complex $AcCl.AlCl_3$ both at −15 °C and at 27 °C led to a product with the empirical formula $C_2H_3OAlCl_4$, i.e. the formation of an "Illary complex" was not confirmed and the problem of the assignment of the 1640 and 1560 cm^{-1} frequencies remained unsolved.

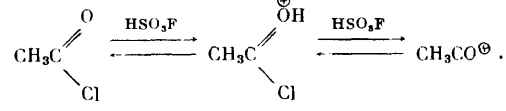
Another system investigated, namely $AcCl.TiCl_4$, did not contain acylium salts and the IR spectrum exhibited two absorption bands at 1620 and 1763 cm^{-1} which have undergone a bathochromic shift relative to ν(CO) for the non-coordinated carbonyl group in AcCl.[67,69]

Calculation of the force constants on the assumption that the 1620 cm^{-1} frequency is due to the $C=O\rightarrow TiCl_4$ coordinate bond led to more reasonable values than for the assignment of the 1763 cm^{-1} frequency to this bond.[69] The authors hypothesis that the 1763 cm^{-1} frequency is associated with the formation of a type (III) coordination complex via the chlorine atom appears to be unjustified, because the formation of such a complex should have been accompanied by a hypsochromic shift of the carbonyl frequency.

Susz[23,67] attributed the ν(CO) frequency in the range 1530 to 1560 cm^{-1} to the aromatic type (II) complexes $ArC(X)=O\rightarrow MX_n$ (MX_n = $AlCl_3$, $TiCl_4$, SbF_5), while in another study[72] frequencies in the range 1620–1630 cm^{-1} were assigned to ν(CO) for the weaker complexes $ArC(X)=O\rightarrow TiCl_4$ and it was noted that $SbCl_5$, being a stronger acceptor, induces a shift of the carbonyl frequency of the initial ArCOX by 210–220 cm^{-1}, while $TiCl_4$ gives rise to a shift of 140–150 cm^{-1}.

The identification of complexes (II) from the C–Hal bond vibrations presents an even greater difficulty. Furthermore, it is still not clear how ν(C–Cl) changes on coordination of MX_n to oxygen.

In most studies the appearance of a new ν(C–X) frequency on coordination of MX_n to oxygen is not reported at all. Cook[63] suggested that such coordination leads to the loosening of the C–Cl bond and to a pronounced bathochromic shift of this frequency to a region inaccessible to observation by IR spectroscopy. On the other hand, Jones and Wood[65] suggest that the force constant of the C–Cl bond increases on coordination of MX_n to oxygen and that ν(C–Cl) undergoes an appreciable hypsochromic shift. These workers attributed a value of 945 cm^{-1} to the ν(C–Cl) frequency in the spectrum of the complex $PhC(Cl)=O\rightarrow AlCl_3$ [for non-coordinated PhCOCl, ν(C–Cl) = 877 cm^{-1}].



Cassimatis and Bonnin suggested[62] that the C–Cl bond in complexes (II) changes very insignificantly and attributed the low intensity vibration at 605 cm^{-1} to ν(C–Cl) for the complex $CH_3C(Cl)=O\rightarrow AlCl_3$ [ν(C–Cl) = 593 cm^{-1} for AcCl]. This second hypothesis that the C–Cl frequency changes only slightly (and that its intensity probably diminishes) appears more probable, since it agrees well with X-ray diffraction data indicating a small change in the C–Cl bond length on coordination to the oxygen atom.

Thus the disappearance of the frequency of the carbonyl group of the acyl halide and the appearance of a new frequency in the range 1530–1630 cm^{-1} indicate the formation of a donor–acceptor complex. However, a reliable assignment of the observed frequencies is as a rule extremely difficult.

One cannot rule out the possibility that, in the case of the acetyl complexes, the appearance of frequencies in the region 1530–1630 cm^{-1} of the IR spectrum may be due to the formation of the cation of protonated acetic acid $CH_3C(OH)_2^{\oplus}$ in the presence of traces of moisture.[73] This possibility is confirmed by the appearance of frequencies in the range 1550–1660 cm^{-1} after the addition of water to acylium salts.[58,74] The $RCOX.MX_n$ systems should therefore be studied in the complete absence of traces of moisture.

It is also necessary to take into account the fact that the salt optical components (especially NaCl and KBr glass) used to record IR spectra are not indifferent to the $RCOX.MX_n$ complexes. This probably explains the partial discrepancies between the IR spectra of the same systems in different publications and the at first sight paradoxical data showing that the crystals of individual complexes (I) exhibit in their IR spectra the presence, apart from their own frequencies, also of those complexes (II).[43]

This disadvantage in the study of the $RCOX.MX_n$ systems can be avoided by using Raman spectroscopy, which permits measurements in sealed glass tubes. Unfortunately Raman spectroscopy has not yet come to be widely used for the study of the $RCOX.MX_n$ complexes and similar systems. As examples of its employment, one may only quote isolated studies.[59,75] Thus, in a study of the spectra of solutions of AcCl in strong Brønsted acids (FSO_3H, $ClSO_3H$, etc.), Corriu et al.[75] showed that equilibrium involving the free AcCl, its protonated form, and the acetyl cation is observed in such systems:

The frequency ν(CO) of the cation $CH_3CO^{\oplus}$ in the Raman spectrum is 2309 cm^{-1}, while that of $CH_3C(Cl)=OH^{\oplus}$ is 1420 cm^{-1}, which indicates a stronger binding of the acyl halide to the proton compared with MX_n.

4. ^{1}H NMR study of the RCOX.MX_n systems

NMR spectroscopy has found extensive applications in the study of the RCOX.MX_n systems in solutions. This method makes it possible to identify complexes (I) and (II), to determine their content in the mixture, and to obtain information about the nature of the distribution of charges in complexes (I) and (II) in solutions of different kinds and about the interconversions between them.[1,5,7,17]

The ^{1}H NMR spectra of these systems were first described by Olah and co-workers.[25,27] The spectra of the AcF.SbF_5 systems in SO_2 or HF contain, apart from the signal due to the initial AcF (doublet with $J_{H-F} \simeq 7$ Hz), two new singlets located in a weaker field. The signal with δ_{CH_3} = 4.08 p.p.m. (singlet) has been assigned to the acetylium salt $CH_3CO^{\oplus}SbF_6^{\ominus}$ (I), while the singlet with the chemical shift δ_{CH_3} = 2.94 p.p.m. was assigned to the coordination complex $CH_3C(F)=O \rightarrow SbF_5$ (II).

The absence of splitting by the ^{19}F nucleus of the signal of the CH_3 group in complex (II), which is observed in the initial AcF, indicates, according to the authors,[25] the existence of the dynamic equilibrium

$$CH_3CO^{\oplus}SbF_6^{\ominus} \underset{SO_2}{\rightleftharpoons} CH_3C(F)=O\rightarrow SbF_5$$

(I) (II)

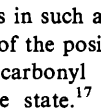
δ_{CH_3}=4.08 p.p.m., δ_{CH_3}=2.94 p.p.m.

The ^{1}H NMR spectroscopic data for complexes (I) and (II) are presented in Table 6. It follows from these results that the signals of the β-hydrogen atoms (here and henceforth this term is given to the hydrogen atoms attached to the carbon atom which is linked to the carbonyl group) in the salts $RCO^{\oplus}MX_{n+1}^{\ominus}$ (I) (R = alkyl, MX_{n+1} = $SbF_6^{\ominus}$, $BF_4^{\ominus}$, $SbCl_6^{\ominus}$, $AlCl_4^{\ominus}$, $SO_3F^{\ominus}$) lie in the range 4.0–4.5 p.p.m. relative to TMS (the chemical shift δ = 3.9 to 4.2 p.p.m. is characteristic of R = CH_3). The resonance of the β-protons in such a weak field indicates a high acidity and hence the location of the positive charge in the acylium salts in solution mainly on the carbonyl carbon atom, as has been observed for the crystalline state.[17] The chemical shifts of the β-protons in the range 2.9–3.6 p.p.m., i.e. in a higher field, are characteristic of complexes (II).

The chemical shifts of the β-protons in the salt $CH_3CO^{\oplus}SbF_6^{\ominus}$ in solution in CH_3NO_2 and $PhNO_2$ have been observed in a higher field than for the solutions in HF or SO_2. Furthermore, in solutions in CH_3NO_2 and $PhNO_2$ there is a sharp rise in the content of complexes (II).[11] In view of the very high regioselectivity of *para*-substitution on acylation of alkylbenzenes by the RCOX.SbF_5 systems (in nitromethane[11] or sulpholan[57]), it was concluded that there are no free ions in such solvents and only close ion pairs are present.

As regards the differences between the chemical shifts for acylium cations with different anions and in different solvents, it is not useful to discuss them because of the low accuracy of the chemical shifts quoted in the literature due to the difficulty of selecting an internal standard for such reactive complexes. As a rule, the ^{1}H NMR spectra quoted in the literature have been recorded using external standards.

In the identification of the donor–acceptor complexes (II) by the ^{1}H NMR method, there are serious complications. Thus it has been found that, in "super acid" media carboxylic acids also form two types of complexes: a protonated acid (δ_{CH_3} = 3.2 p.p.m.) and an acetylium salt (δ_{CH_3} = 4.35 p.p.m.), the chemical shift δ_{CH_3} for the protonated acid being close to those adopted for type (II) complexes (Table 6).



Scheme 6

$$CH_3C(=O)OH \underset{-60^\circ C}{\overset{H^{\oplus}}{\rightleftharpoons}} CH_3C(OH)_2^{\oplus} \underset{-30-0\ ^\circ C}{\overset{-H_2O}{\rightleftharpoons}} CH_3CO^{\oplus}$$

δ_{CH_3}=3.2 p.p.m., δ_{CH_3}=4.35 p.p.m.,

δ_{O-H}=12.4, 13.0 p.p.m.

Table 6. Parameters of the ^{1}H NMR spectra of the acylium salts and the coordination complexes (the chemical shifts are quoted relative to TMS).

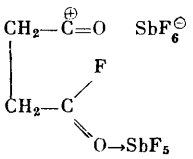
*1 The initial RCOX is also present in the solution.

*2 An ionic-coordination complex is formed.

*3 A different interpretation of the signals was given by Brownstein and Glavincevsky.[79]

*4 The protonated acid $CH_3C(OH)_2^{\oplus}$ is formed.



On this basis, Olah[7,58,80] revised his previous view concerning the presence of complexes (I) and (II) in the RCOF.SbF_5 systems in solutions in HF or SO_2 and assigned the ^{1}H NMR signal observed

in a strong field not to complex (II) but to the protonated acids $RC(OH)_2^{\oplus}$ formed as a result of the partial hydrolysis of ionic complexes (I). The fact that the addition of water to solutions of the $RCOF.SbF_5$ systems in SO_2 led to an increase in the high-field signal intensity and, conversely, that careful isolation from traces of moisture made it possible in certain instances to obtain for the first time solutions of the $RCOF.SbF_5$ systems in SO_2 containing only acylium salts $RCO^{\oplus}SbF_6^{\ominus}$ without any appreciable admixture of substances characterised by high-field signals (2.9–3.5 p.p.m.) constituted important evidence in support of the above hypothesis[57,58,74,76] (Table 6).

The presence or absence of signals due to the OH groups of the protonated acid $RC(OH)_2^{\oplus}$ (12–13 p.p.m. relative to TMS) (see Scheme 6) can apparently serve as an important criterion for the reliable assignment of the signals due to the CH_3 group observed in the region of ~3 p.p.m. Unfortunately, however, due attention has not been devoted to this problem in the literature concerned with the ^1H NMR spectroscopy of the $RCOX.MX_n$ systems.

Thus a reliable identification of the donor–acceptor complexes (II) in solutions by the ^1H NMR method is possible only under conditions where moisture is completely excluded.

The $RCOF.SbF_5$ systems in SO_2 (R = aryl, cycloalkyl, etc.) and $SbF_5.FCO(CH_2)_nCOF.SbF_5$ systems with $n \geqslant 3$ constitute as a rule ionic complexes (I) $RCO^{\oplus}SbF_6^{\ominus}$ and $SbF_6^{\ominus}{}^{\oplus}CO-(CH_2)_n-CO^{\oplus}SbF_6^{\ominus}$ [58] (Table 6). It is of interest that the latter complexes with $n = 2$ have the structure of ionic-coordination complexes in solution in SO_2.

The mutual influence of the oxocarbenium group is responsible for the change in structure from that of the diacylium salt ($n \geqslant 3$) to that of the ionic-coordination complex ($n = 2$). This also probably explains the failure of attempts to synthesise the complexes of SbF_5 with malonic acid difluoride ($n = 1$).

Since solvents such as SO_2 and HF are relatively unsuitable for catalytic reactions,[11] the structure of the $RCOX.MX_n$ system in organic media of low polarities is of special interest.

As shown above, the $RCOX.SbX_5$ (X = Cl, F) systems have been most thoroughly investigated by the NMR method in solvents such as SO_2, HF, CH_3NO_2, $PhNO_2$, and sulpholan, while in weakly polar solvents such as CH_2Cl_2, $C_2H_4Cl_2$, and $CHCl_3$ their investigation is hindered by the poor solubility and high oxidising capacity of antimony(V) derivatives. The NMR data for the structures of these systems in weakly polar solutions are therefore lacking in the literature. On the other hand, the $RCOX.AlX_3$ systems have been studied in both polar and weakly polar organic solvents.

The only solvent in which the ionic salts $RCO^{\oplus}AlCl_4^{\ominus}$ with R = Alk can apparently exist is SO_2. The $AcCl.AlCl_3$ systems in solution in SO_2 have been investigated,[71,79] but the results of these studies do not agree fully and have been given the opposite interpretation in the two investigations.

French investigators[71] concentrated attention on demonstrating the formation of the complex $(CH_3CO)_2CHCO^{\oplus}AlCl_4^{\ominus}$ in the $AcCl.AlCl_3$ system containing an excess of the acid chloride and there is no doubt that this does happen. The chemical shifts δ_{CH_3} = 3.0 and 3.97 p.p.m. are quoted for the salts $(CH_3CO)_2CHCO^{\oplus}AlCl_4^{\ominus}$ and $CH_3CO^{\oplus}AlCl_4^{\ominus}$ respectively in SO_2 (with MS as the external standard). Unfortunately the above workers concentrated attention on cationic species without presenting any data concerning complexes (II). Their second communication[79] reports the presence in the $AcCl.AlCl_3$ system of two complexes with δ = 4.18 and 3.20 p.p.m. This study will be discussed below [see Section (V)].

In all other solvents except $SO_2(C_6H_5NO_2$, CH_3NO_2,[77] CH_2Cl_2,[63,78] $C_2H_4Cl_2$,[77] etc.), the $CH_3COCl.AlCl_3$ system, having an ionic structure in the solid state, exists exclusively as the coordination complex (II). Apart from spectroscopic data, Wilinsky and Kurland[78] also describe chemical tests confirming the foregoing. Although this evidence is in our view not absolute, the conclusion that only complexes (II) are present is incontrovertible.

Thus one may conclude that, on the whole, conditions for the stabilisation of the ionic salts $RCO^{\oplus}MX_{n+1}^{\ominus}$ in weakly polar organic solvents have not so far been found for the $RCOX.MX_n$ (1:1) systems. As regards the complexes $RCOX.AlX_3$ (X = Cl, Br), the formation of the ionic salts $RCO^{\oplus}AlX_4^{\ominus}$ has not been observed for them also in more highly ionising media. We may note that the problem of the stabilisation of acylium salts in organic solvents has a direct bearing on the creation of highly reactive electrophiles.

5. ^{13}C NMR study of the $RCOX.MX_n$ systems

Important information about the composition of the $RCOX.MX_n$ systems in solutions and about the nature of complexes (I) and (II) has been obtained with the aid of ^{13}C NMR spectra.

Firstly, the characteristic chemical shifts $\delta_{\alpha-^{13}C}$ and especially $\delta_{^{13}CO}$ make it possible to identify very reliably complexes of types (I) and (II) in solutions, since the relative changes in the chemical shifts are small on passing from one solvent to another and on replacing an internal standard by an external one, which is an advantage of this method over ^1H NMR spectroscopy. Secondly, the ^{13}C NMR spectra yield additional important information about the structure and distribution of charges in the acyl cations $RCO^{\oplus}$.[7,81]

The ^{13}C NMR spectrum of a solution of the salt $CH_3{}^{13}CO^{\oplus}SbF_6^{\ominus}$ (53% isotope enrichment) in liquid HF was first described by Olah,[27] who erroneously attributed the signal of the carbonyl carbon atom $\delta_{^{13}CO}$ = 194 p.p.m. observed in the spectrum of this solution (quartet with $^2J_{C-C-H}$ = 6.3 Hz) to the $CH_3CO^{\oplus}$ ion. The signal with δ = 152 p.p.m. observed in a strong field, also present in the spectrum of this solution (however, this was reported only in a later communication[82]), was assigned by the authors to the product of the hydrolysis of the acylium salt $RC(OH)_2^{\oplus}$. In a study of the ^{13}C NMR spectra of acetic and benzoic acids in sulphuric acid and oleum at different concentrations, Masiel and Traficante[83,84] also observed two signals in the region of $\delta_{^{13}CO} \simeq$ 190 and 150 p.p.m. Despite Olah's assignment,[27] the signals observed in a weak field were assigned, in conformity with the data of Deno et al.,[85] to the protonated acid ions $RC(OH)_2^{\oplus}$. The logic of the studies of Masiel and Traficante[83,84] and the data of Deno et al.[85] concerning the formation of acylium ions from carboxylic acids in an $H_2SO_4-SO_3$ medium with a high acidity seemingly led to the conclusion that the $\delta_{^{13}CO} \simeq$ 150 p.p.m. signal, arising in the presence of a high content of SO_3 in the H_2SO_4 solution, should be attributed to acylium ions. However, Olah's incorrect assignment prevented the authors from arriving at this conclusion. They were forced to conclude that acylium ions could not be observed and the mysterious signal with $\delta_{^{13}CO} \simeq$ 150 p.p.m. remained unidentified.

The study by Traficante and Masiel[84] forced Olah to return to the problem of the identification of the acylium ion. For this purpose, a joint ^{13}C and ^1H NMR study of RCOOH solutions in the "super-

acid" HSO_3F-SbF_5 was undertaken.[80,82] It was shown clearly that at $T < -30$ °C the above solvent contains only the protonated acid ions $RC(OH)_2^{\oplus}$ characterised by $\delta_{C^1H_3} = 3.2$ p.p.m. and $\delta_{^{13}CO} = 190$ p.p.m. [for $CH_3C(OH)_2^{\oplus}$]. At a higher temperature, the acylium ions with $\delta_{C^1H_3} = 4.2$ p.p.m. and $\delta_{^{13}CO} = 148$ p.p.m. are in equilibrium with the above species. These data agree with Traficante's observations and demonstrate that the unassigned signals in the region of 150 p.p.m. should be attributed to the acylium ions $RCO^{\oplus}$.

The validity of the assignment of the 150 p.p.m. chemical shift to the carbonyl carbon atom of acylium iodide was later demonstrated by solid-phase ^{13}C NMR for the ionic salt $CH_3CO^{\oplus}AlBr_4^{\ominus}$.[86]

Table 7 presents the principal characteristics of the ^{13}C NMR spectra of certain acylium salts and coordination complexes. It shows that the ^{13}CO NMR signal of the $RCO^{\oplus}$ cations is usually observed in the range 145–157 p.p.m. The upfield shift of this signal relative to RCOF or RCOOH (this was the cause of the initial confusion as regards the assignment) is due to the change in the hybridisation of the carbonyl carbon from the sp^2- to the *sp*-hybridised state (see Section IV).

Table 7. Parameters of the ^{13}C NMR spectra of the acylium salts and the coordination complexes (the chemical shifts are quoted in p.p.m. relative to TMS).

System	Solvent	Assignment	^{13}C NMR spectroscopic data			Refs.
			δ_{CO}	$^1J_{CCH}$	$\delta_{\alpha\text{-}C}$	
CH_3COF			163		18	[28]
$CH_3COF \cdot SbF_5$	SO_2-SbF_5	$CH_3CO^{\oplus}$	148	9.3	5 *1	[81]

PhCOOH	HSO_3F-SbF_5	$PhCO^{\oplus}$	154			[81–84]
		$PhC(OH)_2^{\oplus}$	183			

*1 $^1J_{CH} = 147$ Hz for the cation $CH_3CO^{\oplus}$.

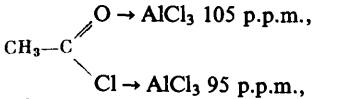
*2 In solution in HF, the values of δ_{CO} for the acetylium cation and the coordination complex are respectively 151 and 193 p.p.m.

*3 The ^{13}C chemical shifts for the *ortho*-, *meta*-, and *para*-, carbon atoms of the aromatic ring are respectively 141, 133, and 149 p.p.m.

*4 The ^{13}C chemical shifts for the *ortho*-, *meta*-, and *para*-, carbon atoms of the aromatic ring are respectively 140, 134, and 166 p.p.m.

The ^{13}C NMR spectra also indicate a significant shielding of the α-carbon atoms of the acylium ions $RCO^{\oplus}$. Thus, for R = alkyl, $\delta_{\alpha-^{13}C} \simeq 0$ (relative to TMS) despite the presence of the neighbouring carbonium ion centre, which agrees with the calculation of electron density based on the results of X-ray diffraction analysis, also indicating a pronounced shielding of the α-carbon atom (see Section III).

Similar values of $\delta_{^{13}CO} \simeq 154-157$ p.p.m. and a similar tendency towards the shielding of the C(1) atom of the aryl group ($\delta = 80-90$ p.p.m.) are characteristic of the $ArCO^{\oplus}$ cations. The appreciable contribution of ketene-like forms to the $ArCO^{\oplus}$ structure is indicated by the chemical shift of the carbon atoms in the 2- and 4-positions in the aryl group (see the footnote to Table 7). Evidently the latter are appreciably deshielded and the maximum positive charge is located on the atom attached to the electron-donating group.[84]



The formation of the type (II) complexes $RC(F)=O \rightarrow SbF_5$ (II) [or the protonated acids $RC(OH)_2^{\oplus}$] does not entail changes in hybridisation and the downfield shift of the signals observed in such cases ($\delta_{^{13}C-O\rightarrow} \simeq 190$ p.p.m.) is entirely logical and is associated with some displacement of electron density from the carbonyl group to the metal atom in MX_n.

The smaller positive charge on the carbonyl carbon atom in type (II) complexes induces a smaller deshielding (acidity) of the β-H atoms and hence a smaller shielding of the α-C atoms. As a result, the ^1H NMR signals of the β-protons in complexes (II) are located at a higher field (Table 6), while the signals of the corresponding α-^{13}C atoms are at a lower field compared with $RCO^{\oplus}$ ($\Delta\delta \simeq 20$ p.p.m.[81]).

6. Non-traditional types of treatment of the NMR spectra of the $RCOX.MX_n$ systems. Hypothesis of the existence of complexes other than $RCO^{\oplus}MX_{n+1}^{\ominus}$ and $RC(X) = O \rightarrow MN_x$

It follows from the foregoing that, in the course of the study of the complexes $RCOX.MX_n$, quite a few erroneous hypotheses were put forward and various contradictions arose, which have now been to a large extent resolved. In this Section we shall consider studies which reached conclusions different from those generally accepted or which we believe to be extremely doubtful on the basis of NMR spectra. Unfortunately, these investigations have not been assessed in the literature, with the exception of Olah's study[28] quoted in a review.[7]

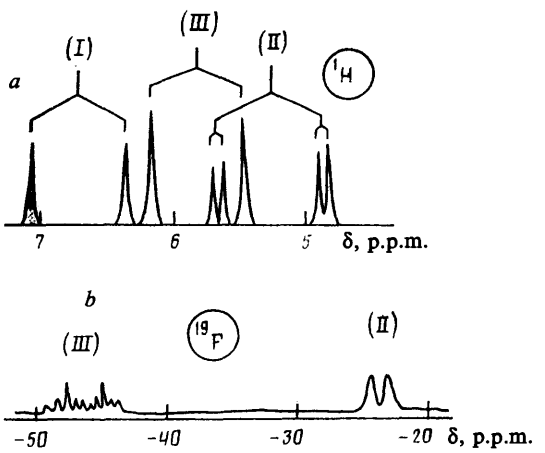
Brownstein and Glavincevsky[79] investigated the complexes formed on interaction of AcCl with $AlCl_3$ in SO_2 by ^1H and ^{27}Al NMR at −24 to −54 °C. The reported composition of the system varies as a function of the reactant ratio. For the molar ratio $AcCl/AlCl_3 \geqslant 1$, a complex with $\delta_{^1H} = 4.18$ and $\delta_{^{27}Al} = 105$ p.p.m. is formed. The structure of a donor–acceptor complex (II) was assigned to it on the basis of the similarity of its ^{27}Al chemical shift to that observed by the same workers[88] for the complex $(CH_3)_2O \rightarrow AlCl_3$. The increase in the amount of $AlCl_3$ in the system to $AcCl:AlCl_3 = 1:(1.5-3)$ leads to the appearance in solution of yet another complex to which the authors[79] attribute the appearance of the second ^1H NMR signal with $\delta_{CH_3} = 3.2$ p.p.m. and the second signal in the ^{27}Al NMR spectrum with $\delta_{^{27}Al} = 95$ p.p.m. The structure of a donor–acceptor complex with additional coordination of one $AlCl_3$ molecule to the chlorine atom was assigned to this new complex:

3.2 p.p.m.

This conclusion is based on the closeness of the chemical shift of the new signal ($\delta_{^{27}Al} = 95$ p.p.m.) to the ^{27}Al chemical shift of the salt $Me_4N^{\oplus}AlCl_4^{\ominus}$.[88]

We believe that these conclusions[79] are erroneous. In our view, the additional coordination of an $AlCl_3$ molecule to the chlorine atom of the donor–acceptor complex (II) should lead to a downfield and not an upfield shift, of the kind observed by the above workers[79] for the signal due to the protons of the methyl group in the ^1H NMR spectrum. The appearance in the ^1H NMR spectrum of signals at a low field with increase in the acidity of the medium has in fact been observed by many workers (see, for example, Deno et al.[85]). A similar behaviour has been observed for the $AcX.nAlX_3$ systems in solution in CH_2X_2 with increase in the AlX_3 concentration.[86] We also think it unlikely that $AlCl_3$ should be coordinated to complex (II) and not to the free AcCl in the presence of free acid chloride in the system whose amount has been shown to be comparable,[79] even for an excess of $AlCl_3$, to the amount of complex (II). The fact that the assignments of the ^{27}Al spectra described by Brownstein and Glavincevsky[79] are actually the opposite of those put forward by other workers,[79,89–91] who assigned the chemical shift $\delta_{^{27}Al}$ = 93 p.p.m. (Δ = 300–500 Hz) to the coordinated $AlCl_3$ ($>C=O \rightarrow AlCl_3$) and the signal in the region of $\delta_{^{27}Al}$ = 102–107 p.p.m. (Δ = 10–30 Hz) to the anion $AlCl_4^{\ominus}$ is also somewhat perplexing.

Yet another study by the same workers[16] was devoted to the investigation of the $AcCl.SbCl_5$ system in solution in SO_2 by ^1H NMR. At −76 °C, the authors observed four signals with δ = 4.23, 3.02, 12.09, and 12.76 p.p.m. The first was attributed to a type (II) donor–acceptor complex, while the chemical shifts of 3.02, 12.09, and 12.76 p.p.m. were assigned to the salt $(CH_3CO)_2CHCO^{\oplus}SbCl_6^{\ominus}$. The authors assume that the last two signals correspond to the hydrogen atoms attached to a carbon or oxygen atom in the two tautomeric forms (see Scheme 5).



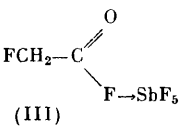


Figure 3. ^1H (*a*) and ^{19}F (*b*) NMR spectra of the $FCH_2COF.SbF_5$ system in SO_2 at −70 °C.

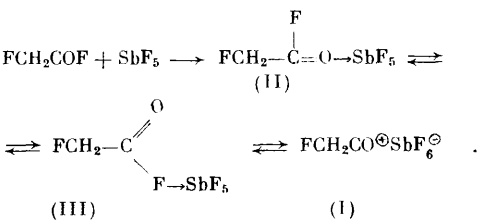

The validity of this interpretation[16] is open to serious doubt. Firstly, the observed ratios of the integral intensities (3 : 1 : 1) do not agree at all with the conclusion that $(CH_3CO)_2CHCO^{\oplus}SbCl_6^{\ominus}$ is present. Secondly, it had been shown earlier[92] that only a single signal with $\delta_{O...H}$ = 12.24 p.p.m., corresponding to the O-linked proton in the symmetrical ketene-like limiting structure, can be observed in a weak field in the ^1H NMR spectra of the salts $(CH_3CO)_2CHCO^{\oplus}MX_{n+1}^{\ominus}$ in solution in SO_2. On the other hand, the chemical shifts and the ratios of the intensities of the signals, attributed in the above study[16] to the diacetylacetylium salt, are fully consistent with the structure of the product of the hydrolysis of $CH_3CO^{\oplus}SbCl_6^{\ominus}$ — the protonated acid salt $CH_3C(OH)_2^{\oplus}SbCl_6^{\ominus}$.[74] The author's interpretation[16] of the ^1H NMR spectrum of a solution of the $CH_3COCl.SbCl_5$ system in SO_2 also appears erroneous.

In conclusion we shall consider Olah's study[28] in which the formation of a coordination complex via a halogen atom is reported:

(III)

In his study of FCH_2COF in the presence of an excess of SbF_5 in solution in SO_2 by the ^1H, ^{13}C, and ^{19}F NMR methods, Olah observed the presence of three complexes in equilibrium, to two of which the structure of the "classical" type (I) and (II) complexes was attributed, while the structure of the previously unknown complex (III) with the $RC(O)F \rightarrow SbF_5$ coordinate bond was assigned to the third complex (Fig. 3).

(III) (I)

Table 8. The assignments of the ^{13}C, ^{19}F, and ^1H NMR chemical shifts of the complexes $FCH_2CO^{\oplus}SbF_6^{\ominus}$ (I), $FCH_2C(F)=O \rightarrow SbF_5$ (II), and $FCH_2C(=O)-F \rightarrow SbF_5$ (III).

Compound	Chemical shift δ, p.p.m.				
	CH_2F			COF	
	^1H	^{19}F	^{13}C	^{13}C	^{19}F
FCH_2COF	5.0	229.4	75.4	159.7	−22.7
$FCH_2C(F)=O \rightarrow SbF_5$ (II)	5.3	229.0	75.9	162.1	−23.8
$FCH_2C(=O)-F \rightarrow SbF_5$ (III)	5.9	232.4	77.1	180.3	−46.6
$FCH_2CO^{\oplus}SbF_6^{\ominus}$ (I)	6.8	234.6	75.4	145.1	–

Table 8 and Fig. 3 present the characteristics of the NMR spectra of the $FCH_2COF \rightarrow SbF_5$ system in solution in SO_2 at −70 to −30 °C. According to the authors,[28] the NMR spectra agree with the presence of equilibria involving complexes (I), (II), and (III). The formation of a complex with structure (III) is indicated by the following data: the intermediate position of the signal due to the FCH_2 group in the ^1H NMR spectrum relative to the corresponding signals of complexes (I) and (II), the virtual absence of changes in the ^{13}C and ^{19}F NMR spectra of this group, which makes it possible to rule out the coordination of SbF_5 to the fluorine atom of the FCH_2 group, the appreciable deshielding of the carbon atoms and

especially the fluorine atom of the COF group, and also the characteristic multiplicity (doublet of quintets) of the signal in the ^{19}F NMR spectrum of this group (Fig. 3 and Table 8). The molar ratios of complexes (II), (III), and (I) depend on temperature and are respectively 20:50:30 at −70 °C and 27:38:35 at −30 °C. Direct structural evidence is apparently necessary for the final confirmation of the possibility of the existence of type (III) complexes.

Although the formation of stable type (III) complexes containing the Hal → MX_n coordinate bond cannot be regarded as rigorously demonstrated, complexes of this type have been postulated[7,28] as intermediates in the conversion of donor–acceptor complexes (II) into ionic salts (I).

VI. Factors influencing the equilibrium between ionic and coordination complexes

Evidently the knowledge of factors influencing the equilibrium (I) ⇄ (II) (especially in solutions) and hence the reactivity of the RCOX.MX_n systems is very important. Unfortunately, there have been no systematic studies on this problem.

We shall consider briefly the few literature data concerning the influence of the nature of the groups R and Hal in RCOHal, the strength of the Lewis acid MX_n, the nature of the solvent, and temperature on the structures of the complexes formed and the equilibrium between them.

1. The influence of the groups R and Hal in RCOHal and of the strength of the Lewis acid

This problem has been examined in a review.[5] It follows from experimental data that the capacity of the halide RCOHal for the formation of ionic complexes diminishes in the sequence

$$F > Cl > Br > I .$$

The tendency to form ionic salts in the RCOX.MX_n systems depends still more significantly on the strength of the Lewis acid (MX_n). Thus strong Lewis acids form predominantly ionic salts, while weaker ones give rise mainly to complexes (II). Unfortunately there is no universal series of the strengths of MX_n. One of the sequences taken from reviews[5,19] is presented below:

$$SbF_5 \simeq AsF_5 > BF_3 \simeq GaCl_3 \simeq SbCl_5 \geqslant AlCl_3 > PF_5 \simeq TiCl_4 > BCl_3 .$$

strength of Lewis acid

The quantitative influence of the acidity of the medium on the stability of the acylium salts formed in the RCOOH − H_2SO_4 − SO_3 systems has been investigated by French workers.[93] The results of studies by ^1H and ^{13}C NMR and IR spectroscopy agree fully with one another and with the studies of Deno et al.[85] and Traficante and Masiel,[83,84] indicating the presence in this system of equilibria between the free acid, its protonated form, and the acylium salt:

$$RCOOH \underset{}{\overset{H_2SO_4}{\rightleftharpoons}} R{-}C(OH)_2^{\oplus}\ HSO_4^{\ominus} \underset{-H_2O}{\overset{H_2SO_4-SO_3}{\rightleftharpoons}} RCO^{\oplus}HS_2O_7^{\ominus} ,$$

(A) (B)

(A)

^1H NMR: δ_{CH_3} = 2.8 p.p.m.,
^{13}C NMR: δ_{CO} = 194 p.p.m.,
IR: ν(CO) = 1620, 1560 cm^{-1},

(B)

δ_{CH_3} = 3.95 p.p.m.,
δ_{CO} = 152 p.p.m.,
ν(CO) = 2309 cm^{-1}.

Fig. 4 illustrates the regions corresponding to the existence of free RCOOH and the ions $RC(OH)_2^{\oplus}$ and $RCO^{\oplus}$ as a function of the acidity of the medium. As can be seen from Fig. 4, the cations $CH_3CO^{\oplus}$ are formed only for high acidities of the medium.

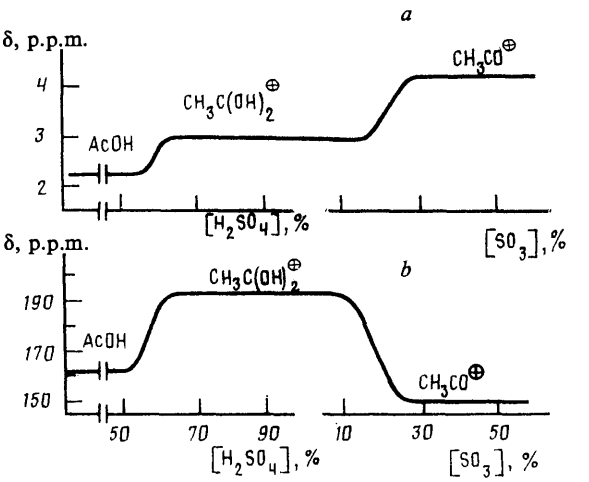

Figure 4. The region corresponding to the existence of the ions $CH_3C(OH)_2^{\oplus}$ and $CH_2CO^{\oplus}$ in the $H_2O-H_2SO_4-SO_3$ system according to ^1H NMR (*a*) [87,93] and ^{13}C NMR (*b*) [85] spectroscopic data.

The nature of the group R exerts a significant influence on the nature of the complexes formed in the RCOX.MX_n system. It follows from the analysis of spectroscopic data[5,17] that an increase in the size of the alkyl group in the sequence $CH_3 \rightarrow C_2H_5 \rightarrow CH(CH_3)_2 \rightarrow C(CH_3)_3$ leads to an increase in the content of donor–acceptor complexes (II) in the equilibrium.

Substituents R exhibiting the −*I* effect also suppress the formation of acylium salts (I). Thus a special study[94] of systems containing $AlCl_3$ and different RCOCl (R = CH_3, C_2H_5, C_3H_7, $ClCH_2$, Cl_2CH, and Cl_3C) by IR spectroscopy showed that the salts $RCO^{\oplus}AlCl_4^{\ominus}$ are not formed if pK_a < 2.9–3.2 for the corresponding RCOOH. For example, only the coordination complex $ClCH_2C(Cl)=O \rightarrow AlCl_3$ exists in the $ClCH_2COCl.AlCl_3$ system.[94]

Acylium salts with −*I* substituents can be obtained only by the reaction of RCOF with a strong Lewis acid such as SbF_5. Thus the salts $ClCH_2CO^{\oplus}SbF_6^{\ominus}$ and $BrCH_2CO^{\oplus}SbF_6^{\ominus}$ proved to be fairly stable and were isolated in a pure state.[95] The relative stability of the salts $HalCH_2CO^{\oplus}SbF_6^{\ominus}$ can be explained by the positive mesomeric effect of the halogen atoms at the α-carbon atom. According to the authors,[95] the presence of this +*M* effect stabilises to some extent the cations $HalCH_2CO^{\oplus}$ as a result of the contribution by the resonance structure in which the halogen atom acquires a partial onium character and the positive charge is delocalised:

$$Hal{-}CH_2{-}CO^{\oplus} \longleftrightarrow Hal^{\oplus}{=}CH_2{-}C{=}O .$$

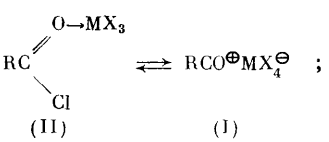
Such stabilisation is insufficient for the salts $Hal_2CHCO^{\oplus}SbF_6^{\ominus}$ and they cannot be obtained. The attempts to synthesise the salt $CF_3CO^{\oplus}SbF_6^{\ominus}$ also proved unsuccessful.[28] These salts could not be detected even spectroscopically. The earlier reports by Lindner and Kranz[96] of the synthesis of $CF_3CO^{\oplus}SbF_6^{\ominus}$ at low temperatures (< −57 °C) should probably be regarded as erroneous.

The influence of the electronic effects of the substituent on the nature of the complexes formed can be traced very clearly, in our view, also in relation to the systems $SbF_5{\cdot}F(O)C-(CH_2)_n-C(O)F{\cdot}SbF_5$ (n = 2−7).[58] For $n \geqslant 3$, the formation of the salts of the dications $SbF_6^{\ominus}{}^{\oplus}CO-(CH_2)_n-CO^{\oplus}SbF_6^{\ominus}$ is observed, while for n = 2 the inductive influence of the oxocarbenium group is already so great that only the monocationic complexes $SbF_6^{\ominus}{}^{\oplus}CO-(CH_2)_2-C(F)=O \rightarrow SbF_5$ are formed.[58]

The replacement of an alkyl group by an aryl group (without substituents in the *ortho*-position) favours the formation of donor–acceptor complexes. However, one should note that the steric effects in the aryl group in ArCOX exert a decisive influence on the structure of the complexes formed. Substituents in the *ortho*-position suppress the formation of donor–acceptor complexes, promoting the formation of acyl cations, which are less sensitive to steric hindrance. Thus the interaction of $TiCl_4$ with 2,6-dimethylbenzoyl chloride or mesitoyl chloride results in the formation of mainly the salts $2,6\text{-}Me_2C_6H_3CO^{\oplus}Ti_2Cl_9^{\ominus}$ and $2,4,6\text{-}Me_3C_6H_2CO^{\oplus}.Ti_2Cl_9^{\ominus}$,[23,67] although a weak Lewis acid such as $TiCl_4$ usually forms only type (II) complexes.[7,17]

2. The nature of the solvent

Ionising solvents favour the formation of ionic complexes (I), while weakly polar solvents favour the formation of coordination complexes (II). An effective illustration of the influence of the nature of the solvent on the structure of the complexes formed in the $RCOX.MX_n$ systems may be provided by the behaviour of the $4\text{-}CH_3C_6H_4COCl.SbSl_5$ system.[17,41] Both salts (I) and complexes (II), whose structure was demonstrated by X-ray diffraction, were isolated for this system. Thus, when $4\text{-}CH_3C_6H_4COCl.SbCl_5$ was dissolved in non-polar CCl_4 (ε = 2.2),[50] orthorhombic crystals of the donor–acceptor complex (II) were isolated, while monoclinic crystals of the ionic salt (I) were isolated from the more polar $CHCl_3$ (ε = 5.05).[50] The acylium salt is converted in CCl_4 into a donor–acceptor complex, which in turn isomerises to an acylium salt on dissolution in $CHCl_3$.



It has been established that the $RCOF.SbF_5$ systems in SO_2 consist exclusively of ionic complexes (I).[7] In liquid HF, the salts $RC(OH)_2^{\oplus}X^{\ominus}$ are also in equilibrium with the acylium salts. In polar organic solvents [nitromethane (ε = 39), nitrobenzene (ε = 35)], the $AcX.SbF_5$ (X = Cl, F) systems represent an equilibrium mixture of complexes (I) and (II). In non-polar organic solvents, the systems with SbF_5 were not investigated.

The $RCOX.AlX_3$ systems have been studied in a wide range of solvents (CH_3Cl_2, $CHCl_3$, $C_2H_4Cl_2$, CH_3NO_2). The set of the available data shows that ionic type (I) species are not formed in the solvents investigated.[9,17,63,78] Admittedly it has been reported[9] that ν(CO) = 2300 cm^{-1} vibrations with an extremely low intensity appear in the IR spectrum of a solution of the $AcCl.AlCl_3$ system in dichloroethane. However, much importance can hardly be attributed to this fact, particularly since, together with the main frequencies as regards intensity, referring to complex (II), the ν(CO) = 1800 cm^{-1} frequency of the initial acetyl chloride is present in the IR spectrum of the solution, which is usually due to secondary reactions of the $RCOX.MX_n$ systems under the influence of the salt optical components.

3. The influence of temperature

The literature data concerning the influence of temperature on the equilibria between the complexes, (I) ⇄ (II), are scanty and contradictory.

Perkampus and Weiss[97] concluded that, as the temperature is reduced, the equilibrium (II) ⇄ (I) shifts towards the formation of the type (II) complex:

(a) R = Ph, $MX_3 = AlBr_3$; (b) R = Me, $MX_3 = AlBr_3$ (−30 °C); (c) R = Et, $MX_3 = AlBr_3$ (−40 °C); (d) R = Et, $MX_3 = GaCl_3$ (−100 °C).

Thus it has been shown that the content of the salt $PhCO^{\oplus}AlBr_3Cl^{\ominus}$ is a maximum at 40–50 °C, diminishing with decrease in temperature. For other systems, such data were not quoted[97] and only the temperatures at which absorption in the region of ν(CO) for the acylium salt begins to be observed were indicated (in brackets).

On the other hand, it has been shown by ^{81}Br NQR that even at 77 K the ionic structure of the salts $CH_3CO^{\oplus}AlBr_4^{\ominus}$ is retained and that a type (II) complex is not formed.[55]

VII. The influence of the structure of acylium salts on their thermodynamic stability

The strength of the Lewis acid MX_n and the nature of the group attached to the carbonyl group exert a significant influence not only on the equilibrium between complexes (I) and (II) but also on the chemical stability of the complexes formed.

It follows from Table 1 that the maximum stability and the highest melting points are characteristic of adducts formed by the strongest Lewis acids. On the other hand, weak Lewis acids form readily fusible and relatively unstable compounds. Thus the complex $AcF.BF_3$, which has the structure of an ionic salt in the solid state, dissociates reversibly into AcF and BF_3 at 20 °C (the boiling point of AcF).

The stability of the complexes $RCOX.MX_n$ also depends on the structure of the group R. The cations $RCO^{\oplus}$, where there is no possibility of an effective stabilisation of $R^{\oplus}$, are resistant to decarbonylation. Thus thermodynamic calculation shows that the decomposition of the acyl cation is a strongly endothermic reaction and does not occur under the usual conditions:[34]

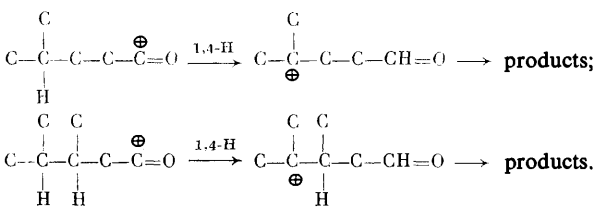
$$CH_3CO^{\oplus} \rightarrow CH_3^{\oplus} + CO,\ \Delta H = 294-340\ kJ\ mol^{-1}.$$

On the other hand, acylium salts with a group R capable of forming a relatively stable carbonium ion are extremely unstable. Thus $(CH_3)_3CCO^{\oplus}SbF_6^{\ominus}$ decomposes to a slight extent at −40 °C, while at room temperature the complex undergoes full irreversible decomposition with liberation of CO. The formation of the t-butyl cation on its decomposition has been demonstrated by NMR:[27]

$$(CH_3)_3C-CO^{\oplus}SbF_6^{\ominus} \rightarrow (CH_3)_3C^{\oplus}SbF_6^{\ominus} + CO.$$

The very high stability of the triphenylcarbenium cation is just as

responsible for the very low stability of the $Ph_3CCO^{\oplus}$ ion, which eliminates CO even at a low temperature:[98]



$$Ph_3C{-}CO^{\oplus} \rightarrow Ph_3C^{\oplus} + CO.$$

Similarly the complex $(CH_3)_3CCOCl.AlCl_3$ is spontaneously decarbonylated at room temperature. It is of interest that in the presence of isopentane the process is suppressed and the main pathway in the reaction of the complex becomes the formation of the ketone $(CH_3)_2CHCOCH_3$. It is believed[99,100] that the ketone detected is formed via the intramolecular 1,2-shift of the methyl group in the acyl cation, while the isoalkane is a donor of the hydride ion:

$$(CH_3)_2\overset{\oplus}{C}{-}\overset{\oplus}{C}{=}O \xrightarrow{\sim 1,2\text{-Me}} (CH_3)_2\overset{\oplus}{C}{-}C(=O){-}CH_3 \xrightarrow{+H^{\ominus}} (CH_3)_2CH{-}C(=O){-}CH_3.$$

Similar intramolecular rearrangements apparently occur in the familiar alkane carbonylation reactions catalysed by Lewis acids.[101]

Together with the intermolecular hydride transfer from RH to $RCO^{\oplus}$, an intramolecular 1,4-hydride shift from the tertiary carbon atom to the carbonyl carbon atom of the $RCO^{\oplus}$ cation can take place at temperatures in the range 60–100 °C:[102]

On the other hand, if the tertiary carbon atoms are not located in the 4-position, then an intermolecular hydride shift takes place in which another $RCO^{\oplus}$ species functions in all probability as the $H^{\ominus}$ acceptor.[102] In the case of n-alkyl groups, both intramolecular and intermolecular hydride shifts are suppressed and such cations n-$RCO^{\oplus}$ do not change under the conditions indicated.

The presence of atoms with a $+M$ effect at the α-carbon atom in the cations $RCO^{\oplus}$ destabilises the cation and, with increase in the number of such groups, the instability also increases. The salts $CF_3CO^{\oplus}SbF_6^{\ominus}$ and $F_2CHCO^{\oplus}SbF_6^{\ominus}$ cannot be detected even at −70 °C, while at −60 °C CF_4 and CF_3H—the products of the decarbonylation of these salts—were identified respectively.[28]

VIII. Conclusion

The complexes of acyl halides with Lewis acids, $RCOX.MX_n$, have a hundred year's long history. The wide scale employment of metal complexes in synthetic organic chemistry began with these particular systems.

During the 50 years which have elapsed since the synthesis of the first well characterised complex $Ac^{\oplus}BF_4^{\ominus}$, extensive factual data have accumulated in this field: a large series of ionic complexes $RCO^{\oplus}MX_{n+1}^{\ominus}$ and donor–acceptor complexes $RC(X)=O \rightarrow MX_n$ have been synthesised, the characteristic features of the structures of complexes of both types in the solid state and in solution have been investigated, spectroscopic methods for the identification of these complexes have been developed, and factors influencing the equilibrium between them have been discovered. However, many problems in this field still remain unsolved and many contradictions in the literature concerning the complexes $RCOX.MX_n$ have not been explained. The equilibria between ionic and donor–acceptor complexes have not been studied systematically, the investigations having been carried out mainly at a qualitative level. There are almost no literature data on the coordination complexes $RC(O)Cl \rightarrow MX_n$ and their role in the equilibrium

$$RCO^{\oplus}MX_{n+1}^{\ominus} \rightleftarrows RC(X)=O \rightarrow MX_n.$$

Overall, one may conclude that the $RCOX.MX_n$ systems have been studied fairly well at a qualitative level. The next stage in their investigation will probably lead to the determination of quantitative data on the equilibria existing in these systems, including equilibria with participation of relatively unstable complexes formed as intermediates.

Electrolytic deposition of metals on aluminium and its alloys

Yu Ya Lukomskii, G M Priyatkin, T V Mulina, V R Opolovnikov, V L Kiseleva, A V Kol'chugin, O L Noskova
Ivanovo Institute of Chemical Engineering

ABSTRACT. The directions of the development of the technology of the deposition of galvanic coatings on aluminium and its alloys are examined. Attention is concentrated on the immersion method with preliminary contact segregation of metallic films, which has nowadays found the greatest practical application. Studies in the theory and practice of the electrodeposition of metals on preoxidised aluminium and also the direct deposition of galvanic coatings, whose main advantage is its universality and the simplicity of the technological process, are considered.

The bibliography includes 239 references.

I. Introduction

Among metallic constructional materials, aluminium has found extensive application. During the period 1950–1980, its world prodution increased almost by a factor of 12.[1] According to forecasts,[2] the requirement for aluminium in the year 2000 will increase by a factor of 4 compared with 1980. Thus multilayer copper–nickel–chromium and nickel–chromium (or binickel) coatings are deposited on it in the production of the protective, decorative trim. In order to protect the surfaces of articles against mechanical wear, thick layers of chromium are deposited and coatings consisting of lead–tin and copper–tin alloys are used to impart antifraction properties. In order to facilitate the welding of articles, use is made of tin–lead, tin–bismuth as well as nickel and silver coatings. The latter are employed to achieve contact and surface electrical conductivity in articles. Brass coatings are deposited on aluminium to facilitate the firm adhesion of its surface to rubber in hot pressing. Threaded aluminium articles are zinc-plated to prevent seizing. Protective cadmium and zinc coatings have been recommended for units where the aluminium components are coupled to components made of other metals in contact with which the corrosion of aluminium is intensified. Aluminium with coatings tinted to simulate "old bronze" or "old silver" are used in the making of artistic articles.[3–9]

However, aluminium has many properties which hinder the formation of high-quality metallic coatings on its surface. These include the high affinity of aluminium for oxygen, as a result of which its surface is rapidly covered by an oxide film in aqueous solutions, and the high negative potential of the activated surface which promotes the segregation of the contact metal. Furthermore, the possibility of the harmful influence of a number of physico-mechanical factors has been noted: such as the difference between the coefficients of the thermal expansion of aluminium and the metals deposited on it, the difference between their crystal lattice parameters, and the presence of hydrogen in the main metal and in the electrolytic deposits.[3,4,9,10] Different workers assess in different ways the importance of the above factors in particular situations. However, a decisive role is attributed to the first two factors: the presence on the coated surface of an oxide film, which prevents the firm adhesion of the coating to the base, and the negative potential of aluminium following its activation, as a consequence of which the corrosion of the metal constituting the base in electrolytes is accompanied by the formation of a porous, frequently powdery, contact deposit, which only weakly adheres to the aluminium surface.

As a consequence of the above difficulties, the attempts to treat aluminium using the same procedure as in the deposition of coatings on metals such as copper or iron have not led to satisfactory results. The electrolytic deposits had an unsatisfactory structure, adhered only weakly to the main metal, and did not meet other operating requirements. Special electrolytes and procedures for the treatment of the surface to be coated are therefore used to coat articles made of aluminium and its alloys. The general problems of the technology of the deposition of galvanic coatings on aluminium have been considered in a series of monographs and review articles.[3–5,8–17,etc.] In accordance with the nature of the preparatory operations and the surface obtained as a result of the preparation, the proposed methods for the deposition of coatings on aluminium are classified as follows:[4,11]

1) deposition of coatings on a rough surface;
2) deposition of coatings on a film of contact metal;
3) deposition of coatings on an oxide film;
4) direct method;
5) other methods.

However, the change in the state of the surface during the preparatory process cannot alone solve all the problems arising in the deposition of coatings on aluminium. Certain changes are in one way or another necessary also in the deposition stage. In a series of procedures, an additional heat treatment operation, usually for the coating of components, is also introduced into the technological scheme. The practical success of a particular process is determined by the extent to which account is taken in its individual stages of the

specific properties of aluminium and of the changes in these properties on passing from one alloy to another.

II. Deposition of galvanic coatings on a rough surface

The deposition of coatings on a rough aluminium surface is apparently the oldest method. The first studies date back to the beginning of this century.[3,4,9] The roughness of the coated surface is increased by mechanical, chemical, or electrochemical treatment. The adhesion increases as a result of the greater surface area of the cathode and the creation of additional bonding with the base as a result of the mechanical fixation ("anchoring") of the deposit in hollows on the surface. Solutions of hydrochloric, hydrofluoric, and chloroacetic acids or their mixtures with sulphuric, nitric, and phosphoric acids are usually employed for the chemical treatment. Electrochemical anodic etching is generally carried out in chloride solutions, sometimes with addition of other salts and acids. Sand blasting and hydroabrasive mechanical treatments are used to increase roughness.[3,4,17,18]

The systematic studies of this method[18–24] are associated with the development of electrochemical etching processes. It has been shown that electrochemical anodic dissolution ensures a greater number, compared with chemical dissolution, of etching sites on the aluminium surface and a greater uniformity of the etching.[20] Best results have been achieved using a hot (70–90 °C) solution of sodium chloride. The introduction of sulphates and tartrates into the solution leads, according to Batashov et al.,[20] to an increase in the ionic conductivity of the surface oxide and promotes the formation of a larger surface. The etching coefficient increases approximately by an order of magnitude and reaches 30–35, which makes it possible to obtain high quality, as regards adhesion, coatings of aluminium from the usual electrolytes: copper coatings from a pyrophosphate solution or nickel coatings from a sulphate solution.[18,20]

The method involving the formation of a rough surface, as an independent type of preparation of aluminium before the deposition of galvanic coatings, is nowadays finding a very limited application for the following reasons:[3,4,9,22,23]

1) insufficient reliability in ensuring a firm adhesion of the coating to the aluminium base;

2) difficulties in obtaining lustrous decorative coatings;

3) weak protective properties of rough coatings.

However, additional electrochemical or more often chemical etching in order to increase somewhat the roughness of the surface is frequently employed as an auxiliary operation in the preparation of aluminium and its alloys for coating by other methods.[5,24–26]

III. Deposition of galvanic coatings with an intervening film of contact metal

The deposition of a film of contact metal before the electrolytic deposition of coatings on aluminium is sometimes referred to as the immersion treatment or immersion preparation. The essential feature of the method is that aluminium is immersed in a corrosive solution containing the ions of a more positive metal M^{z+}. As a result of the action of the corrosive component of the solution (OH^- ions in an alkaline medium and F^-, Cl^-, and BF_4^- ions in an acid medium), the surface of aluminium is activated, the corrosion potential shifts in the negative direction, and a contact exchange reaction takes place:

$$zAl + 3M^{z+} \rightarrow zAl^{3+} + 3M.$$

One selects conditions such that the contact metal is segregated as a thin compact film and can serve as a base on which the galvanic coating is subsequently deposited.

The appearance of the immersion method is associated with the development of the chemical treatment method. In the early studies by Work, designed to achieve a rough surface by chemical methods, it was noted that certain etching solutions with a high content of a salt of a more positive metal not only make the surface of aluminium rougher but also form a contact film, which facilitates the electrodeposition process.[9] At the present time, there exist recommendations concerning the deposition of zinc, tin, nickel, copper, and other metal films. However, only some of them have found a wide-scale practical employment. The technological process involving the deposition of coatings includes the cleaning of the coated surface, the deposition of a film of contact metal, and the electrodeposition of the coatings. In some processes, provision is made for a concluding heat treatment.

The following factors which make it possible to obtain high quality galvanic coatings have been noted. When aluminium is immersed in a corrosive solution for the segregation of the contact metal, a passive film prevents the normal course of the deposition of the metal and the adhesion of the deposit to the base is removed from its surface. The contact metal protects the surface of aluminium against reoxidation. The etching of the aluminium surface in the course of the contact exchange is non-uniform, which results in an increase of its microroughness and improves the conditions for the preparation of coatings firmly adhering to the base. The principal disadvantage of the method is associated with the fact that the contact exchange process and hence the structure of the film depend on the composition of the alloy to be coated. In the deposition of films on different aluminium alloys, it is therefore necessary in many instances to alter the composition of the solutions, the conditions, and sometimes also the procedure for the preparation of the surface.

1. Alkaline solutions

OH^- ions are the strongest activators of aluminium. The activating capacity of alkaline solutions reaches maximum values at pH 15–16 (concentration of alkali 5–7 M). Under these conditions, the rate of the self-dissolution of aluminium at a corrosion potential of $-(1.4-1.8)$ V is 150–170 g $m^2 h^{-1}$.[27–29] The decrease in the rate of dissolution at higher concentrations of alkali is mainly attributed to the formation on the surface of the metal of solid aluminates or their hydrolysis products.[27] $[Al(OH)_4]^-$ is usually quoted as the final product of the overall aluminium dissolution reaction in alkalis:

$$Al + 4OH^- \rightarrow [Al(OH)_4]^- + 3\bar{e}.$$

Another formulation of this reaction, in which the final product is the anion AlO_2^-, can also be encountered. However, this form of formulating the reaction is more arbitrary, because the existence of the above species in aqueous solutions is regarded as unlikely.[30]

The study of the mechanism of the corrosion of aluminium in alkaline solutions has led most investigators to the conclusion that this process proceeds via a stage involving the formation of an

intermediate passive oxide or hydroxide film.[31–33] According to the results of Heusler and Allgaier,[33] in weakly alkaline solutions the film has the structure of bayerite while in strongly alkaline solutions it has the structure of hydrargillite, the rate of corrosion being limited by the process

$$Al(OH)_3 + OH^- \rightarrow [Al(OH)_4]^-.$$

The rate of self-dissolution remains constant within a wide range of potentials. The possibility of the dissolution of aluminium via an active mechanism even at very negative potentials is doubtful[34] and this term is frequently used merely to characterise the high rate of the process. Studies with the aid of rotating disc electrodes have demonstrated a significant influence of the diffusion factor—the supply of OH^- ions to the corroding metal—on the rate of dissolution. It has been suggested that contact films of zinc, tin, copper, and nickel be deposited on aluminium from alkaline solutions.

The commonest method of deposition of a contact metal film on aluminium is the zincate treatment. This method (it has been described in detail[3,9]) was proposed in the USA by Hewitson in 1927. In the USSR, the zincate preparation was first studied in detail by Lainer.[9] At the present time, most publications are devoted to this process. Wide-scale studies are being carried out on the mechanism of the zincate treatment process and new improved electrolytes are being proposed.[35,36]

The zincate treatment involves the immersion of the aluminium article in a solution of sodium zincate. In an alkaline solution of sodium zincate, the surface of aluminium is activated and a film of contact zinc is formed. In an alkaline solution, zinc exists in the form of complex ions and its deposition potential is very negative, which promotes the formation of a compact and thin contact film without deep etching of the main metal. Account is also taken of the favourable ratio of the crystal lattice parameters of the two metals.[3]

In the simplest case, the zincate solution consists of sodium hydroxide and zinc oxide. The thickness and compactness of the zinc film depend on the concentration of the solution, the ratio of the components, temperature, and the period during which the aluminium articles are maintained in the solution. Solutions containing from 5 to 100 g $litre^{-1}$ of ZnO are employed. In concentrated zincate solutions, it is easier to obtain high quality films. Such solutions do not require frequent changing or correction but their high viscosity hinders the washing of the surface and the treatment of articles with a complex profile. On the other hand, dilute ZnO solutions require more careful technological monitoring. The higher the concentration of OH^- ions, which form a complex with zinc, the smaller the thickness and the greater the compactness of the film. It is therefore recommended that a higher ratio of OH^- to zinc ions be maintained in dilute zincate solutions. With increase in process temperature and the exposure time, the thickness of the films increases. The process is generally carried out at room temperature. The duration of the treatment depends on the composition of the coated alloy. For an inadequate exposure, there is insufficient time for the contact coating to cover the main metal and, when the exposure is too long, a thick loose film is produced.[9]

An advantage of the zincate treatment is that it is possible with its aid to coat articles made of both pure aluminium and its alloys. The solutions employed are simple in composition and are cheap. The principal disadvantages are associated with the high percentage of rejects, because of poor adhesion of the coating in the treatment of many alloys,[5,37] and with the low corrosion stability of the zinc film.[3,38,39] In order to obtain a film firmly adhering to the base, careful maintenance of the treatment conditions is required. Best results are obtained on alloys containing copper and manganese. On high-silicon alloys (more than 12% of silicon), it is not possible to achieve a satisfactory adhesion.[9] According to the literature,[8,38] the greatest wastage is on alloys containing electronegative metals: zinc and particularly magnesium. In such cases it is recommended that the treatment be carried out in other contact zinc-plating solutions.[8] The low corrosion stability of the aluminium–zinc–galvanic coating system is associated with the fact that the zinc layer behaves in most cases as the anode both in relation to the coating and to the main metal. In the presence of perforating pores in the coating, the zinc film begins to dissolve vigorously in the first place exerting a protecting effect against the corrosion of the base and the coating. The corrosion of zinc leads to the swelling of the coating caused by the corrosion products.[38,39] Studies carried out to improve the zincate preparation are designed to eliminate the above disadvantages.

The main aspect of the improvement of the zincate treatment consists nowadays in the use of modified zincate solutions, which contain modifying additives: iron, nickel, copper, cobalt, lead, and other metal salts and nitrates, sulphides, and cyanides. The addition of metal ions improves the corrosion properties and structure of the zinc film, as a result of the latter becoming alloyed. Organic compounds are also introduced into zincate solutions: amines, acids, alcohols, and others. A correlation has been noted between the quality of the film and the corrosion potential difference between the film and the coated alloy in the zincate solution. The lower this difference, the sooner should the zinc displacement process be completed and the denser and thinner the zinc film. Although this postulate cannot be regarded as rigorous, it usually holds.[8] It has been shown[40] that, under the conditions of diffusion-dependent limitations, a loose zinc film is formed, whilst under the conditions of kinetic limitations to the rate of the process a compact film is produced. In the presence of modifying agents, the initial potential difference between the zinc film and aluminium diminishes and in the course of the contact treatment it approaches zero, which leads to the retardation of the contact exchange in the course of time. In modified zincate solutions a rigorous maintenance of the duration of the operation is therefore not required and it depends less on the type of alloy to be coated.[41] At the same time, the small potential difference between the zinc film and the aluminium base in the modified solutions, in the treatment of alloys containing magnesium and zinc, leads to the need for additional cathodic polarisation of the aluminium components in the zincate bath.[38]

One of the first most successful modified zincate solutions contains added iron(III) chloride and a tartrate salt.[9] The zinc film deposited from this solution contains a small amount of iron, which increases the corrosion resistance and compactness of the film. The tartrate salt binds the iron ions into a complex, preventing their precipitation in the alkaline solution, and also regulates the rate of formation of the deposit and its structure. The solution can be used to coat alloys which are coated unsatisfactorily in the unmodified zincate solution. Very satisfactory results have been noted for alloys containing magnesium or both magnesium and silicon.

Modified zincate solutions containing copper and nickel complexes (mainly cyanide complexes) have come to be most widely used abroad in recent years. It has been noted that these additives regulate the potential difference between the aluminium alloys and the zinc film,[41] diminish the thickness of the film,[36,42] improve the

lustre of the electrolytic metal deposits,[36,43] and appreciably increase the strength of the adhesion of the coating to aluminium.[36,42,44] Copper and nickel are also effective alloying components which increase the corrosion resistance of the films.[36] For example, in the "Bondal" process, the compact deposit consists of 86% of zinc, 8% of copper, and 6% of nickel, while in the "Bettel" process it consists of 90% of zinc, 5% of copper, and 5% of nickel.[36] It has been noted[38,42,45] that zincate solutions modified by copper and nickel cyanides can be used to coat aluminium alloys containing silicon, magnesium, and zinc.

Organic components are sometimes introduced into the zincate solutions. A wide range of organic additives, functioning as complex forming ligands and surfactants, have been investigated.[3,46] Organic additives make it possible to use more economical dilute zincate solutions and ensure the formation of a thin, compact zinc film strongly adhering to the base.

In a series of technological processes using the zincate method for the preparation of aluminium, provision is made for the treatment of the articles after the deposition of the electrolytic coatings. The influence of such treatment on the quality of the coatings has been investigated by Lainer.[8] Lainer attributes the increase in the strength of adhesion during the heat treatment to the formation of a diffusion layer at the main metal–coating interface. A temperature of 200–250 °C and a treatment time of 30 min are recommended as the optimum conditions for the heat treatment in the nickel plating of aluminium.

Coatings with a more stable quality are obtained in the double zincate treatment of aluminium. It involves the removal of the contact zinc film from the article in nitric or sulphuric acid solutions and the retreatment of the article in a zincate solution. The potential difference between the base and zinc in the case of the double zincate treatment is smaller than in the single treatment. A thinner and denser film is obtained. The process was first investigated by Edwards and Swanson.[47] At the present time, this procedure is applied widely when both the usual and modified zincate solutions are employed.[5,43,48,49] It has been noted that in a number of instances, when after the single treatment the coatings adhere inadequately to the base, the double zincate treatment yields satisfactory results. In some instances, the double zincate treatment ensured the same strength of adhesion of the coating to the base as the single treatment with subsequent heat treatment.[9,50] According to Ref. 51, the use of the double zincate treatment makes it possible to obtain a strength of adhesion which is not inferior to the strength of the main metal. The disadvantages of the double zincate treatment are the increase in the number of technological operations and the additional consumption of reagents.

Aluminium articles coated by a zinc film are frequently copper-plated and electrolytically and chemically nickel-plated; chromium, cadmium, and silver plating as well as coatings consisting of other metals are used more rarely. For the deposition of electrolytic and chemical coatings on a zinc film, both the usual universal electrolytes and special electrolytes yielding better results are employed. These electrolytes are less corrosive to the thin zinc film, which is easily damaged and decomposed in many solutions. The film is deposited immediately after the zincate treatment and careful washing of the components. It has been noted that[52,53] even a short exposure of components with a zinc film to air can reduce greatly the strength of adhesion. The characteristics of a set of special electrolytes are presented below.

Weakly alkaline cyanide electrolytes with pH < 10 having an increased content of free cyanides and added tartrates are recommended for copper plating. It is also recommended that the components be immersed in the electrolyte with current flowing as well as an initial current pulse.[4,5,36,54]

Special electrolytes have been recommended for the deposition of thin electrolytic nickel coatings ("overcoats") on articles with a zinc film. Electrolytes containing citrates, which inhibit the contact exchange between the film and the nickel-plating electrolyte, have been proposed.[8] However, citrate electrolytes are expensive and unstable. Sulphate electrolytes, whose pH is in the range from 5.3 to 5.7, are more convenient for practical use. The electrolysis is carried out at 18–25 °C and at a low cathodic current density (0.5 A dm^{-2}).[52] The chloride-free sulphate matt nickel-plating electrolyte is recommended[55] for the covering of a zinc film by a thin (approximately 1 μm thick) nickel layer. An acetate-glycolate electrolyte, in which Ni^{+} ions are bound in the complex with glycollic acid, has been proposed for the deposition of a thin (2–3 μm) layer of nickel. It differs from sulphate solutions by being less corrosive and less stringent requirements have therefore to be met by the quality of the zinc film.[22,53] The electrolyte has been used successfully for the deposition of electrolytic coatings on aluminium in automatic apparatus. The mechanism of the deposition of nickel on a zinc film from such an electrolyte has been considered.[56]

As noted by Schmeling,[57] the zincate treatment is the most reliable procedure for the preparation of aluminium before chemical nickel plating. In this case, relatively non-corrosive weakly acid and weakly alkaline solutions are used for the deposition of nickel.[55,57–60] In order to reduce the corrosiveness, nickel is introduced in the form of acetate and a large amount of ligands, for example, citrates[59] or lactates,[60] is introduced. When aluminium components with a zinc film are immersed in a chemical nickel-plating solution, the nickel deposition process does not begin immediately. The induction period, lasting usually 10–20 s, is caused by the negative potential of the surface of the component (about −0.75 V), which arises on dissolution of the zinc film. The dissolution of zinc is accompanied by the contact liberation of nickel and the gradual displacement of the potential into the positive region as far as −(0.4–0.45) V (depending on the composition of the aluminium alloy, the thickness of the zinc film, and the composition of the chemical nickel-plating solution). The potential stabilises at this value and the chemical nickel-plating process begins.[58–61]

It has been established[58–61] that the zinc film dissolves almost completely in the chemical nickel-plating solution, but most of the dissolved zinc is subsequently chemically reduced forming the so called "zinc-enriched layer". The thickness of this layer varies from 50 to 300 nm. At the same time, the correlation between the thickness of the "zinc-enriched layer", on the one hand, and its zinc content and its adhesion, on the other, has not been observed. In order to increase the reliability of the adhesion of chemical nickel coatings, it is recommended[55] that, after the zincate treatment, the components be activated for 10–15 s in very dilute sulphuric or sulphamic acid solutions.

Analysis shows that the zincate treatment is widely used both in the USSR and abroad. This procedure is proposed as the main method or one of the main methods for the preparation of aluminium and its alloys before the deposition of electrolytic coatings in modern textbooks of electroplating,[8,62,63,etc.] in monographs,[3,4] in review articles on the coating of aluminium,[48,64–66,etc] and in the Standards of the USSR,[67] the USA,[65] and other countries. The compositions of modern zincate solutions are not as

a rule fully revealed by foreign firms. The solutions are prepared from compositions made up by the producer firm in a dry form or in the form of concentrated solutions.[48] The "Bondal", "Bettel", "Persal", and other processes have found extensive applications. At the same time, the disadvantages of the zincate treatment noted above have stimulated studies designed to devise other processes. This trend is particularly characteristic of the Soviet Union, where the number of studies on the zincate treatment since the 1950's has diminished sharply and the efforts of investigators are concentrated on the development of new technological processes.

In the 1960's, treatment in another type of alkaline solutions (stannate solutions) began to be applied—here aluminium components are coated by a film of contact tin. These films have been mainly used as independent coatings for the improvement of the antifriction properties of the aluminium surface.[3,9,68] The first communications[69,70] concerning the successful use of the stannate treatment before the deposition of electrolytic coatings on aluminium date back to 1964–1965.

The technological process for the coating of aluminium using the stannate treatment includes the cleaning of the aluminium surface by traditional methods, contact treatment in the stannate solution, coating with bronze in a cyanide electrolyte, and copper plating in a cyanide bath.[41,48] In order to avoid the hydrolysis of stannate in the film of solution on the surface of articles, it is recommended that they be transferred to the bronze-coating bath without preliminary washing.[41,48,71] Stannate treatment processes ("Alstan 80" and "Alstan 80A"), in which the thin film is deposited electrochemically in a stannate solution, have appeared in recent years.[48]

Studies[72,73] have demonstrated an appreciable influence of the kinetics of the tin liberation process on the adhesion of the coatings. It has been noted[73] that, in the stannate treatment, there is an initial rapid dissolution of aluminium induced by the high content of free alkali and the elevated temperature of the solution. During the first 10–20 s of the process, about 2000 aluminium atoms are dissolved per deposited tin atom. Subsequently this ratio is altered rapidly, reaching 1:6. At the same time the rates of dissolution of aluminium and of the evolution of hydrogen are reduced, which can be explained by the coverage of the main metal by the contact deposit of tin. The tin deposition process begins on the electropositive components of the alloy. The marked influence of impurities and alloy components on the stannate treatment process is responsible for the dependence of the conditions in the stannate treatment on the type of coated alloys.

Compared with the deposition of zinc from zincate solution, the contact deposition of tin from stannate solution is much slower and less uniform, while the films formed are thinner and more porous. In order to accelerate the deposition of tin and to increase the number of crystallisation centres, the aluminium particles in stannate solutions are sometimes subjected to additional cathodic polarisation. After coating with bronze and subsequent copper plating, the intervening layer between aluminium and copper consists of a tin-enriched bronze.[39]

Modern solutions for stannate treatment contain, together with the main components (sodium stannate and the free alkali), mixtures of additives, usually organic ligands and surfactants, which regulate the structure of the deposit.[74] The solutions used in the technological process are prepared as a rule from compositions supplied by the manufacturers. The commonest compositions are Alstan and Alstan 20 and 30 for the cleaning of the surface, Alstan 70, 75, 80, and 80A for the deposition of tin, and Alstan 71 for the electrolytic coating of tin by a layer of bronze.[39,42,75,76]

The main advantage of the stannate treatment over the zincate treatment is that it can be used to deposit coatings on articles employed under more severe climatic conditions. The tin film is more resistant to corrosion than the zinc film. However, more expensive and scarce reagents are used for the preparation of stannate solutions and the latter are relatively unstable, being hydrolysed, and therefore have to be changed frequently. The conditions in the stannate treatment also depend on the type of alloy coated. Thus, in the coating of aluminium–silicon and aluminium–magnesium alloys, such treatment yields unsatisfactory results. Although the stannate process produces contact films of higher quality, it is therefore recommended only in special applications where a high cost is justified.[39,41,77]

The stannate treatment has not found extensive applications in the USSR. Studies on the stannate treatment process have been carried out at the Academy of Sciences of the Lithuanian SSR and at the Leningrad Polytechnic Institute. The possibility of using pyrophosphate electrolytes in the stannate method for the electrolytic deposition of bronze and copper coatings has been demonstrated.[71,78]

Alkaline solutions are also recommended for contact deposition of copper and nickel films on aluminium, but their use is more limited compared with zincate and stannate solutions. In order to ensure the solubility of Ni^{2+} and Cu^{2+} compounds in an alkaline medium, an excess of ligands is introduced into the solution. It has been suggested in studies carried out in recent years that amines be employed as such ligands. An ammine electrolyte for the contact copper plating of aluminium and its alloys has been developed at the Kharkov Polytechnic Institute.[79,80] In this solution the OH^- ions have a decisive influence on the morphology of the deposit: at pH < 11.9, copper is hardly deposited, while at pH > 13.5 a dark, loose coating is produced. Thus the working pH range is 11.9–13.5. The optimum thickness of the copper deposit is 1.3–1.5 μm. The sublayer of copper ensures the firm adhesion of the subsequent electrolytic deposit to aluminium, although it can be used also as an independent coating. A similar electrolyte for the contact nickel plating of aluminium and its alloys has been proposed in the USA.[81] Ammonia and organic amines are used as ligands in this instance. The treatment is carried out at a pH of about 12 and at room temperature. According to the authors data, the contact nickel film ensures the effective adhesion of the subsequent electrolytic nickel coating to the base.

2. Acid fluoride and fluoroborate solutions

Aluminium dissolves in acid media also with formation of an intervening oxide film.[31] The activating capacity of H^+ ions is much lower than that of OH^-. According to the studies of Thomas and co-workers,[82,83] this factor can be explained by the fact that in the presence of H^+ only the hydroxo-groups forming part of the compositon of the surface oxide are highly reactive, the $Al-\underset{\displaystyle H}{\underset{|}{O}}-Al$ groups are stable, while the $Al-\underset{\displaystyle Al}{\underset{|}{O}}-Al$ oxo-groups are very stable.

Anions may catalyse the aluminium dissolution process. Among them, fluorides are the most effective. In the presence of fluoride, the rate of dissolution of aluminium increases greatly, while the corrosion potential shifts to the negative region as far as −(1.2–1.35) V. The activating capacity of fluorides increases with increase in concentration but in highly concentrated solutions it falls again owing to the formation of a film of fluoroaluminates.[84] The intervening oxide film on aluminium also contains fluorides, whose

concentration diminishes from the outer surface to its barrier component.[85] According to Wiedmer and Grauer,[86] the rate of the dissolution is limited by the supply of the fluoride to the surface of aluminium and by the heterogeneous-phase interaction of the fluoride with the oxide.

Heiman[87] demonstrated the possibility of the contact deposition on aluminium of zinc, cadmium, tin, and copper films from fluoride-containing solutions and their use for the subsequent electrolytic deposition of other metals.

A new technology for the tinning of aluminium wire has been introduced. It involves the contact deposition on a pre-cleaned surface of the metal of a sub-layer of tin from a highly acid fluoride solution. The tin sublayer is coated with copper in a cyanide bath and the wire is then tinned in a fluoroborate electrolyte.[88] A technology for the tinning of aluminium wire has been developed and tested under semi-industrial conditions. Its main operations are the deposition of a film of zinc–nickel alloy from a weakly acid fluoride-containing solution, electrolytic copper plating in a pyrophosphate electrolyte, and tinning.[89] It was noted that both technologies ensure the formation of high quality coatings which withstand welding.

A series of fluorobroate solutions have been proposed for the contact deposition of zinc and its alloys with nickel. Fluoroborates are also effective activators of aluminium, being somewhat inferior in this respect to fluorides.[87] High quality deposits of contact zinc can be obtained from a solution of zinc fluorobrate at pH 3.0.[8] In order to improve the quality of the film, nickel and ammonium fluoroborates are added to the solution.[3,90,91] A solution proposed in a patent[91] is used in the Limeda Al biological process for the deposition of a zinc–nickel alloy film (30–40% of nickel) on aluminium. The articles are immersed in the solution initially without a current and then a brief electrodeposition of the alloy is carried out. In order to increase the strength of adhesion of the film to aluminium, it has been suggested that triethanolamine[92] or Sintanol DS-10[10] be introduced into the solution. It is recommended that, before the contact treatment, etching be carried out in a solution containing fluoroboric acid.[25] Electrolytic coatings can be deposited on the contact film of the zinc–nickel alloy from relatively non-corrosive electrolytes whose pH is in the range 4–10. Best results are obtained for copper plating in a pyrophosphate electrolyte and for nickel plating in a sulphate electrolyte.

By virtue of certain advantages over the zincate treatment, the Limeda Al technology has found applications in a number of undertakings in the USSR. The lower porosity of the film and the improved corrosion reistance of the coatings should be included among the advantages of this technology,[93–95] while its disadvantages comprise the more complex preparation and use of the solutions and also the need to maintain different treatment conditions for different aluminium alloys.[41]

The influence of various factors on the adhesion of electrolytic coatings to aluminium, treated in fluoroborate solutions for contact deposition, has been investigated in recent years.[95–101] According to the authors of these studies, the adhesion of coatings to the main metal is determined by the compactness of the structure of the contact film and is independent of its thickness. If the contact film is not continuous, then on the sections where it is absent the adhesion is unsatisfactory. On the other hand, on the sections where the zinc–nickel alloy film is in contact with the base, the strength of adhesion exceeds the intrinsic strength of aluminium. The adhesion can be impaired by partial etching of aluminium under the contact deposit caused by over-exposure to the fluoroborate solution or by the treatment with a corrosive electrolyte in the deposition of the coating.

3. Acid chloride solutions

Chlorides are effective activators of aluminium in an acid medium. According to the classification proposed by Davydov and Kamkin,[102] chlorides are anodic-anionic activators. In this case activation takes place as a result of the electrical breakdown of the passive film, which can occur even at stationary potentials of $-(0.4-0.65)$ V. It has been noted[103] that, for the activation mechanism indicated, there is a possibility not of a decrease of the thickness of the passive film but merely of an increase in its defectiveness. The latter factor leads to the local character of the dissolution of aluminium accompanied by an increase in the roughness of its surface. Chloride solutions have been proposed for the contact deposition of nickel, iron, manganese, copper, and a number of other metals.[3,9] The contact deposition of nickel on aluminium from a solution of nickel chloride in phosphoric acid has found the greatest practical application in the USSR.[104,105] The nickel film serves as a base for the subsequent chemical or electrochemical nickel plating. The corrosion resistance of the coatings deposited on contact nickel is much higher than that of the analogous coatings deposited on a zincate film.[106,107] However, the employment of the method on a wider scale is prevented by the inadequate reliability of the adhesion of the coatings to the base comprising certain alloys.[108] In a number of instances, it is altogether impossible to obtain high quality contact films. It has been shown that heat treatment improves the strength of adhesion of the coatings to the base.

Solutions for the contact copper plating of aluminium, containing chlorides as activators, have been investigated.[79,109–111] Thus an oxalate electrolyte, incorporating a small amount of chlorides, has been recommended for this purpose.[111] Copper deposits up to 5μm thick adhere satisfactorily to the base and can be used both as a sublayer for the subsequent deposition of electrolytic coatings and as an independent coating, for example, for welding.

IV. Deposition of galvanic coatings on oxidised aluminium

The method consists in the anodisation (sometimes chemical oxidation), after preliminary cleaning, of the surface to be coated followed by the deposition of the electrolytic coating. The process was developed in the 1930's mainly as a result of the studies of Fischer (quoted after Ref. 17), Travers,[112] and Kudryavtsev.[113] Phosphoric acid (more rarely oxalic, sulphuric, chromic, and other acids) is usually employed nowadays to obtain the anodic oxide, but mixtures of acids are also used.[3,17,24,60] Nickel, copper, cadmium, silver, iron, zinc, and chromium are deposited on the anodised aluminium.[11,17,114] Copper plating in a pyrophosphate electrolyte and nickel plating in a sulphate or sulphamate electrolyte are commonest. Apart from the operations indicated, the technological process sometimes involves additional etching before oxidation or after it[9,113,115–118] and a concluding heat treatment of the coatings.[119,120]

An advantage of the method is the improved protecting capacity of the coatings associated with the presence of an oxide film on the surface to be coated. A disadvantage is its high sensitivity to the smallest changes in the composition of the treated alloys. The purer the aluminium, the greater the difficulties arise in its coating. For pure aluminium, anodic treatment altogether fails to yield positive

results. Certain copper-containing and cast alloys are not always coated satisfactorily. The disadvantages of the process are its relatively high cost and the need to have for anodisation special power supply sources with an increased voltage.[3,9,10] For these reasons, the method is nowadays finding only a limited application compared with the immersion method.[48] Modern studies of the deposition of metals on oxidised aluminium are directed towards the investigation of the process mechanism and the improvement of the technology in order to eliminate the above disadvantages.

1. Mechanical theory of the adhesion of electrolytic metal deposits to oxidised aluminium

The commonest is the mechanical theory of the adhesion of an electrolytic deposit to the anodic oxide film. The foundations of the theory were laid by Keller et al.,[121] who noted the dependence of the structure of the anodic oxide on the composition of the anodisation electrolyte and a number of other factors and put forward the hypothesis that the structure of the anodic oxide is the determining factor in the deposition of metallic coatings on it. It was suggested that, since the films obtained in phosphoric acid are distinguished by the presence of numerous large-diameter pores, they should yield best results also on anodisation of aluminium before the deposition of electrolytic coatings on the latter.

The theory treats the anodic oxide as a dielectric having a discrete structure. During the deposition of coatings, the electric current passes mainly through "weak sites" in the oxide layer, which consists of pores, micro-cracks, and sometimes the inclusions of more noble metals. The electrolytic deposit begins to be formed initially within the pores as finely dispersed fibres, which then grow together, forming bridges across the film. Adhesion is achieved as a result of the mechanical fixation of the coating within the pores of the oxide film, which in turn adheres firmly to the main metal.[5,9,122] These postulates have been confirmed by a number of experimental data. At the beginning of the electrolysis, the formation of an electrolytic deposit is observed only at individual points on the cathode. Owing to the high true current density, the first layers of the metal in deposition on an oxide layer have a dark and even black colour regardless of whether copper, nickel, or silver is deposited and acquire the normal form only as the coating grows. According to data of Schardein[122] and Lashmore,[123] firm adhesion is achieved when the pores of the anodic film have been completely filled with the electrolytic deposit. The electrolytic deposits obtained in the pores under these conditions have the form of intertwined tree roots.[124,125] It has been established that the complete filling of the pores of the anodic oxide by the electrolytic deposit takes place in the deposition of coatings at low current densities, apparently owing to the elimination of diffusional limitations. It has been recommended in a number of publications[123,126,127] that, in the deposition of coatings on an anodic oxide, the cathodic current density be gradually and slowly increased (in the first minutes of the electrolysis) from zero to a stationary value. A correlation has been noted between the geometrical size of the pores and the quality of the coatings. It has been confirmed that the largest and most uniformly distributed pores are present in films obtained in phosphoric acid and this explains the finding that, when the latter is used, high quality coatings are obtained.[17,24,121]

It has been established[122] that the pore diameter increases with increase in the anodisation potential. At the same time an improvement in the adhesion of the coatings to aluminium has been noted.[122,123] However, the cathodic electrocrystallisation of metals on films obtained at very high potentials (60–80 V and above) is difficult apparently due to the appreciable thickness of the barrier layer. This feature together with the decrease in the total number of pores leads to a diminution of the number of centres for the electrocrystallisation of the electrolytic deposit and to a decrease in the strength of adhesion.[24,122]

High quality coatings can be obtained starting from a specific thickness of the anodic film.[24,123] For a small thickness (i.e. for a short anodisation time), the adhesion is unsatisfactory. Kishi[24] compares this kind of coating with a tree having weak, shallow roots. Lashmore[123] suggests that the side walls of the pores make the main contribution to adhesion. With increase in the thickness of the anodic film, the lateral surface of the pores increases and thus ensures the necessary strength of adhesion. For a greater thickness of the oxide film, the electrodeposited coatings become non-continuous as a result of the decrease in the number of crystallisation centres.[24,128,129] This phenomenon is usually observed for anodic films obtained in sulphuric acid.

However, certain experimental results cannot be explained satisfactorily on the basis of the mechanical theory of adhesion. According to a number of workers,[24,123,128,129] the difference between the structures and pore sizes of the films obtained in phosphoric acid and other acids (sulphuric, oxalic, and chromic) is small. The pores in the films obtained in these acids can also be completely filled with the electrolytic deposit.[17,124,125] Nevertheless the anodic films formed in phosphoric acid ensure a much greater strength of adhesion of the coatings to aluminium. The structures of sufficiently thick anodic films on different aluminium alloys also differ little,[122] while the strength of the adhesion depends greatly on the type of alloys coated.[9,126]

It has been noted that the electrodeposition of a metal can occur not only in the pores but also on the outer surface of the film[123] as well as on the sharp edges between the hollows in the oxide.[24] These observations led to the creation of the chemical theory of the adhesion of electrochemical metal deposits to anodised aluminium.

2. Chemical theory of the adhesion of electrolytic deposits of metals to anodised aluminium

Aleksandrov, Bogoyavlenskii, and Khudyakov and co-workers[130–137] have developed a chemical theory of the adhesion of coatings to the anodic oxide film. The principal postulates of this theory have been described also in studies by foreign authors.[24,128,129,138] The theory treats the anodic oxide as a colloidal-polymeric formation with semiconducting properties, containing inclusions of anions from the anodisation electrolyte and the components of the aluminium alloys.

According to this theory, the formation of the electrolytic deposit begins simultaneously both in the pores of the oxide and on its surface. The strength of adhesion of the electrolytic deposit to the base is determined not by the mechanical fixation of the deposit within the pores of the oxide layer but by the presence of chemical bonds between the deposited metal and the components of the anodic oxide, mainly the inclusions of anions from the oxidation electrolyte.

The greatest strength of adhesion of the coatings observed when the oxide is formed in phosphoric acid is attributed to the fact that phosphate ions readily penetrate into the anodic oxide during anodisation and create active centres for the electrocrystallisation of metals. The number of crystallisation centres on such oxides is much greater than on oxides obtained in solutions in other acids. It has been observed by the tracer atom method that the number of phosphate ions incorporated in the anodic oxide can be increased by introducing a series of additives (zinc sulphate, polyethyleneimine) or

diminished (sulphuric acid) and hence the strength of adhesion of the coatings to the anodised aluminium can be correspondingly altered.[130,139–141]

The inclusion of the components of the aluminium alloys and their oxidation products in the anodic oxide creates additional crystallisation centres for the deposited metal and hence promotes an increase in the strength of adhesion of the coating to the base. It has been established that the content of the phosphate ions in the oxide increases somewhat with increase in the concentration of the alloy components, which is also accompanied by an increase in the strength of adhesion. Various alloy components promote to different extents the increase in the concentration of phosphate ions in the anodic oxide. These data make it possible to explain, from the standpoint of the chemical theory, also familiar facts such as the difficulties arising in the coating of anodised high-purity aluminium and the dependence of the strength of adhesion on the type of alloy coated.

According to the chemical theory, although the pores in the oxide film do participate in the electrodeposition process they do not play a decisive role. It has been established by X-ray diffraction and electronic spectroscopy[131] that a satisfactory adhesion of the coatings to anodised aluminium can be achieved even when the pores are only slightly filled by the electrolytic deposit. However, the details of the chemical theory have so far been insufficiently worked out to be able to reject the role of pores in the electrocrystallisation processes and in the adhesion of coatings to aluminium oxide.

A positive aspect of the chemical theory is the fact that it creates a basis for the development of a general approach to the analysis of the electrodeposition of metals on oxidised aluminium. The literature of recent years contains data confirming the postulates of both the chemical and the mechanical theory of the adhesion of galvanic coatings to anodised aluminium. It is noteworthy that fundamentally the two theories do not conflict with one another.

3. The development of technological processes for the electrodeposition of metals on oxidised aluminium

Although for reasons indicated, the method involving the deposition of metals on preoxidised aluminium is so far finding limited applications, nevertheless during the last 10–15 years the number of studies devoted to its investigation and improvement has greatly increased. The main bulk of publications were in the USSR, the USA, and Japan. Thus the American Electroplating Society included the study of the electrodeposition of metals on anodised aluminium in its main research projects: Project 41 and Project 61. The results of studies in the USA have been examined by Lashmore,[123,142] Schardein,[122] and Thomas.[143]

Analysis shows that the improvement of the processes for the deposition of coatings on aluminium with preliminary anodisation has the following main aspects: 1) the development of new electrolytes for the deposition of coatings on anodic aluminium oxide and of anodisation procedures; 2) improvement of additional operations for the modification of the anodic oxide and the preliminary preparation of the surface; 3) oxidation and deposition of electrolytic coatings in one bath; 4) combination of the anodisation process with the preliminary liberation of the metal.

Among the current studies devoted to the first aspect, mention should be made of a new technology for the silver plating of anodised aluminium in a highly productive sulphate-ammonia electrolyte,[144] a technology for the nickel plating of anodised aluminium alloys in a sulphate-tartrate electrolyte,[145] a technology for the stepwise anodisation of aluminium articles (reflectors) in a phosphate bath and for the subsequent nickel plating in a citrate electrolyte,[146] and a technology for the copper plating of anodised aluminium alloys.[147] Technological processes for anodisation and subsequent deposition of a series of electrolytic coatings (copper–nickel–chromium, copper–silver, copper–cadmium) on various aluminium alloys have been studied in detail at the Kazan Institute of Aviation and are being introduced into industry.[148–150]

Studies on the partial or complete replacement of phosphoric acid in the anodisation of aluminium by cheaper, mainly sulphuric acid, solutions are being continued. Lukashchuk and Marchenko[151,152] developed a technology for the anodisation of aluminium alloys in a sulphuric acid electrolyte with subsequent electrochemical copper plating. In order to improve the properties of the oxide films, it was suggested that activators—fluorides and fluorosilicates—be introduced into the anodisation solution. These additives increase severalfold the active surface area of the oxide and improve the strength of adhesion to aluminium and its alloys.

The technology for the coating of motor car bumpers made of high-strength aluminium–copper–magnesium alloys with nickel and chromium, developed by Wittrock,[153] has found practical applications in the USA. The first nickel layer is deposited from a sulphamic acid electrolyte on a base anodised in a mixture of phosphoric and sulphuric acids. It was noted that the use of a copper sublayer is undesirable owing to the decrease in the protecting capacity of the coating as a consequence of the enhancement of the contact corrosion in its pores. In one of the latest studies,[126] Wittrock recommends that the anodisation be carried out in a very dilute (3%) solution of phosphoric acid at a high temperature (about 60 °C) with activation of the resulting oxide in sulphamic acid. It is suggested that a sulphamate electrolyte be used for the subsequent nickel plating. The high strength of adhesion of the nickel deposits to the aluminium–zinc–magnesium alloys was noted.

The studies on the second aspect of the modification of the oxide film before the deposition of electrolytic coatings are not fundamentally new. The films are modified in the course of the activation of anodised aluminium—by treatment in dilute acid solutions. The operation became a component of the first technological processes proposed in the 1930's.[3,17] It was established[130] that, after activation, there is an increase in the number of crystallisation centres for the subsequent electrodeposition of the metal, which has a favourable effect on the strength of adhesion of the coating to the base. Best results were noted on treatment of the oxide film in fluoride solutions.

Sulphamic or sulphuric acid solutions have been proposed for the activation of the oxide films.[142,144] It has been noted[154] that the activation of the oxide in sulphamic acid makes it possible to carry out the anodisation process in sulphuric acid and to deposit the electrolytic coatings from electrolytes with the usual composition.

The oxide films can also be activated in the electrolytes for the deposition of electrolytic coatings via a.c. polarisation or by brief electrochemical treatment in solutions for chemical nickel plating.[155,156] In the new technology for the deposition of an iron–nickel alloy on aluminium anodised in phosphoric acid, the activation is carried out in the acid sulphate electrolyte for the deposition of electrolytic coatings.[157] The anodic activation in a dilute solution of hydrofluoric or sulphamic acid after anodisation in a phosphoric acid bath greatly increases the strength of adhesion to aluminium of the nickel coatings obtained in the sulphamate electrolyte.[123]

There have been studies designed to improve the preparatory operations before the deposition of the oxide film. According to Aleksandrov and co-workers,[26,158] etching in 15% hydrochloric acid before anodisation makes it possible to expand the range of permissible phosphoric acid concentrations, the current density, and the process time and also makes it possible to obtain high quality coatings, as regards adhesion, on articles anodised in other acids: sulphuric, chromic, and oxalic. The positive effect of the preliminary etching has been attributed to the increase in the porosity of the oxide films by 5–7%. There is a simultaneous increase in the roughness of the surface, which increases the area of the actual contact between the anodic oxide and the galvanic coating.[141]

The third aspect—anodisation and deposition of galvanic coatings in a single bath—is a comparatively new technological procedure proposed by Mondolfo,[159,160] Bogoyavlenskii and Khudyakov,[161–163] and others. The combination of these two operations is achieved by switching the polarity of the power source. A technology has been developed for the anodisation and deposition of a galvanic coating in a single bath in the preparation of zinc,[164] copper,[160,165–167] cadmium,[165,166] iron,[168] and chromium[169,170] coatings. It was established[164,171] that the nature of the metal cation in the oxidising bath has different effects on the properties of the anodic oxide and the adhesion of the electrolytic deposits obtained from the same electrolyte. The favourable effect of cations is attributed to their incorporation in the oxide film. On deposition of the metal, these cations are reduced, generating additional crystallisation centres and promoting the improvement of the adhesion of the coating to the base.

The advantages of the method involving oxidation and electrodeposition in a single bath consist in the absence of intermediate operations, in which the oxide can undergo undesirable changes, and in a decrease in the total number of operations.[165] However, the operation of a bath in which both oxidation and deposition of the metallic coating take place is fairly complex.

A fundamentally new aspect of the development of the method for the electrodeposition of a metal on oxidised aluminium constitutes the combination of the process involving the preliminary deposition of metals on aluminium films and subsequent anodisation. This aspect is associated with the work of the Japanese investigators Akijama, Yasuchara, and others.[138] It has been established by electron microscopy, X-ray diffraction, and spectroscopic studies that thin films of metals as well as alloy components can be incorporated on anodisation in the oxide film formed in phosphoric acid and can subsequently serve as additional crystallisation centres in the deposition of metals. Japanese workers[138] and subsequently Meckelburg[128] proposed a technology for the copper plating of anodised aluminium involving the preliminary deposition (by a contact or electrolytic process) of iron. On anodisation, the main bulk of the iron coating dissolves but a proportion of it remains as an admixture in the oxide. The preliminary iron plating increases the strength of adhesion of the electrolytic deposits to aluminium and its alloys.

In order to improve the adhesion of the coating the following treatment has been recommended: chemical zinc plating, the removal of the zinc film and anodisation in phosphoric acid, and electrolytic nickel plating.[172] It has been suggested[119] that aluminium can be subjected to an a.c. treatment in a nickel plating electrolyte. A layer of aluminium and nickel oxides is then formed on the surface of aluminium. The current is then changed from a.c. to d.c. and nickel is deposited. It was noted that the metal electrodeposition process can also be carried out in a special bath. In order to improve the adhesion between nickel and aluminium, a final heat treatment of the articles at 100–300 °C is recommended.

An advantage of the above procedure is that it makes it possible to solve the problem of the deposition of galvanic coatings with an oxide sublayer on pure non-alloyed aluminium, while a disadvantage is the increase in the complexity of the technological process.

It is noteworthy that all the proposed improvements have not so far permitted the complete elimination of the main disadvantage of the method—the dependence of the quality of the deposit on the composition of the alloy to be coated.

V. Direct method for the deposition of galvanic coatings

The direct method for the deposition of galvanic coatings on aluminium and its alloys is characterised by the absence of preliminary operations involving the modification of the surface of the base (immersion treatment, anodisation, etc.). The conditions needed to obtain firmly adhering coatings are created directly in the deposition electrolyte by selecting its composition and the electrolysis conditions, while the preliminary preparation of the articles reduces to the cleaning of the surface.

The first attempts at the deposition of electrolytic coatings on aluminium by the direct method refer to the beginning of our century. However, according to Heiman,[87] tests of old patents show that the adhesion of the coatings obtained to the aluminium base does not meet the necessary requirements. Only the direct zinc plating of aluminium in a cyanide electrolyte, proposed by Work,[173] and the Vogt process, quoted after Wernik and Pinner,[3] have found practical applications. Work[173] discovered that, when a cyanide electrolyte is used, it is possible to obtain a satisfactory deposit of zinc on a smooth aluminium surface. In order to improve the quality of the coating, he proposed the replacement of sodium hydroxide in the electrolyte by ammonium hydroxide and the introduction of gelatine as an additive. The subsequent heat treatment of the articles improved the quality of the coating.

The direct zinc plating process in a cyanide electrolyte had been used previously for practical purposes involving the preparation of multilayer coatings.[174] However, the low thermal stability of the resulting coatings and the impossibility of depositing coatings with a thickness greater than 20–30 μm was noted. According to Gruev,[175] heating of the articles above 160–170 °C leads to blistering of the electrolytic deposits.

The Vogt process, developed in 1929 (quoted after Wernik and Pinner[3]), consists of the following main operations: direct electrolytic deposition of a thin layer of zinc from a cyanide electrolyte, brief brass plating in a cyanide bath, and nickel plating in a sulphate electrolyte. In order to strengthen the adhesion of the coating to the base, the articles are subjected to a heat treatment at 230 °C. When necessary, the articles can be additionally chromium-plated. Certain improvements to the Vogt process, concerning the composition of the electrolytes and the electrolysis conditions, were subsequently introduced by Ore[176] and also Edwards and Swanson.[47] Ore[176] recommended that the articles be washed between zinc plating and brass plating and a second heat treatment after chromium plating. The principal change proposed by Edwards and Swanson[47] consists in the additional zincate treatment of aluminium and the removal of contact zinc before the direct electrolytic zinc plating. However, these improvements did not eliminate disadvantages of the Vogt process such as the impossibility of coating alloys with a high

magnesium content (in excess of 3%) and the necessity for the careful maintenance of the recommended treatment conditions.

Among the latest studies on the direct depositions of metals on aluminium, mention should be made of those of Atkinson,[177–179] which provide a preliminary basis for the selection of conditions in the electrodeposition of metals. Atkinson proposed a sulphate nickel plating electrolyte containing fluoroborate ions as the activator and polyligand pyrophosphate–oxalate–amine copper plating electrolytes. However, there is no information about the practical use of these electrolytes.

The principal disadvantage of the methods for the direct electrolytic deposition of metals on aluminium proposed previously, namely the inadequate stability of adhesion of the coatings to the main metal, can apparently be accounted for by the empirical nature and the limiting extent of the studies made.

Since the 1950's, systematic research has been prosecuted at the Ivanovo Institute of Chemical Engineering into the theory and practical application of the direct method for the electrolytic deposition of metals on aluminium.[4] The required electrochemical activity of the surface to be coated was achieved in two ways: by the corrosive interaction of the surface with the electrolyte and by the cathodic activation after switching on the current. Cathodic activation makes it possible to use less corrosive electrolytes and thus reduce the rate of the contact exchange between aluminium and the ions of the metal being deposited. A combination of the two factors indicated above yields stable results as regards the adhesion of galvanic coatings to the base, which are independent of the composition of the aluminium alloy. Under optimum conditions, the strength of adhesion is not inferior to the strength of the main metal.

The present authors' own studies demonstrated the influence of the anionic and cationic compositions of the solutions on the corrosion and cathodic activation of aluminium.[4,180–191] Fluorides are effective activators of aluminium for the deposition on the latter of galvanic coatings. It was recommended that they be introduced into the composition of the electrolytes for this purpose. The characteristics of the influence of these activators on the electrodeposition of metals and the adhesion of coatings as well as the mechanism of their action were investigated over a wide concentration and pH range. The characteristics of the contact exchange between aluminium and the ions of more positive metals present in the electrolyte were studied.

The possibility of the cathodic activation of aluminium in the direct deposition of galvanic coatings had not been established before our investigations, but in a number of instances an increase in the rate of corrosion on cathodic polarisation of the metal was noted. This effect was attributed to a change in the pH of the layer near the cathode as a result of the incorporation of protons in the passive film and its decomposition by hydrogen and also the incorporation of alkali metals into the surface of the aluminium.[192–197]

Our investigations of the cathodic activation of aluminium in the electrocrystallisation of metals[198–201] showed that, in conformity with the ideas of Kabanov and co-workers,[197] Li^+ ions exhibit the most effective catalytic activity.

On the basis of experimental studies on the adhesion of coatings, it was established that it is influenced by electrolytic saturation with hydrogen, as suggested previously. The accumulation of hydrogen at the main metal–coating interface leads to the partial pealing of the coatings in the form of hydrogen blisters. The probability of the formation of blisters increases with increase in current density and depends on the composition of the electrolyte, especially on the presence of hydrogen saturation catalysts or inhibitors. The positive influence of low concentrations of oxidants such as $K_2S_2O_8$ (in the nickel plating electrolyte) and KNO_2 (in the pyrophosphate copper plating electrolyte) has been established.[4,185,202,203] It was also shown for the first time that the introduction into the solutions for the deposition of coatings of small amounts of oxidants can reduce the rate of the contact exchange reaction as a result of the depolarisation of the cathodic corrosion process without appreciable passivation of the main metal.[4,204]

An increase in the adhesion of coatings as a function of time, associated with the escape of adsorbed hydrogen from the main metal–coating interface into the surrounding medium (ageing), has been observed.[205] This process intensifies significantly in the heat treatment of the coated articles, which is frequently used as the final operation in various procedures for the deposition of galvanic coatings on aluminium.

The specific features of the deposition of multilayer coatings on aluminium have been studied. It has been shown that the deposition of upper layers of the coating can lead to a decrease in adhesion and to the formation of blisters as a result of saturation with hydrogen and the corrosion interaction between aluminium and the electrolyte in the pores of the first layer of the coating.[4] The deposition of the upper layer of the coating, for example, cadmium, which can retain hydrogen in the system, can fully suppress the positive influence of the concluding heat treatment on the adhesion of coatings. The conditions and the sequence of the technological operations, which rule out the negative influence of the factors indicated, have been determined on the basis of the studies made.[4,206,207]

Electrolytes for the direct nickel plating, copper plating, and zinc plating have been developed at the Ivanovo Institute of Chemical Engineering and on their basis technological processes for the deposition of single layer and multilayer coatings on various aluminium alloys both in a suspended form and in a loose form in drums have been devised. The technologies thus developed have been included in the USSR Government Standards GOST 9.047-75 and GOST 9.035-84 as well as branch standards and have been applied in industrial undertakings concerned with machine construction, instrument making, and other industries.[4]

In recent years, studies in the field of the direct electrolytic deposition of metals on aluminium have expanded and a considerable proportion of new research has been carried out in the USSR. Attention has been concentrated on the technology of the copper plating and nickel plating of aluminium.

A number of investigations[208–215] were directed towards the further improvement of electrolytes for the coating of aluminium and its alloys, developed at the Ivanovo Institute of Chemical Engineering and also towards their practical application under specific industrial conditions. Thus it has been recommended that sodium sulphate be introduced as a further additive to nickel plating electrolytes;[208] the possibility of replacing sodium chloride by nickel chloride,[209] of sodium persulphate by ammonium persulphate, and of boric acid by sodium acetate[210] has been reported. Data have been published[211–213] concerning the practical use of the electrolyte for the direct nickel plating of articles in a suspended form and in a loose form in drums. It has been suggested that chlorides be used instead of zinc and ammonium sulphates in weakly acid fluoride-containing zinc plating electrolytes.[214,215]

As a result of the study of the properties of polyligand solutions, electrolytes have been developed at the Kharkov Polytechnic Institute for the direct copper plating, bright nickel plating, and

brass plating of cast aluminium alloys.[216–218] A highly productive acid electrolyte based on copper nitrate has been proposed for the direct copper plating of silumin (with subsequent nickel plating and chromium plating).[219]

A patent[220] recommends the use of a pyrophosphate electrolyte for the high speed copper plating of aluminium alloys. The strength of adhesion of the coating to the base is ensured, according to the authors, by the use of a high current density (5–10 A cm^{-2}) in the initial stage of the electrolysis, which leads to the decomposition of the oxide film on aluminium. In a series of reports,[221–224] weakly alkaline electrolytes, containing mixed copper ammine and amine complexes, have been proposed for the copper plating of aluminium articles (especially aluminium sheets). Monoethanolamine, ethylenediamine, pyridine, etc. can be used to prepare the electrolytes. The necessity for the introduction of fluorides into electrolytes in order to improve the adhesion of copper to the base has been pointed out.[223]

Riger[225] suggested a sulphate electrolyte for the direct nickel plating of aluminium and its non-highy alloyed compositions which, together with the traditional chloride and fluoride additives, contains sodium hypophosphite. When this electrolyte is used, high quality coatings up to 40 μm thick, firmly adhering to the base, are obtained. The electrolyte can also be used to deposit wear-resistant composite nickel coatings containing silicon or boron carbide particles. It has been reported[226] that a nickel coating firmly adhering to aluminium is obtained in any electrolyte of the Watts type at a temperature in excess of 150 °C. Kochman et al.[227] recommended a sulphuric acid electrolyte for the direct zinc plating of aluminium, which makes it possible to deposit both bright and black zinc deposits. This electrolyte has found practical use. A complex Niostin electrolyte, based on divalent lead salts and incorporating a reductant and surfactants, has been developed at the Institute of Inorganic Chemistry of the Academy of the Latvian SSR. The application of Niostin ensures the formation of bright coatings on a series of metals, including aluminium alloys.[228]

Technologies have been proposed in which the surface of aluminium is coated by one or two thin layers of metals deposited electrolytically directly on a cleaned surface of the base, after which other coatings are deposited on the surface treated in this way. A technology for the copper plating of aluminium wire, according to which a thin layer (up to 0.1 μm) of tin is deposited electrolytically, before applying the copper coating, from a fluoride electrolyte prepared in a mixed solvent containing ethylene glycol and water has been developed at the Cable Industry Research Institute.[229] It has been recommended[230] that a thin layer of tin be deposited on aluminium articles from an acid fluoroborate electrolyte with subsequent deposition of a bronze (from a pyrophosphate electrolyte) and other coatings from the electrolytes usually employed. In order to increase the strength of adhesion of the coatings to the base, the articles are heat-treated in the concluding stage at 275 °C for 30 min.

A method for the copper plating of aluminium involving the coating of the latter in two stages has been developed in the German Democratic Republic: aluminium is initially coated with a zinc–tin alloy (0.1–0.2 μm) from a fluoroborate electrolyte and then with copper (0.3–0.6 μm) from a pyrophosphate electrolyte at pH 8–8.5. The main copper plating is carried out in a sulphate electrolyte. This procedure is recommended for the copper plating of wire and for the deposition of multilayer protective-decorative coatings.[90] According to the data in Ref. 231, before depositing galvanic coatings the aluminium surface is covered by a layer of iron (up to 1 μm) from a sulphate electrolyte containing fluoroborates or fluorosilicates. After the deposition of the required coatings from the electrolytes usually employed, the articles are heat treated at 150–500 °C. The possibility of using the iron plating electrolytes for the deposition of independent very thick coatings has been noted. Gaynes[232] describes a technology for the iron plating of aluminium alloy with silicon in order to increase their hardness and wear-resistance. This procedure involves the initial electrolytic covering of the base with zinc and then with copper from cyanide electrolytes. Iron plating is carried out in a hot chloride electrolyte. A Hungarian patent recommends that, before depositing a thin layer of nickel from an electrolyte containing fluoroborates, the surface of aluminium should be subjected to additional electrochemical activation in an alkaline solution using non-stationary forms of current.[233]

The development of the direct method for the deposition of electrolytic coatings on aluminium has been stimulated by its simplicity, universality, and the low cost of the technology. At the same time, a considerable proportion of the processes described have been a result of empirical studies. For the development of new highly effective processes, it is desirable to investigate in greatest detail the scientific foundations of the method. There is a prospect of the development of universal electrolytes for the deposition of electrolytic coatings on steel, copper, and aluminium. The use of such electrolytes would make it possible to treat articles made of different materials on a single electroplating line and would ensure greater efficiency of the process.

VI. Other methods

In conclusion we shall consider studies unrelated to the methods listed above. For example, the electrolysis of melts[234] and preliminary deposition of a metal sublayer *in vacuo*[235] or a sublayer of chemical nickel[236] have been proposed for the deposition of coatings on aluminium. It has been recommended[237] that the surface of aluminium be subjected to cathodic activation in hydrochloric acid before depositing a nickel coating. It is suggested that in this case a metastable layer of aluminium hydride is formed on the surface of the specimen. It decomposes during the deposition of nickel, which results in the formation of a strong metal–metal bond. In connection with expansion of the employment of non-aqueous solutions, the corresponding studies devoted to the deposition of galvanic coatings on aluminium have been published.[109,238,239]

The photochemistry of uranyl: spin selectivity and magnetic effects

A L Buchachenko, I V Khudyakov
Semenov Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The very large range of photochemical reactions of uranyl conforms to certain general principles; and these are summarised, correlated, and from them the main types of photochemical reactions are classified. It is shown that the primary fundamental photoreactions of uranyl are selective with respect to electron spin and are therefore magnetosensitive. In these reactions there are found to be magnetic effects, including the most important—a magnetic isotope effect which is accompanied by the separation of uranium isotopes (magnetic ^{235}U and nonmagnetic ^{238}U).

The bibliography includes 126 references.

I. Introduction

Uranium is famous for its ^{235}U isotope, whose natural content is about 0.72%; and on increasing its content by a factor of only 2–3, nuclear fuel is obtained.[1] Salts of the uranyl ion UO_2^{2+}, in which uranium is in a hexavalent state, are common compounds of uranium. The main "non-nuclear" application of uranium compounds is related to the utilisation of the photochemical properties of these salts, which absorb ultraviolet and visible light and have a green luminescence.

Both the luminescence of uranium and its photochemistry have been studied for over fifty years[2] and a large amount of information has been obtained (see a monograph[3] and four reviews[2,4–6]). However a number of questions that are fundamental to the photochemistry and photophysics of uranyl remain:

—whether the large range of photochemical reactions of uranyl conforms to certain general principles, what are these principles (if, of course, they exist); is it possible to predict the photochemical behaviour of uranyl;

—which photochemical reactions of uranyl are primary and which are secondary, which of the photoreduction reactions of uranyl—through electron transfer or through hydrogen atom transfer—predominates; in which reactions is the UO_2 atomic shell of uranyl preserved and in which is it destroyed;

—what is the nature of the spin of the excited state of the uranyl ion UO_2^{2+}; is it singlet or triplet or is it altogether impossible to assign a definite spin multiplicity to this state (such a view has in all seriousness been expressed);

—what are the magnetic properties of the uranoyl ion UO_2^+, formed in the fundamental reaction of excited uranyl; what are the geminate reactions of this ion; are they magnetosensitive, and does the magnetic moment of the uranium nucleus have an effect on the spin behaviour of radical pairs involving the paramagnetic uranoyl ion UO_2^+?

The present article discusses the answers to these questions. The answers to some of them are clearer, while to others they are less certain.

II. Photochemistry of uranyl salts

1. Photoreduction of uranyl salts

The photoexcited uranyl ion participates in processes that are typical for many electronically excited molecules, namely, luminescence and radiationless deactivation. The decrease in intensity of luminescence and the reduction in lifetime of the excited state in the presence of many chemical reagents is regarded as an indication of "chemical" or "physical" quenching of excited uranyl. In its ground state uranyl is a weak electron acceptor (E^0 = 0.06 V relative to a standard hydrogen electrode); on excitation of the uranyl ion its electron affinity increases substantially (E^0 = 2.6–2.7 V).[4–6] In terms of its oxidising properties photoexcited uranyl is similar to molecular fluorine.[7] Therefore the main photochemical reaction of the uranyl ion is removal of a hydrogen atom (or electron) from the donor SH_2:

$$(UO_2^{2+})^* + SH_2 \rightarrow UO_2^+ + SH^\cdot + H^+. \quad (1)$$

This reaction is similar to the reaction of aromatic ketones or quinones excited to the n,π^* state.[4] For them the following general rule is typical: there is an increase in the rate constant with an increase in donor properties and a decrease in ionisation potential (or redox potential) of the donor and a decrease in energy of dissociation of the bond undergoing attack.[2,8–14]

Molecules of solvent (including water) can, in particular, act as a hydrogen donor.[9,15] The reaction of $(UO_2^{2+})^*$ with water

$$(UO_2^{2+})^* + H_2O \rightarrow UO_2^+ + OH^\cdot + H^+ \quad (1a)$$

occurs with a rate constant of $k \cong 10^2$ litre mol^{-1} s^{-1}.[9] Recently it was possible to record the spin adducts of the hydroxyl radical on photoexcitation of uranyl nitrate in water in the presence of a spin trap, providing additional evidence for reaction (1*a*).[15] The lifetime

of luminescence of uranyl in aqueous solution is of the order of several microseconds, so that the quantum yield of reaction (1*a*) is of the order of several percent.[16]

Added quantities of chemical compounds to solutions of uranyl salts also quench $(UO_2^{2+})^*$ in a "physical" manner—without the formation of chemical products:

$$(UO_2^{2+})^* + SH_2 \rightarrow UO_2^{2+} + SH_2. \qquad (2)$$

In the discussion of "reaction" (2) arguments have been more or less developed concerning the formation of exciplexes $[(UO_2^{2+})^*...SH_2]$ [5,10,13,18–20] and complexes in the ground state $UO_2^{2+}...SH_2$.[21] In particular, in the presence of aromatic compounds the formation of π-complexes has been postulated.[10,13,19]

The quantum yields of the reaction products of (1) vary over a wide range—from zero to unity—depending on the nature of SH_2, the solvent, and other conditions.[16–18,22,23]

Uranyl has luminescence in the region 490–650 nm; the absorption spectrum of $(UO_2^{2+})^*$, which was first recorded by Allen et al.,[24] has an absorption maximum at λ = 580 nm.[2,25,26] The kinetics of reactions (1) and (2) can be studied from luminescence quenching (during steady-state or pulsed excitation) or from the kinetics of luminescence decay of $(UO_2^{2+})^*$. A large number of studies have been devoted to the luminescence quenching of uranyl by different organic compounds, metal ions, halide ions, etc. In these experiments either the rate constants of quenching $k_q = k_1$ and k_2 or the Stern–Volmer constants K_{SV} have been determined. In the luminescence quenching the general principle noted above was found: k_q and k_{SV} are higher, the greater the electron-donating properties of the quencher (see, for example the studies of Sandhu et al;[8,10] a summary of k_q values is given by Hoffman et al.[27]).

2. Dualism in the reactivity of photoexcited uranyl

A very large number of organic and inorganic compounds,[2–6,28–33] alcohols,[13,20,33,34–40] organic acids,[24,36,38,41–48] amines,[25] amides,[28] cellulose,[28] phenols,[25,49] benzhydrol,[48] hydroquinone,[50] and others[8,10,14,36,51–58] participate in photooxidation with uranyl salts. The results of detailed EPR studies of the reaction products of (1) involving a very wide range of chemical compounds in the solid state and at low temperatures have been reported by Kemp et al.[28,29] We will not present the results of these detailed studies but will merely discuss the general properties of the reactions of excited uranyl.

Two principal mechanisms of the reactions of the electronically excited uranyl ion can be stated. On the uranium atom in the uranyl ion there are five coordination sites[59] to which ligands add (five water molecules in the complex $[UO_2(H_2O)_5]^{2+}$, two carboxyl anions and one water molecule in the complex $[UO_2(RCOO)_2.H_2O]$, two acetylacetone anions and one tetrahydrofuran molecule in $[UO_2(acac)_2.THF]$, etc.). All of the ligands lie in a single equatorial plane; the O–U–O axis is perpendicular to this plane and the "yl" oxygen atoms are situated at the poles. Hence a dualism is possible in the reactivity of the ion; electronically excited uranyl reacts either on the "equator", involving the uranium atom and the ligands, or on the "pole", involving the oxygen atoms. The first reactions occur intramolecularly, as a rule, and the second reactions are intermolecular. Furthermore, electron transfer from a ligand to the central atom is characteristic of the first reactions (U^{6+} is converted to U^{5+} as a result of this intramolecular transfer), while for the second reactions, hydrogen atom transfer to an "yl" oxygen is a typical feature. A typical example of the first reaction is the photodecarboxylation of salts of carboxylic acids, an example of the second is the photoreduction of uranyl in alcohols. In far from every case has it been possible to distinguish these two routes. Thus, generation of the ·OH radical on photolysis of uranyl salts in water [reaction (1*a*)] can occur by both routes—either by electron transfer from an equatorial ligand and the subsequent deprotonation of H_2O^+ or by an intermolecular reaction involving hydrogen atom transfer from a water molecule to an "yl" oxygen of uranyl. The dualism in the reactivity of excited uranyl is particularly clear when it is possible to establish competition between the two reaction routes. For example, in pure methanol the photolysis of UO_2^{2+} generates $CH_3O^{\cdot}$, while during photolysis in water–methanol mixtures (2:1 by volume) when the equatorial plane of UO_2^{2+} is occupied by water molecules, photoreduction occurs on the "polar" oxygen of uranyl to form the radical $\dot{C}H_2OH$.[34] It is clear that in the first case reaction mainly occurs on the "equator" through electron transfer and subsequent deprotonation while in the second case intermolecular photoreduction of uranyl on the "pole" occurs preferentially.

The photooxidation of lactic acid occurs by different mechanisms at different pH values: at pH > 3.5 it is accompanied by decarboxylation and the formation of acetaldehyde:[41]

$$UO_2^{2+} + CH_3CH(OH)COOH \xrightarrow{h\nu} U^{4+} + CH_3CHO. \qquad (1)$$

at pH 0 dehydrogenation occurs without decarboxylation and a keto acid (pyruvic acid) is formed:

$$UO_2^{2+} + CH_3CH(OH)COOH \xrightarrow{h\nu} U^{4+} + CH_3C(O)COOH. \qquad (2)$$

In the first case lactic acid is present in the form of lactate anion $CH_3CH(OH)COO^-$ and reacts in the coordination sphere (on the "equator") by electron transfer and decarboxylation followed by conversion of $CH_3\dot{C}HOH$ to acetaldehyde.

At low pH values in aqueous solution lactic acid is predominantly in the molecular form and photoreduction occurs on the pole to form the radical $CH_3\dot{C}(OH)COOH$, which is then converted to the keto acid.

On photoreduction of alcohols an isotope effect occurs. In the pairs of systems CH_3OH-CD_3OH and CH_3OD-CD_3OD the isotope effect has a normal sign of $k_1(CH)/k_1(CD) = 2.4–2.9$.[41] In the pairs CH_3OH-CH_3OD and CD_3OH-CD_3OD the isotope effect is very small (0.98 and 0.85) and has the reverse sign.[41] It is clear that the reaction of excited uranyl on the C–H bonds occurs on the "pole" as an intermolecular hydrogen atom transfer while the reaction on the O–H bonds occurs as an intramolecular electron transfer ("equatorial" reaction).

Thus, the dualism in the reactivity of photoexcited uranyl is determined by the competition of reactions along two pathways—on the equatorial plane of the ion and on a "polar" oxygen atom. These routes have a different sensitivity to the reaction conditions and this phenomenon is the reason for the very considerable variability in the chemical behaviour of uranyl.

In certain cases when the formation of U(IV) and new chemical products is recorded using conventional steady-state methods but the formation of primary products of one-electron oxidation or removal of a hydrogen atom is not detected, two-electron oxidation or oxygen atom transfer processes are postulated.[8,10,51,52,60] For

example, according to Sandhu et al.,[60] the oxidation of dialkyl sulphides occurs according to the following reaction:

$$(UO_2^{2+})^* + R_2S \rightarrow U^{4+} + R_2SO. \quad (3)$$

It has been proposed that the same reaction involving oxygen atom transfer [reaction (3)] occurs by reaction of $(UO_2^{2+})^*$ with triphenylphosphine, triphenylarsine, triphenylbismuth, and certain other compounds. However, in the oxidation of dicyclohexyl sulphide in dry acetone the cationic species UO_2^+ are formed,[17] while in the oxidation of a number of other disulphides, radical cations are formed.[18] Addition of dilute hydrochloric acid to a solution of dicyclohexyl sulphide in acetone is accompanied by the formation of U(IV), but only in secondary reactions:

$$UO_2^{2+} + R_2S \overset{h\nu}{\rightleftharpoons} [UO_2^{2+} \ldots R_2S]^* \quad (3a)$$

$$[UO_2^+ \ldots R_2S^+] \xrightarrow{H_2O,\ H^+} UO^{2+} + R_2SO\,. \quad (3b)$$

There is a high probability that all of the remaining reactions of type (3) occur via a one-electron transfer to form UO_2^+ [reaction (1)].

The photoreduction of uranyl nitrate with tri-n-butyl phosphate is accompanied by the formation of nitrite and nitrous acid, which oxidise U(IV). The combination of primary and secondary reactions leads to the results having poor reproducibility and a strong dependence of the yield of U(IV) on temperature, wavelength of exciting light, etc.[23] Moreover, the photolysis of uranyl nitrate can lead to formation of the pair $[UO_2^+, NO_3]$ and nitrite can be formed directly by photoexcitation of nitrate.[23,61]

Uranoyl is an intermediate in the photolysis of a number of uranyl compounds in the solid state.[62,63]

Above, there has mainly been a discussion of the photoexcitation of uranyl in water or other homogeneous solvents. The luminescence of uranyl and its photochemical reactions in heterogeneous and microheterogeneous solutions have also been investigated.[25,64–67] The photochemistry of uranyl adsorbed on colloidal silicon, zeolites, and alumina has been studied in relation to the possible photocatalytic effect of such systems.[65,66] Moreover, it is well known that in heterogeneous media (including micelles) conditions are favourable for the display of different magnetic effects in spin-selective reactions,[68–71] and this circumstance has stimulated additional interest in such studies. However, in principle, the photochemistry of uranyl in heterogeneous systems repeats the normal "homogeneous" chemistry.

3. The radical pair uranoyl–free radical

The primary product of excited uranyl with a donor is the radical pair (RP) $[UO_2^+, \dot{S}H]$, which either dissociates or its partners react together (forward or reverse electron transfer or disproportionation):

$$[UO_2^+, \dot{S}H] \begin{cases} \xrightarrow{k_4} UO_2^+ + \dot{S}H, & (4) \\ \xrightarrow{k_5} UO_2^{2+} + SH_2, & (5) \\ \xrightarrow{k_6} U^{4+} + S. & (6) \end{cases}$$

From a knowledge of the redox potentials of the pairs $E^0(UO_2^{2+}/UO_2^+) = 0.06$ V and $E^0(UO_2^+/U^{4+}) = 0.55$ V relative to a standard hydrogen electrode,[2–6] it can be predicted that oxidising radicals (with a potential $E^0 > 0.06$ V) will regenerate the initial reagents, while the strong oxidising agent—uranoyl—will oxidise many radicals to tetravalent uranium compounds. It is necessary to bear in mind that the values of the redox potentials are significantly dependent on the pH of the solution and the reagents.

Little is known about the cage reactions of the uranoyl ion and therefore different ideas have been put forward. There is definite interest in recording them directly. The cage reactions (4)–(6) are exhibited during laser photolysis, in particular in the photooxidation of the leuco base of a thionine dye (SH_2) sensitised with uranyl nitrate. The conversion of SH_2 to $\dot{S}H$ and S is accompanied by marked spectroscopic changes.[26] In the first instant after a flash the excited state $(UO_2^{2+})^*$ is formed, the "physical" (2) and "chemical" (1) destruction of which lasts 800 ns (Fig. 1). By this time $\dot{S}H$ has accumulated and, what is significant, S is formed in appreciable concentration (Fig. 1). Thus, these direct results demonstrate the occurrence of a successive two-stage oxidation of SH_2 by photoexcited uranyl with primary formation of the uranoyl ion. The quantity of $\dot{S}H$ oxidised in the cage comprises about 5% of the quantity of $\dot{S}H$ formed in bulk [reaction (4)].[26]

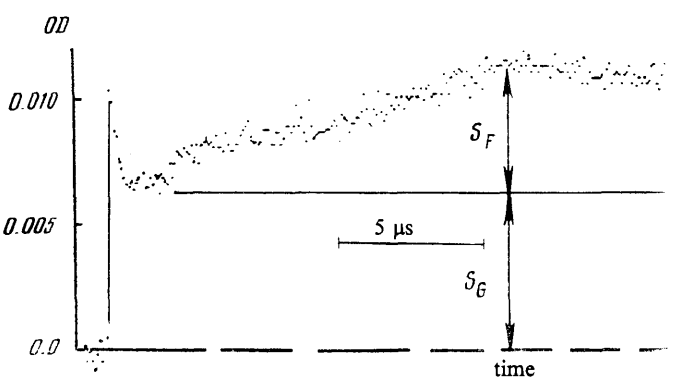

Figure 1. Changes in the optical density *OD* of aqueous solutions of uranyl nitrate in the presence of leucothionine which occur during laser photolysis with $\lambda = 600$ nm.[26] Here S_G is the optical density due to S formed in the cage; S_F is the optical density of S formed in extracage reactions.

The kinetics of the geminate recombination (5) of the pair $[UO_2^+ . .(C_6H_5)_2NH^{+\cdot}]$ obtained by pulsed laser photoexcitation of uranyl nitrate in the presence of diphenylamine in reverse micelles of sodium di(2-ethylhexyl)sulphosuccinate (Aerosol OT) (AOT) have been recorded.[25] In this case uranyl nitrate occurs in aqueous solution inside the micelles. The destruction of the RP is given by a first-order kinetic equation with a constant $k_q = k_4 + k_5$ and depends on the ratio $[H_2O]/[AOT]$, namely, on the size of the micelles. The cage effect in all of the experiments was approximately 0.9.[25] Such experiments are for the time being scarce in number, but they make it possible to record directly both the kinetics of geminate recombination and the magnitude of the cage effects.

There are many indications that excited uranyl has a triplet state, and when it undergoes photoreduction in a triplet RP is formed (see later).

III. Reactivity of the uranoyl ion

There is no doubt that the primary photoprocess—transfer of a hydrogen atom or electron to the uranyl ion [reaction (1)]—occurs with retention of the monolithic shell of UO_2 (see Section II.2). Destruction of this shell occurs in secondary, mainly dark, reactions, about whose mechanism little is known for certain. Amongst these is disproportionation of uranoyl ions

$$UO_2^+ + UO_2^+ + 4H^+ \rightarrow UO_2^{2+} + U^{4+} + 2H_2O, \qquad (7)$$

with regeneration of uranyl and the readily hydrolysed ion of oxygen-free tetravalent uranium. Despite its outward simplicity, the mechanism of reaction (7) is quite complex and has not been completely elucidated.[72] The reaction is significantly accelerated with a decrease in pH, occurs more rapidly in heavy water than in normal water, and is accelerated in the presence of fluoride ions.[72,73] Kinetic schemes that involve the formation of the dimer of UO_2^+ in protonated form UO_2H^{2+} represent the experimental data to the most adequate degree. In the region of pH 2–3 the UO_2^+ cation is relatively stable; in more acidic media the approximate relationship $k_7[H^+]^{-1} \cong 5.0 \times 10^2$ litre^{-2}mol^{-2}s^{-1} (water, 293 K, ionic strength 2.5) is valid.[72]

Another reaction involving destruction of the shell is the exchange of oxygen atoms between uranyl and water molecules. It was known some time ago (see for example, Okuyama et al.[74]) that the dark exchange which is extremely slow ($\sim 10^4$ h) in acid solution is markedly accelerated (by many orders) on irradiation with light in the absorption band of uranyl. It was proposed that exchange occurs in the electronically excited state of the uranyl ion,[74] but doubts about this mechanism arose straight away since no correlation was found between the rate of exchange and the lifetime of the excited (luminescent) state. In strongly acid solutions the rate of exchange decreased substantially, although the lifetime of the excited state increased.[75]

This phenomenon was noted in a series of outstanding studies by Suglobov et al.[16,22,55,58,76,77] on the kinetics and mechanism of photostimulated oxygen exchange between uranyl and water. The kinetic features of the exchange reaction were reliably established: 1) isotopic exchange ($^{16}O-{}^{18}O$) between uranyl oxygen and water is only induced by light that is photochemically active towards UO_2^{2+}; 2) the quantum yield of exchange (the number of fundamental exchange reactions per photochemically active quantum) is considerably greater than unity and amounts to tens or even hundreds in water (depending on the pH), and in the presence of ethanol reaches 3500; this indicates that the exchange reaction is a chain process; 3) the quantum yield has a linear dependence on the concentration of the initial uranyl; 4) it is inversely proportional to the square root of the light intensity; 5) the quantum yield decreases sharply in the presence of small quantities of added persulphate, whose ions do not quench the luminescence of UO_2^{2+} but oxidise uranoyl ions:

$$UO_2^+ + S_2O_8^{2-} \rightarrow UO_2^{2+} + SO_4^{\cdot} + SO_4^{2-}. \qquad (8)$$

All these features clearly demonstrate that the uranoyl ion UO_2^+ (or its protonated form), in which the triatomic shell becomes unstable, is responsible for oxygen exchange:

$$U^{18}O_2^+ + H_3^{16}O^+ \rightleftarrows U^{18}O_2H^{2+} + H_2^{16}O, \qquad (9)$$

$$U^{18}O_2H^{2+} + H_3^{16}O^+ \rightleftarrows U^{16}O_2H^{2+} + H_3^{18}O^+. \qquad (10)$$

Let us adopt the following kinetic scheme of exchange

$$[UO_2^{2+}]^* + H_2O \xrightarrow{W_i} UO_2^+ + OH^{\cdot} \qquad (1a)$$

(The photochemical generation of the uranoyl ion occurs with rate W_i);

$$UO_2^+ + UO_2^{2+} \rightleftarrows UO_2^{2+} + UO_2^+ \qquad (11)$$

the reaction of electron recharging (electron exchange) ensures the propagation of the kinetic chain of oxygen exchange:

$$UO_2^+ + UO_2^+ + 4H^+ \rightarrow UO_2^{2+} + U^{4+} + 2H_2O \qquad (7)$$

(disproportionation, destruction of the uranoyl ion, termination of the kinetic chain).

The scheme assumes a rapid oxygen-isotope exchange of each UO_2^+ ion with water (its mechanism has so far not been discussed), propagation of the chain through electron recharging between the isotopically exchanged UO_2^+ and "native" $UO_2^{2+}$and termination of the kinetic chain through disproportionation of uranoyl ions.

The rate W_i of generating UO_2^+ is equal to φI, where φ is the quantum yield of generation of UO_2^+, I is the intensity (number) of quanta absorbed. The quantum yield of oxygen exchange can be given in the form

$$\Phi = W_i\nu/I = \varphi\nu, \qquad (12)$$

where ν is the length of the kinetic chain. The lifetime of an individual uranoyl ion $\tau^* = \{k_{11}[UO_2^+]\}^{-1}$, while the lifetime of the kinetic chain $\tau = \{k_7[UO_2^+]\}^{-1}$, where the steady-state concentration of $[UO_2^+] = (W_i/k_7)^{1/2}$. Hence we can readily obtain the length of the kinetic chain

$$\nu = \tau/\tau^* = \frac{k_{11}[UO_2^+]}{(k_7W_i)^{1/2}} = \frac{k_{11}[UO_2^+]}{(k_7\varphi I)^{1/2}} \qquad (13)$$

and the quantum yield

$$\Phi = \frac{W_i}{I} = \frac{\varphi^{1/2}k_{11}[UO_2^+]}{k_7^{1/2}I^{1/2}} \qquad (14)$$

The dependences of Φ on $[UO_2^+]$ and I as predicted by Eqn. (14) are consistent with experiment and quantitative determinations of Φ (with the current uncertainty in the constant k_{11}) are in reasonable agreement with the experimental values of Φ.[16]

In solutions of uranyl in perchloric acid ([$HClO_4$] = 0.1 M), Φ = 43, while under the same conditions but in the presence of ammonium persulphate, which suppresses the chain process through reaction (8), Φ^* = 0.08.[16] Since in this case ν = 1, it is easy to determine that the length of the kinetic chain of oxygen exchange of uranoyl in water is equal to $\nu = \Phi/\Phi^* = 540$.

The physical meaning of the dependence of Φ on I is also clear. The greater the intensity of light, the higher the steady-state concentration of UO_2^+ ions, and hence, the rate of quadratic chain termination, and the lower the yield of oxygen exchange.

It is clear that the limiting quantum yield ($\Phi = \varphi\nu$) when φ = 1 is equal to the length of the kinetic chain of oxygen exchange Φ = 540. However, in aqueous ethanol solutions Φ increases with an increase in concentration of ethanol and reaches a maximum value of Φ = 3500.[16] This considerably exceeds the expected value of 540 and would appear to indicate that in aqueous ethanol solutions an increase in φ to unity is insufficient and that it is necessary also to

assume that the rate constants k_7 and k_{11} vary (relative to purely aqueous solutions of uranyl) in Eqns. (13) and (14).

On addition of metal salts to the solutions being studied in perchloric acid there is a change in Φ.[58] The introduction of ions that reduce $(UO_2^{2+})^*$ (Fe^{2+}, Ce^{3+}, Mn^{2+}) leads to an increase in Φ, whereas the introduction of ions that oxidise UO_2^+ (Fe^{3+}, Ag^+) leads to a decrease in Φ.[58]

The most unclear stage in this mechanism is the actual reaction of oxygen exchange in the UO_2^+ ion, namely, destruction of the UO_2 shell. The rate of exchange is strongly dependent on the pH of solution. For example, when $[UO_2^{2+}] = 0.1$ M, with an increase in acidity from 0.01 to 0.4 $HClO_4$ the quantum yield increases from 10 to a maximum value of 80, and then with a further increase in $HClO_4$ concentration it decreases to $\Phi = 1$ at 12 M $HClO_4$. In solutions with pH $\leqslant$ 0.4 both of the oxygen atoms of uranoyl are exchanged (two-oxygen exchange) and the quantum yield of this exchange $\Phi_2 \approx [H^+]^2$.[16] When pH > 1.5 the exchange involves one oxygen, i.e. each oxygen atom is exchanged independently and the quantum yield of exchange $\Phi_1 \approx [H^+]$.[16] It is clear that singly or doubly protonated forms of the uranoyl ion participate in exchange (the reaction occurs on a single oxygen atom [Eqn. (10)] or on both simultaneously) and that exchange is catalysed by hydroxonium ions. Reasonable and plausible chemical schemes of catalytic exchange can be put forward,[77] but they should be treated with caution. Direct methods are needed (with a time resolution of the order of picoseconds) for detecting the intermediate species and their dynamics.

As was mentioned above, in the photoreactions of uranyl with Ph_3P, Ph_3As, R_2S, and R_2SO, transfer of an oxygen atom occurs.[8,10,51,52,60] In this case phosphite is converted to phosphate, sulphide to sulphoxide, sulphoxide to sulphone, and the Ph_3As group to Ph_3AsO. The quantum yield of these reactions is low and equals 0.01–0.05. Photooxidation of sulphoxide to sulphone with uranyl is a thermally activated reaction and required an energy of activation of about 25 kJ mol^{-1},[52] which is unusual for photoreactions. It must be assumed from these characteristics that transfer of oxygen in these reactions is a secondary reaction that occurs with the involvement of the resulting uranoyl ion UO_2^+. In certain cases there is direct evidence for this mechanism (see above).

There is no doubt that destruction of the shell also occurs in $^{235}U-^{238}U$ isotope exchange[54]

$$^{235}UO_2^{2+} + {}^{238}U^{4+} \rightleftarrows {}^{238}UO_2^{2+} + {}^{235}U^{4+} . \qquad (15)$$

For a solution of uranyl in hydrochloric acid (8.0 M), $k_{15} = 7.17 \times 10^{-4}$ litre mol^{-1} min^{-1}.[54] Reaction occurs via the formation of uranoyl and is markedly accelerated by visible and UV light.[54] In the absence of other donors uranyl is photoreduced by U(IV) to form a superequilibrium concentration of UO_2^+.[50,54]

The mechanism of reaction (11), in which electron exchange and hence isotope exchange occur is debatable. The reaction occurs either by one-electron transfer, as according to Eqn. (11),[78] or via a stage involving the formation of a complex[16]

$$UO_2^+ + UO_2^{2+} \rightleftarrows UO_2^+ \ldots UO_2^{2+}, \qquad (16)$$

$$UO_2^+ \ldots UO_2^{2+} \rightarrow UO_2^{2+} + UO_2^+. \qquad (17)$$

The values of the rate constants have been determined: k_{11} = 1–10 litre mol^{-1} s^{-1};[78] k_{16} = 16–30 litre mol^{-1} s^{-1},[16,72] $k_{17} = (1.0 \pm 0.1) \times 10^3$ s^{-1}.[16]

Of the other reactions of uranoyl we should mention the formation of a binuclear complex [reaction (16)] which stabilises uranoyl.[72,79] It is assumed that formation of the complex between uranoyl and the radical resulting from photooxidation of a donor also stabilises UO_2^+.[17,80]

In the photoreduction of (8-crown-6)uranyl perchlorate in acetonitrile, a U(V) compound is obtained which has the formula $UO(18\text{-crown-6})(ClO_4)_3$.[81] It is relatively stable and does not disproportionate, being shielded by the macrocyclic ligand.[81]

The UO_2^+ formed in the primary photochemical reaction, in addition to disproportionation and isotope exchange, participates in reactions with the initial SH_2

$$UO_2^+ + SH_2 \rightarrow U^{4+} + SH_2^{\cdot} \qquad (18)$$

and with the corresponding radical $SH^{\cdot}$ ($SH^{\cdot}$)

$$UO_2^+ + SH^{\cdot} \rightarrow \text{products}. \qquad (19)$$

The latter reaction is rapid,[82–84] and it is frequently geminate. The routes of reactions of the type (18) and (19) can be predicted from the one-electron redox potentials of the reactants.[26,57,58,84]

It was shown by Sergeeva et al.[50] that UO_2^+ oxidises ethanol, ascorbic acid, and hydroquinone. It is very probable that it is reaction (18) involving ethanol that is responsible for the excess value of the quantum yield of U(IV) of 0.5 in the photoreduction of uranyl in aqueous solution containing a high concentration of ethanol rather than the transfer of two electrons as was proposed by Suglobov et al.[22]

Values of k_{19} ranging from 10^4 to 10^9 litre mol^{-1} s^{-1} have been obtained for a number of organic and inorganic radicals acting as partners of uranoyl.[50,82,84]

We should note in conclusion that the whole range of photochemical reactions for the reduction of uranyl is reduced to two key processes—oxidation of the substrate in the inner sphere by one-electron transfer (reaction on the "equator", reaction of the U atom) and removal of a hydrogen atom on the "pole" (reaction of an O atom). These reactions of photoexcited uranyl are primary and are accompanied by retention of the triatomic shell of UO_2. Break-up of this shell occurs in secondary reactions of the further reduction of U(V) to U(IV), occurring both inside the cage and in extracage reactions. Of the latter the most characteristic is disproportionation of U(V) [reaction (7)], which results in the formation of the final photoreduction product of uranyl—uranium(IV).

IV. Spin and magnetic properties of excited uranyl and the uranoyl ion

1. The lowest excited state of uranyl

The question of the spin state of the reacting excited ion of uranyl is of fundamental significance—it determines the spin selectivity of the reactions and the scale of the magnetic effects. A solution to the problem of the nature of the spin state of $(UO_2^{2+})^*$ can be provided by quantum-chemical calculations, an analysis of the lifetimes of luminescence, experiments on energy transfer, and research into magnetic and spin effects in the photochemical reactions of uranyl.

The absorption of uranyl in the visible region is mainly due to transitions from the highest occupied molecular orbital located primarily on the oxygen atoms to the 5*f* orbitals of uranium.[85–92]

These transitions are symmetry-forbidden and have low intensity (extinction coefficient $\varepsilon \cong 10-50$ litre mol^{-1} cm^{-1}). The substantial spin-orbit coupling (SOC) in the uranium atom (it is thought that in the uranium atom the SOC constant is in the region of $\zeta = 1740-2000$ cm^{-1})[87] places in doubt the possibility of assigning a definite spin state to $(UO_2^{2+})^*$. The authors of two studies[93,94] believe that singlet and triplet are so highly mixed and indistinguishable that there is no point in raising the question of the spin state of excited uranyl. However, such a conclusion is scarcely constructive. Thus, detailed calculations[85] indicate that both schemes (interelectron repulsion of the terms greater than the spin-orbit coupling between the terms and *vice versa*) represent the excited states of the uranyl ion, with the first scheme representing them even better. Attempts to determine experimentally the nature of the excited states of the uranyl ion in liquid solution during energy transfer experiments involving organic molecules and molecular oxygen proved unsuccessful.[95,96] The luminescence of uranyl is hardly excited at all by other donors, and there is hardly any evidence of energy transfer from photoexcited uranyl salts (energy of the lowest level $E = 20500$ cm^{-1})[4,96,97] to typical acceptors of triplet energy. In particular, molecular oxygen even at a pressure of 2×10^6 Pa does not quence the luminescence of uranyl.[96] Similar results led Sergeeva et al.[95] to assume that the excited state of the uranyl ion is singlet. However, the low efficiency of energy transfer from $(UO_2^{2+})^*$ to acceptors is a weak argument for such a conclusion, since it may be related to shielding of excitation to the 5*f* orbitals by the outer filled orbitals and the orbitals of the oxygen atoms.[96] Such a cause of inertness in energy transfer is not new, it is known for complex compounds with localised excited states.[2] Claudel et al.[63] have also proposed (without careful reasoning) that the reactive state of $(UO_2^{2+})^*$ in the solid state is singlet.

However, the idea of the triplet nature of $(UO_2^{2+})^*$, first put forward by McGlynn and Smith,[104] has been accepted by the majority of research workers (see, for example, several studies).[48,54,61,76,98–103] Moreover, there is experimental evidence for it, obtained in magnetic circular dichroism at low temperature for uranyl compounds.[98] A number of indications suggest a triplet as the excited reacting state of uranyl. First of all the lifetime of the excited state (2–10 μs in water[2] and 440 μs (!) for a colloidal solution of uranyl bonded to silicon[65]) is too great to belong to a singlet—especially when the presence of the uranium atom with strong spin-orbit interaction (~2000 cm^{-1}) is taken into account. It is true that it still does not follow from this fact directly that this luminescent state is reactive or responsible for the reaction of excited uranyl.

There is other also indirect evidence resulting from the reaction characteristics of excited uranyl. This relates in particular to photoreduction reactions on the "pole", namely, reactions on "yl" oxygen (see Section II.2). As was mentioned above, these are almost identical to reactions of triplet benzophenone: the same H/D isotope effects and reactions on the C–H bonds of alcohols, the same order of increase in quantum yields of photoreduction in the series methanol < ethanol < isopropanol (0.15, 0.31, and 0.34 respectively)[4] and the same absolute values of the rate constants k_1 of photoreduction (about 10^6 litre mol^{-1} s^{-1}). Even in its ground state UO_2^{2+} is similar to benzophenone. For example, it is an acceptor of a hydroxy hydrogen atom (see below), removing it from the radicals $(C_6H_5)_2COH$, CH_3COH, and $CH_3C(OH)COOH$. None of this evidence can be regarded as reliable confirmation; the latter only developed out of magnetic spin effects in reactions of uranyl (see Section V).

2. Magnetic and other physical properties of the uranoyl ion

The uranoyl ion is a primary product of the photoreduction of uranyl salts; it is also obtained by electrochemical or chemical reduction of uranyl.[105] the reducing agents can be free radicals such as $(CH_3)_2COH$, $CO_2^{\cdot-}$, etc.[44,47,106] Uranoyl is a labile species whose lifetime is mainly dictated by the disproportionation reaction

$$UO_2^+ + UO_2^+ + 4H^+ \rightarrow UO_2^{2+} + U^{4+} + 2H_2O. \qquad (7)$$

Its rate constant depends on the pH of the aqueous solution, the solvent, and the composition of the solution, so it is possible to find the conditions under which it achieves a high (up to 10^{-2} M) steady-state concentration of uranoyl[17,51,53,78–81,105,107] (for more detail, see Section III).

The absorption spectrum of uranoyl extends into the visible and infrared regions. The positions of the absorption maxima and values of the extinction coefficients of uranyl are given in several studies.[17,51,53,78,80,103,107–113]

The absorption spectra of UO_2^+ are sensitive to the solvent and depend on the nature and concentration of SH_2 and the concentration of UO_2^{2+}, and these dependences result from the complexation of UO_2^+. The absorption spectra of UO_2^+ are mainly used for identification of this intermediate compound. From the existing data it is possible to distinguish U(V) from U(IV) and U(VI) in the absorption spectra with complete confidence.[17,51,53]

The uranoyl ion has the electron shell [Rn]$5f^1$ and is a free radical. Its EPR spectrum has been recorded at low temperature (77 and 153 K) during electrochemical and photochemical reduction of $UO_2(dmf)_5(ClO_4)_2$ in *N*,*N*-dimethylformamide (dmf) and also $UO_2(dmso)_5(NO_3)_2$ and $UO_2(tep)_2(NO_3)_2$ in dimethyl sulphoxide (dmso) and triethyl phosphate (tep) respectively, which enter into the coordination sphere of uranyl.[110,114] Miyake et al.[110,114] consider that there are two types of spectra comprising isolated lines with the parameters $g_\perp = 2.5$, $g_\parallel \approx 0$, line width 150 mT, symmetrical line (spectrum of the first type) and $g_\perp = 1.97$, $g_\parallel \approx 1.3$, line width 10 mT, asymmetric line (spectrum of the second type). An average value of the *g* factor of $\bar{g} = 1.7$ corresponds to both type of spectrum. Spectra of the first type are obtained by photo- or electro-chemical reduction of perchlorates, and in these the perchlorate anion always remains outside the first coordination sphere and the equatorial plane is occupied by molecules of the organic solvent,[114] while spectra of the second type are obtained by photoreduction of nitrates. In this case the nitrate anion is situated in the equatorial plane of the complexes and remains in it during photoreduction, giving rise to the asymmetry of the EPR spectrum. This interpretation of the spectra is very much in doubt. Firstly, the EPR line ascribed to UO_2^+ is always asymmetric (even in the case of uranyl perchlorate); secondly, the theoretical interpretation of the spectrum is complex and ambiguous and requires a number of doubtful assumptions and approximations concerning the strength and symmetry of the crystal field and the spin-orbit coupling in the UO_2^+ ion. It is all the more difficult to correlate the theoretical and experimental EPR spectra.

It may also be doubtful that the isotropic *g* factor of UO_2^+ has a value close to 1.7, although the fact that it is less than the *g* factor of a free electron (2.0023) has been confirmed with complete reliability.[115–117] It was shown in these three studies[115–117] that the uranoyl ion has a considerable effect on the magnetic resonance parameters of organic radicals that are complexed with it.[28,115–117] Thus, in complexes of UO_2^{2+} with a phenanthrenequinone radical anion PQ^- and neutral radical

$HPQ^{\cdot}$, the g factors and electron relaxation times T_1 differ considerably from the g-factor and T_1 of free $PQ^{\cdot-}$ and $HPQ^{\cdot}$: $T_1(PQ^{\cdot-}) = 4-10$ μs, $T_1([UO_2PQ]^{+}) = 0.8$ μs, the g factors for $PQ^{\cdot-}$, $[UO_2PQ]^{+}$ and UO_2HPQ^{2+} are 2.0045, 1.9940, and 1.9945 respectively.[116] The presence of the uranium atom with its spin-orbit interaction opens up an additional route for paramagnetic relaxation and reduces the electron relaxation times of the complexes. In complexes of substituted *o*-benzo-semiquinones with uranoyl T_1 is even less (<0.2 μs).[117] The decrease in the g factor of the complexes results from the delocalisation of the spin from the organic anion to uranoyl. This means that the g factor of uranoyl is less than the g factor of a free electron.

Evidence for this assertion is provided by the EPR spectrum of the radical pair $^3[UO_2^+, NO_3]$ which is formed by photolysis of a monocrystal of the triethyl phosphate complex of uranyl nitrate $UO_2(NO_3)_2.2OP(OC_2H_5)_3$.[61] The angular dependence of the spectrum is dictated by the anisotropy of the g factor (its primary values lie within the region of 1.996 to 1.871). Even the largest of the components of the g factor is less than 2.0023. The additional interaction between the electrons in the pair has an angular dependence, with its maximum value amounting to 87 mT. This corresponds to a distance of 2.8 Å between the electrons, and it is approximately equal to the distance between the partners in the pair. In itself the observation of the EPR spectrum of a radical pair at the low temperatures used (less than 10 K) is an indication of a triplet precursor of the excited ion $(UO_2^{2+})^*$. However, strictly speaking the sign of the exchange interaction J and hence the spin state of the pair cannot be deduced from the EPR spectrum. Moreover, Giacometti et al.[61] did not estimate the value of J either, although this is possible by comparing the value of a_N—the ^{14}N hyperfine interaction in NO_3. If $J \gg a_N$, the ^{14}N hyperfine splitting in the pair must be $\frac{1}{2}a_N$ in the individual NO_3 radical; if $J \ll a_N$, a_N in the pair must coincide with a_N for the free NO_3 radical.

It is of course necessary to have reliable information about the g factor and hyperfine electron-nuclear interactions on the ^{235}U nucleus in the uranoyl ion. Further efforts are needed to obtain the EPR spectra of this ion in an oriented state—in monocrystals, in liquid crystal systems or by photolysis with polarised light, i.e. under conditions of photoselection with respect to orientation.

The question of the hyperfine coupling (HFC) on the magnetic nucleus of ^{235}U is very important. It is known that in UF_5 radical located in crystal lattices of halides of alkali or alkaline earth metals, the isotropic HFC is 5 mT on average. For UO_2^+ the hyperfine coupling is quite unknown and new measurements of EPR spectra of this ion with an enriched content of magnetic isotope are needed.

The paramagnetism of UO_2^+ is also detected in NMR spectra. This was first demonstrated by Pershin et al.[39] On irradiation of uranyl nitrate in ethanol, paramagnetic shifts and broadening of the NMR lines of ethanol appeared on the recording unit of the NMR spectrometer. The kinetics of the shifts and broadening on turning the light on and off clearly corresponded to the kinetics of the photochemical formation and dark destruction of the paramagnetic UO_2^+ ion. This indicates that the shifts and broadening of the NMR lines of the solvent occur when these molecules enter into the coordination sphere of the UO_2^+ ion and by a rapid exchange of the coordinated molecules with free ones.

The patterns of shifts and broadening are distinctive. The NMR line of the protons of the CH_3 group is hardly shifted and is not broadened, the line due to CH_2 is broadened and shifted downfield, but the hydroxyl protons of ethanol undergo the most broadening and a shift upfield. These are all indications that the paramagnetic shifts are due to contact hyperfine coupling of the unpaired electron with the nuclei of the ligand and that the ligand adds to the UO_2^+ ion via its hydroxyl group and through it spin density from the UO_2^+ ion is partially transferred to the ligand.[39]

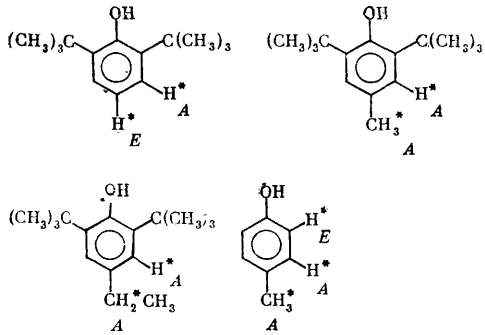
Paramagnetic shifts and broadening of the NMR lines of the solvent were also observed in the photolysis of UO_2^{2+} in dimethyl sulphoxide.[80] The resonance lines due to the methyl groups in the ^1H and ^{13}C NMR spectra were shifted upfield (the magnitude of the shift was proportional to the concentration of paramagnetic UO_2^+ ions). In this case also the shifts and broadening occur on introduction of a solvent molecule into the coordination sphere of the UO_2^+ ion, but they are induced by a pseudocontact interaction (the same sign of the ^1H and ^{13}C shifts indicates this). In other words, in complexes of UO_2^+ with DMSO spin density is not transferred to the ligand (in contrast to complexes of UO_2^+ with ethanol). It is difficult to identify clearly the reason for these differences, but it is most likely that ethanol adds as a ligand to an oxygen atom of UO_2^+ on the pole while DMSO enters the plane of the coordination sphere on the equator.

V. Spin-selective reactions of uranoyl and magnetic effects

Let us return again to the question of the spin state of the excited uranyl ion. It was previously argued that this state has a given multiplicity, namely, a triplet. Since the spin is retained in fundamental reactions, the spin state of the excited ion is converted unchanged into the primary photoreduction product of uranyl—a radical pair—and therefore manifests itself in the spin selectivity of the photochemical reactions of uranyl.

A feature of spin-selective chemical reactions is their magneto-sensitivity, i.e. the sensitivity to the magnetic interactions of electrons and nuclei with an external magnetic field and to electron-nuclear hyperfine coupling. Energetically the magnetic interactions are small, but they are unique in the sense that it is only they that can change electron spins and remove the spin restriction in the spin-selective reaction. The spin restriction means that not all spin states can react, i.e. there are states that are reaction-forbidden.

The notable phenomena related to spin restriction are chemical polarisation of nuclei and electrons (CPN and CPE), the magnetic field effect (MFE), and magnetic isotope effect (MIE).[68–71] The most interesting of these is the MIE, namely, the dependence of the rate of reaction of paramagnetic species on the spin and magnetic moment of their nuclei.[70] It leads to a separation of magnetic and nonmagnetic isotopes in chemical reactions. A magnetic isotope effect has been detected for carbon, oxygen, silicon, and sulphur.[70,119,120] It would be tempting to find this effect also for reactions involving uranium compounds, in which one of the isotopes—^{238}U—is nonmagnetic, while the other—^{235}U—is magnetic (nuclear spin $I = {}^7/_2$, magnetic moment $\mu_I = -0.36\ \mu_N$).[121]



Research into the MIE in uranium aims to reach the solution to three problems: 1) to find reactions of uranium compounds involving paramagnetic intermediates; 2) to find the spin-selective stages in the reactions of these species and to establish the initial spin multiplicity in these stages; 3) to study the distribution of isotopes in the products of these reactions.

A solution to the first problem is evident. It is clear that photoreduction reactions of uranyl give radical pairs with the paramagnetic UO_2^+ ion and that these reactions are most suitable for

solving the subsequent two problems. We shall discuss below the methods for solving them through magneto-spin effects.

1. Chemical polarisation of nuclei in photoreduction reactions of uranyl salts

Chemical polarisation of ^1H nuclei has been observed in the photoreduction of uranyl nitrate with a number of alkyl-substituted phenols, benzilic acid, and benzhydrol (Figs. 2 and 3).[48,102] The polarisation indicators are shown below on the diagram (A = enhanced absorption E = emission):[102]

Polarisation of the extracage products of the recombination of the resulting phenoxyl radicals has also been detected. The reaction involves the fundamental stages (22), (23), and (24) (see section V.3). Phenoxyl radicals are poor electron donors and good acceptors, so the spin-selective reaction (24), resulting in the formation of a phenol with polarised nuclei takes place in the cage.

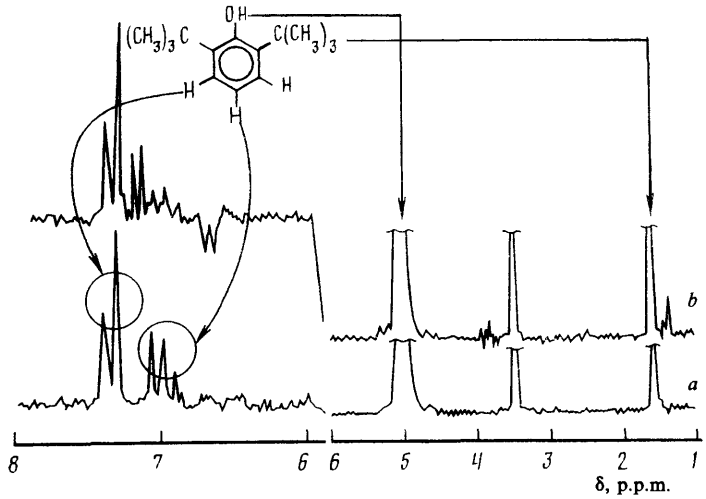


Figure 2. PMR spectrum of a solution of 2,6-di-t-butylphenol and uranyl nitrate in methanol-d_4 before (a) and during (b) irradiation of solution.

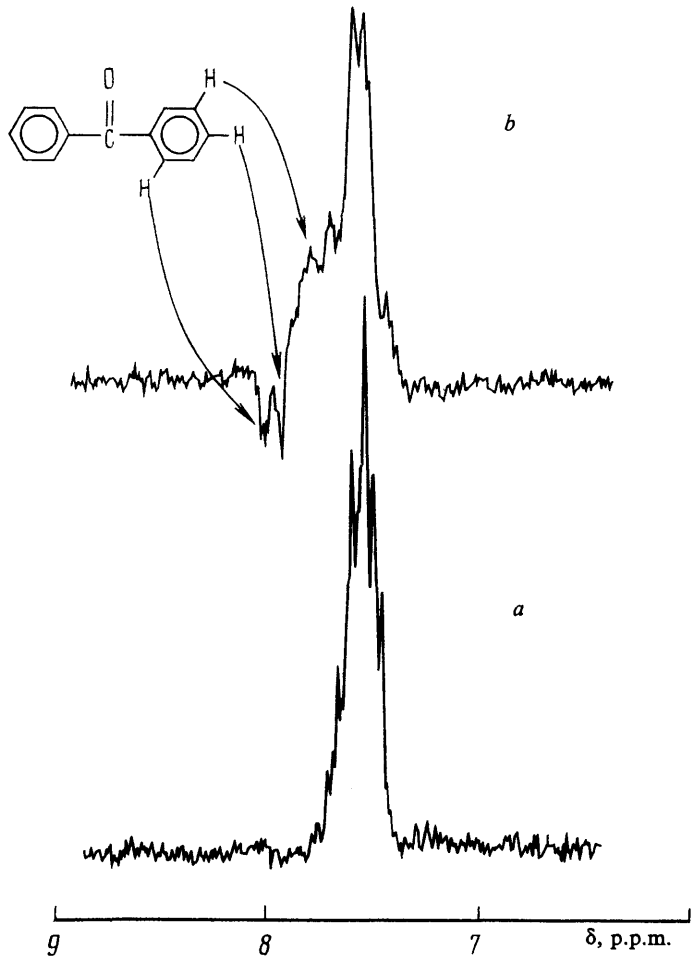
The fact that CPN occurs is not insignificant. It demonstrates the spin selectivity of the reaction and determines the spin multiplicity of the RP, from which the magnetosensitivity of the reactions and magnetoselectivity of the radicals is to be expected.

Chemical polarisation of the protons of the phenols accurately reproduces the polarisation in reactions of the same phenols with triplet benzophenone,[102] and this provides a firm (but not conclusive) basis for the assertion that uranyl reacts in a triplet state and generates a triplet RP.

The ketyl radical of benzophenone is formed as an intermediate on oxidation of benzhydrol and benzilic acid.[48] This radical, on the other hand, is a good donor[44,47] and oxidation of ketyl to ketone occurs in the cage (see scheme below).



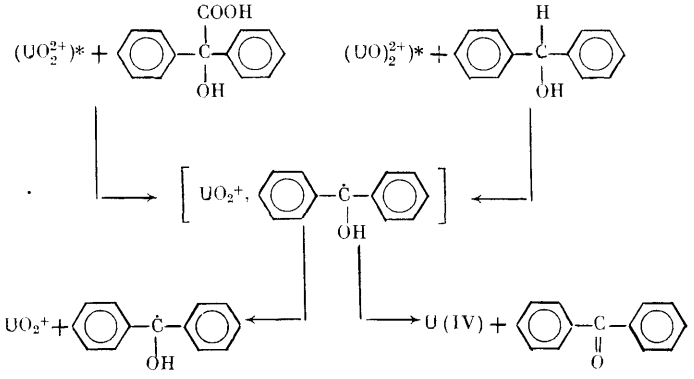


Figure 3. PMR spectrum of a solution of benzilic acid and uranyl nitrate in methanol-d_4 before (a) and during (b) irradiation of solution.[48]

The resulting benzophenone proves to be polarised (Fig. 3). The polarisation signs of the phenols and benzophenone are in agreement with the theoretical values on the basis of the following assumptions:

1) the RP is triplet; 2) the cage product is polarised; and 3) the g factor of uranoyl UO_2^+ is less than the g factor of phenoxyl (ketyl). The latter assumption was substantiated to a sufficient degree of reliability in section IV.1. Thus, the CPN data indicate that the predominant contribution to the reactive form of uranyl is provided by its triplet state, which is preserved during its chemical conversion to an RP.

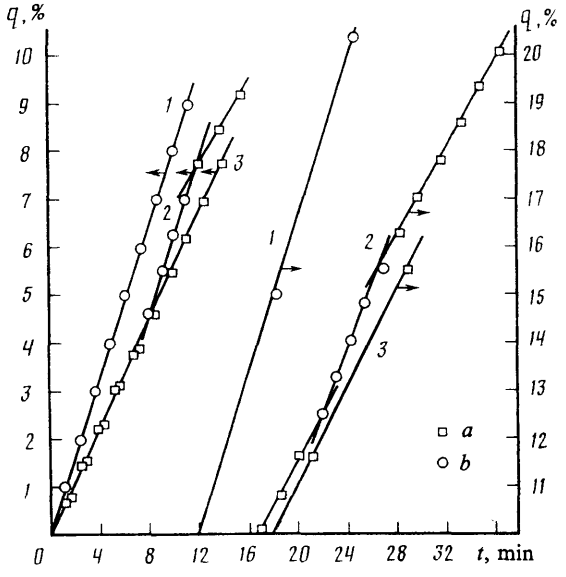

Figure 4. Dependence of conversion (q) on time in the polymerisation of *N,N,N,N*-dimethyldiallylammonium chloride in the earth's field (a) and in an external magnetic field (b):[101] *1*, polymerisation in the magnetic field; *2*, polymerisation with alternate installation and removal of the magnet; *3*, polymerisation in the earth's field.

2. Effect of an external magnetic field

Photochemical reactions that occur via the formation of triplet radical pairs are known to demonstrate significant magnetic field effects (MFE).[1,68–71] It may be expected that the spin-selective photochemical reactions of uranoyl will also be sensitive to an external magnetic field. A clear indication of the triplet multiplicity of the reacting photoexcited uranyl and the subsequent RP is the MFE in the photopolymerisation of *N,N,N,N*-dimethyldiallylammonium chloride photoinitiated with uranyl acetate.[101] The effect is clearly visible in Fig. 4. An external magnetic field (B = 0.17 T) causes a 10–40% acceleration of polymerisation. This result is reproducible regardless of when the field is applied or disconnected. At the same time as an increase in the rate of polymerisation, the molecular weight of the resulting polymer decreases in the field. Both of these results clearly suggest that: 1) initiation is the spin-selective stage, i.e. the UO_2^+ ion and the monomer molecule radical are partners of the primary RP; 2) this primary pair is a triplet, since only under this condition does the magnetic field suppress its conversion to a singlet, which increases the yield of radicals and the efficiency of initiation resulting in an acceleration of polymerisation and a decrease in the kinetic length of the polymerisation chain (or the molecular weight of the polymer). During the reaction there is an accumulation of U(IV) formed in both cage and extracage reactions: the yield of U(IV) decreases in the field.[101] The photodecomposition of uranyl oxalate (or oxalic acid in the presence of uranyl nitrate and a mineral acid) is of considerable interest. This reaction forms the basis of the uranyl oxalate actinometer. By titrating oxalic acid it is possible to determine its decomposition on photolysis with great accuracy. The reaction mainly involves the uranyl-sensitised oxidation of oxalic acid:[3,28,38,45]

$$H_2C_2O_4 \longrightarrow \begin{cases} \longrightarrow CO_2 + CO + H_2O\,, \\ \longrightarrow CO_2 + HCO_2H\,. \end{cases} \qquad (20)$$

Moreover, there is no doubt that an RP involving $CO_2^{\cdot-}$ and UO_2^+ is formed in this reaction. The EPR spectrum of the $CO_2^{\cdot-}$ radical anion in this system was recorded at low temperature.[28] A radical anion released from the cage recombines and oxalic acid (after protonation) is regenerated. An external magnetic field could affect the outflow of radicals from the cage and the rate of consumption of oxalate ions on photolysis, but no effect from a magnetic field on the rate of this reaction involving uranyl containing 10% ^{235}U was found (within the limits of an experimental error of ~2%).[15] A previously unexplained phenomenon was also reported: the strong oxidising agent uranoyl oxidises the strong reducing agent $CO_2^{\cdot-}$ in the cage with low efficiency:[28]

$$^3[UO_2^+,\ CO_2^{\cdot-}] \rightarrow U^{4+} + CO_2. \qquad (21)$$

The reason for this phenomenon and the absence of an MFE in uranyl oxalate reactions would appear to have a common origin. For reaction (21) to occur it is necessary for the triplet pair to evolve into a singlet, which is made difficult because of the lack of hyperfine coupling between the two radical partners, and therefore the RP $[UO_2^+,\ CO_2^{\cdot-}]$ mainly participates in other reactions.[28]

Within the limits of experimental error (2–5%) no MFE was detected by Khudyakov et al.[25,26] in the outflow of free radicals from the solvent cage during pulsed photooxidation of a number of donors in homogeneous and micellar solutions of uranyl salts containing a natural percentage of magnetic isotope.

Triplet–singlet transitions in the pair $[UO_2^+,\ SH^{\cdot}]$ can be induced not only by hyperfine electron-nuclear coupling. Thus, in the photoreduction of uranyl nitrate with hydroquinone and *p*-methoxyphenol at 285–293 K in a viscous solvent, a negative MFE for the outflow of aromatic radicals into the bulk of the solvent was

found.[122] The reason for the negative MFE may be either a triplet mechanism (if the magnetosensitive stage is the action of the magnetic field on mixing of the triplet levels of the exciplex) or a Δg mechanism in the RP.[68] The large difference between the g factors of an organic radical and uranoyl may lead to measurable MFE effects through a Δg mechanism even in a moderate field.[122]

An increase in the content of ^{235}U isotope in the salt from 0.7 to $\approx$10% leads to a build-up of a positive MFE.[122] In fact, increasing the content of magnetic isotope leads to an increase in the content of $[^{235}UO_2^+, SH^{\cdot}]$ pairs, which have more effective HFC constants in both partners than $[^{238}UO_2^+, SH^{\cdot}]$ pairs. With a 10% content of ^{235}U isotope, the effect of the opposite sign is approximately balanced and the magnitude of the MFE is within the limits of experimental error.[122]

Strictly speaking, from the results discussed it is not possible to make any definite quantitative conclusions about the magnetic interactions in an RP involving uranoyl, but the characteristics of the dependence of the MFE on the isotopic composition of uranyl provides a basis for the expectation that HFC with the ^{235}U nucleus contributes to the spin dynamics of the pair, and hence a magnetic isotope effect can be anticipated.

3. Magnetic isotope effect

The photoreduction of uranyl with phenols, as demonstrated above, is a spin-selective reaction; and therefore, in addition to an MFE, an effect from the internal magnetic field of the ^{235}U nucleus, namely, an MIE, can be expected in these reactions. A magnetic isotope effect was detected in the photoreduction of uranyl nitrate with *p*-methoxyphenol (PhOH) in heavy water in the presence of ammonium fluoride.[49] In this system the following fundamental stages occur:

$$(UO_2^{2+})^* + PhOH \rightarrow {}^3[UO_2^+, PhO^{\cdot}] + H^+, \quad (22)$$

$$^3[UO_2^+, PhO^{\cdot}] \longrightarrow UO_2^+ + PhO^{\cdot}, \quad (23)$$

$$^3[UO_2^+, PhO^{\cdot}] \longrightarrow UO_2^{2+} + PhOH, \quad (24)$$

$$UO_2^+ + UO_2^+ + 4HF \rightarrow UO_2^{2+} + UF_4 + 2H_2O. \quad (25)$$

The *p*-methoxyphenoxyl radical formed in the reaction has relatively small HFC constants from the *ortho*-protons and it may be assumed that the a_U constant in $^{235}UO_2^+$, even if it is not that large, will contribute to the effective HFC constant of the radical pair. With conversions of uranyl of less than 20%, Khudyakov et al.[49] detected the depletion of ^{235}U isotope in the precipitate of UF_4. In the initial uranyl nitrate the ratio of $^{238}U:^{235}U$ was 8.93 $\pm$ 0.01, while in the UF_4 reaction product this ratio occurred within the limits 8.970 $\pm$ 0.005 to 8.945 $\pm$ 0.008.[49] This corresponds to an enrichment of the initial unreacted uranyl with ^{235}U isotope and agrees in sign with that expected theoretically: a triplet pair with "magnetic" ^{235}U nuclei should undergo reductive reaction (24) more rapidly, and then the ^{235}U nuclei will separate into regenerated uranyl. The magnitude of the effect is small (apparently, the electron-nuclear interaction in the ^{235}U ion is small in reality), but it exceeds the experimental error of isotopic analysis.

The coefficient of isotope separation determined by us was α = 1.02. This value is small, but significantly exceeds the value of the classical isotope effect, determined, for example, as $(238/235)^{1/4}$ = 1.006. The reaction was conducted in pulsed mode so as to increase the contribution of disproportionation of uranyl [reaction (25)] and to decrease the contribution of the exchange reaction between uranyl and uranoyl [reaction (11)], which is accompanied by a loss of the effect (see Section III).

In the patent literature there are two reports on the separation of uranium isotopes based on the MIE. In one patent[123] the separation of isotopes by photoreduction of uranyl acetate in water or water containing "complexing" components (fluoride, carbonate, oxalate, etc.) is reported. Judging from the description, it appears that the authors[123] started from general conclusions rather than the experimental data.

According to another patent,[124] separation of the isotopes occurs by photopolymerisation of uranyl acrylate in a strong magnetic field in a solution of ethanol. The precipitate is enriched with ^{235}U isotope up to a 50% level. The content of this isotope in the initial nitrate is not reported. It was not possible[15] to reproduce the results of this patent.

Independently and at the same time as the study of Khudyakov et al.[49] a reliable MIE in uranium was detected in the decomposition of uranyl oxalate.[125] On photolysis of acid solutions containing 10% ^{235}U, enrichment of the precipitate—uranium(IV) oxalate—and depletion of the initial uranium(VI) occur.[125] For example, with 18% conversion of uranyl having a ratio of $^{238}U:^{235}U$ = 10:1, it becomes depleted in magnetic isotope (this ratio becomes equal to 10.2:1). For U(IV) this ratio is 9.4:1, the fundamental coefficient of isotope separation being α = 1.08.[125] It is logical that the product of the cage reaction—uranium(IV)—should be enriched. Cage reaction (21) occurs more rapidly for uranoyl containing magnetic isotope (see above).[125] The "destructive" isotopic exchange (11) in extracage reactions is apparently inhibited because uranyl is present as a complex with oxalate. The degree of enrichment decreases with an increase in conversion.[125] The results of this study were subsequently reproduced by Klimchuk.[15]

VI. Conclusion

Certain general principles are in evidence amongst the very large range of photochemical reactions of uranyl.

Firstly, the primary reactions almost always occur with transfer of an electron or hydrogen atom from the partner to uranyl to form the UO_2^+ radical ion.

Secondly, in these reactions the UO_2 shell is preserved, destruction of which occurs in secondary reactions (disproportionation of uranoyl ions, exchange of oxygen atoms, etc.).

Thirdly, the majority of the reactions can be differentiated according to a single important criterion—whether the reaction occurs in the equatorial plane of the uranyl ion (i.e. involving equatorial ligands) or whether it takes place on the "pole" (i.e. involving the oxygen atoms of uranyl). The first reactions take place preferentially as electron transfer, the second occur as a hydrogen atom transfer from the reagent to an "yl" oxygen atom (these latter are almost identical in many respects to the reactions of triplet benzophenone). It is true that the question of transfer of an electron or hydrogen atom, as always, is unclear and the preference for a given route remains uncertain in many cases.

Fourthly, the excited reacting uranyl ion can be confidently assigned a given spin state, namely—triplet. A number of indirect findings (the lifetimes, radiospectroscopy of radical pairs, chemical properties) as well as direct evidence [magneto-spin (CPN) and magneto-field effects] attest in favour of this assertion. Thus,

reactions of excited uranyl are spin-selective and hence magnetosensitive.

In this respect the magnetic properties of the uranoyl ion UO_2^+ become important, and in this case there is considerable uncertainty and much needs to be done to measure the *g* factor and hyperfine coupling in this ion in molecularly oriented systems.

The contribution of the magnetic moment of the ^{235}U nucleus and hyperfine coupling to the spin dynamics of pairs involving a uranoyl radical is of particular interest. The separation of uranium isotopes in spin-selective reactions of uranium compounds based on an MIE over a period of fifteen years has proved to be a vital problem.[71,126] It must be assumed that the presence of a heavy uranium atom and the danger of spin-orbit coupling has deterred researchers of the MIE. However, the scale of the MIE does not vary very much throughout the series of elements for which it was detected (^{13}C, ^{17}O, ^{29}Si, ^{33}S), although the spin-orbit coupling constant in this series increases by a factor of more than ten—from $\zeta = 28$ cm^{-1} (for carbon) to $\zeta = 382$ cm^{-1} (for sulphur).[119,120] This means that the role of spin-orbit coupling in spin dynamics has been exaggerated. At the present time the MIE and separation of uranium isotopes based on it have been detected in two reactions—the photoreduction of uranyl with a substituted phenol and the uranyl-sensitised photodecomposition of oxalic acid. This is, of course, an outstanding result, and it will stimulate interest in heavy multielectron atoms and a measurement of the magnetic resonance parameters of the $^{235}UO_2^+$ ion involving its hyperfine coupling with the ^{235}U nucleus.

The formation of weak complexes by metal ions in aqueous solutions

V E Mironov, V A Fedorov, I D Isaev
Institute of Chemistry and Chemical Engineering, Siberian Division of the USSR Academy of Sciences, Krasnoyarsk

ABSTRACT. The modern approaches to the determination of the composition and the stepwise stability constants of weak metal complexes (K_n = 0.1–5.0) with ionic and molecular ligands in aqueous solutions are discussed. The difficulties in the unambiguous separation of the effects of the medium from those of the short-range specific interaction, described by equilibrium constants, and the consequent unreliability of the lower values of the formation constants, even when the latter are selected on the basis of a critical assessment, are examined. It is recommended that the linear relations between the algebraic sums of the logarithms of the activity coefficients of the components of the equilibria investigated and the ligand concentrations, the standard isotherms, or the measurement of the properties of all the components of the complex formation equilibria be employed for the separation of the long-range and weak short-range interactions.

The bibliography includes 130 references.

I. Introduction

The majority of processes in nature, analytical chemistry, and chemical engineering take place in aqueous solutions. Many characteristic features of such processes are determined by weak ion–ion and ion–molecule interactions leading to the formation of relatively unstable complexes. These complexes are formed and decompose via rapid reactions so that many of their properties are determined by thermodynamic functions. The most important thermodynamic parameters of the complexes in solutions are the equilibrium constants of their formation processes.

The determination of the composition and stability constants of complexes in solutions is one of the problems in physicochemical analysis[1] and constitutes the basis of the chemical theory of solutions,[2] which relates the properties of the solution to its composition. In this theory, the solution is regarded as a system where there are equilibria, obeying the Law of Mass Action, between the initial components and the products of their chemical interaction. However, when weak complexes are formed in aqueous solutions, the effect of the specific interaction is difficult to separate from the influence of the aqueous salt medium whose composition varies.

The thermodynamic functions for the formation reactions of a large number of weak complexes have been compiled in modern handbooks.[3–6] Metal cations M^{z+} with z = 1–4 usually play the role of coordination centres in the compounds considered, while polar molecules A or anions A^{z-} with z = 1–3 serve as the ligands. Analysis of data in handbooks[6] and in original studies (quoted below) shows that the current information about the thermodynamics of weak complex formation and even about the composition of weak complexes in aqueous solutions is extremely contradictory. Even many of the critically selected[5] values of the stepwise stability constants of weak complexes, for example $TlNH_3^+$, are doubtful. This is considered in Section IV of the present review.

During the last 20 years, there has been a renewed growth of interest in the thermodynamics of weak complex formation by metals. Numerous studies of outersphere association,[7–11] detailed investigation of non-aqueous solutions,[12,13] and the development of the theory of homogeneous catalysis[9] played a major role in this connection. The improvement of the level of studies on weak complex formation has been promoted by the application of microwave spectroscopy and computer techniques[14,15] and also by the use of the method involving the measurement of the activities of individual ions.[16]

Numerous new investigations[17–26] have been carried out to revise the information on the thermodynamics of repeatedly investigated complexes with low stabilities. Bjerrum discussed[27,28] the limits of the possibilities for the estimation of low stability constants of associated species in aqueous solutions. A controversy has recently arisen[26,29,30] concerning the reliability and accuracy of the determination of the stepwise formation constants of the weak complexes $CuCl_n^{2-n}$ with n = 1–4. Studies have been published[31–40] in which it is recommended that the compositions of weak associated species be determined taking into account the non-ideality of aqueous solutions with high constant ionic strengths (0.5–4.0). A new standard state has been proposed[41–43] (isopiestic solutions) for the investigation of weak complex formation. The possibilities for the quantitative investigation of weak metal ammines have been expanded.[25,44–47] A similar approach has been extended[48–50] to other ion–molecule complexes with low stabilities. Numerous free energies of transfer of ions from water to non-aqueous and mixed solvents have been surveyed and analysed.[51–53] The practical role of the thermodynamic functions of individual ions has been demonstrated.[54–56]

The most common one-centre complex formation reactions of metal (M) ions with ligands (A) in aqueous solutions are represented by the following reaction equations at the present level of development of chemistry:

$$M(H_2O)_{N,\,solv} + nA_{solv} \rightleftarrows MA_n(H_2O)_{N-nd,\,solv} + ndH_2O_{solv}, \quad (1)$$

where N is the limiting coordination number according to Werner's theory and d is the number of water molecules displaced by one

ligand A from the hydration shell of the central cation M. The ionic charges in Eqn. (1) and whenever possible in the text below are omitted to simplify formulation. The subscripts *solv* in the reactants involved in equilibrium (1) show that the latter interact in a definite sequence with all the remaining components of the solution and in the first place with solvent (water) molecules and with the ions of the supporting electrolyte and the excess ligands. However, these interactions are not included in Eqn. (1) in order to simplify the treatment of the properties of the system. They are frequently referred to as non-specific and are assigned to the effect of the medium or to changes in the activity coefficients.[57]

The constants β_n^0 of type (1) equilibria are expressed by the following relation for any standard state (designated by the superscript 0):

$$\beta_n^0 = \frac{[MA_n(H_2O)_{N-nd}][H_2O]^{nd}}{[M(H_2O)_N][A]^n} \cdot \frac{y_{MA_n(H_2O)_{N-nd}} y_{H_2O}^{nd}}{y_{M(H_2O)_N} y_A^n} = \beta_n \left(\prod_i y_i^{\nu_i}\right)_n, \quad (2)$$

where the square brackets and y_i denote the equilibrium concentrations and the activity coefficients of reactants i, β_n is the product of the concentrations or equilibrium function (but is not a constant! [1]), and ν_i are stoichiometric coefficients. The values of β_n in type (2) equations remain constant only when the concepts of the reactants and the effect of the medium, included in the symbol *solv* or in the values of y_i, are assumed to be fixed. The quantities β_n^0 are standardised in terms of temperature, pressure, and the medium selected as the standard with $I = 0$, I = const., etc. (I = ionic strength).

Whatever the standard state chosen for the study of weak complexes in aqueous solutions, the constancy of the activity coefficients in Eqn. (2) cannot be maintained. Their variation must be taken into account in the determination of n and β_n^0 for type (1) equilibria from "property–composition" diagrams because β_n and $\left(\prod_i y_i^{\nu_i}\right)_n$ are frequently comparable when the stability of the associated species is low.

There is a limitation as regards energy[7] (p. 196) in the determination of the composition and formation constants of weak complexes in solutions using the thermodynamics of reversible processes. To a first approximation, the energy of the thermal motion of the solvent, i.e. water, molecules may be adopted as a measure of this limitation, because complex formation via reaction (1) is studied in an aqueous medium. The energy of the thermal motion of solvent molecules is minimal in the ideal gas model. Such energy is defined as $1.5RT$ and at 298 K it amounts to 3.7 kJ mol^{-1}. The energy of the thermal motion of water molecules in water is comparable to the strength of the hydrogen bond and is approximately equal to 20 kJ mol^{-1}. Assuming that the energies indicated (3.7 and 20 kJ mol^{-1}) are equal to the changes in the Gibbs free energy (ΔG_n°) (it is more correct to compare them with enthalpy changes) during the stepwise occurrence of reaction (1), we obtained from the relation

$$\Delta G_n^0 = -RT \ln {}^{y}K_n^0 \quad (3)$$

where ${}^{y}K_n^0$ are unitary stepwise constants of equilibrium (1), the values of $\lg {}^{y}K_n^0$ at $T = 298$ K, which lie in the range 0.7–3.5 if d in Eqn. (2) is unity and $[H_2O] = 55.5$ M. Hence it follows that cratic stepwise stability constants, varying approximately from 0.1 to 50, correspond to the energy level of the thermal motion of solvent molecules in the ideal gas model and of water molecules under the conditions indicated. The tabulated stepwise stability constants of weak complexes[3–6] lie within these limits. The stepwise stability constants below 0.1, which are frequently quoted in handbooks,[3–6] cannot be regarded as an adequate demonstration of the formation of complexes, which has been emphasised by Krestov[58] and other investigators. Spectral additional justification of the occurrence of specific interactions is needed in systems with $K_n \leqslant 0.1$. In the absence of such justification, there is apparently no point in separating the measured effects from the changes in the activity coefficients.

The introduction of the concept of the formation constant of a complex always presupposes the presence in the solution of the initial reactants and of the molecules of the complex located at some statistical mean distance from one another. This situation is possible when there are delta-type relations between the potential energies of the associated species and the distance between M and A in reaction (1) and the separate existence of the reactants in the associated and dissociated states is likely only when the probability of the intermediate variants is zero. However, over a wide range of concentrations of electrolytes, such a situation does not arise—for example, when the ions have the electronic structure of noble gases. For systems of this kind, one should not determine the low formation cosntants of the complexes because such constants have no definite physical significance according to Kessler [see, for example, Valyashko and Kravchuk[59] (p. 7)].

This review was written with the aim of a critical consideration of the modern approaches to the determination of the composition and stability constants of weak metal complexes with ionic and molecular ligands in aqueous solutions, the analysis of a series of reliable data on the thermodynamics of weak complex formation reactions, and also the formulation of certain recommendations for new research into weak interactions in aqueous solutions.

II. Standardisation of conditions in the study of weak complex formation in aqueous solutions

The relation between the chemical potential of the component (μ_i) and its overall (c_i) and equilibrium ($\{[i]\}$) concentrations in a real solution at a constant temperature and pressure can be expressed by the equations

$$\mu_i = \mu_i^0 + RT \ln c_i y_i^* = \mu_i^0 + RT \ln [i]\, y_i, \quad (4)$$

$$\mu_i = \mu_i^0 + RT\left(\ln c_i + \sum_x b_{i,x}^* c_i^x\right) = \mu_i^0 + RT\left(\ln [i] + \sum_x b_{i,x} [i]^x\right) \quad (5)$$

where μ_i^0 are the standard chemical potentials, while $b_{i,x}^*$ or $b_{i,x}$ are virial coefficients whose values are independent of c_i or $[i]$. The differences between y_i^* and y_i and also between $b_{i,x}^*$ and $b_{i,x}$ consist in the fact that the coefficients marked with an asterisk represent the deviations in the behaviour of the reactants containing component i from ideality, while the coefficients without an asterisk in the superscript position express the analogous properties of only the conventionally free species i_{solv} constituting the system (1). If there is no chemical interaction, for example, no reaction (1), in the system considered, then $c_i = [i]$, $y_i^* = y_i$, and $b_{i,x}^* = b_{i,x}$. In any arbitrarily selected standard state for component i, we have $c_i = [i] = 1$ and $y_i^* = y_i = 1$, although it is frequently assumed that $y_i^* = y_i \to 1$ when $c_i \to 0$.

Logarithmic concentration functions enter into Eqns. (4) and (5); for this reason, real solutions with $c_i \to 0$ cannot be chosen as the standard state because $\mu_i \to -\infty$ when $c_i \to 0$. The hypothetical 1.0 M or 1.0 m (M and m represent the molarity and molality respectively) solutions, having the properties of infinitely dilute solutions, usually serve as the standard state for the determination of thermodynamic functions for the complex formation reactions. The choice of water, an aqueous salt solution at a constant of ionic strength or at a constant molarity, and also of any mixed solvent as the solvent for the system alters only the point from which the excess thermodynamic functions are reckoned or the factors designated by the subscript *solv* in Eqn. (1). A necessary requirement which must be met by the standard state is the constancy of these factors, i.e. the constancy of the concept of "*solv*" and of the quantity y_i. It must be emphasised that water is a fully legitimate reactant involved in equilibrium (1) and its concentration, which varies markedly in the study of weak complexes can be usefully expressed on the same concentration scale as that employed for the other reactants (in the study of complexes in solution, the molarity scale is usually employed) and not the mole fraction scale normally used. When the latter is used, it is incorrect to calculate ΔG_n° by Eqn. (3).[60]

It follows from Eqns. (4) and (5) that the relation between these two ways of taking into account the non-ideality of the behaviour of reactant i is defined by the relations

$$\ln y_i^* = \sum_x b_{i,x}^* c_i^x, \tag{6}$$

$$\ln y_i = \sum_x b_{i,x} [i]^x, \tag{7}$$

the first of which refers to a system with complex formation, whose parameters are included in the quantity $\ln y_i^*$ or in $\sum_x b_{i,x}^* c_i^*$.

Measurable amounts of weak complexes are formed only at high concentrations ($>0.1-0.5$ M) of M and A or of one of these substances. The majority of studies on weak interactions have been carried out hitherto[3-6] at microconcentrations of M (at $c_M \leqslant 1 \times 10^{-2}$ M) and with wide variation of c_A. Complex formation was usually studied in aqueous solutions with variable (from 1×10^{-2} to 15 M) or constant (0.5, 1.0, 3.0, 4.0, and 6.0) ionic strength maintained by inert electrolytes. Sodium perchlorate and ammonium nitrate were usually employed as the latter.

The wide variations of the concentration c_A or c_M, required to investigate weak complexes whatever the choice of the standard state, alter the factors designated by the subscript *solv* in type (1) equilibria or contributing to the activity coefficients in Eqn. (2). Such changes must be taken into account in calculations of n and β_n^0.

After taking logarithms in Eqn. (2), we obtain

$$\lg \beta_n{}^0 = \lg \beta_n + \lg y_{MA_n} + nd \lg y_{H_2O} - \lg y_M - n \lg y_A =$$

$$= \lg \beta_n + \Delta (\nu_i \lg y_i)_n, \tag{8}$$

where the symbol Δ denotes the algebraic sum. Substitution of the general Eqn. (7) in Eqn. (8) affords

$$\lg \beta_n{}^0 = \lg \beta_n + \Delta \left(2.303 \nu_i \sum_x b_{i,x} [i]^x\right)_n . \tag{9}$$

Application of Eqn. (9) to semi-ideal solutions,[61-63] i.e. the restriction of the sum in Eqn. (7) to the quantities $b_{i,1}$, leads to the equation

$$\lg \beta_n{}^0 = \lg \beta_n + \Delta (2.303 \nu_i b_{i,1})_n [i]. \tag{10}$$

If the composition of the test solution changes only as regards the ligand A concentration, then Eqn. (10) simplifies and assumes the following form:

$$\lg \beta_n{}^0 = \lg \beta_n + \lambda_n [A], \tag{11}$$

where λ_n is the algebraic sum of $b_{i,1}$ with allowance for the stoichiometric coefficients ν_i.

Potentiometric study of the equilibrium

$$Ac^-_{solv} + H_2O_{solv} \rightleftarrows HAc_{solv} + OH^-_{solv}, \tag{12}$$

where HAc is acetic acid, in 3.0 M aqueous Na(Cl→Ac) solutions with chromatographic determination of the activity coefficients of acetic acid molecules made it possible to estimate[32] the contributions of the non-ideality of the behaviour of all the reactants as the salt composition of the medium is varied. It is seen from the data in Table 1 that the replacement of chloride ions by acetate ions increases to the maximum extent (compared with other reactants) the activity coefficients of hydroxide ions, but there is at the same time an appreciable increase in the activity coefficients of acetate ions and a significant fall of y_{HAc}. On the other hand, the algebraic sum of the logarithms of the activity coefficients of the reactants ($\Delta \lg y_i$) involved in equilibrium (12), i.e.

$$\Delta \lg y_i = \lg y_{OH^-} + \lg y_{HAc} - \lg y_{Ac^-} \tag{13}$$

varies appreciably less than the activity coefficients of any individual reactant. The ratio $\Delta \lg y_i / c_{Ac^-}$ then remains almost constant and amounts to 0.07 ± 0.01 at all the concentrations of chloride and acetate ions.

Table 1. The logarithms of the activity coefficients of the reactants involved in equilibrium (12) in 3.0 M Na(Cl→Ac) solutions at 298 K.

c_{Ac^-}, M	$\lg y_{OH^-}$	$\lg y_{Ac^-}$	$-\lg y_{HAc}$	$-\lg y_i$ from Eqn. (13)	$-\lambda_i = \Delta \lg y_i / c_{Ac^-}$
0.5	0.07	0.04	0.07	0.04	0.08
1.0	0.14	0.08	0.13	0.07	0.07
2.0	0.30	0.20	0.24	0.14	0.07
3.0	0.45	0.30	0.33	0.18	0.06

Calculations have shown[31] that β_1, approximately equal to unity, changes by almost 100% if λ_1 in Eqn. (11) amounts to only ~0.2, as happens in many mixtures of uni-univalent electrolytes with I = const. Hence it is clear that, in the study of weak acido-complexes in aqueous solutions with I = const., it is essential to determine both β_n and λ_n in Eqn. (11).

The study of the behaviour of non-electrolytes in aqueous solutions of the majority of inorganic salts with variable and constant ionic strengths has recently[61] led to the equation

$$\lg y_i = \sum_j b_{i,j}^* c_j, \tag{14}$$

where the Sechenov's constants $b_{i,j}^*$ depend only on the nature of the non-electrolyte i and the ions j. Eqn. (14) is valid for all systems without strong interactions between the molecule i and the ions j.

The activity coefficients of the ion i are expressed by the following equation over a wide range of ionic strengths:

$$\lg y_i = -Az_i^2\sqrt{I}/(1 + B\mathring{a}\sqrt{I}) + b_i^*I, \quad (15)$$

where A and B are the Debye–Hückel constants calculated theoretically, $\mathring{a}$ is the conventional ionic radius, and b_i^* is the second virial coefficient. The first term on the right-hand side of Eqn. (15) is constant at I = const. if it is assumed that $\mathring{a}$ is invariant. By analogy with Eqn.(14), it is suggested that one assumes[33] that the activity coefficients of the ions and ionic strengths, which are constant in magnitude but variable as regards composition, are described by the equation

$$\lg y_i = F_i(I) + \sum_j b_{i,j}^* c_j, \quad (16)$$

in which $F_i(I)$ are characteristic constant functions of the ion i independent of the nature of the ion j.

The applicability of Eqn. (16) to mixtures of uni-univalent electrolytes with a constant molarity or molality has been repeatedly confirmed.[18,19,31] Eqn. (16) is frequently valid for mixtures of uni-bivalent and bi-univalent electrolytes of the type of sodium sulphate or barium chloride for constant overall molar concentrations[33] but not constant ionic strengths I.

Throughout many years, the model of semi-ideal solutions was used successfully[23,64] in the study of copper(II), cobalt(II), and iron(III) chloride complexes as well as other weak associated acido-species formed by reaction with the cations M in 3–12 M solutions of hydrochloric acid and lithium, magnesium and calcium chlorides as well as similar solutions[26] with variable ionic strengths. The corrections for the variation of the activity coefficients in such solutions were introduced in terms of averaged system parameters (y_{av}) expressed by the relation

$$\lg y_{av} = a + bc_{Cl^-}, \quad (17)$$

where a and b are constants for a specific salt medium with a variable ionic strength. The similarity of the methods used to take into account the non-ideality of the solutions with constant ionic strengths I = 0.5–6.0 and for variable ionic strengths $I \geqslant 3$ is clearly seen from the comparison of Eqns. (16) and (17).

The need to take into account the changes in the activity coefficients of the Cd^{2+} ions in 3.0 N aqueous solutions of sodium sulphate and perchlorate arose already in the old investigations of cadmium sulphate complexes.[65] It was established that the measured activities of sulphate ions can be accounted for by the hypothesis of the formation of only the $CdSO_4$ complexes with a stability constant of 7 ± 2, while the activities of the cadmium cations in the same solutions are reproduced by the hypothesis that the complexes $Cd(SO_4)_n^{2-n}$ [sic] are formed with ν_n = 8 ± 1, 10, and 110 for n = 1, 2, and 3 respectively.

McKay[66] cast doubt on the low thermodynamic functions for complexes standardised using solutions with high and constant ionic strengths immediately after the publication of the first edition of the Handbook of Stability Constants.[3] Pitzer and Brewer[67] pointed out as early as 1961 that there is no point in using solutions with high and constant values of I for the study of weak acido-complexes, since the Harned coefficients for I = const. = 0.1–3.0 are approximately constant.

Kul'ba and Mironov[68] noted in 1963 that the values of n and β_n for the weak acido-complexes TlA_n^{1-n} with $n > 1$, where A^- = Cl^-, Br^-, I^- or SCN^- are conventional thermodynamic parameters which include both the short-range specific interaction of Tl^+ with A^- and the changes in the activity coefficients of ions reacting in 3.0 or 4.0 M aqueous solutions of Na(ClO_4→A). It has been shown[31] that the changes in the composition of the majority of uni-univalent electrolyte solutions with I = const. make it possible to determine the stepwise stability constants of acido-complexes of ~10 with an error not less than 10% without taking into account the variability of the activity coefficients, the error increasing with decrease in K_n.

Eqn. (11) was first used for a detailed study of weak multistep acido-complex formation by Vierling,[34,69] who investigated lead(II) chloride and bromide complexes in 4.0 M aqueous Na(ClO_4→A) solutions, where A^- = Cl^- or Br^-, with complete replacement of perchlorate ions by halide ions. Potentiometric, solubility, and spectrophotometric methods were used as the basis for these investigations. Unfortunately, the relevant communications do not give a mathematical analysis of the reliability of the simultaneous calculation of β_n^0 and λ_n on the basis of Eqn. (11). The necessity to analyse the different hypotheses concerning the formation of weak acido-complexes in connection with the determination of β_n and λ_n in aqueous solutions with high ionic strengths was first confirmed by Belevantsev et al.[40] This conclusion was reached from the applicability tosolutions with constant molarities and molalities of the Harned rule with a single virial coefficient α' in the general equation

$$\lg y_{\pm}^{(I+II)} = \lg y_{\pm}^{(I)} - \alpha' c_{II} - \alpha'' c_{II}^2 \quad (18)$$

where $y_{\pm}^{I+II)}$ and $y_{\pm}^{(I)}$ are the mean ionic activity coefficients in mixtures of electrolytes (I) and (II) with I = const. and in the pure electrolyte (I) with the same ionic strength, c_{II} is the concentration of electrolyte (II) in the mixture, and α' and α'' are Harned coefficients, usually with $\alpha' \gg \alpha''$. However, the limited applicability of the Harned rule is generally known.[70,71] At the same time, Eqn. (11) is valid for many aqueous salt systems. This contradiction can be accounted for by the fact that λ_n is the algebraic sum of the Harned coefficients. The high values of the latter, as well as the terms quadratic in c_{II}, cancel out in this sum judging from the data in Table 1. It is important that Eqn. (11) is frequently applicable to solutions with variable ionic strength as a result of the applicability of the Storonkin–Lagunov rule[72] to these systems. It has been noted[40] that the values of λ_n in Eqn. (11) as well as those of $\lg y_{\pm}$ can be divided into components corresponding to individual ions. At the same time, accurate calculations of the λ_n from the mean ionic activity coefficients are by no means always possible, while the Harned coefficients for individual ions are extremely useful for the estimation of the effects of non-ideality.

The values of λ_1 for equations of type (11) have been determined[36,73] in the study of solutions with microconcentrations of outer-sphere tris(phenanthroline)iron(II) monoperchlorate complexes, keeping the ionic strength I, the normality N, and the molarity M constant using mixtures of two salts and also at a constant activity of water a_{H_2O}. It was found (Table 2) that the replacement of the constant parameters in the sequence I, N, $M \simeq a_{H_2O}$ reduces significantly the value of λ_1, i.e. diminishes the effect of non-ideality. The changes in I or N in the range 0.25–0.75 have little influence on λ_1, but none of the methods of standardising the conditions in the study of weak perchlorate complexes indicated ensures the constancy of the activity coefficients. The replacements Na(F→Cl), Na(F→Ac), and (Na_2→Li_2)SO_4, i.e. of one singly-charged ion by another singly-charged ion, had little influence on λ_1, while the replacement of fluoride or chloride ions by divalent sulphate ions did exert a significant influence.

It has been established[74–79] that the coefficients λ_1 are almost constant for the equilibria in the formation of microamounts of

$H^+ - A^{z-}$ associated species and certain metal acido-complexes in mixtures of $NaClO_4$ with NaCl, NaBr, NaI, $NaNO_3$, and $LiClO_4$ at constant ionic strengths I = 0.5, 1.0, 2.0, 3.0, 4.0, and even 6.0 (Table 3). The constancy of λ_1 is maintained also for 3.0 M Na(Cl→Ac) solutions[32] in which 0.1–3.0 M acetate ions (Ac^-) are protonated, i.e. the process takes place under the conditions of an ionic automedium (Table 1).

Table 2. The coefficient λ_1 (accuracy to within ±20%) in Eqn. (11) [36,39,73] for tris(phenanthroline)iron(II) monoperchlorate complexes.

Supporting salt	λ_1 at				
	I=0.25	I=0.75	N=0.25	M=0.25	a_{H_2O}=0.99

In order to reduce the activity coefficients λ_1 in Eqn. (11), recommendations have been formulated[80] concerning the rational selection of electrolytes for the study of weak acido-complexes. According to these recommendations, the difference between the logarithms of the mean ionic activity coefficients ($\Delta \lg y_\pm$) and the activities of water (or osmotic coefficients) in solutions of an inert electrolyte BX and the ligand-supplying salt BA should be minimal. Analysis of the parameters

$$\Delta \lg y_\pm = (\lg y_{\pm BX} - \lg y_{\pm BA})\, m^{-1}, \quad (19)$$

$$\Delta\varphi = (\varphi_{BX} - \varphi_{BA})\, m^{-1}, \quad (20)$$

where m is the molality and φ are osmotic coefficients, showed[63,70,71] that, for $\Delta \lg y_\pm$ and $\Delta\varphi$ tending to zero, the microcomponents of the type (1) equilibria in BX + BA mixtures induce a minimal change in the activity coefficients. For example, such changes have been observed for acetic acid (Table 3) and also for thallium(I) [24] and lead(II) [81] chloride complexes in isopiestic $NaClO_4$ + NaCl solutions which are nearly isomolar.

Krigintsev[82] and Ryazanov suggested[41–43] isopiestic solutions of mixtures of BX with BA as a new standard state. It is recommended that, when the latter is used, the entire experimental effect be included in the thermodynamic functions for equilibrium (1). On this assumption, no account is taken of the differences between the following parameters:

$$\Delta \lg y_\pm = (\lg y_{\pm MX_z} - \lg_{\pm BX})\, m^{-1}, \quad (21)$$

$$\Delta \lg y_\pm'' = (\lg y_{\pm MX_z} - \lg y_{\pm BA})\, m^{-1}\ . \quad (22)$$

The main feature is that one neglects the difference between the degrees of associaiton of ions in mixtures of the BX and BA salts, which makes an appreciable contribution even to the properties of 1.0 M Na(Cl→F) solutions[83] owing to the different strengths of the $Na^+(H_2O)_xCl^-$ and $Na^+(H_2O)_xF^-$ ion pairs.

A novel, purely chemical approach to complex non-ideal solutions put forward by Poppi[84,85] is noteworthy. It is based on allowance for the formation of solvates and transformation distributions. The non-ideality of such solutions is taken into account in terms of the hypothesis of an ideal solution of a continuous set of solvates. However, this procedure for taking into account non-ideality has not so far undergone the necessary tests on a sufficient number of specific examples. This also applies to a promising unified concept within the framework of which reduced ionic activity coefficients are used as characteristics of the non-ideality of the solutions.[86]

In many systems, the quantities λ_n in Eqn. (11) remain virtually constant when constant ionic strengths are varied in the range 0.5–4.0 (Table 3). The constancy of λ_n has been frequently demonstrated in relation to the behaviour of weak acids in mixtures of two electrolytes. The values of λ_n for the stepwise protonation of anions, i.e.

$$nH^+ + A^{z-} \rightleftarrows H_nA^{n-z} \quad (23)$$

were determined for systems with z = −1, −2, and −3. On the basis of the constancy of λ_n at constant ionic strengths I in the range 0.5–4.0, a method was developed for the separation of the medium effect from the effect of weak complex formation.

It is important to stress that the coefficients λ_n are constants even in those systems where the values of $\lg y_i$ in Eqn. (8) depend significantly on the constant ionic forces in mixtures of two electrolytes. The abolition of the differences between the values of $\lg y_i$ as a result of the cancellation of the third virial coefficients in equations of type (5) explains this finding. According to data in handbooks,[87] the quantities $b_{i,1}$ are almost constant for 0.1–0.6 m aqueous Na(ClO_4→A) solutions with A^- = Cl^-, Br^-, or I^-, but

decrease appreciably with increase in the molality of mixtures of $Li(ClO_4 \rightarrow A)$ and $K(F \rightarrow A)$. Mixtures of MSO_4 (M = Zn, Cu) with sodium, potassium, magnesium, and bismuth(II) sulphates as well as sulphuric acid can be divided into three groups as regards the nature of the dependences of $\Delta \lg y_{\pm}$ on I:[88] for the first group, the dependence has a maximum, for the second it has a minimum, and for the third the values of $\Delta \lg y_{\pm}$ remain almost constant over the entire range of ionic strengths I.

Potentiometric determinations of the activity coefficients of microamounts of tris(ethylene diamine)cadmium(II) [89] from the e.m.f.'s of cells with transport in 1 M aqueous $Li(ClO_4 \rightarrow A)$ solutions showed that b_i [Eqn.(16)] varies with increase in I in the same way as $y_{\pm}$ for $LiClO_4$ + LiA mixtures.

The influence of the charge of the ion A^{z-} in equilibrium (23) on λ_n in Eqn.(11) is of interest. There exists the view that the relation[79,90]

$$\lambda_n \simeq n\lambda_1 \qquad (24)$$

is valid, as can be seen from the data for oxalic acid, or that $\lambda_1 \simeq \lambda_2 \simeq \lambda_3$, as can be seen from the values of λ_n for citric acid (Table 3). Preference is usually given to Eqn.(24), but, unfortunately, the experimental data concerning the influence of ionic charges in equilibrium (1) on the λ_n are not unambiguous[90] and have been obtained only in isolated studies. In a new investigation,[26] Bjerrum notes that the following relation is valid for weak acido-complexes in solutions with high variable ionic strengths:

$$(y_{M^{z+}}y_{A^-})/y_{MA^{z-}} \approx (y_{MA^{z-1}}y_{A^-})/y_{MA_2^{z-2}} \approx \ldots \approx y_{MA_n^{z-n}}y_A/y_{MA_{n-1}^{z-n+1}}.$$

Allowance for the non-ideality of solutions with the aid of Eqns.(4), (5), or (11) does not meet the entire set of Guggenheim's requirements[61] (p. 5) for semi-ideal mixtures. This set includes the requirement that the solutions, for example, of BX and BA, at constant temperatures and pressures be mixed without a heat or volume change. Comparison of the data in Tables 3 and 4 shows that the substitution $Na(ClO \rightarrow A)$ at constant values of I in the range 1.0 – 6.0 hardly affects the values of λ_1 in Eqn.(11) but does alter appreciably $\lambda_{1(H)}$ in the equation

$$\Delta H_1^{\upsilon} = \Delta H_1 + \lambda_{1(H)}c_{Ac^-} \qquad (25)$$

where ΔH_1 and ΔH_1° are the enthalpy changes standardised by I M $NaClO_4$ and $Na(ClO_4 \rightarrow A)$ solutions, while $\lambda_{1(H)}$ are coefficients taking into account the influence of the non-ideality of the behaviour of H^+ and Ac^- in $Na(ClO_4 \rightarrow Ac)$ solutions on the coefficient λ_1. It is important to note that the values of $\lambda_{1(H)}$ are much higher than those of λ_1 (see the data in Tables 3 and 4).

Analysis of the heats of protonation of NH_3 and OH^- shows[91] that $\lambda_{1(H)}$ for ammonia is appreciably lower than for the OH^- ion, while the influence of the ionic strength I on these coefficients $\lambda_{1(H)}$ is consistent with the equation of Pitzer's theory (with the exclusion of concentrated nitrate solutions).

The absence of an appreciable influence of constant ionic strength on λ_1 at I = 0.5 – 6.0 (Table 3) led to the conclusion[40,79] that it is desirable to investigate weak acido-complexes at high ionic strengths of solutions with the replacement of a small proportion (< 10 – 20%) of the inert anions by the ligand ions. This conclusion is valid because the ions of any inert salts are little inferior to reactants forming weak complexes as regards their capacity for complex formation. In the light of the Storonkin – Lagunov rule[72] and Bjerrum's studies,[18,29,64] solutions with a variable ionic strength are more suitable as the standard state for the study of weak acido-complexes in aqueous solutions than a medium with a constant ionic strength. A correction for the non-ideality of the behaviour of the reactants involved in the type (1) equilibrium on formation of weak acido-complexes can be introduced, to a first approximation, on the basis of Eqn.(11) even at $I \neq$ const.

Table 4. The value of ΔH_1^0 for the reaction $H^+ + Ac^- \rightleftharpoons HAc$ and $\lambda_1(\Delta H)$ for I M aqueous solutions of NaA and $Na(ClO_4 \rightarrow A)$ at 298 K.[78]

I	A	ΔH_1^0, kJ mol^{-1}	$-\lambda_1(\Delta H)$
1.0	Cl^-	0.83	0.16±0.02
3.0	Cl^-	3.31	0.42±0.04
1.0	Br^-	0.72	0.07±0.03
3.0	Br^-	3.20	0.35±0.02
1.0	I^-	0.69	0.04±0.03
3.0	I^-	2.83	0.26±0.02
6.0	I^-	5.17	0.52±0.05
1.0	ClO_4^-	0.65	0
3.0	ClO_4^-	2.05	0

III. Classification of experimental methods

Various classifications of experimental methods for the study of complex formation in solution have been proposed in the literature,[3,92–94] but they do not take into account the specific features of the weak interaction in terms of type (1) reaction equations. The latter include four types of substances: (1) a simple or complex coordination centre M; (2) a ligand A; (3) the complex MA_n or the complexes $\sum_n MA_n$ formed; (4) the solvent H_2O. Measurement of the equilibrium concentrations [M], [A], $[MA_n]$ or $\sum_n [MA_n]$, and $[H_2O]$, i.e. of any of the reactants, and also of the functions $F\{[M]\}, F\{[A]\}, F\{[MA_n]\}$ or $F(\sum_n [MA_n])$, and $F\{[H_2O]\}$ sets limits, in our view, to the first group of methods for the study of weak complex formation in aqueous solutions. The second group comprises methods in which measurements are made of the acitivities (designated by braces) of the reactants or the functions of their activities, i.e. $F(\{M\})$, $F(\{A\})$, $F(\{MA_n\})$ or $F(\sum_n \{MA_n\})$, , and $F(\{H_2O\})$. This is the group of methods involving the measurement of activity.

The approaches to the mathematical analysis of experimental data for weak complex formation, for example, the determination of n and β_n^0, change on passing from concentration methods to activity measurement methods. The separation of experimental methods into the group of concentration methods and the group of activity measurement methods is associated with the need to take into

account the changes in the activity coefficients of the reactants in Eqn. (2) for any choice of standard state.

In a number of studies[7,37,95–98] on weak acido-complexes, fundamentally different information has been obtained about the values of n and β_n^0 for type (1) equilibria, which can be explained by failure to take into account the specific features of the experimental methods, noted above, in the mathematical treatment of the results. The differences are observed most often[95–98] when data obtained by the $F(\{M\})$ methods, for example the potentiometric method using an electrode reversible with respect to M, are compared with data obtained by the $F(\{A\})$ or $F\{[A]\}$ methods, for example the potentiometric method using an electrode reversible with respect to A or the method involving the measurement of solubility. The contribution of the disregarded changes in the activity coefficients of the ions M in the $F(\{M\})$ methods has frequently led to higher values of n and β_n^0 for halide, thiocyanate, and sulphate complexes than those obtained by treating the data in terms of the $F(\{A\})$ methods. A similar difference has been observed in the analysis of the results obtained by the $F\{[M]\}$ and $F(\{M\})$ methods or the $F\left(\sum_n [MA_n]\right)$ and $F(\{M\})$ methods.[7,97] The conventional parameters of the complex formation equilibria, involving both chemical interaction and the effect of the medium, have been determined in numerous investigations,[7] although their conventional nature has been rarely mentioned. The differences between the values of n and β_n^0 considered usually disappeared in the mathematical analysis of the experimental data using Eqns. (11) or (17). However, additional parameters then appeared in the form of the quantities λ_n or "b", whose values depended on the type of experimental method.[96]

An unusual case of the scatter of the values of n and β_n^0 for weak complexes has been observed[99–101] when the extraction method was used. The replacement of one extractant by another frequently alters the thermodynamic parameters of the equilibria investigated in the aqueous phase. For example, the extraction of traces of tris(phenanthroline)ruthenium(II) perchlorate from 0.75 M aqueous solutions of sodium sulphate with chloroform or acetophenone led[101] to significantly different values of the logarithms of the stepwise formation constants of the outer-sphere complexes $[RuPhen_3](ClO_4)_n^{3-n}$ (Phen = phenanthroline) for $n = 1$ and 2; these values proved to be 2.38 and 1.73 or 5.43 and 2.49 for extraction with chloroform and acetophenone respectively. Such differences are caused by the change in the standard conditions on replacement of the type of extractant. Aqueous solutions saturated by the extracting solvent constitute the standard state when extraction methods are used to investigate complex formation in aqueous solutions.

In an attempt to obtain more objective information about weak complexes in aqueous solutions, investigators have sometimes used[81] in Eqn. (2) the concentrations of some of the reactants involved in equilibrium (1) and the activities of others. Such calculations yielded estimated thermodynamic parameters of the type (1) equilibrium, the extent to which they are conventional being difficult to estimate.

For the experimental study of weak complex formation by concentration methods, it is useful to employ in the mathematical treatment of the experimental data the activity coefficients of one or several (but not all) components of the equilibria. In particular, one should avoid using the mean ionic activity coefficients in the study of weak stepwise complex formation, although some investigators[102] do not agree with this claim. From our point of view, their information about the stability constants of weak complexes can be regarded as merely qualitative but not quantitative.

The application of experimental activity methods is complicated by the need to carry out all the calculations in terms of activities or to obtain additional information about the activity coefficients of the reactants whose activities have been measured experimentally. The determination of reliable values of n and β_n^0 for weak complexes by the activity methods involves direct or indirect determination of the activity coefficients of both molecules and individual ions.[25]

The $F\left(\sum_n [MA_n]\right)$, methods, in which measurements are made for example, of the optical densities of solutions, chemical shifts, heats of reaction, etc., are sometimes (especially for $n = N = 1$) most useful for the experimental study of weak complex formation. However, these methods, which yield the dependence of the given parameter $\bar{P}$ on c_A, entail the necessity to solve equations of the type

$$\bar{P} = \sum_{n=0}^{N} (P_n [MA_n])/c_M, \qquad (26)$$

where P_n are the molar coefficients of the parameter $\bar{P}$ of the complexes MA_n. The solution of type (26) equations for weak complexes is associated with the need to find simultaneously n, β_n^0, and λ_n, as well as P_n and $\lambda_{n(P)}$, where the coefficients $\lambda_{n(P)}$ reflect the influence of the medium on the values of P_n. Judging from data (Table 4) for the influence of the medium on the enthalpy of protonation of acetate ions, the values of $\lambda_{1(\Delta H)}$ in this system are several times higher than the values of λ_1. Hitherto, in studies on weak complexes by the $F\left(\sum_n [MA_n]\right)$ methods, the influence of the medium on $\lambda_{n(P)}$ was usually disregarded. Such neglect of the values of $\lambda_{n(P)}$ has frequently led to significant differences between the constants for the protonation of strong acid anions in aqueous solutions[103] (p. 40) in calculations based on values of $\bar{P}$ obtained by different methods. The simultaneous determination of n, β_n^0, P_n, λ_n, and $\lambda_{n(P)}$ from a single smooth curve relating P to [A] for $n > 1$ has not been carried out and, judging from the first attempts,[90] is scarcely possible. The use of the $F\left(\sum_n [MA_n]\right)$ methods for the study of type (1) equilibria can be specially recommended in combination with the measurements of λ_n, P_n, and $\lambda_{n(P)}$ independent of the parameter $\bar{P}$. Such experimental methods must be sought. Electrodes reversible with respect to weak complexes MA_n may be useful, in addition to different types of molecular, microwave, and ultrasonic spectroscopy, but in such experiments it is essential to take into account the influence of the medium on the standard potentials.

IV. Complexes with molecular ligands

Ammonia is a classical ligand of the molecular type. The study of the formation of metal ammines in aqueous solutions by Bjerrum[104] determined the development of a large series of modern aspects of the chemistry of complex formation in condensed phases. However, in Bjerrum's studies the majority of problems concerning the formation of weak ammines in solutions were not solved. Until recent years, the very marked dependence of the formation constant of the complex $MgNH_3^{2+}$ on the type of magnesium salt[104] (p. 154) from the solubility of which in aqueous ammonia solutions the constant had been calculated was not understood. The solubilities at

291 K of magnesium naphthalene-β-sulphonate, cinnamate, and oxalate, led to $\lg\beta_1$ = 0.02, −0.13, and −0.66 respectively for the $MgNH_3^{2+}$ ion.

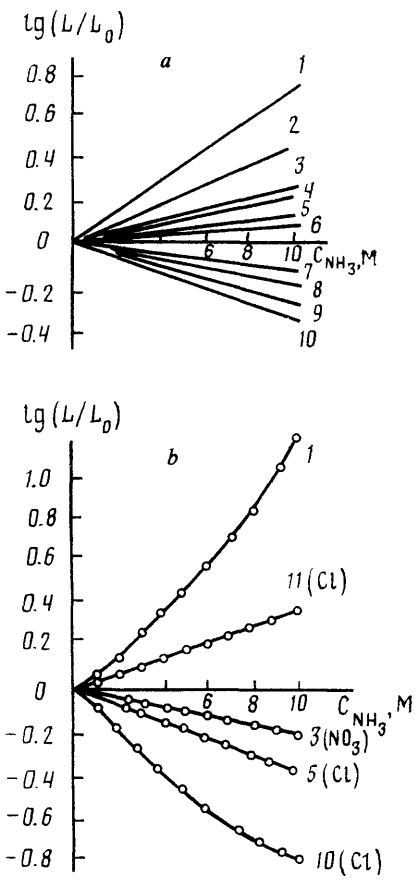

Figure 1. Dependences of the logarithms ($\lg L/L_0$) of the relative solubilities of thallium(I) salts (*a*) and hexamminecobalt(III) salts (*b*) on the ammonia concentration in 1.0 M aqueous solutions of ammonium perchlorate (nitrate (NO_3) or chloride (Cl)] at 298 K (L_0 represents the solubilities of the salts at c_{NH_3} = 0): *1*, perchlorates; *2*, iodides; *3*, nitrates; *4*, bromides; *5*, chlorides; *6*, bromates; *7*, carbonates; *8*, sulphates; *9*, oxalates; *10*, iodates; *11*, hexacyanoferrates.[25]

The decrease in the stability constant of the complex $TlNH_3^+$ with increase in ammonia concentration in aqueous solutions could not be explained[104] (p. 183). The value of this constant was unjustifiably included also among critically selected constants.[5] The marked increase in the solubility of $[Co(NH_3)_6](ClO_4)_3$ with increase in ammonia concentration in solution[105] in practical applications in the hydrometallurgy of non-ferrous metals[106,107] and the marked decrease in the solubility of $[Co(NH_3)_6]_2(SO_4)_3$ with increasing concentration of ammonia in water remain unexplained.

Systematic studies have been recently carried out[25,44–47,108–110] on the formation of weak ammines in relation to ammonia solutions of thallium(I) lithium, sodium, magnesium, calcium, strontium, barium, hexammine- and tris(ethylenediamine)cobalt(III), and a number of other simple and complex cations, which do not hydrolyse appreciably at pH < 11, in aqueous solutions with c_{NH_3} = 0–10 M. The principle standard state in the majority of these investigations consisted of 1.0 M solutions of ammonium perchlorate, nitrate, or chloride at 298 K. A number of experiments have also been carried out in 0.25, 0.50, 2.0, and 4.0 M solutions of ammonium salts at 293, 298, 303, and 308 K. A distinctive feature of the series of studies considered was the simultaneous measurement of the equilibrium concentrations or activities of the central cations, ammonia, the complexes, and water, i.e. the properties of all the reactants involved in type (1) equilibria. Electrodes reversible with respect to M and NH_3, measurements of the solubility of sparingly soluble salts, extraction, electronic spectroscopy, and NMR were used.

It is clear from the data in Fig. 1 and similar relations that the solubility of sparingly soluble salts in aqueous ammonia solutions at I = const. cannot be used to determine n and β_n^0 for type (1) reactions without taking into account the influence of the anion of the dissolved salt, although the anions considered are not appreciably associated with the cations M^{z+}.[3–6] Experiments designed to measure the vapour pressure of ammonia over aqueous salt solutions showed[44] that the potassium cation and the ClO_4^- anion do not influence appreciably the activity of ammonia in its aqueous salt solutions. Taking into account the fact that the potassium cation does not form ammines in aqueous solutions[3–5] while the solubility of $KClO_4$ in 1 M NH_4ClO_4 solutions with c_{NH_3} = 0–10 M is constant (0.040 M at 298 K),[47] a new extrathermodynamic assumption was introduced on the basis of the above postulate:

$$y_{K^+} = y_{ClO_4^-} = 1, \qquad (27)$$

where y_{K^+} and $y_{ClO_4^-}$ are the activity coefficients of the ions K^+ and ClO_4^- in aqueous ammonia solutions at 298 K. Assumption (27) served as the basis of a quantitative characterisation of the stepwise formation of weak ammines of a number of metals in aqueous solutions at c_{NH_3} = 0.1–10 M and also of the calculation of the activity coefficients of individual ions in aqueous-salt ammonia solutions. The calculation showed that the logarithms of these coefficients (Table 5) are positive for anions but negative for the majority of cations, including NH_4^+. Under these conditions, hydroxopentamminecobalt(III) has a zero value of the logarithm of the activity coefficient in 0.1–10 M ammonia solutions, i.e. ammonia is not appreciably bound by the cation, while the $Coen_2CO_3^+$ cation (en = ethylenediamine) actually salts out ammonia, like the anions.

A nearly zero value of the activity coefficient of the iodide ion combined with the similarity of the behaviour in aqueous ammonia solutions of potassium and caesium cations suggest that the extrathermodynamic assumption (27) is in many respects identical with the usual assumption[111,112] that the activity coefficients of the I^- and Cs^+ ions are equal. However, for the study of weak metal ammines in aqueous solutions, assumption (27) is better justified and more convenient[25,44] than the caesium iodide ionic scale.

On the basis of assumption (27), the composition and formation constants of thallium(I) ammines have been calculated[25] from the solubilities L of the salt $TlClO_4$ (Fig. 1) adjusted to a constant ionic strength of 1.0 based on the sum of the salts NH_4ClO_4 and $TlClO_4$.

The calculations were performed by the method of least squares on the basis of the equation

$$(L/L_0 - 1)\{H_2O\}\{NH_3\}^{-1} = K_1^0 + K_1^0 \cdot K_2^0\{NH_3\}\{H_2O\}^{-1}, \quad (28)$$

where L_0 and L are the solubilities of $TlClO_4$ in 1.0 M (NH_4 + Tl)ClO_4 solutions in the absence or presence of ammonia. The activities of water and ammonia (on the molarity) scale, required for the solution of Eqn. (28), were expressed in terms of the molarity scale.

Table 5. The logarithms of the activity coefficients of individual ions in 1.0 M aqueous ammonia solutions of NH_4A at c_{NH_3} = 10 M and 298 K.[25,44]

Ions	lg y	A^- in NH_4A	Ions	lg y	A^- in NH_4A
Tl^+	−0.95	ClO_4^-	NO_3^-	0.45	NO_3^-

The potentiometric measurements of the activities of thallium(I) ions with the aid of the Tl(Hg) electrode in aqueous ammonia solutions led to values of K_n^0 for the thallium(I) ammines which agreed with those found for the solubility of $TlClO_4$ only after correcting the measured e.m.f.'s of the cells with transport for the liquid-junction potentials arising at the interfaces between the solutions: 1 M NH_4ClO_4|1M NH_4ClO_4 + x M NH_3. These potentials, determined with the aid of iodide and perchlorate membrane electrodes, were 3.0 mV for 1.0 M ammonia.

The Bjerrum formation functions $\bar{n}'$ of thallium(I) ammines were calculated by means of the following equation from the experimental values of $\{NH_3\}$ and y_{NH_3} in the studies under consideration:

$$\bar{n}' = (c_{NH_3} - \{NH_3\}/y_{NH_3})/c_{Tl^+}, \quad (29)$$

which led to negative values of $\bar{n}'$ for c_{NH_3} = 0.1 − 10 M. Additional measurements of $\{NH_3\}$ and y_{NH_3} were performed for aqueous ammonia solutions of the potassium salts KX. The corrections Δn were applied to $\bar{n}'$ on the basis of the above data in accordance with the equation

$$\Delta\bar{n} = (c_{NH_3} - \{NH_3\}/y_{NH_3})/c_{KX}. \quad (30)$$

The Bjerrum functions $\bar{n}$, from which the compositions and formation constants of the complexes $Tl(NH_3)_n^+$ were calculated, had been determined from the relation

$$\bar{n} = \bar{n}' - \Delta\bar{n}\ . \quad (31)$$

The values of $\Delta\bar{n}$ from Eqn. (30) were more negative than the values of $\bar{n}'$ found from Eqn. (29). Hence the values of $\bar{n}$ based on Eqn. (31) were positive and the least squares solution of the equation

$$\sum_n (\bar{n} - n)\{NH_3\}^n\{H_2O\}^{-n}\beta_n^0 = 0 \quad (32)$$

led to formation constants agreeing (Table 6) with the above parameters obtained with the aid of the $F(\{Tl^+\})$, $F([Tl^+])$, $F(\{NH_3\})$, and $F\left(\sum_n [Tl(NH_3)_n^+]\right)$ methods. ^{205}Tl NMR was employed as the last method. The constants K_n were calculated from the chemical shifts of the ^{205}Tl signal taking into account the influence of ammonia on σ_2' in accordance with the equation

$$\sigma_0 = \sigma_0' + \alpha_0 c_{NH_3} \quad (33)$$

where σ_0' and σ_0 are the chemical shifts in aqueous solutions without ammonia and at an ammonia concentration c_{NH_3}, while α_0 are coefficients taking into account the influence of ammonia on the chemical shift of ^{205}Tl present as the aquo-complex.

The low accuracy of the measurement of small changes in the optical density ($\Delta\overline{D}$) of Tl^+ solutions due to added ammonia precluded the determination of K_n for $Tl(NH_3)_n^+$ from electronic spectra in agreement with data produced by other methods (Table 6). This finding has already been explained.[113] The contribution of the formation of $Tl(NH_3)_2^+$ to $\Delta\overline{D}$ led to a low value of K_1 calculated from $\Delta\overline{D} = F(\{NH_3\})$.

The study of the influence of the ionic strength I of the solutions on the formation constant of the complex $TlNH_3^+$ afforded[44] the equation

$$\lg K_1^0 = \lg K_1 - 0.065I, \quad (34)$$

where K_1^0 is the constant at 298 K and $I \to 0$.

Tests of the possibility of determining the composition and stability of weak inner-sphere ammines of thallium(I) and a number of other metals with the aid of a wide range of experimental methods have made it possible to apply a similar approach to the study of the outer-sphere interaction of ammonia with coordinatively saturated inert cobalt(III) complexes. The calculations showed (Table 7) that hexammine- and tris(ethylenediamine)cobalt(III) combined with up to four ammonia molecules in the outer sphere in aqueous solutions. The binding strength of each succeeding molecule compared with the previous one diminishes in conformity with the statistical effects $S_{n,n+1}$ [104] for the limiting coordination number $N = 4$.

*The values of $\lg K_n^0$ were obtained from the solubility of hexamminecobalt(III) perchlorate in 1.0 M ammonium perchlorate solutions.

**The values of $\lg K_n^0$ were obtained from the averaged data for the extraction of ammonia into chloroform and potentiometric data obtained using an ammonia electrode at $I \simeq 2$.

***From electronic spectra t $I = 1$.

The low solubility (3×10^{-4} M at 298 K) of hexamminecobalt(III) perchlorate in 1.0 M NH_4ClO_4 solutions made it possible to investigate the outer-sphere ammonia derivatives of this complex only by the $F(\{M\})$, $F\{[M]\}$, and $F\{[MA]\}$ methods. The high solubility of tris(ethylenediamine)cobalt(III) perchlorate made it possible to investigate its ammonia derivatives in terms of the activity of ammonia, i.e. by the $F(\{A\})$ method, at $I \simeq 2$. In the study of hexamminecobalt(III) derivatives, it was observed[25,44] that the influence of ionic strength in the range 0.1–1.0 is represented by the relation

$$\lg K_1^0 = \lg K_1 + 0.54I. \quad (35)$$

Extrapolation in terms of Eqn. (35) to $I = 2$ yielded $\lg K_1 = 1.49$. Within the limits of error, this value agrees with that (Table 7) found for the outersphere complex $[Coen_3](NH_3)^{3+}$. This finding suggests that the $Coen_3^{3+}$ and $Co(NH_3)_6^{3+}$ ions have approximately the same ability to combine with ammonia in aqueous solutions.

The formation constants of the outer-sphere ammonia derivatives of hexamminecobalt(III) and the ionic activity coefficients in aqueous ammonia solutions (Table 7) provide a quantitative idea[106] about the increase in the solubility of $[Co(NH_3)_6](ClO_4)_3$ and the decrease in the solubility of $[Co(NH_3)_6]_2(SO_4)_3$ [107] in aqueous solutions with increase in the concentration of ammonia.

The method for the study of ammonia derivatives of metals considered above was extended to weak methylamine, pyridine, ethylenediamine and other relatively unstable complexes of cations with molecules in aqueous solutions.[25,44,48–50]

V. Acido-complexes

Careful studies of the stepwise formation reactions of weak acido-complexes of metals in aqueous solutions by different methods indicate the impossibility of obtaining a single set of stepwise stability constants with the representation of the experimental data obtained by different experimental methods. This situation has been demonstrated recently in relation to zinc chloride complexes.[114] It is entirely reasonable because the values of K_n^0 for these complexes leads to values of $\Delta_r G_n^0$ comparable to $1.5RT$, while reliable unambiguous isolation of the small contribution of the specific interaction of Zn^{2+} with Cl^- against the background of inevitable significant changes in the ionic acitivity coefficients is virtually impossible. However, only allowance for the changes in the activity coefficients in 3.0 M aqueous $(Na \to H)ClO_4$ solutions with the aid of an equation of type (11) led to the possibility of describing the complex form of the solubility curve for molybdenum(VI) oxide.[32] Other conceivable ways of explaining this curve with a complex shape did not lead to its quantitative representation in terms of the constants of the Law of Mass Action.

Data obtained solely by thermodynamic methods for the investigation of weak stepwise formation of acido-complexes without extrathermodynamic assumptions usually do not permit an unambiguous differentiation between the changes in the activity coefficients and the formation of the complex MA_{n+1} after the real formation of the associated species MA_n. Under favourable conditions, such differentiation can be achieved[31] on the basis of spectroscopic measurements at several wavelengths but that too is not unambiguous because no account is taken of the influence of the composition of the ionic medium on the molar extinction coefficients of the reactants.

Many weak inner-sphere and outer-sphere acido-complexes have been investigated[3–6] by the potentiometric method with the aid of electrodes reversible with respect to the proton or the central ion of the complex using cells with transport. In studies of this type, corrections were frequently introduced for the liquid junction potentials.[115] The correct application of such corrections led to the experimental determination of the activities or equilibrium concentrations of individual ions, M. The liquid junction potentials have been usually assumed to be proportional to the ligand concentrations and the proportionality coefficients b_A have been determined from experimental data. Such calculations have been carried out, for example, in the study of weak hydroxo-complexes of calcium, strontium, and barium in 3 M $Na(ClO_4 \to OH)$ solutions[116]

and of lead(II) and cadmium acetate and benzoate complexes in 1.0 M (Na, H)(ClO_4→A) solutions, where A represents acetate or benzoate ions,[117] and in a number of other systems.[3-5] The changes in the e.m.f.'s of the cells investigated as a function of the ligand concentration were attributed in the above studies to the contributions by β_n^0 and b_A. The calculations showed (Table 8) that variation of the coefficients b_A alters appreciably the calculated values of β_n^0 and even the values of n. The scale of the influence of the liquid junction potentials increases sharply[118] with decrease in the association constants determined. When an unreliable correction is applied for the liquid junction potentials, the constants have the significance of only semiquantitative characteristics of weak complex formation equilibria,[117] although they represent satisfactorily [with the differences $\sigma(E) \leqslant 0.1$ mV] the experimental data. A combination of different values and different corrections for diffusion potentials does not influence appreciably $\sigma(E)$, which hinders the selection of reliable information about the systems investigated.

*E_d = diffusion potential.

Vierling[34,69] studied the equilibria

$$Pb^{2+} + nA^- \rightleftarrows PbA_n^{2-n} \qquad (36)$$

where A are chloride and bromide ions and $n_{max} \geqslant 4$ according to the e.m.f.'s of cells with transport [containing Pb(Hg) electrodes] on the basis of Eqn. (11) without corrections for liquid function potentials. In the calculations of n, β_n^0, and λ_n, use was made of up to a thousand experimental e.m.f.'s at different ligand concentrations. The system (36) was investigated in 4.0 M $Na(ClO_4 \rightarrow A)$ solutions at $c_{A^-} = 0-4.0$ M.

The traditional expression for the complex formation function Φ is

$$\Phi = c_{Pb^{2+}}/[Pb^{2+}] = 1 + \sum_{n=1}^{N} \beta_n [A]^n \qquad (37)$$

and includes β_n standardised by variable composition $Na(ClO_4 \rightarrow A)$ solutions. Vierling replaced it by the relation

$$\Phi = 1 + \sum_{n=1}^{N} \beta_n^0 [A]^n \exp(\lambda_n [A]), \qquad (38)$$

where β_n^0 were standardised with 4.0 M $NaClO_4$ solutions and the quantities β_n, β_n^0, and λ_n were linked by relations (11). The contributions of the diffusion potentials in such calculations enter into the quantities λ_n. The parameters of Eqns. (37) and (38) were calculated from the dependences of ΔE on [A] using at $T = 298$ K the equation $\Delta E = 59.2 \lg \Phi$, where ΔE is the experimental e.m.f. The method of least squares with the minimisation of $\delta(E)$ led Vierling[34] to the data compiled in Table 9. It was found that the employment of a gigantic set of accurate experimental data makes it possible to represent the latter (within the limits of the error of the determination of ΔE) both by Eqn. (37) and by Eqn. (38) with different variations of β_n and λ_n. However, the application of Eqn. (38) yielded a series of values of β_n^0 for all the values of n equal to 1, 2, ..., N, while the application of Eqn. (37) frequently led to zero values of β_n for certain values of n. The λ_n found had different signs and did not depend regularly on the values of n. Only when the potentiometric study of equilibrium (36) was supplemented by solubility and spectrophotometric data did Vierling arrive at the unambiguous, from his point of view, conclusion[34] that in 4.0 M $Na(ClO_4 \rightarrow A)$ solutions with [A] = 0–4.0 and at $T = 298$ K, all the complexes PbA_n^{2-n} with $N = 4$ for A = Cl^- and $N = 5$ for A = Br^- are formed in succession. However, the very high values $\lambda_n = 0.232$, 0.244, 0.151, 0.399, and 0.309 for $n = 1-5$ were obtained for $PbBr_n^{2-n}$ from the measurements of the solubility of lead(II) bromide, in contrast to the potentiometric data (Table 9).

Table 9. Data for the formation of the complexes $PbCl_n^{2-n}$ and $PbBr_n^{2-n}$ obtained with the aid of Hg(Pb) electrodes in 4.0 M $Na(ClO_4 \rightarrow Cl)$ and $Na(ClO_4 \rightarrow Br)$ solutions at 298 K.[34,39]

**$\beta_n \leqslant 0$ were obtained.

The system of thiocyanate complexes $(Nibipy_3)(SCN)_n^{2-n}$, investigated on the basis of the solubility of tris(2,2'-bipyridyl)-nickel(II) in 4.0 K (F→SCN) solutions, was analysed[63] in terms of Eqns. (37) and (38) using 12, 40, and 86 experimental solubilities.

The picture observed for the complexes PbA_n^{2-n} (Table 9) was in many respects repeated (Table 10) for the tris(2,2'-bipyridyl)nickel(II) thiocyanate complexes but, in contrast to the $PbBr_n^{2-n}$, the values of λ_n found were comparatively low, amounting to 0.04 ± 0.01 for all the values of n. Calculations for this system showed that a small set of comparatively accurate (errors of about ±1%) data, usually provided by the solubility method, does not permit the determination of reliable values of stepwise stability constants equal to 1.0 and below for $n \geqslant 3$ in combination with λ_n. The errors in the determination of the values of K_n^0 in Table 10 for $n \geqslant 3$ are comparable to the constants themselves. The high correlation of the quantities n, β_n^0, and λ_n with one another in equations of type (38) hinders an unambiguous and reliable calculation of all these functions from smooth $\Phi\{[A]\}$ curves for $n \geqslant 3$. Detailed analysis of the methods for the calculation of all the parameters of Eqn. (38) in systems of relatively unstable complexes has been correctly referred to as estimation of these parameters.[35] A reliable determination of β_n^0 and λ_n is possible only for $n = 1$; when $n \geqslant 3$, it is difficult to hope (Table 8) for the selection of a single reliable series of values of β_n^0 and λ_n with low errors of the determination of these functions. The validity of this conclusion has been confirmed by careful investigation.[35] However, the use of the values of λ_n found in independent experiments or calculations can increase the accuracy of the determination of the stepwise stability constants of the complexes by Eqn. (38).

***$\beta_n \leqslant 0$.

The application of Eqn. (38) to a series of systems investigated previously demonstrated convincingly the conventional significance of many of the values of β_n for weak complexes with $n > 1$, which was noted in previous studies.[68] For example, the results of potentiometric measurements with the $Coen_3^{2+}$, $Coen_3^{3+}|Pt$ electrode in $NaClO_4 + Na_2SO_4$ solutions at constant ionic strengths, which were interpreted previously in terms of the hypothesis of the formation of a series of outer-sphere complexes $[Coen_3](SO_4)_n^{3-2n}$ (n = 1, 2, 3), were reproduced by means of the quantities β_1^0 and λ_1 with a high correlation coefficient (>0.995).[98] The validity of this treatment of potentiometric data has been confirmed by measurements of the activity of the sulphate ion and by thermochemical studies. A similar situation has been noted for other weak acido-complexes.[37,98,119]

The linear relation between $\lg\Phi$ and [A] in systems with formation of the acido-complexes MA_n in the absence of appreciable changes in the slopes of the above straight lines as a function of constant ionic strengths has been suggested[40,79] as proof of the absence of complex formation. This proof is based on the identification of the virial coefficients $b_{i,1}$ and $b_{i,1}^*$ in Eqn. (5) and on the claim that they are not influenced by the variation of constant ionic strengths in the range 0.5–4.0. Numerical data similar to those in Tables 3 and 11 were used by the authors[40,79] as a basis for such identification. In reality, for linear relations between $\lg\Phi_M$ and [A] or between $\lg y_M$ and [A], it is not permissible to differentiate on the basis of the data considered the effect of non-ideality and complex formation[31] without resorting to extrathermodynamic assumptions or additional experimental studies.

Table 11. The changes in the conventional diffusion potentials (E_d') and the contribution to the latter of the hydrogen ion activity coefficients (y_{H^+}) at 298 K.[115]

However, re-examination[120] of the Debye–Hückel theory taking into account the shielding of ions by water molecules leads to the possibility of partitioning the experimental values of the second virial coefficient. Such partitioning has already been achieved[121] in relation to a large set of experimental data for aqueous magnesium sulphate solutions with variable ionic strengths in the temperature range 273–423 K. The forces of attraction between the Mg^{2+} and SO_4^{2-} ions were expressed in terms of their association constants and only the effects of repulsive forces were included in the second virial coefficient. Unfortunately the subdivision was based on mean ionic activity coefficients which consist of unequal contributions by cations and anions, even in dilute solutions of ions with very similar electrostatic properties, for example, NH_4^+ and Cl^-.[15] Furthermore, it has been shown that $y_{M^{z+}}$ and y_{Cl^-} vary in fundamentally different ways with increase in the concentrations of aqueous solutions of

ammonium, nickel, and cadmium chlorides. This fact is associated with the increase in the stability of MCl_n^{2-n} in this series of M^{z+}. In view of the need for the summation of $\lg y_{M^{z+}}$ and $\lg y_{Cl^-}$ in order to find $\lg y_{\pm}$, it is difficult to find from the values of the latter the real values of n and β_n for weak acido-complexes. The linear relations between $\lg y_{\pm}$ and for example, concentrations in solutions of alkali metal or alkaline earth metal chlorides are replaced by non-linear relations for y_{H^+} and y_{Cl^-}. This usual phenomenon[54] indicates the desirability of determining n and β_n^0 for equilibrium (1) from the activities of individual ions, the specific features of the behaviour of which are obliterated in the mean ionic functions.

It is frequently forgotten[7,102] that the vast majority of modern data on equilibria of type (1) have been obtained from the activities of the cations and not from the mean ionic parameters. About 40% of the known values of β_n [3-6] have been calculated from the e.m.f.'s of cells with transport incorporating M^{z+}/M^0 indicator electrodes. The changes in the e.m.f.'s (ΔE, mV) of such cells after the introduction of ligands into the test solutions at 298 K are expressed by the equation

$$\Delta E = E_d + 59.2/z \lg C_u/\{M^{z+}\}, \quad (39)$$

where E_d is the liquid junction potential. The relative activities of the ions M^{z+} enter into Eqn. (39) within the quantity E_d.[54] These ionic activities are standardised by solutions in relation to which the values of ΔE have been measured.

The data in Table 11 show how the activity coefficients y_{H^+} vary in aqueous solutions at constant ionic strengths. These changes have been calculated from conventional diffusion potentials (E'_d), which are related to E_d in Eqn. (38) by the expression

$$E'_d = E_d + 59.2/z \lg y_{M_{z+}}.$$

Judging from Table 11, the variation of the constant ionic strengths from 0.5 to 3.0 does not affect appreciably the changes in y_{H^+} as well as the changes in λ_n (Table 3). The transition from 3.0 M (Na→H)ClO_4 solutions to 3.0 M (Li→H)ClO_4 solutions alters y_{H^+} by 4.5 $[H^+]$ mV mol litre^{-1}, i.e. $\lg y_{H^+}$ changes by 0.065, which agrees with λ_1 for the protonation of the acetate ion in 3.0 M (Na→Li)ClO_4. It has been recommended[115] that the numerical y_{H^+} data in Table 11 be used for the selection of ionic media, the variation of the composition of which causes minimal changes in the activity coefficients of the individual ions. The effect of these changes for y_{H^+} in (Li→H)ClO_4 media is much smaller than in (Na→H)ClO_4. The replacement of Cl^- or ClO_4^- by OH^- affects y_{H^+} less than the replacement of Na^+ by H^+, etc.

The need to use the ionic activities, and not mean ionic parameters, to characterise weak acdio-complex formation has been recently demonstrated by Yagodin, Solovkin, and co-workers.[122,123] Equations were proposed for the calculation of the activity coefficients of individual ions in media at constant ionic strengths and the errors in the extrapolation of β_n to I→0 on the basis of the Debye–Hückel theory were estimated. It must be emphasised that in systems with highly charged cations, for example Zr^{4+}, the detection of a whole series of weak complexes having the composition $Zr(NO_3)_n^{4-n}$ was a consequence only of the neglect of the changes in the ionic activity coefficients following the change in the composition of the salt medium.[123] It may be that the detection of stepwise acido-complex formation in M^{5+} solutions[124] is also associated with the contributions by the inconstancy of the activity coefficients like part of the experimentally determined effect described by the β_1 in similar systems.[125]

Bjerrum compared the available information about β_n and n for weak acido-complexes in 10 M H(ClO_4→Cl) and 1–10 M Cl^- solutions. The constancy of the activity coefficients of the Cl^- ions is taken into account with the aid of second virial coefficients. Spectrophotometric and extraction data, which make it possible to measure the MA_n concentrations, were used by Bjerrum in the study of weak acido-complexes,[18,20,26] but the influence of the salt media on the partition coefficients and the molar extinction coefficients of the complexes MA_n was not taken into account. Studies on weak acido-complexes based on the Bjerrum approach merit further expansion but it would be desirable to base future research on Eqn. (11) or on allowance for the second and third virial coefficients. The Storonkin–Lagunov rule[72] suggests that the applicability of Eqn. (11) extends over a wide range of variable concentrations (from 0.1–1 to 5 M) of the anions in aqueous solutions. The activity of water in the test solutions with $I \neq$ const. can be sometimes more usefully employed in equations of type (11) [126] rather than the concentrations of the ligand anions.

VI. Conclusion

The properties of aqueous solutions involving the formation of weak complexes of metal ions are characterised by formal activity coefficients (the conventional physical model) or the contribution due to the occurrence of complex formation reactions is isolated from the latter[121] (the conventional chemical model). The physical model alone frequently reproduces more accurately the properties of the solutions than does allowance for its chemical component, but one must remember that the initial model is based on several empirical parameters. The results obtained by thermodynamic methods do not provide procedures for the unambiguous separation of the experimental properties into the "physical" and "chemical" components when the stability of the complexes MA_n is low without resorting to extrathermodynamic assumptions. However, when account is taken of the two components of the second virial coefficient,[121] such separation is sometimes possible. The simplest assumption involves the attribution of the entire weak interaction in accordance with the type (1) equation to the physical model if the latter can be reproduced by the second virial coefficient alone.

However, on the basis of the determination of the activities of all the individual ions and molecules involved in the equilibria investigated and also with the aid of standard isotherms,[1] the second virial coefficient of the activity can be sub-divided into contributions due to the changes in the activity coefficients and the formation of complexes with a definite composition. A similar subdivision is possible when account is taken of the shielding of ions by water molecules[120] for complex formation in aqueous solution.

The attempts to isolate the contribution of chemical interactions on the basis of spectroscopic data are frequently unreliable because they are based on the assumption of the constancy of the spectroscopic molar parameters in solutions with very different compositions. A reliable separation of the effect of changes in these parameters from the effect of the formation of complexes is hardly possible, which has been demonstrated in the determination of the association constants of ions in aqueous solutions of strong acids.[103] Only the unitary stepwise association constants in excess of 1–5 can serve as reliable thermodynamic indicators of the formation of weak complexes subject to the condition that these constants have been determined from data obtained by a fundamentally different experimental method in accordance with the classification in

Section III of the present review. The information about the formation of weak complexes based on low values of K_n^0, presented in the new international handbooks as critically selective,[5] is frequently unreliable.

Naturally a property of systems with very weak complexes ($k_n < 0.1$) cannot be considered in isolation from the kinetics and mechanisms of the formation of the complexes[127,128] because the formation reactions of such complexes do not obey the principle of the minimisation energy and the Law of Mass Action is not applicable to them. The fluctuation theory, the thermodynamics of non-equilibrium systems, and molecular-kinetic models should be used more widely in the future for the study of systems of this kind, typical examples of which are aqueous solutions of alkali metal halides, nitrates, sulphates, and a number of other salts. The empirical and extrapolation methods for the determination of the stabilities of weak complexes in such systems[129] cannot be regarded as reliable. Furthermore very large errors in the determination of low formation constants are inevitable (for example, $\lg K_5$ for $AuCl_5^{2-}$ is -2.0 ± 1.0).[130]

Polymer monolayers and Langmuir–Blodgett films. Polymerisation reactions in organised molecular ensembles; structural transformations and properties

V V Arslanov
Institute of Physical Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The method of preparation, structure, and properties of monolayers on the surface of a liquid and of Langmuir–Blodgett films on surface-active monomers are discussed. The influence of the chemical composition and structure of monomer molecules, the conditions for the preparation of organised ensembles, and the conditions in polymerisation reactions for the structural-morphological transformations in monolayers and Langmuir–Blodgett films are considered.

The bibliography includes 128 references.

I. Introduction

Polymer monolayers and Langmuir–Blodgett films (LBF) should occupy in the next few years a position in the problem of multilayer two-dimensional structures consistent with their scientific and applied importance. This refers both to the unique possibilities of the assembly and study of two-dimensional polymer systems with controlled orientation and distances between the chains and their elements and to the prospects for the application of Langmuir–Blodgett (LB) ensembles in modern technology. The study of the specific characteristics of the behaviour of organised ensembles of macromolecules at interfaces between two fluids or at a solid/fluid interface makes it possible not only to achieve in practice the advantages of polymeric LBF already recognised (thermal and mechanical stability, resistance to the action of corrosive media) but also to construct new generation superstructures taking into account the chain structure of the polymers.

Polymeric LBF are nowadays obtained by three procedures which provide for (1) the formation of polymer monolayers on the surface of a liquid (usually water) and their transfer to a solid support, (2) the formation of monolayers made up of monomers, their polymerisation, and their transfer to a solid support, and (3) the formation of monomer monolayers, their transfer to a solid support, and their polymerisation in the LBF.

It is important to emphasise that, for compounds having the same chemical composition, LBF differing in structural organisation can be obtained depending on the method of formation. This is associated, for example, with different conditions in the polymerisation reactions carried out on liquid and solid surfaces, with the rotation of the monomer molecules in the preparation of the LBF, etc. For this reason, the current stage (in many respects, the initial stage) of the development of studies in the field of polymer LBF should include in the first place the comparative analysis of the three procedures for their formation indicated above. In the first case, attention should be concentrated on the study of the thermodynamic, structural-morphological, and molecular-kinetic features of the behaviour of polymer monolayers on the surface of a liquid which distinguish them from low-molecular weight analogues. A striking example of the existence of such differences is the possibility of obtaining stable monolayers from water-soluble polymers.

The regulation of the structure and properties of LBF during their preparation by the second method reduces mainly to the selection of known or the construction of new diphilic monomer molecules with a definite disposition of hydrophilic and hydrophobic fragments and their polymerisation, which is achieved preferentially with the aid of UV irradiation. Here so far little attention has been devoted to the use of the possibilities of a liquid support, the variation of the composition of which makes it possible to influence both the structure of the monolayer and the polymerisation process.

The third procedure for the formation of LBF has become most widely known in connection with the wide-scale employment of diacetylene derivatives. Photopolymerisation is carried out in two ways: either each transferred monolayer or the multilayer LBF as a whole is polymerised. The first method leads to the breakdown of the correlation between neighbouring LBF layers, while the second involves the retention of the three-dimensional crystal lattice of the monomer. The main problem arising in this method for the preparation of LBF is associated with the shrinking of the polymer which leads to the formation of defects (cracks, cavities, and folds).

Together with the increase in the thermal and mechanical stability of polymer LBF noted above, it is possible to realise with their aid also other, hitherto unused, possibilities of molecular architecture: the controlled phase separation in a mixed monolayer with immobilisation of the low-molecular-weight compound carrying a definite functional group; the fixation of additives introduced into the support; the formation of stable multilayers of polymers on a liquid surface and their transfer to a solid support, etc.

Polymer LBF are nowadays used in microelectronics as resistors and insulating layers with high specific characteristics. There are good prospects for the application of polar and alternating non-centrosymmetrical LBF in non-linear optics. Conducting polymers (for example, polyalkylthiophenes) are not inferior as regards their parameters to the known LBF consisting of charge-transfer complexes. Photochromic transformations (reversible *cis–trans* isomerisation and aggregation) can be used in the recording and representation of information. Molecular electronics, different types of sensors, multilayer selective membranes, and many other self-evident and merely predicted applications of polymer LBF require a significantly more vigorous investigation of these unique objects.

Langmuir's brilliant studies on the chemistry surfaces, for which he was awarded the Nobel Prize in 1932, served as a basis for the current spurt in the research into the monolayers (ML) and multilayer films obtained by the method also proposed by Langmuir (1920) and developed by his colleague Blodgett (1935). A historical survey of the studies on these unique objects has been given by Tredgold.[1] The present interest of physicists in the LBF was initiated by the elegant studies of Kuhn and his school on molecular architecture.[2] By virtue of Blinov's reviews,[3,4] the Soviet reader was able to become acquainted with the latest advances in the physics of LBF. Problems of the physical chemistry and mechanics of monolayers of low-molecular-weight surfactants and polymers have been described by Trapeznikov[5] and his students. The methodological problems of the formation of monolayers and LBF have been dealt with in reviews[1–4] and in the monographs of Adam,[6] Harkins,[7] Izmailova et al.,[8] and Gaines[9] and also in other communications.[10–12]

It is surprising that, despite the wide-scale research into monomer and polymer monolayers and LBF, reviews devoted to the present state of this problem are still lacking. The only exception is the publication by Tieke,[13] in which the properties of films of butadiynes and butadienes on the surfaces of water and solids are discussed.

In connection with the differences in the behaviour of polymer and monomer monolayers mentioned above and also with the abundance of data on this problem, the present review is devoted solely to the analysis of the polymerisation reactions of monomers on the surface of a liquid and in a LBF and the phase and structural-morphological transformations in these systems caused by these reactions. In addition, owing to the existence of a sufficient number of publications describing the methodological aspects of the problem under discussion, the latter have been excluded from the present review together with studies in the field of organised protein structures, which require independent analysis.

II. The preparation of monolayers on the surface of a liquid and of Langmuir–Blodgett films

The monolayers on the surface of a liquid (water, glycerol, dioxane, mercury, and gallium) consist of films of usually diphilic compounds one molecule thick. The monolayer is formed when a dilute solution of the surfactant in a volatile solvent spreads. In many instances, such films can be produced by the spreading of the bulk phase of the given substance. The phase state of the monolayer is recorded with the aid of compression isotherms: the dependence of the surface pressure (π) on the area per molecule or the monomer residue (A). In the general case, when the area is diminished, the gaseous, liquid, and solid states of the monolayer are produced. Each state of the monolayer is characterised by a definite orientation (thickness) of the molecules, which depends on the available area and the cohesive and adhesive properties of the system.

When the solid support is moved slowly through the surface of the liquid with the monolayer, the latter is deposited on the support. Successive upward and downward movements of the support lead to the formation of a Y-type centrosymmetrical LBF. Polar X- and Z-type LBF are obtained with the aid of special procedures. In X-type layers, the hydrophobic components of the molecule are directed towards the support, while in the Z-type layers they are turned in the opposite direction. Alternating LBF consist of layers of two and more compounds alternating in a specified sequence. They were obtained using several Langmuir baths. The LBF are usually formed from the monolayer in the liquid state. Solid monolayers are transferred by Shaefer's method, bringing into contact the surfaces of the solid support and the monolayer (horizontal transfer). In the course of the deposition of the monolayer, a specified surface pressure is maintained.

III. Polymerisation reactions in monolayers

One of the causes of the wide-scale interest in LBF is the possibility of reproducing the structure of the monolayer when it is transferred from the surface of the liquid to a solid support. The construction of a monolayer with the required structure on the surface of a liquid is a simpler problem than its construction on the surface of a solid. Indeed, slight changes in the chemical composition or structure of the molecules (increase in chain length, introduction of multiple bonds, change from single-chain to multichain lipids, change from an alcohol to an acid or ester, etc.) are instantly reflected in the compression isotherm. The structure of the monolayer is also extremely sensitive to changes in the pH and the temperature of the support, the introduction into the latter of electrolytes or other special additives, and the presence of slight admixtures of surfactants in the monolayer. Since the influence of these factors on the structure and properties of monolayers of low-molecular-weight compounds, such as the monomers, has been studied in fair detail, we are able to devote more attention to the characteristics of the behaviour of these systems associated with polymerisation reactions in monolayers.

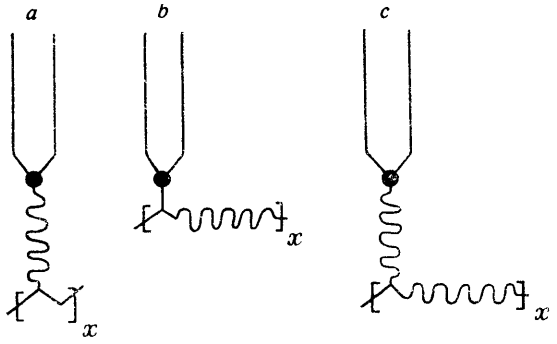
1. Polymerisation of diphilic monomers containing multiple bonds in the polar component

Systematic studies on the influence of the chemical composition and structure of monomer molecules on the properties of monolayers and polymerisation reactions have been carried out recently by Ringsdorf and co-workers.[14–18]

The aim of the polymerisation of monomeric lipids (models of biomembranes) in organised systems (monolayers, bilayer lipid membranes, vesicles) is to increase their stability. However, polymerisation frequently leads to such an increase in the rigidity of the system that the formation of liquid phases is ruled out. To prevent this and to make sure that the main chains do not hinder the self-organisation of the side groups, flexible hydrophilic spacers are introduced into the monomer molecules. This leads to the formation of polymers of three types containing a spacer in the side chain (Fig. 1*a*), the main chain (Fig. 1*b*), and in both chains (Fig. 1*c*).[19,20] Such architecture makes it possible to achieve in the polymerised lipid an adequate degree of independence of the movements of the side chains. It is essential to note that a flexible spacer, leading

normally to the expansion of the monolayers, does not always increase their stability and hence the possibility of their transfer to a solid support.

The length of the spacer introduced between the lipid component and the polymer chain (Fig. 1*a*) influences the properties of the monolayer of not only the monomer but also of the polymerised system.



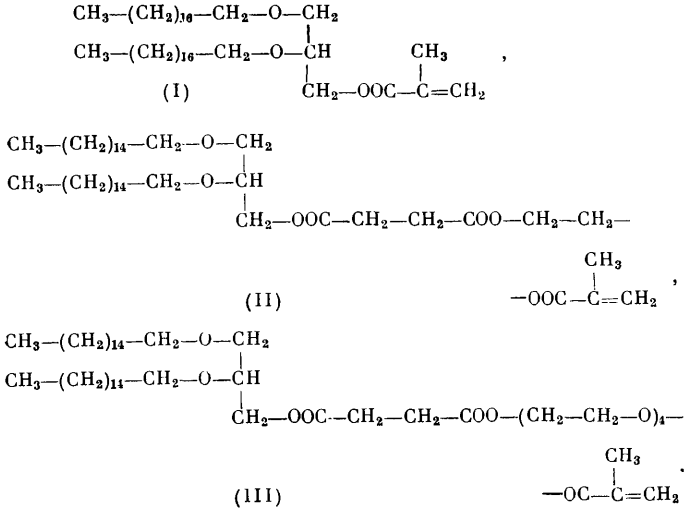


Figure 1. Three types of polymers containing a hydrophilic spacer in the side chain (*a*), the main chain (*b*), and the side and main chains (*c*).[20]

Fig. 2 illustrates the $\pi-A$ relations for the monolayers of two-chain methacrylate lipids (I), (II), and (III) with an increasing length of the spacer.[19,20]

An increase in the length of the hydrophilic spacer leads to the expansion of the monolayers: regions of expanded liquid and transition states appear for compounds (II) and (III). Nevertheless the monolayers of all the monomers retain a solid state with identical limiting areas and high decomposition pressures.

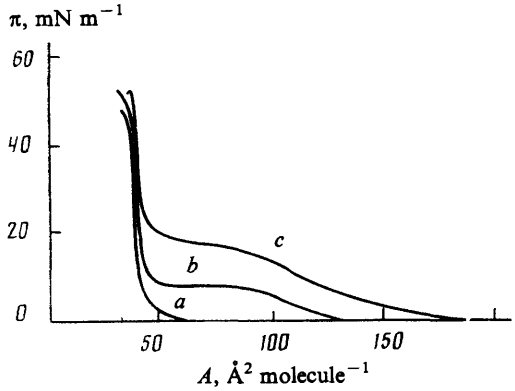

Figure 2. Surface pressure (π)/area (A) isotherms for monomeric lipids: *a*, (I), 20 °C; *b*, (II), 30 °C, *c*, (III), 30 °C.[19,20]

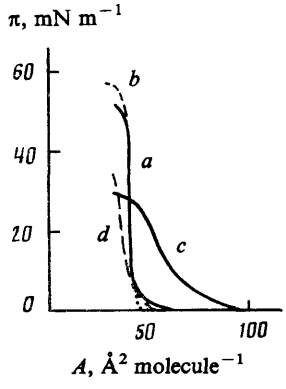
The compression isotherm for compound (I) photopolymerised in the monolayer virtually repeats the $\pi-A$ relation for the monomer,[20] i.e. the highly organised structure of the monolayer is retained during polymerisation (Figs. 3*a* and 3*b*). However, for the polymer obtained by the homopolymerisation of the lipid (I) in solution and then deposited on the surface of water, the $\pi-A$ relation (Fig. 3*c*) has a different form: there is no solid state and the monolayer decomposes at low surface pressures. This indicates a low capacity of the monomer without a spacer for self-organisation. In the presence of even a short spacer [the monomer (II)], the picture changes (Fig. 3*d*). The $\pi-A$ isotherm for the homopolymer obtained in solution from the lipid (II) is characterised by the presence of only the solid state, which indicates a high capacity of the macromolecules for self-organisation in the monolayer.



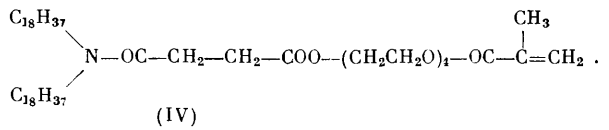


Figure 3. Surface pressure/area isotherms for monomeric (*a*) and polymeric (*b*–*d*) lipids: *a*, (I); *b*, (I), polymerised in the monolayer; *c*, (I), polymerised in solution; *d*, (II), polymerised in solution.[20]

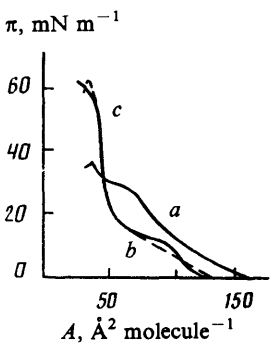
Evidently, on polymerisation of the lipid (II) in the monolayer, the $\pi-A$ relation has a similar form. Finally, in the polymerisation of a monomer containing a fairly long spacer [the lipids (III) and (IV)] the condensation of the monolayer is much less marked (Fig. 4): the

isotherms for the polymers obtained by polymerisation in the monolayer (Fig. 4*b*) and in solution (Fig. 4*c*) have an expanded state region:[19]

(IV)

The incorporation of a flexible spacer in the main chain (Figs. 1*b* and 1*c*) is achieved as a rule by the copolymerisation of the corresponding monomers in solution. For example, the monomer (II) and 2-hydroxyethyl acrylate have been used for this purpose.[20]



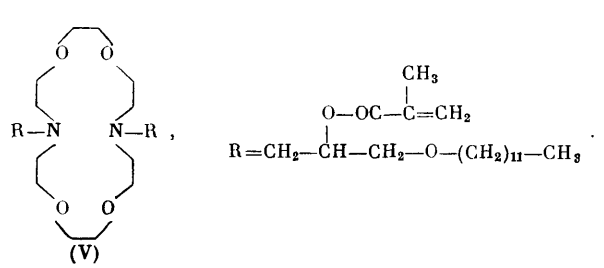


Figure 4. Surface pressure/area isomers for monomeric (*a*) and polymeric (*b*, *c*) lipids: *a*, (IV); *b*, (IV), polymerised in the monolayer; *c*, (IV), polymerised in solution.[19]

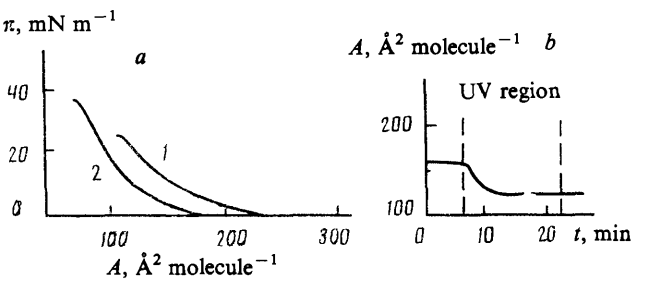
Thus the introduction of a flexible spacer with a definite link between the main chain and the lipid group intensifies the tendency of the polymers to undergo self-organisation in the monolayer and provides a possibility of choice: the formation of monolayers from the monomer and its subsequent polymerisation or the formation of the monolayer from the homopolymer.

The first steps have been taken in the study of polymerisation processes in monolayers of crown-ethers, which are important compounds.[21] Fig. 5*a* illustrates the compression isotherm for the monolayer of 1,10-bis(3-dodecyloxy-2-methacryloyloxypropyl)-1,10-diaza-18-crown-6 (V).

(V)

The isotherm, which is typical for the liquid state, is characterised by low decomposition pressures. The photopolymerisation of the crown-ether (V) under a nitrogen atmosphere leads to the shrinkage of the monolayer (Figs. 5*a* and 5*b*) and to a steeper $\pi-A$ relation.



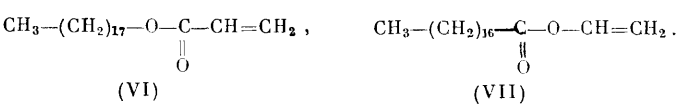


Figure 5. Surface pressure/area (*a*) isotherms for monomeric (curve *1*) and polymeric (curve *2*) crown-ether (V) and the dependence of the area of the monolayer of compound (V) on the duration of UV irradiation (*b*).[21]

The preparation of stable monolayers of LBF from polymerised crown-ethers leads to prospects for a more effective utilisation of these compounds as selective membranes and also as models of biomembranes. The success in the development of the latter aspect of this field is guaranteed by the fact that crown-ethers [for example, the monomer (V)] form bilayer lipid membranes and stable vesicular solutions.[21]

Generally speaking, a decrease in the area of the monolayer on polymerisation is not obligatory. As a result of the polymerisation of classical systems such as octadecyl acrylate (VI) and vinyl stearate (VII), the area of the monolayer increases, the degree of expansion depending on the area over which polymerisation has been carried out.

(VI) (VII)

Fig. 6 presents the $\pi-A$ relations for the octadecyl acrylate monolayer at a water/nitrogen interface before its irradiation with electrons and after exposure to an electron beam (30 s, 70% conversion). Evidently an increase in the area over which polymerisation has been carried out leads to an increase in the limiting area A_0.[22] Two facts are also of interest: the degeneracy of the point of inflection corresponding to the transition from the liquid state of the monolayer to the solid state and the possibility of polymerisation for large areas (42 Å^2 molecule^{-1}, π = 0). The first result reflects the structural changes in the monolayer associated with the fact that the polymerisation of the heat groups prevents close packing of the hydrocarbon chain and the second indicates a domain structure of the monolayer for large areas. Comparison of the data obtained for the water/air and water/nitrogen interfaces permits the conclusion that the polymerisation reaction is initiated by the products formed in the aqueous phase on irradiation of the system:[22] the reaction does not occur (remains unchanged during

irradiation) in the first case owing to the presence of atmospheric oxygen, which suppresses the activity of the hydrated electron, while in the second it does not occur when a compound (*N,N'*-dimethyl-*p*-nitrosoaniline), binding these products, is introduced into the aqueous support. Since the nitrosoaniline reacts with both water radiolysis products—the hydrated electon and the OH radical—it is so far not clear which of these species initiates the polymerisation.[22]

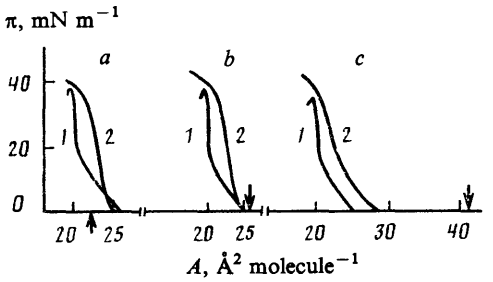

Figure 6. Surface pressure/area isotherms for the octadecyl acrylate (VII) monolayer on the water/nitrogen interface before (curve *1*) and after (curve *2*) 30 s UV irradiation; area for which the polymerisation was carried out (indicated by arrows (Å^2 molecule^{-1}): *a*, 22; *b*, 26; *c*, 42.[22]

The expansion of the monolayer is observed in the photopolymerisation of vinyl stearate.[23] The polymerisation reaction does not take place in air owing to the formation of ozone, which converts vinyl stearate into stearic acid. However, in circulating air, which reduces the time of contact between ozone and the monolayer, it is possible to achieve 50% conversion (in nitrogen, the conversion is 80%). The rate constant for the polymerisation reaction of vinyl stearate in the monolayer (N_2) for large areas (40 Å^2 molecule^{-1}) exceeds by a factor of 3 the rate constant for the polymerisation of the monolayer having an area of 22 Å^2 molecule^{-1}. This is apparently associated with the higher self-organisation of the monomer molecules in the domains[24] on the surface of water compared with the close-packed monolayer subjected to forced compression. However, the polymerisation of vinyl stearate on the surface of water leads in all cases to a more regular structure of the polymer and to a less effective monolayer than for the polymer obtained in solution.

Beredjick and Burlant,[25] who investigated the polymerisation of octadecyl methacrylate (VIII) in the monolayer on the surface of water, arrived at a similar conclusion.

$$CH_3-(CH_2)_{17}-O-\underset{\underset{O}{\|}}{C}-\underset{\underset{CH_3}{|}}{C}=CH_2 \quad .$$

(VIII)

It is of interest that the photopolymerisation occurring at the interface with argon and air can be accompanied both by the shrinkage (argon) and expansion (air) of the monolayer (Fig. 7). Fig. 8 illustrates the compression isotherms for octadecyl methacrylate and its polymers obtained under various conditions. Evidently, in contrast to the isotherm for the compression of the octadecyl acrylate monolayer (Fig. 6), the $\pi-A$ relation for the octadecyl methacrylate monolayer has no break point corresponding to the transition to the solid state. Furthermore, the decrease in the slope of the isotherm beyond A = 25 Å^2 molecule^{-1} indicates the onset of the decomposition of the true monolayer[26] in this range of areas. Such behaviour is associated not only with the steric hindrance to the formation of a close-packed monolayer[25] but also with its low stability. The bulk-phase or two-dimensional polymerisation of the monomer alters sharply the properties of the monolayer. The expansion of the monomer monolayer in the polymerisation reaction in air can be explained by the formation of a polymeric peroxide (copolymerisation with oxygen). The rate of this reaction is three times higher than the rate of polymerisation of the monomer in the monolayer at the water/argon interface.

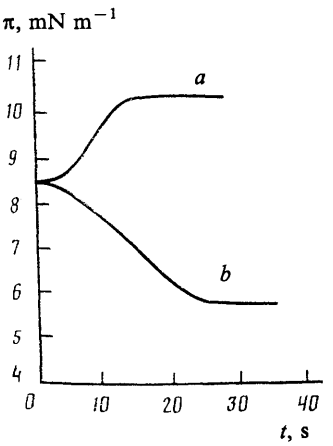

Figure 7. Dependence of the surface pressure on the duration of UV irradiation of the octadecyl methacrylate monolayer on the water/air (*a*) and water/argon (*b*) interfaces.[25]

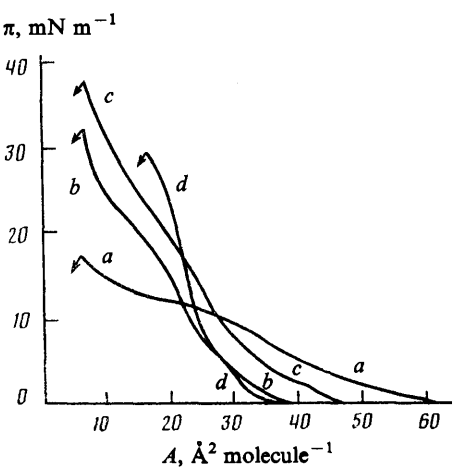

Figure 8. Surface pressure/area isotherms for octadecyl methacrylate (*a*) and poly(octadecyl methacrylate) (*b*–*d*) obtained by polymerising the monomer in the monolayer on the water/argon (*b*) and water/air (*c*) interfaces and in solution (*d*).[25]

Thus inappreciable changes in the structure and composition of the monomers [position of the oxygen bridge in the polar part of the molecules of the monomers (VI) and (VII), transition from the acrylic to the methacrylic monomer] lead to a significant alteration of the structural organisation of the monomer monolayers and induce differences in their response to the polymerisation conditions.

The results of studies on the monolayers of the two isomeric monooctadecyl esters of fumaric (ODF) and maleic (ODM) acids reflect in a clear-cut form the high susceptibility of the monolayers to the molecular structure. The isotherms for the cadmium salts of ODF and ODM, illustrated in Fig. 9, are clearly distinguishable.[27,28] The larger areas of the *cis*-isomer (ODM) compared with the *trans*-compound (ODF) reflect the fact that the head group of the ODM molecule occupies a larger area. The polymerisation induced by UV irradiation on the surface of water increases the area of the monolayer for ODF and decreases it for ODM, but the compression isotherms are identical for both polymers (Fig. 9).

$$CH_3-(CH_2)_{17}-OCOCH=CHCOOH.$$
(IX)

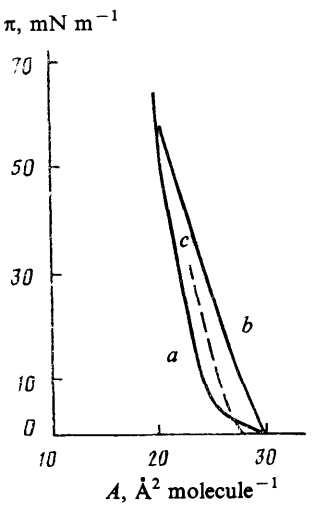

Figure 9. Surface pressure/area isotherms for the cadmium salts of octadecyl fumarate (*a*), octadecyl maleate (*b*), and the polymer (*c*) obtained by polymerising the salts in the monolayer.[27]

By varying the ratio of the components in mixed monolayers, it is possible to achieve a definite change or constancy (for a 25% content of ODF) of the area in polymerisation which gives rise to the hope that LBF free from cracks may be prepared. We may note that, whereas the structures of the films of polymeric ODF and ODM differ both on the surface of water and in the LBF, the polymeric monolayers and the LBF (subjected to UV and thermal polymerisation) have identical organisations and a higher thermal stability. The dimerisation of ODM and ODF with formation of cyclobutane rings was not observed.[27,28] Nevertheless, a cyclisation process, leading to the formation of an extremely unusual polymer structure, takes place in monolayers starting with compounds analogous to compound (IX) but containing a more complex central group: aliphatic monoesters of phenylenediacrylic acid:

$$C_nH_{2n+1}OCOCH=CHC_6H_4CH=CHCOOH,$$
(X)

$n=7$, 10, 12, 14, and 18.

A characteristic feature of the behaviour of these compounds on the surface of water is that an increase in the length of the hydrocarbon group leads not to the condensation but to the expansion of the monolayer.[29] Thus the limiting area of the monolayer of compound (X) with n = 14 is 27 Å^2 molecule^{-1}, which corresponds to A_0 for unsaturated aliphatic acids: A_0 = 24 Å^2 molecule^{-1} for n = 12 and A_0 = 34 Å^2 molecule^{-1} for n = 18. On photopolymerisation in the monolayer (π = 20 mN m^{-1}), the area of the latter (n = 12) increases by 20% and the surface pressure increases from 20 to 50 mN m^{-1} for A = const. Such appreciable changes of the parameters of the monolayer are due to the alteration of its structure during polymerisation, which leads to the breakdown of the parallel orientation of the benzene rings and the formation of chains of cyclobutane rings with mirror symmetry (Fig. 10).

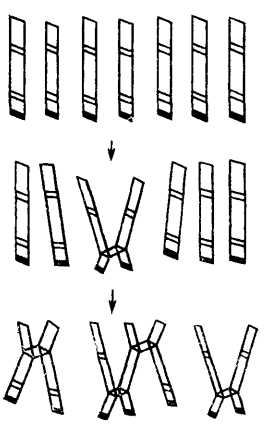

Figure 10. The change in the structure of the monolayer on photopolymerisation of an aliphatic monoester of phenylenediacrylic acid (X).[29]

A similar structure is formed also on polymerisation of these monoesters in the LBF (Z-type, 20 layers), It has been shown by UV spectroscopy[29] that the organisations of the molecules in the LBF and in the bulk-phase crystal differ significantly: in the bulk phase, the molecular packing resembles that in a Y-type LBF. As a result of these differences, the monoesters (X) with n = 14 and 18, which are photostable in the crystalline state, readily polymerise in the monolayer under the influence of UV radiation. The latter fact demonstrates the notable possibilities of monolayers and LBF in molecular engineering.

The degree of shrinkage or expansion of the monolayer as a result of polymerisation, which is a function of many parameters, depends also on the area of the monolayer for which the process takes place. For example, in the photopolymerisation of a two-chain lipid, as in

that of compound (X), containing the styrene group (XI), the shrinkage of the monolayer diminishes with increase in the area over which the polymerisation reaction takes place and disappears altogether when a close-packed monomer monolayer is polymerised.[30]

$$(C_{18}H_{37})_2\overset{+}{N}(CH_3)(CH_2C_6H_4{=}CH_2)Cl^- .$$
(XI)

This factor complicates in many respects the studies of the kinetics of polymerisation reactions in monolayers which are in any case not simple and therefore not popular. Evidently, the most reliable data on the rate of consumption of the monomer can be obtained with the aid of optical spectroscopy. In their absence, the reaction order and rate constant are found from the change in the area of the monolayer[30] or the surface potential,[23] specifying at the same time the type of function describing the variation of the surface concentration of the monomer.

2. Polymerisation of diphilic monomers containing multiple bonds in the hydrophobic component. Diacetylenes

Among the surface-active monomers investigated in monolayers and in LBF, diacetylene derivatives have firmly retained leading positions. This is explained by the interest in the study of two-dimensional solid-phase photopolymerisation and by the prospects for the application of thin layers made up of macromolecules with long chains of conjugated bonds oriented in the plane of the monolayer.

Tieke's review,[13] published in 1985, on the monolayers and LBF of diacetylene surfactants summarises the brief but extremely vigorous periods of their investigation. In recent years, there has been a significant expansion of the geography of these studies, the ideas concerning the behaviour of traditional diacetylene monomers and polymers have been deepened, and new compounds have been synthesised.

The properties of the monomer monolayers examined above are characteristic also of diacetylene surfactants on the surface of water. The interest in compounds of this class and in particular in the diynoic acid (XII), encouraged by the synthesis of homologous series of the latter,[31,32] is due to the possibility of studying the influence of the chain length and of the position of the diacetylene group relative to the carboxy-group on the stability[33] and other properties of the monolayers.

$$CH_3{-}(CH_2)_{m-1}{-}C{\equiv}C{-}C{\equiv}C{-}(CH_2)_n{-}COOH \text{ or } C_mC_n .$$
(XII)

Fig. 11 illustrates the dependence of the decomposition pressure of the monolayers of long-chain diynoic acids on the surface of water as a function of the overall chain length $L = m + n + 5$.[34] The parameter m, with increase of which (or with increase in L) the decomposition pressure π_c increases linearly, plays an important role in increasing the stability of the monolayers. For low values of n, this increase is steeper and the influence of n on the variation of the stability is manifested to a lesser extent than the influence of m. With decrease in n, i.e. as the diyne group approaches the head group, the stability increases appreciably both as a consequence of the decrease in the perturbation of the packing of the hydrocarbon chains of the diyne group[33] and by virtue of the activation of the carboxy-group by the diyne group. The stability of the monolayer increases greatly after the introduction of $CdCl_2$ (10^{-3} M) into the aqueous subphase.[35] The acid $C_{12}C_0$ forms a condensed film only on a support of this kind. The increase in stability can be explained in this instance by the formation of a salt which is controlled by the pH of the support. According to IR spectroscopic data, the transfer of the acid to the cadmium salt is completed at pH 6.5.[36] The concentration of Cd^{2+} ions in the support influences the stability of the monolayer in two ways.[33,37] High $CdCl_2$ concentrations greatly increase the decomposition pressure of the monolayer and diminish A_0 while low ones promote a decrease in stability owing to the formation in the monolayer of small amounts of a polymer, this effect intensifying when other divalent ions are employed (Ba^{2+}, Ca^{2+}, Cu^{2+}, Zn^{2+}, and Mn^{2+}). On the other hand Collins[38] showed that, compared with the stability of the monolayers of $C_{16}C_8$ and $C_{16}C_0$ acids on different supports, the first monomer forms more stable monolayers on the surface of water while the second forms them on the surface of an aqueous $CdCl_2$ solution.

In this instance one must emphasise that inadequate attention has

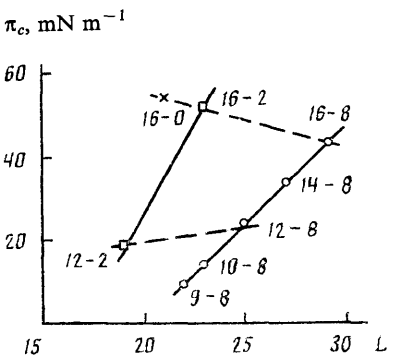

Figure 11. Dependence of the decomposition pressure (π_c) of solid monolayers of diynoic acids C_mC_n on the overall chain length L (T = 12 °C).[34]

In this instance one must emphasise that inadequate attention has been devoted to problems of stability in modern studies on monomer monolayers and the very concept is treated in a narrow sense, although more than 40 years ago Cris[39] proposed reliable criteria for the determination of this important characteristic of the monolayer. We may note the results of studies by Owens et al.,[33] who investigated the influence of the rate of compression of the monolayer of the $C_{12}C_8$ acid on the $\pi-A$ relations. At a rate of compression of the monolayer of 1.3 Å^2 molecule^{-1} min^{-1}, the isotherms hardly differ from relations obtained by other workers and have values of π_c reaching 30 mN m^{-1}. When the rate of compression is reduced by a factor of 4, π_c diminishes to 1 mN m^{-1}. The authors[33] attribute such behaviour to the loss of molecules from the monolayer. The cause of this effect, observed for diynoic acids also in other investigations,[38,40] still remains unexplained. However, if one assumes that the molecules cannot pass from the monolayer to the support, the only cause of such low values of the surface pressure may be a high rate of three-dimensional crystallisation. In order to elucidate the mechanism of the instability of the monolayer, it is essential to carry out more detailed investigations: the determination of the equilibrium pressure of the spreading and hysteresis of the compression isotherm at different temperatures and rates of compression. The high rigidity of the monolayers of diacetylenes gives rise also to other problems associated with the

measurement of the surface pressure of Wilhelmy's method. In this case, and also for rigid monolayers of other monomers and especially polymers, important information can be obtained from data for the viscoelastic behaviour of the monolayer.

Polymerisation of diacetylenic carboxylic acids in monolayers on the surface of water has been studied in greatest detail by Tieke[13] and Day and Ringsdorf.[41] The architecture of the acid molecule influences the course of the photopolymerisation reaction in the following way. Monomers with L from 25 to 29 (m = 12, 14, and 16) polymerise at 20 °C in nitrogen; for L = 23 and m = 10, polymerisation occurs at 2 °C and for m = 5 and 8 the acids in the monolayer do not polymerise at all.[41] If polymerisation occurs, then it proceeds at any surface pressure from 0 to π_c. Consequently the degree of orientation is higher even at π = 0. In the latter case, domains, formed on spreading of the acid as a result of the interaction between the hydrocarbon chains, are present on the surface of water. Clearly, despite the low values of π, fragments of the monolayer are in the solid state because in the liquid state of the monolayer, as in solution, in a melt, and in the liquid crystal state, the polymerisation of diynoic acids is impossible.[42,43] The polymerisation of the acid $C_{12}C_8$ at π = 0 leads to a decrease in area by 10% and at π = 10 mN m^{-1} the decrease is by 15%. The degree of conversion of the monomer can be judged from the degree of shrinkage. However, kinetic studies are difficult owing to the lack of reliable calibration methods. It is believed[38,41] that the degree of conversion of diyne surfactants in the monolayer reaches 100%.

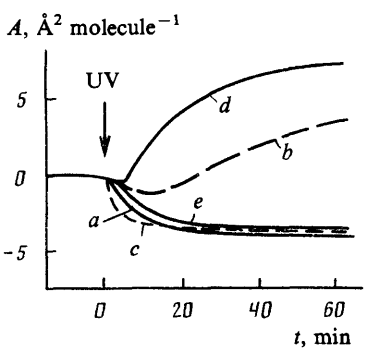

Figure 12. Dependence of the area per molecule of the monolayer of the acid $C_{12}C_8$ on the duration of UV irradiation; polymerisation conditions: π = 10 mN m^{-1}, T = 0–2 °C: *a*, water, pH 6.0, N_2; *b*, water, pH 6.0, air; *c*, 3 × 10^{-4} M M^+, pH 10.5, N_2; *d*, 3 × 10^{-1} M M^{2+}, pH 10.5, N_2; 3 × 10^{-4} M dM^{2+}, pH 5.5, N_2.[41]

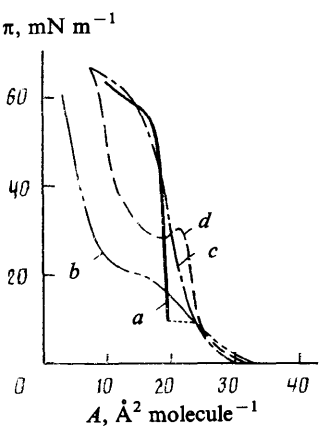
other hand, for all the divalent ions (Be^{2+}, Mg^{2+}, Ca^{2+}, Ba^{2+}, and Cd^{2+}) at high pH (10.5) a perturbation of the packing is observed. Under these conditions, there is a possibility of the occurrence of side reactions, for example, the formation of carbenes by reaction with water. The decrease of the pH to below 6 restores the ability of the salts to polymerise with topochemical control.

Following the procedure of Day and Ringsdorf,[41] we shall compare the compression isotherms for polymer monolayers obtained from the acid $C_{14}C_8$ under different conditions. As can be seen from Fig. 13, the polymerisation in the monolayer at π = 10 mN m^{-1} leads to a system which is rigid to the maximum extent. A less rigid monolayer is formed when the polymerisation is carried out at π = 0 and A = 60 Å^2 molecule^{-1}. These differences are understandable since close packing of the monomer domains is observed in the polymerisation of the first system, while in the polymerisation of the second the domains are distributed over a larger area and regions with a free water surface are present between them. On compression of the smaller layer, close packing cannot be achieved. The monolayer of a specimen polymerised in block, dissolved and deposited on the surface of water, is unstable and has a low decomposition pressure (Fig. 12). Evidently, the self-organisation of the monomer molecules on the surface of water is more effective than that of the molecules linked to one another into a long chain.



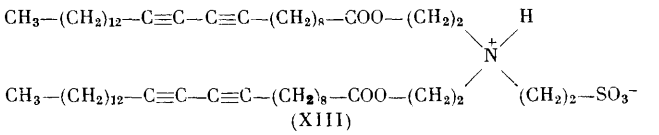


Figure 13. Compression isotherms for the $C_{14}C_8$ polymer at 20 °C: *a*, polymerisation at π = 10 mN m^{-1}; *b*, polymer obtained in block; *c*, polymerisation at π = 0 and A = 60 Å^2 molecule^{-1}; *d*, monomer.[41]

Fig. 12 illustrates the kinetics of the shrinkage of the monolayers for different polymerisation conditions.[41] Polymerisation in the presence of O_2 leads initially to a slight shrinkage, after which appreciable expansion is observed. Evidently, the formation of the polymer is followed by the ozonolysis of the conjugated bonds with formation of hydrophilic groups. This is shown by IR spectroscopic data indicating the appearance of bands at 1255, 1020, and 800 cm^{-1}. As can be seen from Fig. 12, the polymerisation is influenced by the ionic charge and the pH of the subphase. The salts of singly charged ions (Li^+, Na^+, and K^+) polymerise at high pH with shrinkage, by analogy with acids on the surface of water. On the

Consequently, the highly organised rigid two-dimensional structure of polydiacetylenes can be obtained only by the polymerisation of the monomer on the surface of the liquid.

The topochemical control of the polymerisation reaction in the monolayer imposes fairly rigid conditions of the packing of the monomer molecules.[14,44,45] It would appear that, if diynoic acids polymerise in the monolayer and at π = 0, then the photopolymerisation of the monolayer in the solid state should be achieved without obstacles. However, the acid $C_{12}C_8$ does not exhibit photoreactivity at high degrees of compression (A_0 = 23 Å^2 molecule^{-1}, pH 6.8),[44] while the two-chain diyne lipid (XIII)

polymerises only in one of two solid phases, namely in the less condensed phase A at $\pi \leqslant 20$ mN m^{-1} (Fig. 14).[14,43]

(XIII)

The causes of such behaviour are revealed by the schematic disposition of the lipid molecules in phases A and B illustrated in Fig. 14. The vertical displacement of the molecules relative to one another prevents the topochemical polymerisation reaction. By varying the composition of the support and temperature, it is possible to influence the region corresponding to the existence of each phase. The data of Tamura et al.,[44] who established the decrease of the reactivity of the acid $C_{12}C_8$ with decrease in the area of the monolayer, are consistent with these ideas. However, in his study of the behaviour of the two acids with different positions of the diyne group ($C_{16}C_8$ and $C_{16}C_0$), Collins[38] arrived at the opposite conclusion. The acid containing the unsaturated bonds in the centre of the chain was distinguished by a much lower reactivity in the monolayer.

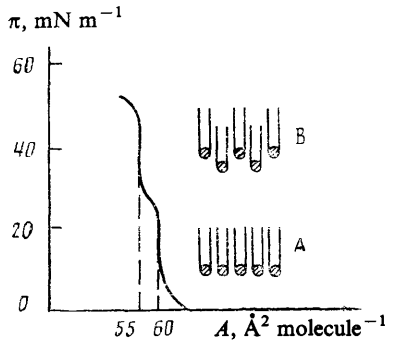

Figure 14. The surface pressure–area relation for the monolayer of the diyne lipid (XIII) at 41 °C at pH 2.[43]

The combination of data obtained by means of the Langmuir balance with UV spectroscopic data,[46] which presents no serious technical difficulties, makes it possible to follow *in situ* the polymerisation in the monolayer on the surface of water. In contrast to monomer monolayers, the polymerised monolayers of diacetylenes strongly adsorb in the visible region. For this reason, the observation of the variation of the optical density with increase in the duration of UV irradiation yields information about the degree of conversion of the monomer. Differences between the reflection spectra of the monolayer of the acid $C_{14}C_8$ on the surface of pure water and on that of an aqueous $CdCl_2$ solution have been recently established.[47] In the former case (254 nm; 0.4 mW cm^{-2}; 15 °C; 20 mN m^{-1}; 26.5 Å^2 molecule^{-1}; N_2) (Fig. 15*a*), the blue form of the acid (610 nm), formed in the initial stages of the polymerisation reaction, is converted into the red form (529 nm) with increase in the duration of UV irradiation. Similar spectra have been published in another communication,[46] where it is noted that the red form can be obtained also after prolonged heating of the blue form at temperatures above that of the phase transition of the monomer. In the polymerisation of the monomer on the surface of the $CdCl_2$ solution (4×10^{-4} M; pH 6.5; 20 mN m^{-1}; 22.3 Å^2 molecule^{-1}) on which it is more close-packed, only the red form can be detected (Fig. 15*b*). This effect can be explained by the differences between the mechanical stresses arising in the polymerisation of monolayers having different limiting areas. Indeed, as can be seen from Fig. 16, an increase in surface pressure is accompanied by an increase in the intensity of the band corresponding to the red form of the partly polymerised monolayer of the acid $C_{14}C_8$ on the surface of water and a decrease in the intensity of the band due to the blue form.[47] These stages are reversible and are reproduced in a large number of cycles (Fig. 17).

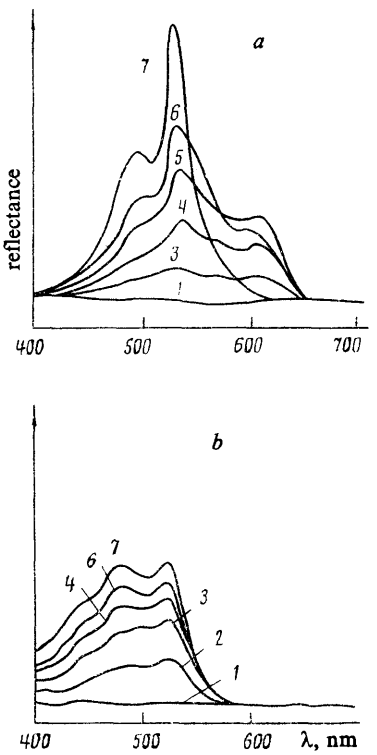

Figure 15. The reflectance spectra of monolayers of the diynoic acid $C_{14}C_8$ on the surface of water (*a*) and of an aqueous $CdCl_2$ solution (*b*); UV irradiation time (min): *1*, 0; *2*, 10; *3*, 20; *4*, 30; *5*, 40; *6*, 50; *7*, 100.[47]

The reversibility of the photochromism is based on the deformation of the monomer monolayer lattice, i.e. is determined by the phase transition induced by the change in surface pressure. It has been noted[44] that the reversible transition between the red and blue forms of the acid $C_{12}C_8$ in the monolayer, observed when the pH of the support is varied between 5 and 6, is not associated with the

isomeric changes in the main polymer chain (transformation of the diacetylene bonds into butatriene bonds) but is related to the structural disordering of the side chain. For the monolayer of the symmetrical diacetylene containing urethane groups [compound (XIV)], reversible photochromism is not observed owing to the strong interactions between the side chains.[47]

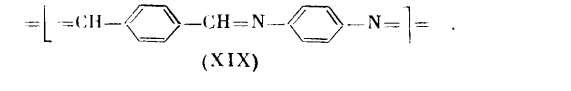
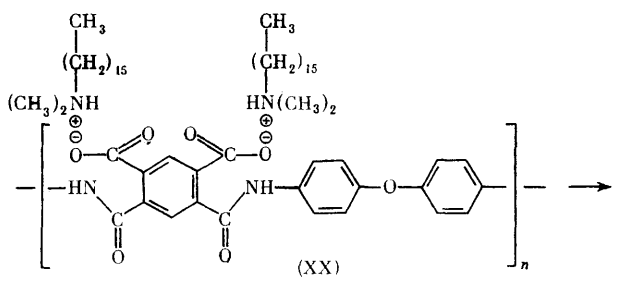
3. Polycondensation reactions and polymer-analogue transformation.

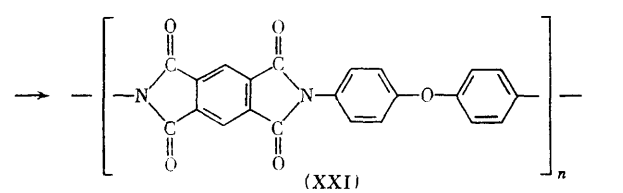


The polycondensation reactions in monolayers have not so far become very common owing to the more rigid requirements as regards the reacting compounds and the conditions of the synthesis: the compatibility of the components in the binary monolayer, the solubility in the support of one of the reactants and its adsorption on the monolayer of the other, desorption of low-molecular-weight reaction products from the monolayer, etc. One can state confidently that much more attention will be devoted to these reactions in the immediate future because with their aid it is possible to obtain two-dimensional ensembles with unique properties.

The synthesis of aromatic polybenzimidazoles in accordance with the scheme[48]

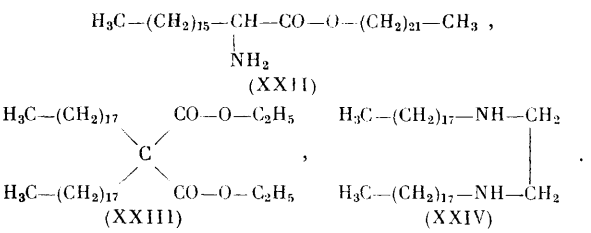


is instructive in this respect. The monolayer of dialkylterephthalaldimine (XV), which, as can be seen from the scheme above, contains no long alkyl chain, is formed on an acidified aqueous support containing the tetramine (XVI). The polyanil (XVII) formed, is converted into the polybenzimidazole (XVIII) as a result of the oxidative cyclodehydrogenation reaction. The latter reaction, controlled by the transport of oxygen and occurring in the monolayer on the surface of water at room temperature, does not occur in a LBF (21 layers) even at 120 °C. This can be readily demonstrated by the absence of changes in the colour of the LBF and is confirmed by optical spectroscopic data. The complete conversion in the LBF is attained at temperatures above 220 °C and such films are stable in air at 420 °C.



A similar approach has been used in the synthesis of thermostable aromatic Schiff bases from dioctadecylterephthalaldimine, forming the monolayer, and *p*-phenylenediamine introduced into the support.[49] The polycondensation reaction leads to a significant expansion of the monolayer and, with increase in the concentration of the diamine in the support, this effect intensifies and the resulting polymer [polyphenylterephthalaldimine (XIX)] has a higher molecular weight.

It is of interest to note that this synthesis cannot be carried out in solution owing to the rapid crystallisation of terephthalaldimines, while the polymer (XIX), synthesised by an alternative procedure from the corresponding aldehyde and the diamine, does not dissolve in solvents suitable for deposition and does not form a monolayer on the surface of water. Consequently, the polycondensation in the monolayer and subsequent formation of the LBF (Z-type, 25 layers) is the only procedure for the preparation of organised ensembles of the polymeric aromatic azomethine (XIX), whose thermal stability is high. The foregoing refers to ultrathin films of polyimides. Hitherto, the minimum attainable thickness of such films, obtained on a rotating support from solutions of a polyamidoacid with subsequent conversion into the imide form (thermal at 300 °C or chemical in a mixture of acetic anhydride and pyridine) was 0.1 μm.[50] Films with a thickness corresponding to between one and two hundred layers can be obtained with the aid of monolayers and LBF. For this purpose, one obtains initially monolayers of the alkylamine salt of the polyimidoacid (XX) on the surface of water and then, after the transfer to a solid support, the chemical conversion into the imide form is carried out:[50,51]



(XX)

(XXI)

The structure and electrical and mechanical properties of the LBF of poly *N,N'*-bis(phenoxyphenyl)pyromellitimide (XXI) have been investigated,[52] while in another study[53] it was demonstrated by scanning tunnel microscopy that the structural organisation of the monolayer on the surface of water is retained also after its transfer to the surface of highly oriented pyrolytic graphite.

Polycondensation in monolayers of long-chain α-aminoacids, diamines, and diesters has been described.[14,54] Naturally, together with the head group and the alkyl chain, the pH of the support exerts a major influence on the structure of the monolayer. The ionisation of the amino-group on an acid subphase leads to a more expanded state of the monolayer with a lower decomposition pressure than on an alkaline subphase. In the polycondensation of docosyl 2-aminooctadecanoate (XXII), the expansion of the monolayer was observed, while the monolayer of the polymer formed on reaction of diethyl 2,2-dioctadecylmalonate (XXIII) with *N,N'*-dioctadecylethylenediamine (XXIV) occupies a smaller area than the initial 1 : 1 mixture of compatible monomers.

(XXII)

(XXIII) (XXIV)

The oriented polypeptide films thus formed served as models of biomembranes.[54]

One of the effective ways of constructing new macromolecules and their organised ensembles with various functions involves carrying out polymer-analogue reactions in monolayers. However, with the exception of the elegant studies by Fariss et al.,[55] there have been virtually no studies on this aspect of the field. This confirms yet again the considerations put forward above concerning the low degree of utilisation of the possibilities of the subphase for reactions in monolayers.

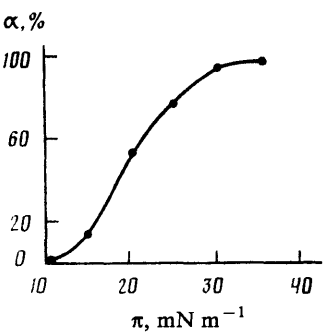


Figure 18. Dependence on surface pressure of the degree of conversion (α) of octadecyl acrylic acid in the monolayer on the surface of water.[55]

The aim of the study mentioned above was to increase the resulting capacity of an electronic resistor based on polyoctadecylacrylic acid by grafting aromatic ester groups to it. Since monomeric esters do not polymerise in the monolayer, a monolayer of octadecylacrylic acid (XXV) was formed initially on the surface of water and photopolymerised. Next benzyl alcohol (XXVI) was introduced into the support and a polymer-analogue reaction (esterification) was carried out. The degree of conversion α of the polymeric acid depends on the degree of polymerisation, the unpolymerised acid being apparently incapable of esterification. The degree of conversion of the monomer (XXV) is in its turn determined by the surface pressure at which it is polymerised in the monolayer, reaching 100% at $\pi = 35$ mN m^{-1} (Fig. 18). The degree of conversion of the acid groups of the polymer depends in a

complex manner on the pH of the subphase and varies from 0 to 70% with decrease in pH (Fig. 19), the degree of conversion of the monolayer greatly exceeding the maximum degree of conversion attained in aqueous solution. The linear resolution achieved by Schaefer's method of the 20 layer LBF of the polyester (electron-beam resistor) reaches 80 nm.

$CH_3-(CH_2)_{17}-C(=CH_2)-COOH$ (XXV); $HO-CH_2-C_6H_5$ (XXVI).

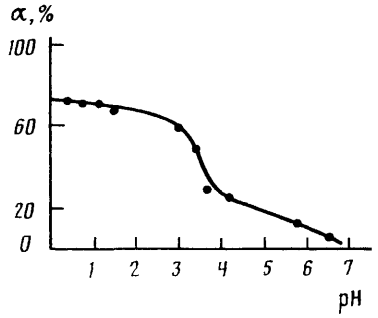

Figure 19. Dependence of the degree of conversion of the acid groups into ester groups of poly(octadecylacrylic acid) in the monolayer on the surface of water on the pH of the support.[55]

The high sensitivity of the organisation of the monolayer to changes in a large number of system parameters facilitates the control of their assembly and can be used for molecular switching. We shall consider the switching mechanism based on a phase transition in monolayers of silane lipids containing different numbers of hydrocarbon chains:[56] [γ-(*N*-octadecylsuccinylamino)-propyl]-triethoxysilane (XXVII), [γ-(*N*, *N*-dioctadecylsuccinylamino)-propyl]-triethoxysilane (XXVIII), and tris(octadecanoyloxy-methoxy)({[γ-(triethoxysilyl)propyl]succinyl}amino)methane (XXIX).

$CH_3(CH_2)_{17}-NHCO-CH_2-CH_2-CONH-(CH_2)_3-Si(OC_2H_5)_3$ (XXVII).

$(CH_3(CH_2)_{17})_2N-CO-CH_2-CH_2-CONH-(CH_2)_3-Si(OC_2H_5)_3$ (XXVIII).

$(CH_3(CH_2)_{16}COO-CH_2)_3C-NHCO-CH_2-CH_2-CONH-(CH_2)_3-Si(OC_2H_5)_3$ (XXIX).

Fig. 20 demonstrates the influence of the number of chains and of the pH of the support on the state of the monolayers of silane lipids. On an acid support (pH 2), all lipids form solid monolayers. At pH 5.8, the monolayers of compounds (XXVII) and (XXVIII) expand, while the monolayer of the three-chain lipid (XXIX) remains in the solid state. According to IR Fourier spectroscopic data,[56] at these pH the monolayers of the monomers do not hydrolyse. The lipids are therefore subjected to polycondensation at pH 2. The polymerisation on the surface of water leads to the formation of a brittle monolayer of the single-chain silane (XXVII) and of an elastic monolayer, suitable for transfer to a solid support, of the two-chain lipid (XXVIII). The three-chain lipid (XXIX) does not polymerise on the surface of water due to steric hindrance. The monolayer method makes it possible to determine directly the molecular weight of the polymer during the reaction. The molecular weights of the silane lipids, calculated by the equation

$$M_w = RT/(\pi A)_{\pi \to 0},$$

for $\pi < 0.2$ mN m^{-1} amounted to $(6-15) \times 10^4$ after 60 min from the start of the polymerisation. On heating the monolayer of the polymerised compound (XXVIII), a phase transition is observed from the solid to the liquid-crystal state, whose temperature (T = 44 °C) agrees with the transition temperature found by differential scanning calorimetry for an aqueous solution of this lipid. At this temperature, the permeability of the monolayer of the polymerised lipid (XXVIII), deposited on the surface of porous glass by the Langmuir–Blodgett method, to NaCl and a fluorescent probe charges by an order of magnitude.[56]

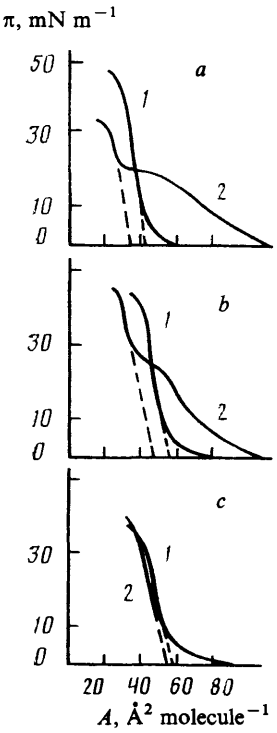

Figure 20. The surface pressure/area isotherms for the monolayers of single-chain (*a*), two-chain (*b*), and three-chain (*c*) silane lipids: *1*, pH 2; *2*, pH 5.8.[56]

Evidently, the possibilities of molecular switching based on a phase transition, predicted to occur in the stage involving the formation of the polymer monolayer, are not restricted by permeability. Another important aspect of the studies of monolayers and LBF of silane compounds is the modelling of decorative layers (of γ-aminopropyltriethoxysilane, etc.) for adhesion polymer systems,[57] the mechanism of the action of which still remains unexplained[58] despite vigorous investigations.

IV. Polymerisation reactions in Langmuir–Blodgett films

1. Diacetylenes

The structure of the LBF of monomers is determined by the transfer conditions, the organisation of the monolayers on the surface of water, and the properties of the solid support.

On the geometrically and energetically uniform surface of water, it is impossible to create an extended monolayer of diacetylenes with identical orientation of the monomer molecules. The attempts to increase the area of the domains in the monolayer, which are of great practical interest, have been at the centre of attention of investigators. The reported formation of regions in the monolayer with a uniform orientation having an area of several square centimetres[59] on spreading a 1:1 mixture of diacetylenic acid and hexadecane from a solution in chloroform was checked.[40] The author also used benzene as the solvent and together with hexadecane applied octadecane (from 1 to 33 mol%) for the formation of the binary monolayer. The largest domains (100 × 500 μm) are formed in a monolayer of the pure acid $C_{12}C_8$, deposited from benzene, and the smallest (from 1 × 1 to 1 × 10 μm) are produced in the system subjected to the test. The morphology of the monolayer on the surface of water is appreciably influenced by the solvent, admixtures and additives, the temperature and composition of the support, and the surface pressure.[40] Impurities in chloroform (ethanol) diminish the size of the domains.[60] The use of hexane, octane, cyclohexane, or aromatic hydrocarbons as the solvent instead of chloroform increases the size of the domains by a factor of 10. The dynamic annealing of the monolayer of the acid $C_{14}C_8$ leads to the transformation of the structure of the monolayer and the formation of domains whose size amounts to several square millimetres.[61]

As in the monolayer on the surface of water, the polymerisation of diacetylenes in the LBF is topochemically controlled. This type of reaction takes place without diffusion and with minimal movements of the molecules forming the crystal lattice.[62] Since the reaction zone is characterised by a definite size and form, which depend on the structure of the lattice, the topochemical control presupposes minimal changes in the form and size of the zone (minimal deformation of the surface zone) during and at the end of the polymerisation reaction.[63,64]

Fig. 21 illustrates schematically the topochemical polymerisation reaction.[64] The transformation from the monomeric to the polymeric single crystal is accompanied by the concerted rotation of the monomer units. This transformation can be regarded as a special case of a phase transition. Bubeck[64] divided topochemical reactions into two subtypes—homogeneous and heterogeneous. In the former case (Fig. 22*a*), the products form a solid solution with a statistical distribution in the lattice of the initial material. This case occurs in the absence of causes increasing the reactivity of the monomer (lattice defects, traps, etc.). With increase in the degree of conversion and with a significant difference between the lattice parameters of the monomer and the polymer, the limit of solubility may be reached. This leads to the formation of a new phase, which may induce perturbations in the structure of the initial lattice and hence arrest further polymerisation.

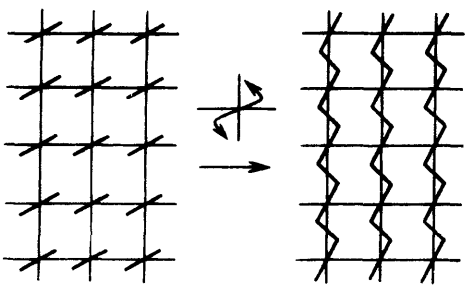

Figure 21. Schematic illustration of topochemical polymerisation.[64]

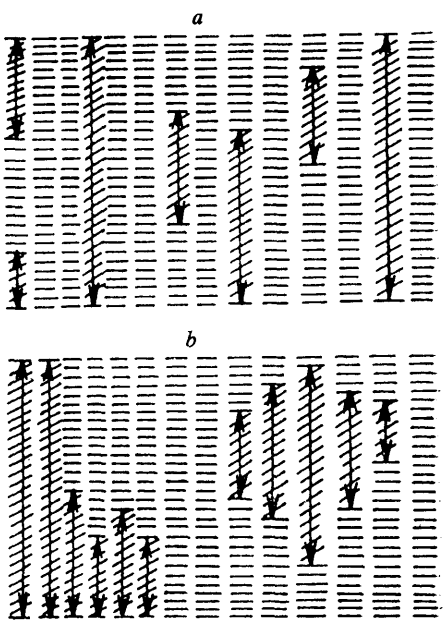

Figure 22. Schematic illustration of homogeneous (*a*) and heterogeneous (*b*) topochemical polymerisation.[64]

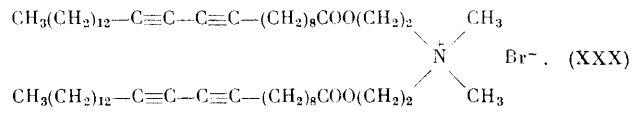
The heterogeneous subtype of the reaction (Fig. 22*b*) presupposes the presence of a phase structure in the reaction products within the monomer matrix already in the initial stages of conversion. It occurs when the product formed is capable of increasing the reactivity of the monomer. Evidently, the nucleation of the phase regions can also be induced by the presence of random impurities or special additives in the monomer lattice.



The high transparency of the LBF of diacetylenes and the change in their colour on polymerisation make it possible to monitor visually the course of the polymerisation and quantitative studies of photochemical processes. Significant differences in the photochemistry of the polymerisation of diyne surfactants on the surface of water and in the LBF are not usually observed. Admittedly, differences in the behaviour of these two systems have been inferred[13,65] from the fact that the absorption spectra of the monolayer on the surface of water have an isosbestic point, in contrast to the LBF. This point reflects the presence of a direct transition between the electronic structures of the blue and red forms of the polymers without passage through any intermediate states. Its existence in the spectra of the monolayers might be associated with the greater mobility and capacity for reorganisation of the molecules on the surface of the liquid.[13] However, the latest data for the acids $C_{14}C_8$ (Fig. 15)[47] and $C_{12}C_8$[44] do not confirm the presence of an isosbestic point in the spectra of monolayers on the surface of water. The incomplete clarity of the picture as regards photochromic transitions in monolayers and LBF is also indicated by the wide variety of interpretations of these transitions. Among the causes responsible for the photochromic transformations, the following have been discussed: the influence of the isomerisation of bonds,[66] the conformational transformations,[67] aggregation effects,[68] disordering of the side chains,[44] and the stresses arising in the polymerisation process.[69] Probably the above effects make different contributions to the photochromic transformations of polyacetylenes in monolayers and LBF. Here it is necessary to take into account the fact that in the case of LBF oxygen hardly affects the polymerisation reaction and also data[44] indicating the reversibility of the photochromic transitions in monolayers and their irreversibility in LBF.

Monochromatic light with the wavelength $\lambda = 254$ nm is usually employed for polymerisation of LBF of diacetylenic surfactants. The absorption band of the monomer is located in precisely this region of the spectrum and the polymerisation reaction is therefore initiated by the absorption of a photon by the diyne group, the quantum yield ($\Phi = 10$) showing that the absorption of one photon initiates the formation of the entire polymer chain.[70] If the specimen is subjected to preliminary pulsed irradiation by monochromatic light with a short wavelength, then the subsequent polymerisation proceeds on exposure to light with $\lambda \leqslant 500$ nm. Since the photopolymerisation should not occur under these conditions, it has been assumed[13,64] that the oligomer formed on UV irradiation induces the self-sensitised polymerisation. Sensitised polymerisation in the visible region is observed when the LBF of diacetylenes are doped with dye molecules. This process has been investigated in detail by Bubeck et al.[71] in relation to electron-donating and electron-accepting dyes. The quantum yield of this type of polymerisation is extremely low: the dye molecules must absorb a thousand photons for one monomer molecule to react.

The examples of photochemical reactions examined refer to two subtypes of topochemical polymerisation reactions: homogeneous and heterogeneous.[64] When LBF are irradiated with monochromatic light at $\lambda = 254$ nm, the excitation of the monomers and hence the initiation of the reactions assume a statistical character and lead to the homogeneous growth of polymer chains in the lattice. For longer wavelengths at which the sensitisation or self-sensitisation of polymerisation takes place, the reactions involve primarily monomers present near the dye or oligomer molecules. This leads to the heterogeneous growth of the polymer phase in the monomer matrix and to a less perfect morphology of the film.

Annealing exerts an appreciable influence on the structure, the spectroscopic properties, and the polymerisation of diyne surfactants in LBF.[40,44,72] Heating of the LBF of the $C_{10}C_8$ acid at 40–80 °C and the subsequent photopolymerisation result in the appearance of a new intense band in the absorption spectra at $\lambda = 704$ nm (blue form) and also increase the degree of order in the layers (X-ray diffraction). Annealing at $T > 90$ °C leads to the breakdown of orientation in the LBF and precludes its polymerisation.[72] Under these conditions, the band at 704 nm vanishes, which indicates its relation with the organisational structure of the LBF. On the other hand, breakdown of order has been observed[40] in the LBF of $C_{12}C_8$ together with a decrease in reactivity at an annealing temperature exceeding only 59 °C. If one bears in mind that the melting points of these monomers differ by only 4 K,[13] then the differences in the behaviour of the acids cannot be explained from the standpoint of the given phase transition.

The degree of conversion of the monomer and the rates of the polymerisation reactions, which determine their effectiveness, have remained little investigated and there are no reliable data for the molecular weights of the polymers obtained in LBF. For example, the M_w for diyne surfactants, obtained from viscosity data,[73] proved to be 200 000, while according to the view of Göbel et al.,[45] based on diffraction studies, in the polymerisation of dimethylbis(2-hexacosa-10,12-diynoyloxyethyl)ammonium bromide (XXX) the chain length does not exceed 50 units.

(XXX)

Evidently these parameters are affected by the same factors which determine the photochemistry of the polymerisation reactions described above and the morphology of the LBF considered below. The complete conversion in the LBF is not attained in photopolymerisation with topochemical control and the approach to the maximum degree of conversion is asymptotic.[16] This is associated with the fact that either the packing of only some of the molecules in the layers corresponds to the topochemical control, or that the structural organisation of the layers breaks down in the course of the reaction, or is caused by both factors. The complete conversion is attained on irradiation of diacetylenes with X-rays or γ-rays,[74] whereupon the quantum yield is 10^{12} [sic. (Ed. of Translation)].

The polymerisation of diynes containing a second functional group [for example, compound (XXXI)] is of interest because it can be carried out in two stages by irradiating the LBF with light at different wavelengths characteristic of each type of reactive group.[16] By alternating the irradiation, it is possible to vary the architecture of the change in the LBF at will.

$$CH_3(CH_2)_{13}—C\equiv C—C\equiv C—(CH_2)_8—CH_2—OOC—CH=$$
$$= CH—COOH.$$
(XXXI)

Structural-morphological studies on LBF are carried out by X-ray diffraction (small angle scattering, fine structural analysis in the vicinity of the edge of the X-ray absorption), electron diffraction,

different versions of optical spectroscopy, electron and polarisation-optical microscopy, scanning tunnel microscopy, X-ray photoelectron spectroscopy, surface plasma resonance, etc.

LBF made up of diacetylenes have as a rule a Y-structure with hydrocarbon chains inclined relative to the normal to the support at an angle of 30–50°.[16,65,75] The preparation of polar LBF of diacetylenes (X- and Z-types) requires special procedures.[76] Like the sublayers of aliphatic acids, diacetylenic LBF can crystallise spontaneously with formation of a three-dimensional lattice.[13] This tendency intensifies with decrease in the overall length of the acid chain.[77] The crystal structures of the monomeric and polymeric LBF of diynoic acids and the alcohol $C_{10}C_2$ are identical with the structures of these specimens in bulk-phase crystals.[78]

The polymerisation of diyne surfactants leads to an increase in the repeat period and to a decrease in the angle of inclination of the chains to the normal. The increments in the repeat period depend on the surfactant structure and reach 30% for the acid $C_{16}C_0$.[65] However, comparison of the structures of the LBF and a sputtered film of the acid $C_{10}C_8$ [79] led to the unexpected conclusion that the degree of order in the LBF is smaller and that on polymerisation the angle of inclination to the normal increases for the LBF and diminishes for the sputtered films. These differences may be caused by the instability of the polymerisation LBF on exposure to X-rays: in the determination of the structures of the films by fine structural analysis near the edge of the X-ray absorption (EXAFS), the blue form of the LBF is converted into the red form, whereas the sputtered films remains unaltered in the visible part of the spectrum. Polymerisation takes place in each layer (with the exception of ω-derivatives) and the macromolecular chain is arranged parallel to the support. The cations distributed between the head groups of neighbouring monolayers do not form an intrinsic lattice. As a result of the polymerisation, the initial domain texture of the monomeric LBF is established. In the domains, the macromolecular chains are packed parallel to one another but the orientations of the chains in different domains differ. The shrinkage accompanying the polymerisation of the LBF predicates the appearance and growth of cracks and cavities. The sharp difference between the changes in the volume of the unit cell on polymerisation, found[78] for the acid $C_{10}C_2$ and the alcohol $C_{10}C_2$ (388 and 217 Å^3 respectively) is reflected in the texture of the LBF: in contrast to the polymeric acid, the diyne polymeric alcohol forms significantly less effective polymer structures. The thickness of the LBF, the number of layers, and the changes in the repeat period also influence the degree of defectiveness of the polymeric LBF.[76] The mechanical properties of the LBF are determined on the basis of their ability to cover the pores of solid supports without being ruptured.[16]

In conclusion it must be emphasised that at the present time a fairly detailed analysis of the behaviour of monolayers and LBF of diphilic monomers can be achieved only for diacetylenic surfactants because none of the monomers of other classes have been subjected to such intensive and comprehensive studies in organised systems.

2. Polymerisation of diphilic monomers containing multiple bonds in the ω-position

The bias in the studies on the polymerisation of monomeric surfactants in LBF is in many respects due to their use as resistors. This applies fully to ω-tricosenoic acid (XXXII) and its salts.

$$CH_2=CH-(CH_2)_{20}-COOH\,.$$
(XXXII)

The polymerisation of ω-tricosenoic acid in Y-type LBF (electron beam) takes place via an ionic mechanism, which is indicated by the low activation energies, the insensitivity to the presence of free radicals and oxygen, and the first order of the reaction.[80] The angle of inclination of the aliphatic chains to the normal for the monomeric LBF depends on the surface pressure at which the monolayer is transferred to a solid support (π_{tr}). According to X-ray diffraction data,[81] this angle is 33°, 30°, and 27° for π_{tr} = 20, 25, and 30 mN m^{-1}. During polymerisation, the angle of inclination increases by 4° and the film itself becomes less ordered.[80] There is a close relation between the structure of the LBF of the polymerised acid (XXXII) and the characteristics of its multilayer ensembles used as electronic resistors in microlithography. The high contrast and sensitivity of the negative resistors based on the acid are due to the monodispersity of the polymer and the coherence of the LBF. The first fact can be explained by the appearance of mechanical stresses in the solid-phase polymerisation of the monomer, which limits the growth of the chains, and the second is caused by the high packing density of the hydrocarbon chains.[82,83] It is of interest to compare the properties of multilayers of ω-tricosenoic acid obtained by the Langmuir–Blodgett method and vacuum sputtering. The larger repeat period for the LBF (56.3 Å at π_{tr} = 30 mN m^{-1} compared with 49.6 Å) and the smaller angle of inclination of the chains (27° and 38° respectively) indicate a more organised structure of the acid in the LBF.[81] Peterson and Russell[84] do not rule out the possibility of the epitaxial growth of the multilayers when ω-tricosenoic acid is deposited on a solid support.

The high interlayer adhesion in the LBF of ω-tricosenoic acid shows that polymerisation is possible not only in the plane of the layers but also between them. It is of interest[85] that the solid-phase polymerisation is initiated by the defects of the crystallites in the vicinity of which the orientation of the atoms readily changes. The interface between the layers of the LBF can be regarded as a controlled defect.[86] Therefore in this particular region with a low structural organisation the initiation and growth of the chains are most likely. Furthermore, the interlayer polymerisation in Y-type LBF of ω-compounds can be facilitated by the penetration of the ends of the chains into neighbouring layers. This feature is apparently characteristic of all ω-monomers forming Y-type LBF and, depending on the purpose of the LBF, the high interlayer adhesion can play both a positive and a negative role. In order to eliminate polymerisation between the layers, it is useful to generate polar X- or Z-structures, although this can be by no means always achieved, or to obtain alternating LBF separating the monomer monolayers by inert (for example, aliphatic acid) intervening layers.[80,86] In order to prevent the interlayer polymerisation of the diynoic ω-acid C_0C_{20} in a LBF (Y-type, 135 monolayers), alternating polymeric structures with arachidonic acid have been obtained.[87]

3. Polymerisation of monomers containing multiple bonds in the polar component

The study of the monolayers and LBF of vinyl stearate and octadecyl acrylate has a long history.[88] Nevertheless, these classical subjects still remain within the range of interests of investigators.

In the radiation-induced polymerisation (^{60}Co) of vinyl stearate, there is no interlayer poymerisation problem because, regardless of the method of preparation of the LBF (Y- or X-transfer), only X-type multilayers are formed. The irradiation is carried out at low temperatures ($T \leqslant 0$ °C) at which the degree of conversion is low and then, after the removal of the radiation source, the post-polymerisation is carried out and its kinetics are investigated.[89] The

reaction proceeds via a free-radical mechanism, oxygen inhibiting the process as in polymerisation in a monolayer. At low pressures π_{tr} = 10–12 mN m^{-1}, the degree of conversion is low, which can be explained by the low packing density of the molecules. The increase of π_{tr} to 17–19 mN m^{-1} makes it possible to achieve 100% conversion of the monomer, which depends in its turn on temperature, the irradiation time and dose, and the temperature and duration of the post-polymerisation reaction. As a result of the polymerisation reaction, the orthorhombic structure of the monomer in the LBF is converted into the hexagonal structure of poly(vinyl stearate).[90] Mixed monolayers of vinyl and ethyl stearate are solid solutions for any component ratio.[88,90] These systems can be used to construct fairly thick (1000 layers) polar (X-type) skeletised LBF.

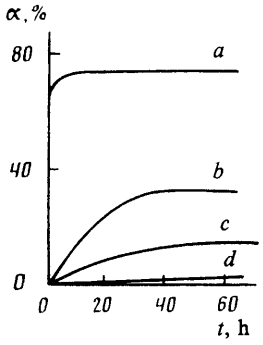


Figure 23. Dependence of the degree of conversion on the duration of the radiation-induced post-polymerisation of octadecyl acrylate in block (*a*, *d*) and in LBF (*b*, *c*): *a*, hexagonal lattice; *d*, triclinic lattice; *b*, X-type LBF; *c*, Y-type LBF; T = 20 °C.[91]

The slight differences between the chemical structures of the vinyl stearate (VII) and octadecyl acrylate (VI) molecules influence significantly the behaviour of these monomers in the LBF. Fig. 23 illustrates the dependence of the degree of conversion on the post-polymerisation time at 20 °C (^{60}Co irradiation at −196 °C) for X- and Y-type octadecyl acrylate LBF and also a block monomer in the hexagonal and triclinic crystal forms. Evidently the rate and limiting conversion depend on the type of LBF, the parameters assuming intermediate values between those for bulk-phase crystals of the two modifications.[91] The less dense packing of the X-type LBF obtained at low π_{tr} promotes higher rates of polymerisation and higher degree of conversion compared with Y-type LBF. The relative disposition of the curves in Fig. 23 of Ref. 91 led to the conclusion that hexagonal and triclinic packing corresponds to the X-type and Y-type LBF respectively. On comparing these results with the data presented above for vinyl stearate, it can be seen that the degree of conversion of the acrylic monomer is appreciably lower for the same X-type LBF and, in contrast to vinyl stearate, a higher rate and a higher degree of conversion correspond to smaller values of π_{tr}, affording LBF with less dense packing. However, the picture changes sharply in the photopolymerisation of octadecyl acrylate and vinyl stearate and the copolymerisation of their mixtures (Fig. 24). The rate of polymerisation and the degree of conversion of vinyl stearate in X-type LBF are much lower than for octadecyl acrylate in the same vinyl stearate LBF subjected to radiation-induced polymerisation.[92] With increase in the content of octadecyl acrylate in the mixture with vinyl stearate, the degree of conversion rises and reaches 95% for the LBF of the acrylic monomer (Fig. 24). The differences in the behaviour of these monomers have been explained[92] by differences between their structures, ensuring, in the case of octadecyl acrylate, the conjugation of the C=C and C=O bonds, which increases the reactivity of the monomer.

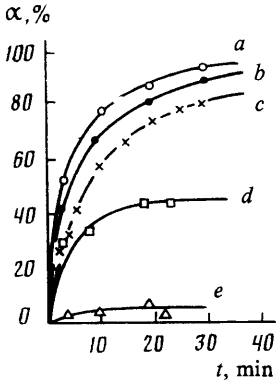

Figure 24. Dependence of the degree of conversion on the duration of the photopolymerisation of octadecyl acrylate (*a*), vinyl stearate (*e*), and their mixtures (*b*–*d*) in X-type LBF: *b*, 8:2; *c*, 1:1; *d*, 2:8; T = 10 °C, N_2.[92]

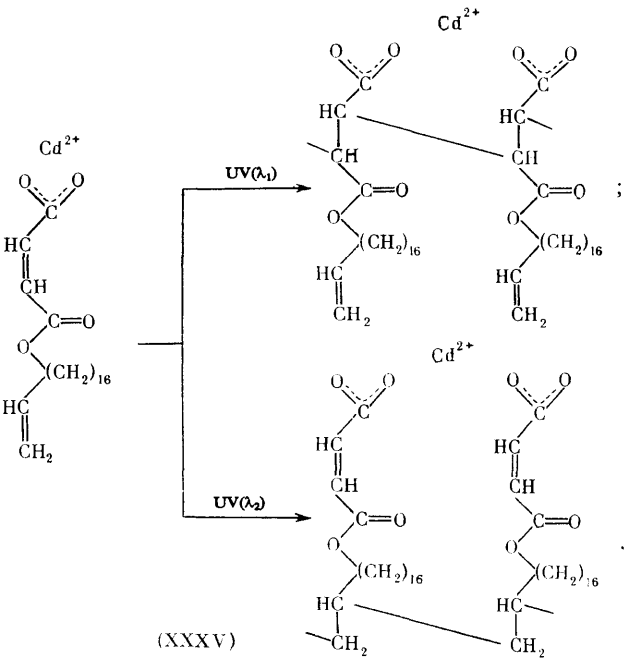
An exceptionally large increase (30%) in the repeat period has been observed[93] in the photopolymerisation of 2-eicosenoic acid (XXXIII) in a LBF (Y-type, up to 30 layers).

$$CH_3-(CH_2)_{16}-CH=CH-COOH\,.$$
(XXXIII)

The increase in this parameter during polymerisation reaction is accompanied by a phase transition between the monomer and polymer matrices. Since the phase separation in the concluding stage of the polymerisation reaction takes place via the migration of the monomer molecules and the formation of their clusters in the polymer matrix, it has been suggested[93] that the molecules in the layers possess a much higher mobility than has been assumed hitherto. The question of the possible involvement of the molecules of neighbouring layers of the LBF in the phase separation therefore requires elucidation.

An important difference between the photopolymerisation of 2-eicosenoic acid and vinyl monomers, examined above, is the absence of the influence of atmospheric oxygen on the polymerisation reaction, which is explained by the close packing of the hydrocarbon chains, preventing the diffusion of oxygen.[93] Although in our view this conclusion conflicts with the author's claim that the monomer molecules possess a high mobility, the fact itself is of undoubted practical interest.

The radiation-induced polymerisation[94] or photopolymerisation[95,96] of octadecylacrylamide (XXXIV) results in the formation of high-quality Y-type LBF which can be used as negative resistors.



$$CH_3-(CH_2)_{17}-NH-CO-CH=CH_2\,.$$
(XXXIV)

According to X-ray diffraction, electron diffraction, and IR spectroscopic data,[94] phase transitions are not observed in the polymerisation process and the side chains retain their orientation.

A convenient object for the study of the influence of the configuration of the double bond or the organisation of monomers in the LBF and their polymerisation is provided by the isomers octadecyl fumarate (ODF) and octadecyl maleate (ODM) (IX). A thorough analysis was carried out by the low-angle IR transmittance and reflectance spectroscopy of the structures of the LBF (Y-type, 9 and 20 layers) obtained by transferring the ODF and ODM monomers from the surface of water onto a KRS-5 prism and an aluminium support and then polymerised, and of the LBF of polymers transferred from an aqueous support.[27] It was established that the molecular structure of the LBF is independent of the support on which the polymerisation has been carried out. The molecules of the cadmium salt of ODF are oriented along the normal to the surface of the support, whereas the molecules of its analogue have an appreciable angle of inclination, which is associated with the conformational limitations of the *cis*-configuration of the double bond of ODM. On polymerisation, a profound reorganisation of the molecules of the *cis*-isomer in the LBF takes place, as a result of which the aliphatic chains are arranged along the normal to the surface. Both monomers ultimately give rise to polymers whose IR spectra are indistinguishable. Two important features distinguish the LBF of these compounds. Firstly, there is a possibility of thermopolymerisation (up to 145 °C). Although it leads to a less ordered structure (thermally induced disorder accompanying polymerisation) compared with photopolymerisation, it has definite prospects. Secondly, the formation of non-shrinking LBF for a 1 : 3 ratio of ODF and ODM prevents the appearance of cracks and stresses in the multilayer structure. For these systems, it is of interest to determine the molecular weight of the polymer obtained in the LBF. It was noted above that the cessation of chain growth on polymerisation in two-dimensional structures and the formation of monodisperse polymers are associated with the appearance of stresses. If this mechanism is valid, then the molecular weights of the polymers obtained in the LBF from individual compounds and their mixture should differ.

4. Polymerisation of certain other diphilic monomers

The introduction of the double bond in the ω-position in octadecyl fumarate increases the ease of controlling the structure and properties of the LBF. Irradiation of ω-octadecenyl fumarate (XXXV) by UV light at different wavelengths leads to selective polymerisation:[97]

(XXXV)

If we recall that reaction between neighbouring layers is possible in polymerisation of monomers containing terminal double bonds (ω-tricosenoic acid) in Y-type LBF, then one can readily foresee the prospects for such bifunctional surfactants in the preparation of systems with high interlayer and intralayer adhesion. In alternating and polar LBF, compounds of this type are capable of forming polymer networks.

Long-chain derivatives of dienes also polymerise in two stages.[13] When the LBF of docosyl penta-2,4-dienoate (XXXVI), a monobasic dienoic acid ester, is irradiated with UV light (λ = 250 nm), the dimerisation reaction takes place initially in the first stage. It is rapid, the conversion is complete, and it involves only the C(3)=C(4) bonds. The second stage (polymerisation at λ = 210 nm) occurs at low rates and the degree of conversion does not exceed 80%:

$$CH_3-(CH_2)_{21}-O-\overset{\overset{O}{\|}}{C}-CH=CH-CH=CH_2\,,$$
(XXXVI)

$$CH_2=CH-(CH_2)_{21}-O-\overset{\overset{O}{\|}}{C}-CH=CH-CH=CH_2\,.$$
(XXXVII)

It is believed[98] that the differences between the reactivities of the C(3)=C(4) and C(1)=C(2) bonds are due to the different dispositions of these groups relative to the interlayer plane. The end groups have a greater freedom to change their conformation compared with the C(1)=C(2) groups located deeper within the lattice. In the analogous compound ω-tricosenyl penta-2,4-dienoate (XXXVII), containing a third double bond in the ω-position, there is

a possibility of a third polymerisation stage. Despite the fact that the vinyl groups in the ω-position are at the interface between the layers, polymerisation under the influence of the electron beam proceeds with difficulty.[98]

The monoesters of dibasic dienoic acids polymerise in LBF with 100% conversion.[16] Although the rate of the photopolymerisation reaction and the degree of conversion of hydrocarbon [compound (XXXVIII)] and fluorocarbon [compound (XXXIX)] derivatives of muconic acid are identical, their UV absorption spectra differ significantly.

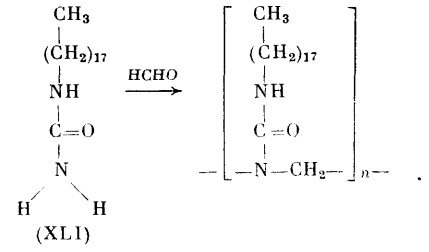
$$CH_3(CH_2)_{16}CH_2-O-\overset{\overset{O}{\|}}{C}-CH=CH-CH=CH-COOH\ ,$$

(XXXVIII)

$$H(CF_2)_{10}-CH_2-O-\overset{\overset{O}{\|}}{C}-CH=CH-CH=CH-COOH\ .$$

(XXXIX)

This shows that the orientation environments of identical chromophoric groups in the LBF of these compounds are not the same. Evidently, the differences are established in the Y-type LBF formation stage: the fluorine-containing surfactants are transferred to a solid support for areas greater by a factor of 1.5 than the hydrocarbon muconates. The stability of the LBF of these compounds was estimated from their ability to cover pores (0.2 μm) in a polypropylene membrane. The monomeric and polymeric LBF (2–6 layers) of compound (XXXVIII) cover the pores without disrupting the coherence of the film. The LBF of compound (XXXIX) in any form are incapable of covering the pores. Such behaviour of the fluorocarbon muconic monoesters can be explained by the small chain length and by the weak interchain interactions.[16] On the other hand, tridecylpentadienoic acid, a hydrocarbon analogue of compound (XXXIX), does not form a LBF at all.[99]



In contrast to diacetylenic derivatives, surfactants of the diene series, containing an unsaturated group at the edge or in the middle of the hydrocarbon chain, have remained uninvestigated. By analogy with diyne and ethylene surfactants, one may claim that the migration of the diene group along the chain in the direction of the polar group can initially reduce the stability of the monolayer and the quality of the LBF and then increase these characteristics of the system. The results of studies on the structure of the LBF made up of mixed monolayers of β-parinaric acid (XL) and stearic acid then lend a definite support to these considerations.[100]

$$trans\text{-}C_2H_5(CH=CH)_4(CH_2)_7COOH\ .$$

(XL)

According to X-ray diffraction data the LBF consisting of the individual acid (XL) are amorphous and do not have a layered structure. With increase in the concentration of stearic acid, the degree of order in the LBF increases but polymerisation again disrupts the organised structure of the LBF.

A novel example of a polymerisation reaction in the LBF, leading to the formation of a network polymer, is provided by the polycondensation of octadecylurea (XLI) with formaldehyde, which diffuses into the LBF from the vapour phase:[86,101]

(XLI)

The methylene bridges connecting the polar head groups, do not prevent the close packing of the molecules in the layers. On raising the temperature, a network polymer is formed as a result of the interaction of formaldehyde with the NH groups.[102] Here we again encounter the situation where the reaction is possible only in the organised ensembles but not in the bulk phase.

V. Prospects for the application of polymeric Langmuir–Blodgett films

The prospects for the application of LBF may well satisfy those who indulge in the wildest fantasies. Fairly complete information has been published[1–4,12,103–107] about the possible applications of LBF, low-molecular-weight surfactants, and partly, polymeric surfactants. The majority of the applications of LBF comprising small molecules hold also for polymer systems. The molecular groups carrying a definite functional group are immobilised in the polymer (a network polymer is best) matrix by forming a mixed monolayer with the matrix or are grafted via a spacer of definite length in the side chain or the main chain of the polymer (polymer-analogue transformations, copolymerisation). An important advantage of such systems is that the "guest" molecules may not in fact possess pronounced surface-active properties and may not form their own stable monolayer on the surface of the liquid.

In any case, the application of LBF in both fundamental and applied research is based on the possibility of assembling uniform two-dimensional structures with a controllable thickness and orientation of the molecules in the layers. The controllable structural organisation of monomers in monolayers and LBF (the inclination of the molecules, the distances between them, the influence of the environment, the positions of the functional groups, isomerisation, etc.) make it possible not only to investigate the theoretical questions concerning polymerisation reactions in these systems but also to synthesise new materials, whose preparation is impossible under other conditions (in the melt, in solution, and in the solid phase).

The phase transitions in individual and mixed monomer monolayers, the thermodynamics and kinetics of polymerisation, copolymerisation, polycondensation, and grafting reactions, carried out under different physical influences (UV irradiation, electron beam, radiation, temperature) or under the influence of initiators and cross-linking agents introduced into the aqueous (monolayer) or gaseous (monolayer and LBF) phases, represent the range of

problems requiring nowadays an appreciably greater attention of investigators.

The molecular weights and molecular weight distributions of polymers, obtained when they are synthesised in monolayers, the mechanism of the termination of chain growth and of the formation of monodisperse polymers in LBF, and sensitised and self-sensitised photopolymerisation effects await a more detailed development.

Langmuir–Blodgett films provide a unique possibility of constructing models of boundary layers comprising combined (with polymers) materials, which constitute the basis of modern materials science.[57,108,109] The regulation of intralayer and interlayer polymerisation make it possible to generate gradient boundary structures with different levels and ratios of adhesive and cohesive strengths and a specified free volume, sorption-diffusion properties, stresses within cracks, etc. Consequently, the mechanism of the of adhesion interactions in polymer/metal and polymer/finishing agent/metal systems and the principles governing the protection of metals against corrosion by organic coatings associated with it may not only be comprehended at a deeper level but can also be used to create a new generation of polymeric protective coatings.[58,105,110] After considering reactions at the support/first LBF layer interface, Barraud et al.[86] identified the adhesion problem as the main one. When acids are deposited on an aluminium support coated by the oxide, salts are formed (for example, aluminium stearate) which ensure an effective adhesion to the support. The intensification of adhesion interactions with supports made of noble metals, germanium, and silicon constitute a more complex problem. Studies designed to devise gradient transition zones in polymer/adhesion junctions are being prosecuted at the Institute of Physical Chemistry of the USSR Academy of Sciences.

An important advantage of the organised layered structure of monomers is that certain polymers can be obtained only by polymerising monomers in the monolayer on the surface of a liquid or in a LBF or the formation of the LBF by them is possible only via the stage involving the synthesis of the polymer in the monolayer. In the former case, one is dealing with monomers polymerising under the conditions of a topochemical reaction, while in the latter the problem concerns polymers from which monolayers cannot be formed on the surface of water in view of their negligible solubility (polyimides, dense network polymers).

A wide range of compounds, polymerising in monolayers and in LBF, have been synthesised and used to devise models for biological membranes by Ringsdorf and co-workers.[14–20] The "architects" from Mainz (Federal Republic of Germany) have successively improved lipid molecules by introducing polarisable groups into the hydrophobic and/or hydrophilic parts of the molecules and by altering the length of the spacer in the side chain and/or the main chain. Ultimately the biomembrane models stabilised by photopolymerisation became very similar to the original.

Together with the use of polymer monolayers and LBF in fundamental research, polymers are used nowadays in modern engineering and in the first place as calibrated insulating and active layers in metal–dielectric–metal and metal–dielectric–semiconductor systems and also as optical and electron beam resistors in high-resolution microlithography.[1,76,81–83,95,96,111]

Much attention has been devoted recently to the study of non-linear optical effects in both centrosymmetrical and polar and alternating polymeric LBF.[1,3,4,103,112] The high non-linear susceptibilities in polydiacetylenes are due to the presence of chains of conjugated bonds. The influence of the length of the chain of conjugated bonds on the cubic magnetic susceptibility has been investigated[113] for LBF comprising mixed monolayers of arylbutadienes and hexatriyne with poly(isobutyl methacrylate). The introduction of hexatriyne into LBF makes it possible to obtain a longer chain of conjugated bonds compared with diyne derivatives and hence a greater intensity of the third harmonic signal.[113] The effects associated with the doubling of the frequency of the light (generation of the second optical harmonic) are being investigated using polar and alternating as well as centrosymmetric LBF in an electric field which eliminates the centre of inversion. Together with thin (several bilayers) films, LBF containing hundreds of bilayers began to be used.[114,115] The combination of non-linear optical properties of the LBF with the possibility of using them as light guides [optic fibres?][112,116] has opened up prospects for the application of these systems in integrated optics, in recording devices, and in information storage and reproduction devices.

The iodine-doped diacetylene LBF have a fairly high electrical conductivity. For example, whereas the specific conductances of LBF comprising diacetylenic acids containing a diyne group in the centre of the chain ($C_{16}C_8$)[117] and in the ω-position (C_0C_{20})[87] do not exceed 10^{-2} and 5×10^{-8} Ω^{-1} cm^{-1} respectively, after doping with iodine the specific conductance increases by 3–4 orders of magnitude. However, LBF comprising polythiophenes, whose electrical conductivity and stability are greater, are of major interest nowadays from this point of view.[118,119]

The possibilities of polymeric LBF as partition membranes have perhaps still not been utilised. The regulation of the thickness, structure, and composition of the LBF deposited on a porous support makes it possible to vary within wide limits the productivity and selectivity of membranes. Membrane gas-separation processes and processes involving the reverse-osmotic separation of solutions have been investigated using LBF comprising diacetylenes[120] and organosilicon[56] and other polymers.[121] An appreciable increase in the number of publications on this field is to be expected soon. They will discuss the properties of LBF partition membranes consisting of interesting compounds such as derivatives of cyclodextrins,[122–125] calixarenes,[126,127] crown-ethers,[21] and macrocyclic polyamides.[128]

* * *

In conclusion, it must be emphasised that the monomer polymerisation processes in monolayers and LBF examined in this part of the review together with the associated changes in the structural organisation and properties of these planar systems represent one aspect of the general problem of Langmuir–Blodgett polymer films. The second aspect involves analysis of the behaviour of monolayers and LBF of polymers synthesised by traditional methods. Although studies on the polymer monolayers, which are only part of this aspect, have long been prosecuted, much less attention is devoted nowadays to problems of the preparation of LBF and the relation between the properties of monolayers and LBF comprising macromolecules than to monolayers and Langmuir–Blodgett films comprising monomers. On the other hand, polymer monolayers have a series of specific features. These include the possibility of obtaining stable monomolecular films from water-soluble polymers and polymers without pronounced diphilic properties, a broad relaxation spectrum, and a high kinetic stability of monolayers. The above features of polymer monolayers will apparently attract in the immediate future the attention of specialists using LBF for the solution of applied problems. The author plans to devote his next review to the analysis of these systems.

ABSTRACT. Data on the oxidation of PH_3 and AsH_3 by metal complexes and oxygen compounds of metals and non-metals and on their catalytic and coupled oxidation by dioxygen, ozone, and peroxide compounds are analysed. The methods for the activation of oxidants, phosphine, and arsine, ensuring the acceleration of the oxidative reactions in processes involving the elimination of the extremely harmful impurities PH_3 and AsH_3 from gases, are examined.

The bibliography includes 176 references.

I. Introduction

Reactions involving oxidation by metal complexes and free and bound oxygen are used widely to remove the extremely toxic impurities AsH_3 and PH_3 from gases.[1–4] These impurities are present in the effluent gases from phosphorus, carbide, metallurgical, phosphide, hypophosphite, and other industries and are evolved in the processing of phosphorus slags.[1–5] Reactions involving the oxidation of PH_3 and AsH_3 by dioxygen are used to purify oxygen-containing gases while oxidation of phosphine and arsine by bound oxygen is employed for the detoxification of oxygen-free gases.[1–4] However, there are no reviews in the literature of the oxidation reactions of PH_3 and AsH_3. Certain reactions of PH_3 and AsH_3 have been described.[6–12]

The present review discusses the principal features of the kinetics and mechanisms of the majority of the known reactions involving the oxidation of PH_3 and AsH_3 by metal complexes and the oxygen compounds of metals and non-metals as well as their catalytic and chemical oxidation by dioxygen, ozone, and peroxide compounds.

In the analysis of the oxidation reaction PH_3 and AsH_3, it was observed that a common feature of the fast reactions is the many-electron nature of the rate-limiting stage involving an even number of electrons in the case of PH_3 and an odd number of electrons in the case of AsH_3. On the other hand, in processes where an odd number of electrons is transferred in the rate-limiting stage of the oxidation of the PH_3 and an odd number of electrons is transferred in the corresponding stage in the oxidation of AsH_3 are slow. The observed effect made it possible to divide the PH_3 and AsH_3 oxidation reactions into two groups: complementary and non-complementary reactions.[13] The number of electrons involved in the oxidation-reduction reactions depends on the type of stable valence states of the oxidant and their redox potentials.[14] The rate of reaction increases with increase in the number of electrons participating in the rate-limiting stage. Four methods for the acceleration of the PH_3 and AsH_3 oxidation reactions are most common: (1) the use of solvents or carriers which stimulate the formation of polynuclear complexes ensuring the transfer of the necessary number of electrons: (2) the use of catalysts which are capable of being reduced by PH_3 and AsH_3 in the presence of an oxidant with participation of the required number of electrons and which are rapidly regenerated by the oxidant to the initial state; (3) the application of catalysts which permit the separation of the rate-limiting stage into two slow stages: the reduction of the catalyst by PH_3 or AsH_3 with participation of the required number of electrons and the reoxidation of the catalyst by the oxidant; (4) the introduction of additives (activators) which ensure the coupled oxenoid oxidation of PH_3 and the non-oxenoid oxidation of AsH_3. In a number of instances, several methods are used simultaneously to accelerate the reduction of metal complexes and free and bound oxygen by phosphine and arsine.[11,12]

II. The many-electron rate-limiting stage

The oxidation of PH_3 and AsH_3 to the phosphate and arsenate respectively, i.e.

$$PH_3 - 8e + 4O^{2-} \rightarrow PO_4^{3-} + 3H^+, \quad (1)$$

$$AsH_3 - 8e + 4O^{2-} \rightarrow AsO_4^{3-} + 3H^+, \quad (2)$$

proceeds with participation of eight electrons and can occur in principle as a multistage process. We shall consider the thermodynamics of such successive oxidation. The oxidation of PH_3 and AsH_3 reduces the electron density of the P and As atoms and converts them into electron acceptors. As a result, phosphate and arsenate as well as the intermediate and final products of the

oxidation of PH_3 (phosphinite, phosphonite, phosphite, and phosphate) and AsH_3 (arsenite and arsenate) are stabilised in basic media owing to the formation of bonds with the bases. Presumably the rate constants for the oxidation of PH_3 and AsH_3 by bound and free oxygen are higher, other conditions being equal, in alkaline media than in acid media as a consequence of the formation of a donor–acceptor bond with the bases in the transition state. Thus for identical oxidising capacities of the reactants, alkaline media are more favourable for the oxidation of PH_3 and AsH_3. Since at high pH many oxidants are sparingly soluble and have a low redox potential, the oxidation-reduction reactions of PH_3 and AsH_3 were investigated in greater detail at low pH.[11,12]

Fig. 1 illustrates the distribution of energy in the successive oxidation of PH_3 in two-, four-, six-, and eight-electron processes. The redox potentials of the two-, four-, six-, and eight-electron oxidation of PH_3 in acid and alkaline media were calculated from data in handbooks using the law of the conservation of energy.[15] It is possible to use weaker oxidants for the oxidation of PH_3 in an alkaline medium than in the acid medium (see Table 1 at the end of the review). Since in most cases the oxidation reactions of PH_3 were investigated in the presence of an acid, which ensured the homogeneous occurrence of the process, we shall consider the distribution of energy among different stages in an acid medium. Phosphorus gives rise to stable compounds of the following oxidation states: P^{-3}(PH_3, PR_3); P^{-1}(PH, R_3PO, H_3PO); P^{+}[$R_2(RO)PO$, $H_2(HO)PO$, HPO, R_2P_2, R_4P_4]; P^{+3}[$R(RO)_2PO$, P_2O_3, $P(RO)_3$, PCl_3, $H(HO)_2PO$]; P^{+5}[$(RO)_3PO$, $P(RO)_5$, $(HO)_3PO$, P_2O_5, PCl_3O, PCl_5].[16]

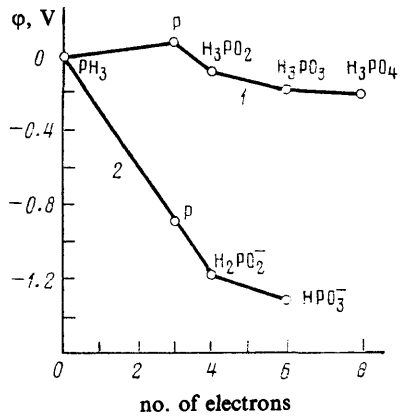

Figure 1. The oxidation-reduction potentials of three-, four-, six-, and eight-electron oxidation of phosphine to phosphorus, hypophosphorus, phosphorus, and phosphoric acids respectively in acid (curve *1*) and alkali (curve *2*) media.

The oxidation state varies in the above series in steps corresponding to an even number of electrons.[17] Other valence states of the P atom, differing from P^{-3} by an odd number of electrons (P^{-2}, P^{0}, P^{+2}, and P^{+4}), are unstable.[17] The stability of the P^{-2}, P^{0}, P^{+2}, and P^{+4} valence states increases somewhat in the presence of the P–P bond [P_2H_4, P_2R_4, P_4R_6, P_4, $P_2H_2(O)_2(OH)$, $P_2(RO)_4$, P_2Cl_4, $P_2(HO)(O)_2$].[18] However, diphosphorus compounds are obtained either from substances already containing P–P bonds or by the reaction of the P^{+3} acid chlorides with P^{-3} compounds (secondary phosphines, alkyl phosphides, alkali metals).[18] In the oxidation of PH_3, the formation of diphosphorus products is hindered by the necessity for the involvement of two PH_3 molecules in the rate-limiting stage.

One-, three-, five-, and seven-electron oxidation of PH_3, leading to the regeneration of unstable intermediates, is thermodynamically less viable than the two-, four-, six-, and eight-electron oxidation leading to the formation of stable intermediate or final products. Bearing in mind the rules stating that the variation of free energies is linear,[14] one can assume that the non-complementary oxidation of PH_3 should be appreciably slower and should require a higher activation energy than the complementary oxidation.[13] Similar rules are characteristic of the complementary and non-complementary transitions also in other oxidation-reduction reactions.[13,14,19,20]

The thermodynamic, activation, and kinetic parameters of the rate-limiting stage of the oxidation of PH_3 depend not only on the complementarity but also on the total number of participating electrons. Fig. 1 shows that, in the successive complementary oxidation of PH_3, the energy is distributed non-uniformly among different stages. If P^{-1} compounds are formed in the interaction as intermediates (two-electron rate-limiting stage), then the first stage can be carried out only using oxidants with a redox potential in excess of 0.06 V. If P^{+1} compounds are generated as intermediates (four-electron rate-limiting stage), then weaker oxidants with redox poentials in excess of −0.08 V are suitable for the initial step. The six- and eight-electron reactions can occur using oxidants having redox potentials in excess of −0.14 and −0.15 V respectively. Similar rules have been established also for the reduction reactions of many-electron reactants.[21–24].

The overall energy effect in the rate-limiting stage increases with increase in the number of active electrons and reaches a maximum when the process involves eight electrons of PH_3. Since a large number of molecules (phosphine, several oxidant and base molecules) usually participate in a many-electron rate-limiting stage, it follows that, with increase in the number of active electrons, the role of the entropy prohibition becomes more pronounced.[13] However, if the solvent or the carrier stimulate the formation of polynuclear complexes containing bases in the coordination sphere, the entropy barrier is lowered.[14] Positive changes in the activation entropy are observed when the polynuclear complex forms fairly stable compounds with PH_3. Metal complexes forming phosphides on interaction with PH_3 are especially effective. The phosphides generate the ions of d^8–d^{10} metals from CuCl, $AgNO_3$, $HgCl_2$, AuCl, $PdCl_2$, and $PtCl_2$.[16] The coordinated phosphide anion has more marked reducing properties than PH_3. The molecules deprotonated by the complex-forming agent are usually oxidised much faster than the initial molecules.[25] Polynuclear complexes can be detected by physical[26] and physicochemical methods.[27]

The formation of polynuclear metal complexes is promoted by solvents with a low dielectrical constant and mono- and poly-dentate ligands having at least two unshared electron pairs with similar energies (F^-, Cl^-, Br^-, I^-, O^{2-}, HO^-, S^{2-}, HS^-, Se^{2-}, Te^{2-}). The content of polynuclear complexes in solution increases in turn with increase in the total concentration of the metal.[26] As a rule, the amount of polynuclear complexes ($C_{Ox_iY_i}$) depends on the total

concentration of the oxidant ($C_{Ox\Sigma}$) and the ligands (C_Y) as described by the formula[26]

$$C_{Ox_jY_i} = \frac{C_{Ox\Sigma}\gamma C_{Ox}^{j-1} C_Y^i}{1 + \gamma C_{Ox}^{j-1} C_Y{}^i}.$$

When $\gamma C_{Ox}^{j-1} C_Y^i > 1$ and $C_{Ox_jY_i} = C_{Ox\Sigma}$, we have $\gamma = C_{Ox_jY_i}/C_{Ox}^j C_Y^i$.

Polynuclear metal complexes are reduced by phosphine in the following way: one of the metal ions of the polymeric complexes is bound to PH_3 and electrons are transferred from phosphine to other ions of the intermediate. This mechanism operates in the reduction of a many-electron oxidant.[21–24]

The stability of polynuclear oxygen-containing compounds depends on the acidity of the medium and usually increases as half the sum of the electronegativities of the central atom and oxygen approaches 2.5.[28] Since phosphine and arsine do not form complexes with high-valence forms of the metal, the oxygen compounds react with PH_3 and AsH_3 via an outer-sphere mechanism. Phosphine adds to an O atom of the polynuclear oxygen compound. The nearest central metal atom effects the transfer of electrons from PH_3 to the remaining ions of the intermediate and transfers non-bridging O atoms to phosphine. The loss of oxygen atoms by this centre is made good by the oxygen atoms from other oxygen compounds of the polynuclear ensemble.

Iodide and bromide ions are most often used as catalysts ensuring the oxidation of PH_3 and AsH_3 by metal complexes and bound oxygen via separate mechanisms. In order to estimate their catalytic properties in the reduction of various oxidants, a correlation equation has been proposed.[29] The oxidation reaction usually begins with the stage involving the formation of a complex of PH_3 with the oxidant. It follows from data on the mechanisms of the oxidative reactions of PH_3 that metal complexes form intermediates with a central atom–phosphorus bond, while oxygen compounds of metals and non-metals give rise to products with an O–P bond:

$$PH_3 + Ox_j \overset{K_1}{\rightleftarrows} Ox_j(PH_3). \quad (3)$$

Next comes the inner-sphere or outer-sphere redox reaction of the intermediate $Ox_j(PH_3)$. Coordinated bases (O^{2-}, OH^-, H_2O, ROH, RO^-, Cl^-, Br^-, I^-, etc.) add to phosphine:

$$(PH_3)Ox_j \overset{K_2}{\rightleftarrows} (PH_3O_m)\,Red_j. \quad (4)$$

The process terminates with the decomposition of the complex formed by the reduced form of the oxidant (Red_j) and the oxidised phosphine (PH_3O_m):

$$(PH_3O_m)\,Red_j \xrightarrow{k_0} PH_3O_m + j\,Red. \quad (5)$$

The equilibrium constant K_2 can be determined from the difference between the redox potentials φ_1 and φ_2:

$$\lg K_2 = \frac{(\varphi_1 - \varphi_2)\,RT}{nF}, \quad (6)$$

where n is the number of electrons which in the given instance are transferred from the reductant to the oxidant and F is the Faraday (96 500 coulomb mol^{-1}). According to this mechanism, the effective rate constant k is given by

$$k = k_0 K_1 K_2. \quad (7)$$

It follows from Eqns. (6) and (7) that

$$\lg k = \lg k_0 + \lg K_1 + \frac{RT}{nF}(\varphi_1 - \varphi_2). \quad (8)$$

The quantities φ_1 and φ_2 characterise the oxidation-reduction potentials of the oxidant and phosphine respectively in the intermediate complex.[30] On complex formation, the oxidation-reduction potentials of the reactants involved change and frequently in the opposite directions.[30] As K_1 varies, the effective rate constant k therefore passes through a maximum. The formation of a complex between Ox_j and PH_3 facilitates, on the one hand, the inner-sphere redox transfer of electrons and, on the other hand, lowers the redox potential of the oxidant φ_1. As a result of the formation of a stable complex with PH_3, the oxidant is converted into a reductant.[30] Metal phosphides [$(HgCl)_3P$, Cu_3P, Ag_3P, Au_3P] exhibit only reductive properties. It follows from Eqn. (8) that the rate constant for the reduction of the oxidant by phosphine increases with increase in the redox potential of the oxidant in the half-reaction involving an even number of electrons (n). Mononuclear and polynuclear complexes of the oxidant can participate in the rate-limiting stage. The transition state in the rate-limiting stage is stabilised if the system contains species capable of forming donor–acceptor and dative bonds with the oxidised P atom and the reduced oxidant. Since an increase and decrease in the positive charge on the P atom enhances the "hard" and "soft" properties respectively,[14] a combination of species of both types in the system is optimal. Since oxygen-containing molecules (H_2O, ROH) stabilise the positively charged states of the P atoms while iodide ions stabilise the reduced forms of the metal complexes, aqueous and alcoholic solutions of alkali metal iodides are most often employed as the solvent in PH_3 oxidation reactions.[11,12]

The concerted transfer of an appreciable number of electrons in the rate-limiting stage takes place stepwise via the formation and subsequent reactions of unstable intermediates which have definite albeit short lifetimes.[31] Such intermediates, formed as a result of one- or two-electron transfer, are present in shallow energy wells.[31] The energy profile of a many-electron rate-limiting stage involves several transition states. The saw-tooth form of the energy barrier in a many-electron rate-limiting stage is due to the fact that the simultaneous transfer of more than one electron is prohibited by the Franck–Condon principle.[13] The Franck–Condon barrier increases sharply in the transfer of two electrons.[13,14] The intermediate complex is rearranged in small energy wells, which makes it possible to overcome the Franck–Condon barrier. Other important limitations to the many-electron transfer in the rate-limiting stage arise from the rule of the conservation of electron spin[32] and of the symmetry of the interacting orbitals.[33,34] The energy wells are shallow if the successive transfer of a large number of electrons in the rate-limiting stage takes place without the infringement of these rules.

The main driving force of a many electron rate-limiting stage is the difference between the energies of the one-electron and many-electron stages [Eqn. (8)]. The greater this difference, the greater the probability of the many-electron transition. Exothermic reactions are preferred because a definite energy is required to rearrange the intermediates. Low activation energies are characteristic of all the steps in a many-electron rate-limiting stage owing to the high degree of utilisation of the energy of formation of new bonds in the dissociation of old ones.[35]

Eqn. (8) can be used to predict reactions with participation of other many electron-donors, since the known correlations (see, for example, Tobe[13] and Basolo and Pearson[14]) are used only for estimations relating to one-electron reactions. In conformity with Eqn. (8), a three-electron transfer in the rate-limiting stage is preferred in the oxidation of AsH_3. It can be seen from Fig. 2 that the redox potential $\varphi_{AsH_3 \rightarrow As} = -0.65$ V, while the redox potentials of the six- and eight-electron transfers reach -0.18 and 0.05 V respectively. Oxidants ensuring the energetically favourable three-electron oxidation of AsH_3 in the rate-limiting stage are therefore rapidly reduced by arsine.[6]

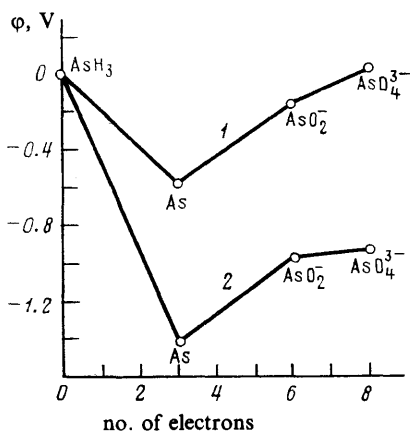

Figure 2. The oxidation-reduction potentials of three-, six-, and eight-electron oxidation of arsine to arsenic, arsenious, and arsenic acids in acid (curve *1*) and alkaline (curve *2*) media.

Oxidants capable of effecting the six- and eight-electron transfer (HIO_3 or H_5IO_6) convert AsH_3 directly into $HAsO_2$ or H_3AsO_4 without the preliminary liberation of As. The point is that the successive oxidation of AsH_3 to As and then of As to $HAsO_2$ or H_3AsO_4 is energetically less favourable than the direct transformation $AsH_3 \rightarrow HAsO_2$ (or H_3AsO_4). The $AsH_3 \rightarrow HAsO_2$ and $AsH_3 \rightarrow H_3AsO_4$ redox potentials are only -0.18 and 0.05 V respectively, while the $As \rightarrow HAsO_2$ and $As \rightarrow H_3AsO_4$ redox potentials are respectively 0.25 and 0.58 V. The rates of reduction of six- and eight-electron oxidants by AsH_3 and PH_3 are therefore similar. In reactions with oxidants promoting the transfer of an odd number of electrons, the reactivity of AsH_3 is appreciably higher than that of PH_3.

Other features are observed in the oxidation of ammonia. Nitrogen forms stable compounds when it exists in the following oxidation states: $N^{-3}(NH_3)$, $N^{-1}(NH_2OH, NH_2Cl)$, $N^0(N_2)$, $N^{+1}(NHCl_2)$, $N^{+3}(HNO_2)$, and $N^{+5}(HNO_3)$.[36] In contrast to the increase in the positive charge on As and P, its increase on nitrogen is accompanied by an increase in the redox potential (Fig. 3). It follows from Fig. 3 that, in the oxidation of NH_3 in an alkaline medium, two-, four-, six-, and eight-electron transfers take place preferentially in the rate-limiting stage. Similar transfers in an acid medium are distinguished by high redox potentials. The most favourable six-electron transfer is hindered by the necessity for the involvement of two NH_3 molecules in the slow stage. It follows from a comparison of Figs. 1–3 that concerted four-, six-, and eight-electron oxidation is preferred for PH_3, three- and six-electron oxidation is preferred for AsH_3 and two- and four-electron oxidation is preferred for NH_3. The above properties of PH_3, AsH_3, and NH_3 influence significantly the kinetics of the oxidation reactions of the hydrides. The different behaviour of the hydrides is due to the sharp decrease in the energies of the bonds formed by the heteroatoms with hydrogen in the sequence (energy in kJ mol^{-1}) N–H (380) > P–H (323) > As–H (281) > Sb–H (256) and in the heats of formation of the hydrides in the sequence (heats expressed in kJ mol^{-1}) NH_3 (−46.2) > PH_3 (9.6) > AsH_3 (67.0) > SbH_3 (144.6).[36] The probability of the concerted three-electron oxidation with abstraction of all the hydrogen atoms therefore increases in the same sequence and the tendency towards the synchronous two-electron oxidation, accompanied by the loss of only two hydrogen atoms, diminishes.

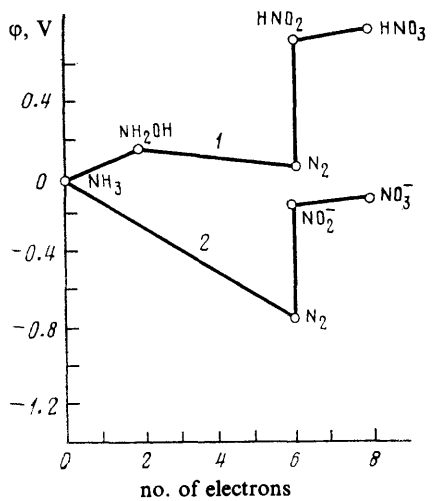

Figure 3. The oxidation-reduction potentials of two-, six-, and eight-electron oxidation of NH_3 to hydroxylamine, nitrogen, and nitrous and nitric acids respectively in acid (curve *1*) and alkaline (curve *2*) media.

The many electron single-state oxidation of PH_3 is facilitated by the fact that the intermediate phosphorus compounds (+1, −1, +3) are characterised by a much greater capacity for complex formation than phosphine. The intensification of the ligand properties of the phosphorus atom as it is oxidised lowers the entropy barrier in the multistep rate-limiting stage. On the other hand, the ligand properties of the nitrogen atom are rapidly weakened as ammonia is oxidised. This increases the energy barrier in the multistep rate-limiting stage and limits the number of electrons transferred simultaneously.

Thus oxidation mechanisms with many-electron rate-limiting stages are energetically favourable for PH_3 and AsH_3. The entropic obstacles are not so great if the intermediate complex is formed

before the rate-limiting stage. The barriers associated with the rules of the conservation of electron spin and the Franck–Condon principle are removed by virtue of the multistep nature of the slow stage where one or two electrons are transferred in each step.

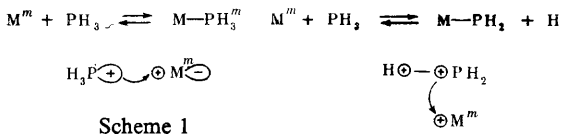
III. PH_3 and AsH_3 oxidation reactions and orbital symmetry rules

In the analysis and prediction of the chemical properties of PH_3 and AsH_3, account is taken of the predominantly *s* character of the unshared electron pair,[37,38] of the relatively low ionisation potentials (10.5 and 9.8 eV respectively), of the high electron affinities (0.77 and 1.07 eV respectively), of the high polarisabilities and the large dimensions of the 3*s* and 3*p* orbitals,[39] of the presence of valence *d* levels,[10] and of the tendency of the diffuse σ*-bonds to effect the σ,*n*- and σ,π-coupling of these molecules.[40] In order to account for the mechanisms of the reactions of PH_3 and AsH_3, the orbital symmetry rules, which have found wide applications in organic and inorganic chemistry and catalysis,[32–43] will be used in the present review.

According to Hammond's postulate,[32] in exothermic reactions the energy and the structure of the transition state are close to those of the initial reactant while in endothermic reactions they are close to those of the product. In order to determine the nature of the activation, it is therefore necessary to have information about the nodal structures, energies, and populations of the frontier orbitals (HOMO and LUMO) of the reactants and products.[33,34] Data on the structures of PH_3, AsH_3 and their oxidation products, obtained by quantum-chemical,[34,41–52] photoelectron spectroscopic,[41,44] and X-ray spectroscopic[53–62] methods, are important. According to calculations,[34,42,43] the molecular orbitals of NH_3, PH_3, AsH_3 and SbH_3 have the following configurations:

$$\text{for } NH_3\text{: } (a_1)^2(e)^4(2a_1)^2(3a_1)^0(2e)^0,$$

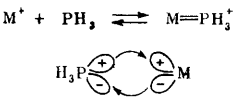
$$\text{for } SbH_3,\ PH_3 \text{ and } AsH_3\text{: } (a_1)^2(e)^4(2a_1)^2(2e)^0(3a_1)^0.$$



In contrast to NH_3, the 2*e* orbitals of the PH_3, SbH_3, and AsH_3 molecules occupy a lower energy level than the $3a_1$ orbitals, since the 2*e* molecular orbitals of stibine, phosphine, and arsine belong mainly to the 3*d* type.[34–41] The usual parallel decrease in the ionisation potentials of the molecule and atom are not observed in the series of hydrides NH_3, PH_3, AsH_3, and SbH_3:[41] the ionisation potentials of atoms diminish on passing from N to Sb and the ionisation potentials of the hydrides vary in the opposite sequence: $NH_3 < PH_3 < AsH_3 < SbH_3$.[34,41] This reversal of the sequence on passing from atoms to molecules of the hydride is induced by the increase in the contribution of the *s* orbital of the heteroatom to the occupied *n* orbital of the hydride with increase in the size of the heteroatom (E) and with decrease in the H–E–H bond angle.[34,41]

It follows from the data presented that, in contrast to NH_3, the PH_3 and AsH_3 molecules tend to form donor–acceptor and dative bonds with complex-forming agents. In contrast to the ammonia molecule, the HOMO and LUMO in phosphine and arsine form respectively P–H and As–H σ- and σ*-bonds. The frontier orbitals are predominantly of σ character and to a much lesser extent the n character, which is reflected, in our view, in the chemical properties of the hydrides PH_3 and AsH_3. Thus, the two-sided exchange reactions of PH_3 of the type [σ + σ], [σ + π], and [σ + ππ] are therefore symmetry-prohibited. Owing to the difference between the energies of the $2a_1$ and *e* orbitals, reactions of the type [σσ + σ], [σσ + π], and [σσ + ππ] are difficult for PH_3. The one-sided homolytic processes proceed at elevated temperatures or in the presence of radicals.[7] One-sided heterolytic reactions of the type [*n* + *n*] require the participation of (soft) electrophiles or nucleophiles.[8] Reactions involving the nucleophilic addition and the electrophilic substitution of H atoms are therefore typical for phosphines with a P–H bond.[8]

By virtue of the presence of valence *d* orbitals, phosphine exhibits a tendency to undergo both one-sided and two-sided exchange reactions with the reactants containing occupied *d* and π orbitals. Donor–acceptor electron transfer occurs on formation of complexes between phosphine and "hard" protic and aprotic acids (H_2SO_4, $TiCl_4$, $AlCl_3$, BCl_3).[6] Synchronous donor–acceptor and dative electron transfers are observed in the interaction of PH_3 with "soft" transition metal complexes having high redox potentials and low charges (Ag^I, Au^I, Cu^I, Hg^{II}, Pd^{II}, Pt^{II}) [16] and polar unsaturated molecules.[8]



The donor–acceptor one-sided interaction of PH_3 with a metal cation (M^+) leads to the appearance of an unstabilised phosphonium ion, in contrast to the ammonium ion. The dative one-sided electron transfer from the cation M^+ to PH_3 is thermodynamically unfavourable, since it leads to the formation of unstable negatively charged phosphine. The two-sided exchange interaction, in which two close *d* and *s* orbitals of the cation interact in concert with the frontier orbitals of PH_3, is more favourable. The reverse transfer is not accompanied by an appreciable localisation of electrons on one of the fragments. Complexes with close *d* and *s* levels, populated overall by two electrons, are most suitable for such interaction.[33] This is indicated by the particular tendency of PH_3 to form complexes with ions of d^{10} metals (Ag^I, Cu^I, Hg^{II}, Au^I).[63]

The orbital diagrams of single bond formation (Scheme 1), electrophilic substitution (Scheme 2), and double bond formation (Scheme 3) reactions with participation of phosphine and a d^{10} metal ion are presented below:

Scheme 1

Scheme 2

Scheme 3

Scheme 1 illustrates the unshared orbital of PH_3 and an unoccupied orbital of the *p* metal cation, while Scheme 2 illustrates the nodal structures of the P–H σ-bond and the unoccupied orbital of the cation. It follows from the comparison of the orbitals that nucleophilic addition and electrophilic substitution reactions are symmetry-allowed for PH_3.[33] The mode of reaction depends on the redox potential of the complex. The higher the redox potential, the more likely the formation of metal phosphide complexes. Thus $AgNO_3$, $CuHSO_3$, $HgCl_2$, and $PdCl_2$ form phosphides on interaction with PH_3, while AgCl, AuCl, CuI, BCl_3, $TiCl_4$, $AlCl_3$, and SiF_4 give rise to phosphine complexes.[6,16]

Scheme 3 illustrates the orbital diagram for the appearance of the $H_3P{=}M^+$ double bond. The PH_3 orbitals are presented as five equivalent sp^3d orbitals. Three of these are used for bonds with H atoms, while in the other two the remaining electrons are accommodated in two ways depending on whether they are paired or not. In the singlet state the electrons are paired and occupy one of the accessible orbitals. This form participates in complex formation reactions with d^{10} metal ions, whose frontier orbital are constructed similarly (Scheme 3).[32,33] In the triplet state, the electrons are located in different orbitals. This form is preferable for reactions with radicals.[32,33]

It is seen from Scheme 1 that, on interaction with complexes of *s* and *p* elements, phosphine is hardly activated, since the hybridisation of the phosphorus atom is not altered. On the other hand, on coordination to complexes of *d* metals, phosphine is activated because the hybridisation of the phosphorus atom becomes significantly different (Scheme 3). A similar change in the hybridisation of the phosphorus atom occurs also on formation of complexes of *d* metal phosphides.

In order to assess the nature of the activation of the reactants needed for the occurrence of the reaction, one must have information about the electronic structure of the products.[14,32] The point is that the activation energy falls as the electronic configurations of the initial and final substances are approached.[14,32] The PH_3 oxidation products (oxygen compounds of phosphorus) have been thoroughly investigated by quantum-chemical[41] and UV and X-ray spectroscopic[41,61] methods. The main conclusion is that, with increase in the number of P–O bonds, the *d* character of the phosphorus atom becomes more pronounced.[61] In order to accelerate the PH_3 oxidation reactions, it is therefore necessary to intensify, by means of activation, the *d* character of the phosphorus atom. This is achieved by coordinating PH_3 to d^{10} metal ions which have close *d* and *s* levels (Cu^I, Au^I, Ag^I, Hg^{II}).

IV. Oxidation by the halogens

In contrast to NH_3 and AsH_3, gaseous PH_3 does not react with the halogens.[64] The interaction of NH_3 with the halogens leads to the formation of haloamines.[37] Arsine reacts vigorously with chlorine; it ignites even at the temperature of liquid nitrogen.[6] The reaction with bromine and iodine is rapid at room temperature with formation of arsenic halides.[6] Ammonia, which possesses a distinct unshared electron pair, as already mentioned, reacts with the halogens (X_2) via an S_N2 mechanism. Arsine, which has a weak unshared electron pair and is characterised by weak As–H bond energy, interacts with the halogens via homolytic mechanisms. The rate of the reaction of NH_3 with X_2 increases with increase in the redox potential of the halogens and the N–X bond energy (i.e. on passing from Br_2 to Cl_2).[37] The reactivity of arsine in this reaction is determined mainly by the As–X bond energy. In the liquid phase, all three hydrides are readily oxidised by the halogens.[65]

These reactions are widely used for the liquid-phase purification of gases.[2–4] Phosphine,[65,66] phosphine derivatives,[10] phosphites, and phosphorus halides[67] readily react with the halogens,[16,17] hypohalites,[68] and alkyl halides:[10,68]

$$PH_3 + 4Cl_2 + 4H_2O \rightarrow (HO)_3PO + 8HCl, \quad (9)$$

$$PH_3 + 4Br_2 + 4H_2O \rightarrow (HO)_3PO + 8HBr, \quad (10)$$

$$PH_3 + 2I_2 + 2H_2O \rightarrow (HO)H_2PO + 4HI, \quad (11)$$

$$PH_3 + 4HXO \rightarrow (HO)_3PO + 4HX, \quad (12)$$

$$R_3P + Cl_2 \rightarrow R_3PCl_2, \quad (13)$$

$$(RO)_3P + Cl_2 \rightarrow (RO)_2ClPO + RCl, \quad (14)$$

$$Cl_3P + Cl_2 \rightarrow PCl_5, \quad (15)$$

$$(PhO)_3P + Cl_2 \rightarrow (PhO)_3PCl_2. \quad (16)$$

Phosphorus(III) derivatives, which possess, in contrast to PH_3, a distinct unshared electron pair, react vigorously with the halogens,[68] forming nucleophilic addition or substitution products[68]—phosphonium salts and phosphoranes. The nucleophilic attack by the tertiary phosphine is directed to the atom with the highest LUMO coefficient (effective positive charge). Despite the fact that the P–O bond is much stronger than the P–Cl bond, tertiary phosphines attack the halogen atom in alkyl hypohalites in which the LUMO is localised. The halophosphonium salts, formed on interaction of PR_3 with hypochlorites, i.e.

$$R_3P + Cl{-}OR \rightarrow [R_3PCl]OR \rightarrow [R_3POR]Cl,$$

rearrange to the stable alkoxyphosphonium salts.[68] When the reaction is carried out in methanol, optically active phosphines are converted into phosphine oxides with the inverted configuration:

$$[R_3PCl]OR + MeOH \rightarrow R_3PO + MeCl + ROH.$$

Compounds with the RCO–Br, CCl_3–Cl, and Br–$CHArSO_2Ph$ bonds behave similarly. However, compounds with the Cl–CH_2R and Cl–COR bonds attack tertiary phosphines via the carbon atom.[68]

NH_3 behaves similarly to a tertiary phosphine. The oxidation of NH_3 to N_2H_4 and N_2 by sodium hypochlorite takes place in stages with the intermediate formation of chloramine:[36]

$$NH_3 + NaClO \rightarrow NH_2Cl + NaOH,$$

$$NH_2Cl + NH_3 + NaOH \rightarrow N_2H_4 + NaCl + H_2O,$$

$$N_2H_4 + 2NH_2Cl \rightarrow N_2 + 2NH_4Cl.$$

The interaction of coordinated ammonia with Cl_2 leads to the formation of the products of the electrophilic substitution of hydrogen atoms by chlorine atoms. The oxidation of platinum(II) ammines with chlorine results in the formation of dichloramineplatinum(IV).[37]

Since, in contrast to PR_3 and NH_3, PH_3 has weak nucleophilic properties, the driving force of the attack is to a large extent the energy of the bond formed.

The kinetics and mechanism of the oxidation of PH_3 by the halogens [reactions (9)–(12)] in solutions have been investigated.[65,66] The rates of reactions (9)–(12) increase with increasing concentrations of X_2 and PH_3 and of temperature and fall with increase in the content of X^- and in the pH. When the pH and C_{X^-} are varied, the ratios of the different forms of X^+ (X_2, X_3^-, XOH, XO^-) also vary:

$$X_2 + H_2O \rightleftarrows XOH + HX, \quad (17)$$

$$XOH + OH^- \rightleftarrows XO^- + H_2O, \quad (18)$$

$$X_2 + X^- \rightleftarrows X_3^-, \quad (19)$$

The above species are characterised by different reactivities in relation to PH_3.[12] The reactivity of the halogen compounds diminishes sharply in the sequence $X_2 > XOH > X_3^- > XO^-$ (see Table 1 at the end of the review).[11] Since the rate constants for the hydrolysis of X_2 [reaction (17)] and XOH [reaction (18)] decrease appreciably on passing from Cl_2 ($pK \simeq 4$) to Br_2 ($pK \simeq 9$) and I_2 ($pK \simeq 12$) and from ClOH ($pK \simeq 8$) to BrOH ($pK \simeq 9$) and IOH ($pK \simeq 13$),[36] iodine reacts with PH_3 in both acid and weakly alkaline solutions while chlorine reacts only in neutral and acid solutions.[12] In neutral and weakly alkaline solutions, the mixed systems $ClOH-Br_2-H_2O$, $ClOH-I_2-H_2O$, and $BrOH-I_2-H_2O$ exhibit a high reactivity.[12] In such systems, the halogen characterised by low hydrolysis rate constants plays the function of the catalyst, while the halogen which exhibits a higher tendency towards hydrolysis is the oxidant. Thus the interaction in the $PH_3-ClOH-I_2-H_2O$ system takes place via a separate mechanism in the following manner: phosphine is oxidised via Eqn. (11), while the I^- ion is reoxidised back to I_2 by hypochlorous acid:

$$2HI + ClOH \rightarrow I_2 + HCl + H_2O. \quad (20)$$

The catalytic effect is due to the fact that in neutral and weakly alkaline media, reactions (11) and (20) are faster than reaction (12).[11] The equilibrium constants of reaction (19) increase significantly in the sequence Cl_3^- ($pK \simeq 1$) < Br_3^- ($pK \simeq -1$) < I_3^- ($pK \simeq -4$).[36] Therefore the addition of I^- ions has a negative effect on reaction (11).

The facts listed above show that reactions (9)–(12) proceed via the formation and hydrolysis of phosphorus halides in accordance with the mechanism

$$PH_3 \xrightarrow[-H^+]{X^+} PH_2X \xrightarrow[-HX]{H_2O} PH_2(OH) \xrightarrow[-H^+]{X^+} PH(OH)X \xrightarrow[-HX]{H_2O}$$

$$\rightarrow PH(OH)_2 \rightarrow (HO)H_2PO \xrightarrow[-H^+]{X^+} (HO)XHPO \xrightarrow[-HX]{H_2O}$$

$$\rightarrow (HO)_2HPO \xrightarrow[-H^+]{X^+} (HO)_2XPO \xrightarrow[-HX]{H_2O} (HO)_3PO. \quad (21)$$

Since the P–X bond energy diminishes rapidly in the sequence F > Cl > Br > I, it follows that PI_5 does not exist, in contrast to PF_5, PCl_5, and PBr_5.[10] Therefore the oxidation of PH_3 by iodine in water terminates in a stage involving the formation of $(HO)_2HP$, which isomerises to $(HO)H_2PO$.[11]

The hydrogen atoms of PH_3 are substituted by X^+ in the rate-limiting stage in accordance with the S_N2 mechanism (see Scheme 2). The intermediate halo-derivatives of phosphorus(III) and phosphorus(V) hydrolyse immediately after their formation, so that it is impossible to detect them.[11] The high rate of hydrolysis is due to the fact that the energies of the P–O (86 kcal mol^{-1}) and P=O (146 kcal mol^{-1}) bonds are higher than the energy of the P–X bond (44–79 kcal mol^{-1}).[10]

The parallel variation of the reactivities of the halogens (Cl_2 > Br_2 > I_2 > HClO > HBrO > HIO) and the ionisation potentials [Cl (12.97 V) > Br (11.81 V) > I (10.45 V)] and of the oxidation-reduction potentials [Cl_2 (1.36 V) > Br_2 (1.07 V) > I_2 (0.54 V), ClOH (0.94 V) > BrOH (0.76 V) > IOH (0.49 V)] and the electron affinities [Cl (3.8 eV) > Br (3.54 eV) > I (3.29 eV)] is observed.[36] The active species X^+ is formed as a result of the reactions

$$H_2O + X_2 \rightleftarrows H_2OX^+ + X^-, \quad (22)$$

$$XOH \rightleftarrows X^+ + OH^-. \quad (23)$$

The X^+ formation constant increases in the sequences Cl_2 ($pK \simeq 30$) < Br_2 ($pK \simeq 20$) < I_2 ($pK \simeq 10$) and HClO ($pK \simeq 58$) < HBrO ($pK \simeq 53$) < HIO ($pK \simeq 39$).[69] Since the electrophilicity and the equilibrium concentration of X^+ vary in parallel as a function of its nature, its reactivity depends only slightly on the nature of X_2 and HXO.[12]

The tendency towards the formation of X^+ increases sharply in the sequence $F^+ \ll Cl^+ < Br^+ < I^+$,[69] since the metallic properties of the halogens intensify in the same sequence.[36] There is little evidence for the existence of Cl^+ or Br^+, but the I^+, I_3^+, and I_5^+ ions as well as I_2Cl^+, I_2Br^+, and ICl^+ have been thoroughly investigated.[36] The I^+ ion is highly electrophilic. It exists in media with weakly nucleophilic properties, for example in acid solutions.[36] The Cl_2, Br_2, and I_2 molecules, which have the $(\sigma)^2(\sigma^*)^2(\pi)^4(\sigma)(\pi^*)^4$ structure,[36] tend to exhibit the delocalisation of the antibonding π^* electrons. Thus the delocalisation of the π^* electrons over the unoccupied *d* orbitals tends to strengthen the X–X bond. Since, as already mentioned, PH_3 tends to form dative bonds with complex-forming agent (Cu^+, Ag^+, Au^+, Hg^{2+}, Pt^{2+}, Pd^{2+}), the unusual reactivity of the halogens in the PH_3 oxidation reaction becomes understandable. This reactivity is caused by the two-sided exchange interaction of the halogens with phosphine, which facilitates the formation of an intermediate complex. The fairly inert PH_3 molecule is activated in this complex as a result of the change in hybridisation $sp^3 \rightarrow sp^3d$. The latter structure is better prepared for oxidation than the initial sp^3 structure.

Another feature of the halogens is their tendency to polymerise in the presence of X^-.[36] The energetically favourable single-stage many-electron oxidation of phosphine is associated with this important property. Since the fraction of polyhalides increases with increase in the concentration of the halogens, the latter exhibit reactivity at elevated concentrations (10^{-3}–10^{-1} M).[11]

Different features are observed in the oxidation of AsH_3 by the halogens in an aqueous medium:[70]

$$AsH_3 + 3X_2 + 2H_2O \rightarrow HAsO_2 + 6HX. \quad (24)$$

The rate constants for the reactions of AsH_3 with the halogens (see Table 1) are higher than those for the analogous reactions of PH_3.[70] In constrast to PH_3, arsine is oxidised at low concentrations of the halogens (10^{-4}–10^{-5} M for I_2). The oxidation of AsH_3 in the mixed systems $ClOH-KI-H_2O$ and $ClOH-NaBr-H_2O$ takes place readily at KI concentrations higher by an order of magnitude than in the oxidation of PH_3.[70] The point is that, in contrast to

PH_3, AsH_3 is oxidised by the halogens homolytically. Such behaviour of AsH_3 is caused by its tendency to dissociate into the elements.[6]

Thus phosphine reacts with the halogens via a heterolytic mechanism, while arsine reacts via a homolytic mechanism.

V. Oxidation by oxygen compounds of the halogens

Phosphine and arsine are very readily oxidised by the oxygen compounds of bromine(V),[71-74] iodine(V),[75-78] and iodine(VII):[79-81]

$$PH_3 + HIO_3 \rightarrow (HO)_2HPO + HI, \quad (25)$$

$$PH_3 + H_5IO_6 \rightarrow (HO)_3PO + HI + 2H_2O. \quad (26)$$

PH_3 undergoes substitutional oxidative hydroxylation in reactions (25) and (26). Iodine(V) and iodine(VII) react similarly with AsH_3:

$$AsH_3 + HIO_3 \rightarrow HAsO_2 + HI + H_2O, \quad (27)$$

$$AsH_3 + H_5IO_6 \rightarrow H_3AsO_4 + HI + 2H_2O. \quad (28)$$

Since the IO_3^- and $H_4IO_6^-$ ions do not react with PH_3 and AsH_3, the rates of reactions (25)–(28) increase sharply after the addition of a very small amount of acid.[75-81] At pH 3–4, phosphine and arsine are rapidly oxidised by HIO_3 and H_5IO_6.[75-81]

Bromine(V) and especially chlorine(V) and chlorine(VII) compounds exhibit a very low reactivity in reactions of type (25)–(28).[71-74]

The appreciable reactivity of HIO_3 and H_5IO_6 in dilute acid solutions is caused by the relatively high proton affinity:

$$IO_3^- + H^+ \rightleftharpoons HIO_3, \quad K = 10 ,$$
$$H_2IO_6^{3-} + H^+ \rightleftharpoons H_3IO_6^{2-} \quad K = 10^{15} ,$$
$$H_3IO_6^{2-} + H^+ \rightleftharpoons H_4IO_6^-, \quad K = 2 \cdot 10^{10} ,$$
$$H_4IO_6^- + H^+ \rightleftharpoons H_5IO_6, \quad K = 3 \cdot 10^3 .$$

In contrast to $HClO_3$, $HBrO_3$, and $HClO_4$, the molecules of HIO_3 and H_5IO_6 exhibit "soft" properties, which are necessary for the formation of adducts with diphilic PH_3. Reactions (25)–(28) are characterised by the presence of an induction period, which diminishes after the introduction of KI or $HClO_4$.[75,78] Even at low KI or $HClO_4$ concentrations (10^{-4} M), the induction period disappears.[80] In terms of their effectiveness, the KI and $HClO_4$ additives are similar.[75-81] The optimum acid concentration is equal to the initial concentration of $H_4IO_6^-$ or IO_3^-.[78,80] Potentiometric study has shown that the redox potential of the reacting system gradually increases during the induction period.[78,80] The point is that the redox potentials of the IO_3^- and $H_4IO_6^-$ ions are respectively 0.26 and 0.70 V, while those of the HIO_3 and H_5IO_6 molecules are 1.20 and 1.64 V. The system begins to absorb PH_3 actively only after the attainment of the redox potential characteristic of HIO_3 or H_5IO_6. Hence one may conclude that H_3PO_3 accumulates and the HIO_3 and H_5IO_6 molecules, responsible for the reaction, are formed during the induction period.

The geometry of the oxy-anions XO_4^- and XO_3^- is determined by the sp^3 hybridisation of all the valence electrons of the halogen atom.[36] The O–X–O angles are in all cases close to the tetrahedral value. However, the *d* orbitals also definitely participate in the formation of X–O π-bonds.[36] Judging from the redox potential, compound (IX) with a potential of 1.1 V is formed under the influence of iodide ions. Compounds in which iodine is present in intermediate valence states are not produced in reactions (25)–(28).

The substitutional hydroxylation of PH_3 by iodine(V) and iodine(VII) compounds can be represented as follows:

$$PH_3 \xrightarrow[-H^+]{IO_3OH} [(IO_2)\,PH_2OH]^- \xrightarrow[-H^+]{H^+} [(IO)PH(OH)_2]^- \xrightarrow{H^+} \longrightarrow OP(OH)_2H + HI, \quad (29)$$

$$PH_3 \xrightarrow[-H^+]{IO_3OH} [(IO_3)PH_2OH]^- \xrightarrow[-H^+]{H^+} [(IO_2)PH(OH)_2]^- \xrightarrow[-H^+]{H^+} \longrightarrow [(IO)P(OH)_3]^- \xrightarrow{H^+} (HO)_3PO + HI. \quad (30)$$

The six- and eight-electron reactions (29) and (30) apparently take place in one stage via three or four two-electron steps with shallow energy wells in the course of the reaction. The driving force of the many-electron rate-limiting stage is the increase in the exothermic heat evolution with increase in the number of electrons participating in the reaction (Fig. 1). The entropy barrier of the many-electron type is lowered as a consequence of the tendency of the phosphorus atom to form intermediates containing iodine in all possible intermediate valence states. The analogous bromine and chlorine compounds do not have this property and are incapable of effecting the many-electron process in one stage because of entropic factors. Therefore, as X varies in the sequence HIO_3 (1.08 V) < $HBrO_3$ (1.44 V) < $HClO_3$ (1.47 V) [36] (see Table 1 at the end of the review), the reactivity and the redox potential vary in opposition.

Arsine is oxidised by oxygen compounds of iodine(V) similarly to phosphine and the rates of oxidation are also similar. The formation of arsenious acid as the product indicates the many-electron nature of the rate-limiting stage in which six electrons participate. The direct oxidation $AsH_3 \rightarrow HAsO_2$ is energetically more favourable than the multistage oxidation via the formation of As and its subsequent oxidation to $HAsO_2$. The redox potential of the reaction $AsH_3 \rightarrow HAsO_2$ is −0.18 V and that of the reaction $As \rightarrow HAsO_2$ is 0.25 V. AsH_3 and PH_3 therefore have similar reactivities in relation to iodine(V) (see Table 1).

The oxygen compounds of the halogens are activated by metal ions in a high oxidation state as a result of the increase in the redox potential and the polarity of the oxidant. Thus the reactions involving the oxidation of PH_3 by halates and perhalates are accelerated by molybdenum(VI) [71,76] and tungsten(VI) [77,81] complexes. Metal ions in the highest oxidation states are coordinated to the oxygen compounds of the halogens via the O atom. Halates and perhalates add to PH_3 via the other oxygen atom. The oxidant activated in this way gives up an O atom to phosphine more readily. In the presence of Cl^- ions, ICl, characterised by a potential of 1.1 V, participates in reactions (25) and (26).

VI. Oxidation by oxygen compounds of nitrogen

The oxygen compounds of nitrogen oxidise PH_3 and AsH_3 fairly readily via the reactions[11-12,82-86]

$$PH_3 + 2N_2O_4 \rightarrow 4NO + (HO)_3PO, \quad (31)$$

$$AsH_3 + HNO_3 \rightarrow As + NO + 2H_2O. \quad (32)$$

These compounds are used to remove PH_3 and AsH_3 from gases[2-4] (see Table 1 at the end of the review). Under these conditions, PH_3 interacts effectively only with concentrated HNO_3 solutions (above 25%),[2] while AsH_3 reacts rapidly also with dilute nitric acid.[6] The conversion curve for the oxidation of PH_3 by nitric acid (dependence of the rate of reaction on the amount of absorbed PH_3) passes through a maximum, which indicates the involvement of N_2O_4, and not HNO_3, in the reaction. N_2O_4 is formed by the reaction

$$HNO_3 + HNO_2 \rightarrow N_2O_4 + H_2O. \quad (33)$$

The remaining oxygen compounds of nitrogen (NO, N_2O, HNO_2, and HNO_3) are relatively inactive.[11,12] These data show that, in contrast to AsH_3, PH_3 is oxidised only by oxygen compounds of nitrogen(IV), in the presence of which there is a possibility of a many-electron rate-limiting stage with participation of an even number of electrons. Phosphorus(III) compounds exhibit a tendency to interact with the O atoms of the oxygen compounds of nitrogen[7,87] owing to the high P=O bond energy (611 kJ mol^{-1}).[10] The rate-limiting stage in the oxidation of organophosphines and phosphites by *N*-oxides (R_3NO) is the nucleophilic addition of an O atom to phosphorus(III). The rate of oxidation of phosphorus(III) derivatives by pyridine *N*-oxide diminishes in the sequence

$$PCl_3 > PhCl_2P > Ph_2PCl \gg (PhO)_3P > (EtO)_3P \gg Ph_3P > Bu_3P > Et_2PhP.$$

On the other hand, in the oxidation of phosphites by the oxide N_2O_4 the electrophilic addition of an O atom to the phosphorus(III) atom takes place in the rate-limiting stage. This is indicated by the series of reactivities of phosphorus(III) compounds in relation to N_2O_4: $P(RO)_3 \gg P(PhO)_3$.[10] When account is taken of the data presented, the mechanism of the oxidation of PH_3 by the oxide N_2O_4 can be represented as follows:

$$N_2O_4 + PH_3 \rightleftarrows (N_2O_4)PH_3 \xrightarrow[-NO]{} (NO_2)PH_2(OH) \xrightarrow[-NO]{} PH(OH)_2, \quad (34)$$

$$PH(OH)_2 + N_2O_4 \rightleftarrows (N_2O_4)PH(OH)_2 \xrightarrow[-NO]{} (NO_2)P(OH)_3 \xrightarrow[-NO]{} (HO)_3PO. \quad (35)$$

Reaction (31) includes two four-electron stages. In each stage there are in its turn two two-electron steps to which shallow energy wells correspond. The entropy barrier in the many-electron transition is overcome by virtue of the formation of a complex between N_2O_4 and PH_3 or, in the general case, between N_2O_4 and phosphorus(III). As a result of complex formation with participation of the O atoms of the oxygen compounds of nitrogen and the phosphorus(III) atom, the reactions involving the oxidation of phosphorus(III) derivatives by nitrogen oxides are very rapid.[7]

The oxidation of phosphine by nitrogen dioxide is accelerated by Ag^+ ions. A small amount of added $AgNO_3$ (10^{-4} M) ensures a high reactivity of these and dilute (<10%) solutions of nitric acid.[2,11] The kinetic equation for the oxidation of PH_3 by nitric acid does not then change.[11] Like other d^{10} ions (Cu^+, Au^+, Hg^{2+}), Ag^+ ions form phosphides on interaction with phosphine.[6] The deprotonation of phosphine on formation of the phosphide tends to reduce the redox potential of the electron donor. Furthermore, as already mentioned above, on formation of *d* metal phosphides, the hybridisation of the P atom changes ($sp^3 \rightarrow sp^3d$). In contrast to the initial phosphine, activated phosphine interacts more readily with an O atom in N_2O_4 as a result of the enhancement of the role of the $d_\pi - p_\pi$ interaction. Reaction (31) is also accelerated by mercury(II) chlorides, which form the phosphides $(HgCl)_3P$ (see Table 1).[11]

The iodide ion is also an effective catalyst of the oxidation of phosphine by the acids HNO_3 and HNO_2.[12] In the presence of I^-, the oxidation of phosphine by nitric acid proceeds via a stepwise mechanism:[82-86]

$$2HNO_3 + 6KI + 2H_2O \rightarrow 3I_2 + 2NO + 6KOH, \quad (38)$$

$$2I_2 + PH_3 + 2H_2O \rightarrow (HO)H_2PO + 4HI. \quad (39)$$

Reactions (38) and (39) are faster than the direct oxidation of PH_3 by HNO_3 (see Table 1).[11,12]

Consequently reaction (31) is accelerated following the enhancement of the electron-accepting properties of the phosphorus atom as a result of the replacement of hydrogen atoms by metals or if a strong nucleophile (the I^- ion) is used as the electron transferring agent. The point is that the oxides N_jO_i are ambident oxidants.[32-34] The LUMO and HOMO are located on the N and O atoms respectively. For this reason, the N atom reacts preferentially with nucleophiles and the O atom with electrophiles. Thus amines, in which there is a distinct unshared orbital, enter preferentially into diazotisation or nitrosation reactions.[36] Phosphine, which is characterised by the presence of a weak non-bonding level, reacts with the oxygen atoms of nitrogen oxides. Furthermore, in contrast to amines, PH_3 has a valence *d* orbital capable of $d_\pi - p_\pi$ conjugation with an oxygen atom in N_jO_i.

Thus, a characteristic feature of PH_3 is a tendency to undergo outer-sphere oxidation by oxygen compounds in which an O atom is present as a bridge.

VII. Oxidation by oxygen compounds of sulphur, selenium, and tellurium

The oxidation of PH_3 by concentrated H_2SO_4 is widely used in industry[2-4] (see Table 1 at the end of the review):

$$3H_2SO_4 + PH_3 \rightarrow 3SO_2 + (HO)_2HPO + 3H_2O, \quad (40)$$

$$H_2SO_4 + PH_3 \rightarrow S + (HO)_2HPO + H_2O, \quad (41)$$

$$H_2SO_4 + PH_3 \rightarrow H_2S + (HO)_3PO. \quad (42)$$

Reactions (40)–(42) take place at a high rate only at H_2SO_4 concentrations in excess of 90 wt.%.[2,3] At such a concentration, the monomeric and trimeric SO_3 molecules, responsible for the reaction, are formed:[36]

$$2H_2SO_4 \rightleftarrows SO_3 + H_3O^+ + HSO_4^-,$$

$$3SO_3 \rightleftarrows (SO_3)_3, \quad (43)$$

and the redox potential of SO_3 also increases. Sulphur trioxide oxidises PH_3 in accordance with the mechanism

$$PH_3 + SO_3 \rightleftarrows SO_3PH_3,$$

$$SO_3PH_3 \rightarrow S + (HO)_2HPO,$$

$$H_2O + SO_3PH_3 \rightarrow SH_2 + (HO)_3PO,$$

$$(SO_3)_3PH_3 \xrightarrow[-SO_2]{} PH_2(OH)(SO_3)_2 \xrightarrow[-SO_2]{} \longrightarrow PH(OH)_2(SO_3) \xrightarrow[-SO_2]{} OPH(OH)_2. \quad (44)$$

Reactions (40)–(42) are accelerated appreciably after the addition of a small amount of $HgSO_4$,[2] which forms phosphides with PH_3. As already mentioned, on passing to the phosphide state, the reduction potential increases and the phosphorus atom undergoes sp^3d hybridisation, which is convenient for the $d_\pi-p_\pi$ interaction with an oxygen atom of sulphur trioxide. The participation of monomeric and trimeric sulphur trioxide in the process is indicated by the high order of the reaction with respect to H_2SO_4. The occurrence of reactions (41) and (42) is direct evidence for the real occurrence of the eight-electron single-stage oxidation of PH_3, since in the intermediate valence states (SO_2 and S) sulphur does not oxidise PH_3 but does oxidise organophosphines.[68] The low redox potential of H_2SO_4 (only 0.2 V) and the high rate of reactions (40)–(42) indicate unambiguously that many-electron single-stage PH_3 oxidation processes are preferred. The many-electron rate-limiting stage takes place stepwise and there are small energy wells in the reaction pathway. The entropy barrier in reaction (44) is lowered by virtue of the involvement in it of the associated species $(SO_3)_3$ and the formation of a complex with participation of the phosphorus atom and an oyxgen atom of sulphur trioxide. The depth of the energy wells diminishes as the hydrogen atoms of PH_3 are substituted by OH groups, since the tendency of the phosphorus atom towards complex formation increases as the redox potential of the intermediate products falls (see Scheme 1). The substitution of H by OH groups activates the phosphorus atom[10] and there is at the same time an increase in the bond angle between the substituents and a change in hybridisation.[38] The majority of phosphorus(III) derivatives have a bond angle of approximately 100°.[38]

Such an angle is as a rule formed by substituents tending to enter into a $p_\pi-d_\pi$ interaction (OH, F, Cl, Br, I, C_6H_5) and a $\sigma-d_\pi$ interaction (Me). Electron-accepting bonding is achieved via the unoccupied d orbital of the phosphorus atom and the non-bonding p_π orbital or the σ-bond of the substituent. As a result, a double bond is formed between the phosphorus atom and the substituent, which alters the hybridisation of phosphorus and intensifies the tendency towards the formation of a complex with SO_3. Substituents of the type of H, CN, and SiH_3, which are incapable of $p_\pi-d_\pi$ and $\sigma-d_\pi$ conjugation, form a bond angle much smaller than 100° and are characterised by weak ligand properties.[38]

The oxygen compounds of selenium and tellurium which are analogues of H_2SO_4 are reduced by phosphine to the elements[82–85,88] (see Table 1):

$$2H_2SeO_3 + PH_3 \rightarrow 2Se + (HO)_3PO + 2H_2O, \quad (45)$$

$$2H_2TeO_3 + PH_3 \rightarrow 2Te + (HO)_3PO + 2H_2O. \quad (46)$$

High rates of reactions (45) and (46) are attained at an acid concentration in excess of 0.1 M.[82–85,88] The rates of these reactions increase after the addition of HCl and especially HBr and HI.[82] Since halide ions stimulate the disproportionation of selenium(II) and tellurium(II) compounds,[36] i.e.

$$3H_2O + 2TeCl_2 \rightleftarrows H_2TeO_3 + Te + 4HCl, \quad (47)$$

$$3H_2O + 2SeCl_2 \rightleftarrows H_2SeO_3 + Se + 4HCl, \quad (48)$$

It follows that reactions (45) and (46) take place via the reduction of selenium(IV) and tellurium(IV) to selenium(II) and tellurium(II) respectively. The polymeric compounds $(TeO_2)_j(H_2O)_l$ and $(SeO_2)_j(H_2O)_l$, predominating in acid solutions,[84] take part in the rate-limiting stages of reactions (45) and (46):

$$(TeO_2)_4 + PH_3 + 8HX \rightarrow 4TeX_2 + (HO)_3PO + 4H_2O, \quad (49)$$

$$(SeO_2)_4 + PH_3 + 8HX \rightarrow 4SeX_2 + (HO)_3PO + 4H_2O. \quad (50)$$

The oxygen compounds of selenium(IV), tellurium(IV), and sulphur (VI), which are capable of forming polymeric compounds, ensure the synchronous many-electron oxidation of PH_3, which is energetically more favourable than the two-electron oxidation (Fig. 1). Therefore, despite the low redox potentials of the oxygen compounds, sulphur(VI) selenium(IV), and tellurium(IV) are fairly rapidly reduced by phosphine.[82–85] In the intermediates formed in reactions (45) and (46) the bond linking the oxygen compounds of selenium(IV) and tellurium(IV) to PH_3 is formed via an O atom. The oxidation-reduction decomposition of the intermediate takes place as a result of the transfer of an oxygen atom from the oxygen compounds of selenium(IV) and tellurium(IV) to the phosphorus atom in PH_3.

VIII. Oxidation by oxygen compounds of 3*d* metals

Sulphuric acid solutions of chromium(VI) and manganese(VII) are widely used in laboratory and industrial practice[2–4] for the removal of PH_3 and AsH_3 from gases.[11,12,89–91] PH_3 and AsH_3 are oxidised by oxygen compounds of chromium(VI) in accordance with the equations[89–91]

$$Na_2Cr_2O_7 + PH_3 + 4H_2SO_4 \rightarrow (HO)_2HPO + Cr_2(SO_4)_3 + Na_2SO_4 + 4H_2O, \quad (51)$$

$$2Na_2CrO_4 + 2AsH_3 + 5H_2SO_4 \rightarrow 2As + Cr_2(SO_4)_3 + 2Na_2SO_4 + 8H_2O. \quad (52)$$

Reaction (51) takes place satisfactorily only in very concentrated sulphuric acid solutions (>12 M) and in the presence of high contents of chromium(VI) ($>10^{-3}$ M). The oxidation of AsH_3 takes place vigorously in relatively dilute H_2SO_4 (>1–2 M) and at a lower chromium(VI) concentration ($<10^{-4}$ M).[89–91] The different behaviour of PH_3 and AsH_3 in sulphuric acid solutions of chromium(VI) is due to the fact that the oxidation of phosphine via a six-electron mechanism and of arsine via a three-electron mechanism to phosphorus(III) and arsenic respectively is energetically favourable (see Table 1 at the end of the review).

Chromium(VI) in solutions participates both in reversible dimerisation reactions and in acid–base reactions:[36,92]

$$CrO_4^{2-} + H^+ \rightleftarrows CrO_3(OH)^-, \quad K = 3.1 \cdot 10^8,$$
$$CrO_3(OH)^- + H^+ \rightleftarrows H_2CrO_4, \quad K = 2 \cdot 10^1,$$
$$2CrO_3(OH)^- \rightleftarrows Cr_2O_7^{2-} + H_2O, \quad K = 4.1 \cdot 10^3.$$

The scheme involving reversible reactions presented above is applicable only to solutions containing HNO_3 and $HClO_4$.[93] A chlorochromate ion is formed in solution in HCl and a sulphate complex is produced in H_2SO_4:[92]

$$CrO_3(OH)^- + HCl \rightleftarrows CrO_3Cl^- + H_2O, \quad K = 17,$$
$$CrO_3(OH)^- + HSO_4^- \rightleftarrows CrO_3(SO_4)^{2-} + H_2O, \quad K = 4.$$

It follows from the above equations that the predominance of a particular form of chromium(VI) in aqueous solutions depends on its concentration and the pH of the medium. The monomeric acid chromate ion exists in dilute solutions. With increase in concentration, the dichromate ion becomes the dominant form. The degree of protonation of these ionic species depends on the pH of the medium. Electron-accepting properties are characteristic of chromium trioxide. When CrO_3 is dissolved in the presence of HCl and H_2SO_4 in hydroxylated organic solvents, chromic acid esters are formed:[69]

$$AcOH + CrO_3 \rightleftarrows AcOCrO_3H,$$
$$2AcOH + CrO_3 \rightleftarrows (AcO)CrO_2 + H_2O.$$

In pyridine, CrO_3 exists as the complex $Py.CrO_3$ with a Cr–N bond.[69]

The interaction of monomeric chromium(VI) complexes with PH_3 is difficult owing to the complementary prohibition. The oxidising capacity of the chromium(VI) monomer corresponds to three electrons, while the reducing capacity of PH_3 corresponds to six or eight electrons.

In contrast to chromium(VI), chromium(V) readily oxidises triphenylphosphine:[93]

$$CrOL_2^+ + Ph_3P \rightarrow CrL_2^+ + Ph_3P{=}O,$$

where HL is 2-ethyl-2-hydroxybutyric acid. The reaction mechanism includes the transfer of an oxygen atom in accordance with the scheme

$$CrOL_2^+ + Ph_3P \rightleftarrows [Ph_3P{-}O{-}CrL_2]^+ \rightarrow Ph_3P{=}O + CrL_2^+.$$

The intermediate complex with a bridging O atom undergoes oxidation-reduction decomposition in the rate-limiting stage.[93] On the other hand, the oxidising capacity of the dimer, corresponding to six electrons, ensures the complementarity of the reaction involving the reduction of the dichromate by phosphine.

Another situation arises in the oxidation of AsH_3 by chromate. In this case, the requirement for the complementarity of the rate-limiting stage is satisfied also in the absence of dichromate. The reducing capacity of AsH_3 and the oxidising capacity of chromate are equal and corresponding to three electrons. As a result, AsH_3 is readily oxidised by chromates to arsenic at relatively low concentrations (1–2 M) and in the presence of a low chromium(VI) content ($< 10^{-4}$ M).[89–91] In the presence of added copper(II) and iron(III) salts, which tend to be involved in one-electron transfer, reactions (51) and (52) proceed readily at a much lower acidity (10^{-1} M). In weakly acid media at a chromium(VI) concentration of 10^{-4} M, monochromate ions, incapable of the complementary oxidation of AsH_3 and PH_3 to the acids, predominate. Copper(II) and iron(III) salts, which participate jointly with monochromate ions in the rate-limiting stage, make the reactions complementary. Chromium(VI), copper(II) ions, or iron(III) ions, used in isolation, oxidise phosphine at the concentrations indicated.[11] Jointly with monochromate, iron(III) or copper(II) ions ensure the occurrence of four-electron transfer in the slow stage:

$$[XCu(CrO_3OH)PH_3] + H_2O \rightarrow CuX + Cr(OH)_3 + (HO)_2HP,$$
$$[XCu(CrO_3OH)PH(OH)_2] + H_2O \rightarrow CuX + Cr(OH)_3 + (HO)_3PO.$$

Copper(II) ions are regenerated via the reaction

$$3CuX + NaCrO_3OH + 7HX \rightarrow 3CuX_2 + CrX_3 + 4H_2O + NaX.$$

Copper(II) and iron(III) ions promote the oxidation of phosphine by oxygen compounds of chromium(VI)[11,12] only at a low acidity of the medium[89–91] where chromate ions predominate in the system. At a high acidity, which promotes the formation of dichromates, iron(III) and copper(II) ions do not affect the rate of oxidation of PH_3 by chromium(VI). The effectiveness of copper(II) and iron(III) salts increases with decrease in acidity and decreases with increase in acidity, passing through a maximum as the X^- concentration rises.

The most significant promoting effect is exerted by added bromide and particularly iodide ions, which ensure the operation of the stepwise reaction mechanism.[11,12,89–91] In the presence of halide ions, phosphine and arsine do not interact directly with chromium(VI). Chromium(VI) oxidises halide ions to the halogens:

$$2Na_2CrO_4 + 6NaBr + 8H_2SO_4 \rightarrow 3Br_2 + Cr_2(SO_4)_3 + 5Na_2SO_4 + 8H_2O, \quad (53)$$

while halogens are in turn reduced back to the halide ion by phosphine or arsine:

$$4Br_2 + PH_3 + 4H_2O \rightarrow (HO)_3PO + 8HBr, \quad (54)$$
$$3Br_2 + AsH_3 + 2H_2O \rightarrow HAsO_2 + 6HBr. \quad (55)$$

Arsine is, as usual, effectively oxidised under milder conditions than phosphine.[89–91] The oxidation of AsH_3 requires chromium(VI), acid, and NaX concentrations lower by an order of magnitude than in the oxidation of PH_3. This is associated with the fact that the atomic halogen, stabilised in the coordination sphere of chromium, functions as the agent transferring electrons from AsH_3 to the chromate, while the transfer of electrons from PH_3 to the dichromate ion is effected by a polyhalide ion. The formation of polyhalide ions requires a higher concentration of halide ions than for the generation

of halogen atoms.[36] The catalytic activity of halide ions increases, as usual, in opposition to their redox potentials.[11,12,89–91] The oxidation of phosphine and arsine by oxygen compounds of manganese(VII) takes place in acid and alkaline media in the following way[82–85,94] (see Table 1):

$$2KMnO_4 + PH_3 + H_2SO_4 \rightarrow 2MnO_2 + (HO)_2HPO + + K_2SO_4 + H_2O, \quad (56)$$

$$2KMnO_4 + AsH_3 + H_2SO_4 \rightarrow 2MnO_2 + HAsO_2 + + K_2SO_4 + 2H_2O. \quad (57)$$

The oxidation of PH_3 and AsH_3 in alkaline and especially in neutral and acid media is rapid (Table 1).[94] Manganese(VII), which forms stable manganese(V) and manganese(VI) ions,[36] ensures both one- and two-electron oxidation of AsH_3 and PH_3. Furthermore, manganese(V) readily disproportionates to manganese(VI) and manganese(IV).[36]

The reactivity of manganese(VII) with respect to PH_3 in a neutral medium decreases in the presence of AsH_3. The coupled oxidation of PH_3 and AsH_3 by manganese(VII), which is fairly rapid, has been used in practice. The synergism is due to the fact that AsH_3 reduces manganese(VII) to manganese(VI), while PH_3 converts manganese(VI) into manganese(IV).

The rate of oxidation of PH_3 and AsH_3 increases significantly after the addition of halide ions.[82,94] The effectiveness of halide ions increases in opposition to the redox potentials.[82–85] In the presence of halide ions, manganese(VII) is reduced to manganese(II):

$$8KMnO_4 + 5PH_3 + 12H_2SO_4 \rightarrow 8MnSO_4 + 5(HO)_3PO + + 4K_2SO_4 + 12H_2O, \quad (58)$$

$$6KMnO_4 + 5AsH_3 + 9H_2SO_4 \rightarrow 6MnSO_4 + 5HAsO_2 + + 3K_2SO_4 + 14H_2O. \quad (59)$$

In the presence of halide ions, the mechanisms of reactions (58) and (59) change. In the absence of X^-, phosphine and arsine react with an O atom in oxygen compounds of manganese. The oxidation-reduction decomposition of the phosphine complex of manganese(VI) leads to the transfer of an O atom from manganese(VII) to PH_3, the decomposition being rapid as a consequence of complementarity. Manganese(VII) is reduced to a transfer of both an even number [reduction to Mn(V)] and an odd number [reduction to Mn(II, IV)] of electrons.

Manganese dioxide vigorously oxidises PH_3 and AsH_3 only above 300 °C. The reaction takes place in the gas phase and is inhibited by the PH_3 oxidation products—manganese(II) phosphates, which preclude the access of PH_3 to MnO_2. In the liquid phase, the reactivity of MnO_2 increases rapidly after the addition of iodide ions.[85] Halide ions ensure the occurrence of reactions (58) and (59) via a new, faster pathway.[85] In this case, PH_3 and AsH_3 do not react directly with manganese(VII), the latter oxidising the halide ions to the molecular halogen:

$$2KMnO_4 + 10KX + 8H_2SO_4 \rightarrow 2MnSO_4 + 5X_2 + 6K_2SO_4 + + 8H_2O. \quad (60)$$

Phosphine and arsine reduce in turn the halogen to the halide.[82–85] Halides are universal effective catalysts of the oxidation of PH_3 and AsH_3 for the majority of known oxidants.[11,12]

Being a strong nucleophile, the halide reacts more readily than PH_3 and AsH_3 with the central atom of the oxygen compound. The complementary oxidant converts X^- into X^+ while a non-complementary one generates from X^- the X^0 radical, which dimerises rapidly to X_2.[11] As a result, both complementary and non-complementary oxidants form the oxidant X_2, which is suitable for the oxidation of PH_3 and AsH_3. Furthermore, the X_2 molecules tend to form the polyhalides X_n.[36] Since the probability of the formation of X_n increases with decrease in the $2X^- \rightarrow X_2$ redox potential and with decrease in the X_2 concentration, a high rate of reaction is attained at fairly appreciable X^- concentrations.[11,12]

Solutions containing $10^{-3}-10^{-2}$ M of iodide ions or $10^{-2}-10^{-1}$ M bromide ions are most often used.[82]

Halogen atoms rather than molecules are the most suitable oxidants for the oxidation of AsH_3. In contrast to PH_3, AsH_3 is therefore oxidised at a lower X^- concentration[94] (Table 1).

It was noted above that the reactivity of the halogens with respect to PH_3 and AsH_3 decreases in parallel with their redox potentials: $Cl_2 > Br_2 > I_2$.[11,12] On the other hand, the catalytic activity of the halogens increases in opposition to the redox potentials of the halide ions: $I^- \gg Br^- > Cl^-$. The point is that the reactivity of X_2 is described by the equation

$$\frac{W}{[X_2][PH_3]} = k_{X_2},$$

while the catalytic activity of halide ions is described by the formula

$$\frac{W}{[PH_3][Ox][X^-]} = kK = k_{X^-},$$

where k is the rate constant and K the equilibrium constant of the reaction

$$Ox + 2X^- \rightleftarrows Red + X_2.$$

Since K increases with decrease in the $2X^- \rightarrow X_2$ redox potential, it follows that k_{X^-} and k_{X_2} form antiparallel series.[11,12]

The behaviour of oxygen compounds of chromium(VI) and manganese(VII), widely used for the removal of PH_3 and AsH_3 from gases,[82–85] was examined above. The oxygen compounds of other 3*d* metals are used for the oxidation of PH_3 in analytical practice.[11] In a strongly acid medium (~10 M), vanadium(V) is slowly reduced by phosphine[95] (see Table 1):

$$8NH_4VO_3 + PH_3 + 12H_2SO_4 \rightarrow (HO)_3PO + 8VOSO_4 + + 4(NH_4)_2SO_4 + 12H_2O. \quad (61)$$

A high acidity is necessary for the formation of polynuclear vanadates, capable of ensuring the complementary many-electron single-stage oxidation of PH_3. In order to accelerate reaction (61), halide ions are usually introduced.[95] Iodide ions exhibit the highest activity.[95] Heteropolyacids, the active principle of which is free VO_2 ions,[96] also oxidise PH_3 slowly. In contrast to PH_3, arsine is oxidised rapidly by heteropolyacids.[97] The rate of oxidation of AsH_3 by a heteropolyacid increases after the introduction of iodide ions.[97] In the HCl–HX system, phosphine and arsine are oxidised by the compounds ClBr and ClI.

The data presented show that, although the oxygen compounds of 3*d* metals do possess high redox potentials, they are reduced slowly by phosphine owing to their inability to ensure the complementary

many-electron single-stage oxidation of PH_3. However, they vigorously oxidise AsH_3, which reduces, in contrast to PH_3, the oxygen compounds of *d* metals via a homolytic mechanism. In the presence of X^- ions, phosphine is rapidly oxidised also by one-electron oxidants.

IX. Oxidation by metal complexes

Iron(III) and copper(II) chlorides are widely used to remove phosphines and arsine from gases,[2-4,12] since iron(II) [98,99] and copper (I) [100,101] chlorides are readily regenerated by dioxygen.[11] For the purification of oxygen-free gases, use is made of periodic action apparatus, on which the PH_3 and AsH_3 oxidation and regeneration stages are separated in time, while continuous operation apparatus is used for the detoxification of oxygen-containing gases.[2-4] Iron(III) chloride oxidises PH_3 in accordance with the scheme

$$8FeCl_3 + PH_3 + 4H_2O \rightarrow 8FeCl_2 + (HO)_3PO + 8HCl. \quad (62)$$

The reaction proceeds only at a high phosphine concentration. At low PH_3 concentrations, reaction (62) is very slow.[102-104] The rate of reaction increases sharply when concentrated (>3 M) $FeCl_3$ solutions are used.[105-107] Such a concentration is attained after the deposition of $FeCl_3$ from aqueous solution onto a carrier.[105-107] The high order of the reaction with respect to $FeCl_3$ indicates the involvement in the process of polynuclear iron(II) complexes, which are generated only at high iron(III) chloride concentrations.

The reactivity of polynuclear iron(III) complexes on carriers increases after the introduction of small amounts of $HgCl_2$ (10^{-4} M).[2,3] At a low $FeCl_3$ concentration ($<10^{-1}$ M), the reactivity is independent of the added $HgCl_2$. Iron(III) sulphates do not exhibit an appreciable reactivity in relation to PH_3 in an acid medium.[102] In weakly acid media, where polynuclear iron(III) complexes arise, phosphine is oxidised rapidly in the presence of silver(I) sulphate. In the absence of silver(I) ions, the reaction does not occur. In acetic acid media, which ensure the formation of the trinuclear complexes $Fe_3(OH)_2(AcO)_6^+$,[27] phosphine is also not oxidised.[103]

Silver(I) and mercury(II) ions stimulate the process by virtue of the formation of the phosphides AgH_2P and $(HgCl)_3P$, which, as already mentioned, have a higher reactivity than the initial phosphine. Only the dinuclear complexes $Fe_2Cl_9^{3-}$ arise in chloride solutions,[36] ensuring the two-electron oxidation of phosphine. In heterogenised systems, more reactive polynuclear iron(III) complexes are formed. They effect the many-electron energetically more favourable single-stage oxidation of PH_3 to $(HO)_3PO$. The reactivities of the deposited and dissolved iron(III) chlorides therefore differ significantly.[105-107] Dissolved iron(III) chlorides have a low reactivity,[104] whilst deposited ones have a high reactivity.[105] Iodide ions accelerate reaction (62) effectively,[102-104] exhibiting the highest activity when dissolved (and not deposited) iron(III) chlorides are used.[102-104,106] In the presence of iodide ions, reaction (62) proceeds via two stages: iron(III) chloride oxidises iodide ions to polyiodides and the latter are then reduced by phosphine, which regenerates iodide ions.[102-104,106]

Thus iodide ions are more suitable for the acceleration of the oxidation of phosphine by non-complementary oxidants, while silver(I) and mercury(II) are best for complementary oxidants. Cerium(IV) behaves similarly to iron(III).[108,109] Despite its very high redox potential (1.5 V), cerium(III) sulphate hardly interacts with PH_3 in the absence of catalysts. In the presence of halide ions, cerium(IV) is rapidly reduced by phosphine via the reaction

$$8Ce(SO_4)_2 + PH_3 + 4H_2O \rightarrow (HO)_3PO + 4Ce_2(SO_4)_3 + 4H_2SO_4. \quad (63)$$

In the presence of halide ions, the reaction is divided into two slow stages: the first of these involves the formation of Cl_2, ClBr, and ClI, which are reduced by phosphine in the second stage.[108,109] When these stages take place separately, they obey the same rules as in a catalytic process.[110] As usual, the catalytic activity of halide ions in reactions (63) increases in opposition to the redox potential: $I^- \gg Br^- > Cl^-$ [108-110] (see Table 1 at the end of the review).

In contrast to iron(III) and cerium(IV) salts, the reactivity of copper(II) chlorides and sulphates increases sharply in the presence of copper(I).[113-115] In the presence of copper(I) ions in concentrated solutions of copper(II) salts (>1 mM), the following reactions proceed at a satisfactory rate:

$$3CuSO_4 + PH_3 + 3H_2O \rightarrow 3Cu + 3H_2SO_4 + (HO)_2HPO, \quad (64)$$

$$8CuCl_2 + PH_3 + 4H_2O \rightarrow 8CuCl + (HO)_3PO + 8HCl, \quad (65)$$

$$3CuCl_2 + AsH_3 \rightarrow As + 3CuCl + 3HCl. \quad (66)$$

Copper(II) ions, which are characterised by high redox potentials of the $Cu^{II} \rightarrow Cu^{I}$ (+0.153 V) and $Cu^{II} \rightarrow Cu^{0}$ (+0.337 V) transitions, oxidise PH_3 and AsH_3 at high rates[111,112] (Table 1). In concentrated solutions[113-115] and when carriers are used,[116,117] polynuclear saturated copper(II) and copper(I) complexes, which exhibit an enhanced reactivity,[111-115] play a dominant role.[118,119] Reactions (64)-(66) are accelerated by the CNS^-,[120] Br^-,[121-123] and I^- [124-126] ions (see Table 1).

Calculations by the CNDO, MVG, and HMO quantum-chemical methods have been performed for the aquophosphine complexes of copper(II) and iron(III) with different contents of X^- ions.[127-133] The $P-H_P$ and $HO-H_O$ bonds are weakened and the amount of their ionic character increases, a positive charge appears on the phosphorus atom, a negative charge appears on H_2O, and strong bonds are formed with the P, H_P, and H_O atoms, especially in the case of oxygen-containing anions. With increase in the negative charge on the complex, the $P-OH_2$ and $Cu-H_P$ bonds are strengthened while the P-Cu bond is loosened. This stimulates the oxidation-reduction decomposition of the complex involving the oxidation of phosphine and the reduction of copper(II). With decrease in the negative charge on the complex, the P-Cu and H_P-OH bonds are strengthened, which induces an acid-base reaction, copper(II) being reduced to copper(I) as a result of the oxidation-reduction decomposition of zerovalent copper. Reaction (65) is effectively accelerated by palladium(II) [134-136] of mercury(II) and copper(I) [134-138] chlorides. The synergistic effects arising under the joint action of copper(I) and palladium(II) or mercury(II) is due to the fact that copper(I) chlorides activate PH_3 differently compared with palladium(II) or mercury(II) chlorides.[137,138] Mercury(II) [138,139] and palladium(II) [140] chlorides activate phosphine by substituting the H atoms by $HgCl^+$ or $PdCl^+$ with formation of the phosphides $(HgCl)_3P$ or $(PdCl)_3P$.[138] Copper(I) chlorides promote the loosening

of the electron cloud of the phosphorus atom by forming a complex with palladium(II) or mercury(II) phosphide.[138] In the mixed complex, the phosphorus atom assumes the sp^3d configuration, which is convenient for oxidation. It is known[32] that the activation energy diminishes as the electronic configurations of the initial reactants and products approach one another. Since according to literature data[61] the phosphorus atom in phosphates has a pronounced d character, the change in hybridisation of the type $sp^3 \rightarrow sp^3d$ favours PH_3 oxidation reactions.

Gold(III) chlorides, which react very rapidly with phosphine even in dilute solutions (see Table 1), are reduced by phosphine in a different way:[141]

$$8AuCl_3 + 3PH_3 + 12H_2O \rightarrow 8Au + 3(HO)_3PO + 24HCl. \quad (67)$$

Like reaction (65), reaction (67) is accelerated by gold(I) chlorides.[11] However, in contrast to copper(II) in reaction (65), gold(III) is reduced also in the absence of gold(I) chlorides.[141] Gold(I) performed a dual function in this reaction. On the one hand, it activates phosphine, like other d^{10} ions, by virtue of the formation of phosphine complexes and, on the other hand, gold(I) ions participate together with gold(III) in the oxidation of PH_3. A mixed heteronuclear gold(III, I) phosphine complex undergoes inner-sphere decomposition with transfer of four electrons from PH_3 to Au(III) and Au(I). Reaction (67) is accelerated particularly effectively by added HBr, HI, and HCl as a result of the formation of ClBr and ClI. Gold(I) is continuously regenerated as a consequence of the oxidation of zerovalent gold by gold(III).

Platinum(IV) chlorides are reduced by phosphine similarly to gold(III):[142]

$$3Na_2PtCl_6 + 2PH_3 + 6H_2O \rightarrow 3Pt + 2(HO)_2HPO + 6NaCl + 12HCl. \quad (68)$$

The reaction is accelerated by platinum(II) chlorides, which perform a dual function: they activate PH_3, forming a phosphine complex, and, together with platinum(IV), they oxidise phosphine via a six-electron mechanism. Platinum(II) is continuously regenerated as a result of the oxidation of zerovalent platinum by platinum(IV). In a HCl–HX solution, reaction (68) is propagated by the ClBr and ClI species. Phosphine reduces platinum(II) chlorides very rapidly[138,140] (Table 1):

$$4PdCl_2 + PH_3 + 4H_2O \rightarrow Pd + (HO)_3PO + 8HCl. \quad (69)$$

The reactions of PH_3 with palladium(II) complexes [$PdCl_2(PhCH)_2$, $Pd(AcO)_2$, $(PPh_3)_2Pd(OAc)_2$] in non-aqueous solvents (chloroform, dioxane) leads to the formation of insoluble palladium compounds.[140] In all the compounds isolated, the oxidation state of palladium has been shown by the X-ray photoelectron spectroscopic method to be close to 2+, Pd–P bonds are present (demonstrated by the EXAFS method), and an acid (HCl, HOAc) is formed in the solutions over the precipitate. This indicates the acid–base nature of the interaction of PH_3 with palladium(II) complexes in a non-aqueous medium, which is accompanied by the heterolysis of the P–H bond and the formation of the PH_2 phosphide species coordinated to palladium (this is indicated by the ^{31}P NMR spectra of the chloride complex):

$$PH_3 + n\,PdX_2 \rightarrow PH_{3-n}(PdX)_n + nHX.$$

The extent of this process is regulated by selecting the basicity of the solvent. After the interaction of palladium acetate complexes with PH_3, an appreciable amount of acetic anhydride is formed in solution over the deposit.[140] This fact (together with ^{31}P MAS NMR data for the deposit) indicates the presence of oxidised forms of phosphine in the coordination sphere of palladium. All the palladium compounds isolated after interaction with PH_3 in non-aqueous media are readily hydrolysed in water with formation of $(HO)_3PO$ and zerovalent palladium. Thus the coordinated phosphine is oxidised via the formation of bonds between the coordinated phosphorus and the O atoms of the ligand. In contrast to oxygen compounds of metals and non-metals, forming outer-sphere complexes with PH_3 via an O atom, the metal complexes oxidise PH_3 via inner-sphere mechanisms.

As already mentioned, phosphine is activated only by metal ions capable of a two-sided exchange interaction. Low-valence forms of the metal usually possess such properties. Therefore the high-valence metal complex reduction reactions are as a rule activated by complexes of metals in low valence states. In a two-sided exchange interaction, the phosphorus atom of phosphine assumes an electronic configuration similar to that of the phosphorus atom in the products. Such activation of the reactant lower significantly the activation energies for the reactions.[143]

X. Oxidation by dioxygen, ozone, and peroxide compounds

The use of O_2, O_3, H_2O_2, and $Na_2S_2O_8$ for the oxidation of PH_3 is an extremely promising procedure, since the reaction products are harmless.[2–4] However, despite the high redox potentials of the oxidants listed above, the reactions

$$2O_2 + PH_3 \rightarrow (HO)_3PO, \quad (70)$$

$$4O_3 + PH_3 \rightarrow (HO)_3PO + 4O_2, \quad (71)$$

$$4H_2O_2 + PH_3 \rightarrow (HO)_3PO + 4H_2O, \quad (72)$$

$$4Na_2S_2O_8 + PH_3 + 4H_2O \rightarrow (HO)_3PO + 4Na_2SO_4 + 4H_2SO_4, \quad (73)$$

are very slow.[11,12,144–146]

The two-electron reduction of dioxygen to the peroxide or the four-electron reduction to water is thermodynamically very favourable, while the one-electron reduction of O_2 to O_2^- or HO_2^- takes place with absorption of heat.[147] On the other hand, the transfer of a pair of electrons to an O_2 molecule is impossible as a consequence of the spin prohibition, since dioxygen has a triplet ground state. The oxidation of organic and inorganic substances by dioxygen therefore proceeds via successive one-electron stages involving radical exchange mechanisms.[147] The rate of these processes is limited by the thermodynamic difficulty of the transition $O_2 \rightarrow O_2^-$. The one-electron transition generates the radicals O_2^- and HO_2^- with a very high redox potential. The non-complementarity and the negative potential of the one-electron transition $O_2 \rightarrow O_2^-$ hinder the oxidation of PH_3 at low concentrations of the latter (10^{-2}–10^{-1} vol.%) and at the normal temperature.[7,9,10] At elevated temperatures and high PH_3 and O_2 concentrations, conditions are created for the transfer of two electrons:[9,10]

$$PH_3 + O_2 \rightarrow PH + H_2O + O. \quad (74)$$

Severe conditions are necessary to overcome the spin prohibition in redox transitions. As mentioned above, the $sp^3 \rightarrow sp^3d$ transition to the triplet state, necessary for the removal of the spin prohibition, is facilitated at elevated temperatures. The O atom deformed by reaction (74) stimulates the explosive oxidation of PH_3.[9]

The oxidation of phosphine at low concentrations by dioxygen is fairly rapid in the presence of $CuCl_2$ and $FeCl_3$.[148–151] Phosphine reduces $CuCl_2$ and $FeCl_3$ to CuCl and $FeCl_2$ respectively. The initial state of the copper and iron salts is regenerated on treatment with O_2.[11] The addition of iodide and bromide ions accelerates the stages involving the reduction of copper(II) and iron(III) by phosphine,[124] but retards the stage in which copper(I) and iron(II) are oxidised by oxygen.[98] Palladium(II) [138] and mercury(II) [152] chlorides have a positive influence on the first stage and do not affect the second.[134,135] Single step mechanisms of the oxidation of PH_3 by dioxygen in the presence of metal complexes have not been described.[11] The I^-/C and PdO/C systems exhibit a high activity (Table 1).

The relative inertness of H_2O_2 in reaction (73) mentioned above is associated with the unusual properties of the frontier orbitals.[153,154] The peroxide bond in H_2O_2 is altogether unpolarised, since the high dipole moment, induced by the presence of the lone electron pairs on the oxygen atom in the peroxide group, is compensated by the uniform charge distribution and does not affect the dipole moment of the O–O bond.[153] The dipole moment of the H_2O_2 molecule is determined by the dipole moments of the H–O bonds and is equal to 2.2 D.[153] A π^*-type antibonding orbital plays the role of the HOMO, while the role of the LUMO is assumed by a σ^*-type antibonding orbital.[153] The type $[\sigma+\sigma]$ interaction of H_2O_2 with PH_3 is symmetry-prohibited, while the oxidative addition of H_2O_2 to PH_3 requires that a high symmetry barrier be overcome owing to the pronounced *s* character of the lone pair. The nucleophilic substitution of the OH^- group in H_2O_2 by phosphine is difficult because of the low polarity of the HO–HO bond and of phosphine. The reaction is accelerated somewhat in highly acid media by virtue of the protonation of the H_2O_2 with formation of the polar $H_3O_2^+$ species.[154] The addition of bromide and iodide ions[144] and also of $FeCl_3$ and $CuCl_2$ [145] accelerates reaction (72). In contrast to the dioxygen, hydrogen peroxide oxidises PH_3 via a single step mechanism in the presence of metal complexes.[145,146]

As a result of complex formation, metal ions increase the polarity of H_2O_2 and facilitate the interaction of PH_3 with an O atom of the peroxide bond. Iron(III) and copper(II) halides are therefore particularly effective at low acidities of the medium where there are no $H_3O_2^+$ ions. Metal and hydrogen ions act similarly, but their effectiveness is significantly different. In order to attain the same effect, a lower concentration of the metal ions than that of hydrogen ions is required.[144,145] The oxidation of AsH_3 by H_2O_2 takes place at lower concentrations of X^-, $CuCl_2$, and $FeCl_3$ than the oxidation of PH_3.[146]

Ozone is one of the most vigorous oxidants[155] and yet reaction (71) is very slow. The low reactivity of O_3 compared with PH_3 [154] is caused by the unusual electronic structure of ozone. The following filling of molecular orbitals corresponds to the unexcited state of the O_3 molecule: $(\sigma)^4(\pi)^2(2p)^4(\pi)^2(\sigma)^2$.[36] The O_3 molecule has an angular shape and a low polarity (0.17 D).[36] Two-sided $[\sigma+\sigma]$ reactions are therefore symmetry-prohibited and one-sided reactions are hindered by the very low basicity of PH_3 ($pK = -14$).

The configurations of the HOMO and LUMO of ozone, like those of H_2O_2, are favourable to the reactions with OH^- and X^-. In an alkaline medium, O_3 reacts with OH^-, generating an OH radical.[155] However, despite the extremely high redox potential, the OH radical oxidises PH_3 only weakly, since it is a one-electron oxidant. The most active catalyst of reaction (71) at pH 11–12 is the iodide ion.[146]

In the presence of SO_2 or P_2O_3, phosphine undergoes coupled oxidation by dioxygen in an alkaline medium:

$$PH_3 + 4SO_2 + 4O_2 + 4NaOH \rightarrow 4Na_2SO_4 + (HO)_3PO + 4H_2O, \quad (75)$$

$$PH_3 + 2P_2O_3 + 4O_2 + 5NaOH + H_2O \rightarrow 5NaH_2PO_4. \quad (76)$$

The addition of alcohol lowers somewhat the rates of reactions (75) and (76) but does not stop them completely. The oxenoid reaction (75) begins with the formation of peroxomonosulphuric acid:

$$HSO_3^- + O_2 \rightarrow HSO_5^-. \quad (77)$$

Subsequently the HSO_5^- anion oxidises PH_3:

$$4H_2SO_5 + PH_3 \rightarrow 4H_2SO_4 + (HO)_3PO. \quad (78)$$

In contrast to H_2O_2 and $H_2S_2O_8$, Caro's acid transmits its oxygen atoms to phosphine. In the rate-limiting stage, the phosphine molecule approaches the peroxide oxygen atom in H_2SO_5 along the O–O bond line; by virtue of the high polarity of the oxidant,[154] its occupied non-bonding *s* orbital overlaps the unoccupied p_{σ^*} orbital of the peroxide bond. The appearance of electrons in the antibonding orbital leads to the weakening and successive dissociation of the O–O bond.[154] This entails the formation of a new bond between the phosphorus atom of phosphine and an oxygen atom of the peroxomonosulphate. The unusual properties of H_2SO_5 are associated with the presence in peroxo-monoacids of a polarised peroxide bond (0.9 D) with a relatively low energy of the LUMO (−9.3 eV). The occurrence of reaction (76) is ensured by the monoperphosphoric acid H_3PO_5, the polarity of the peroxide bond of which is similar to that in H_2SO_5.[153]

Thus phosphine can undergo coupled oxidation by dioxygen in the presence of additives inducing oxenoid oxidation.

XI. Conclusion

The principal features of the kinetics and mechanisms of the majority of the reactions, described in the literature, involving the oxidation of PH_3 and AsH_3 by complexes and oxygen compounds with metals and non-metals and the catalytic and coupled oxidation by dioxygen, ozone, and peroxide compounds were analysed above.

Table 1 presents the rate constants for the majority of the catalytic and non-catalytic low-temperature reactions involving the oxidation of PH_3 and AsH_3 by various oxidants in acid, neutral, and alkaline solutions and in the gas phase. The halogens (Cl_2, Br_2, I_2) and their derivatives (HClO, HBrO, HIO, HIO_3, HIO_4, $HBrO_3$), the oxygen compounds of nitrogen (NO_2), sulphur, selenium, and tellurium (H_2SO_4, H_2SeO_3, H_2TeO_3) as well as transition metals ($KMnO_4$, $H_2Cr_2O_7$, HVO_3), and *d* metal complexes ($AuCl_3$, $AuBr_3$, $AuCl_2I$, $AuCl_2Br$, $CuCl_2$, $CuBr_2$, CuClBr, CuClI, CuBrI, H_2PtCl_6, H_2PtBr_6, H_2PtI_6, Na_2PdCl_4, $FeCl_2I$, $FeBr_2I$, $CeCl_3I$) react faster with PH_3 and AsH_3 than any other oxidants. The most effective catalysts of the reactions in which PH_3 and AsH_3 are oxidised by various oxidants are alkali metal iodides and copper(II) halides.

Table 1. Kinetic parameters of the reactions involving the oxidation of PH_3 and AsH_3 by metal complexes and free and bound oxygen at 298 K and 10^{-2}–10^2 Pa.

The catalytic activity of catalysts deposited on carbon (C) in reactions involving the oxidation of PH_3 and AsH_3 by oxygen is characterised by first-order rate constants (k_1, min^{-1}). The reactivity of substances oxidising PH_3 and AsH_3 without catalysts is characterised by second-order rate constants:

$$k_2 = W/[Ox][Red], \text{ litre mol}^{-1} \text{ min}^{-1},$$

where W is the reaction rate (mol litre^{-1} min^{-1}) and [Ox] and [Red] are the molar concentrations of the oxidant and reductant in the liquid phase.

The catalytic activity of hydrogen ions and metal complexes is characterised by third-order rate constants:

$$k_3 = W/[Ox][Red][H^+], \text{ litre}^2 \text{ mol}^{-2} \text{ min}^{-1},$$

$$k_3 = W/[Ox][Red][M^{n+}], \text{ litre}^2 \text{ mol}^{-2} \text{ min}^{-1},$$

where $[H^+]$ and $[M^{n+}]$ are the molar concentrations of hydrogen and metal ions.

The catalytic activity of two-component mixed systems containing H^+ and X^- ($X^- = Cl^-, Br^-, I^-$) ions is characterised by fourth-order rate constants:

$$k_4 = W/[Ox][Red][H^+][X^-], \text{ litre}^3 \text{ mol}^{-3} \text{ min}^{-1},$$

where $[X^-]$ is the molar concentration of X^- ions.

The catalytic activity of three-component mixed systems incorporating the H^+, X^-, and M^{n+} ions is characterised by fifth-order rate constants:

$$k_5 = W/[Ox][Red][H^+][X^-][M^{n+}], \text{ litre}^4 \text{ mol}^{-4} \text{ min}^{-1}.$$

The rate constants were measured with a relative error of $\pm 10\%$. The catalysts based on *d* metal ions in the highest oxidation states [W(VII), Mo(VII)] propagate the process, like hydrogen ions, via an associative mechanism. They activate oxidants via coordination, which increases their redox potential and polarity.

The ions of *d* metals in intermediate oxidation states [Cu(II), Pd(II), Ag(I)] and alkali metal halides effect the reaction via a separate stage (oxidation-reduction) mechanism. Arsine and phosphine reduce the halogens and metal ions to halide ions and the metals, which oxidants regenerate the initial states of the metal ions and the halogens.

The complexes of *d* metals in the highest oxidation states [Hg(II), Cu(I)] activate phosphine and arsine via coordination. By virtue of the close positions of the *d* and *s* orbitals and the tendency towards a two-sided exchange interaction, they stimulate the $sp^3 \rightarrow sp^3d$ hybridisation of the phosphorus atom in PH_3. The oxygen compounds of high valence metal and non-metal ions oxidise phosphine via an outer-sphere mechanism, oxygen ions acting as a bridge, while metal complexes in an intermediate valence state oxidise phosphine via an inner-sphere mechanism.

In contrast to metal ions, halide ions are poorly coordinated to non-polar oxidants. Alkali metal halides therefore exhibit a high catalytic activity only in the presence of protic acids or metal ions which intensify the electrophilicity of oxidants.

In order to reduce the acidity of the medium, mixed systems containing a protic and an aprotic acid simultaneously are frequently employed. Thus negatively charged oxidants, present in the form of anions, oxidise PH_3 and AsH_3 acted upon jointly by hydrogen, metal, and halide ions. With the aid of H^+ and M^{n+} ions, it is possible to ensure in a three-component system in a weakly acid medium an effective positive charge in the oxidant, which is necessary for the manifestation of the catalytic properties of halide ions.

In neutral and alkaline solutions, the complexes of *d* metals in an intermediate valence state, which are soluble in such media, exhibit a high reactivity in relation to PH_3. The solubility of metal ions at high pH is increased sharply by ammonia, amines, polyhydric alcohols and hydroxyacids. An increased rate of oxidation of PH_3 by metal complexes is attained in an alkaline solution by virtue of the joint action of hydroxide and metal ions, generating the phosphite ion, which is a stronger reductant than PH_3. In alkaline systems, the reduced metal complexes are regenerated by oxygen. Metal complexes are therefore highly active catalysts of the oxidation of PH_3 by oxygen in an alkaline medium.

The phosphide ion is generated not only in an alkaline solution but also in a neutral medium under the influence of metal complexes containing "hard" ligands (AcO^-, SO_4^{2-}, Py, NR_3). Such ligands induce the inner-sphere acid–base decomposition of phosphine complexes of metals with formation of metal phosphides. The acid–base mechanism predominates as a result of the strengthening of the bonds between the metal and the phosphorus atom of PH_3. Phosphine is converted into the phosphite ion and acquires nucleophilic reactivity. In the presence of "soft" ligands (Cl^-, Br^-), phosphine becomes an electrophile by virtue of the manifestation of an effective positive charge on the phosphorus atom and reacts vigorously with the nucleophiles in the coordination sphere. By varying the nature of the ligands, it is therefore possible to induce either nucleophilic or electrophilic reactivity in the coordinated phosphine.

In the presence of Cl^-, Br^-, and I^- ions in aqueous solutions, phosphine reacts with coordinated H_2O molecules to form the products of its oxidative hydroxylation [$(OH)_3PO$, $(OH)_2HPO$, $(OH)H_2PO$]. In non-aqueous solutions with metal salts, the previously unknown reactions involving the O-, N-, and C-phosphorylation of organic compounds proceed selectively and rapidly. In alcoholic solutions of copper(II), platinum(IV), and iron(III) halides, phosphine interacts with the inner-sphere ROH molecules (R = Me, Et, Pr, iso-Pr, Bu, iso-Bu, Pe, iso-Pe, Oct) with formation of the products of the oxidative alkoxylation of phosphine—trialkyl phosphates [$(RO)_3PO$] and dialkyl phosphites [$(RO)_2HPO$]. In solutions of $CuCl_2$ or $Cu(OAc)_2$ in primary or secondary amines (NRH_2, NR_2H), the products of the oxidative amination of phosphine are formed—phosphorus triamides [$P(NR_2)_3$ and $P(NRH)_3$]. In alcoholic solutions of PtX_2 and $Cu(OAc)_2$, the products of the oxidative hydroxyalkylation of phosphine are obtained—the tris(α-hydroxyalkyl)phosphines $P(HOCRH)_3$ and $P[HO(CH_2)_n]_3$. In solutions of $Cu(OAc)_2$ in acetonitrile (MeCN) and benzonitrile (PhCN), the products of the oxidative cyanomethylation [tricyanomethylphosphine $P(CNCH_2)_3$] and cyanoarylation [tris(*o*-cyanoaryl)phosphine $P(o\text{-}CNC_6H_4)_3$] are formed. The product of the oxidative C-phosphorylation of pyridine by phosphine is synthesised in pyridine solutions of $CuCl_2$ or $Cu(OAc)_2$—tris(*p*-pyridyl)phosphine $P(o\text{-}C_5H_4N)_3$.

In mixed non-aqueous solutions of copper(II) salts, a mixture of products is obtained, in contrast to single component solutions. Thus the products of the oxidative C-phosphorylation of benzene (PPh_3) and pyridine [$P(o\text{-}C_5H_4N)_3$] are formed in solution in C_6H_6–C_5H_5N in the presence of $CuCl_2$ or $Cu(OAc)_2$.

The processes involving the oxidative O-, N-, and C-phosphorylation of organic compounds by phosphine and $CuCl_2$ and $Cu(OAc)_2$ solutions are accelerated by copper(I) ions like other reactions of PH_3. The yield of the products of the oxidative O-, N-, and C-phosphorylation by phosphine falls sharply after the addition of H_2O (> 5%), since there is an increase in the yield of inorganic phosphates.

In processes involving the O-, N-, and C-phosphorylation by phosphine, copper(II) ions are reduced to copper(I) ions or zerovalent copper. These products are readily regenerated by oxygen. A solution containing $CuCl_2$ or $Cu(OAc)_2$ after regeneration can be used again for the absorption of PH_3. The copper salts are separated by vacuum distillation from the products of the oxidative phosphorylation by phosphine and can be reused.

The new oxidative O-, N-, and C-phosphorylation reactions are much simpler than those known previously. Either metallated organic products and phosphorus halides or alkali metal phosphides and halo-derivatives of organic compounds participate in these reactions.[175,176]

By virtue of the high rates of the new oxidative O-, N-, and C-phosphorylation reactions, gases with a low PH_3 content (< 1.0%), for example, the effluent gases from phosphorus and hypophosphite factories, can be used as the raw materials in these processes.[4]

I. Introduction

The great interest shown in the last two decades in the chemistry of organotellurium compounds is due to the possibility of using them in various branches of science and engineering[1,2] and in preparative organic chemistry.[3–5] Derivatives of tetracoordinate tellurium (σ-telluranes) of the type $RTeX_3$ and R_2TeX_2, where X is an electronegative substituent, occupy a key position in the chemistry of organotellurium compounds. It is possible to convert them comparatively readily into various types of derivatives of dicoordinate, tricoordinate, pentacoordinate, and hexacoordinate tellurium.[1,2] σ-Telluranes are distinguished by an increased stability compared with the selenium and especially sulphur compounds with analogous structures. The presence of lone electron pairs and unoccupied *d*-orbitals in the tellurium atom in these compounds as well as in tellurium tetrahalides is responsible for their electron-donating properties (in interactions with Lewis acids) and electron-accepting properties (in interactions with Lewis bases). This review gives a systematic account and surveys the available data on the structures of tellurium tetrahalides and σ-telluranes in the crystalline state and in solutions and of the complexes based on them.

II. The structures of tellurium tetrahalides and σ-telluranes in the crystal state and in solutions

1. The structure of tellurium tetrahalides in the crystal state and in solutions

In conformity with the theory of valence electron pair repulsion,[6] tellurium tetrahalides should have a trigonal bipyramidal (TBP) structure with a lone electron pair (LP) as a phantom ligand occupying one of the equatorial positions. Such a structure of the above compounds has been confirmed by studies on $TeCl_4$ in the gas phase by electron diffraction.[7] The tellurium tetrachloride molecule has the TBP structure with an average Te–Cl length of 2.33 Å. According to the authors,[7] the $Cl_{eq}-Te-Cl_{eq}$ bond angle is probably less than 120° but more than 90°, while the $Cl_{ax}-Te-Cl_{ax}$ bond angle is about 170°.

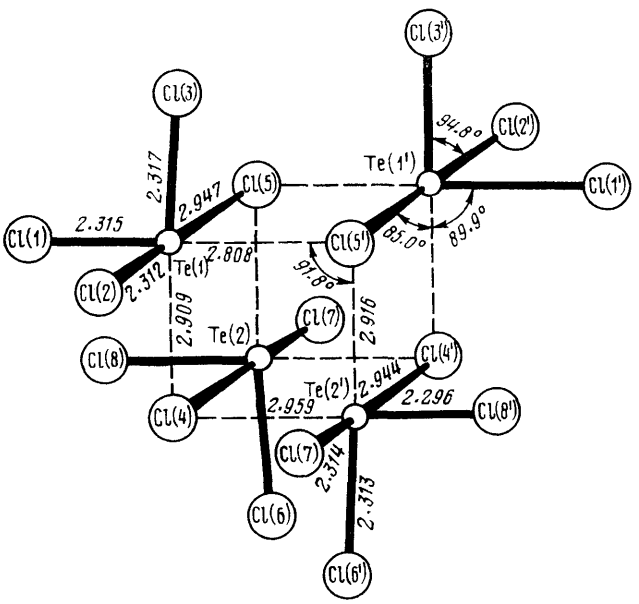

Figure 1. The structure of the tetramer Te_4Cl_{16}.[9]

However, as a consequence of secondary interactions involving tellurium atoms, the structure of tellurium tetrahalides in the crystal state is not quite so evident. Structures of all tellurium

tetrahalides have now been investigated by X-ray diffraction: the tetrachloride,[8–10] the tetrabromide,[8,11] the tetraiodide,[12–14] and the tetrafluoride.[15,16]

The crystal structure of tellurium tetrachloride is made up of isolated Te_4Cl_{16} tetramers[9,10] (Fig. 1). Each tellurium atom is joined to three terminal chlorine atoms by bonds whose average length is 2.311 Å, which is close to the Te–Cl bond length found in gaseous $TeCl_4$ (2.33 Å). The terminal chlorine atoms and the tellurium atom form a trigonal pyramid with average bond angles of 94.8°. The tellurium atom is also joined to three bridging chlorine atoms by bonds 2.929 Å long, which complete the environment around the tellurium atom to form a highly distorted octahedron. The average $Cl_{bridge}–Te–Cl_{bridge}$ bond angle is 85°.

Comparison of the data for tellurium tetrachloride with X-ray diffraction data for compounds with bonds of saturated types—ionic in $[TeCl_3]^+[AlCl_4]^-$,[17] where the tellurium atom has a distorted octahedral configuration ($Te–Cl_{term}$ = 2.276 Å, Te...Cl = 3.062 Å), and covalent in the $[TeCl_6]^{2-}$ ion[18] (Te–Cl = 2.54 Å) led the authors[10] to the conclusion that bonding intermediates between the two extreme types of bonds described above takes place in $TeCl_4$ and that there is only partial charge transfer from the bridging chlorine atoms to the tellurium atoms.

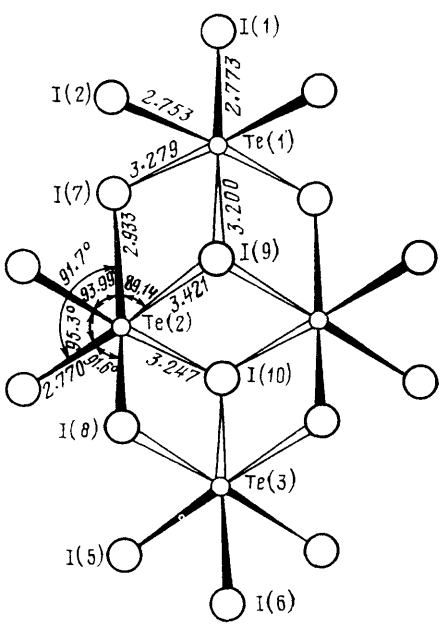

Figure 2. The structure of the tetramer $Te_{14}I_{16}$.[13]

Tellurium tetrabromide has a similar structure.[11] In the tetramers Te_4Br_{16}, the bond lengths are $Te–Br_{term}$ = 2.496 Å and $Te–Br_{bridge}$ = 3.054 Å.

Although the TeI_4 structure[13,14] (Fig. 2) is made up of $(TeI_4)_4$ tetramers, like those of $TeCl_4$ and $TeBr_4$, it is not isomorphous in relation to them. This structure consists of four edge-linked TeI_6 octahedra. As a result of this and in contrast to $TeCl_4$ and $TeBr_4$, three types of iodine atoms were detected in tellurium tetraiodide: those linked to a single tellurium atom (terminal bonds whose length is 2.769 Å), those linked to two tellurium atoms (bridged bonds whose length is 3.108 Å), and those linked to three tellurium atoms (pyramidal bonds whose length is 3.232 Å). The comparatively short intermolecular I...I bonds (3.870, 3.892, and 3.932 Å) join together separate tetramers.[14]

Tellurium tetrafluoride has a different structure.[15,16] The tellurium atom in this compound has three terminal fluorine atoms (average bond length 1.866 Å) and two bridging fluorine atoms with an average bond length of 2.181 Å. The fluorine atoms are located at the vertices of a distorted square pyramid and the individual TeF_5^- fragments are joined via the bridging fluorine atoms, forming infinite chains (Fig. 3). When account is taken of the lone pairs, the coordination around tellurium can be regarded as octahedral.

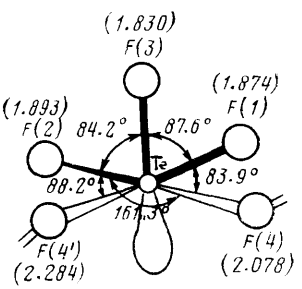

Figure 3. The structure of TeF_4.[15,16]

The availability of crystallographic data permitted the correct interpretation of spectroscopic data, in particular the ^{35}Cl NQR spectrum of $TeCl_4$,[19–21] the ^{81}Br NQR spectrum of $TeBr_4$,[21] and the ^{127}I NQR spectrum of TeI_4.[22,23] The NQR spectrum of $TeCl_4$ consists of six lines, which can be assigned to covalently linked chlorine atoms forming part of the composition of two non-equivalent $TeCl_3$ groups in the tetrameric structure (bridging chlorine atoms which are largely ionic are not manifested in the spectrum).[20,21] The ^{81}Br NQR spectrum of $TeBr_4$ is similar.[21] In the ^{127}I NQR spectrum, 10 non-equivalent iodine atoms can be detected in conformity with crystallographic data. Of these, six were identified as terminal atoms, two were identified as bridging atoms, and two were identified as pyramidal iodine atoms, which follows from their quadrupole splitting constants and the asymmetry parameters.[23]

X-Ray diffraction data for tellurium tetrahalides, and in the first place tellurium tetrachloride,[8–10] made it possible to explain the earlier extremely contradictory conclusions, obtained mainly with the aid of IR spectroscopy, concerning the structures of these compounds in the crystal state and in solutions. On the basis of the electrical conductivity of $TeCl_4$ in the melt, determined by dissociation in accordance with the scheme $TeCl_4 \rightleftarrows TeCl_3^+ + Cl^-$,[24] and also comparison of the IR and Raman bands of TeX_4 in the solid state[25–28] with the spectra of complexes of tellurium tetrahalides containing $TeCl_3^+$ ions,[17,26,28–30] it was concluded that the compound has an ionic structure ($TeCl_3^+Cl^-$)., This finding is confirmed by the results of conductimetric measurements for $TeCl_4$ solutions in a number of solvents.[29,31] Many other workers[32–34] concluded, on the basis of the same data, that tellurium tetrahalide has a covalent structure both in the solid state and in solutions.

Table 1. The average bond lengths (Å) and bond angles (degrees) in the molecules of the σ-telluranes $RTeX_3$.

[a] The first figure denotes the Te–X_{eq} bond length and the second denotes the average Te–X_{ax} bond length. [b] The Te...I = 3.703 Å and I...I = 3.337 Å secondary bonds. [c] The I...I = 3.239, 3.772 Å secondary bonds.

The weak bonding of the structural units in the TeX_4 tetramers in the solid phase is responsible, according to Buss and Krebs,[10] for the ready decomposition, both homolytic and heterolytic, depending on the temperature, the nature of the solvent, and concentration. This explains many of the properties of the melt and solutions of $TeCl_4$, in particular the electrical conductivities and the solubilities in polar and non-polar solvents. In the latter (benzene, toluene), $TeCl_4$ is monomeric,[34,35] exhibiting limited association with increase in concentration, although according to the results of Greenwood et al.,[36] $TeCl_4$ and $TeBr_4$ are trimeric in the solvents indicated. Data concerning the structure of $TeCl_4$ in solutions in polar solvents are again contradictory. Some investigators[30,34,37] believe that $TeCl_4$ is not ionised in acetonitrile and propionitrile, while others[31,36] concluded that ionisation takes place in these and other polar solvents (acetone) with formation of $TeCl_3^+$ and Cl^- or of $L_2TeX_3^+$ and X^-, where L is a solvent molecule. At the same time, there is no doubt about the presence of complexes of the latter type in highly electron-donating solvents [dimethyl sulphoxide (DMSO), dimethylformamide (DMF), and pyridine].

2. The structure of σ-telluranes

Derivatives of tetracoordinate tellurium, which can be formally regarded as the products of the substitution of one ($RTeX_3$) or two (R_2TeX_2) halogen atoms in molecules of tellurium tetrahalides, have the common name σ-telluranes. The non-equivalence of the substituents at the tellurium atom in these compounds poses the problem of their preferential disposition (axial or equatorial). According to the polarity rule,[38] which has been extended to σ-telluranes,[39,40] the axial positions in the trigonal bipyramids in σ-telluranes are always occupied by the most electronegative substituents—the halogen atoms. This structure of organic derivatives of tetracoordinate tellurium has been confirmed by X-ray diffraction data.

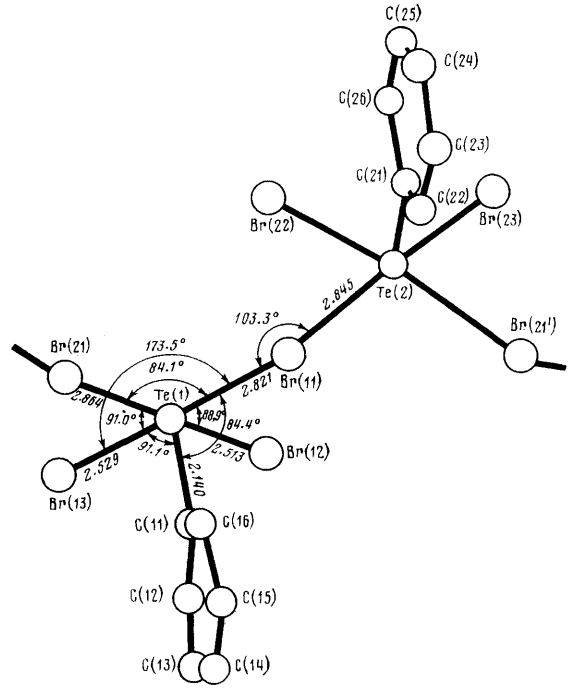

Figure 4. Geometry of the phenyltellurium tribromide molecule.[50]

(a) The structure of the σ-telluranes $RTeX_3$

The structures of a considerable number of organyl tellurium trihalides have now been investigated by X-ray diffraction: the trifluorides,[41] trichlorides,[42–49] tribromides,[44,50–53] and triiodides.[44,54,55] The principal data on the geometries of these compounds are presented in Table 1.

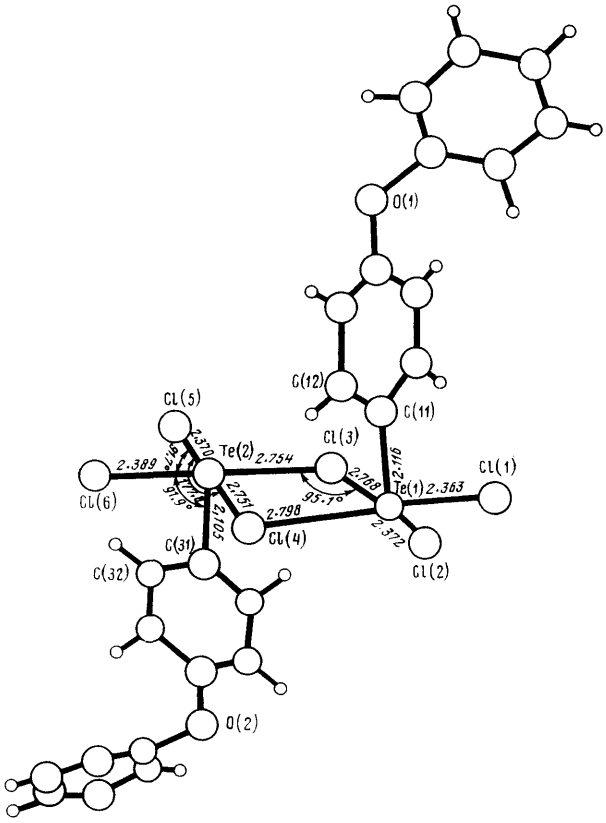

Figure 5. Geometry of the 4-phenoxyphenyltellurium trichloride molecule.[45]

As for tellurium tetrahalides, the real structure of the majority of the σ-telluranes $RTeX_3$ in the crystal state barely corresponds to the theoretically predicted trigonal bipyramidal structure. When account is taken of secondary interactions, the principal structural unit in these compounds $CTeX_4$, containing a pentacoordinate tellurium atom, has the square pyramidal configuration of the bonds around the tellurium atom with the organic group in the apical position. The tellurium atom is located virtually in the plane of the base of the square pyramid formed by the four halogen atoms, deviating slightly from it. Two halogen atoms form shorter (terminal) bonds, while the other two form longer (bridge) bonds which link the tellurium atoms of individual pyramids into polymeric or dimeric structures. The individual dimers are joined to one another by weak secondary Te...X bonds whose lengths greatly exceed those of the $Te-X_{bridge}$ bonds. The structures of typical representatives of polymeric and dimeric organyl tellurium trihalides (phenyltellurium tribromide[50] and 4-phenoxyphenyltellurium trichloride[45]) are presented in Figs. 4 and 5.

The σ-telluranes with two trihalotelluro-groups located at the same [bis(trichlorotelluro)methane[46]] (Fig. 6) or neighbouring [1,2-bis(tribromotelluro)cyclohexane][52] carbon atoms have the monomeric structure. Each tellurium atom in these compounds has a square pyramidal geometry with the exception that both Te–X bridge bonds are intramolecular. The structure of bis(trichlorotelluro)methane is presented in Fig. 6. It is noteworthy that the intermolecular Te...Te contacts in the above compounds are much shorter than in the σ-telluranes with a single TeX_3 group and amount to 3.417 Å in bis(trichloro)methane, for example.

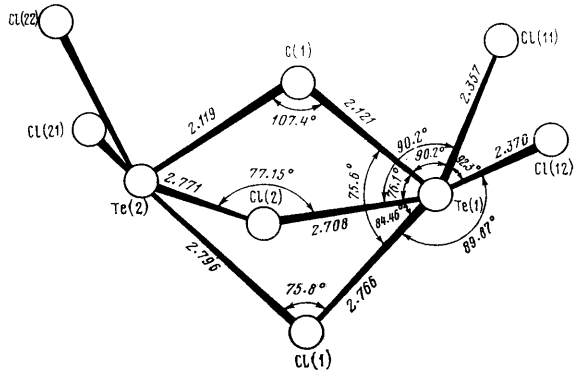

Figure 6. Geometry of the bis(trichlorotelluro)methane molecule.[46]

2-Biphenylyltellurium trihalide, containing the bulky 2-biphenylyl group, also has a monomeric structure with a trigonal-bipyramidal disposition of the ligands around the tellurium atom.[51,54,55] The geometry of the 2-biphenylyltellurium tribromide molecule[51] is illustrated in Fig. 7. The axial positions in the trigonal-bipyramidal structures of these compounds are occupied by halogen atoms, the angles between which are 178.5° for the tribromide, 176.5° for the α-modification of 2-biphenylyltellurium triiodide, and 176.0° for the β-modification. In other words, electronegative axial ligands are repelled to a greater extent from the lone pair than from the organic groups. It is of interest to note that, in conformity with the polarity rule,[38] the axial Te–X bonds are much longer than the equatorial bonds (Table 1). Short intermolecular Te...C contacts are observed in the molecules of 2-biphenylyltellurium trihalides, their length being 2.945 Å for the tribromide and 3.32 and 3.18 Å for the α- and β-triiodides respectively (the sum of the van der Waals radii of tellurium and carbon is 3.90 Å [56]). These contacts are responsible for the ease of the conversion of 2-biphenylyltellurium trihalides into 5,5-dihalodibenzotellurophenes on heating.[57] Intermolecular Te...X contacts have been detected in 2-biphenylyltellurium trihalides: 3.713 Å for the tribromide and 3.703 Å for the β-triiodide. Although they are smaller than the sums of the van der Waals radii of the corresponding elements (4.15 Å for Te and Br and 4.35 Å for

Te and I), they greatly exceed the lengths of the Te–X_{bridge} bonds (Te–Br = 2.829–2.932 Å, Te–I = 3.153 Å). The structures of the α- and β-modifications of 2-biphenylyltellurium triiodide are similar, differing only in the intermolecular contacts involving heavy atoms. Whereas β-modification contains, together with the Te...I secondary contacts, also I...I contacts whose length is 3.337 Å,[55] I...I contacts, whose lengths are 3.239 Å and 3.772 Å, were found in the α-modification.[54] The difference between the natures of these intermolecular interactions affects the colour of the compounds: the crystals of the β-modification are red and those of the α-modification are black.

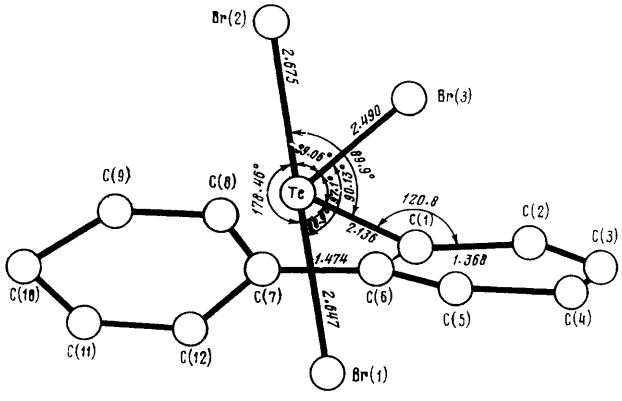

Figure 7. Geometry of the 2-biphenylyltellurium tribromide molecule.[51]

The degree of association and, what is most important, the molecular geometry of organyltellurium trihalides change significantly when they contain electron-donating atoms (oxygen, nitrogen) capable of intramolecular coordination to the tellurium atom. 8-Ethoxy-4-cyclooctenyltellurium trichloride[47] (Fig. 8) has a square pyramidal structure, like other organyltellurium trichlorides whose apex is occupied by a carbon atom. However, whereas in other σ-telluranes $RTeCl_3$ there are four chlorine atoms in the base of the pyramid, two of which are bridging, in the given compound there are three chlorine atoms, the lengths of the bonds of which with tellurium have the usual values (2.355–2.505 Å) and an O atom in the base of the pyramid. The Te...O distance (2.419 Å) is much smaller than the sum of the van der Waals radii of tellurium and oxygen (3.60 Å). Very weak secondary Te...Cl bonds, linking the molecules into dimers, were also found in the crystals. Their length (3.558 Å) is appreciably greater than those of the Te–Cl_{bridge} bonds (2.717–2.768 Å) observed in other organyltellurium trichlorides. 7-Ethoxycycloheptyltellurium tribromide probably has a similar structure.[53]

Another representative of the σ-telluranes $RTeX_3$, in which strong intramolecular Te ← N coordinate bonds were found is 2-(phenylazophenyl-C,N′)tellurium trichloride[48] (Fig. 9). Its bonds around the tellurium atom have an octahedral configuration. The apical Cl atoms (the Te–Cl bond lengths are 2.483 and 2.491 Å) form an angle of 171.7° with one another; the equatorial positions are occupied by the third Cl atom (the Te–Cl bond length is 2.406 Å), the bidentate organic ligand (the Te–C bond length is 2.114 Å), and the lone pair. The intramolecular Te ← N coordinate bond is of special interest. Its length (2.417 Å) is much smaller than the sum of the van der Waals radii (3.70 Å) and approaches the lengths of the usual Te–N covalent bonds. The molecule is monomeric and no Te...Cl contacts shorter than the sum of the van der Waals radii were detected in it.

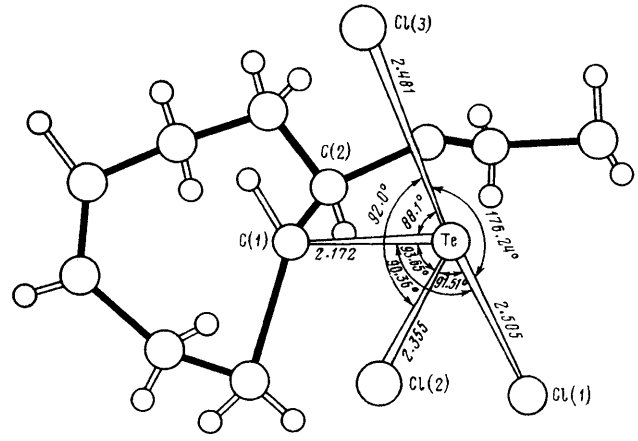

Figure 8. Geometry of the 8-ethoxy-4-cyclooctenyltellurium trichloride molecule.[47]

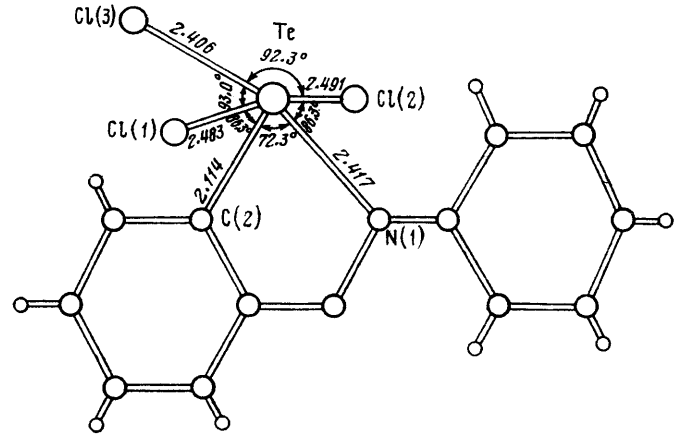

Figure 9. Geometry of the (2-phenylazophenyl-*C,N′*)tellurium trichloride molecule.[48]

The polydenticity of the organic ligand in 2,6-diacetylpyridinetellurium trichloride[49] leads to a structure of a new type which had not been encountered previously in the series of organyltellurium halides (Fig. 10). The coordination polyhedron of

the tellurium atom can be described as a distorted pentagonal bipyramid with two axial Te–Cl bonds (2.492 and 2.500 Å); the equatorial positions are occupied by a Cl atom ($Te-Cl_{eq}$ = 2.431 Å), the lone pair, and the three atoms of the tridentate organic group: the carbon atom (Te–C = 2.129 Å), the nitrogen atom (Te...N = 2.402 Å), and the oxygen atom (Te...O = 2.878 Å).

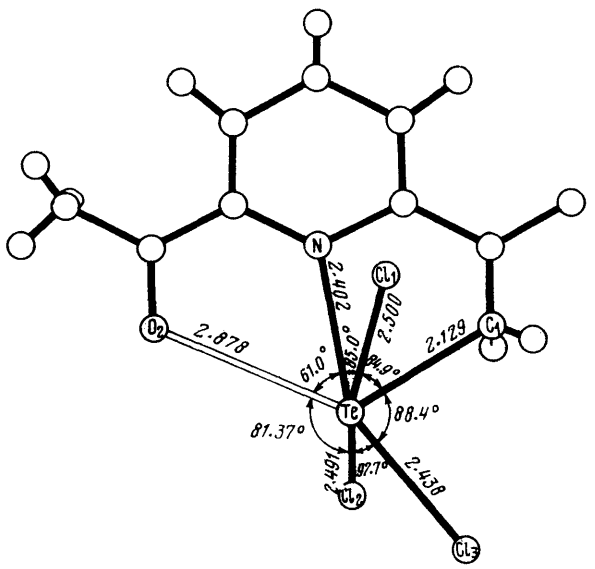

Figure 10. Geometry of the 2,6-diacetylpyridinetellurium trichloride molecule.[49]

Although the lengths of the neighbouring two bonds do exceed the sums of the covalent radii of the corresponding elements (2.07 Å for Te and N and 2.03 Å for Te and O), nevertheless they are much smaller than the sum of the van der Waals radii of these elements (3.70 Å for Te and N and 3.60 Å for Te and O [56]). The presence of the Te–N and Te–O coordinate bonds has been confirmed also by IR spectroscopic data: the shift of the vibrations of the pyridine ring from 997 cm^{-1} in 2,6-diacetylpyridine to 1012 cm^{-1} in the trichloride; the two carbonyl absorption bands at 1676 and 1712 cm^{-1}, observed in the spectrum of free 2,6-diacetylpyridine, are replaced in tellurium trichloride by a single vibration at 1707 cm^{-1}.[49] It is also of interest that the presence of coordinate bonds in the given trichloride increases significantly its resistance to hydrolysis.

The IR and Mössbauer spectra of organyltellurium trihalides, mainly the aryl derivatives, examined in Refs. 58–63 and 64–67 respectively, in general agree with X-ray diffraction data. By virtue of the wide variety of the Te–Hal bonds found in the σ-telluranes $RTeX_3$, they are of interest for NQR spectroscopy. However, the NQR spectroscopic data for these compounds are so far lacking in the literature.

The question of the aggregation of organyltellurium trihalides in solutions is important for the chemistry of the complexes based on them. Conductimetric data for solutions in acetonitrile, acetone, and nitrobenzene show that organyltellurium trichlorides do not dissociate into ions.[68–71] Organyltellurium tribromides and triiodides dissociate in the same solvents into ions ($RTeX_2^+$ and X^-) according to Khandelwal and co-workers,[70,71] although it has been claimed[61] that CH_3TeBr_3 is a non-electrolyte in nitrobenzene. On the other hand, aryltellurium trihalides containing amino(or dimethylamino)-groups in the ring, behave as 1:1 electrolytes in the solvents listed above regardless of the nature of the halogen.[63,72] This is probably due to the greater polarity of the Te–Hal bonds in the latter compounds owing to the presence in them of strong electron donors — the amino(or dimethylamino)-groups.

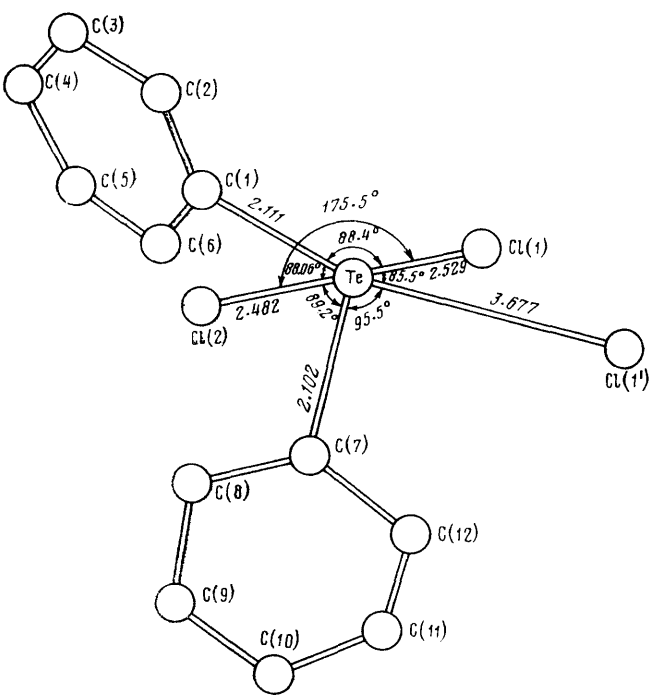

Figure 11. Geometry of the diphenyltellurium dichloride molecule.[43]

The results of cryoscopic studies on organyltellurium trihalides in general agree with conductimetric data. Aryltellurium trichlorides are monomeric in solutions [with the exception of amino(dimethylamino)-derivatives], exhibiting a weak association with increase in concentration,[39,68–70] while the tribromides and triiodides are partly dissociated.[63,70–72] On the other hand, in the case of the methyltellurium trihalides there is a monomer–dimer equilibrium in solution in benzene,[60,61] methyltellurium tribromide being more associated than its chlorine analogue.

(b) The structure of the σ-telluranes R_2TeX_2

Among diorganyltellurium dihalides, diorganyltellurium dichlorides have been most thoroughly investigated by X-ray diffraction.[43,73–81] Other tellurium dihalides (difluorides,[82] dibromides,[83] and diiodides[84,85]) are represented by single examples.

Table 2. The average bond lengths (Å) and bond angles (degrees) in the molecules of the σ-telluranes R_2TeX_3.

[a] The extreme limits of the bond lengths are quoted in a number of instances for the secondary bonds. [b] The arithmetical mean lengths of individual types of bonds have been adopted. [c] A, infinite chains; B, tetramers. [d] Data are lacking. [e] The chains are formed as a result of the Te...Br secondary interactions (3.71, 3.80 Å). [f] The chains are formed via O—H...Cl intermolecular hydrogen bonds (2.45 Å).

This review does not deal in detail with cyclic σ-telluranes, information about which can be found in other publications.[2,86,87] The most important structural characteristics of diorganyl tellurium dihalides are presented in Table 2.

The σ-telluranes R_2TeX_2 are characterised by the trigonal-bipyramidal disposition of the ligands around the tellurium atom, the halogen atoms always occupying axial positions. The X—Te—X angles are less than 180°, which shows that the halogen atoms are more strongly repelled from the lone pair of tellurium than from the equatorial organic groups. Diphenyltellurium dibromide, for which the Br—Te—Be angle exceeds 180°, is an exception.[83] The steric interactions between the bromine atoms and the phenyl rings[83] cannot be the cause of the increase in the angle, since in di(4-chlorophenyl)tellurium diiodide,[85] containing the more bulky iodine atoms, the I—Te—I bond angle is less than 180°. The structure of diphenyltellurium dichloride[43] is presented in Fig. 11.

In the majority of the σ-telluranes R_2TeX_2 investigated secondary Te...X interactions have been observed, the weakest being those in the difluorides. The lengths of these bonds are smaller than the sums of the van der Waals radii with the corresponding elements but greatly exceed the lengths of the Te—X bridge bonds in the σ-telluranes $RTeX_3$. The halogen atoms involved in the secondary bonds supplement the coordination around tellurium to the octahedral configuration. These interactions bind the individual molecules into infinite chains or tetramers. The bond length ratio Te...X/Te—X makes it possible to estimate roughly the degree of intermolecular association of the corresponding diorganyltellurium dihalides. Difluorides are least associated; dialkyltellurium dihalides are more associated than the diaryl derivatives.

In certain σ-telluranes R_2TeX_2, the Te...X secondary interactions are insignificant and the secondary bonds involving other atoms are shorter. In di(4-bromophenyl)tellurium dichloride,[7] the shortest linkages arise due to the Te...Cl interactions (4.67 and 5.54 Å), but they exceed significantly the sum of the van der Waals radii of Te and Cl (4.0 Å [56]). The individual molecules of this compound are linked by weak secondary Te...Br interactions (3.71 and 3.80 Å), the corresponding bond lengths being smaller than the sum of the van der Waals radii of Te and Br (4.15 Å [56]). The Te...Cl secondary interactions (3.884 Å) do not play an important role also in di(4-hydroxy-3-methylphenyl)tellurium dichloride.[79] The O—H...Cl intermolecular hydrogen bonds (2.45 Å) are energetically more favourable.

The secondary interactions with participation of heavy atoms (tellurium and iodine) in the molecules of diorganyltellurium dihalides are of special interest. The colour of these compounds, which varies from orange to dark-violet, is determined by the nature of the intermolecular bonds (Te...I or I...I). The compounds less coloured in the crystalline state have only the intermolecular Te...I bonds, while the dark-violet compounds contain in the main the I...I intermolecular bonds. Indeed, in the dark-violet di(4-chlorophenyl)-tellurium diiodide[85] and 1,1-diiodo-1-thia-4-telluracyclohexane[88] the intermolecular bonds are of the I...I type, whose lengths are 3.85 and 4.14 Å for the first compound and 3.66 and 3.90 Å for the second. On the other hand, in the yellow-orange 1,1-diiodo-3,4-benzo-1-telluracyclopentane[89,90] (Te...I = 3.653, 3.878 Å), the pale-red 1,1-diiodo-1-oxa-4-telluracyclohexane[91] (Te...I = 3.692, 3.814 Å), 10,10-diiodophenoxatellurin[92] (Te...I = 3.74, 3.79 Å),

and the red 5,5-diiododibenzotellurophene[93] (Te...I = 3.696, 3.617 Å), the secondary Te...I bonds are observed.

The IR spectra of the σ-telluranes R_2TeX_2 [58,94–97] agree with the trigonal-bipyramidal structure of the molecules of these compounds.[94,96,97] The Mössbauer spectra of diorganyltellurium dihalides, indicating that, regardless of the nature of the halogens these compounds have the same structure in the crystalline state, have been examined in a number of studies.[64–67,98]

The available information about the NQR spectra of compounds of the type R_2TeX_2 is extremely limited.[99,100] Two resonance lines have been observed in the ^{35}Cl NQR spectrum of dimethyltellurium dichloride,[99] while only one such line has been found in the NQR spectra of the diphenyl derivatives $(C_6H_5)_2TeX_2$ (X = Cl, Br, I).[100] While the first result agrees with X-ray diffraction data[73,74] (non-equivalence of the Te–Cl bonds), the data for diphenyltellurium dihalides do not. According to the results of Kondo et al.,[99] the Te–Cl bond in $(CH_3)_2TeCl_2$ is more ionic than in $TeCl_4$.

In contrast to organyltellurium tribromides and triiodides, which dissociate in solution into $RTeX^+$ and X^-, the σ-telluranes R_2TeX_2 are not electrolytes according to conductimetric data.[61,69–71] This is also indicated by the results of the determination of the molecular weights. An exception is 1,1-diiodo-3,4-benzo-1-telluracyclo-pentane,[89] the conductivity of which in dimethylformamide is typical for a 1:1 electrolyte and the observed molecular weight of this compound is appreciably lower than the theoretical value, indicating its existence in the ionic form.

III. Electron-donating properties of tellurium tetrahalides and σ-telluranes

Tellurium tetrachloride and its organic derivatives exhibit electron-donating properties in their reactions with Lewis acids. One of two alternative structures is usually attributed to the complexes formed: the donor–acceptor structure (I) or the ionic structure (II):

$$TeCl_4 + MX_n \rightarrow Cl_4Te \cdot MX_n, \quad \text{(I)}$$

$$TeCl_4 + MX_n \rightarrow [TeCl_3]^+ [MX_nCl]^-. \quad \text{(II)}$$

The conclusions concerning the existence of structures (I) or (II) are based mainly on vibrational spectroscopic data.[17,29,30,101,102–104] Bands in the range 343–345 cm^{-1}, characteristic of the $AlCl_4^-$ anion, have been observed in the Raman spectra of the complex of $TeCl_4$ with $AlCl_3$ in the melt and in the solid phase. This supports the structure (II).[101] The structure is also indicated by X-ray diffraction data for the complex.[17] The structure of the complex is made up of layers formed by highly distorted octahedra in which three terminal chlorine atoms are much closer to the tellurium atom than the other three, which are in their turn part of the composition of the $AlCl_4^-$ tetrahedra (Fig. 12).

Analysis of the vibrational spectra led to the conclusion that the crystalline complexes $TeCl_3^+ . AlCl_4^-$, $TeCl_3^+ . SbCl_6^-$, $TeCl_3^+ . AsF_6^-$, and $PCl_6^- . TeCl_7^+$ [actually $TeCl_4 . PCl_5$ in Ref. 30 (Ed. of Translation)] and their solutions in solvents of different polarity (benzene and acetonitrile) are ionic.[30] However, more detailed study of the Raman spectra of the complex $TeCl_4 . SbCl_5$ in the solid state[102] showed that its structure resembles that of the molecular complex $SeCl_4 . SbCl_5$ and is of the donor–acceptor type. In the highly polar nitromethane, it dissociates into the ions $TeCl_4^+$ and $SbCl_6^-$. It is of interest to note that the solid, freshly prepared, complex $TeCl_4 . SbCl_5$ is ionic and metastable. Its prolonged exposure to room temperature entails the disappearance of the bands characteristic of the $SbCl_6^-$ ion.[102]

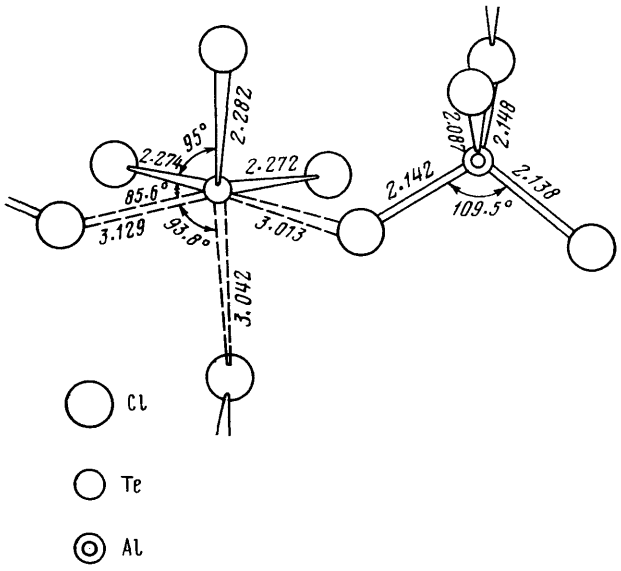

Figure 12. The crystal structure of the complex $TeCl_4 . AlCl_3$.[17]

The complexes of $TeCl_4$ with BCl_3 in polar solvents exhibit an electrical conductivity typical for 1:1 electrolytes,[104] which indicates the presence of the ions $TeCl_3^+$ and BCl_4^-. This has been confirmed by IR spectroscopic data.[105] It is of interest to note that $TeCl_4$ and BBr_3 afford $TeBr_4$ quantitatively on interaction, but the latter does not react with BBr_3.[106]

The interaction of TeF_4 with SbF_5 [107] leads to the formation of trifluorotelluro(IV)-μ-fluorobis[pentafluoroantimonate(V)], which also has the ionic structure $TeF_3^+ . Sb_2F_{11}^-$ with appreciable interaction between the ions via the fluorine atoms. On the other hand, the interaction of $TeCl_4$ with Group III metal halides ($AlBr_3$, $GaBr_5$, $GaCl_3$) [108] results in the formation of stable, highly polar, 1:1 electron-donating complexes.

Conclusions concerning the structure of the complexes of σ-telluranes with Lewis acids are also as a rule based on the analysis of the vibrational spectra and these systems are regarded as ionic.[109,110] The possibility of the formation of the cations $RTeCl_2^+$ has been demonstrated by a series of complexes of

organyltellurium trichlorides with $SbCl_5$, which are insoluble in non-polar solvents.[109] The ionic structure of these complexes, whose composition is $RTeCl_3.SbCl_5$, follows from the similarity of their IR spectra to those of the ionic complexes $RSeCl_3.AlCl_3$ [109] and from the observation of bands characteristic of the $SbCl_6^-$ ion.[110]

The interaction of $RTeCl_3$ with $AlCl_3$ is of special interest. The formation of compounds of the type $[RTeCl_2]^+[AlCl_4]^-$ has been postulated in a series of studies. Indeed $C_6H_5TeCl_3$ does not interact with benzene to form $(C_6H_5)_2TeCl_2$,[111] while 2-trichlorotellurodiphenylmethane does not cyclise to 10,10-dichlorotelluroxanthene in the absence of $AlCl_3$.[112] On the other hand, the addition of $AlCl_3$ makes it possible to achieve the above reactions by virtue of the enhancment of the electrophilic nature of the trichlorotelluro-groups in the above aryltellurium trichlorides probably as a result of the formation of the complexes $[RTeCl_2]^+[AlCl_4]^-$.

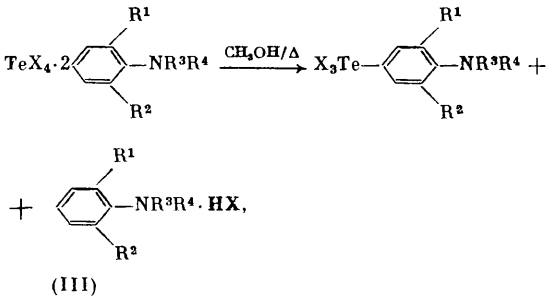
Thus in the majority of the studies quoted, carried out using vibrational spectroscopy, it was concluded that the complexes of $TeCl_4$ and σ-telluranes with Lewis acids are ionic. It is believed[30,101,102,104,109,110] that the complexes are formed as a result of the transfer of a Cl^- ion from the tellurium-containing donor to the acceptor. However, this mechanism cannot be regarded as the only one possible. Much depends on the strength of the Lewis acid and the nature of the medium in which the complexes are present. Thus, according to IR and UV spectroscopic and mass-spectrometric data, the complexes of R_2TeI_2 with I_2 have a distorted octahedral structure in the crystalline state and are donor–acceptor compounds.[113,114] This conclusion also follows from a study[115] in which the crystal and molecular structures of dimethyltellurium tetraiodide were investigated. It has the structure of a molecular adduct in which the individual $(CH_3)_2TeI_2$ and I_2 molecules are linked mainly by the $-I\ldots I-I$ intermolecular bonds. The interaction of dialkyltellurium diiodides with mixed halides also results in the formation of the molecular complexes $R_2TeI_2.IX$ (X = Cl, Br).[116]

The above data refer to the structure of the complexes of $TeCl_4$ and σ-telluranes with Lewis acids in the crystalline state or in solution in highly polar solvents. However, on passing to non-polar solvents, these systems acquire a qualitatively different structure. The dipole moments of the complexes of $TeCl_4$ with Group IIIA metal halides, having the composition $TeCl_4.MX_3$ (MX = $AlBr_3$, $GaCl_3$, $GaBr_3$), are in the range 6–10 D.[35] Such polarity precludes the attribution of the structure of ion pairs to these complexes. On the other hand, the bridged structures, whose formation cannot be ruled out *a priori*, should have significantly smaller dipole moments. On the basis of these data and the absence of electrical conductivity in benzene, it has been concluded that these are donor–acceptor complexes.[35] The bond in them is formed via the lone pair of the tellurium atom and the unoccupied orbitals of the central atom of the Lewis acid and, judging from calorimetric data and dielectric constant measurements, it is fairly strong and polar. Comparison of the IR spectra of solutions of these complexes in benzene with those of typical donor–acceptor systems $R_2S.MX_3$ [117] reveals a virtually complete identity of the spectra in the region corresponding to the absorption by the acceptor. Other studies[118,119] have led to a similar conclusion about the nature of the bond in the complexes of the σ-telluranes $RTeX_3$ and R_2TeX_2 with $SbCl_5$ in benzene.[118,119] A characteristic feature of the latter systems is also the formation of the complexes $D.3SbCl_5$ (D = donor molecule).[118] An exception is the $(C_6H_5)_2TeI_2$ + $SbCl_5$ system in which halogen exchange probably takes place.[119] The results obtained by combined thermal analysis indicate the molecular nature of the complexes formed.[119] The dipole moments of the 1:1 complexes are in the range 6–8 D, while those of the 1:3 complexes are in the range 10–13 D, which indicates the ionic structure of the latter.[118] The electrical conductivity of the complexes having the simplest composition, observed in nitrobenzene,[118] does not rule out the possibility that they are donor–acceptor in nature. Judging from the heats of formation of the complexes, the electron-donating capacity of the tellurium atom in the σ-telluranes is determined primarily by the number of aromatic groups and their nature.[119,120]

IV. Electron-accepting properties of tellurium tetrahalides and σ-telluranes

1. Electron-accepting properties of tellurium tetrahalides

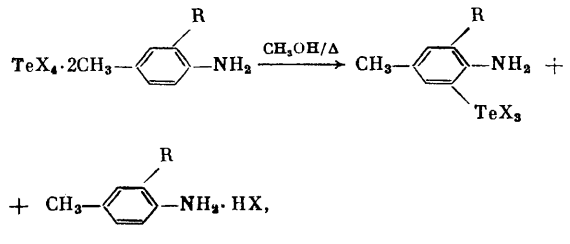
The relatively low-lying unoccupied *d* orbitals of the tellurium atom are responsible for the electron-accepting properties of its tetracoordinate derivatives, the subject of numerous investigations. A considerable proportion of them involve the study of the electron-accepting properties of tellurium tetrahalides, which are moderately strong Lewis acids in relation to various N-, P-, O-, S-, and Se-containing organic donors. The complexes have been, as a rule, isolated in the solid state and investigated by various physicochemical methods.



(a) Complexes with N-donors

In the literature devoted to the study of the electron-accepting properties of tellurium tetrahalides, most attention has been devoted to their interaction with N-containing bases. The reactions of TeF_4 with aliphatic amines (trimethylamine and tetramethylethylenediamine) result in the formation of crystalline 2:1† and 1:2 adducts.[121] Bands characteristic of the TeF_5^- anion have been detected in the IR spectra of these systems,[122] which made it possible to attribute to them the ionic structures $[TeF_3.L_2]^+[TeF_5]^-$ and $[TeF_3.L]^+[TeF_5]^-$ respectively. An octahedral structure has been proposed for the cation $[TeF_3.L_2]^+$, in which the tellurium atom is surrounded by three fluorine atoms, two electron-donating ligand atoms in the *cis*-positions, and the lone pair at one of the vertices. The nature of the relative positions of the monodentate ligands in the complexes has not been elucidated.[121]

On interaction with TeX_4 (X = Cl, Br, I), aromatic amines[72,123–126] form 2:1 complexes which are sparingly soluble in the usual organic solvents. However, after prolonged heating of these complexes in dry methanol, electrophilic substitution of one of the aromatic rings takes place in the *p*-position (relative to the amino-groups) with formation of tellurium trihalides (III) or, if the *p*-position is



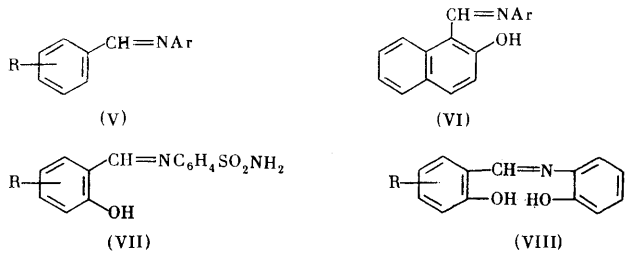
† In the designation of the composition of the complexes, here and henceforth the first figure denotes the number of electron-donating molecules and the second denotes the number of electron-accepting molecules.

occupied, substitution in the *o*-position takes place with formation of compounds (IV):[72,123]

(III)

$R^1 = R^2 = R^3 = R^4 = H$; $R^1 = R^2 = R^3 = H$; $R^4 = CH_3$; $R^1 = R^2 = H$; $R^3 = R^4 = CH_3$; $R^1 = R^3 = R^4 = H$, $R^2 = CH_3$; $R^1 = R^2 = CH_3$, $R^3 = R^4 = H$,

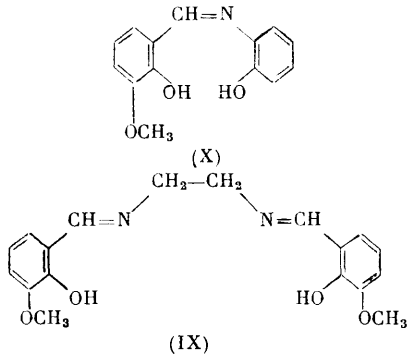
(IV)



R = H, CH_3.

The interaction of $TeCl_4$ with heterocycles containing an sp^2-hybridised nitrogen atom results in the formation of mainly 2:1 complexes.[29,127–130] The reaction with the bidentate 2,2′-bipyridyl results in the formation of a 1:1 adduct[128] and the formation of complexes of both compositions has been noted only for pyridine.[29,31] According to conductimetric and vibrational spectroscopic data, these complexes are ionic.[29] The anion is Cl^-, while the cation, $[TeCl_3.L_2]^+$, is a pseudo-octahedron with a lone pair at one of the vertices. X-Ray diffraction demonstrated the *trans*-octahedral structure of the 2:1 adduct of $TeCl_4$ with pyridine.[131] In this case, the lone pair of the tellurium atom is not stereoactive.

In contrast to $TeCl_4$, the reaction of TeF_4 with pyridine affords only a 1:1 adduct.[132] Its treatment with aqueous HF results in the formation of more complex fluorides: $C_6H_5NH.TeF_5$ and $(C_6H_5NH)_2.TeF_6$.



Thiopicolinamides[130] react with $TeCl_4$ to form 2:1 complexes. It follows from the analysis of IR and ^1H NMR spectroscopic data that the tellurium atom is coordinated to the pyridine nitrogen atom and the nitrogen atom of the thioamide group. Judging from the molar conductances in solutions in DMF, these complexes can be regarded as 1:2 electrolytes.

Tellurium tetrachloride exhibits electron-accepting properties also in relation to hydrazones[133] and Schiff bases (V)–(VIII),[134–136] with which it forms mainly 2:1 complexes. The complexes with type (VII) azomethines possess antibacterial properties.[135]

(V) (VI) (VII) (VIII)

However, the reaction of $TeCl_4$ with the azomethines (IX) and (X) affords 1:1 complexes. The reason for the conflict between the results of the above studies[136,138] is obscure, since the electron-donating compounds (VIII) and (IX) employed in these investigations have very similar structures.

(X)

(IX)

The shift of the stretching vibration bands of the C=N bond in the IR spectra of the adducts compared with the initial Schiff bases has led to the conclusion[134,135,137] that N → Te coordinate bonds are formed via the lone pairs of the azomethine nitrogen atoms.

(b) Complexes with O-donors

Tellurium tetrachloride exhibits electron-accepting properties in relation to the oxygen atom in the C=O, N → O, P → O, and S → O groups. The interaction of $TeCl_4$ with acetamide and its derivatives[138] and 2-hydroxybenzylideneacetophenones[139] results in the formation of 2:1 complexes, in which, judging from IR spectroscopic data, the tellurium atom is coordinated to the carbonyl oxygen atom. The electrical conductivities of solutions of the complexes of $TeCl_4$ with acetamide and its derivatives are characteristic of 1:1 electrolytes and made it possible to attribute the structure $[TeCl_3L_2]^+Cl^-$ to the complexes.[138]

Pyridine[31] and 2,6-lutidine[140] *N*-oxides form 2:1 complexes on interaction with $TeCl_4$ (pyridine *N*-oxide also gives rise to a 1:1 complex). Conductimetric measurements and analysis of the IR spectra indicated that the complexes of pyridine *N*-oxide, containing Cl^- as the anion, have an ionic structure.[31] The splitting of the stretching vibration bands of the N → O group in the IR spectrum of the complex of 2,6-lutidine, similar to that observed for the *cis*-octahedral complexes $MCl_4.2L$ (M = Hf, Ta, Th; L = R_nYO,

Y = N, P, S, etc., n = 2, 3), made it possible to postulate a *cis*-disposition of the ligands also in the 2,6-lutidine complex.[140]

Dialkyl sulphoxides react with $TeCl_4$ to form 2:1 and 1:1 complexes. This is particularly characteristic of dimethyl sulphoxide.[20] The complex with the simplest composition is a molecular compound both in solution and in the crystalline state. This follows from the dipole moment determined in benzene and the ^{35}Cl NQR spectrum in the solid phase. On the other hand, conductimetric data for the 2:1 complexes indicate the ionic structure $[TeCl_3.2(CH_3)_2SO]^+Cl^-$. It has been postulated[20] that the structures of complexes of both types are made up of octahedra, one of the vertices of which in the 1:1 complex is occupied by the lone pair of the tellurium atom. Dicyclohexyl sulphoxide reacts with $TeCl_4$ to form the complex having the simplest composition.[120] The complexes of $TeCl_4$ with diethyl and dibutyl ethers, investigated by the dielectric constant titration method, have a similar composition.[35]

According to the dielectric constant titration data, under isomolar series concentration conditions in solutions in benzene, $TeCl_4$ reacts with $(C_6H_5)_3PO$ to form complexes having only two compositions: 1:1 and 2:1.[141] Judging from the dipole moments, they are donor–acceptor complexes. One of the vertices of the octahedron in the 1:1 complex is probably occupied by the lone pair of tellurium, while the octahedral 2:1 complex has the *cis*-structure.

(c) Complexes with S-donors

According to the dipole moment and calorimetric titration data, $TeCl_4$ reacts with the dialkyl sulphides $(C_3H_7)_2S$ and $(C_7H_{15})_2S$ to form 1:1 complexes.[20,35] The dipole moments of the complexes (5–9 D) and the low electrical conductivities in benzene demonstrate their donor–acceptor nature. Complexes with the simplest composition are formed also on interaction of $TeCl_4$ with the sulphides $RS(CH_2)_nSR$ (R = alkyl, n = 2–10) [142] despite the presence of two sulphur atoms in the latter.

Much attention has been devoted to the study of complexes in which an sp^2-hybridised sulphur atom functions as the donor centre. Both $TeCl_4$ and $TeBr_4$ form 2:1 complexes with tetramethylthiourea (TMTU).[143–145] It has been established by X-ray diffraction[143–145] that these complexes have an octahedral structure in which the sulphur atom is in the equatorial plane in the *trans*-position. The structure of the complex $TeBr_4.2TMTU$ is illustrated in Fig. 13. The slight distortions of the coordination unit are treated as a consequence of packing effects[144] or of the influence of the lone pair of the tellurium atom.[145]

Comparison of the long-wavelength IR spectra of the complexes of TMTU in the solid state and in solution[128] in the light of X-ray diffraction data[143–146] indicated that the *trans*-octahedral structure is retained also in solutions. The determination of the molecular weights in solution in tetramethylene sulphone and of the electrical conductivity in solutions in nitrobenzene and tetramethylene sulphone led to the conclusion that these complexes are monomeric and weakly ionised.[128]

N,N'-Substituted thioureas also form 2:1 complexes with $TeCl_4$ which are non-conducting in DMF and DMSO.[147] The shift of the bands in the range 600–700 cm^{-1}, referring to the vibrations of the C=S groups, led to the conclusion that the adducts have an octahedral structure with the apical S-coordination of the organic bases.

It is of interest to note that TMTU reduces tellurium(IV) derivatives in acid solutions, which leads to the formation of the complexes $Te^{(III)}:Te(L)Cl_2$.[143]

Various thiones can also function as S-containing donors. The 2:1 complex of $TeCl_4$ with benzimidazolethione has the *cis*-configuration with coordination to the sulphur atoms according to X-ray diffraction data.[149] On the other hand, the analogous complex with benzothiazolethione, isolated from solution in dioxane, has the *trans*-octahedral structure.[150]

Adducts of the type $TeX_4.L_2$ have also been obtained by the reaction of TeX_4 (X = Cl, Br, I) with thiazolidine-2-thione. IR spectroscopic data in the solid state have lead to the hypothesis that the complexes have an octahedral structure[151] in which the tellurium atom is coordinated to the nitrogen atom of one of the ligand molecules and the sulphur atom of the other.

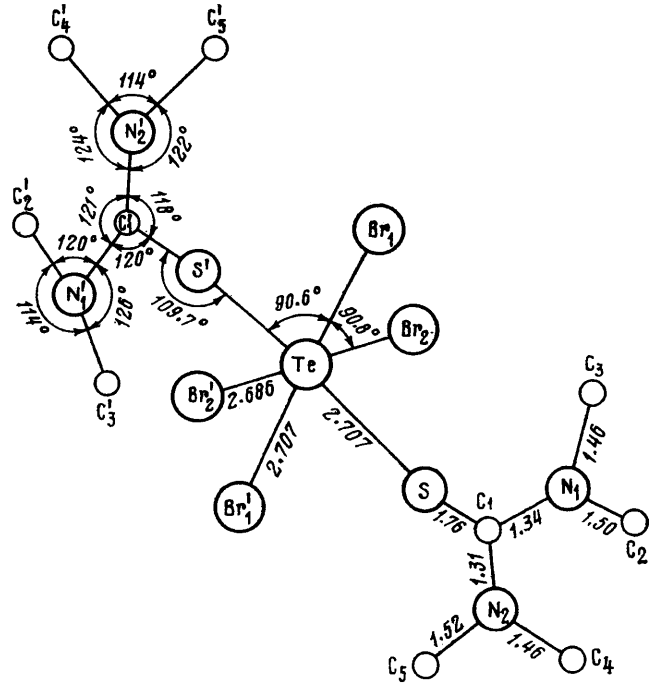


Figure 13. The structure of the adduct $TeCl_4.2TMTU$.[143,144]

Measurements of the electrical conductivities of the above systems showed that these are 1:1 electrolytes and the low electrical conductivities in solution in DMF have been explained by the tight bond between the cation and the anion.

Tetramethyl(ethyl)dithiooxamides constitute another type of sulphur-containing donors forming 1:1 complexes with $TeCl_4$ and $ArTeCl_3$.[152,153] The long-wavelength IR and the Raman spectra indicate an octahedral structure of the complexes containing bidentate ligands coordinated to the sulphur atoms of the thiocarbonyl groups.

The complex formation reaction of tetramethylthiuran disulphide is unusual. The interaction of this donor with TeX_4 (X = Cl, Br, I) results in the elimination of one sulphur atom and the formation of 1:1 complexes between tetramethylthiuram sulphide and TeX_4.[154] It follows from the IR spectra that tellurium is coordinated to the thione sulphur atoms.

Complexes of $TeCl_4$ with the thiosemicarbazones and semicarbazones of benzaldehyde, salicylaldehyde, acetophenone, and 2-hydroxyacetophenone, having the 1:1 structure, have also been described.[155] The IR and NMR spectra confirm the coordination of the tellurium atom via the azomethine nitrogen atom, the sulphur atom of the C=S/O group, and the phenolic oxygen atom (if it is present in the benzene ring).

The interaction of $TeCl_4$ with $(C_6H_5)_3PS$ leads to the complex with the simplest composition whose structure is analogous to that of the complex of $TeCl_4$ with $(C_6H_5)_3PO$ described above.[141]

2. Electron-accepting properties of the σ-telluranes $RTeX_3$

In contrast to tellurium tetrahalides, a characteristic feature of which is the formation of 2:1 adducts, organyltellurium trichlorides form mainly 1:1 complexes.

Aryltellurium trichlorides react with pyridine (Py), 4-picoline, and 4-picoline *N*-oxide to form 1:1 complexes.[68] The first two complexes which behave in solution in nitromethane as 1:1 electrolytes, have the structure $[ArTeCl_2.L]^+Cl^-$. The complex of 4-picoline *N*-oxide is a weak electrolyte and its formula is $ArTeCl_3.L$.

According to IR spectroscopic and conductimetric data, an octahedral structure has been attributed to the 1:1 complexes of $ArTeCl_3$ with the bidentate ligands bipyridyl and phenanthroline and to the 2:1 complexes of 4-phenoxyphenyltellurium trichloride with the monodentate pyridine, pyridine *N*-oxide and tri(*n*-octyl)-phosphine oxide.[156] The complexes of aryltellurium trichlorides with a series of N-, P-, and O-containing bases (trimethylamine, pyridine, benzimidazole, triphenylphosphine, triphenylphosphine oxide, and dimethyl sulphoxide), isolated in a pure state, have been described.[157–159] The complexes have the 1:1 composition and are apparently dissociated in acetonitrile judging from the electrical conductivities of the solutions. The composition and enthalpy of formation of the complex of $C_6H_5TeCl_3$ with $(C_6H_{13})_2SO$ have been investigated by calorimetric titration in benzene.[120]

Organyltellurium trichlorides exhibit electron-accepting properties also in relation to S-containing bases. In the study[154] quoted above, it was shown that the aryltellurium trihalides $4\text{-}C_2H_5OC_6H_4TeX_3$ (X = Cl, Br, I) as well as tellurium tetrahalides interact with tetramethylthiuram disulphide. This entails the elimination of one sulphur atom and the formation of 1:2 tetramethylthiuram sulphide complexes. However, no conclusions were reached about the structure of these complexes.

The 1:1 complexes of $RTeCl_3$ and $RTeBr_3$ with TMTU [62,160] have a square pyramidal structure with organic substituents in the apical positions and the three halogen atoms and the S-coordinated ligand molecule in the base of the pyramid according to IR and ^1H NMR spectroscopic data. As in the case of tellurium tetrahalides, the interaction of aryltellurium trichlorides with thiourea is accompanied by the reduction of tellurium (IV) and the formation of tellurium(II) complexes.[161]

The interaction of a number of aryltellurium trichlorides with electron donors of the type $(C_6H_5)_3P=X$ (X = LEP, O, S, Se) and also with $C_6H_5PO(CH_3)_2$ has been investigated[141] by the dipole moment method under isomolar series concentration conditions in solutions in benzene. The formation of 1:1 complexes in reactions with aryltellurium trichlorides and of 1:1 and 2:2 complexes in reactions with $TeCl_4$ was observed. The dipole moments corresponding to the interaction of the components indicate the donor–acceptor nature of the bond between them. Analysis of the dipole moments shows that the coordination unit of the complex consists of a pseudo-octahedron in which the donor is in the *cis*-position relative to the lone pair of tellurium and in the *trans*-position relative to the chlorine atom. Judging from the dipole moment (13.21 D) of the octahedral complex $TeCl_4.(C_6H_5)_3PO$, the donor molecules in it are in the *cis*-position relative to one another. The decrease in the dipole moments on passing from the $TeCl_4$ complexes to the $C_6H_5TeCl_3$ complexes for the same donors shows that the electron-accepting capacity of tellurium in its tetracoordinate derivatives is determined by the number of phenyl groups linked directly to the tellurium atom. It is of interest to note[162] that, on interaction of $ArTeCl_3$ with the thiosemicarbazones (TSC) of benzaldehyde, salicylaldehyde, acetophenone, and 2-hydroxyacetophenone, ionic tricoordinate tellurium(II) complexes $[ArTe.(TSC)_2]^+Cl^-$, in which the tellurium atom is coordinated via the sulphur atom, are formed.

3. Electron-accepting properties of the σ-telluranes R_2TeX_2

The amount of data on the electron-accepting capacity of diorganyltellurium dihalides is extremely limited. The 1:1 complexes of $(C_6H_5)_2TeCl_2$ [157] and $(C_6H_5)_2Te(NO_3)_2$ [163] with certain N-, P-, O-, and S-containing Lewis bases (trimethyl- and triethyl-amines, pyridine, triphenylphosphine, pyridine *N*-oxide, tetramethylthiourea, triphenylphosphine oxide, and others) have been isolated. The 2:1 adducts of dicyclohexyltellurium dihalides,[164] α,α-bispropiophenone-tellurium dihalides,[165] and diphenacyltellurium dihalides[166] with N-containing donors such as diethylamine, pyridine, piperidine, morpholine, and pyrrolidine have been investigated. Spectroscopic studies (IR and ^1H NMR) have shown that, whereas the initial tetracoordinate tellurium compounds exhibit keto-enol tautomerism, the adducts exist mainly in the keto-form. The 1:1 complex of $(C_6H_5)_2TeCl_2$ with $(C_6H_{13})_2SO$ has been investigated by calorimetric titration in benzene.[120] Comparison of the enthalpy of formation of this complex with the analogous quantities for the complexes of $TeCl_4$ and $C_6H_5TeCl_3$ with the same donor indicates that the electron-accepting capacity of tellurium-containing compounds decreases with the increase in the number of phenyl groups in the acceptor molecule.

Data published[167] on a series of complexes of "dibenzotelluorophene dichloride" with various donors are erroneous. The compound to which the authors attributed the structure of dibenzotelluorophene dichloride is not in fact the latter.

— o0o —

The literature data presented in this review show that, despite the considerable number of studies devoted to complexes of tellurium tetrahalides and σ-telluranes, this field of coordination compounds requires further studies. Whereas the electron-accepting properties of tellurium compounds have been more or less investigated, their electron-donating capacity, especially that of σ-telluranes, has been studied to a very slight extent. Nevertheless, complexes of this type can play an important role in the chemistry of derivatives of tetracoordinate tellurium. The virtual lack of energy characteristics of the complex formation reactions of derivatives of tetracoordinate tellurium makes it essential to carry out planned and systematic studies in this field. Hitherto investigations have been limited to a narrow range of σ-telluranes. In view of this, the study of the complex formation reactions of σ-telluranes, in which the electronic and steric nature of the substituents at the tellurium atom as well as the nature of the organic donors and acceptors involved in the complex formation are varied widely, is of definite interest. Investigations of this kind make it possible to establish the rules

governing the variation of the electron-donating and electron-accepting properties of σ-telluranes as a function of the nature and number of the halogen atoms and the organic groups at the tellurium atom. The results of studies on the complex formation reactions of the σ-telluranes $RTeX_3$ and R_2TeX_2, in which the tellurium atom is involved in intramolecular interaction with an atom or groups of atoms forming part of the composition of the same molecules, may be of definite interest for the problem of competitive reactivity. The X-ray diffraction and NQR methods should be applied to an increasing extent in the study of complexes based on derivatives of tetracoordinate tellurium. Finally, it is entirely likely that certain tellurium complexes can find practical applications about which nothing is known with the exception of data on the antibacterial properties of complexes of tellurium tetrachloride with Schiff bases containing sulphamide groups.

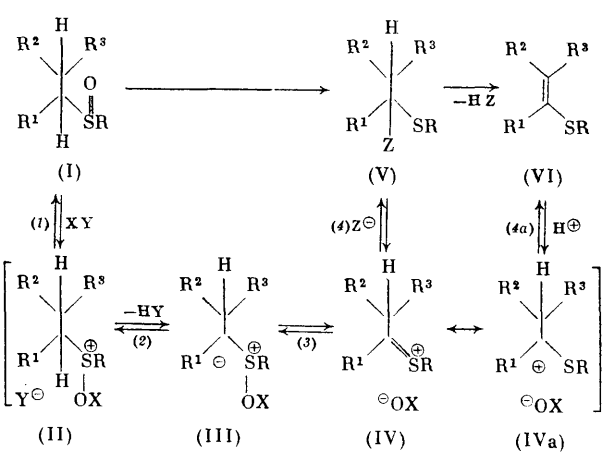
I. Introduction



The conversion of sulphoxides by electrophilic reagents to α-substituted sulphides, which was discovered by R Pummerer in 1909,[1] was named after him by Horner[2] half a century later in honour of the original discoverer of this reaction. A number of reviews[3–11] are devoted to a study of its mechanism and certain synthetic aspects. At the same time, the use of the Pummerer reaction (PR) and related conversions in fine organic synthesis, which has undergone a particularly intense development in recent years, has hardly been reviewed at all, if the short selection of material by Welzel[12] and the highly specialised review of Fedorov et al.[13] devoted to the use of the PR in the synthesis of heterocyclic compounds are excluded. This circumstance has prompted us to analyse the available information on this topic, mainly covering the literature of the last ten years.

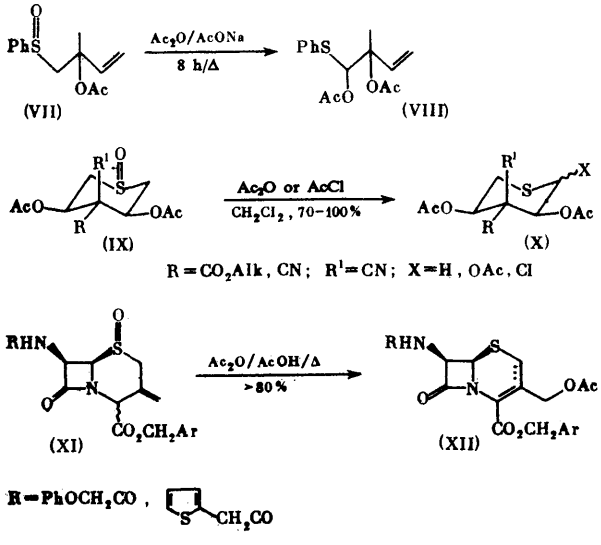
II. Current theory of the mechanism of the Pummerer reaction

The most comprehensive information about the probable mechanism of the PR is contained in reviews by Oae.[10,11] The overall scheme now reduces to four successive reversible stages *(1)*–*(4/4a)* (Scheme 1), and the rate-determining stage can change depending on the nature of the initial reaction components. Examples are known in which either of these stages becomes rate-determining.[11] The first of them consists of the formation of an oxysulphonium salt (II) (an "activated" sulphoxide)[14] or, in other words, a pre-Pummerer intermediate (PPI), from a primary or secondary sulphoxide (I). The second involves the generation of an oxysulphonium ylid (III) by removal of an α-proton by the counterion. Heterolysis of the S–O bond in the ylid at the third stage leads to the formation of the Pummerer intermediate (PI) proper (IV)/(IVa), which is stabilised finally by an external nucleophile to give an α-substituted sulphide (V) or forms a vinyl sulphide (VI) through elimination of the β-proton. In the case of acyloxysulphonium ions (II), the acyl residue within the corresponding PPI can act as this nucleophile.[11,15]

The reagents XY used to "activate" the initial sulphoxide are usually simple and mixed anhydrides and chorides of carboxylic acids, other halides of (in)organic acids, and the acids themselves, including Lewis acids, catalytic quantities of which added to these "activators" sometimes accelerate the PR, and also certain other reagents.[11,14] Acyloxy and chloride ions are most common among the external nuclephiles $Z^{\ominus}$, although uncharged molecules and functional groups of the substrate that become involved in the PR can fulfil this role. When these compounds are acid-labile, in order to neutralise the acids formed at stages *(2)* and *(4/4a)*, extensive use is made of bases; these are as a rule nitrogenous, including dicyclohexylcarbodiimide, which in particular achieves high enantio-selectivity in a reaction involving chiral sulphoxides.[15,16]

Scheme 1

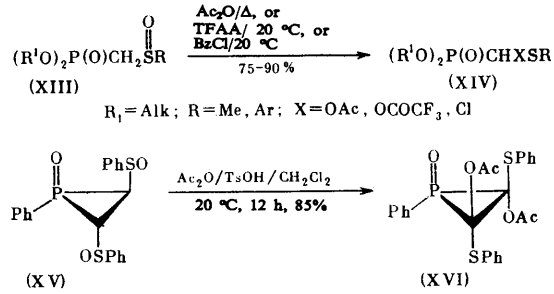
The existence of the cationoid S-containing species (II)–(IV) as actual intermediates of the PR has so far not been established unequivocally.[10,11] However, the ability of sulphoxides, and in particular DMSO,[6,17] to give thermally labile complexes with different electrophilic reagents, such as adducts with HCl[17] or with trifluoroacetic anhydride (TFAA),[18] the latter decomposing to a PR product even at −30 °C, is well known. Indirect confirmation of the involvement of the PPI (II) in the PR is provided by the large



amount of data on the reaction between "activated" sulphoxides and *O*- and *N*-nucleophiles.[11,14]

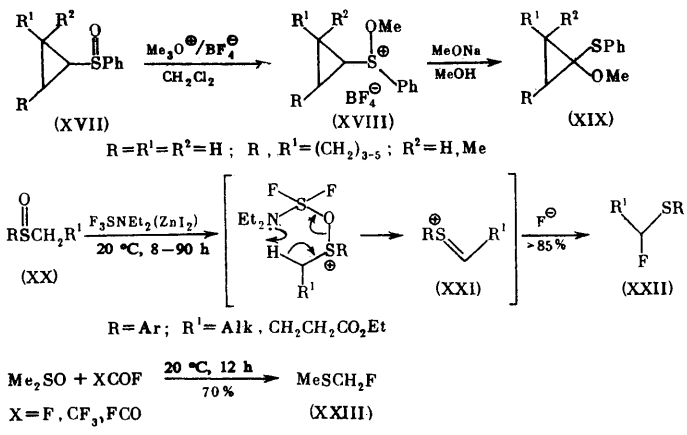
With regard to the PI (IV/IVa), as representatives of a class of methylenesulphonium salts[11] their instability generally appears to be quite natural. The simplest example of this type of cationoid species, $H_2C{=}\overset{\oplus}{S}Me/SbCl_6$, was obtained from methylthiochloromethane comparatively recently.[19] In relation to the PR, there is only indirect evidence, as in the case of the PPI (II), for the existence of such an intermediate.[10,11] Additional information will be given below (Section VII).

III. Synthesis of α-substituted sulphides, carbonyl compounds, and alcohols



At the present time the Pummerer reaction serves as an extremely valuable synthetic method of achieving a simple conversion from readily available primary and secondary sulphoxides to *gem*-functionalised sulphides. Further hydrolytic, redox, and other conversions of the latter to various carbonyl compounds and their derivatives is simply a question of procedure, the efficiency of which depends in many respects on the nature of the functional groups that are present in the molecule of the initial substrate. Just as important for the overall process as a whole is the nature of the electrophilic and nucleophilic reagents that are used, which has been recorded in most of the reviews mentioned above. The same questions are discussed below with account taken of the latter results concerning the possibility of achieving a selective conversion of the sulphinyl group in the presence of other functional substituents. For example, the isoprene derivative (VII) can be readily converted to the acetoxysulphide (VIII),[20] while sulphoxides (IX) are converted to α-substituted tetrahydrothiopyrans (X)[21] (Scheme 2). In the case of allyl sulphoxides it is possible in this way to introduce an acetoxy group into the γ-position relative to the sulphur atom. In particular, the PR of the cephalosporin derivatives (XI) readily gives γ-acetoxy sulphides (XII),[22] which are apparently formed by allylic isomerisation of the initial *gem*-product.

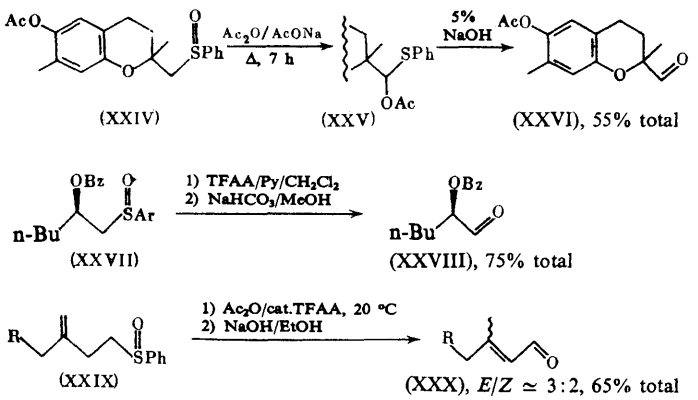
Scheme 2



The presence of an electron-withdrawing group at the α-position relative to sulphinyl assists the participation of the latter in the PR, and in addition increases the degree of asymmetric induction for optically active substrates.[11,15] Thus α-phosphoryl sulphoxides (XIII) under different conditions and in high yield are converted to the corresponding acyloxy- or chloro-sulphides (XIV).[23] For example, chiral (XIII) (R^1 = Me, R = *p*-Tol) gives the acetoxy-sulphide (XIV) (X = OAc) with an enantiomeric purity (EP) of about 25%[23] (Scheme 3). Similarly, the phosphirane disulphide (XV) yields *trans*-diacetate (XVI).[24]

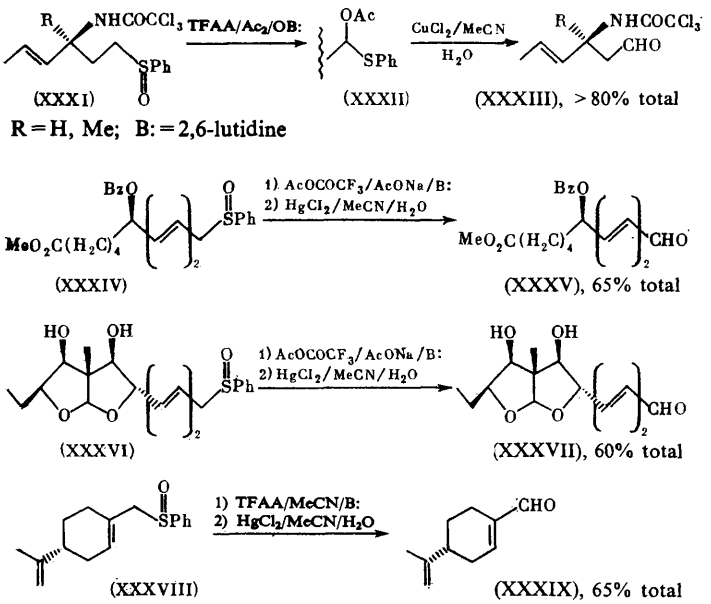
Scheme 3

Using the Pummerer reaction it is possible to carry out the synthesis of structures that were only recently considered exotic. For example, cyclopropanone derivatives such as methoxysulphides (XIX) are prepared from (XVII) and a Meerwein salt with a total yield of 40–60% via the stable oxysulphonium salts (XVIII)[25] (Scheme 4). Other such fairly important compounds include the α-fluorides (XXII), which were recently synthesised in almost quantitative yield by "activation" of the sulphur atom in (XX), catalysed in a number of cases by ZnI_2, and apparently occurring via a PI of the type (XXI).[26,27] As a result of the PR of DMSO with certain acyl fluorides, methylthiomethyl fluoride (XXIII) was isolated in high yield.[28]



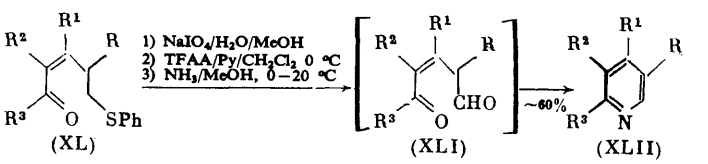
Scheme 4

It stands to reason that α-substituted sulphides (V), in particular their acyloxy derivatives, can be readily converted to the corresponding aldehydes and ketones; and in this sense primary and secondary sulphoxides are latent precursors of such compounds by



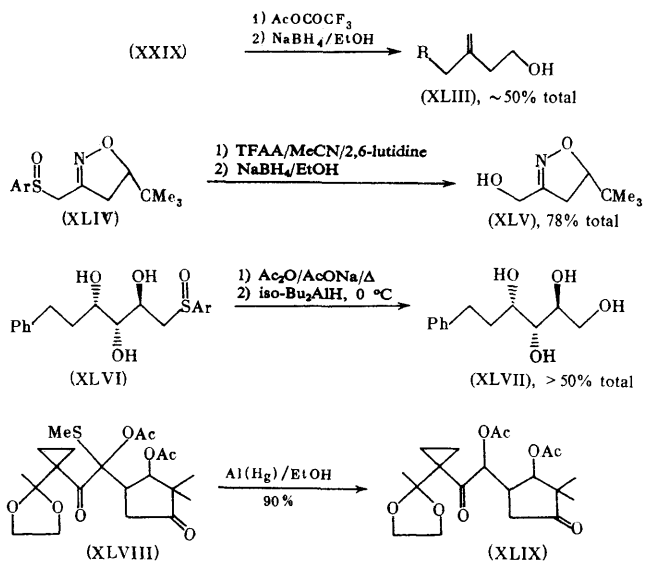
the Pummerer reaction. For example (Scheme 5), in one of the variants for the synthesis of α-tocopherol from the sulphoxide (XXIV) via the acetoxysulphide (XXV), aldehyde (XXVI) is derived.[29] In another case the unstable intermediate *gem*-acetoxysulphide formed by the PR from the chiral sulphoxide (XXVII) is readily converted in high yield in a weakly alkaline medium to the aldehyde (XXVIII) without appreciable racemisation of the α-centre.[30] On the other hand, the β,γ-unsaturated aldehydes initially formed from the isoprenoid homallylic sulphoxides (XXIX) undergo smooth isomerisation to the conjugated aldehydes (XXX).[31]

Scheme 5



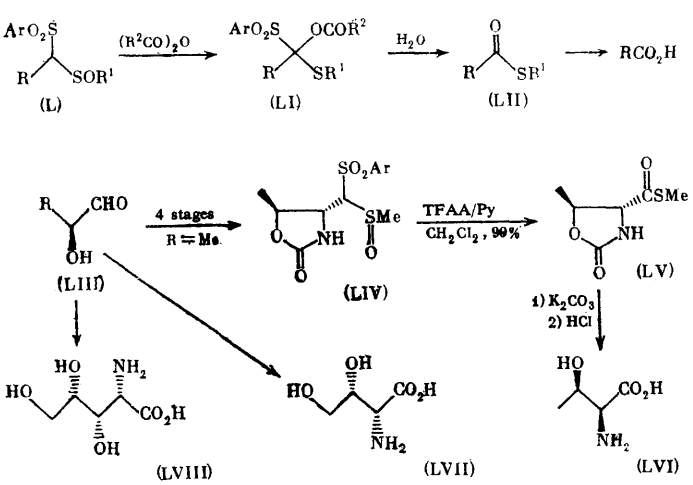
It should be noted that the conditions recorded above for the hydrolytic cleavage of *gem*-acyloxysulphides are not optimal in every case, especially when base- or acid-labile functional groups are present in their molecules. In such cases it is recommended to use Cu(II) and Hg(II) salts, which provide mild conditions for conducting the reaction, as catalysts (c.f. the study of Sugihara et al.).[32] In particular, in the synthesis of certain antitumour antibiotics, the labile β-trichloroacetamidoaldehydes (XXXIII) can be readily obtained from sulphoxides (XXXI) via the hydrolytic cleavage of acetoxysulphides (XXXII) catalysed by $CuCl_2$.[33] The use of $HgCl_2$ for the same purpose is illustrated by the conversion of the functionalised sulphoxides (XXXIV), (XXXVI), and (XXXVIII) without isolation of the intermediate trifluoroacetoxysulphides to the corresponding diene aldehydes (XXXV)[34] and (XXXVII),[35] which have served as building blocks in the total syntheses of 5-desoxy-leukotriene *D* and (±)-asteltoxin (an inhibitor of oxidative phosphorylation) respectively, as well as perillaldehyde (XXXIX)[36] (Scheme 6).

Scheme 6



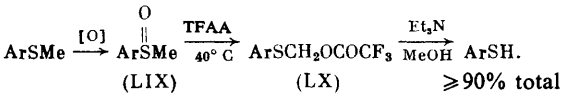
The use of a sulphoxide as a masked carbonyl compound, particularly if the latter is very unstable, is demonstrated by the preparation of pyridines (XLII) from sulphides (XL) once again without isolation of both the intermediate sulphinyls and the glutaconic aldehyde derivatives (XLI).[37] This method is successfully used at a key stage in the synthesis of the neurotoxin molecules—acromelic acids A[38] and B.[39]

R, R^1 = H, Me, $(CH_2)_2OMe$; R^2 = H; R^3 = Me; R^2, R^3 = $(CH_2)_4$



Sufficiently stable products of the PR of a number of acyloxysulphides can provide a direct source of primary and secondary alcohols, and the number of examples of such reactions, which are carried out as a rule in two variants, has steadily increased in recent times. Thus in Scheme 7, hydride reduction of the products of the PR involving (XXIX), and without their isolation, readily yields the corresponding linear γ-terpenols (XLIII),[40,41] which clearly could not be obtained with the inclusion of an intermediate hydrolytic stage (c.f. Scheme 5). Similarly the isoxazolidine sulphoxide (XLIV) is converted to the masked α-ketol (XLV) without saturation of the C=N bond,[42] while (XLVI) is converted to the arabitol derivative (XLVII).[43] Another variant of the reductive conversion from PR products to alcohols and their esters is illustrated by the desulphurisation with an aluminium amalgam of the relatively stable acetoxysulphide (XLVIII) prepared from the corresponding ketosulphoxide to give the α-keto acetate (XLIX)—a key compound in one of the schemes for the total synthesis of illudane sesquiterpenes.[44]

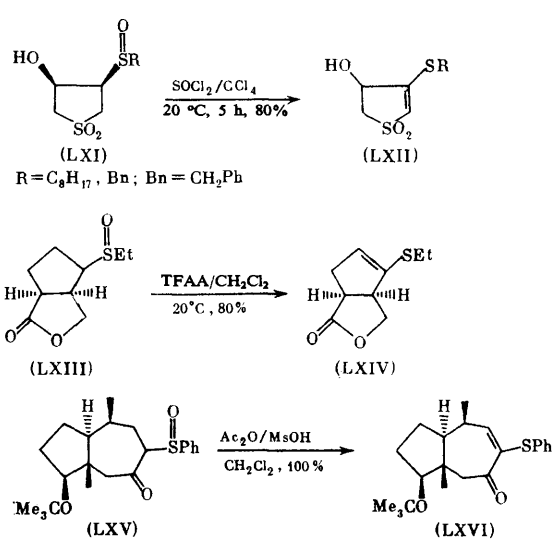
Scheme 7



The Pummerer reaction can be readily used for the conversion to carboxylic acids from sulphoxides of the type (L), which contain an effective leaving group such as arylsulphonyl, making it possible to generate the thiol ester (LII) from intermediate (LI) (Scheme 8). In omitting a review of the methods for making the initial structures (L), based primarily on S-containing C_1-synthons,[45] we shall merely note here the recently developed stereocontrolled method of obtaining *syn*-β-hydroxy-α-amino acids from chiral α-hydroxyaldehydes (LIII).[46] Thus, the α-sulphinylsulphone (LIV) in the end gives thioester (LV) in high yield, which is then converted in a conventional manner to *D*-threonine (LVI). *L*-γ-Hydroxythreonine (LVII) and the polyhydroxyamino acid (LVIII) are obtained in a similar manner.

Scheme 8

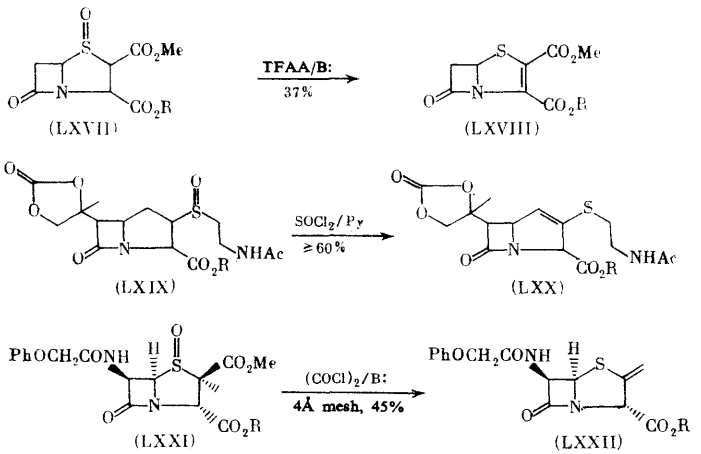
The possibility of simple demethylation of (hetero)aromatic methylthioesters is an example of the use of the PR in the chemistry of protected groups that is worth considering.[47,48] Thus, the readily available sulphoxides (LIX) are converted in boiling TFAA to the corresponding arylthioesters (LX), which are then cleaved to the required thiophenols in virtually quantitative overall yield.



Thus, a primary or secondary sulphinyl group is a fairly versatile source for obtaining α-substitututed sulphides, carbonyl compounds, and their corresponding alcohols via the Pummerer reaction. It should be emphasised that the first of these compounds, primarily *gem*-acyloxysulphides and/or *gem*-chlorosulphides, under certain conditions act as counterparts of cationoid species of the type (IV)/(IVa), which open up new and currently quite extensively used opportunities for forming a C–C bond (see Section VII).

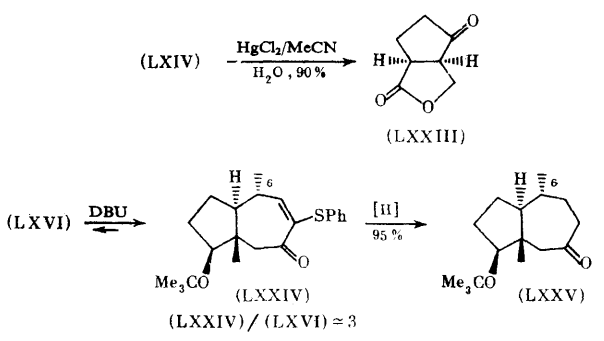
IV. Synthesis and certain properties of vinyl sulphides

Because of the cationoid nature of the PI (IV)/(IVa), one of the methods used to stabilise it involves the elimination of a β-proton to give vinyl sulphides (VI), which can also be formed through α-elimination of the *gem*-derivatives (V), especially if an electron-withdrawing substituent occurs at the β-position relative to the sulphur atom (see several studies).[1–11] Amongst recent examples, the preparation of vinyl sulphides of the type (VI) using $SOCl_2$ and certain other standard reagents such as $Sn(OTf)_2$ (Tf = F_3CSO_2) [54] as "activators" has been reported in a series of studies by Warren et al.[49–53] Similarly, treatment of *cis*-hydroxysulphinyl derivatives of sulpholane (LXI) with $SOCl_2$ gives vinyl sulphides (LXII) in high yield,[55] and the bicyclic sulphoxides (LXIII)[56] and (LXV)[57] on treatment with acid anhydrides readily afford olefins (LXIV) and (LXVI) respectively (Scheme 9).



Scheme 9

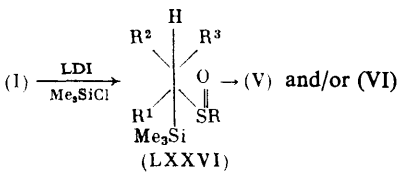
The Pummerer reaction is very widely used at the present time in the synthesis of penicillin analogues, in particular those containing a vinyl sulphide residue (Scheme 10). Thus, for example, sulphoxides



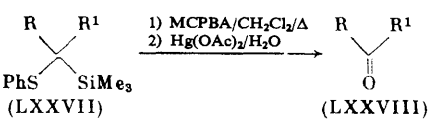
(LXVII) are converted to individual diesters (LXVIII),[58] carbapenams (LXIX) gives sulphides (LXX),[59] and compounds (LXXI), containing a carboxyl group in the vicinity of sulphinyl, are converted to olefins (LXXII).[60]

Scheme 10

B: = 2,6-collidine; R = *p*-$CH_2C_6H_4NO_2$



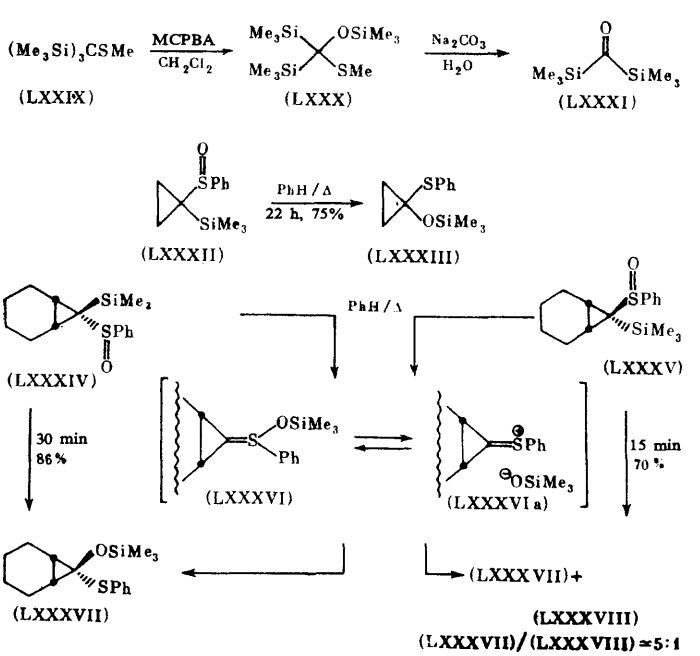
One of the obvious aspects of the synthetic use of vinyl sulphides is their conversion to carbonyl compounds; for example, (LXIV) gives the precursor (LXXIII) of sarkomycin in a recently published scheme of its total synthesis.[56] Exhaustive reduction of the vinyl sulphide function is rarely encountered. In the case of the ketovinyl sulphide (LXXIV) this method has been successfully used for yielding the precursor (LXXV) of the sesquiterpene pseudoguaiane after isomerisation of the C(6) site of the initial epimer (LXVI) using 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).[57]



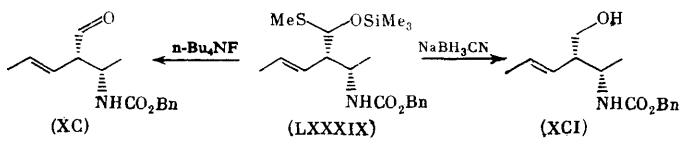
Thus, primary and secondary sulphoxides may be regarded as a direct source of obtaining substituted vinyl thioethers.

V. Silyl variant of the Pummerer reaction

It is well known[61] that thermally labile α-silyl sulphoxides (LXXVI), one of the methods for the synthesis of which is the *C*-silylation of initial compounds (I) deprotonated by lithium diisopropylamide (LDI), readily isomerise to α-silyloxysulphides (V) (Z = $OSiMe_3$). Further study of this silyl variant of the PR (SPR), which accompanies the formation of vinyl sulphides (VI), has identified the considerable possibility of using this reaction by interaction of (I) with silyl halides, in particular trimethylsilyl halides or their equivalents, as "activators" of the process, which evidently involves intermediates (II)–(IV)/(IVa) (X = $SiMe_3$, $SiMe_2Bu$-t, etc.).[62–64] It should be noted that in this case as well as the formation of products purely from the SPR—(V) (Z = $OSiMe_3$) and (VI)—a competing reduction of sulphoxides (I) to the corresponding sulphides occurs at the same time, and this is especially typical for (cyclo)aliphatic compounds.[65]

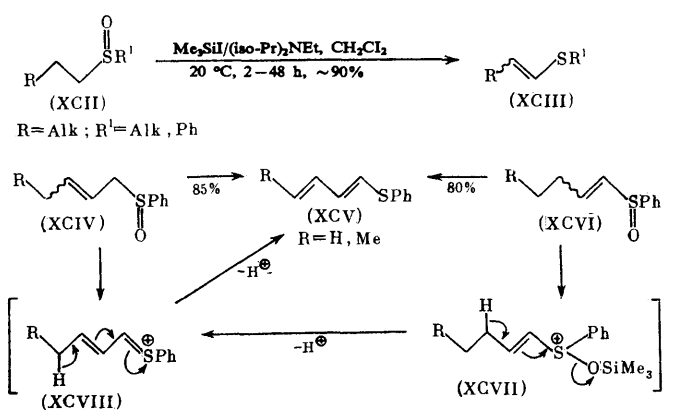


gem-Silyloxysulphides of the type (V) that are accessible using the SPR are, as a rule, very unstable compounds which are readily converted under hydrolytic conditions to the carbonyl products corresponding to the initial (LXXVI). This circumstance has predetermined a method of obtaining them *in situ* from silylsulphide C_1-synthons[45] as an alternative to the *C*-silylation of sulphoxides (I). For example, refluxing in THF or CCl_4 of the products of the oxidation of silylsulphides (LXXVII) by *m*-chloroperbenzoic acid (MCPBA) and subsequent hydrolytic treatment of SPR products catalysed by Hg(II) gives ketones (LXXVIII) in 50–80% yield.[66]



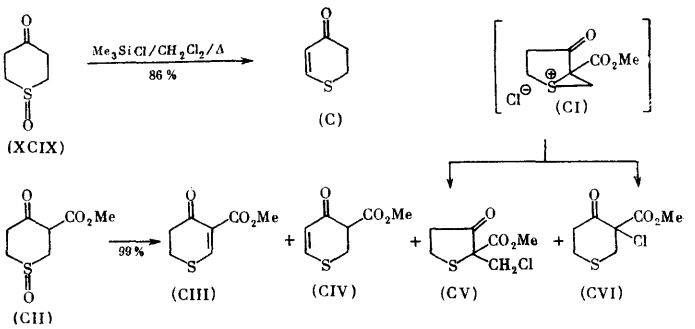
R, R^1 = Alk, All, Bn. Ph; All = $CH_2CH{=}CH_2$.

Scheme 11



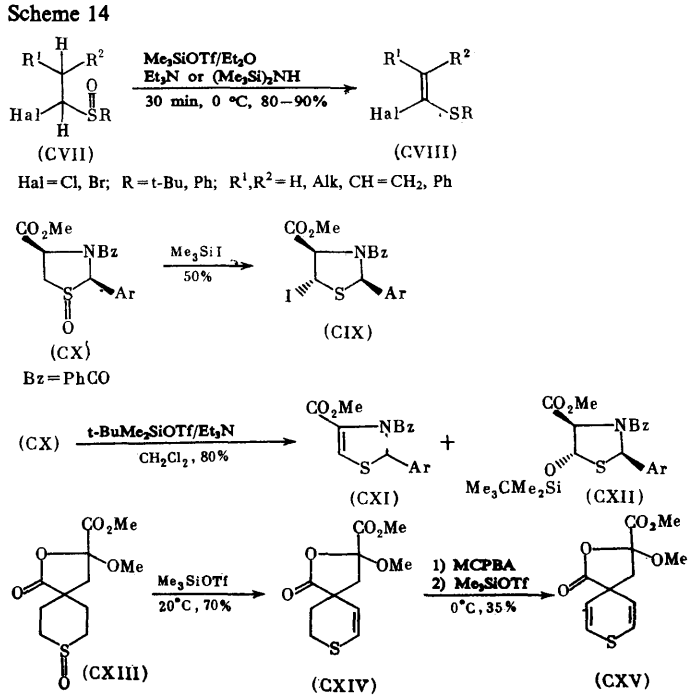
In specific cases the unstable α-silyloxysulphides can be isolated and used as individual compounds. Thus, as in Scheme (11), the tris(trimethylsilyl) sulphide (LXXIX) is smoothly converted to the heteroatomic methane derivative (LXXX), which is then converted to the simplest bis(trimethylsilyl) ketone (LXXXI).[67] Correspondingly, the *gem*-phenylsulphinyltrimethylsilylcyclopropanes (LXXXII), (LXXXIV), and (LXXXV) rearrange in boiling benzene to the cyclopropane derivatives (LXXXIII), (LXXXVII), and (LXXXVIII),[68] which are related to (XIX). The stereochemical result of the reaction in the case of (LXXXIV) and (LXXXV) indicates the preference for *exo*-attack by the counterion on the cation in (LXXXVIa), formed from intermediate (LXXXVI).

Like acyl derivatives (V) (Z = OCOR), the related silyloxy derivatives can be readily converted to the corresponding carbonyl compounds or their hydride reduction products; this is illustrated by the preparation of the aldehyde (XC) and alcohol (XCI) from *gem*-silyloxysulphide (LXXXIX).[69]



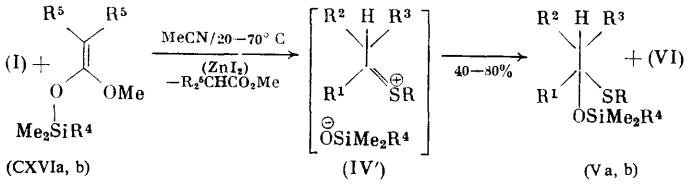
In the same way as the traditional variant, the SPR opens up a simple means of access to a whole range of functionalised vinyl sulphides. Thus, treatment of sulphoxides (XCII) with Me_3SiI in the presence of a Hünig base gives vinyl thioethers (XCIII) in high yield[70] (Scheme 12). In the case of allyl sulphoxides (XCIV) and vinyl sulphoxides (XCVI), whatever their stereochemistry, diene sulphides (XCV) are stereospecifically formed under the same conditions, probably via intermediates (XCVII) and (XCVIII).[70]

Scheme 12



The presence of other functional groups in the vicinity of sulphinyl in molecules involved in the SPR of sulphoxides can cause other processes to take place. For example, in Scheme 13,[71] ketone (XCIX) on treatment with Me_3SiCl is readily converted to ketosulphide (C), whereas ketoester (CII) under the same conditions gives a mixture of sulphides in the ratio (CIII):(CIV):(CV):(CVI) ≃ 75:10:10:5, of which derivatives (CV) and (CVI) are evidently formed from the episulphonium intermediate (CI). It is interesting to note that when Ac_2O or TFAA are used as "activators", the same sulphoxide (CII) mainly (90%) gives a mixture of the (trifluoro)-acetates corresponding to chlorides (CV) and (CVI) in the ratio of ≃ 5:1.[71]

Scheme 13



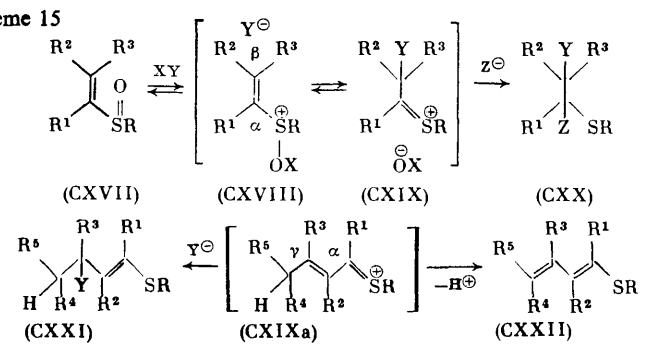
Considerable opportunities for the synthesis of different functionalised vinyl sulphides are opened up by the use of trimethylsilyl trifluorosulphonate (trimethylsilyl triflate, Me_3SiOTf) and other silyl triflates, which on "activation" of the initial sulphoxide liberate a virtually non-nucleophilic counterion. In particular, in Scheme 14, application of this method starting from α-halosulphoxides (CVII) leads to the smooth preparation of a series of acid-labile vinyl sulphides (CVIII), which is difficult to achieve when Me_3SiCl or Me_3SiI are involved.[72,73] Similarly, when the latter is used, the thiazolidine sulphoxide (CX) is mainly converted to the iodide (CIX), whereas with the use of t-$BuMe_2SiOTf$, a mixture of sulphides in the ratio (CXI):(CXII) ≃ 2:1 is obtained from (CX).[74] Finally, by carrying out the SPR with Me_3SiOTf twice, it is possible to synthesise the unstable vinyl sulphide (CXV) in satisfactory overall yield from (CXIII) via the monovinyl sulphide (CXIV).[75]

Scheme 14

Using this silyl variant of the PR, there is a current trend towards research into "activators" that achieve both the mildest conditions for generating the key PPI (II) and the possibility of effective control over the course of subsequent reactions involving the counterion $Y^{\ominus}$. In this respect the use of silyl triflates in combination with different bases appears in many cases to be the best way of suppressing unwanted side reactions. As a development of this approach, the use of the ketenacetals (CXVIa, b) as "activators" of

(CXVIa, b) (IV′) (Va, b)

R^4 = Me (a), t-Bu (b); R^5 = H, Me



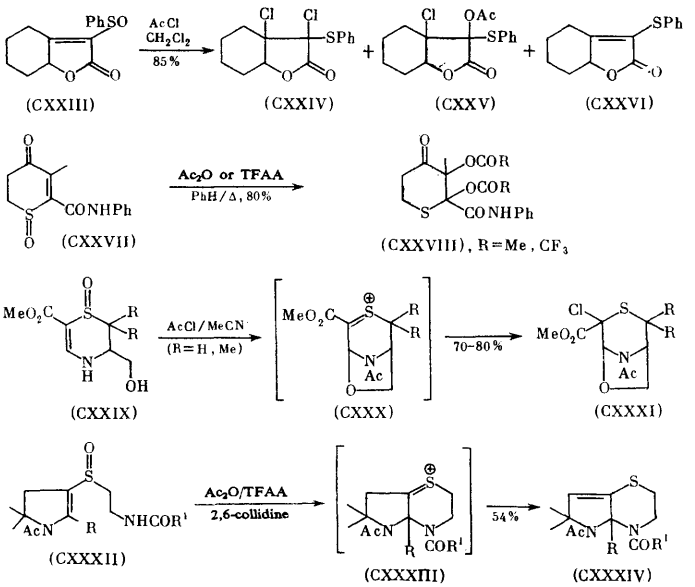
the SPR was recently proposed.[76–78] In this variant when components (I) and (CXVI) are allowed to stand in MeCN in the presence of 1.2–2.4 mole equivalents of ZnI_2, this generally gives a mixture of silyl ethers (Va, b) and vinyl sulphides (VI), whose ratio depends on the nature of the initial substrate (I). The reaction evidently occurs via a stage involving the PI (IV′), which when the trimethylsilyl ketenacetal (CXVIa) is used can react with the carbanion of methyl acetate or methyl isobutyrate formed as a result of decomposition of the latter (see Section VII). This does not occur in the case of acetal (CXVIb), which contains a sterically bulky substituent.

Thus, the SPR provides a simple means of converting sulphoxides to α-silyloxysulphides or related vinyl thioethers that have considerable synthetic potential.

VI. Vinyl sulphoxides in the Pummerer reaction

Up to the present time the Pummerer reaction involving linear and cyclic vinyl sulphoxides (CXVII) (Scheme 15), achieving simple ways for their effective functionalisation, has been studied quite extensively.[79] The main feature of these compounds is that because of the electron-acceptor properties of the PPI (CXVIII), there is the possibility of attack by an external (or internal) nucleophile on its β-centre. A similar stabilisation of the cationoid PI (CXIX) leads in the end to α,β-disubstituted sulphides (CXX). When a hydrogen atom occurs at the γ-position of the initial molecule of (CXVII), the PI, as a result of an allylic shift, can take the form of (CXIXa), which gives the vinylogue derivatives (CXXI) or the diene sulphides (CXXII) (c.f. Scheme 12). Heterolysis of the C–Y bond in the PI (CXIX) will formally give reduction products of the initial vinyl sulphoxides (CXVII).

Scheme 15



(CXVII) (CXVIII) (CXIX) (CXX)

(CXXI) (CXIXa) (CXXII)

All of these PR routes for (CXVII) have been widely introduced at the present time. In particular, in Scheme 16, treatment of the sulphinyllactone (CXXIII) with AcCl gives a mixture of sulphides in the ratio (CXXIV):(CXXV):(CXXVI) ≃ 5:1:1,[79] whereas the diacycloxysulphides (CXXVIII) are obtained from (CXXVII) by treatment with Ac_2O or TFAA.[80,81] Conversion of the sulphoxides (CXXIX)[82] and (CXXXII)[83] to the corresponding bicyclic derivatives (CXXXI) and (CXXXIV) can serve as an example of the intramolecular stabilisation of a PPI of the type (CXVIII) via the intermediate ions (CXXX) and (CXXXIII).

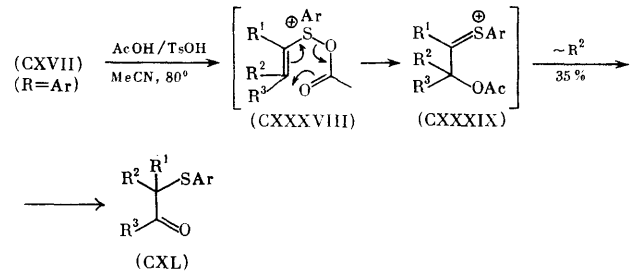
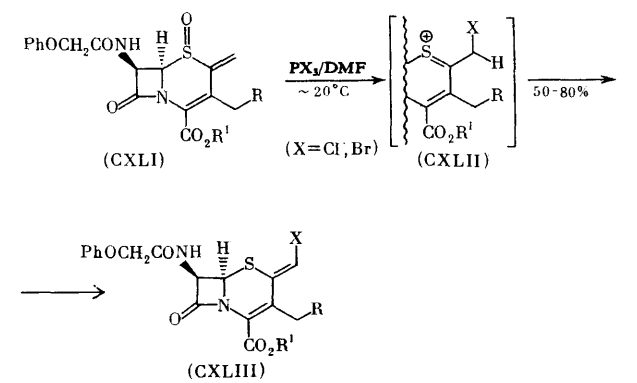
(CXXXII) (CXXXIII) (CXXXIV)

R = CO_2Me; R^1 = p-$CH_2C_6H_4NO_2$

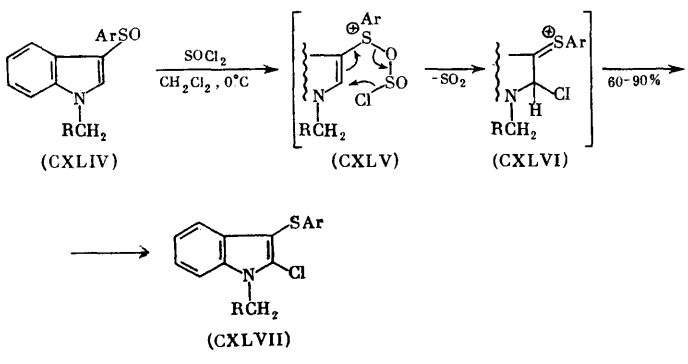
"Activation" of aryl vinyl sulphoxides (CXVII) with chloroketenes which are readily generated from suitable acid chlorides has become the basis of a method that is widely used at the present time to obtain substituted γ-butyrolactones (CXXXVII), including natural products.[84–90] The reaction evidently occurs via the [3,3]rearrangement of the compact zwitterionic PPI (CXXXV) followed by intramolecular cyclisation of the PI (CXXXVI). The relatively high rate of the latter compared to rotation of the C–CS bond accounts for the high enantioselectivity of this process, which makes it possible when using a monosubstituted chloroketene to go from optically active (CXVII) to lactones with three induced chiral centres.[85] The method has been successfully applied to the synthesis of (–)-methyl jasmonate,[86] certain physostigmine alkaloids,[89] and also a series of natural γ-butyrolactones.[87,88,90]



(CXXXV) (CXXXVI)



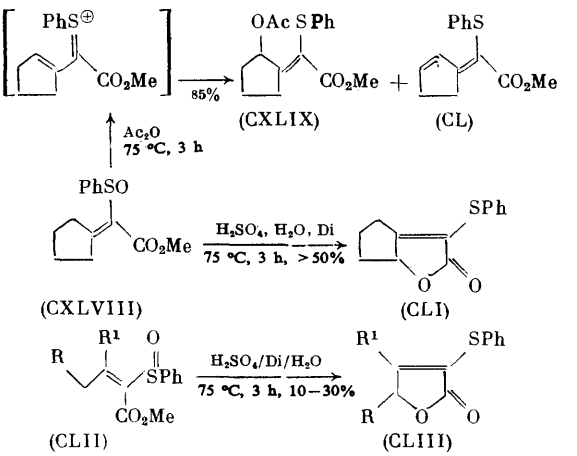
(CXXXVII)



R^1,R^2,R^3 = H, Alk, Bn, Ar

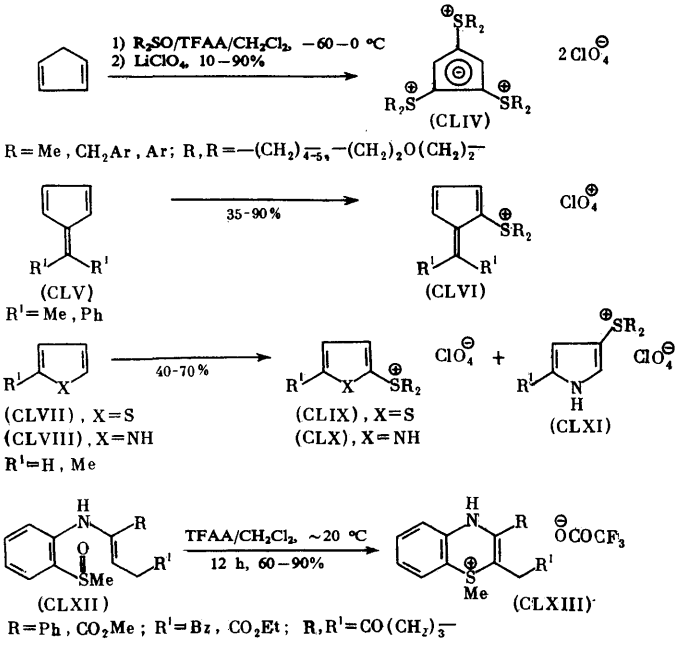
With regard to the possible PR mechanism, one of the ways of stabilising the cationoid PI (CXIX) not included in Scheme 15 may involve a 1,2-shift of the R^2 and R^3 β-substituents. Examples of reactions of this type are for the time being fairly limited, but amongst them special mention should be made of the recently reported skeletal rearrangement of (CXVII) series aryl vinyl sulphoxides to ketosulphides (CXL), induced by TsOH in boiling MeCN and occurring preferentially via the formation of (CXXXVIII) and (CXXXIX)[91] (Scheme 17). The preparation of the halosulphoxides (CXLIII), which are evidently formed via PI (CXLII), under conditions of the Vilsmeier reaction from cephalosporin sulphoxides (CXLI) can be regarded as a specific case.[92] Similarly, the β-indole derivatives of the type (CXLIV), which are formally classed as vinyl sulphoxides, are readily converted by $SOCl_2$, probably via intermediates (CXLV) and (CXLVI), to the α-chloro-β-sulphides (CXLVII).[93,94]

Scheme 17



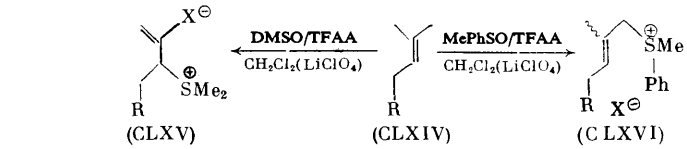
In addition to the routes given above in Scheme 15, the vinyl variant of the PR is illustrated by the conversion of the sulphoxide (CXLVIII) to a mixture of vinyl sulphides in the ratio (CXLIX):(CL) ≃ 3:2 or to the lactone (CLI)[79] (Scheme 18). Similarly, vinyl sulphoxides (CLII) on heating with dilute H_2SO_4 give the dihydrofuranones (CLIII).[79]

Scheme 18



Thus, there is a direct Pummerer route from vinyl sulphoxides to sulphides that are functionalised at the α, β-, and γ-positions.

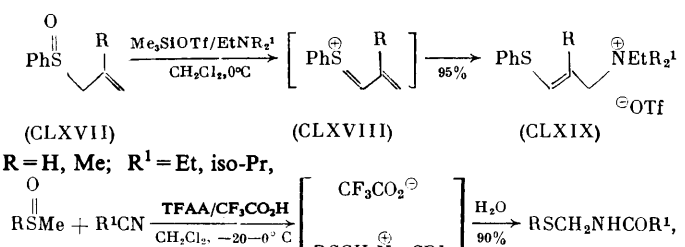
VII. Electrophilic properties of the intermediates of the Pummerer reaction



As mentioned above (Section II), the existence of the probable PR intermediates (II) and (IV)/(IVa), which are classified as weakly electrophilic species, has been indirectly supported by the results of the reaction between sulphoxides and different nucleophiles (external and internal). At the same time recent data provide additional information about the nature of the individual stages of this reaction, extending the possibilities for controlling it, and hence new horizons are opened up in the rapidly developing synthetic organic chemistry of sulphur-containing compounds.

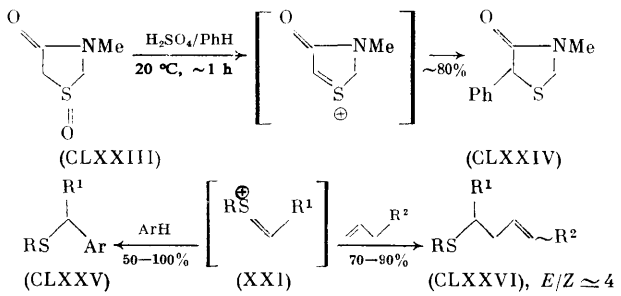
In this respect the recently developed method for the synthesis of stable perchlorates of sulphonium salts from cyclopentadiene and (benzo)fulvenes[95-98] (Scheme 19) is of considerable interest. Thus, low-temperature treatment of sulphoxides "activated" by TFAA with cyclopentadiene or fulvenes (CLV) gives the tris-(CLIV) or mono-sulphonium salts (CLVI) in up to 90% yield, which are evidently formed respectively by attack on PPI of the type (II) by these *C*-nucleophiles. Derivatives of thiophene,[99] pyrrole, and indole[100-102] may fulfil a similar role. In particular, thiophenes (CLVII) are readily converted in this way to perchlorates (CLIX), while pyrroles (CLVIII) are converted to a mixture of the regioisomeric salts (CLX) and (CLXI) that is equilibrated on treatment with a proton acid. An example of the intramolecular interaction of a probable PPI with a reactive C=C bond is the smooth conversion of enaminosulphoxides (CLXII) to trifluoroacetates (CLXIII) by treatment with TFAA.[103]

Scheme 19



Taking into account the above, the recently established possibility of obtaining the fairly stable dimethyl sulphonium salts (CLXV) in this way from unactivated trisubstituted olefins (CLXIV)[104,105] proved unexpected. It was established in this case that this reaction, formally an ene reaction and accelerated by added quantities of $LiClO_4$, is regiospecific in a series of linear isoprenoid oligoolefins and is accompanied by allylic isomerisation with formation of the terminal sulphonium salt (CLXVI) in the case of thioanisole *S*-oxide.

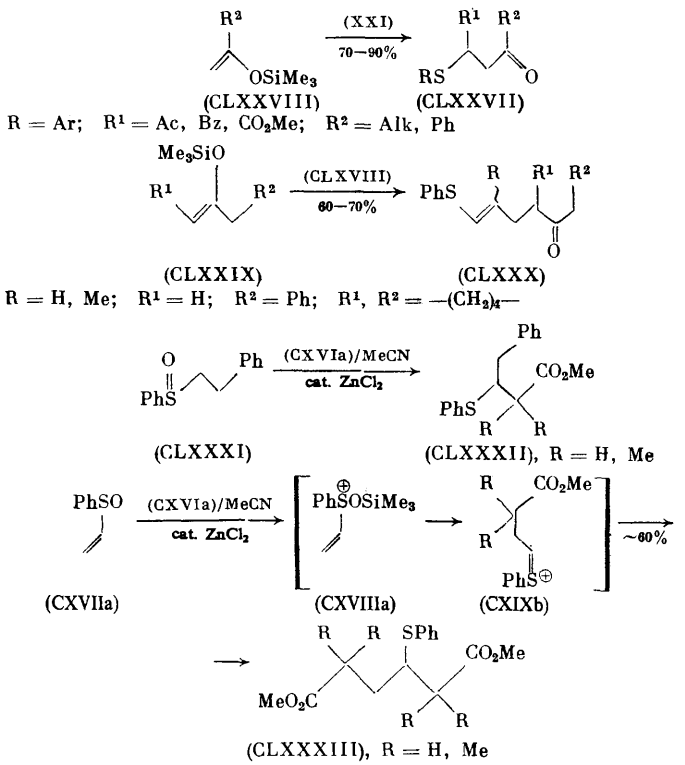
The results of the synthetic application of the electrophilic properties of PR intermediates at the present time have proved much more fruitful in relation to the PI (IV) than to the evidently much more stable PPI (II). In this case inter- and intra-molecular stabilisation of the probable cationoid species (IV) by nucleophiles is now represented equally well and is illustrated below by the derivation of various α-functionalised sulphides from suitable linear and cyclic sulphoxides.



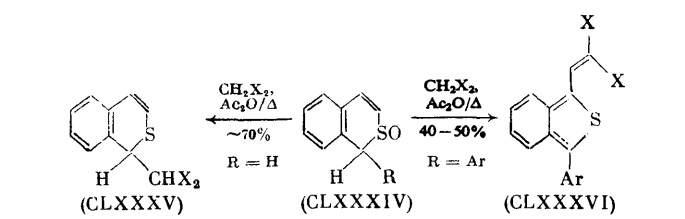
A unique example of this type of intermolecular interaction is the Me_3SiOTf-induced formation of ammonium salts (CLXIX) from allyl sulphoxides (CLXVII) in the presence of tertiary amines, including a Hünig base, which proved to be the only external nucleophiles capable of stabilising the PI (CLXVIII),[106,107] and there is also the Ritter reaction of sulphoxides (CLXX) to amides (CLXXII), which evidently occurs via the formation of nitrile salts (CLXXI)[108] (Scheme 20).

Scheme 20

Recorded cases of the involvement of a PI of the type (IV) in a reaction with external *C*-nucleophiles are much more widespread. Thus, in Scheme 21, the thiazolidine β-ketosulphoxide (CLXXIII) is readily phenylated on treatment with conc. H_2SO_4 in benzene to the ketosulphide (CLXXIV),[109] which is a special case of the (hetero)-arylation of PIs (XXI) that are generated by different methods from linear sulphoxides (XX) and mainly have a β-electron-withdrawing susbtituent, and resulting in products (CLXXV).[110–115] The presence of such a substituent is in no way obligatory for the formation of β-vinyl sulphides (CLXXVI) from PI (XXI) and functionalised terminal alkenes, which occurs quite readily by an ene type of reaction; (CLXXVI) have been successfully used at the key stages of the synthesis of a number of natural products.[116–122]



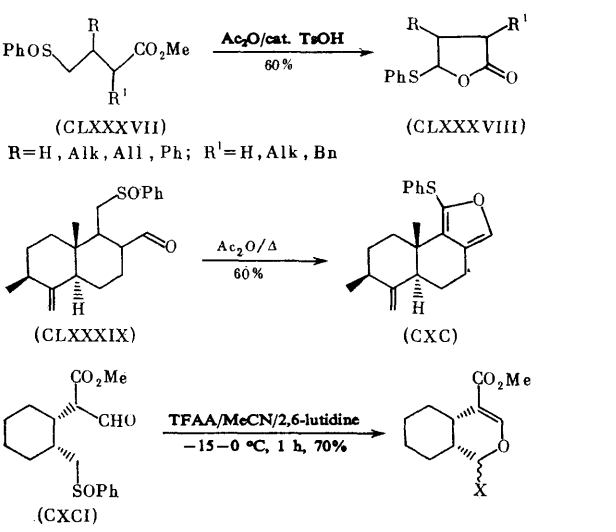
Scheme 21



Of the *C*-nucleophiles that are suitable for intermolecular combination with a PI of the type (VI), particular importance is starting to be attached to silyloxyolefins such as (CLXXVIII) and (CLXXIX) (Scheme 22), which are widely used in current synthetic practice to form a C−C bond by a directed aldol condensation.[63,123] In accordance with this approach, the low-temperature generation of PI (XXI) or (CLXVIII), usually carried out with the involvement of "activator" reagents such as $Sn(OTf)_2$ or Me_3SiOTf in the presence of a Hünig base, bis(trimethylsilyl)(trifluoro)acetamide, or Me_3SiI finally gives the corresponding products of α-*S*-ketoalkylation (CLXXVII)[124,125] or γ-*S*-ketoalkylation (CLXXX).[107,126] Similarly, on treatment with an excess of ketenacetal (CXVIa)—an "activator" and *C*-nucleophile at the same time—the sulphoxide (CLXXXI) is readily converted to sulphide (CLXXXII),[77] evidently as a result of attack on a PI of the type (XXI) by the carbanions of methyl acetate or methyl isobutyrate (c.f. Section V). Under such conditions (CXVIa) and vinyl sulphoxide (CXVIIa) give adduct (CLXXXIII),

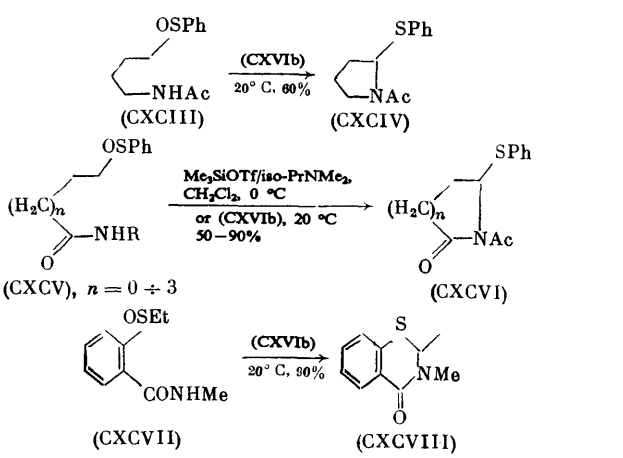
whose formation can only be logically accounted for by the successive reaction of the above carbanions with PPI (CXVIIIa) and PI (CXIXb).[78]

Scheme 22



A familiar method for generating *S*-ylids from sulphoxides and C–H acids[11] in the case of derivatives of benzothiapyrans (CLXXXIV) leads to products of their α-*C*-alkylation (CLXXXV) or ring contraction products—benzothiophenes (CLXXXVI).[127]

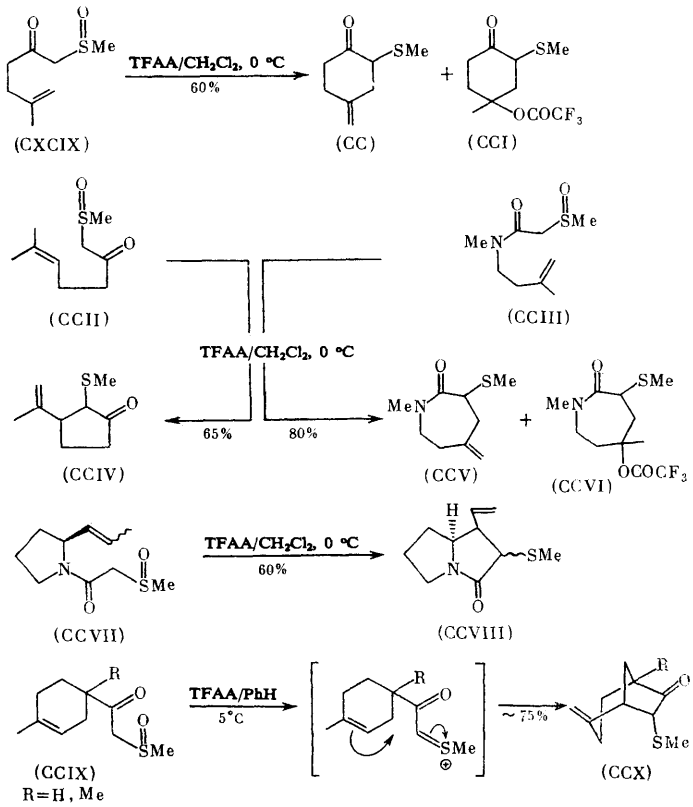
X = Ac, CO_2Et, Bz; Ar = Ph, *o*-BrC_6H_4, *o*-MeC_6H_4, 2, 3, 5, 6-Me_4C_6H



The methods of stabilising PIs of the type (IV) generated *in situ* using internal *O*-, *N*-, or *C*-nucleophiles as predicted from the probable mechanism of the PR open up considerable possibilities for the regiocontrolled synthesis of different heterocyclic and carbocyclic structures from suitable precursors. The conversions of γ-sulphinylcarboxylate esters (CLXXXVII) to lactones (CLXXXVIII),[128] aldehyde (CLXXXIX) to furan (CXC),[129] and sulphoxide (CXCI) to a mixture of (CXCIIa) and (CXCIIb) in the ratio ≃ 1:4, which is subsequently used in the synthesis of the iridoid aglycone of sweroside,[130] can be given as examples (Scheme 23).

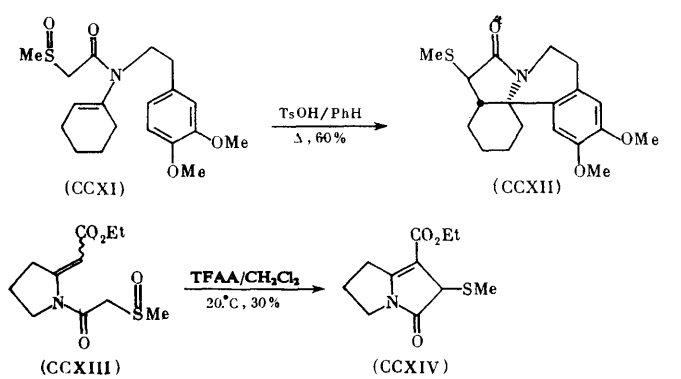
Scheme 23

Of *N*-nucleophilic functional groups that are capable of undergoing an intramolecular reaction with a PI, the only known example up to the present time is the amide group.[131–135] For example, in Scheme 24, the amidosulphoxide (CXCIII) in the presence of ketenacetal (CXVIb) readily gives the pyrrolidine derivative (CXCIV),[134] whereas sulphinylamides (CXCV) are readily converted under mild conditions to the heterocyclic sulphides (CXCVI). Treatment of the optically active sulphoxide (CXCV) (*n* = 0, R = H) with Me_3SiOTf gives the corresponding chiral lactam (CXCVI) with an enantiomeric purity of 70%.[132] By using ketenacetals (CXVIb) in the case of (CXCVII) it is possible to synthesise the benzothiazine (CXCVIII),[134] which is unobtainable when traditional "activators" such as Ac_2O are used.[133]



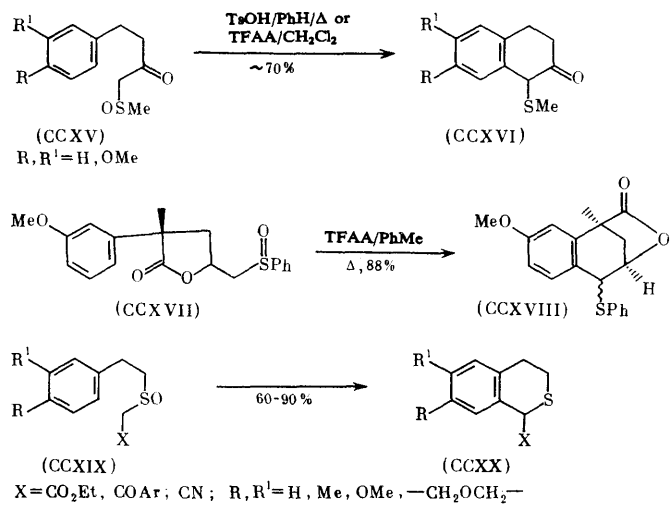
Scheme 24

An unactivated C=C bond within the molecules of unsaturated sulphoxides also can and does serve as a nucleophilic residue that participates in the stabilisation of the corresponding PI, and in all of the known examples this variant of the PR requires β-ketosulphinyl substrates.[136–141] Thus, in Scheme 25, the keto derivative (CXCIX) can be readily converted to the mixture of cyclohexane



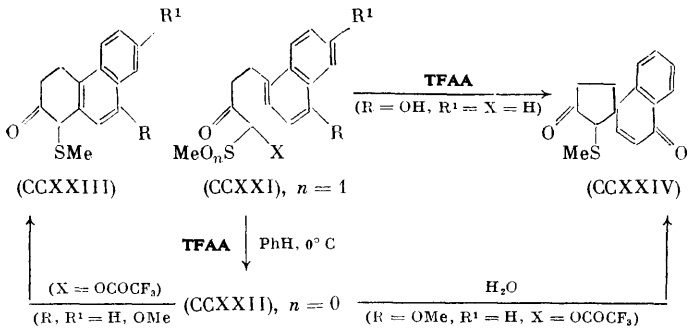
α-ketosulphides (CC) and (CCI).[138] The five-membered product (CCIV) (*cis*:*trans* ≃ 2:1)[138] and seven-membered (CCV) and (CCVI)[139] are obtained from sulphoxides (CCII) and (CCIII) by the same method. The bicyclic compounds (CCVIII)[140] and (CCX)[141] are prepared in high yield by electrophilic cyclisation of the precursors (CCVII) and (CCIX) respectively.

Scheme 25



The results of cyclisation of sulphinyl derivatives of enamides by the Pummerer reaction, such as the reactions of (CCXI)[142–145] and (CCXIII)[146] to the erythrinan (CCXII) and pyrrolizidine (CCXIV) respectively, indicate that an increase in nucleophilic capacity of an internal C=C bond is not always accompanied by an increase in the efficiency of the process (Scheme 26).

Scheme 26

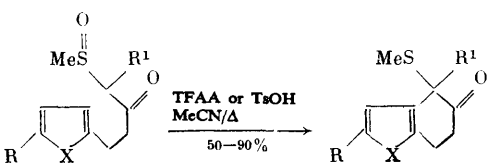


In addition to those reactions considered above, a large number of possible variants of the intramolecular stabilisation of PIs generated by various methods involving a (hetero)aromatic residue of the initial molecule have been reported. Thus, the well-established[147,148] cyclisation of aromatic ketosulphoxides of the type (CCXV) to tetralones (CCXVI) (Scheme 27) has now been considerably extended through examples of the synthesis of related five-, six-, and seven-membered bi- and tri-cyclic structures.[149–153] In particular, the conversion of the phenyl sulphoxide (CCXVII) to the tricyclic lactone (CCXVIII) is used as the basis of the enantio-controlled synthesis of (+)-aphanorphine.[153] The series of benzothiopyrans (CCXX) is prepared in a similar manner from sulphoxides (CCXIX) and a number of their derivatives.[154–158]

Scheme 27

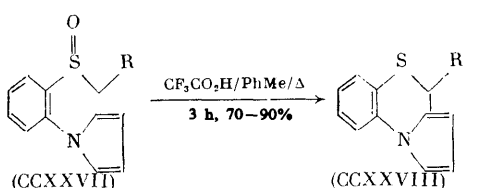
In principle, cyclisation of the above ketosulphoxides induced by carboxylic anhydrides can occur, as a result of equilibrium (*4*) (Scheme 1), with the involvement of *gem*-acyloxysulphides of the type (V) (Z = OCOR) as kinetically independent species. This is quite extensively used (c.f. Section III) for the formation of a C–C bond based on stable *gem*-derivatives of this series,[159,160] and in particular for the two-stage preparation of these cyclisation products.[112–122,136–141] During the direct cyclisation of keto-sulphoxides, *gem*-derivatives of the type (V) can sometimes be isolated[136–141] or detected spectroscopically. Thus, in Scheme 28,[149] analysis of a mixture of (CCXXI) (X = H) and TFAA by NMR spectroscopy indicates that there is a rapid formation of the sulphide (CCXXII) (X = $OCOCF_3$), which is then slowly converted to the tricyclic product (CCXXIII). It is worth noting that treatment of the reaction mixture at this stage with 1 mole equivalent of H_2O gives the spirodiketone (CCXXIV), as does the addition of TFAA in benzene to (CCXXI) (R = OH, R^1 = X = H).

Scheme 28



(CCXXIII) (CCXXI), $n = 1$ (CCXXIV)

(CCXXII), $n = 0$

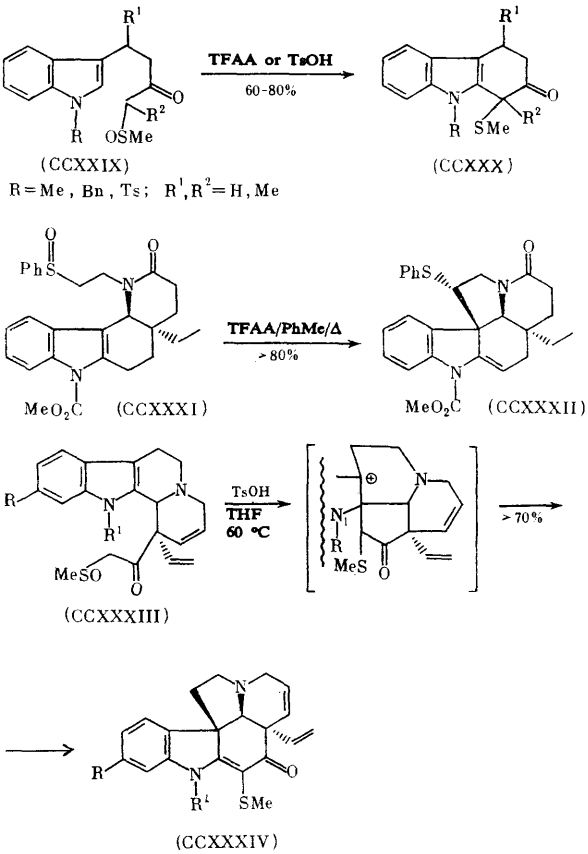


The application of this approach to the synthesis of condensed pyrrole and thiophene derivatives is demonstrated (Scheme 29) by the cyclisation of the precursors (CCXXV) to ketosulphides (CCXXVI) on treatment with different "activating" agents.[161] Similarly, heating of sulphoxides (CCXXVII) with CF_3CO_2H in toluene gives the tricyclic sulphides (CCXXVIII) in high yield.[162]

Scheme 29

(CCXXV) (CCXXVI)

X = NH, S; R = H, Ph; R¹ = H, CONHPh,



(CCXXVII) (CCXXVIII)

R = CO_2Et, Bz, CN.

The use of the PR for the stereoselective synthesis of polyheterocyclic structures such as indole alkaloids has proved extremely productive. As an illustration, Scheme 30 shows the preparation from the bicyclic precursor (CCXXIX) and tetracyclic precursors (CCXXXI) and (CCXXXIII) of the corresponding tricyclic compound (CCXXX) and pentacyclic compounds (CCXXXII) and (CCXXXIV), which act as key products in the total synthesis of olivacine and ellipticine,[161,163] (±)-8-oxotabersonine,[164] vindorosine, and vindoline.[165,166] These reactions have been used as the basis for the recently developed strategy for the total synthesis of other pentacyclic indole alkaloids.[167–171]

Scheme 30

R = H, OMe; R¹ = Me, CH_2OMe

Thus, sulphoxides can be successfully used in the PR for the intra- and inter-molecular variants of forming a C–C, C–N, C–O, and C–S bond, which is difficult to achieve by other methods.

Thus, the PR at the present time is a powerful tool in fine organic chemistry, making it possible to obtain in different ways from various primary and secondary sulphoxides functionalised linear, carbocyclic and heterocyclic sulphides, sulphonium salts, carbonyl compounds, and other classes of organic compounds.

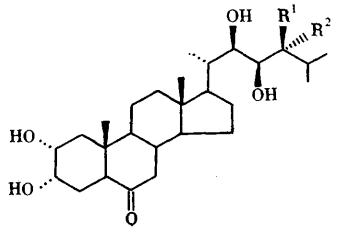
The synthesis of brassinosteroids, a new class of plant hormones

F A Lakhvich, V A Khripach, V N Zhabinskii
Institute of Biorganic Chemistry, Academy of Sciences of the Belorussian SSR, Minsk

ABSTRACT. Data on methods of synthesis of brassinosteroids are correlated. In view of their extremely low reported content in nature, the role of chemical synthesis from other natural steroids as the main source of obtaining these hormones for detailed study and practical use is assessed.



The bibliography contains 224 references.

I. Introduction

Hyopotheses have been expressed many times on the possible hormonal function of steroids in plants because of the numerous functions of steroidal compounds as hormones in man and the higher animals,[1,2] insects[3,4] and certain fungi,[5] and also of their wide distribution in the plant world.[1,3] The first real confirmation of the role of steroids as hormones in higher plants was obtained in 1979 when American scientists established the structure of brassinolide (VIII), a powerful growth stimulant, isolated from rape pollen.[6] Subsequently several compounds, structurally and functionally related to brassinolide, called the brassinosteroids (BS),[7–9] were isolated from various sources and identified, and heralded a new group of phytohormones. Some of these compounds, which today number close to 30, are given below.[10] The ecdysteroids are the closest in structure of the brassinosteroids.[3,4]

brassinone, $R^1=R^2=H$ (I)
castasterone, $R^1=Me$, $R^2=H$ (II)
epicastasterone, $R^1=H$, $R^2=Me$ (III)
homocastasterone, $R^1=Et$, $R^2=H$ (IV)
dolichosterone, $R^1R^2=CH_2$ (V)
homodolichosterone, $R^1R^2=CHMe$ (VI)

norbrassinolide, $R^1=R^2=H$ (VII)
brassinolide, $R^1=Me$, $R^2=H$ (VIII)
epibrassinolide, $R^1=H$, $R^2=Me$ (IX)
homobrassinolide, $R^1=Et$, $R^2=H$ (X)
dolicholide, $R^1R^2=CH_2$ (XI)
homodolicholide, $R^1R^2=CHMe$ (XII)

Features of the chemical structure of BS are the presence of 2α,3α- and (22*R*, 23*R*) diol groupings, a *trans* junction of rings A and B, and a 6-keto group [compounds (I)–(VI)] or a lactone function in ring B [compounds (VII)–(XII)]. Certain compounds do not contain some of the above groupings and are probably biosynthetic precursors of the corresponding BS with a complete set of functions. Compounds with an additional methyl group at C-25 have also been isolated.

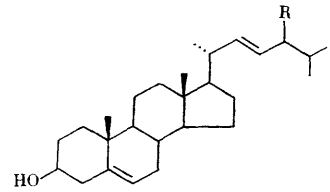
In view of the extremely low BS content reported in plants (10^{-5}–10^{-12}%) and the short period in which they have been investigated, it must be assumed that the inventory of natural products of this type is far from complete. For the same reason it is difficult to judge at present the real distribution of BS in various plants. At the same time it follows quite unequivocally from the available data that the method of isolation from natural raw material cannot be considered as a practical route for providing the BS required for their study and possible use in plant culture. Individual attempts to make this approach of practical value have not changed the overall position.[11–13] This explains the wide range of investigations on BS synthesis begun in various countries directly after establishment of the brassinolide structure. Up to the present time several schemes have been developed for the partial synthesis of BS from other groups of natural steroids. Total synthesis is obviously only of theoretical interest since it requires the formation of the exceptionally complex stereochemistry of these considered compounds which contain 11–13 chiral centres in the molecule. It must be emphasised that even a partial synthesis is an extremely complex task particularly when forming the polyfunctional side chain.

Widespread investigations on the synthesis of BS have led to the publication of a large number of papers devoted to this problem, including several reviews.[7,8,14–28] In addition the rapid

accumulation of new information and the limited availability of the majority of foreign reviews, coupled with the lack of them in the domestic literature, has made preparation of the present review urgent.

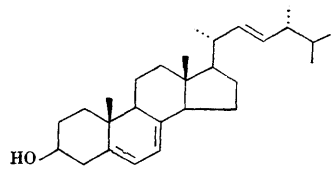
II. General principles characteristic of syntheses of the natural brassinosteroids

Any scheme for the synthesis of BS may be divided provisionally into two parts, (a) the formation of the structural elements of the tetracyclic nucleus characteristic of BS and (b) construction of the side chain of the molecule. For the first time investigators have encountered the need to construct a polyfunctional side chain containing 4 asymmetric carbon atoms (a task only known in the case of the steroids, however that is simpler) and the traditional steroid chemistry methods developed during investigations on ecdysone synthesis may be used to functionalise the cyclic portion of the molecule.



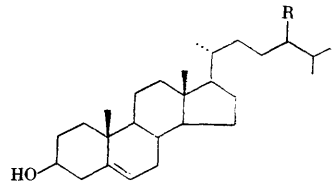
When solving problems of the strategy and tactics of BS synthesis, particularly for practical use, it is necessary to consider several circumstances, primarily the level of growth stimulating activity of a BS, its relative synthetic availability and sources of steroid raw material. The most acceptable starting materials are the available natural steroids containing a Δ^{22}-bond in the side chain, such as stigmasterol (XVI) and ergosterol (XVII). The available cholesterol (XVIII) and β-sitosterol (XIX), which do not contain such a bond, enable the preparation only of BS analogues with a non-functional side chain, possessing as a rule comparatively little activity. The use of 22-dehydrocampesterol (XIV) and brassicasterol (XV) is extremely attractive. These have recently become commercially available due to the development of efficient methods for their isolation.[29–33] Other possibilities are linked with the use as starting materials of cholic acid derivatives such as hyodeoxycholic acid (XX) and steroids of the pregnane series, particularly pregnenolone (XXI) which is used in the pharmaceutical industry for making drugs.

Depending on the starting materials used and the target products all the synthetic schemes may be divided into two large groups:

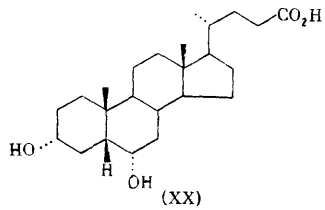


— syntheses retaining the native carbon skeleton of the starting material,

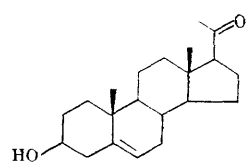
— syntheses forming new carbon–carbon bonds in the side chain.



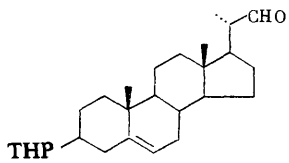
It is obvious that syntheses of the first group are simpler and more economical since no changes are required in the carbon skeleton. In addition the possibilities of using this approach are limited by the availability of sterols having the required carbon skeleton and functionality enabling construction of all the structural elements of the desired compound to be effected. For example the comparative availability of ergosterol and stigmasterol requires only direct functionalisation of the starting material, without breaking and forming new C–C bonds, in syntheses of epibrassinolide and homobrassinolide respectively. At the same time due to the limited availabity of 22-dehydrocampestrol (XIV), which possesses the appropriate carbon skeleton, the main method for the synthesis of brassinolide is still the conversion of stigmasterol into the 22-aldehyde [for example compounds (XXII) and (XXIII)] by fission of the $C_{22}-C_{23}$ bond and subsequent introduction of the $C_{23}-C_{28}$ fragment. Depending on the starting material, other variants of constructing the side chain of brassinolide include the introduction of $C_{22}-C_{28}$ or $C_{24}-C_{28}$ fragments (in the case of initial steroids of the pregnane series or the C_{23} series respectively)



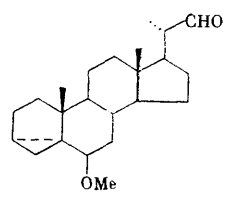
22-dehydrocholesterol, R = H (XIII)
22-dehydrocampesterol, R = α-Me (XIV)
brassicasterol, R = β-Me (XV)
stigmasterol, R = α-Et (XVI)



(XVII)



R = H (XVIII)
R = α-Et (XIX)



(XX)

(XXI)

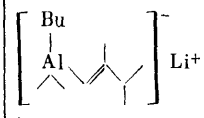
(XXII)

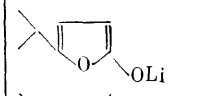
(XXIII)

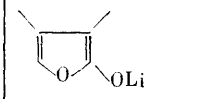
THP = tetrahydropyran-2-yl

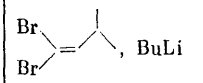
An optimum choice of the sequence of transformations to be carried out in the cyclic portion and the side chain is absolutely essential for the provision of an efficient synthetic scheme, since in many cases the overall yield and number of stages is linked directly to it. Although the choice of variants for constructing structural fragments of the BS molecule is comparatively large, the sequence of using them in a synthetic scheme has paramount importance for the achievement of the maximum positive effect overall. A general illustration of the features and efficiency of the schemes developed for BS synthesis is given in Table 1.

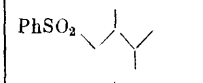
Table 1. Syntheses of the most important natural BS.

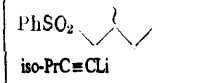


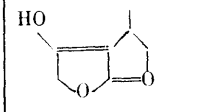


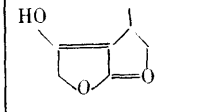


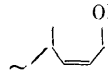


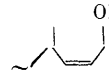


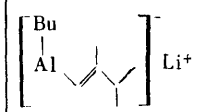


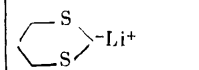


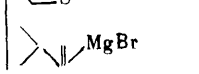


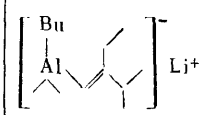


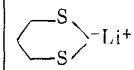


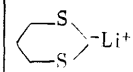












BS	Starting material	Type of synthesis	Method of forming side chain			No. of steps	Overall yield, %	Refs.
			carbon atoms introduced	substrate functional group	reagent

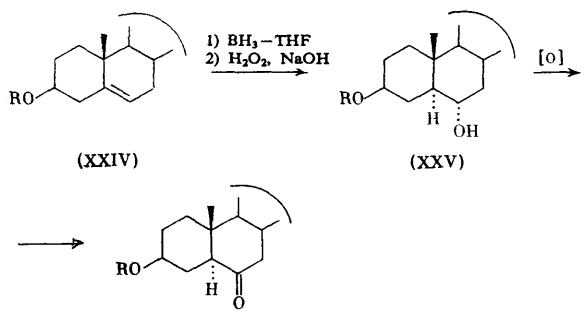
Note. A denotes ring A with preformed functionality; B_o, B_k and B_l denote ring B with 6-hydroxy-, 6-keto- or with the 7-oxa-6-ketc functions respectively; S denotes preformed side chain.

Brassinosteroids belonging to the 6-keto steroid series with a saturated side chain are, in the majority of cases, direct synthetic precursors of the corresponding lactones since Baeyer-Villiger oxidation is particularly convenient after forming all the remaining structural fragments of the molecule. The only exceptions are the $\Delta^{24(28)}$-brassinosteroids in which lactonisation must be effected in one of the synthetic stages before construction of the unsaturated side chain. However, as in the first case, the preparation of steroids of this group, such as dolichosterone (V) [42,63] and homodolichosterone (VI),[42,87,88] differs from the synthesis of the corresponding 7-oxa derivatives (XI) and (XII) only in the absence of the lactonisation stage. The 24(28)-unsaturated BS containing an additional 25-methyl substituent, particularly 25-methyldolichosterone and 25-methyl-2,3,-diepidolichosterone have been obtained by a similar scheme.[89,90]

The synthesis of 6-desoxobrassinosteroids also includes the obligatory stage of obtaining the 6-keto derivatives, the carbonyl function being removed by hydrogenolysis in the concluding stage of the synthesis (in the case of saturated BS) or at the stage preceding the introduction of the unsaturated side chain [in the case of $\Delta^{24(28)}$-BS].[42,91] An example of the first approach in the synthesis of 6-deoxocastasterone[42] by the Huang-Minlon reduction of castasterone (II), and of the second is the preparation of 6-deoxo-dolichosterone via removal of the keto group of the intermediate 2α,3α-diacetoxy-20-methylpregnan-6-one by conversion into the ethylenedithioketal and desulphurisation of the latter with Raney nickel.[42]

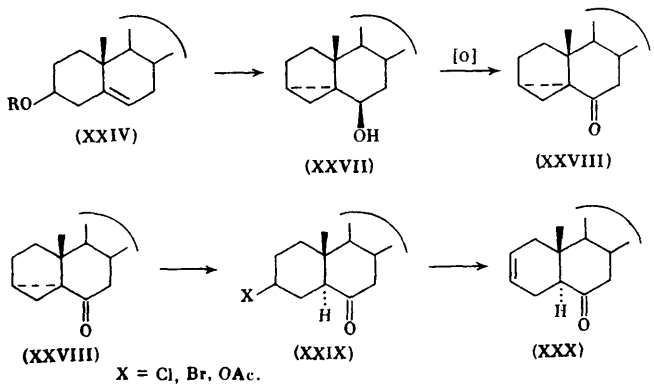
The synthesis of the epimers and related 2-deoxy derivatives differs insignificantly from the preparation of 6-ketobrassinosteroids of the 2α,3α-dihydroxy series. In the case of typhasterol[35,49,58,59]



and teasterone[49,58,59,92] for example the 3-substituted 6-ketones are used directly.

III. Formation of functions characteristic of the cyclic portion of the brassinosteroid molecule

As already mentioned, the main starting materials used for BS synthesis are sterols and derivatives of pregnane and bile acids. In the majority of these compounds there is 3β-OH group and a Δ^5-bond or 5,7-diene system. The presence of the structural elements indicated limits the number of possible methods of forming BS functionality and determines the choice of corresponding transformations of the initial compound.

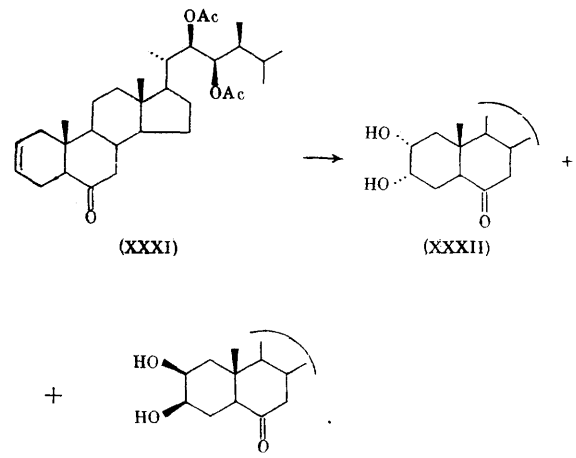


The methods usually used for creating 2α,3α-dihydroxy-6-keto functionality are known from classical steroid chemistry[1] and were later developed and improved during work on the synthesis of ecdysones.[3,4,93] They include as a rule the sequential introduction of the 6-keto group, a Δ^2-bond and its hydroxylation.

One of the methods of obtaining 6-ketones widely used in BS synthesis consists of hydroboration of Δ^5-derivatives (XXIV) with the BH_3–THF complex, oxidation of the resulting trialkylborane with alkaline hydrogen peroxide and subsequent conversion of alcohol (XXV) into ketone (XXVI).[34–36,52–56,82,83]

(XXIV) (XXV) (XXVI)

Another more efficient and universal method, distinguished by its simplicity, consists of using the rearrangement, which is specific for Δ^5-steroids, of the 3-tosyloxy- or 3-mesyloxy derivatives (XXIV) into the cyclic alcohols (XXVII), which are then oxidised to the cycloketones (XXVIII).[39–47,49–51,57–62,65–81,84–87,90,94–95] The presence of a cyclopropane fragment in the latter molecule affords the possibility of conversion into the corresponding 3-substituted 6-ketones (XXIX), for example by fission of the propane ring by hydrochloric,[57,67,96] hydrobromic,[97–102] or by a mixture of acetic and sulphuric acids.[39,49,59,60]

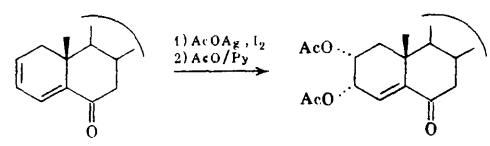


(XXIV) (XXVII) (XXVIII) (XXIX) (XXX)

Subsequent elimination of HX from the molecule of (XXIX, X = Cl, Br) gives the unsaturated ketones (XXX). A similar route comprising fission of the elements of TsOH or MsOH from (XXIX, X = OTs, OMs) may also be used.[39] However it is frequently used in syntheses including hydroboration of the Δ^5-bond.[34–36,52–56,82,83,103]

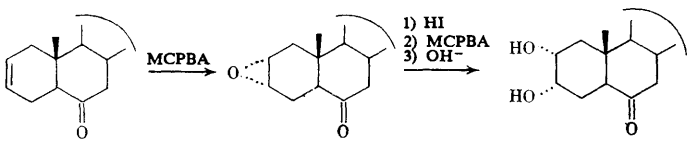
Recently the one-step transformation of the cycloketones (XXVIII) into Δ^2-steroids (XXX) has gained wide usage in syntheses of BS. The method is similar to that developed by Barton[104,105] and later used by other authors in BS synthesis[46,70,71] for the isomerisation of (XXVIII) by TsOH into the sulpholane. Examples are isomerisation by pyridinium hydrobromide,[106] and by sodium[50,107] or lithium[108,109] bromide in the presence of TsOH on boiling in DMF and also the recently proposed method[110] for thermal isomerisation by heating cycloketones in toluene with pyridinium tosylate. A possible mechanism for the reaction has been discussed.[111]

The introduction of 2α,3α-dihydroxy functionality into compound (XXX) is effected by hydroxylation of the Δ^2-bond by a catalytic or equimolar amount of osmium tetroxide[112–114] providing a high yield of α-diols (XXXII).[114]



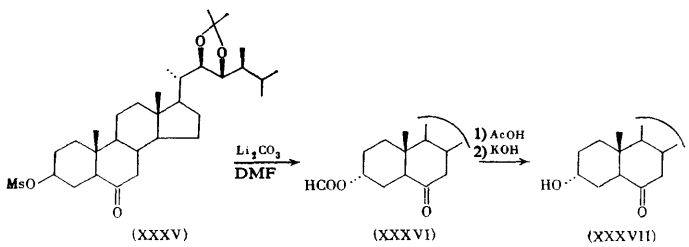
However, the formation of significant quantities of the isomeric dervatives (XXXIII) has been reported in certain cases. For example, diols (XXXII) and (XXXIII) were obtained in 77 and 14% yield respectively on hydroxylation of the enone (XXXI) with a catalytic amount of OsO_4.[49]

(XXXI) (XXXII)

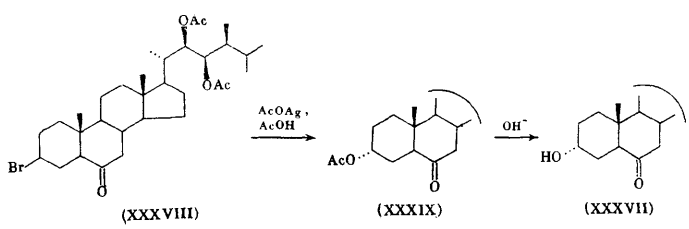


(XXXIII)

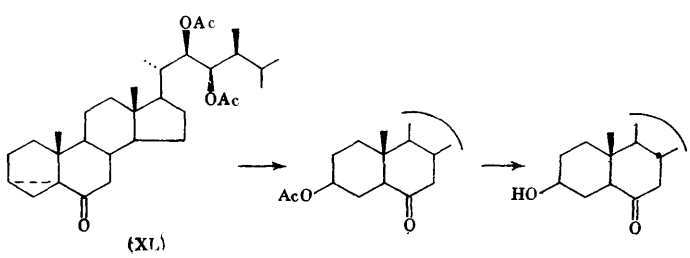
Methods of forming 2,3-dihydroxy functionality in ring *A* without using the expensive and toxic osmium tetroxide are of interest. One of them[115–125] is based on the Woodward hydroxylation of the $\Delta^{2,4}$-6-ketones (XXXIV). The formation of 2α,3α-dihydroxy derivatives, and not their 2β,3β-epimers,. occurs in contrast to the corresponding Δ^2-6-ketones.



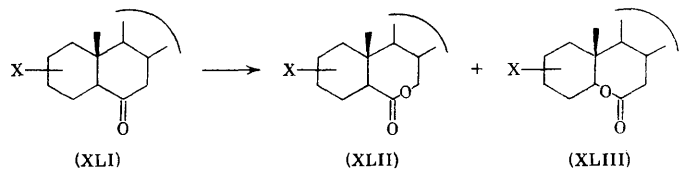
(XXXIV)



The second method consists of epoxidation of Δ^2-6-ketones with m-chloroperbenzoic acid (MCPBA) and subsequent transformation of the epoxide into the diol.

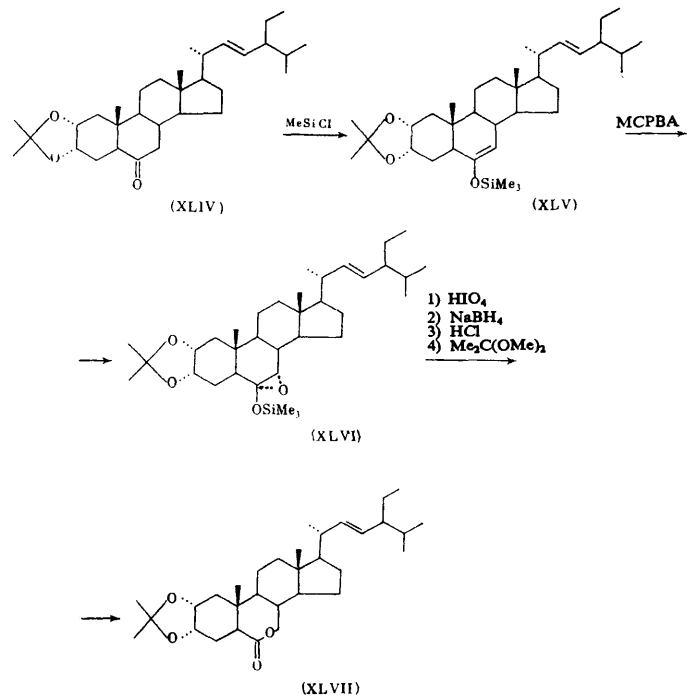


The usual method of obtaining BS of the 2-deoxy series consists of nucleophilic replacement of 3β-mesyloxy- or 3β-bromo-6-keto derivatives with the aim of reversing the configuration at C-3. Treatment of the sulphonate (XXXV) with lithium carbonate in DMF with subsequent boiling of the resulting 3α-formate (XXXVI) in aqueous acetic acid and hydrolysis with aqueous methanolic alkali leads to typhasterone (XXXVII) in 22% yield calculated on (XXXV).[35,59,60]

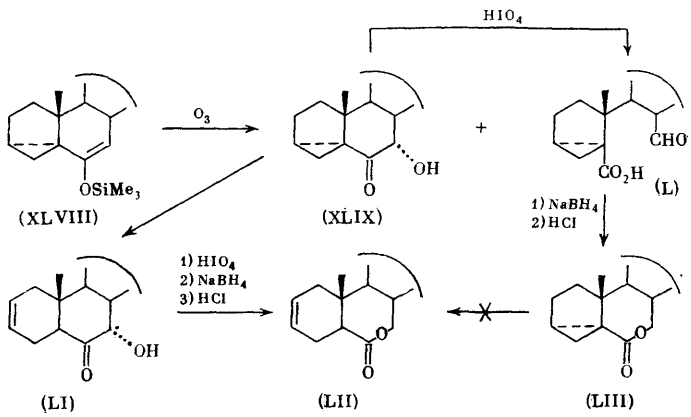


A more effective method, using reaction of the bromide (XXXVIII) with silver acetate in acetic acid and subsequent hydrolysis of the triacetate (XXXIX), gave triol (XXXVII) in 46% overall yield.[49]

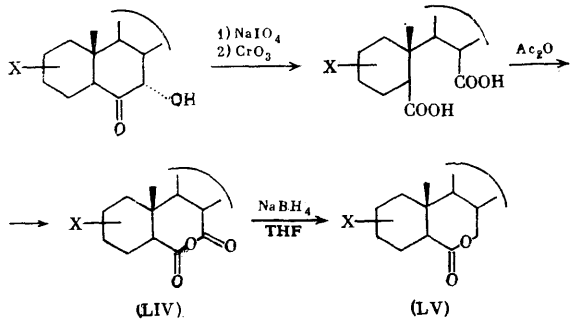
The formation of 2β-6-keto functionality in the synthesis of teasterone was achieved by simple fission of the propane ring in compounds of type (XL) by a mixture of acetic and sulphuric acids[49,59,60] and subsequent alkaline hydrolysis of the acetate group.



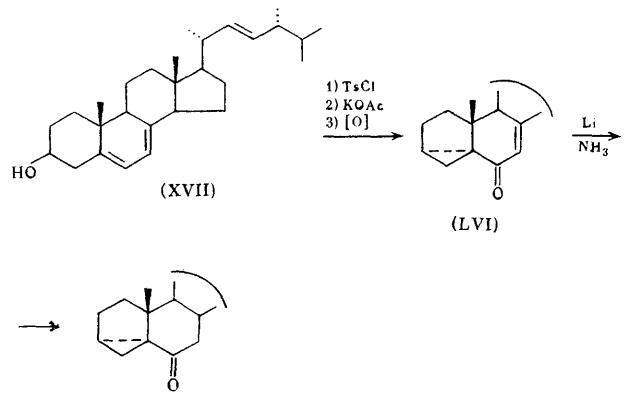
The standard method of introducing a lactone function into ring *B* is the Baeyer-Villiger oxidation of the 6-ketones (XLI) with trifluoroperacetic acid.[7,8,127–130] Since the ratio of the isomers (XLII) and (XLIII) formed depends appreciably on the nature and stereochemistry of the substituents in ring *A* [131] and is greatest in the case of 2α,3α-disubstituted derivatives, the oxidation is carried out, as a rule, as the final step of the synthesis being also linked with the relative lability of the lactone ring.



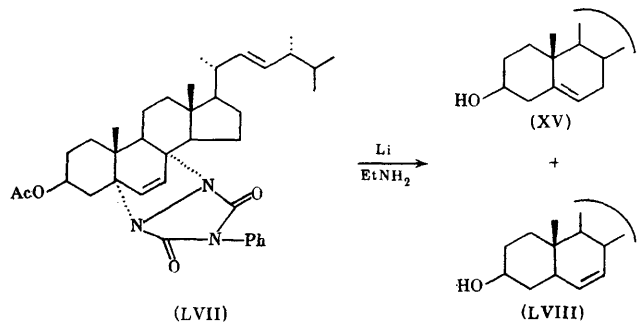
Although the fraction of the required lactones (XLII) is maximal for 2α,3α-diols, protected derivatives (acetates or acetonides) are usually used in the oxidation as a result of which a higher yield of products is achieved and separation of the regioisomers is facilitated. In addition, according to patent data,[132] good results may also be achieved on oxidation of unsubstituted 2α,3α(22*R*,23*R*)-tetraols with trifluoroperacetic acid in the presence of sodium trifluoroacetate. The application of MCPBA as a reagent for obtaining lactones according to Baeyer-Villiger has been reported.[72,79,133]



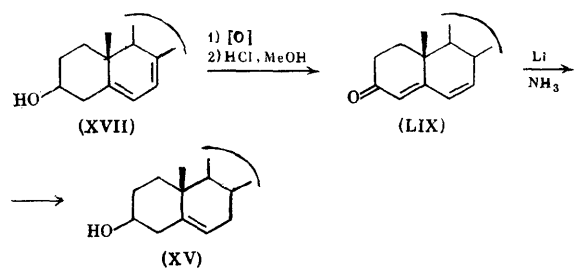
An alternative means of lactonising ring *B* through the silylated enol ether (XLV) obtained from the ketone (XLIV) was developed by Japanese workers in the synthesis of dolicholide.[42] Treatment of ether (XLV) with MCPBA gives epoxide (XLVI) (53%) together with a certain quantity of the 7α-hydroxy-6-ketone (17%). Oxidative fission of the epoxide (XLVI) with periodic acid, subsequent reduction and relactonisation with restoration of the protecting grouping in ring *A* led to lactone (XLVII).



A modification of this approach is the recently proposed method[134] of forming the cyclic portion of brassinolide using ozonolysis of the silylated enol (XLVIII) which leads to a mixture of 7-hydroxy ketones (XLIX) and *B*-seco derivative (L) (depending on the reaction conditions the latter may not be formed). Fission of the hydroxyketones (XLIX) with periodic acid gives the aldehydoacid (L) in quantitative yield, which is then converted by borohydride reduction and acid treatment into the cyclic lactone (LIII). Since all attempts to transform (LIII) into the Δ^2-steroid (LII) proved to be unsuccessful, the latter was synthesised from the unsaturated ketol (LI) by a similar sequence of conversions in 79% yield calculated on ketol (XLIX).



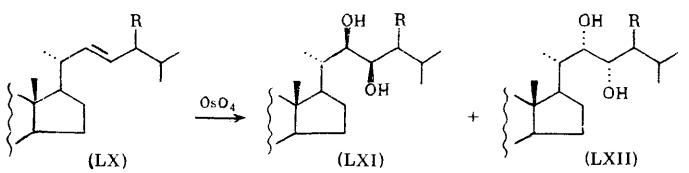
It must be noted that the principle of constructing the lactone fragment by the oxidative degradation of α-ketols of the (XLIX) type into *B*-seco derivatives and subsequent ring closure was proposed for the first time in a study[135] where a related sequence of conversions was carried out and the exceptionally high regioselectivity of the reduction of a carbonyl group in ring *B* of the anhydride (LIV) was shown to provide a high yield of the lactone (LV).



In conclusion it is necessary to mention the features of constructing the cyclic portion of the BS molecule when ergosterol (XVII) acts as starting material. The presence of an additional Δ^7-bond in its ring *B* requires an additional stage for its reduction with subsequent construction of the AB portion of the BS molecule by one of the means considered above. Thus reduction of the cyclic enone (LVI) was effected with lithium in liquid ammonia.[65]

According to another method[67] brassicasterol (XV) was obtained by the reduction of the adduct (LVII) with lithium in ethylamine. The adduct (LVII) was obtained from ergosterol acetate by Diels-Alder addition of 4-phenyl-1,2,4-triazolin-3,5-dione. The resulting mixture of 5,22- and 7,22-dienes (XV) and (LVIII) (3 : 2) was used for the following stage without separation. Different variants of the direct reduction of the ergosterol 5,7-diene system with dissolved metals (Li, Na, K) have been proposed,[69,105,136] and in the second of them attempts were undertaken to clarify the differences in the isomeric content of the products depending on the reaction conditions and the character of the substituent at position 3 of the ergosterol molecule from a mechanistic point of view. The formation of a mixture of Δ^5- and Δ^7-sterols is a drawback to the method described above for the reduction of ergosterol.

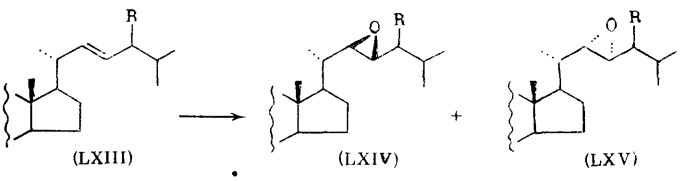
A sequence of reactions has been proposed[137] enabling brassicasterol to be obtained without admixture of its Δ^7-analogue. The Oppenauer oxidation of the hydroxydiene (XVII) and subsequent acidic isomerisation of the $\Delta^{4,7}$-3-ketone leads to the $\Delta^{4,6}$-3-ketone (LIX) which gives brassicasterol (XV) on reduction with Li in liquid ammonia.



In spite of the fact that there is no information in the literature to data on the use of ergosterol in the synthesis of BS by alternative means, i.e. not by reduction but through the *trans*-formation of the Δ^7-bond, such an approach would seem to be extremely interesting.

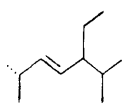
IV. Construction of the side chains of brassinosteroids

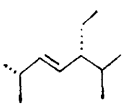
The construction of the side chains of BS is a fairly complex problem for the solution of which it is necessary to develop original methods in addition to using known general principles.[3,4,93,138–140] Depending on the desired and the initial compounds the construction of the chain may be effected without changing or by changing the carbon skeleton of the initial molecule. In the latter case the key step of introducing the chain is usually a nucleophilic addition reaction of a suitable carbanion to a C-22, C-23 or C-24 carbonyl derivative of a steroid. The few examples to date of the use of other reactions to obtain a C–C bond may also be classified according to the number of the atom forming the new bond.

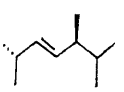


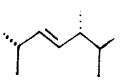
1. Syntheses retaining the carbon skeleton

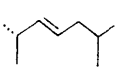
When a side chain with a preformed carbon skeleton is present the problem of obtaining the BS reduces to the construction of the 22,23-diol grouping. The simplest method of introducing this is hydroxylation of a Δ^{22}-bond with osmium tetroxide.





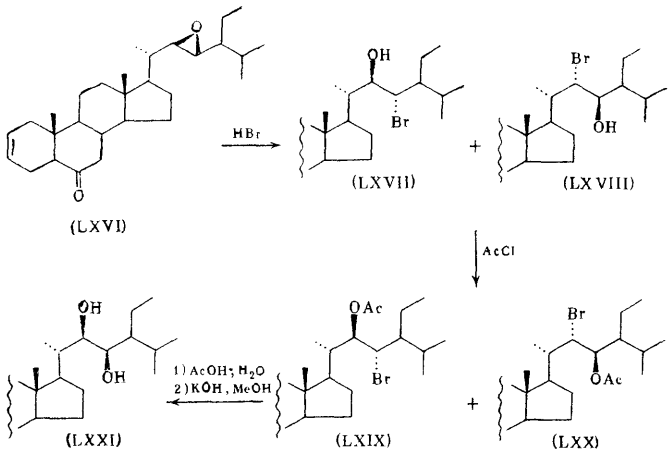






In all cases the reaction leads to the formation of both possible diols (LXI) and (LXII) the ratio of which depends on the size and configuration of the substituent R at C-24 (Table 2). Although the ratio of isomers, as a rule, proves to be unfavourable for the synthesis of the natural BS this route was used repeatedly for their preparation, particularly in the early period of investigations. In addition the method is used widely in the synthesis of the (22*S*,23*S*) analogues of the natural brassinosteroids[39,46,57,97–101,141–149] and is also used in the recently proposed process of isolating[150] 22,23-dihydroxycyclostigmastanones, intermediates for BS, from the mixture of phytosterols of sugar cane. Consideration of the mechanism of hydroxylation and the reasons for the preferential formation of isomers of type (LXII) has been undertaken.[77]

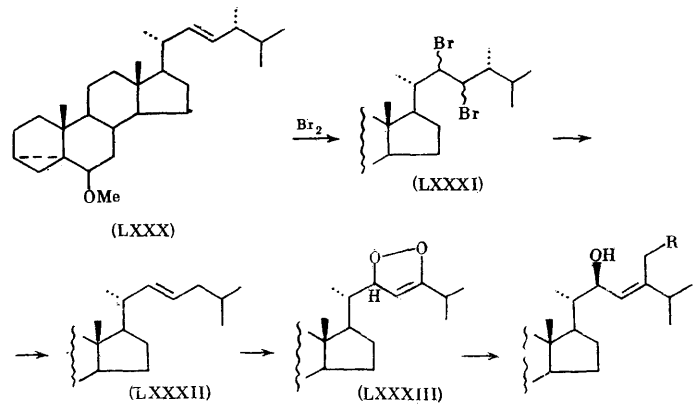
Other stereochemical results were observed in the oxidation of the Δ^{22}-bond with peracids leading to (22*R*,23*R*)-epoxide as the main reaction products.[138,143,151–153] For example on epoxidation of the dehydrocholesterol derivative (LXIII, R = H) the ratio of epoxides (LXIV) and (LXV) was 2:1,[143] and on oxidation of the related derivatives of campesterol (R = α-Me) and stigmasterol (R = α-Et) the ratios of the pairs of isomers (LXIV) and (LXV) were 1.5:1 [46] and 1.1:1 [76] respectively.



The resulting epoxides differ in chromatographic mobility, the (22*R*,23*R*) derivatives being usually less polar. It was shown[154] that ^{13}C NMR spectroscopy may serve as a convenient method for assigning configuration at the C-22 and C-23 centres.

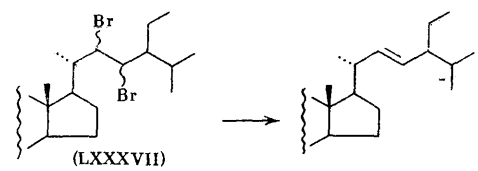
Table 2. Ratio of isomeric diols on hydroxylation of Δ^{22}-steroids with osmium tetroxide.

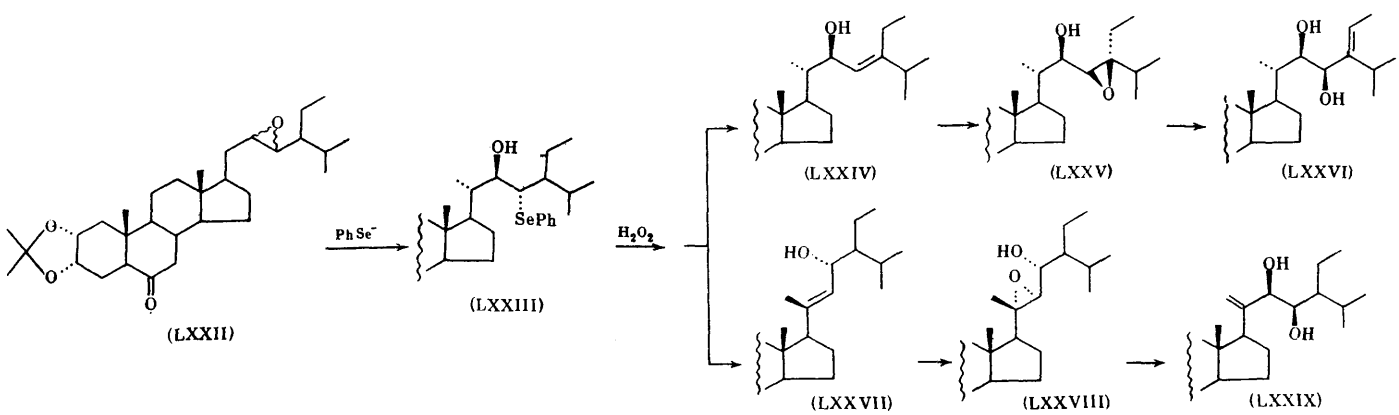
Side chain structure	Ratio (LXI):(LXII)	Refs.
	1:6.7	[133]
	1:2.0	[134]
	1:4.6	[133]
	1:6.5	[57]
	1:1.0	[67, 133]
	1:2.7	[69]
	1:2.4	[112]
	1:2.3	[133]
	1:2.5	[135]
	1:2.3	[133]



The predominant formation of (22*R*,23*R*)-epoxides on reacting Δ^{22}-steroids with peracids enabled a route to be proposed for the synthesis of (22*R*,23*R*)-diols which is more efficient than hydroxylation with OsO_4 and is based on a transformation of the epoxide ring.[46,47,74–78,155] Thus, in order to form the homobrassinolide (X) side chain, the epoxide (LXVI) was treated with HBr giving a mixture of the bromohydrins (LXVII) and (LXVIII). Treatment with acetic anhydride in pyridine led to the acetates (LXIX) and (LXX) the hydrolysis of which with 80% acetic acid at

90–100 °C proceeds with the inversion of the configuration of the carbon atom linked to bromine. The diol (LXXI) was obtained by subsequent deacylation of the hydroxy-acetates.[74,75] The application of this approach provides a fairly efficient route to brassinosteroids of the natural type.

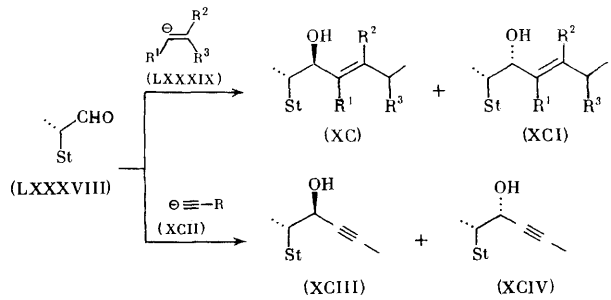




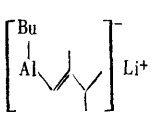
The formation of the C-24 centre with retention of the carbon skeleton of the initial steroid has been described with few examples. This route is used particularly to obtain homodolicholide (XII) and homodolichosterone (VI) from stigmasterol (XVI) through 22,23-epoxides of the (LXXII) type.[79,87] Fission of the epoxide ring of (LXXII) by the phenylselenyl anion, obtained from diphenyl diselenide and sodium borohydride, led to the alcohol (LXXIII) mixed with its regioisomer. Treatment of the mixture with hydrogen peroxide gave an inseparable mixture of the allylic alcohols (LXXIV) and (LXXVII) the epoxidation of which with subsequent treatment of the epoxides (LXXV) and (LXXVIII) with aluminium isopropoxide gave a mixture of the diols (LXXVI) and (LXXIX). After separation of the mixture the diol (LXXVI) was converted into homodolicholide (XII). A similar means of constructing the side chain was used in the synthesis of dolicholide (XI).[156]

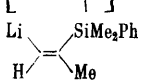
A method of converting the side chain of ergosterol into the 23-ene-22α-hydroxy derivative (LXXXVI), a key intermediate in the synthesis of brassinolide (VIII),[36] has been proposed.[136] It comprises the bromination of the methyl ether (LXXX), subsequent conversion of the dibromide (LXXXI) into diene (LXXXII), treatment of a solution of the diene in pyridine with molecular oxygen and fission of the epoxide (LXXXIII) by hydrogenation over Lindlar catalyst. Removal of the OH group at C-28 in the alcohol (LXXXIV) was effected by conversion of it into the mesylate with subsequent reduction of (LXXXV) with lithium aluminium hydride.

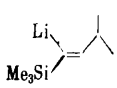
It is interesting that the dibromide (LXXXVII) of the stigmasterol series undergoes debromination under dehydrobromination conditions[157] and this may be used for the protection of the Δ^{22}-bond.[98]

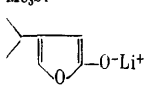


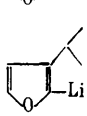
2. Construction of the side chain with the formation of new carbon–carbon bonds











a) Syntheses with the participation of the C-22 centre

The presence of a Δ^{22}-bond in the stigmasterol molecule enables reconstruction of the carbon skeleton to be carried out in the following way. The missing portion of the chain containing the centres C-24, C-25 and C-23 in final form or accessible to the final form is added to a C_{22} fragment (22-aldehyde) obtained for example by ozonolysis of a sterol derivative with a protected Δ^5-bond. In the majority of cases vinyl (LXXXIX) [36,42,61,62,80,81,158–159] or ethynyl (XCII) [34,35,40–45,49–51,57–60,82,160–163] carbanions, obtained from the corresponding organometallic compounds, were used as nucleophiles for addition to the aldehyde (LXXXVIII). In all cases a mixture of the 22α-OH-(XC), (XCIII) and 22β-OH-(XCI), (XCIV) isomers was formed by the reaction

St = steroidal skeleton

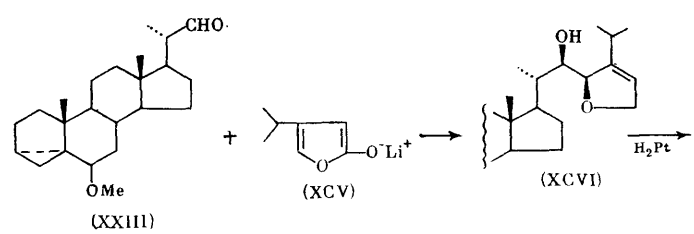


Table 3. Comparative efficiency of reagents in the nucleophilic addition to the 22-aldehyde.

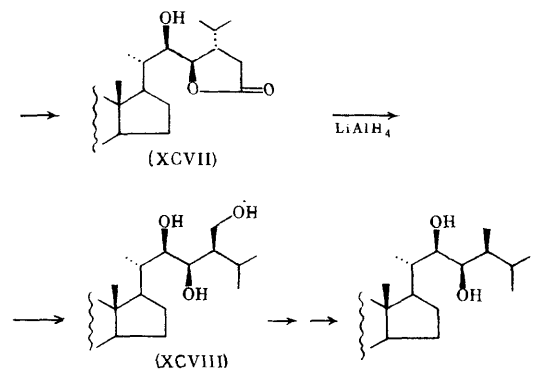

Reagent	Overall Yield, %	Ratio of isomers 22α-OH:22β-OH	Refs.
Li–C≡CPr-iso	76	1:1	[34]
	76	3:2	[35]

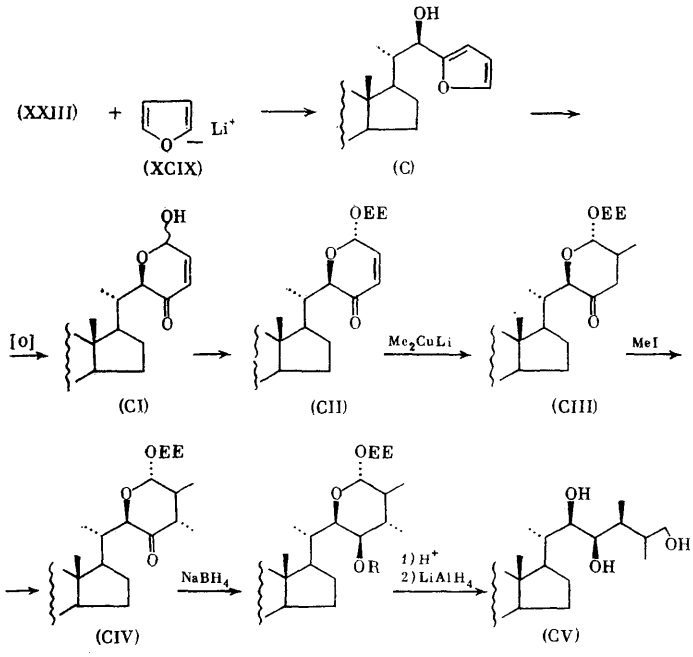
	96	4.5:1	[164]
	99	7:3	[165]
$Me_2CHC{\equiv}CSnBu_3$	78	9:1	[163]

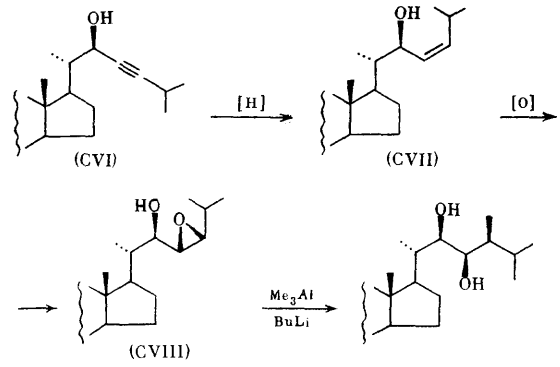
The ratios, yield and the route of further transformations into the desired products is determined by the structure of the nucleophile. Attempts have been undertaken in the course of investigations on the synthesis of BS to optimise the key stage (aldol reaction) by choice of reagent. The comparative efficiency of some of these is given in Table 3.

Among the reagents studied the heterocyclic derivatives provide a high yield and good stereoselectivity for the process and seem extremely promising. In addition the adducts formed in these cases enabled, as a rule, ready transformation into the desired compound through the minimum number of stages. Thus the use of the anion of 3-isopropylbut-2-enolide (XCV) in the reaction with the aldehyde (XXIII) enabled the formation of centres C-22 and C-23 simultaneously with a high stereoselectivity.[37]

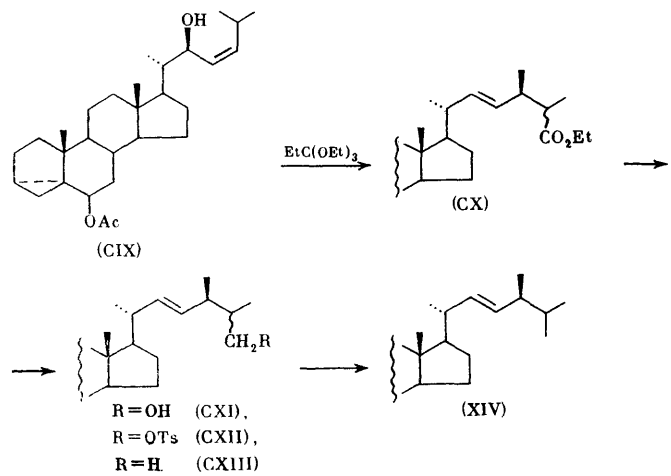


Subsequent reduction of the butenolide intermediate (XCVI) also occurred selectively leading to the (24*S*)-isomer in 78% yield. The reductive fission of lactone (XCVII), protection of the dihydroxy grouping in the trihydroxy derivative (XCVIII), oxidation of the hydroxyl at C-29 into the ketone and decarbonylation completed the formation of the side chain of brassinolide with an overall yield of 32% calculated on aldehyde (XXIII).

A related method of constructing the brassinolide side chain through the lactone (XCVII) obtained by the transformation of adducts of aldehyde (XXIII) with 3-isopropyl-2-lithiofuran has been used.[164] It is characterised by high yield and good selectivity at the addition stage, however it requires a large number of stages for the subsequent transformation into the desired product.



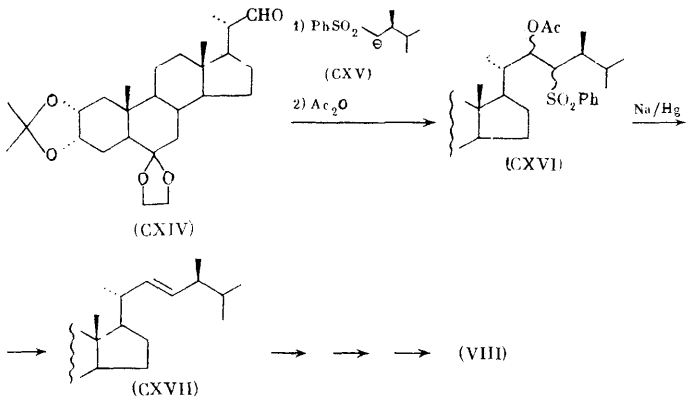
The route based on the use of the 2-lithiofuran (XCIX) is similar to those considered.[165]



The adduct (C) formed in this case was oxidised with *N*-bromosuccinimide to the lactone (CI) as an unseparable mixture of anomers which was converted into a mixture of the corresponding ethoxyethyl ethers with (CII) predominating. The sequence of stages of conjugated addition of lithiummethylcuprate to the enone (CII), α-methylation of ketone (CIII), sodium borohydride reduction of the carbonyl group in the dimethyllactone (CIV) and ring opening gave the triol (CV). Protection of the *vic*-diol grouping and removal of the 27-hydroxy function by hydride reduction of the corresponding mesylate led to the formed side chain of brassinolide in an overall yield of more than 40% calculated on (XXIII).

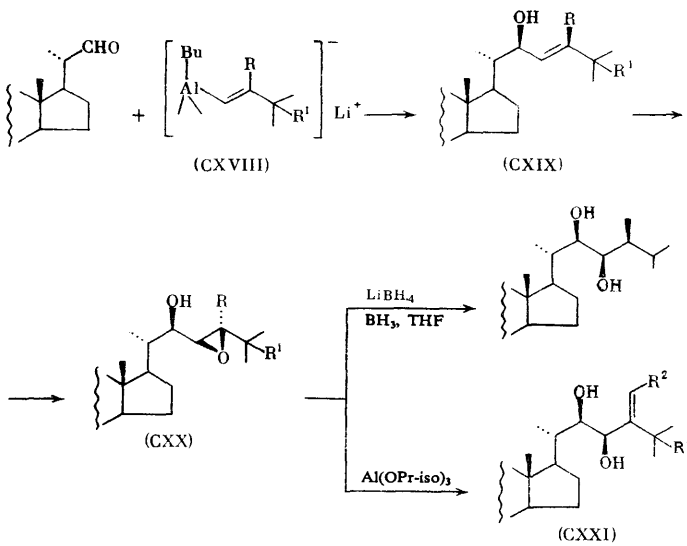
In the syntheses based on the use of the acetylenic alcohols (CVI) the comparatively low stereoselectivity of the stage of adding the acetylides may be partially compensated by converting the by-product 22β-alcohol into the 22α-alcohol by the sequence of stages of oxidation to the ketone and hydride reduction,[35,42] leading to inversion of the configuration at C-22. The usual route of the subsequent conversions includes hydrogenation of the acetylenic alcohols (CVI) over Lindlar catalyst[34,35,57,160] or Raney nickel in the presence of ethylenediamine[42,44] to the *cis*-olefin (CVII), epoxidation of the latter with t-butyl hydroperoxide in the presence of vanadyl acetylacetonate[34–36] or by the action of MCPBA [40–42] and ring opening of the epoxide (CVIII) with trimethylaluminium in the presence of n-butyllithium.[40–45,49–51]

The accomplishment of the last stage is, however, linked with distinct practical difficulties[35] since introduction of the methyl group at position C-24 is sometimes carried out by a complex multistage synthesis[25–34] comprising hydrocyanation of the epoxide (CVIII) and subsequent transformation of the CN group on C-24 into methyl.



Another route for transforming the allylic alcohols (CVII) to the brassinolide side chain is the application of the Claisen rearrangement.[57,58,160] Thus rearrangement of the alcohol (CIX) using triethyl orthopropionate gave a mixture of epimers at C-25 of the ester (CX), the reduction of which led to the corresponding alcohol (CXI). Subsequent tosylation of (CXI) and reduction of the tosylate (CXII) with lithium aluminium hydride gave the cyclic alcohol (CXIII) which was then isomerised into 22-dehydrocampesterol (XIV).[160]

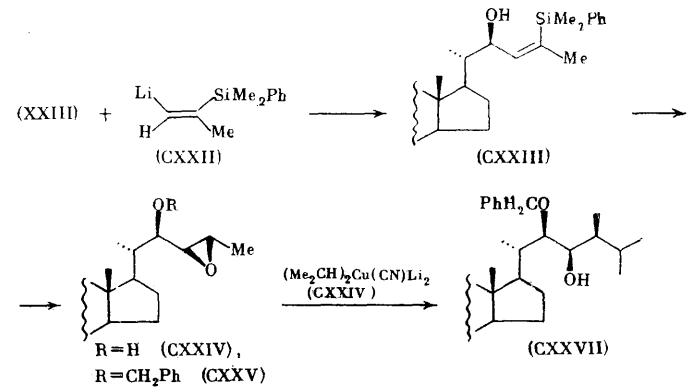
A drawback of this approach to BS synthesis is the need to apply to compound (XIV) the methods considered above for the functionalisation of a side chain with a preformed carbon skeleton which leads to a comparatively low yield of final product with a significant total number of steps (more than 20).



The formation of only one centre at C-24 at the first stage of making the Δ^{22}-derivatives has been used[46–48] and is based on the reaction of anion (CXV), generated from the corresponding sulphone, with aldehyde (CXIV). Acetylation of the product and reduction of the acetoxysulphone (CXVI) with sodium amalgam leads to compound (CXVII), which has the side chain of

22-dehydrocampesterol, and was converted into brassinolide (VIII) through the 22,23-epoxide.

Similar principles may be used to obtain the 28-nor analogues of BS containing no chiral centre at C-24.[48,85]

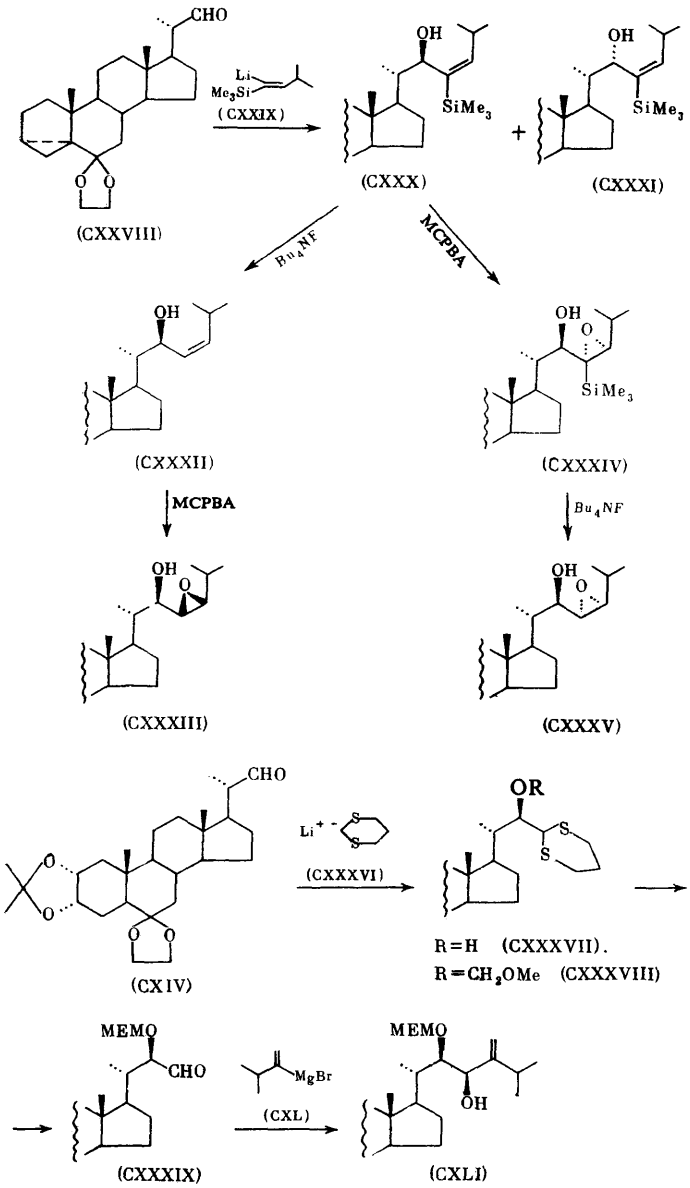


Among the methods using vinyl carbanions the most used are reactions with the lithium alkylaluminium derivatives (CXVIII)[36,42,61,62,80,81] leading to the formation of the Δ^{23}-derivatives (CXIX) as in the case of the allylic alcohols (CVII) considered above.

R=Me, Et; R^1=H, Me; R^2=H, Me

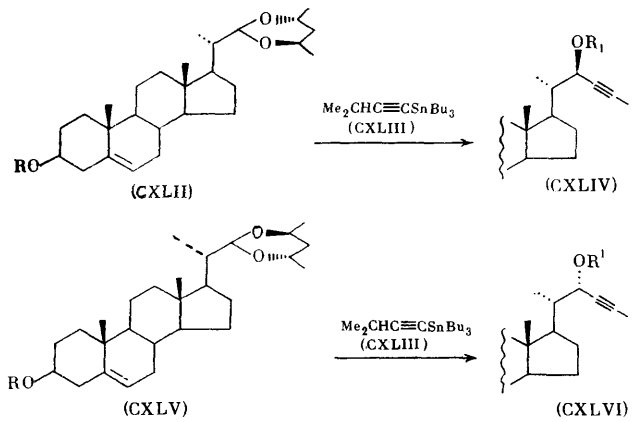
Further transformation is effected by conversion into the 22,23-epoxide and subsequent reductive fission of the oxide ring of (CXX) contrary to the Markownikoff rule leading to the brassinolide side chain.[36] Isomerisation of the epoxides (CXX) on boiling in toluene with aluminium isopropoxide is a convenient method of obtaining the diols (CXXI),[42,61,62,80,81] which are intermediates for 24(28)-unsaturated brassinosteroids.

The vinylsilanes (CXXII) have been shown to be useful in the reaction with the aldehyde (XXIII).[158] Epoxidation of the adduct (CXXIII) with subsequent removal of the dimethylphenylsilyl grouping gives the epoxide (CXXIV). Interaction of the benzyl ether (CXXV) with the mixed cuprate (CXXVI) and subsequent fission of the ether (CXXVII) with lithium in liquid ammonia leads to a diol with a complete brassinolide side chain.



A method of forming the brassinolide side chain using vinylsilanes of type (CXXIX) has been proposed.[159] The presence of a bulky substituent stabilising the carbanion and bonded directly to the anionic centre of the nucleophile enabled a significant increase in the stereoselectivity of the reaction and in the yield of adduct. Thus addition of the anion (CXXIX) to the aldehyde (CXXVIII) proceeds with the formation of the alcohols (CXXX) and (CXXXI) in a ratio of 10:1 in 97% overall yield.

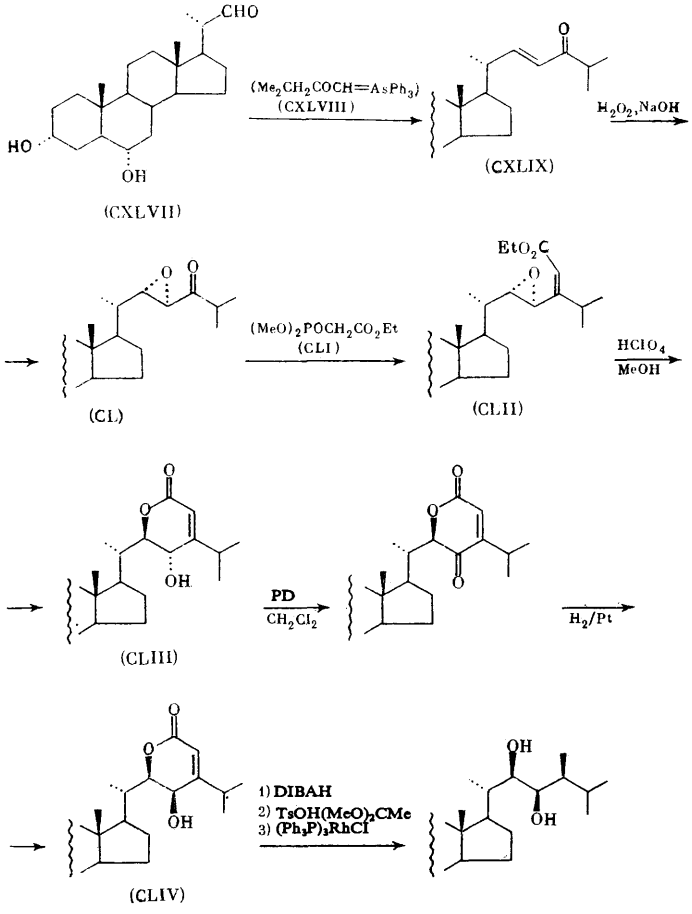
Desilylation of (CXXX) and subsequent epoxidation of (CXXXII) led to the epoxide (CXXXIII) from which the brassinolide side chain may be constructed by the methods described above.[40–45,49–51] A change in the reaction sequence [epoxidation of (CXXX) and then desilylation of (CXXXIV)] led to the isomeric epoxide (CXXXV).



Treatment of the aldehyde (CXIV) with the lithium salt of the dithiane (CXXXVI) in tetrahydrofuran at −20 °C and subsequent protection of the hydroxy group in the adduct (CXXXVII) with chloromethyl methyl ether led to the dithiane (CXXXVIII) in 85% yield. Its dethioacetalation proceeds quantitatively without epimerisation at C-22 and gives the aldehyde (CXXXIX) which was then used for the stereoselective formation of the C-23 centre in the synthesis of dolicholide (XI) and dolichosterone (V)[63,64] by reaction with the Grignard reagent (CXL) obtained from 2-bromo-3-methyl-1-butene. Conversion of the alcohol (CXLI), formed selectively in 73% yield, into the corresponding diol was achieved by the sequential stages of protecting the 23-hydroxy group as the acetate,

hydrolysis with dilute hydrochloric acid, acetylation and saponification of the diacetate with potassium hydroxide solution.

28-Norbrassinolide was synthesised by a similar route using isobutylmagnesium bromide.[63,82,84] The selective addition of vinylstannanes to the 23-aldehyde has been described.[166]

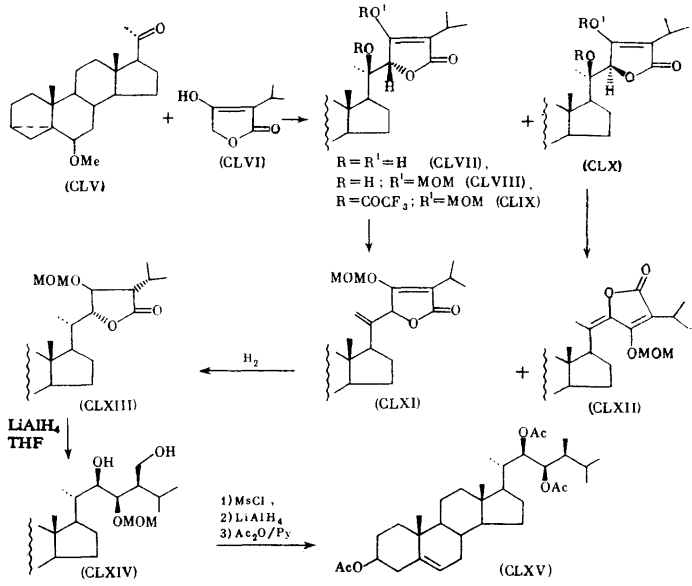


According to patent literature[167,168] an efficient means of influencing the stereochemistry of 22-hydroxy derivatives consists of the use in the addition reaction of the stereoisomeric acetals (CXLII) and (CXLV), which correspond to the aldehyde with added 2-methylpentane-2,4-diol. Their reaction with the acetylide (CXLIII) occurs with high stereoselectivity, leading to an epimeric mixture of the acetylenic derivatives (CXLIV) and (CXLVI) in a ratio of 95:5 and 11:89 for (CXLII) and (CXLV) respectively.

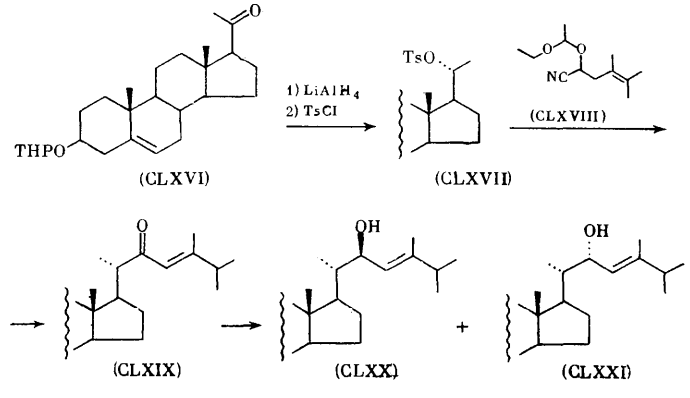
Organoarsenic compounds have been used to form the brassinolide side chain.[169] The aldehyde (CXLVII) obtained from hyodeoxycholic acid (XX) was treated with the ylid (CXLVIII) with the formation of α,β-unsaturated ketone (CXLIX).

Epoxidation of (CXLIX) with alkaline hydrogen peroxide gave the epoxyketone (CL) which, by Wittig-Horner reaction with compound (CLI), was converted into the epoxyester (CLII). The lactone (CLIII) was obtained by acid treatment of (CLII). The natural stereochemistry of the substituent at C-22 was thus formed. Inversion of the configuration at C-23 was achieved by sequential oxidation and reduction of the 23-hydroxyl group. Reduction of (CLIV) with diisobutylaluminium hydride (DIBAH), treatment of the resulting hemiacetal with 2,2-dimethoxypropane and

decarbonylation completed construction of the brassinolide side chain.



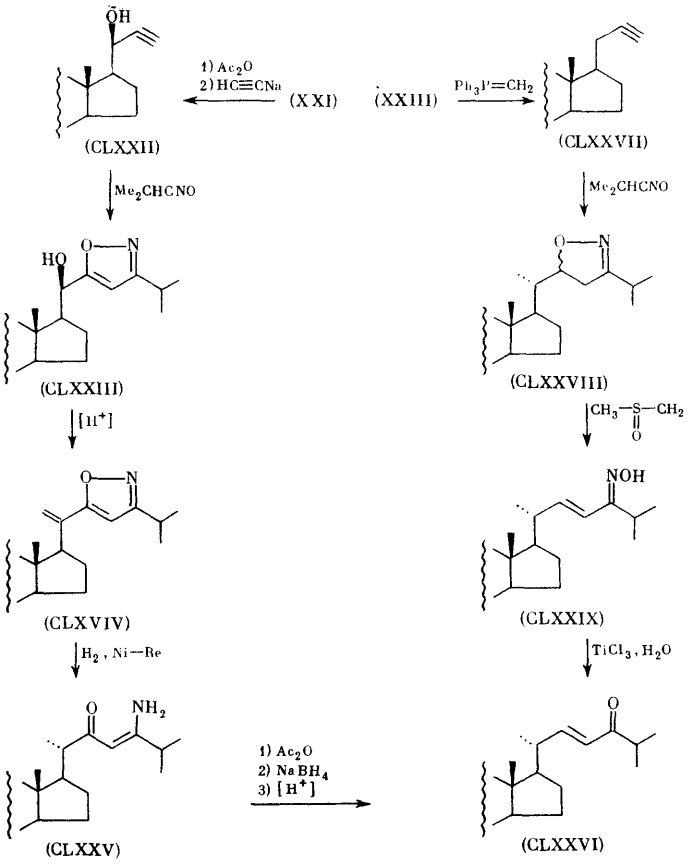
PD = pyridinium dichromate



b) Syntheses with the participation of the C-20 centre

The main part of this section consists of syntheses the key stage of which is the nucleophilic addition reaction of the 3-isopropyltetronic acid anion (CLVI) to a C-20-ketone of the pregnane series (CLV).[52–55] It is interesting to note that the addition succeeds only for the derivatives (CLVII) with an unprotected hydroxyl group and the reaction does not take place in the case of the corresponding methoxymethyl ether. The diol (CLVII), obtained together with a little epimer (CLX) in a ratio of 91:9 in 84% overall yield, is used for further conversions. Protection of the secondary hydroxy group in compound (CLVII) as the methoxymethyl ether and subsequent treatment of (CLVIII) with trifluoroacetic anhydride in the presence of triethylamine and 4-pyrrolidinopyridine led to the acetate (CLIX), which on boiling in benzene with 1,8-diazabicyclo[5,4,0]undec-7-ene gave a mixture of the 5-ylidenetetronates (CLXI) and (CLXII) in a ratio of 82:18 in 73% overall yield. The saturated lactone (CLXIII) was obtained as the main product by catalytic hydrogenation of the main isomer (CLXI). Reductive fission of the ring in compound (CLXIV), removal of the 28-hydroxy group by conversion of the alcohol (CLXIV) into the 28-mesyloxy derivative with subsequent reduction with lithium aluminium hydride and acetylation led to the triacetate (CLXV) in 29% yield [based on (CLV)] which has the brassinolide side chain with protected hydroxyl groups.[52–56] A similar sequence of reactions for the tetronate (CLXII) enabled preparation of a side chain with a 22(*S*),23(*S*),24(*R*) configuration of substituents.

Another route using the 20-ketopregnanes to construct the brassinosteroid side chain, which has been suggested[170] includes conversion of the 20-keto group of pregnenolone (CLXVI) into a (20*R*)-tosyl (CLXVII) and subsequent alkylation of the tosylate (CLXVII) with the protected cyanohydrin (CLXVIII). Reduction of the resulting enone (CLXIX) with diisobutylaluminium hydride leads to the formation of a mixture of the allylic alcohols (CLXX) and (CLXXI) in a ratio of 97:3. Further construction of the brassinolide side chain from allylic alcohol (CLXX) was carried out similarly to that described previously.[136]



MOM – methoxymethyl

The method of constructing steroidal side chains using the nitrile oxide approach[171–181] possesses great potential and may be used successfully in the synthesis of brassinosteroids. Two means of obtaining the Δ^{22}-24-ketone (CLXXVI) from pregnenolone (XXI)

are shown below. The first method comprises the addition of isobutyronitrile oxide to the acetylenic alcohol (CLXXII), dehydration of the alcohol (CLXXIII), hydrogenation of (CLXXIV) and conversion of the enaminoketone (CLXXV) into the Δ^{22}-24-ketone (CLXXVI) by sequential acetylation, borohydride reduction and acid hydrolysis. The route to (CLXXVI) through the isoxazoline (CLXXVIII), obtained from the olefin (CLXXVII) and isobutyronitrile oxide by a 1,3-dipole cycloaddition reaction, is more convenient. Isomerisation of the isoxazoline (CLXXVIII) by base leads to the α,β-unsaturated oxime (CLXXIX), treatment of which titanium trichloride gives (CLXXVI). The use of Δ^{22}-24-ketones in the synthesis of brassinosteroids has been demonstrated[169,182,183]

In addition to the approaches discussed it is also necessary to mention the recently proposed improved methods of obtaining starting and intermediate compounds for the synthesis of BS, including the 20-formyl-[184–186] and 20-carboxypregnanes,[181,187,188] the 22,23-diols and their derivatives[150,189] and a new method of forming the side chain through 17(20)-pregnenes.[190,191]

Simultaneously with the development of investigations on the synthesis of the natural brassinosteroids attempts have been undertaken to obtain biologically active analogues of them differing in the structure of the side chain or of the cyclic portion of the molecule. In some cases as, for example, in the synthesis of epibrassinolide (IX), preparation by the synthetic route[39,69–70] preceded detection of the hormone in nature. The same methods are generally used to make modified BS as for the natural compounds. Up to the present the synthesis of a large number of derivatives has been effected, including compounds with a transformed side chain,[39,46,57,61,97–101,133–140] a modified cyclic fragment[145,192,217–222] or containing modification in both portions of the molecule.[192,207,209–215,223,224] As might be expected compounds are found among the analogues synthesised which are comparable in activity with the natural hormones. This shows the prospect of further search in this direction.

The methods discussed for forming the cyclic portion and the side chains of BS encompass data published up to the present in the scientific and patent literature. In addition investigations in this region continue to develop vigorously which affords the promise in the very short term of original approaches and of a wider application of methods and reactions known and used in other classes of natural products to the synthesis of BS.

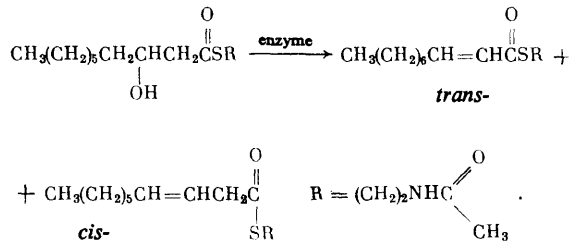
Acetylenic amino acids

S A Abdulganeeva, K B Erzhanov
Institute of Chemical Sciences, Academy of Sciences of the Kazakh SSR, Alma-Ata

ABSTRACT. The methods of synthesis, application, and mechanisms of the biological action of α- and γ-amino acids containing an acetylene residue in the molecule that gives rise to the specific ability of these compounds to deactivate irreversibly certain enzymes are reviewed.



The bibliography includes 96 references.

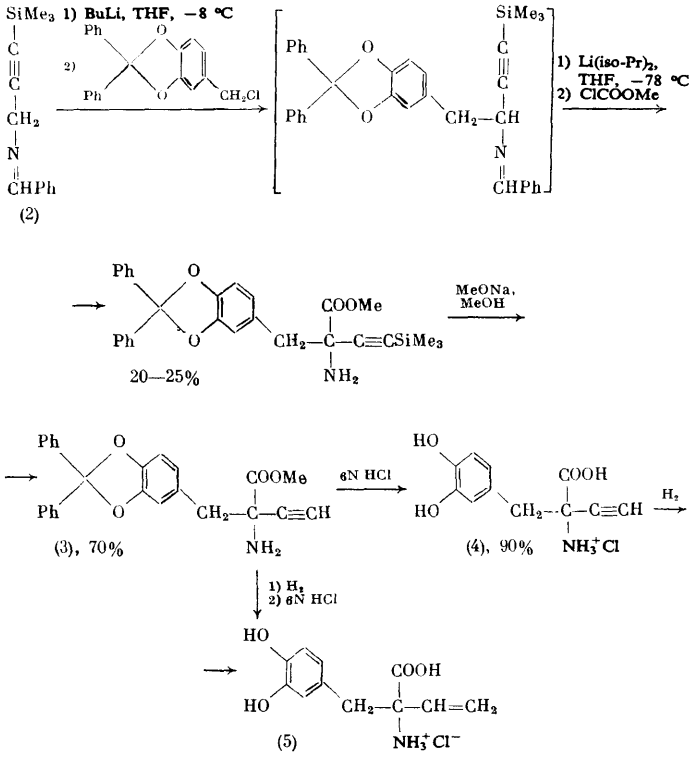
I. Introduction

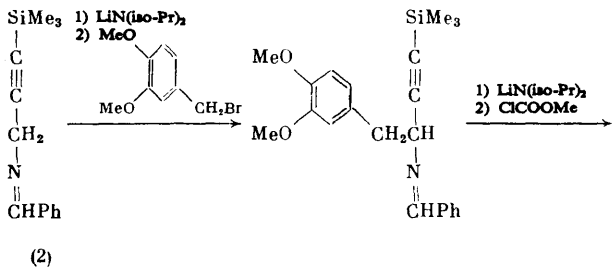
The growing interest in unsaturated amino acids is stimulated by their potential biological activity as specific irreversible enzyme inhibitors. A study of the action mechanism of these inhibitors shows that they contain functional groups which when treated with enzymes form new highly reactive groups. The latter immediately interact with nucleophiles in the active sites of the enzymes, as a result of which covalent compounds are formed between inhibitors and enzymes, leading to inhibition of the activity of the latter. Thus, the enzymes catalyse their own deactivation, which is also known as "suicidal" deactivation, while the compounds that cause the suicidal deactivation are called "suicide substrates".[1–5] It is found that compounds that contain carbon–carbon triple bonds act on enzymes that catalyse isomerisation, oxidation, elimination, and transamination. Thus acetylenic ketones inhibit dehydrogenases and aldolases, acetylenic amines inhibit monoamine oxidases bound to flavin, and acetylenic hydroxyacids inhibit lactate dehydrogenases.[4,6] The fundamental chemical principles of the action of acetylenic compounds appear to be mainly derived from the fact that they can be converted enzymically to conjugated allenes. The latter are strong Michael acceptors, whereas the former are not very chemically reactive.[7] A typical example of highly specific deactivation of this type is the irreversible suppression of β-hydroxydecanoyl thioester dehydratase by 3-decynoyl *N*-acetylcysteamine (1). This enzyme plays an important part in the synthesis of unsaturated fatty acids and catalyses the reversible conversion of hydroxydecanoyl thioesters to α,β-*trans*- and β,γ-*cis*-unsaturated compounds:

On treatment with the enzyme, amide (1) isomerises to an allene which reacts with histidine at the active site of the enzyme, causing the irreversible deactivation of the latter.[8]

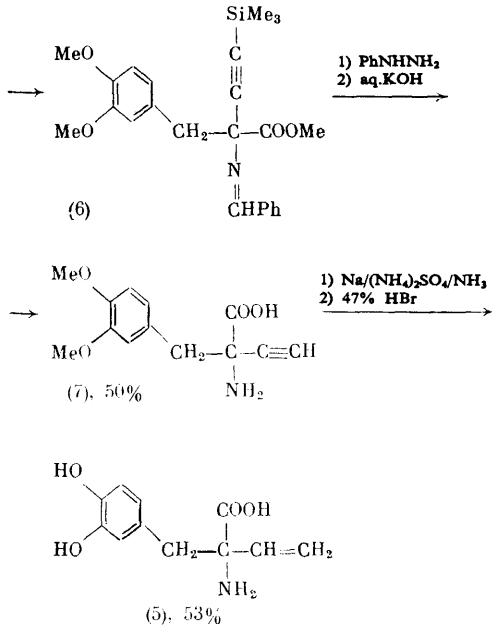


II. α-Amino acids

1. α-Ethynyl-α-amino acids

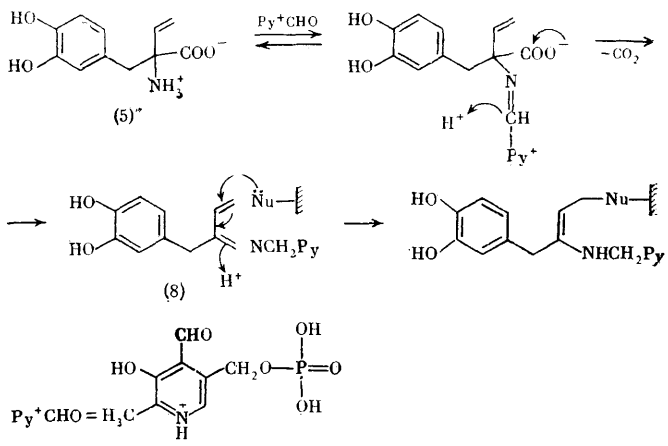


In 1977 α-ethynyl-3,4-dihydroxyphenylalanine (4) and α-vinyl-3,4-dihydroxyphenylalanine (5), which were the first examples of α-substituted α-amino acids with an unsaturated function on the quaternary α-carbon atom, were synthesised.[9] These analogues of dihydroxyphenylalanine (DOPA) proved to be inhibitors of DOPA decarboxylase.

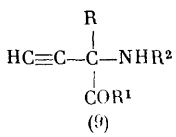


In order to obtain amino acids (4) and (5), Taub and Patchett[9] alternately introduced protected 3,4-dimethoxyphenylmethyl and carboxyl functions into the propargyl synthon (2). A diphenylmethylene group, which is stable during chromatography on silica gel but is readily removed by mild acid treatment, was used to protect the base-sensitive catechol function. After removal of the

protecting groups the acetylenic amino acid (4) was obtained with an overall yield of 13–16% [based on the initial synthon (2)]. On partial hydrogenation of the protected amino ester (3) followed by acid hydrolysis as in the case of (3) → (4) it was possible to obtain the hydrochloride of α-vinyl-α-amino acid (5) with a yield of about 70% [based on amino ester (3)].

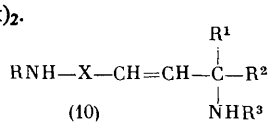


At almost the same time Metcalf and Jung reported[10] their own variant of the synthesis of amino acids (4) and (5), which differed from the above in that the regioselective alkylation of aldimine (2) was carried out with 3,4-dimethoxybenzyl bromide. In order to generate an anion from aldimine (2) use was made of lithium diisopropylamide, which can avoid the dialkylation that occurs to a considerable degree when n-butyllithium is used as the base. The benzyl and trimethylsilyl protecting groups were removed by successive treatment of the imine ester (6) with phenylhydrazine and an aqueous solution of potassium hydroxide. The acetylenic amino acid (7), which was obtained with a 50% overall yield based on 3,4-dimethoxybenzyl bromide, was subsequently reduced with sodamide and treated with 47% hydrobromic acid, and after neutralisation α-vinyl-DOPA (5) was isolated.



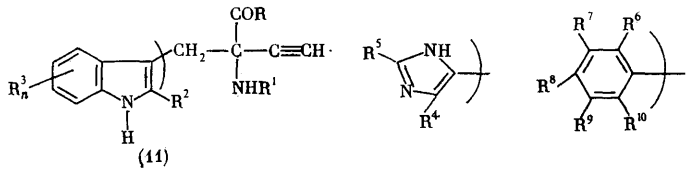
By using 3,4-isopropylidenedioxybenzyl bromide instead of 3,4-dimethoxybenzyl bromide for the regioselective alkylation of aldimine (2), it was possible to obtain the acetylenic amino acid (4) with an overall yield of 24%.

Metcalf and Jung[10] examined the possible mechanism of deactivation of DOPA decarboxylase by β,γ-unsaturated α-amino acids in the case of α-vinyl-DOPA (5). The process is initiated with the formation of a Schiff base between the amino acid and the coenzyme of the decarboxylase—pyridoxal phosphate. After decarboxylation of the Schiff base the vinylimine (8) is formed, which reacts with the nucleophile of the active site of the enzyme to form a strong covalent bond, resulting in irreversible deactivation of the latter. The authors assumed that α-acetylene-DOPA also deactivates the carboxylase by the same mechanism.



By successive alkylation and acylation of the carbanions obtained from 3-trimethylsilylpropyne-2-ylbenzaldimine (2) with various electrophilic reagents, Metcalf et al.[10–24] obtained a large number of α-ethynyl-α-amino acids and their esters, amides, thioesters, thioamides, lactams, and other derivatives (9),[10–16] (10),[17–19]

and (11),[20–24] which can be used as reagents to combat pathogenic viruses, bacteria, and fungae, as stimulants of the nervous systems, antidepressants, tranquillisers, agents for treating Parkinsonism, rheumatoid arthritis, carcinoid syndromes, bronchospasmatic conditions in asthmatics, manic disorders, and other conditions induced by high levels of 5-hydroxytryptamine and other polyamines that play an important part in cell division and growth, since compounds (9)–(11) are irreversible inhibitors of the decarboxylases that participate in the formation of polyamines from the corresponding amino acids.



(9)

R = $MeS(CH_2)_2$, $PhCH_2S(CH_2)_2$, (*S*)-(5-desoxyadenosynyl-5)-*S*-methylthionethyl, $H_2NC(=NH)NH(CH_2)_3$, $R^3NH(CH_2)_n$, $n = 3,4$, R^3 = H, Alk, CO_2Alk, $C(O)CH(NH_2)R^4$, R^4 = H, Alk, CH_2Ph; R^2 = H, C(O)Alk, CO_2Alk; R^1 = OH, OAlk, CO_2Alk, NH_2, $N(Alk)_2$.

(10)

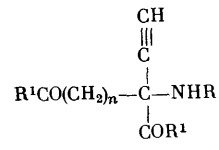
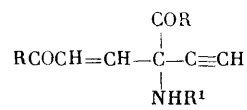
(11)

R = OH, OAlk, NH_2, R^1 = H, C(=O)Alk, CO_2Alk; R^2 = H, Me; R^3 = H, OH, OAlk, CO_2Alk, Hal, Me; $n = 1,2$; R^4, R^5 = H, Hal, $Alk(C_{1-4})$; R^6–R^{10} = H, Me, Et, t-Bu, Cl, F, OR^{11}, R^{11} = H, $Alk(C_{1-8})$, $C(=O)Alk(C_{1-6})$, C(=O)Ph, $C(=O)Alk(C_{1-6})Ph$.



As a continuation of studies on the synthesis and properties of derivatives of α-acetylenic α-aminoacids, Casara and Metcalf[25] developed another general method for their synthesis by regioselective alkylation of a common synthon—the urethane (14), which was readily obtained in 65% yield by amidoalkylation of bis(trimethylsilyl)acetylene (12) under conditions of the Friedel–Crafts reaction.

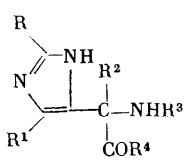
(12) (13) (14), 65%



R = CH_2Ph (75%), $CH_2CH=CH_2$ (70%), $(CH_2)_5Me$ (60%).

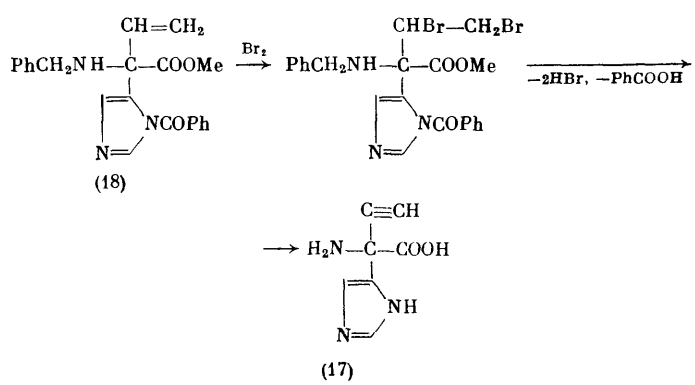
By changing the initial amide (13) and varying the electrophiles (E), Metcalf et al.[26–29] increased the number of amino acids and their derivatives synthesised by the same method to include (15) and (16), which irreversibly inhibit glutamic acid decarboxylase, stimulate the activity of the nervous system, and have bactericidal activity.

(15)



R = H, R^2CO; R^2 = $Alk(C_{1-4})$, $OAlk(C_{1-4})$, H_2NCHR^3CO; R^3 = H, Alk, CH_2Ph, $CH_2C_6H_4$—OH-*n*; R^1 = OH, OAlk, NR^4R^5; R^4 = R^5 = H, Alk, $NHCHR^6CO_2H$; R^6 = H, Alk, CH_2Ph, $CH_2C_6H_4$—OH-*n*; $n = 1 \div 3$.

(16)



R = OH, OAlk, NR^2R^3(R^2, R^3 = H,Alk), $NHCHR^4CO_2H$(R^4 = H, Alk, $CH_2C_6H_4$—OH-*n*); R^1 = H, Alk, CH_2Ph, $CH_2C_6H_4$—OH-*n*.

In synthesising the amino acid derivatives (17), which exhibit antihistamine activity, Metcalf and Jung[30,31] introduced the acetylene function by successive bromination and didehydrobromination of histidine derivatives of amino acids with protected amine and acid functions (18).

(17)

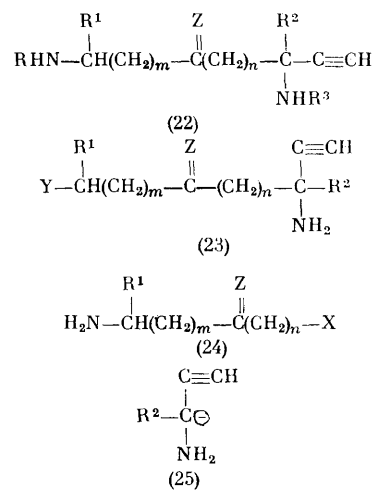
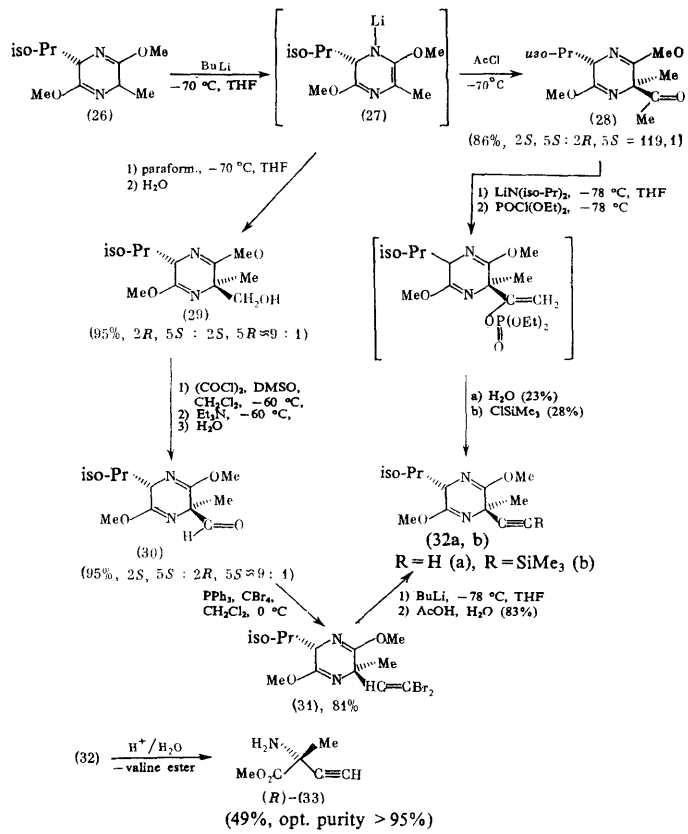
(18)

(17)



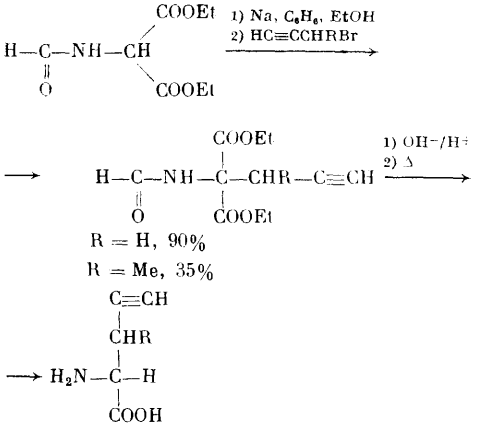
In 1983 Dugat and Verny[32] suggested another approach to derivatives of α-ethynyl-α-amino acids starting from ethyl 2-chloro-2-methyl-3-butynoate (19).

The simplest α-ethynyl-α-amino acid — 2-amino-3-butynoic acid (20), which Metcalf and Jung were not able to obtain[10] — was first isolated by Kuroda et al.[33] in its *L*-form from a cultural liquid of *Streptomyces*, and it is produced by the microorganisms *Streptomyces catenulae*. It appeared to be unstable in aqueous solution so it was isolated and determined by the authors as its acetyl derivative (21).[34] It is an antibiotic that is active towards Gram-positive bacteria and inhibits alanine racemase.



α,δ-Diamino-α-ethynyl-α-amino acids and their derivatives (22), which deactivate amino acid decarboxylase, have been proposed by Gerhard and Van Dorsselaer as antitumour agents.[35]

R = H, $R^4C=O$ (R^4 = Alk, Ph, Ph—Alk), residue of *L*-amino acid, R^1 = H, Alk; *m*, *n* = 0, 1 (*m*+*n* = 1); Z = O, CH_2; R^2 = H, $R^5C=O$ (R^5 = OH, when R = R^3 = H, R^5 = OAlk, NR^6R^7, where R^6, R^7 = H, Alk, residue of *L*-amino acid); R^3 = H (R = H, R^3 = H), $R^4C=O$; Y = Br, Cl, I, TsO, MsO; X = Br, Cl, I.

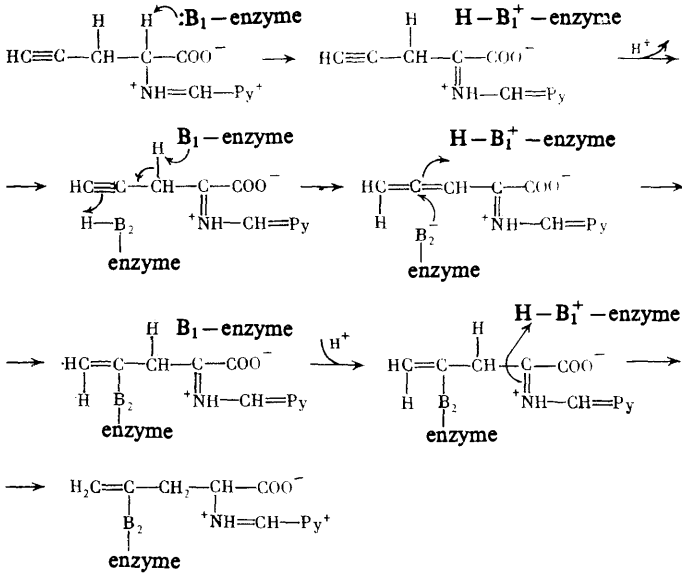


Compound (22) was obtained by either amination of the phthalimide derivatives of compounds (23) with hydrazine or methylamine followed by treatment with strong acid or reaction of amines (24) with the carbanion (25). At the same time the acetylene and amino groups in (23)—(25) were protected in a suitable manner.

In 1988 Schöllkopf et al., starting from the cyclic bislactim diether of *L*-valine and alanine (26), carried out the asymmetric synthesis of (*R*)-α-ethynylalanine (33) — a potential suicidal inhibitor of glutamic acid decarboxylase — in two ways.[36] A key stage of the first method was the regio- and stereo-selective acetylation of the *N*-lithiated ether (27) to the 2-acetyl-2,5-dihydropyridine (28) with a 90% excess of the (2*S*, 5*S*)-enantiomer. Compound (28) was converted by phosphorylation and subsequent hydrolysis or trimethylsilylation to 2-ethynyldihydropyrazines (32a, b), acid hydrolysis of which gave (*R*)-α-ethynylalanine (33) with an overall yield of 10—12% based on the initial ether (26). In the second method treatment of the lithiated bislactim ether (27) with paraformaldehyde followed by hydrolysis gave the alcohol (29) with an optical purity of 90%, which was oxidised with a mixture of oxalyl dichloride and dimethyl sulphoxide to the aldehyde (30). A Wittig reaction of the latter with triphenylphosphine dibromomethylene gave the 2-dibromoethylene-2,5-dihydropyrazine (31), which was converted by dehydrobromination and acid hydrolysis to the 2-ethynyldihydropyrazine (32a) in higher yield but with slightly lower stereoselectivity than in the first case. When the other enantiomer of the initial bislactim ether (26) is used it is possible to obtain the (*S*)-enantiomer of α-ethynylalanine in a similar manner.

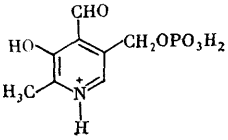
2. α-Propargyl-α-amino acids

The first known example of α-propargyl-α-aminoacids was propargylglycine (34a), which was prepared in 1949 by Gershon et al.[37] from sodium formamidomalonate during research on active bactericidal agents amongst glycine analogues. The same authors subsequently reported the propargylglycine homologue—2-amino-3-methylpentynoic acid (34b).[38]



(34a, b)

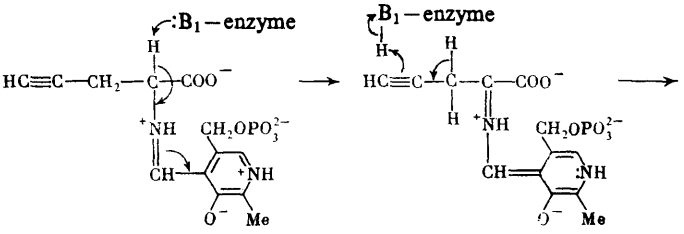
R = H (a), 89%

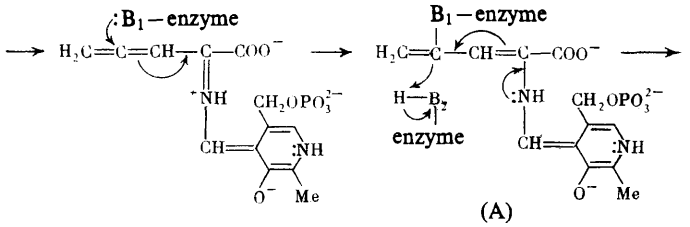


R = Me (b), 71%

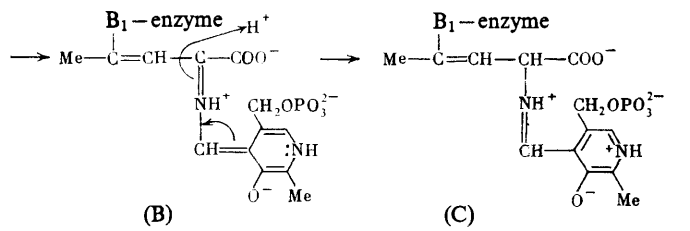
It transpired that both amino acids (34a, b) actively inhibit the growth of yeast *Saccharomyces cerevisiae* and mould *Ercherihia* [Eschericia?] *coli* microorganisms.

In 1971 Scannel et al.[39] found that *L*-propargylglycine can be obtained microbiologically from cultivation of *Streptocetes*. As a result of fundamental biochemical studies by Walsh, Abeles, Marcotte, et al.,[40–45] it was established that inhibition of the growth of bacteria[41,43] and fungae[45] by propargylalanine is caused by its ability to deactivate irreversibly the enzymes bound to pyridoxal phosphate as the coenzyme—γ-cystathionase,[40,42] cystathionine γ-synthetase, methionine γ-lyase,[43] *L*-alanine transaminase, and others[44]—which take part in the biosynthesis or metabolism of the corresponding amino acids, and hence to disrupt the growth and development of cells, tissues, and complete organisms. As a result of a study on the suicidal deactivation of rat liver γ-cystathione with α-propargylglycine labelled with ^{14}C, ^{2}H, and ^{3}H isotopes, a mechanism for the process was put forward.[40,42] According to this mechanism, after bonding of the amino group of propargylglycine with the aldehyde group of the coenzyme, one of the bases (B_1) of the active site of γ-cystathionase by reacting alternately with the hydrogen atoms of the α- and β-carbon atoms of propargylglycine catalyses the isomerisation of the Schiff base and rearrangement of the acetylene residue to a highly reactive allene.[40,42] The authors assume that one of the acid groups of the active site of the enzyme ($H-B_2$) assists the formation of the allene by protonating the δ-carbon atom of the propargylglycine residue. It is very probable that after deprotonation, a base (B_2) adds to the allene, forming a covalent bond between enzyme and deactivator. A study of the hydrolysis products of the adduct between deactivator and enzyme showed that cysteine and tyrosine residues in the active site of the enzyme act as nucleophiles (and bases) forming a covalent bond with the deactivator. However, the authors do not exclude the possibility that the number of bases involved in the process may in fact amount to more than two.

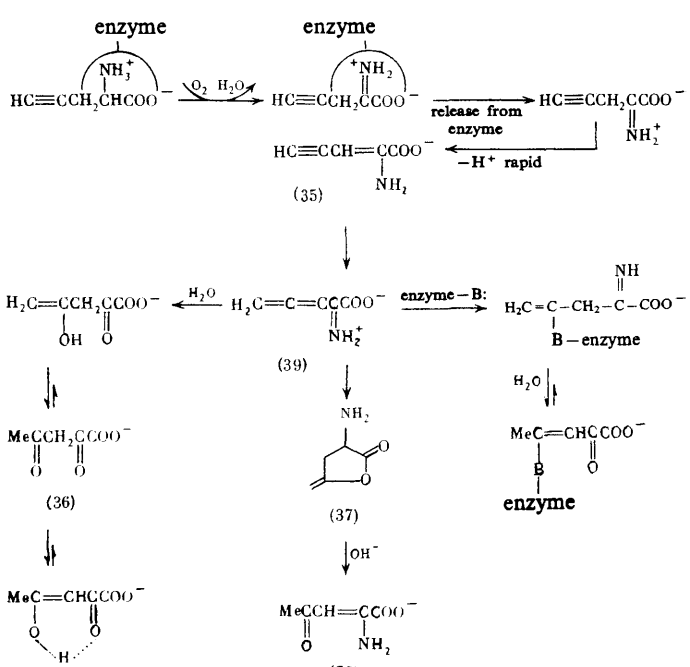




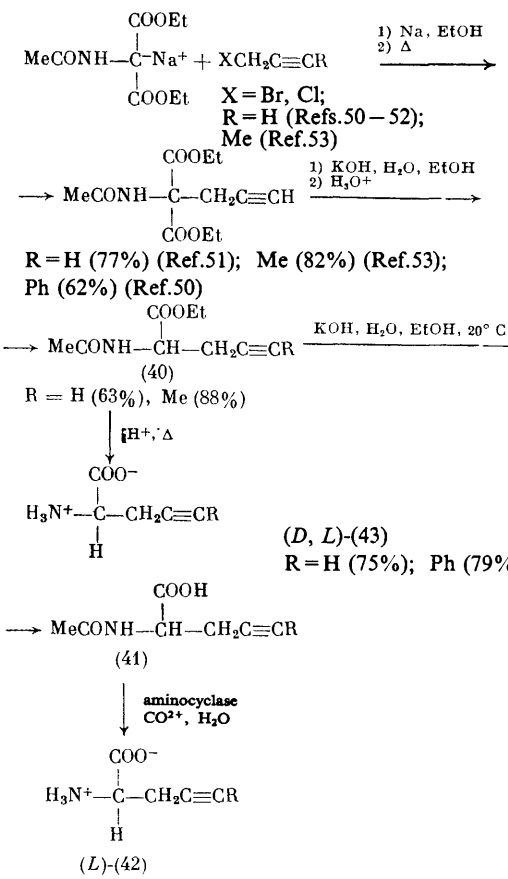
where Py^+-CHO is pyridoxal phosphate bound to the enzyme:



and B_1 and B_2 are bases (or nucleophiles) at the active site of the enzyme.

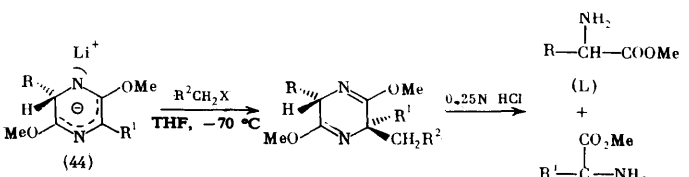


It is possible that the sequence of action of bases B_1 and B_2 is somewhat different to that described above. Johnston et al.[43] put forward a modified mechanism for the deactivation by *L*-propargylglycine of two enzymes—cystathionine γ-synthetase and methionine γ-lyase—from different types of bacteria. The main stages of this mechanism are the same as for the above, namely: reaction of propargylglycine with the coenzyme (pyridoxal phosphate), isomerisation of the acetylene residue of bound propargylglycine to an allene group with the participation of a minimum of two bases (or nucleophiles: B_1 and B_2) in the active site of the enzyme, and final protonation of the α-carbon atom of the deactivator, possibly through proton exchange with the solvent. The main difference from the previous mechanism is that Johnston et al.[43] assume that isomerisation of the γ,δ-double bond of the deactivator in adduct (A) to a β,γ-double bond occurs. As a result the final adduct mainly has structure (B) (according to the visible absorption spectra of the adduct between methionine γ-lyase and the deactivator) or (C) (in the case of cystathionine γ-synthetase.



The action of *D*- and *L*-propargylglycine on *D*- and *L*-amino acid oxidases bound to flavin as the coenzyme has been studied in detail.[46–49] It was established that *D*-propargylglycine is oxidised by a *D*-oxidase to the 2-aminopent-2-en-4-ynoate (35), which is then converted to acetopyruvate (36) or to the iminodiene lactone (37), and the latter after treatment with alkali gives 2-amino-4-oxo-2-pentenoate (38). Compounds (35) and (38) form charge transfer complexes with a *D*-amino acid oxidase and act as noncovalent inhibitors. However, after oxidation of propargylglycine the activity of the oxidase is not completely regenerated by the usual methods. Therefore, it was assumed by the authors that the enzyme undergoes not only reversible modification but also irreversible (covalent) modification as a result of the reaction of a nucleophilic residue (B:) in the active site of the enzyme with a highly reactive metabolite of propargylglycine, which may be the conjugated allenimino acid (39).

B—nucleophile of active site of enzyme

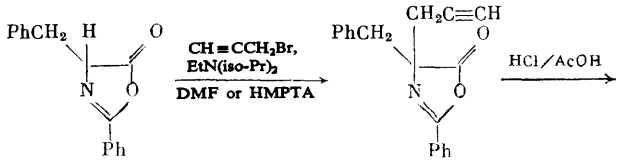


In biochemical studies use is made not only of *L*-propargylglycine obtained microbiologically[39] but also of racemic *D,L*-propargylglycine synthesised by the Gershon method modified by different authors.[50–53] Stereospecific hydrolysis of the acetamide group of the *D,L*-acetamide (41) by pig kidney aminoacylase in the presence of cobalt acetate or chloride gives *L*-propargylglycine (42). The *D*-form of the ethyl ester of the amino acid acetamide (41) is isolated from the filtrate.[53]

R=H (80%) (Ref.52); Me (86%) (Ref.53).

On conventional acid hydrolysis of the racemates of the acetamide ethyl esters (40), the corresponding amino acids (43) are obtained in a racemic form.

Diastereoselective alkylation of the lithiated bislactim ethers (44) followed by hydrolysis of the resulting intermediates was carried out by Schöllkopf et al.[54–59] for the asymmetric synthesis of the methyl esters of (*R*)-α-propargylglycine (45a) and certain other β-acetylenic α-amino acids (45b–d).



(45a–d)

Amino ester (45)	R	R^1	R^2	Yield, %	Optical Purity, %	Refs.

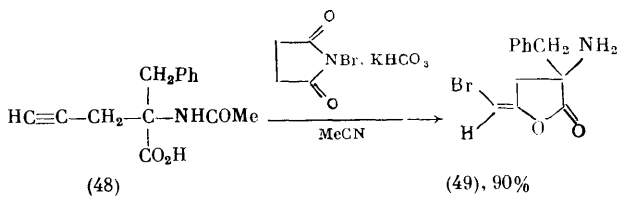
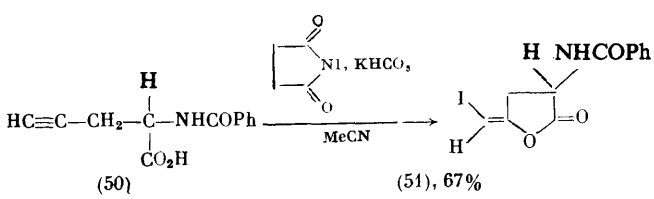
In 1984 O'Donnell et al.[60] demonstrated the possibility of obtaining α-propargylglycine (34a) in good yield (68%) by propargylation of the Schiff base of ethyl glycinate with diphenyl ketone in acetonitrile in the presence of potash and tributylammonium bromide as a phase transfer catalyst.

Propargylglycine is not used solely as a suicidal inhibitor of enzymes:[40–41] it has been used to establish the chemical structure of the active sites of enzymes[61,62] and also to synthesise tritium-labelled norleucine-containing peptides[52,53] and other novel peptides.[63]

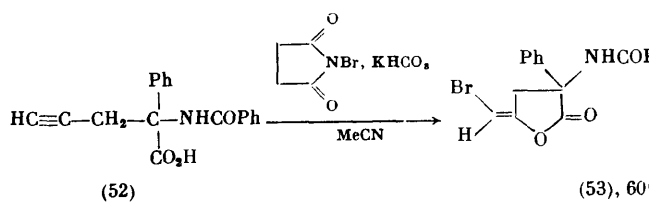
The original synthesis of α-propargylphenylalanine (47) by reaction of propargyl bromide with the oxazoline (46) in the presence of a tertiary amine in dimethylformamide or hexamethylphosphoric triamide has been reported.[64]



(46)

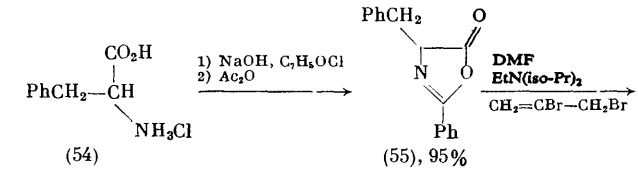


(47) 25%

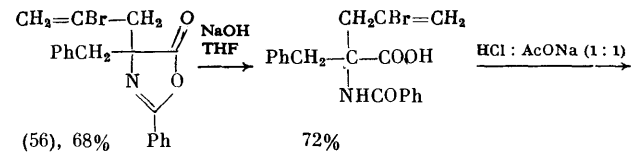


Katzenellenbogen et al.[65] subsequently used amides of propargylphenylalanine (48), propargylglycine (50), and propargylphenylglycine (52) for the synthesis of the five-membered lactones (49), (51), and (53), which proved to be inhibitors of serine protease.[65]

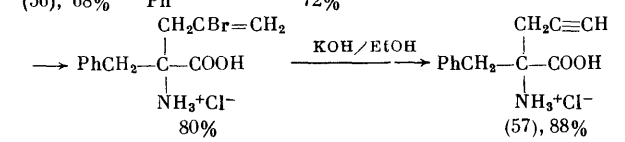
(48) (49), 90%



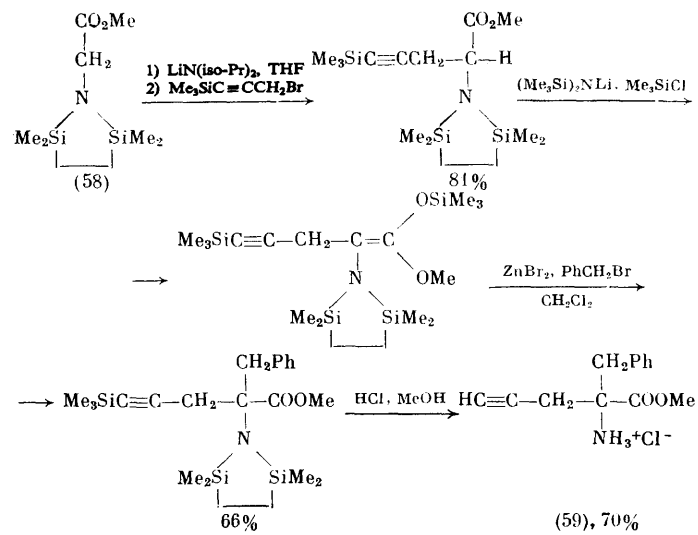
(50) (51), 67%



(52) (53), 60%

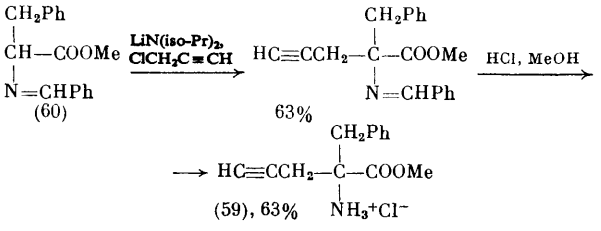


The synthesis of propargylphenylalanine was carried out by the authors in three ways. In the following scheme is depicted the method in which the 2-bromo-2-propenyl group, which was introduced into the 2-benzyloxazolone (55) obtained by reaction of phenylalanine hydrochloride with benzoyl chloride, was used as the propargyl synthon. After three-stage hydrolysis of the alkylated oxazoline (56) in different media propargylphenylalanine (57) was isolated with a total yield of 33% [based on phenylalanine (54)].

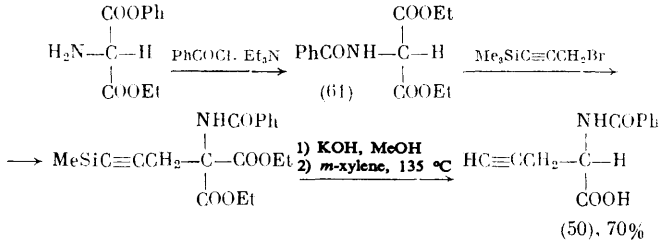


(54) (55), 95%

(56), 68% 72%

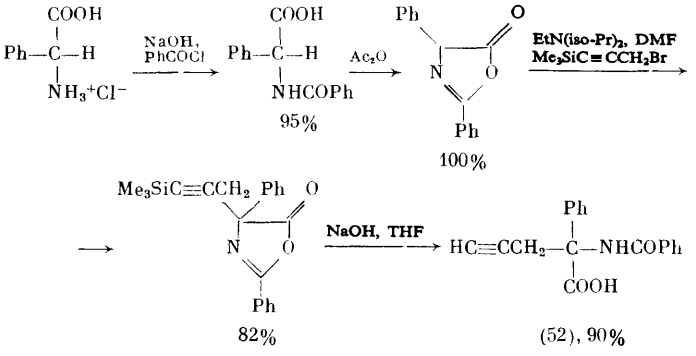


Alternative approaches to propargylphenylalanine (57) include the selective alkylation of the suitably protected α-amino acid derivatives (58) and (60). In the first method the adduct of methyl glycinate and 1,1,4,4-tetramethyldichlorosilylethylene (58) was first alkylated with 1-bromo-3-trimethylsilyl-2-propyne in the presence of lithium diisopropylamide and then benzylated under Friedel–Crafts conditions. After acid hydrolysis the methyl ester of propargylphenylalanine hydrochloride was isolated with an overall yield of 37%.

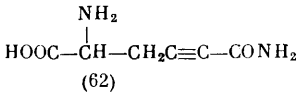


(58) (59), 70%

In the second method the benzylidenimine of phenylalanine methyl ester (60) after treatment with lithium diisopropylamide at −78 °C was alkylated with 1-chloro-2-propyne. After removal of the benzylidene protecting group by acid hydrolysis, the methyl ester

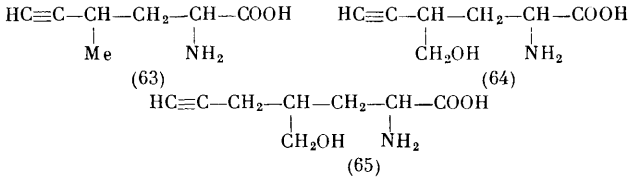


of propargylphenylalanine hydrochloride (59) was isolated with a total yield of 38%.

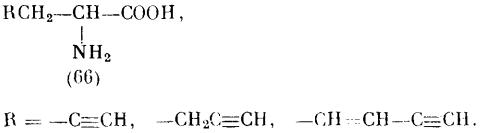


Sofia et al.[65] used the method of Gershon for the synthesis of propargylglycine benzamide (50), namely, diethyl malonate benzamide (61) was alkylated with 1-bromo-3-trimethylsilyl-2-propyne:

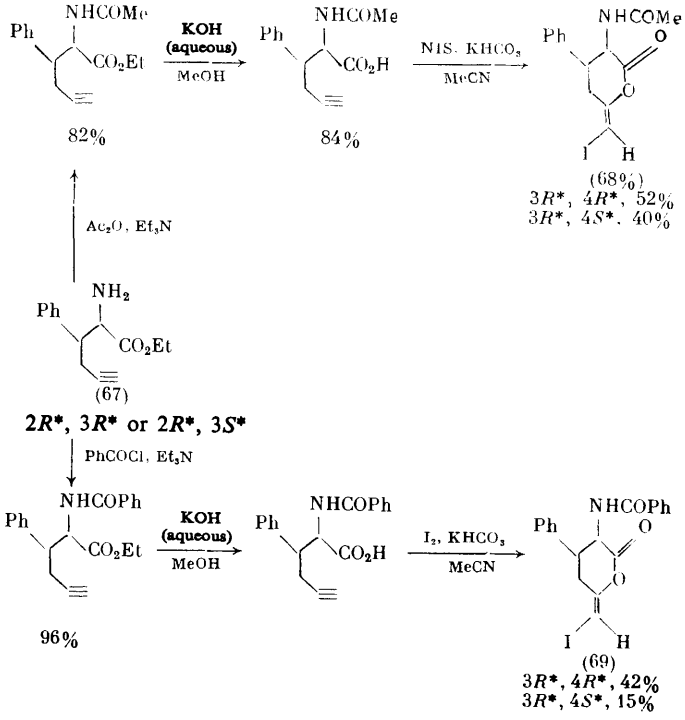
The benzamide of propargylphenylglycine (52) was synthesised using the methods described above in the following way:



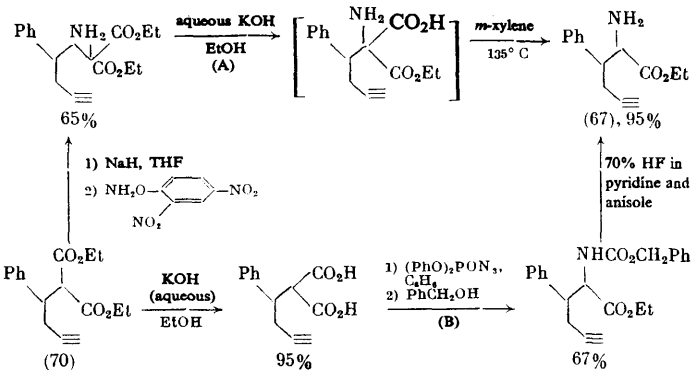
The carbamoyl derivative of propargylglycine—2-amino-5-carbamoyl-4-pentynoic acid (62)—has been isolated by Japanese biochemists from a cultural liquid of *Streptomyces* bacteria, which are capable of producing this antibiotic.[66]



3. γ-Ethynyl-α-amino acids

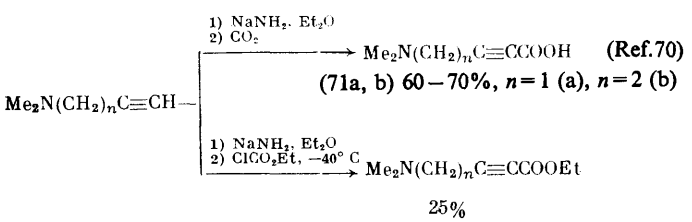


Information about γ-ethynyl-α-amino acids is limited. The isolation of two γ- and one δ-ethynyl-α-amino acids (63)–(65) from seeds of *Euphoria longan* plants was reported.[67]



Several acetylene-containing amino acids of the type (66) were later isolated by extraction from a culture of *Basidomycetes* (for example, *Amanita Pseudoporphria*).[68]

In synthesising the iodomethylidenetetrahydro-2-pyranones (68) and (69), which, like the five-membered lactones (49), (51), and (53) described above,[65] act as irreversible inhibitors of serine protease, Sofia and Katzenellenbogan[69] used as the starting compound ethyl 2-amino-3-phenyl-5-hexynoate (67), which after protection of the amine group with acetyl or benzoyl functions underwent hydrolysis and iodolactonisation.



The γ-ethynyl-α-amino acid ethyl ester (67) was synthesised from the substituted malonate ester (70) either by successive amination and decarboxylation (route A) or by a modified Curtius rearrangement (route B).[69]

III. γ-Amino acids

1. α-Acetylenic γ-amino acids and their derivatives

The first syntheses of α-acetylenic γ-, δ-, and ε-amino acids date back to the late 1950s when Olomucki and Marszak[70–74] put forward several methods for the preparation of 4-dimethylamino-2-butynoic acid (71a), its homologues, and esters, without touching on the question of their possible biological activity.

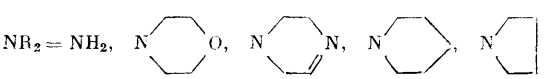
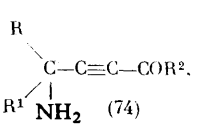
Subsequently Hennion and Perrino,[75] in studying the synthesis and conversions of certain α-acetylenic tertiary amines, obtained 4,4-dimethyl-4-dimethylamino-2-butynoic acid (72).



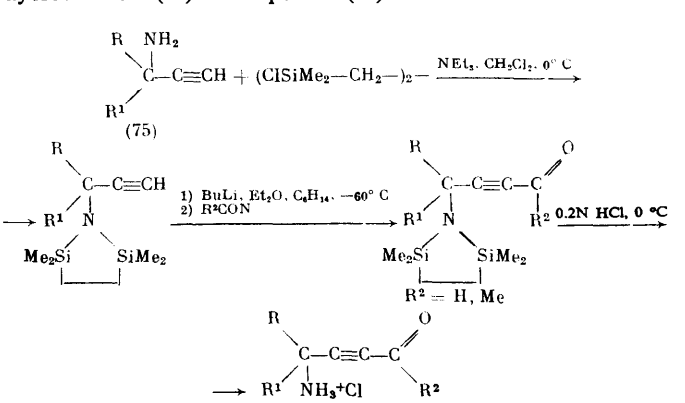
(72), 52%

Bert and Johnston[76] in 1972 were the first to consider the biological activity of α-acetylenic γ-amino acids. They synthesised 4-aminotetrolic acid (73) and some of its derivatives as simple conformationally strained analogues of the neuromediator—γ-aminobutanoic acid (GABA)—in order to establish a correlation between the structure and activity of γ-amino acids.



(73)

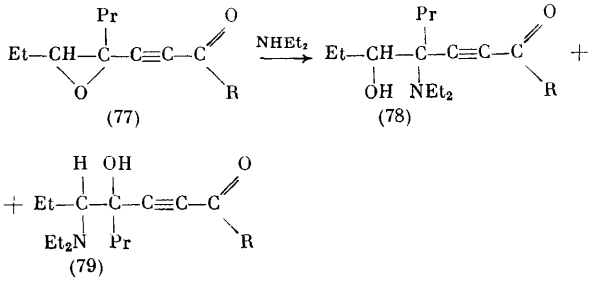
All of the γ-amino acids (73) that were synthesised proved to be inhibitors of the stimulation of central neurons, but they were weaker than GABA.



In the middle of the 1980s the aminoacetylenecarbonyl compounds (74), amongst which were amides of γ-carbon atom-substituted analogues of γ-aminobutynoic acid, were proposed[77] for the therapeutic treatment of alcoholism.

(74)

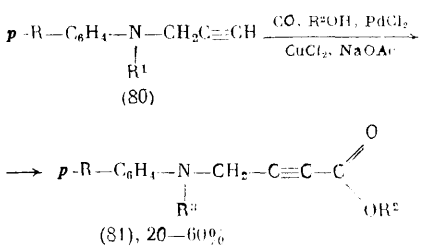
R and R^1 are hydrocarbon or heteroatomic hydrocarbon groups, R + R^1 is a cycloalkylene or heterocycloalkylene group, R^2 = H, Alk, NH_2.



They were synthesised from the acetylenic amines (75), by replacing the acetylenic hydrogen with an aldehyde, carbonyl, or amide function after initial protection of the amino group. Subsequent acid hydrolysis under mild conditions gave the hydrochlorides (76) of compounds (74).

(76)

Some of the hydrochlorides (76) exhibited antitumour properties.[77]



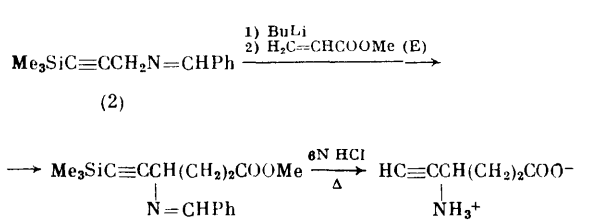
By aminating the epoxyacetylenic acid derivatives (77), Larionov et al.[78] in 1985 synthesised certain esters and amides of α-acetylenic hydroxyamino acids (78) and (79). The biological activity of the latter was not studied.

(77) (78) (79)

R = OMe, NEt_2

It was recently demonstrated by the present authors that for the synthesis of *N*-substituted α-acetylenic γ-amino acid esters in sufficient yield for preparative purposes, it is possible to utilise the oxidative alkoxycarbonylation of acetylenic amines (80) with carbon monoxide in alcohols under conditions of homogeneous catalysis by palladium chloride.[79,80]

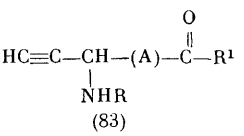
(80) (81), 20–60%



R = H, Cl; R^2 = Me, Et; R^3 = Me, $CH_2C{\equiv}CCOOMe$.

The amino esters (81) exhibit weak fungicidal and antistaphylococcal activity.

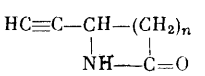
2. γ-Ethynyl-γ-amino acids



γ-Ethynyl analogues of GABA have attracted the attention of research workers because they have proved to be active inhibitors of GABA α-ketoglutarate transaminase from mammalian brain. Therefore they have very considerable potential for application in therapy as psychotropic agents. Metcalf and Jung[81,82] put forward a possible mechanism of their action which is similar to that described above for other irreversible enzyme inhibitors containing an acetylene function.[40,42,43]

The first example of this class of amino acids—4-amino-5-hexynoic acid (82) was obtained by alkylation of the protected aldimine (2), used subsequently for the synthesis of α-ethynyl-α-amino acids.[9,10]

(2) (82), 53%



By varying the electrophilic reagent (E), Metcalf and Jung[83–86] obtained a large group of γ-amino acids (83) and their lactams (84) in racemic and enantiomerically pure forms. Some of these compounds had a beneficial effect in the treatment of functional disorders of the nervous system caused by Parkinsonism, chorea, epilepsy, alcohol syndrome, psychoses related to schizophrenia, manic depression, and hyperkinesia. Other compounds had hypothermal, myorelaxant, cholinergic, antibacterial, anticonvulsive, analgesic, sedative, and tranquillising activity.

(83)

Gittos and Letertre proposed another route for the synthesis of 4-amino-5-hexynoic acid (82)—from derivatives of 2-vinylcyclopropane-1,1-dicarboxylic acid (85).

(85) (82)

R, R^1 = $OAlk(C_{1-4})$, R + R^1 =  , R^2, R^3 = $Alk(C_{1-4})$.

In 1989 Tabor et al.[88] carried out the enantioselective synthesis of (*S*)-γ-acetylene-γ-aminobutyric acid (89a) and its vinyl analogue—(*S*)-*trans*-γ-butenynyl-γ-aminobutyric acid (89b)—with greater than 95% enantiomeric purity by phthalimide substitution of the homochiral alcohols (86a, b) followed by desilylation of the imides (87a, b), oxidation of the imidoalcohols (88a, b), and removal of the phthalimide and trimethylsilyl protecting groups.

IV. Various mono- and poly-acetylene -containing amino acids

In addition to the information given above on the synthesis and biological properties of α- and γ-amino acids, there are separate reports in the literature on the preparation of certain other acetylenic and polyacetylenic amino acids.

Dumont et al.[89] synthesised the diacetylenic amino acids (90) by reaction of acetylenic amines or amides with haloacetylenic acids.

$$R^1R^2N(CH_2)_n-C\equiv CH + BrC\equiv C(CH_2)_n-COOH \xrightarrow[EtNH_2]{Cu^I} \longrightarrow R^1R^2N(CH_2)_nC\equiv CC\equiv(CH_2)_m-COOH,$$

R^1 = H, Me, COH; R^2 = H, Me; n = 1–6; m = 2, 4. (90)

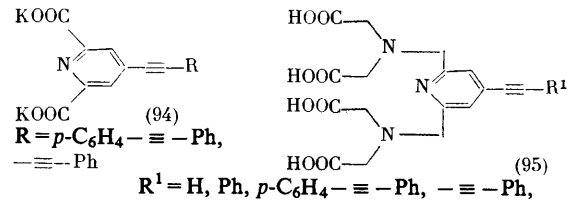
When this reaction was carried out with primary amines, the amino group was first protected by formylation, and after formyl derivatives (90) were obtained, R^1 = HCO, R^2 = H, they were deformylated with caustic soda to the corresponding amino acids (90), $R^1 = R^2 = H$.[89]

Acid hydrolysis of nitriles of *N*-alkynylamino acids (91) gave the corresponding amino acids (92) in 90% yield.[90]

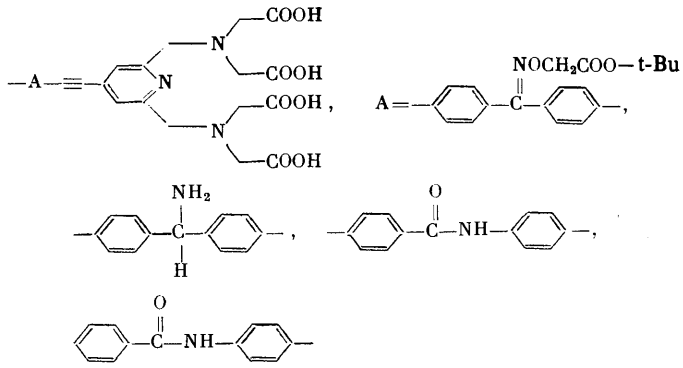
$$R-\underset{\displaystyle R^1}{\overset{\displaystyle C\equiv CH}{\overset{|}{C}}}-NH-(CH_2)_2-CN \xrightarrow{HCl,\ Et_2O} R-\underset{\displaystyle R^1Cl^-}{\overset{\displaystyle C\equiv CH}{\overset{|}{\overset{+}{C}}}}-NH_2-(CH_2)_2-COOH,$$

(91) (92), 90%

R = R^1 = Me, Et; R = Me, R^1 = Et.



Ahmed et al.[91] isolated the polyacetylenic amino acids (93) from cultures of *Fayodia bisphaerigera* fungae. The structure of the acids was reliably established by a range of physicochemical studies and by counter-synthesis.

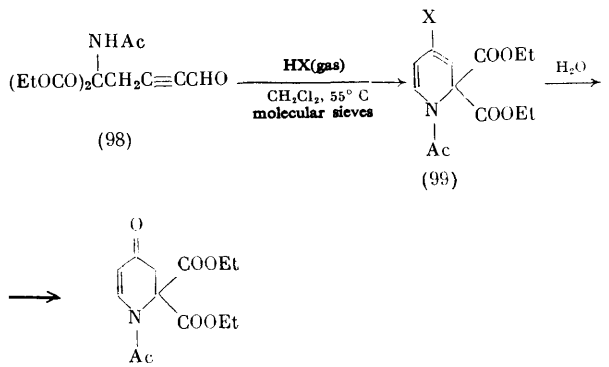


trans-HO–CH_2–CH=CH–$(C\equiv C)_3$–COX, (93)

X = OMe, NHCHRCOOMe, R = H, Me.

In recent years amino acid derivatives containing an acetylene residue in the molecular structure have attracted the attention of research workers as complexing agents and as synthons for the derivation of novel compounds with interesting and useful properties.

Takalo, Hänninen, et al.[92–94] in a multistage synthesis obtained a number of polyconjugated derivatives of ethynylated pyridinecarboxylic acids (94) and pyridinaminocarboxylic acids (95) in order to study the spectroscopic properties of their metal complexes.



The alkyl esters of *N*-propargyl-*N*-alkoxycarbonylglycine (6) were used[95] to obtain 1-propargyl-2,4-dioxoimidazolidine (97)—an intermediate in the synthesis of pyrethroid insecticides and acaricides

$$HC\equiv CCH_2-\underset{\displaystyle (96)}{\overset{\displaystyle CH_2COOR^1}{\overset{|}{N}}}-COOR + NH_3 \xrightarrow[atm.pressure]{0-100^\circ C} \longrightarrow HC\equiv CCH_2\overset{\displaystyle CH_2COOR^1}{\overset{|}{N}}-COOR \xrightarrow[2)\ H^+,\ H_2O]{1)\ NaOMe,\ \Delta}$$

$$\longrightarrow HC\equiv CCH_2N\begin{array}{l}C(=O)\\ \\ NH\end{array}\!\!-\!\!\!-\!\!\!-\!

It was found by Roduit and Wyler[96] that the propargylacetylaminomalonic acid derivatives (98) readily cyclise, forming dihydropyridines (99), which are then hydrolysed to trihydropyridones (100). Dihydropyridines are known to be widely used in pharmacology and in biological studies.

(100), up to 85%

X = Cl, Br

This review of information in the literature on amino acids of various structures that contain an acetylene residue in the molecule, obtained by both chemical and microbiological methods, provides an indication of the extensive possibilities of using these compounds as biologically active agents whose specific physiological action is mainly due to their ability to modify irreversibly the active sites of certain enzymes by disrupting the chain of biochemical reactions of vital amino acids. Acetylenic amino acids are also used as synthons for the preparation of various compounds that have properties with useful practical applications.

Characteristic features of radical polymerisation occurring under the influence of non-traditional initiators

S I Kuchanov
Lomonosov Moscow State University

ABSTRACT. The kinetics of free radical polymerisation processes during which macromolecules grow stepwise are examined. A general approach suitable for the calculation of the molecular weight distribution of the products of the polymerisation initiated by various classes of non-traditional initiators is formulated. The effectiveness of this theoretical approach is illustrated in numerous examples of the solution of specific practical problems.

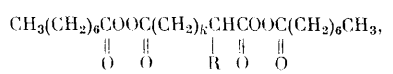
I. Introduction

A common feature of a large proportion of radical polymerisation processes is a decrease in molecular weight with increase in the concentration of traditional initiators, which imposes fundamental limitations on the increase in the productivity of the corresponding processes. This is associated with the fact that the length of the material chain in the absence of transferring agents is equal either to the length of the kinetic chain or to twice its length respectively in cases where the termination reaction proceeds via a combination or disproportionation mechanism. An increase in the rate of polymerisation as a result of an increase in the rate of initiation in the processes considered therefore leads to a simultaneous decrease in the length of the kinetic chain and hence to a decrease in molecular weight.

This undesirable effect can be avoided by employing non-traditional radical polymerisation initiators whereupon the material chain consists of several elementary chains whose number increases continuously in the course of the process. An increase in the molecular weight of the polymer with conversion and a narrowing of its molecular weight distribution are then observed. These features are qualitatively different from those noted in the usual processes.



This review deals with questions concerning the quantitative description of such pseudolive radical polymerisation initiated by non-traditional compounds of two classes. The first includes polyfunctional initiators, for example, polyperoxides, containing more than one labile group in each molecule. The second contains so called "inferters" participating in chain transfer and termination reactions apart from initiation. A characteristic feature of both classes of these non-traditional initiators is that during polymerisation processes with their participation macromolecules capable of further reactivation and chain propagation are formed.

II. Polyfunctional initiators

1. Introduction

In conformity with their name, the molecules of polyfunctional initiators contain two or more functional groups capable of forming free radicals on decomposition. These groups are characterised by the chemical nature of the labile interatomic bond present in them, for example, the bond in the azo- and peroxy-groups. A fairly large number of chemically different types of polyfunctional initiators are now known. Information about the structure and method of synthesis of these compounds can be found in reviews.[1–6] Polyperoxides, in relation to which the general theoretical postulates will be illustrated below, have been most thoroughly investigated among them (to a large extent as a result of the fundamental research by Ivanchev and co-workers[7–16]).

The molecules of polyfunctional initiators can differ by the number of labile groups of various types. The simplest among initiators of this kind, such as, for example, diacyl diperoxide

(I)

contain two labile groups. For a sufficient length of the methylene bridge separating them, when the number k of the CH_2 units exceeds 6–8, both these groups decompose independently.[12,15] The entire discussion below will refer solely to polyinitiators with similar kinetically independent labile groups.

Generally speaking, the peroxy-groups in the diperoxide (I) have different thermal stabilities, since one of them contains an unsubstituted acyl group while the other has an α-substituted acyl group. The difference between the rate constants for the decomposition of these groups may be very appreciable depending on the nature of the substituent R. Thus Ivanchev and co-workers[9,10,12,15] determined the kinetic parameters of the thermolysis of a large number of different polyperoxides which they synthesised and also established the dependence of these parameters on the length k of the bridge, the nature of the substituent R, and the number of peroxy-groups in the molecules. Some data concerning the parameters, indicated above, of the decomposition of polyfunctional initiators have also been presented in communications by other investigators (see, for example, Refs. 17–20).

It has been established[12,18] that polyperoxides with independent peroxy-groups are most suitable for practical application. The rate of polymerisation initiated by such compounds will evidently be identical, under the conditions of the applicability of the Flory principle,[21] with the rate of polymerisation under the influence of traditional monofunctional initiators containing the same peroxy-groups and present at the same overall concentrations in both systems mentioned above.[22,23] The task of the quantitative theory of homopolymerisation with participation of polyfunctional initiators is therefore only the calculation of the molecular weight distribution (MWD) and of its statistical moments while for joint polymerisation it also includes the calculation of the composition distribution of the products formed.

2. The polymerisation mechanism

The main feature of the polymerisation in the presence of polyfunctional initiators consists in the formation, during the process, of macromolecules containing labile groups in the main chain (within it and/or at its ends). The mechanism of the formation of such macromolecules is illustrated schematically in Fig. 1 for the simplest case of the synthesis of monomers of the type of polystyrene under the influence of a diperoxide with the same peroxy-groups. The decomposition of any of the peroxy-groups results in the formation of a pair of free radicals each of which recombines, after the readdition in the course of its growth of a certain number of monomers, with one of the other similar macroradicals, generating macromolecules of the "dead" polymer. The latter contain only the elementary polymer chain and differ by the number of terminal peroxy-groups whose subsequent decomposition leads to the formation of a pair of polymeric radicals capable of further growth and recombination.

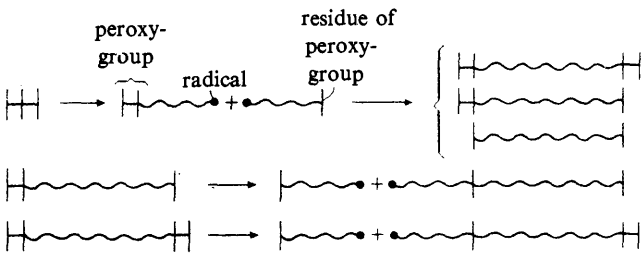


Figure 1. Schematic illustration of the formation of the polymer chain during polymerisation initiated by a symmetrical diperoxide.

The set of such parallel-consecutive reactions characterises the polymerisation-recombination mechanism of the formation of macromolecules in the presence of polyfunctional initiators discussed here.[1,23] Naturally, if the molecules of the initiators include more than two labile groups, then the molecules of the macroinitiator formed during polymerisation may contain these groups not only at the edge but also within the main chain. The structure of such macromolecules, formed during the consecutive decomposition of peroxy-groups and of the recombination of macroradicals, may be complex (Fig. 2). An arbitrary polymer chain may consist of any number m of elementary chains separated by peroxide clusters containing one, two, three, etc. peroxy-groups. The term "cluster" implies here a sequence of peroxy-groups bounded either by two elementary chains or by an elementary chain and the end of the macromolecule. In the former case, the cluster is referred to as closed and in the latter as semi-open.

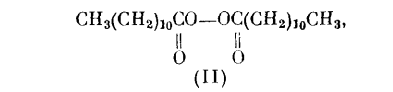

Figure 2. Schematic illustration of one of the polymer chains formed during the process presented in Fig. 1.

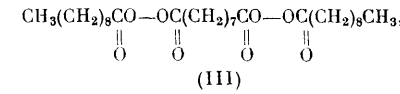
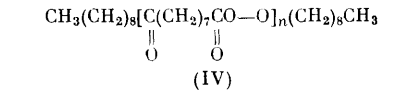
For polyinitiators with independent functional groups, the thermal stability of each of them should not depend on the cluster to which it belongs and on the site where it is located. The decomposition constant for any such peroxy-groups will then be identical with the constant characterising it in the molecule of the initial polyinitiator.



Examples of similar polyperoxides are well known.[1–3,5] The rate of polymerisation W initiated by such compounds should not evidently depend on their functionality for the same overall concentration C of peroxy-groups in the reaction system and is described by the usual formula

$$W = k_p M (I/k_t)^{1/2}, \text{ where } I = 2fk_dC, \quad (1)$$



used in the traditional theory of radical polymerisation with participation of monofunctional initiators.[21] The following notation is used here and henceforth: I and f are the rate and efficiency of initiation, M is the concentration of the monomer, and k_d, k_p, and k_t are respectively the rate constants for the elementary reactions involving the decomposition of the peroxy-groups and chain propagation and termination. In conformity with the Flory principle, these constants do not change on passing from monofunctional to polyfunctional initiators, which has been confirmed in relation to the peroxides

(II)

(III)

(IV)

by the experimental data presented in Fig. 3.

In contrast to the kinetics, the traditional theory of radical polymerisation cannot be used for the calculation of the molecular weight characteristics of the polymer. Thus even the simplest formula of this theory[21]

$$P'_N = \frac{2}{1+\lambda}\nu, \text{ where } \nu = \frac{W}{I}, \ \lambda = \frac{k_{td}}{k_t}, \ k_t = k_{td} + k_{tc}, \quad (2)$$

which relates the number-average degree of polymerisation P_N of the macromolecules for the initial conversions to the length of the kinetic chains ν and also to the constants of elementary reactions

involving chain termination by the combination (k_{tc}) and the disproportionation (k_{td}) of the radicals, proves to be invalid. Contrary to Eqn. (2), the average molecular weight begins to increase from the very beginning of the polymerisation, provided that it is initiated by polyfunctional compounds.[1-3,5] This result follows naturally from the polymerisation-recombination mechanism of the formation of macromolecules (Fig. 1), because the formation in the polymer of one or two new elementary chains, depending on whether the kinetic chain is terminated by combination or disproportionation, corresponds to each effectively decomposed labile bond.

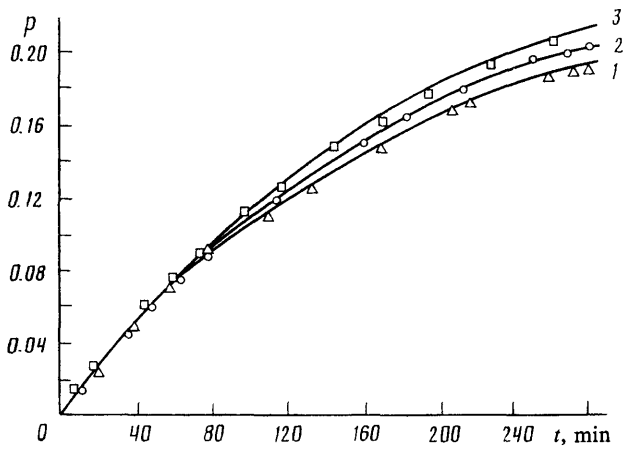


Figure 3. Kinetic curves for the polymerisation of styrene in bulk at T = 80 °C and at a peroxy-group concentration $C^0 = 2.5 \times 10^{-3}$ M for initiation by monoperoxides (curve *1*), diperoxides (curve *2*), and polyperoxides (curve *3*) containing 18 peroxy-groups.[23]

3. The superposition principle

For the calculation of the molecular weight distribution of the products of polymerisation initiated by polyperoxide, it is convenient to distinguish the macromolecules in terms of the number m of elementary chains included in them. The total number $l = l^{(1)} + l^{(2)} + \ldots + l^{(m)}$ of the monomer units in the given macromolecule will determine (neglecting the contribution of the peroxide clusters) its molecular weight. For the calculation of the numerical molecular weight distribution $f_N(l, t)$ of the polymer formed by time t, one can use the expression

$$f_N(l, t) = \sum_{m=1}^{\infty} P_m(t)\, W_m(l), \tag{3}$$

where $P_m(t)$ is the fraction of the macromolecules containing m elementary chains at time t and $W_m(l)$ is the conventional probability that the degree of polymerisation of such a macromolecule is l.

In conformity with the general ideas of the statistical chemistry of polymers, instead of the molecular weight distribution of the polymer one can use its generating function

$$G_N(s, t) = \sum_{l=1}^{\infty} f_N(l, t)\, s^l, \tag{4}$$

ich is fully equivalent to the molecular weight distribution but is more convenient in the calculation of its statistical moments.[24] These characteristics, which determine in particular, the number-average, weight-average, and z-average molecular weights of the polymer, can be calculated as the corresponding derivatives of the generating function $G_N(s)$ at the point $s = 1$. The molecular weight distribution itself can be found from Eqn. (4) by expanding $G_N(s)$ in a power series in terms of s.

For the calculation of the molecular weight distribution, it is necessary to find separately two generating functions:

$$U(x, t) = \sum_{m=1}^{\infty} P_m(t)\, x^m; \quad g(s) = \sum_{l=1}^{\infty} \varphi_l s^l. \tag{5}$$

the first of which corresponds to the distribution $P_m(t)$ of the macromolecules with respect to m elementary chains and the second corresponds to the distribution of these chains with respect to l monomer units in them. The generating function of the molecular weight distribution can then be obtained after substituting the function $g(s)$ in $U(x,t)$ instead of its argument x. One obtains as a result the important relation[23]

$$G_N(s, t) = U(g(s), t), \tag{6}$$

which represents the mathematical formulation of the principle of the superposition of the distributions φ_l and P_m.

The first of these evidently represents molecular weight distribution of the elementary chains, the length of each of which (in the given case $k_{td} = 0$) is made up of two lengths of kinetic chains. Their distribution with respect to length is described by the most probable Flory distribution whose generating function

$$g_k(s) = \frac{(1-a)s}{1-as}, \text{ where } a = 1 - 1/\nu, \tag{7}$$

is determined by the unique parameter a, which depends solely on the average length ν of the kinetic chain [see Eqn. (2)]. Evidently the distribution φ_l of the elementary chains is identical with the molecular weight distribution of the products of polymerisation under the influence of a traditional monofunctional initiator and is described by the generating function $g(s) = g_k^2(s)$. Its substitution in Eqn. (6) yields a solution of the problem of the calculation of the molecular weight distribution of polymer chains subject to the condition that the generating function $U(x, t)$ of the distribution $P_m(t)$ is known.

However, the procedure indicated is valid only in the case where the kinetic parameter ν does not vary during polymerisation as a consequence of the variation of the monomer or initiator concentrations. On the other hand, if such variation does occur then, instead of the function $g(s)$, its average value

$$\langle g(s) \rangle = \int_0^t g(s, t')\, I(t')\, dt' \Big/ \int_0^t I(t')\, dt', \tag{8}$$

should be substituted in Eqn. (6). Here the angular brackets denote averaging with respect to time of the characteristic placed between them.

When traditional monofunctional initiators are used, whereupon each polymer chain consists of one elementary chain, Eqn. (8) evidently describes the molecular weight distribution of the polymerisation products over the entire range of conversions taking into account the consumption of the monomer and initiator during the process. Such consumption may induce a broadening of the

molecular weight distribution with respect to conversion, which is undesirable for practical purposes, and which is characterised by the quantitatively appreciable increase with conversion of the polydispersity coefficient $K' = P'_W/P'_N$ which is equal, by definition, to the ratio of the weight-average and number-average degrees of polymerisation. Eqns. (7) and (8) make it possible to obtain simple formulae for these statistical characteristics:

$$P'_N = 2\langle\nu\rangle, \quad K' = \frac{3\langle\nu^2\rangle}{2\langle\nu\rangle^2}. \tag{9}$$

The effect of the conversion-induced broadening of the MWD indicated can be appreciably diminished if the polymerisation is carried out in the presence of polyperoxides containing a sufficient number of functional groups. This fundamental conclusion follows directly from the general expressions

$$P_N = P'_N P''_N, \quad K = K'' + \frac{(K'-1)}{P'_N}, \tag{10}$$

which can be derived simply from the superposition principle (6) (formulated above) taking into account Eqn. (8). According to Eqn. (10), the molecular weight and the polydispersity coefficient of the polymer obtained depend on similar characteristics: both on the distribution with respect to the lengths of the elementary chains [Eqns. (9)] and on the distribution P_m of the macromolecules with respect to the number m of such chains. The average value $P''_N = \overline{m}$ of this random quantity, which is identical at the end of the polymerisation with the average number of the effectively decomposed labile bonds in the polyperoxide molecule, can be fairly large when the functionality of the polyperoxide is high. In the latter case, the transition from monofunctional to polyfunctional initiators should be accompanied by an appreciable (by the factor P''_N) increase in the average molecular weight and by the simultaneous narrowing of the molecular weight distribution. For sufficiently large values of P''_N, when it is possible to neglect the second term in Eqn. (10) for K compared with the first, the use of polyperoxides makes it possible to suppress completely the conversion factor for the non-uniformity of the molecular weight distribution. The latter can be determined in this case only by the polydispersity coefficient K'' of the distribution P_m, which, as will be seen from the discussion below, is usually not unduly great.

We shall now consider how the superposition principle can be extended to the polymerisation reactions of monomers of the type of methyl methacrylate in which the fraction of the radicals [λ in Eqn. (2)] losing their activity via the disproportionation mechanism is non-zero. As a result of the elementary kinetic chain termination step via this mechanism, the macromolecules lose their activity, being converted into macro-initiator molecules with formation of an additional elementary chain at the end of each of them. However, in contrast to chain termination via combination, its length is equal to the length of not two but only one kinetic chain. Consequently the following formula constitutes an extension of Eqn. (6):

$$G_N(s, t) = U(\langle g_k^2(s)\rangle, \langle g_k(s)\rangle; t), \tag{11}$$

where $U(x, y; t)$ is the generating function of the joint distribution of polymer chains with respect to m and i elementary chains formed respectively by the combination and disproportionation of the radicals. It is easy to obtain from Eqn. (11) a relation, analogous to Eqn. (10), containing the quantities

$$P'_N = \frac{2\langle\nu\rangle}{1+\lambda}; \qquad K' = \frac{(\lambda+1)(3-\lambda)}{2}\frac{\langle\nu^2\rangle}{\langle\nu\rangle^2}. \tag{12}$$

Naturally, with increase in λ, the efficiency of the formation of polyinitiators falls as a consequence of the decrease in the fraction of the combination steps leading to the strengthening of the polymer chains. In order to estimate this effect quantitatively, it is sufficient to find from Eqn. (11) the generating function $U(x, y; t)$.

4. Polyinitiators with labile groups of one type

According to the superposition principle described above, in order to calculate the molecular weight distribution in the case of chain termination via combination, it is sufficient to find the generating function $U(x, t)$ of the distribution $P_m(t)$ of macromolecules with respect to m elementary chains. In order to find $U(x, t)$, the corresponding system of kinetic equations was formulated[23] for this distribution and its exact solution was found. According to the latter, for any initial distribution α_j of polyperoxide molecules with respect to j peroxy-groups, the distribution P_m has the generating function

$$U(x,t) = \frac{(1-\rho)x}{1-\rho x}, \quad P_m = (1-\rho)\rho^{m-1}. \tag{13}$$

The form of the α_j distribution affects only the nature of the time variation of the single parameter ρ:

$$\rho(t) = 1 - \sum_j a_j[1-(1-\theta)^j]\Big/\theta\sum_j ja_j,$$
$$\text{where } \theta = f(1-e^{-\tau}), \quad \tau = k_d t. \tag{14}$$

In the case of function (13), the superposition principle (10) leads to a simple expression for the molecular weight distribution when account is taken of Eqn. (7):

$$f_N(l,t) = \frac{(1-\rho)}{2\sqrt{\rho}}(1-a)\{[a+(1-a)\sqrt{\rho}]^{l-1} -$$
$$-[a-(1-a)\sqrt{\rho}]^{l-1}\}. \tag{15}$$

It is evidently unimodal. The use of Eqns. (10) makes it possible to obtain from Eqn. (13) the formulae

$$P_N = P'_N(1-\rho)^{-1} \text{ and } K = (1-\rho)K' + 2\rho, \tag{16}$$

which are valid over the entire range of conversions when account is taken of Eqn. (9).

According to the first of these formulae, the molecular weight increases during the process from P'_N, obtained when the monoperoxide is used, to a maximum value P_N^{max} which depends on the distribution, α_j, of the peroxy-groups in the polyperoxide molecules and on the efficiency of the initiator f. In the case of polyinitiators with a fairly high functionality, the theory predicts a linear dependence of the molecular weight of the polymer on the conversion over a wide range of the latter. Under these conditions, the slope of the straight line is proportional to the functionality of the polyinitiator, in conformity with Eqns. (14) and (16). These theoretical predictions are satisfactorily confirmed by the experimental data presented in Fig. 4.

An extension of Eqn. (13), taking into account the possibility of chain termination via disproportionation, has been obtained[23] with the aid of the kinetic approach:

$$U(x,y;t) = \frac{V(x,y;t)}{V(1,1;t)}, \quad V(x,y;t) = \frac{(1+dy)^2}{1-b^2x} - 1,$$
$$\text{where } d = \lambda\rho(1-\rho)^{-1}, \quad b^2 = (1-\lambda)\rho. \tag{17}$$

In the case where the length of the kinetic chain ν is large and

constant, the superposition principle (11) makes it possible to find from Eqn. (17) the following expression for the molecular weight distribution of the polymer:

$$f_N(l, t) = \frac{1 - b^2}{2b(d^2 + b^2 + 2d)}\{(d + b)^2 e^{-l/(1-b)\nu} - (d - b)^2 e^{-l/(1+b)\nu}\}, \quad (18)$$

which, like the molecular weight distribution defined by Eqn. (15), is unimodal.

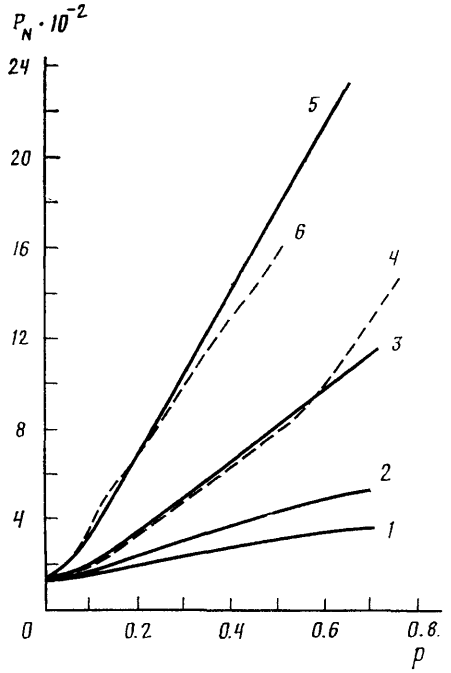

Figure 4. Variation of the number-average molecular weight of polystyrene with conversion in the polymerisation of styrene in bulk in the presence of oligoperoxides with different average numbers of groups; number of groups: *1*, 1; *2*, 2; *3*, and *4*, 4.6; *5*, and *6*, 10.7. Continuous lines—theoretical data; dashed lines—experimental data.[12]

The following formulae serve as extensions of Eqns. (16):

$$P_N = \frac{\lambda + 1}{\lambda + 1 - \rho} P'_N,$$

$$K = \frac{\lambda + 1 - \rho}{\lambda + 1} K' + \frac{(2 - \lambda)^2 \rho (\lambda + 1 - \rho)}{2(1 - \rho + \lambda\rho)}. \quad (19)$$

They demonstrate to what extent the disproportionation reaction eliminates all the advantages of employing polyfunctional initiators. Indeed, regardless of the type of the latter and the kinetic polymerisation parameters, it is impossible, according to Eqns. (19), to increase the molecular weight of the polymer (compared with that which is obtained under the same conditions using the usual monoperoxide) by a factor greater than $(\lambda + 1)/\lambda$. For example, in the polymerisation of methyl methacrylate, where λ is close to 0.5, this factor is close to 3. In such systems, the transition from monoinitiators to polyinitiators is much less effective, as follows from the second Eqn. (19), for the restriction of the increase in the conversion-induced non-uniformity of the polymerisation products. The above factor is one of the fundamental disadvantages of the use of polyperoxides in practice.

5. Polyinitiators with labile groups of several types

The use of polyperoxides containing peroxy-groups with different thermal stabilities leads to extensive possibilities for the molecular design of polymers.[1-6] Under these conditions, questions concerning the dependence of their statistical characteristics on the functionality, composition, and structure of the initial initiating compounds arise. The answers to these questions are provided by the quantitative theory, developed by Ivanov et al.,[31] some of the main results of which are presented below.

The general formulae (3)–(10) for the calculation of the molecular weight and the molecular weight distribution remain valid also on passing to polyinitiators with several types of peroxy-groups. However, the forms of the distribution functions $P_m(p)$ of the macromolecules with respect to m elementary chains are naturally different. In order to find this distribution, it is very convenient to employ a statistical approach according to which any arbitrarily selected macromolecule in the reaction system can be regarded as the realisation of a random process involving conventional motion along the macromolecule.[21,24] It is found that such a random process, describing the products of the homopolymerisation initiated by arbitrary polyperoxides with independent groups, may be a Markov chain. This result is valid for any number r of types of labile groups regardless of the way in which they are distributed among the molecules of the initial polyperoxide. The nature of the distribution will influence only the statistical parameters of the Markov chain; the matrix $\mathbf{Q}$ (with the elements ν_{ij}) of the transitional probabilities and the vector $\vec{v}$ (with the components v_i) of the initial states. In the case considered, the following expression is an extension of Eqn. (13):

$$U(x, t) = \sum_{i=1}^{r} \sum_{j=1}^{r} v_1 x [(\mathbf{E} - \tilde{\mathbf{Q}}x)^{-1}]_{ij} \nu_{j0}, \quad (20)$$

where $\mathbf{E}$ is a unit matrix (with the elements δ_{ij}), $\tilde{\mathbf{Q}}$ the matrix of the transitions (with the elements ν_{ij}, $i \neq 0, j \neq 0$) between r non-return states, and ν_{j0} the probability of the transition from such a jth state to the zeroth state, which is absorbing.

All the parameters of the Markov chain in Eqn. (20) are expressed in terms of the kinetic structural parameters of the initial polyinitiator. The former include the decomposition constants k_{di} and the efficiences of the initiation f_i ($i = 1, \ldots, r$) by all types of peroxy-groups, while the latter include the fractions of the chemically individual polyperoxide molecules with a fixed set of numbers of groups of all types and the order in which they alternate.

The structure of the macromolecules in the given case is similar to that illustrated in Fig. 3 with the sole difference that the peroxide clusters can now consist of groups of different types. In the statistical approach, it is convenient to distinguish (to differentiate arbitrarily) the radicals, elementary chains, and clusters as a function of the mode of their formation. Thus, in the effective decomposition of an ith type labile group, a pair of macroradicals is formed to which the same type i is attributed. Each step involving the recombination of two such macroradicals of types i and j leads to the formation of the elementary chain (ij). The peroxide clusters can

be differentiated in accordance with the same principle in terms of their types as a function of the type of radicals which were formed at one time at the ends of the given cluster. Consequently the elementary chain (ij) is connected to the chain (kl) by a closed cluster of type (jk), while a semiopen cluster of type $(j0)$ or $(0j)$, containing the 0, 1...peroxy-groups, connects the elementary chain to the end or start of the macromolecule. The molecules of the initial polyperoxide are included among the open clusters.

The concentrations N_{ij} of the peroxide clusters of different types (ij) as well as the rates I_i of generation of macroradicals of types $i = 1, ..., r$, i.e.

$$I_i = 2f_i k_{di} C_i, \quad C_i = C_i^0 \exp(-k_{di} t), \quad I = \sum_{i=1}^{r} I_i , \tag{21}$$

are determined by the elements ρ_{ik} and ρ_{kj} of the matrices $\boldsymbol{\rho}$ and $\boldsymbol{\sigma}$:

$$\rho_{ik} = N_{ik} \Big/ \sum_{k=0}^{r} N_{ik} \; (i, k = 1, \ldots r), \quad \rho_{i0} = N_{i0} \Big/ \sum_{k=0}^{r} N_{ik}; \tag{22}$$

$$\sigma_{kj} = \int_0^t \frac{I_k I_j}{I} \, dt' \Big/ \int_0^t I_k dt', \quad \rho_{0k} = N_{0k} \Big/ \sum_{k=1}^{r} N_{0k}, \tag{23}$$

in terms of which all the parameters of the Markov chain in Eqn. (20) are expressed simply by means of the formulae

$$\nu_{ij} = \sum_{k=1}^{r} \rho_{ik} \sigma_{kj} \; (i, j = 1, \ldots r), \quad \nu_{i0} = \rho_{i0} \tag{24}$$

$$v_i = \sum_{k=1}^{r} \rho_{0k} \sigma_{ki} \; . \tag{25}$$

The overall concentration of the polymer molecules Π is equal to the difference between the initial I^0 and current $I(t)$ concentrations of the initiator molecules:

$$\Pi = I^0 - I(t) = I^0 \left[1 - \sum_{\vec{j}} \alpha(\vec{j}) \prod_{i=1}^{r} (1 - \theta_i)^{j_i} \right], \tag{26}$$

where $\alpha(\vec{j})$ is the fraction of the molecules of the initial polyperoxide having a functionality vector $\vec{j}$ with the components $\{j_1, ..., j_i, ..., j_r\}$ equal to the numbers of functional groups of each type. The quantities

$$\theta_i = f_i [1 - \exp(-k_{di} t)] \quad (i = 1 \ldots, r), \tag{27}$$

have the significance of the probability that an arbitrarily selected peroxy-group of the ith type decomposes effectivey at time t.

All the formulae in subsection 3 are valid in the general case considered. Thus the average number of elementary chains in the macromolecule

$$P_N'' = \sum_{i=1}^{r} \sum_{j=1}^{r} v_i [(\mathbf{E} - \tilde{\mathbf{Q}})^{-1}]_{ij} = \sum_{i=1}^{r} C_i^0 \theta_i / \Pi, \tag{28}$$

and hence, according to Eqn. (10), also the number-average molecular weight of the polymer are independent, for the given $\alpha(\vec{j})$ distribution, of the sequence of the peroxy-groups of different types in the polyinitiator molecules. However, the microstructure of the polyperoxide nevertheless exerts an influence on the form of the molecular weight distribution and the degree of its polydispersity K [Eqn. (10)], as follows from the formula

$$K'' = 1 + \sum_{i=1}^{r} \sum_{j=1}^{r} v_i [(\mathbf{E} - \tilde{\mathbf{Q}})^{-2} \tilde{\mathbf{Q}}]_{ij} \Big/ \left\{ \sum_{i=1}^{r} \sum_{j=1}^{r} v_i [(\mathbf{E} - \tilde{\mathbf{Q}})^{-1}]_{ij} \right\}^2 . \tag{29}$$

In the simplest and experimentally most thoroughly investigated case of initiators with two types of peroxy-groups, the general formula (20) reduces to the form

$$U(x, t) = \frac{x(b_1 + b_2 x)}{1 - d_1 x + d_2 x^2}, \tag{30}$$

where

$$b_1 = v_1 \nu_{10} + v_2 \nu_{20}, \quad b_2 = v_1 (\nu_{12} \nu_{20} - \nu_{22} \nu_{10}) + v_2 (\nu_{21} \nu_{10} - \nu_{11} \nu_{20})$$
$$d_1 = \nu_{11} + \nu_{22}, \quad d_2 = \nu_{11} \nu_{22} - \nu_{12} \nu_{21} . \tag{31}$$

When the conditions $b_2 < 0$ and $d_2 > 0$ hold, analysis of Eqn. (30) predicts the possibility of the appearance in the initial polymerisation stage of a bimodal molecular weight distribution, which may then become unimodal as the degree of conversion increases. This nature of the evolution of the molecular weight distribution was in fact observed in certain experiments[5,8,11,12] when the process was initiated by peroxide with two types of labile groups having different thermal stabilities. The polydispersity coefficient K can be easily calculated by Eqn. (10) because Eqn. (29) reduces to the simple form

$$K'' = \frac{4(1 - d_2) - (b_1 + d_1)(3 - d_1 - d_2)}{(2 - b_1 - d_1)^2} \tag{32}$$

when $r = 2$.

In order to find with the aid of the generating function (30) the molecular weight distribution or the polydispersity coefficients (10) and (32), it is necessary to find beforehand with the aid of Eqn. (31) the parameters of the Markov chain, which are fully defined, according to Eqns. (24) and (25), by the matrices $\boldsymbol{\rho}$ and $\boldsymbol{\sigma}$. Their elements can be calculated by Eqns. (22) and (23) provided that the concentrations N_{ik} of the different clusters (ik) are known. Several ways of finding the concentrations N_{ij} for different types of initial polyperoxides have been proposed.[31] The polyperoxides can be both individual chemical compounds and mixtures of molecules differing in the number of peroxy-groups of different types (composition) and their sequence (structure).

Examination of such mixtures is of practical importance because oligomeric initiators are usually synthesised by the polycondensation method.[1-6] As a consequence of the random character of its reactions, the products of this process naturally have a distribution with respect to composition and structure. The latter has been described in many cases[24] by a Markov chain whose non-return states are peroxy-groups of r types and the zeroth absorbing state corresponding to going outside the limits of the molecule. If the matrix of the transition probabilities between the non-return states of this Markov chain is denoted by $\tilde{\mathbf{Q}}^0$ and its initial vector is denoted by $\overleftarrow{v}^0$, when the matrix ρ can be written in the form

$$\boldsymbol{\rho} = [\mathbf{E} - \tilde{\mathbf{Q}}^0 (\mathbf{E} - \mathbf{D})]^{-1} \tilde{\mathbf{Q}}^0 \mathbf{D}, \tag{33}$$

where **D** is a diagonal matrix with the elements $\theta_i\delta_{ij}$. Other parameters in Eqns. (22) and (23) are defined similarly:

$$\rho_{i0} = \sum_{j=1}^{r} \{[\mathbf{E} - \tilde{\mathbf{Q}}^0(\mathbf{E} - \mathbf{D})]^{-1}\}_{ij} v_{j0}^0, \tag{34}$$

$$\rho_{0i} = \frac{I^0}{\Pi} \sum_{j=1}^{r} v_j^0[\theta_j\delta_{ji} + (1-\theta_j)\rho_{ji}], \tag{35}$$

$$\Pi = I^0 - I(t) = I^0\left[1 - \sum_{i=1}^{r} v_i^0(1-\theta_i)\rho_{i0}\right]. \tag{36}$$

Together with Eqns. (10) and (28), Eqns. (34) and (36) provide an exhaustive solution of the problem of the calculation of the number-average molecular weights of the products of polymerisation initiated by polyperoxides with Markov statistics of the sequence of labile groups of different types in them.

The possibility of using a statistical approach to the calculation of the molecular weight distribution of the polyperoxide-initiated polymerisation products is associated with the independent decomposition of all their labile groups. This factor serves as yet another illustration of Flory's idea,[21] which is of general importance for the chemistry of polymers. In the spirit of this idea, the molecular weight distribution functions depend on time only in terms of probability parameters, which in the systems examined here are the elements σ_{kj} [see Eqn. (23)] of the matrix σ and the components θ_i see Eqn. (27) of the vector $\vec{\theta}$.

Rigorous kinetic examination shows that the formulae derived by the statistical method retain their form in systems where the temperature varies during polymerisation. However, the time variation of the probability parameters in these formulae is determined by expressions more general than in the case of an isothermal process. Such an expression, which is an extension of Eqn. (27), is

$$\theta_i(t) = \int_0^t f_i(t')\, k_{di}(t') \exp\left[-\int_0^{t'} k_{di}(t'')\, dt''\right] dt', \tag{37}$$

while in the calculation of the quantities σ_{kj} [see Eqn. (23)], one should take into account the time variation of the kinetic parameters f_i and k_{di} in the functions I_i [Eqn. (21)]. The above explanations make it possible to embrace by the theory described above the polymerisation processes occurring in practice with a programmed increase in temperature, which have a number of advantages compared with isothermal processes.[5]

6. Synthesis of block copolymers

Polymerisation processes with participation of polyinitiators having two types of groups with markedly different thermal stabilities are apparently of greatest practical interest. Such polyperoxides are characterised by decomposition constants $k_{d1} \gg k_{d2}$, which makes it possible to carry out the polymerisation in two stages. In the first stage, carried out at a specific temperature, virtually only the more labile peroxy-groups of the first type decompose with formation of polymer molecules containing peroxide clusters comprising the groups of the second type in the main chain, which are capable of further reactions. After raising the temperature in the polymerisation system, the process goes over to the second stage, during which the less labile groups of the second type are decomposed which is accompanied by the growth of the macroradicals formed and their subsequent recombination. If the monomer is replaced at the end of the first stage, then molecules containing blocks of different monomers are formed during the second stage. This method of synthesis of block-copolymers is extremely simple and promising.[13–15,25–30]

The change in the composition and structure of polyperoxide makes it possible to influence the architecture and statistical characteristics of the block-copolymers formed. In the simplest case, it is possible to select as the initiator an asymmetric diperoxide of the type of, for example, compound (I) with an appropriate substituent R ensuring a sufficient difference between the thermal stabilities of the two peroxy-groups. In particular, the use of a boron atom as R leads to a difference between the decomposition constants k_{d1} and k_{d2} for these groups differing by a factor greater than 20,[12] which guarantees the possibility of carrying out the two-stage synthesis of a block copolymer with participation of the initiator.

The formation during the synthesis of homopolymer molecules as side products in both stages is a disadvantage in this case. It can be eliminated in the first stage by going over from diperoxides to symmetrical triperoxides which contain two identical groups of the first type separated by a central, more stable group of the second type.[10,32] In order to reduce to a minimum the formation of the homopolymer also in the second stage of the process, it is necessary to carry it out in the presence of a polyperoxide with the highest possible functionality and it is desirable to have alternating groups of both types. The latter factor promotes an increase in the uniformity of the compositions of the copolymerisation product, because it ensures a regular alternation in the latter of macromolecular blocks each of which consists in the given instance of a single elementary chain.

In the general case of an arbitrary polyperoxide, selected by guesswork, the block of monomer ith type units in the molecule of the block-copolymer can consist of any number n of elementary chains of the corresponding monomer. The random quantity n has the distribution function $(1-\rho_{ii})\rho_{ii}^{n-1}$, so that the average number of elementary chains in one block is $(1-\rho_{ii})^{-1}$. The distribution of the blocks of the ith monomer with respect to lengths is described by Eqn. (7) and by Eqn. (15) for a constant length ν of the kinetic chain, but in the latter equation ρ must be replaced by ρ_{ii}.

The superposition principle, in a somewhat more general formulation, can also be used for the calculation of the distribution of the block-copolymer with respect to composition. In contrast to the homopolymer, the macromolecules of a binary block-copolymer are characterised by the composition vector $\vec{l}$ (instead of the degree of polymerisation l), whose components l_1 and l_2 are equal to the numbers of monomer units of the first and second type. The corresponding type of elementary homopolymer chain corresponds to each of these types, and the numbers m_1 and m_2 of such chains in the macromolecule can also be regarded as components of the vector $\vec{m}$. When such notation is used, the principal relations (3)–(6) of the superposition principle retain their significance if one goes over in them from the scalar variables l and m to the vector variables $\vec{l}$ and $\vec{m}$. As a result of this, it is sufficient to find a generating function $U(\vec{x}, t)$ of the distribution of polymer chains with respect to the vector $\vec{m}$ characterising them. The solution of the given problem leads to the following expression for this function $U(x_1, x_2)$:[31]

$$\frac{\rho_{01}\rho_{10}x_1 + \rho_{02}\rho_{20}x_2 + (\rho_{01}\rho_{12}\rho_{20} + \rho_{02}\rho_{21}\rho_{10} - \rho_{01}\rho_{22}\rho_{10} - \rho_{02}\rho_{11}\rho_{20})x_1x_2}{1 - \rho_{11}x_1 - \rho_{22}x_2 + (\rho_{11}\rho_{22} - \rho_{12}\rho_{21})x_1x_2}. \tag{38}$$

The subsequent substitution in this formula, instead of x_1 and x_2, of the generating functions $<g_1(s_1)>$ and $<g_2(s_2)>$ of the distributions with respect to the lengths of the elementary chains of each of the two types yields an expression for the generating function $G_N(\vec{s})$ for the required distribution $f_N(\vec{l}, t)$.

The average number $\overline{m}_1$ and $\overline{m}_2$ of the elementary chains of both types per polymer molecule can be calculated simply from Eqn. (38):

$$\frac{\overline{m}_1}{\Pi}=\frac{\rho_{12}+(\rho_{11}+\rho_{21})\rho_{10}}{\rho_{12}\rho_{20}+\rho_{21}\rho_{10}+\rho_{10}\rho_{20}},\quad \frac{\overline{m}_2}{\Pi}=\frac{\rho_{21}+(\rho_{22}+\rho_{12})\rho_{20}}{\rho_{12}\rho_{20}+\rho_{21}\rho_{10}+\rho_{10}\rho_{20}}. \quad (39)$$

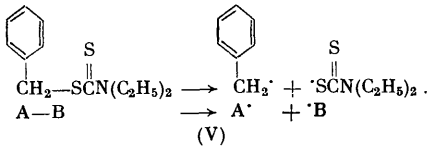
They define the average composition of the block-copolymer:

$$\langle\zeta_i\rangle=\langle\nu_i\rangle\overline{m}_i/(\langle\nu_1\rangle\overline{m}_1+\langle\nu_2\rangle\overline{m}_2)\quad (i=1, 2). \quad (40)$$

where $2<\nu_1>$ is the average length of the elementary chain of the i-th type.

The quantities e_1 and e_2, equal to the fractions of the monomer units of each type forming part of the composition of the homopolymers formed during the synthesis as side products, are important process characteristics. Theory yields simple expressions for these quantities:

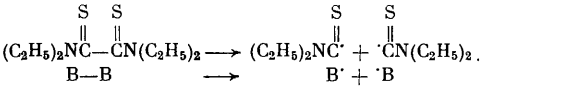
$$e_i=\Pi\rho_{0i}\rho_{i0}/C_i^0\theta_i(1-\rho_{ii})^2\quad (i=1, 2), \quad (41)$$



They are suitable for the estimation of the efficiency of the practical employment of various polyinitiators in the synthesis of block copolymers.

III. Iniferters

1. Introduction



The term "iniferters", proposed first by Otsu and co-workers,[33] is a result of the combination of three words: *Ini*tiator–Trans*fer* agent–*Ter*minator. A characteristic feature of an iniferter is that it participates in all three reactions mentioned above: initiation, chain transfer, and chain termination. Certain features of the polymerisation of monomers such as styrene, methyl methacrylate, methyl acrylate, etc. in the presence of a whole series of such compounds have now been investigated. Among them, mention may be made of various phenylazomethanes, dithiocarbamates, disulphides, etc.[33–50] The studies by Japanese workers and especially those by Otsu and co-workers,[33,34,36,41–52] who discovered a series of characteristics of the polymerisation with participation of iniferters, are outstanding among these investigations. The extensive possibilities of the use of these compounds for the molecular design of polymers synthesised has also been demonstrated.[42,44,45,50–52]

A common feature of all iniferters, regardless of their structure, is the presence in their molecules of labile interatomic bonds capable of decomposing under the conditions of the synthesis with formation of a pair of primary radicals at least one of which is not converted into the polymeric radical although it does participate in chain termination reactions. *S*-Benzyl-*N*,*N*-diethyldithiocarbamate can be quoted as an example of an iniferter:

(V)

It has been used to initiate the photopolymerisation of styrene.[49,55–57] The decomposition of a molecule of this initiator affords two primary radicals, A (benzyl) and B (dithiocarbamyl), with appreciably different chemical reactivities. The primary active radical A is capable of further growth after the addition of the monomer to it, while the second primary radical B hardly reacts with the monomer under the conditions of the synthesis as a consequence of its unduly low reactivity. Apart from such asymmetric compounds, there exist also symmetrical iniferters of the type of tetraethylthiuram disulphide:

(VI)

On decomposition, they afford two identical inactive radicals B. Together with the recombination of radicals of this type with one another at a fairly low concentration, they can combine with the monomer and can thus initiate polymerisation. Depending on what is the main cause responsible for the decomposition of the labile bond, thermo- and photo-iniferters are distinguished. The ability of various chemical compounds to function as iniferters of each of these types has been discussed in a review by Australian workers.[59]

2. The mechanism and kinetics of polymerisation

During the process with participation of an iniferter, polymer chains containing a fairly labile bond at the end are formed. Subsequently each of these bonds can break down under the influence of heat or light with formation of a macroradical and a small radical B, incapable of initiating a new polymer chain. On the other hand, after the addition of a certain number of monomer species, the macroradical recombines with the stable radical B and is converted into a polymeric macroiniferter molecule. The latter decomposes again into a pair of radicals differing significantly in their reactivity, and so on. In conformity with this picture of stepwise polymerisation, each polymer chain exists in succession in two states: the live state (as a macroradical) and the dead state (as a macromolecule). Since the polymer chain lives for a very short time, compared with its inactive state, one can assume that it grows in separate steps. In each such step, the molecular weight increases exactly by one length of the elementary chain.

The characteristic features of the mechanism of radical polymerisation in the presence of iniferters can be understood by resorting to the general kinetic scheme for this process, which assumes the following form, for example, in the case of an asymmetric iniferter I of type (V):

$$\begin{aligned}
&(a)\ \mathrm{I}\xrightarrow{k_d'}\mathrm{A}+\mathrm{B}\ \text{chain initiation}\\
&\left.\begin{aligned}(b)\ &\mathrm{A}+\mathrm{M}\xrightarrow{k_{pA}'}\mathrm{R}(1)\\ (c)\ &\mathrm{R}(l)+\mathrm{M}\xrightarrow{k_p}\mathrm{R}(l+1)\end{aligned}\right\}\text{chain propagation}\\
&\left.\begin{aligned}(d)\ &\mathrm{R}(l)+\mathrm{R}(n)\xrightarrow{k_{tc}}\mathrm{P}(l+n)\\ (e)\ &\mathrm{R}(l)+\mathrm{R}(n)\xrightarrow{k_{td}}\mathrm{P}(l)+\mathrm{P}(n)\\ (f)\ &\mathrm{R}(l)+\mathrm{B}\xrightarrow{k_t'}\mathrm{P}(l)\mathrm{B}\\ (g)\ &\mathrm{B}+\mathrm{B}\xrightarrow{k_t''}\mathrm{BB}\end{aligned}\right\}\text{chain termination}\\
&\left.\begin{aligned}(h)\ &\mathrm{R}(l)+\mathrm{I}\xrightarrow{k_t}\mathrm{P}(l)\mathrm{B}+\mathrm{A}\\ (i)\ &\mathrm{R}(l)+P(n)\,\mathrm{B}\xrightarrow{k_{PB}}\mathrm{P}(l)\,\mathrm{B}+\mathrm{R}(n)\end{aligned}\right\}\text{chain transfer}\\
&(j)\ \mathrm{P}(l)\,\mathrm{B}\xrightarrow{k_d}\mathrm{R}(l)+\mathrm{B}\qquad\text{chain reinitiation}.
\end{aligned}\quad (42)$$

Apart from the usual reactions of traditional radical polymerisation, this scheme includes the reinitiation reaction (*j*), which constitutes the main feature of the process considered. A second important feature of the process is that the chain termination in it is effected solely by reaction (*f*) via the recombination of the polymeric and inactive primary radicals.

Indeed, rigorous analysis of the kinetic equations correpsonding to Scheme (42) has shown[55] that the chain termination reactions (*d*), (*e*), and (*g*) can be frequently neglected compared with reaction (*f*). The condition for such neglect is a sufficiently high value of the dimensionless parameter $\Phi = k'_t(k_t k''_t)^{-1/2}$, which depends solely on the elementary chain termination constants. This condition is always fulfilled, because the above constants for diffusion-controlled reactions are linked, in terms of order of magnitude, by the relations $k''_t \sim k'_t \sim (10^2-10^3)k_t$.

The theoretical expressions for the rate of polymerisation under the influence of iniferters,[55] i.e.

$$W = k_p M\sqrt{I/k_t^e}, \text{ where } k_t^e = k_t\Phi, \qquad (43)$$

have the same form as for traditional polymerisation. The only difference is the replacement of the usual termination rate constant k_t by its effective value k_t^e. The ratio of the latter to the former is equal to Φ and therefore even for the same rate of initiation I the use of iniferters retards the rate of polymerisation by more than an order of magnitude compared with the usual initiators.

The systems in which the rate constant k_d for the breakdown of the terminal labile bond in the molecule is independent of its length and is identical with the constant k'_d for the decomposition of the iniferter are simplest. For ideal systems, where the familiar Flory principle[21] holds for all the elementary reactions, the reduced rate of polymerisation

$$W/M = k_p\sqrt{k_d C^0/k_t^e}, \quad I = k_d C^0 \qquad (44)$$

is constant and proportional to the square root of the initial iniferter concentration C_I^0.

Together with ideal systems, where this condition holds,[41,47] a considerable number of monomer + iniferter pairs have been observed experimentally for which the rate of polymerisation varies from the very beginning of the process.[41,42,44] A typical form of the kinetic curve for such non-ideal systems is illustrated in Fig. 5. It shows that in the initial stage of the conversion, the rate of its change diminishes, starting from an initial value W_0, gradually attaining a stationary value W_S.

In order to account for this form of the kinetic curve, the hypothesis of the possible breakdown of the Flory principle in the polymerisation initiation reactions with participation of certain iniferters was put forward and justified experimentally.[55] For this purpose, the rate of decomposition of the terminal labile groups within narrow fractions of macroiniferters of different molecular weight, obtained in the course of the photopolymerisation of styrene in the presence of compound (V), was measured by the spin trapping method.[55–57] The results of this experiment, presented in Fig. 6, demonstrate a fairly sharp decrease in the reinitiation rate constant k_d with increase in the number of units l of the oligoiniferters up to a certain limiting value k_d for values of l exceeding ~100 units. After the attainment during the polymerisation process of P_N close to 100, the rate of polymerisation actually attains a constant value, in full agreement with Eqn. (43). The latter predicts also a proportionality between the initial (W_0) and stationary (W_S) rates of polymerisation and the square root of the concentration of iniferters. This conclusion was confirmed experimentally[55–57] in relation to the photopolymerisation of styrene in the presence of the iniferter (V) over a wide range of concentrations of the latter. Furthermore, it was found that the observed experimental ratio W_0/W_S is virtually constant in this range and equal to approximately three. This in fact agrees with the theoretical predictions, if one takes into account the dependence of the rate constants k_d for the decomposition of macroiniferters on their length illustrated in Fig. 6.

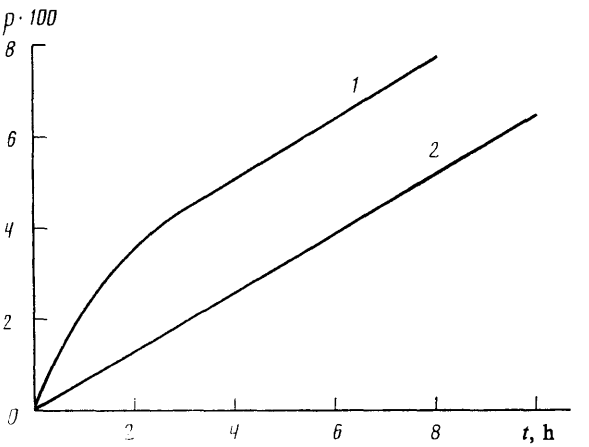


Figure 5. Kinetic curves for the photopolymerisation of styrene in solution in benzene in the presence of the iniferter (II) (curve *1*) and the macroiniferter (curve *2*) containing about 170 styrene units.[55–57]

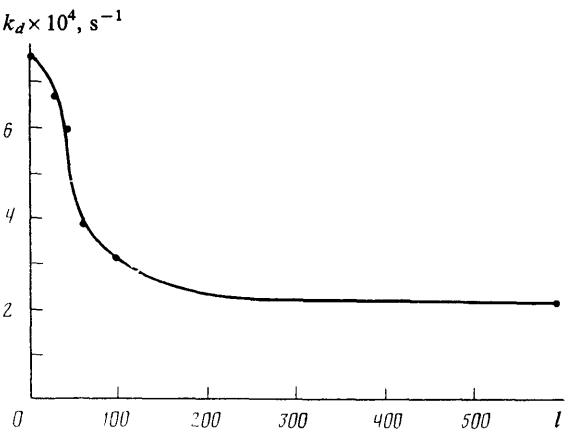

Figure 6. Dependence of the rate constant for the decomposition of the labile bond in the macroiniferter (oligostyrene with a terminal thiocarbamate group) molecule on the degree of polymerisation of the latter.[55–57]

Since this dependence in the given system is important only for macroiniferters whose length is less than 100 units, in the case of the initiation and polymerisation by higher-molecular-weight homologues

one may expect a constant rate of polymerisation W from the very beginning of the process. Furthermore, this value of W should agree with the stationary rate of polymerisation W_S carried out under the same conditions in the presence of the low-molecular-weight iniferter (V). Indeed, the experimental kinetic curve *2* in Fig. 5 fully confirms these theoretical conclusions.

The very fact that there is virtualy no chain termination via the interaction of polymeric radicals with one another during polymerisation in the presence of the iniferter leads to interesting conclusions concerning the kinetics of certain extremely important industrial processes. These include the polymerisation of vinyl monomers in bulk, which is of great interest in the manufacture of plastics and especially organic glasses. During such processes, a sharp increase in the rate of polymerisation is usually observed in the region of moderate conversions, which can exceed by several tens its initial value. This phenomenon, referred to as the "gel effect", is extremely undesirable in the planning of industrial manufacturing processes, because it induces overheating in the reaction system and the impairment of the operating parameters of the polymer.

The cause of the "gel effect" is the appreciable decrease in the rate constants k_t for reaction (*d*) and (*e*) in Scheme (42) associated with the significant retardation of the mutual diffusion of the macroradicals when the solution becomes concentrated as a result of the conversion of the monomer into the polymer. Since in the course of polymerisation with participation of an iniferter these chain termination reactions do not play a significant role, there is every reason to expect the absence of the "gel effect" in such processes. This theoretical conclusion was convincingly confirmed[58] in the bulk polymerisation of styrene and methylmethacrylate in the presence of *N,N,N',N'*-tetraethylthiuram disulphide as the iniferter.

In conclusion of this section, it is natural to formulate the quantitative conditions for the applicability of the iniferter mechanism of radical polymerisation decribed above. Here it is most important to answer the question whether or not a specific initiator will manifest the properties of an iniferter. This depends both on the occurrence of the reinitiation reaction and on the choice of the reaction pathway for the less reactive of the two primary radicals formed on decomposition of the initiator molecule.

This primary radical B has two possibilities of reacting—either with the monomer M or with the polymeric radical R. The predominance of one of these reactions depends on the relation between their probabilities $\mathscr{P}_a = k_{pB}\mathrm{M}$ and $\mathscr{P}_t = k'_o\mathrm{R}$. Evidently, if the activation reaction of the primary radical B predominates, the traditional radical polymerisation occurs. Otherwise, when $\mathscr{P}_a \ll \mathscr{P}_t$, whereupon the chain termination reaction becomes dominant for B, iniferter polymerisation takes place. The range of rates of polymerisation corresponding to this is wider the greater the ratio $k'_{pA}k'_{pB}$ of the rate constants for the addition of the monomer to the active (A) and inactive (B) primary radicals. Only for a sufficiently large difference between the reactivities can the following inequalities hold:

$$1 \ll \frac{W}{W^*} \ll \frac{k'_{pA}}{k'_{pB}}, \text{ where } W^* \frac{k'_{pB}k_p}{k'_t}\mathrm{M}^2. \qquad (45)$$

When these inequalities are valid, the iniferter polymerisation mechanism operates. The first inequality implies that the rate of polymerisation must be fairly high compared with the characteristic value W^* so that the primary radicals B do not have enough time to initiate the polymer chains. On the other hand, according to the second inequality, the rate W should be significantly smaller than the quantity $(k'_{pA}/k'_{pB})W^*$ to rule out the chain termination by the primary radicals A which leads to the formation of polymer molecules incapable of reinitiation.

3. The molecular weight distribution and its characteristics

In the iniferter mechanism of polymerisation, the macromolecules consist of several elementary chains. This makes it possible to employ the superposition principle formulated in Section II.3 for the calculation of the molecular weight of the polymer in ideal systems. The generating function

$$U(x, t) = [\mathrm{e}^{(x-1)\tau} - \mathrm{e}^{-\tau}]/[1 - \mathrm{e}^{-\tau}], \text{where } \tau = k_d t, \qquad (46)$$

found neglecting the chain transfer reactions, leads to the simple expressions

$$\mathrm{P}_N = \frac{\tau\langle\nu\rangle}{1 - \exp(-\tau)}, \quad K = \frac{[1 - \exp(-\tau)]}{\tau}\left[\tau + 2\frac{\langle\nu^2\rangle}{\langle\nu\rangle^2}\right] \qquad (47)$$

for the number-average degree of polymerisation and the polydispersity coefficient. An increase in the number of elementary chains in the macromolecule naturally promotes an increase in their molecular weight and a narrowing of the molecular weight distribution, which can be seen from Eqns. (47). However, the opposite effects are induced by a decrease in the course of the polymerisation of the length $\nu = \nu^0\mathrm{M}/\mathrm{M}^0$ of the kinetic chain from its initial value $\nu = \nu^0$ to $\nu = 0$ when the monomer concentration changes from M^0 to 0. When account is taken of this effect, Eqns. (47) assume the following form:

$$\mathrm{P}_N = \frac{\nu^0(1 - e^{-\beta\tau})}{\beta(1 - e^{-\tau})}, \ \beta = \frac{C^0}{\mathrm{M}^0}\nu^0, \ \nu^0 = \frac{k_p\mathrm{M}^0}{(k_t\Phi k_d C^0)^{1/2}}; \qquad (48)$$

$$K = (1 - e^{-\tau})[\beta \operatorname{cth}(\beta\tau/2) + 1]. \qquad (49)$$

The quantity P_N increases with time from $\mathrm{P}^0_N = \nu^0$ to $\mathrm{P}^*_N = \nu^0\beta^{-1}$, where the parameter β^{-1}, having the significance of the average number $\bar{m}$ of elementary chains in the macromolecule of the final polymer, can be fairly large in the iniferter polymerisation mechanism. In this case, the limiting value $K = 1 + \beta$ of the polydispersity coefficient [Eqn. (49)] corresponding to $\tau \to \infty$ differs little from unity, which indicates a fairly high degree of uniformity of the molecular weight distribution of the final polymerisation product. Eqns. (48) and (49) predict a monotonic time variation of the quantities P_N and K. As regards the molecular weight distribution function, an explicit expression can be quoted for it in two important cases. One of them refers to the region of initial conversions:

$$f_N(l, t) = (\tau/\nu^0)\exp[-\tau(z/\tau - 1)^2]\psi(z),$$
$$\psi(z) = \exp(-2z)\mathrm{I}_1(2z)/z, \quad z = (l\tau/\nu^0)^{1/2}, \qquad (50)$$

where I_1 is a modified first-order Bessel function of the first kind. The other describes the final polymerisation products:

$$f_N(l, \infty) = [\nu^0\Gamma(1/\beta)]^{-1}(l/\nu^0)^{1/(\beta-1)}\exp(-l/\nu^0), \qquad (51)$$

where Γ is the Euler gamma-function.

The inclusion in the consideration of reactions (*h*) and (*i*) of Scheme (42), which take into account the chain transfer to the iniferter, leads to only non-fundamental modifications of Eqns. (46)–(49). They all retain their form as functions of τ when the average length ν of the kinetic chain is replaced in them by the average length $\nu[1 + k_1C^0(k_t\Phi k_d C^0)^{-1/2}]^{-1}$ of the elementary chain.

In the more general model of ideal polymerisation, the labile bonds in the initial iniferter and in the polymer molecules differ kinetically. For a large difference $k'_d \gg k_d$ between the rate constants k'_d and k_d for their decomposition reactions, the polymerisation will actually occur in two stages. In the first comparatively short stage, all the molecules of the initial iniferter decompose and macromolecules, each of which consists of exactly one elementary chain, are formed. During the second, longer stage, these macroiniferter molecules initiate further polymerisation. Here it is significant that the molecular weight distribution of the products formed is initially broadened and then narrowed. Such non-monotonic variation of the polydispersity coefficients k is possible in systems where the rate constant k_d for the breakdown of the labile bond diminishes fairly sharply as a function of the length of the macroiniferter molecule containing it. This theoretical conclusion follows from the solution of the system of kinetic equations quoted[55] for an arbitrary $k_d(l)$ relation. The experimental $K(t)$ curves obtained for the polymerisation of styrene in the presence of the iniferter (V)[56] pass in certain cases through a maximum, confirming the theoretical conclusions.

One of the most characteristic features of polymerisation with participation of iniferters is the linear increase with the degree of conversion p of the number-average molecular weight of the products formed.[38,41–43,48,53–57] This relation $P_N = (M^0/I^0)p$ follows directly from the iniferter polymerisation mechanism itself in the range of conversions $p \gg p^* = k_p(I^0/k_t\Phi k'_d)^{1/2}$, where there is virtually no initial initiator in the reaction system. Since each initiator molecule initiated the polymer chain on decomposition, the concentration of such chains corresponding to $p \gg p^*$ is identical with I^0.[42,44–45,53–57] For fairly low conversions, comparable to p^*, the expression $P_N = (M^0/I^0)p$ is naturally invalid because in this range of conversions the number of polymer chains increases with conversion. A correct extrapolation of the variation of P_N to the point $p = 0$ yields $P_N = \nu^0 = k_pM(k_t\Phi k'_dC^0)^{-1/2}$, which reflects the fact that the macromolecules formed at the very beginning of polymerisation consist of only one elementary chain.

In conclusion of Section III, one may say that at present there is sufficient experimental justification of the main features of the iniferter polymerisation mechanism. Naturally, in individual specific processes there is a possibility of side reactions which are not represented in Scheme (42) and which must be taken into account in kinetic calculations for the polymerisation and the molecular weight distribution of its products. Allowance for these side reactions involves the specific features of a particular monomer–iniferter pair, each of which can differ in its non-fundamental characteristics. On the other hand, the most characteristic general features typical for the iniferter polymerisation mechanism are reflected by its simplest kinetic Scheme (42).

IV. Conclusion

Radical polymerisations in the presence of polyfunctional initiators and iniferters have a whole series of common features despite the fundamental differences between the mechanisms of the formation of polymer chains. We shall now list the main features of this kind which distinguish these processes from the usual polymerisation with participation of traditional initiators.

The most important feature is the continuous growth of the molecular weight of the polymer with conversion, which is described by a linear law for a fairly large average number of elementary chains in the macromolecule. Under these conditions, the initial initiator disappears in the very early stages of the process, after which the number of polymer chains remains unchanged and only their length increases.

The second common feature of the processes is that the mechanism of the formation of macromolecules during polymerisation promotes a decrease in the conversion-induced broadening of the molecular weight distribution associated with the exhaustion of the concentrations of the monomer and initiator during the process. For the same reason, one should expect an appreciable increase in the non-uniformity, as regards composition, of the products of joint polymerisation obtained at advanced conversions.

The third common feature of the two processes is the formation during them of macroinitiator molecules, which are capable, after liberation, of promoting further growth of the molecular weight under appropriate conditions on coming into fresh contact with the monomer. This property makes it possible to employ both types of non-traditional initiators for the synthesis of block-copolymers. Polyperoxides make it possible under these conditions to obtain macromolecules with a fairly large number of blocks, while iniferters are used to obtain diblock copolymers.

The principal disadvantages of polyfunctional initiators are the ineffectiveness of their use in the polymerisation of monomers of the type of methyl methacrylate, where the fraction of radicals destroyed via the disproportionation mechanism is fairly large. The polymerisation initiated by iniferters is free from this disadvantage. The use of iniferters makes it possible, in addition, to eliminate almost completely the undesirable "gel-effect", manifested in the bulk polymerisation reactions of certain monomers. Polyperoxides do not allow this.

Polyfunctional components in radical polymerisation and in the preparation of polymer compositions

S S Ivanchev
"Plastpolimer" Scientific-Industrial Association, Leningrad

ABSTRACT. The possibilities in the use of polyfunctional components in polymerisation systems are surveyed and analysed in the present review. The kinetics and mechanisms of the chemical reactions of polyfunctional monomers, initiators, emulsifying agents, and modified reactive fillers in radical polymerisation are examined. The kinetics and mechanism of polymerisation in systems with polyfunctional emulsifying agents or modified fillers are considered from the standpoint of considering them as locally organised systems with a regulated distribution of components.

A classification of polyfunctional components based on the available data is proposed.

The bibliography includes 90 references.
